- Encourage the patient to hold the contraction for 5–10 seconds.
- Let the patient relax.
- Have the patient repeat the exercise 10 times each hour when awake.

Providing Initial Patient Teaching

The nurse teaches the patient and family that the casted extremity must be uncovered until it is completely dry and supported on pillows to the level of the heart to control swelling; ice packs should be applied as prescribed over the fracture site for 1 or 2 days. The patient is taught to elevate the casted arm or leg when seated to promote venous return and control swelling, unless ACS is suspected, where the extremity is at the level of the heart. The patient needs to understand that the body part will be immobilized after casting.

Positioning

If a body cast is in place, the nurse turns the patient as a unit toward the uninjured side every 2 hours to relieve pressure and to allow the cast to dry. It is important to avoid twisting the patient's body within the cast. Sufficient personnel (depending on the size of the patient and type of cast) are needed when the patient is turned so that the fresh cast can be adequately supported with the palms of the hands at vulnerable points (i.e., body joints) to prevent cracking.

Teaching the Patient Self-Care

Self-care deficits occur when a portion of the body is immobilized. The nurse encourages the patient to participate actively in personal care and to use assistive devices safely. The nurse assists the patient in identifying areas of need and in developing strategies to achieve independence in ADLs. Patient teaching is discussed in Box 42-10.

Providing Continuing Care

The nurse prepares the patient for cast removal or cast changes by explaining that the cast is cut with a cast cutter, which vibrates. The cutter does not penetrate deeply enough to hurt the patient's skin. The cast padding is cut with scissors. Refer to Box 42-11.

The formerly casted body part is weak from disuse, stiff, and may appear atrophied. Therefore, support is needed when the cast is removed. The skin, which is usually dry and scaly from accumulated dead skin, is vulnerable to injury from scratching. The skin needs to be washed gently and lubricated with an emollient lotion.

BOX 42-10 Patient Education

Cast Care

- Move about as normally as possible, but avoid excessive use of the injured extremity, and avoid walking on wet, slippery floors or sidewalks.
- If the cast is on an upper extremity, you may use a sling when you ambulate. To prevent pressure on the cervical spinal nerves, the sling should distribute the supported weight over a large area and not on the back of the neck. Remove the arm from the sling and elevate it frequently.
- Perform prescribed exercises regularly, as prescribed.
- Elevate the casted extremity to heart level frequently to prevent swelling. For example: when lying down, elevate the arm, so that each joint is positioned higher than the preceding proximal joint (e.g., elbow higher than the shoulder, hand higher than the elbow).
- Do not attempt to scratch the skin under the cast. This may cause a break in the skin and result in the formation of a skin ulcer. Cool air from a hair dryer may alleviate an itch. Do not insert objects, such as coat hangers, inside the cast to scratch itching skin. If itching persists, contact your provider.
- Cushion rough edges of the cast with tape.
- Keep the cast dry, but do not cover it with plastic or rubber because this causes condensation, which dampens the cast and skin. Moisture softens a plaster cast (a wet fiberglass cast must be dried thoroughly with a hair dryer on a cool setting to avoid skin burns).
- Report any of the following to the provider: persistent pain; swelling that does not respond to elevation; changes in sensation; decreased ability to move exposed fingers or toes; changes in capillary refill, skin color, and temperature.
- Note odors around the cast, stained areas, warm spots, and pressure areas. Report them to the provider.
- Report a broken cast to the provider; do not attempt to fix it yourself.

BOX 42-11 GUIDELINES FOR NURSING CARE

Removing a Cast

Equipment

Cast scissors, cast saw, and cast spreader (if necessary); eye protection, Ace wraps, splints as indicated, adhesive tape (optional)

Implementation

NURSING ACTIONS	RATIONALE
1. Inform the patient about the procedure.	1. Facilitates cooperation and reduces fear about the procedure
2. Reassure the patient that the electric saw or cast cutter will not cut the skin. (Explain that the blade oscillates to cut the cast and vibrations will be felt.)	2. Reduces anxiety
3. Wear eye protection (patient and operator of the cast cutter).	3. Protects eyes from flying cast particles
4. Bivalve the cast using a series of alternating pressures and linear movements of the blade along the line to be cut.	4. Cuts cast in halves; avoids burning sensation from prolonged contact of oscillating blade with padding
5. Cut the padding with scissors.	5. Releases all of the casting materials
6. Support the body part as it is removed from the cast.	6. Reduces stresses on body part that has been immobilized
7. Gently wash and dry the area that has been immobilized.[a] Apply emollient lotion.	7. Removes dead skin that has accumulated during immobilization; keeps skin supple
8. Teach the patient to avoid rubbing and scratching skin.	8. Prevents skin breakdown
9. Collaborate with the physical therapist to teach the patient to resume active use of the affected body part gradually within the guidelines of the prescribed therapeutic regimen.	9. Protects weakened body part from excessive stress; progressive exercises reduce stiffness and restore muscle strength and function
10. Teach the patient to control swelling by elevating the extremity or using an elastic bandage if prescribed.	10. Facilitates circulation (i.e., venous return) and controls fluid pooling

[a]If a new cast is to be applied, follow guidelines for application of a cast and associated nursing care.

The nurse and physical therapist teach the patient to resume activities gradually within the prescribed therapeutic regimen. Exercises prescribed to help the patient regain joint motion are explained and demonstrated. Because the muscles are weak from disuse, the body part that has been casted cannot withstand normal stresses immediately. In addition, the nurse teaches the patient with noticeable swelling of the affected extremity after cast removal to continue to elevate the extremity to control swelling until normal muscle tone and use are reestablished.

SKELETASKIN TRACTION

Skin traction is used to control muscle spasms and to immobilize an area before surgery. Skin traction is accomplished by using a weight to pull on traction tape or on a foam boot attached to the skin. The amount of weight applied must not exceed the tolerance of the skin. Adhesive tape and weights greater than 5 to 7 lb (Gösling & Giannoudis, 2015) are avoided as they may cause avulsion of the superficial skin layers.

Buck's Extension Traction

Buck's extension traction (unilateral or bilateral) is skin traction to the lower leg. The pull is exerted in one plane when partial or temporary immobilization is desired. In general, this form of traction is used to immobilize fractures of the proximal femur before surgical fixation or when only a light traction weight is necessary.

Before the traction is applied, the nurse inspects the skin for abrasions and circulatory disturbances. The skin and circulation must be in healthy condition to tolerate the traction. The extremity should be clean and dry before the foam boot or traction tape is applied.

To apply Buck's traction, one nurse elevates and supports the extremity under the patient's heel and knee while another nurse places the foam boot under the leg, with the patient's heel in the heel of the boot. Next, the nurse secures Velcro straps around the leg. Traction tape overwrapped with elastic bandage in a spiral fashion may be used instead of the boot. Excessive pressure is avoided over the malleolus and proximal fibula during application to prevent pressure ulcers and nerve damage. The nurse then passes the rope affixed to the spreader or footplate over a pulley fastened to the end of the bed and attaches the weight—usually 5 lb—to the rope.

Nursing Alert
The nurse must check nonadhesive traction frequently because it tends to slip when the traction weight is applied. Assessment of pressure on the fibula is essential because of the risk of nerve impingement; the peroneal nerve passes around the neck of the fibula just below the knee. Assess for inability to dorsiflex the foot and toes, a foot drop, or sensation in the web between the great toe and second toe.

Skin breakdown, nerve pressure, and circulatory impairment are complications that may develop as a result of skin traction. Skin breakdown results from irritation caused by contact of the skin with the tape or foam and shearing forces. Older adults are at greater risk for this complication because of their sensitive, fragile skin.

Nursing Alert
The nurse must promptly investigate every report of discomfort expressed by the patient in traction.

Circulatory impairment is manifested by cold skin temperature, decreased peripheral pulses, slow capillary refill time, and bluish skin. DVT, a serious circulatory impairment, may be manifested by unilateral calf tenderness, warmth, redness, and swelling (see Chapter 18).

SKELETAL TRACTION

The goals of skeletal traction are to maintain alignment of the injured limb and counteract the shortening of the injured limb from muscle spasm before definitive treatment can occur. Skeletal traction is applied directly to the bone. This method of traction is used occasionally to treat fractures of the femur, the tibia, and the cervical spine. The traction is applied directly to the bone by use of a metal pin or wire (e.g., Steinmann pin or Kirschner wire), which is inserted through the bone distal to the fracture, avoiding nerves, blood vessels, muscles, tendons, and joints. Tongs applied to the head are fixed to the skull to apply traction that immobilizes cervical fractures.

After local anesthesia and skin preparation by the surgeon, using surgical asepsis, a small skin incision is made and sterile pin(s) are drilled or wire is placed through the bone. The patient feels pressure during this procedure and possibly some pain when the periosteum is penetrated.

After insertion, the pin or wire is attached to the traction bow or caliper. The ends of the pin or wire are covered with corks or tape to prevent injury to the patient or caregivers. The weights are attached to the pin or wire bow by a rope-and-pulley system that exerts the appropriate amount and direction of pull for effective traction. Skeletal traction frequently uses 7 to 12 kg (15 to 25 lb) to achieve the therapeutic effect. Usually the weight of 15 to 25 lb of traction is sufficient to restore bone length during the first few days after injury when muscle spasms can be intense. The nurse is aware that the weights applied initially must overcome the spasms of the affected muscles that pull on the fractured bones and shorten the limb.

Often, skeletal traction is balanced traction, which supports the affected extremity, allows for some patient movement, and facilitates patient independence and nursing care while maintaining effective traction. The Thomas splint with a Pearson attachment (Fig. 42-14) is frequently used with skeletal traction for fractures of the femur. Because upward traction is required, an overbed frame is used.

When skeletal traction is discontinued, the extremity is gently supported while the weights are removed. The pin is cut close to the skin and removed by the physician. Then internal fixation, casts, or splints are used to immobilize and support the healing bone.

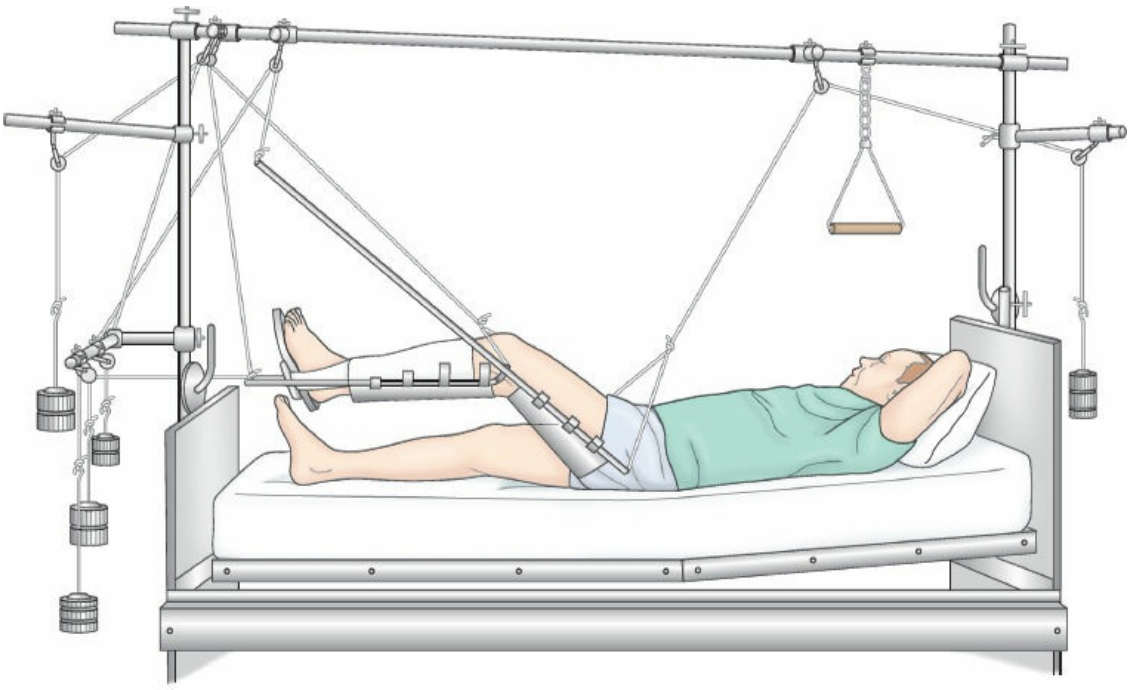

FIGURE 42-14 Balanced suspension skeletal traction with Thomas leg splint. The patient can move vertically as long as the resultant line of pull is maintained.

External fixators are often used to maintain position of unstable fractures when the use of a cast is prohibited or the patient's condition is unstable and precludes a surgical procedure to stabilize the fracture. They can also be used to manage open fractures with soft tissue damage or severe comminuted (crushed or splintered) fractures while permitting active treatment of damaged soft tissues. Complicated fractures of the humerus, forearm, femur, tibia, and pelvis are often managed with external skeletal fixators. The fracture is reduced, aligned, and immobilized by a series of pins or screws inserted directly into the bone above and below the fracture and secured with the use of a metal frame. Pin position is maintained through attachment to a portable frame. The fixator facilitates patient comfort, early mobility, and active exercise of adjacent uninvolved joints; thus, complications due to disuse and immobility are minimized.

Nursing Alert

The nurse never adjusts the clamps on the external fixator frame. It is the surgeon's responsibility to do so.

Nursing Management

Maintaining Effective Traction

When skeletal traction is used, the nurse checks the traction apparatus at least once per shift to see that the ropes are in the wheel grooves of the pulleys, that the ropes are not frayed, that the weights hang freely, and that the knots in the rope are tied securely. The nurse also evaluates the patient's position because slipping down in bed results in ineffective traction.

Maintaining Positioning

The nurse must maintain alignment of the patient's body in traction as prescribed to promote an effective line of pull. The nurse positions the patient's foot to avoid footdrop (plantar flexion), inward rotation (inversion), and outward rotation (eversion). The patient's foot may be supported in a neutral position by orthopedic devices (e.g., foot supports).

Preventing Skin Breakdown

The patient's elbows frequently become sore, and nerve injury may occur if the patient repositions by pushing on the elbows. In addition, patients frequently push on the heel of the unaffected leg and elbows when they raise themselves in bed. Therefore, the nurse should protect the elbows and heels and inspect them for pressure ulcers. A trapeze should be suspended above the patient, to encourage movement without using the elbows or heels. Areas that are particularly vulnerable to pressure caused by a traction apparatus applied to the lower extremity include the ischial tuberosity, popliteal space, Achilles tendon, and heel. If the patient is not permitted to turn on one side or the other, the nurse must make a special effort to provide back care and to keep the bed dry and free of crumbs and wrinkles. The patient can assist by holding the overhead trapeze and raising the hips off the bed. If the patient cannot do this, the nurse can push down on the mattress with one hand to relieve pressure on the back and bony prominences and to provide for some shifting of weight. A pressure-relieving air-filled or high-density foam mattress overlay may reduce the risk of pressure ulcer.

For change of bed linens (top to bottom rather than side to side), the patient raises the torso while nurses on both sides of the bed roll down and replace the upper mattress sheet. Then, as the patient raises the buttocks off the mattress, the nurses slide the sheets under the buttocks. Finally, the nurses replace the lower section of the bed linens while the patient rests on the back. Sheets and blankets are placed over the patient in such a way that the traction is not disrupted.

Providing Pin-Site Care

The wound at the pin insertion site requires attention. The goal is to avoid infection and development of osteomyelitis (Box 42-12). Osteomyelitis is an acute or chronic inflammation of the bone caused by infection. There is wide variability on pin care, and research on outcomes is scarce, thus further studies are warranted. However, the National Association of Orthopaedic Nurses Guidelines for Orthopaedic Nursing (Smith & Dahlen,

2013) offers specific recommendations for pin care, which are as follows:

- Pins located in areas with considerable soft tissue should be considered at greatest risk for infection.
- At sites with mechanically stable bone–pin interfaces, pin care should be done on a daily or weekly basis (after the first 48 to 72 hours, when drainage may be heavy).
- Chlorhexidine 2 mg/mL solution is considered to be the most effective cleansing solution for pin-site care. Saline should be used if chlorhexidine solution is contraindicated such as those with hypersensitivity to Chlorhexidine gluconate or other formula ingredients.
- Strict handwashing should always take place before and after skeletal pin-site care.
- Patients and families should be taught pin care before discharge. They should be required to demonstrate the prescribed care and provided with written instructions that include signs and symptoms of infection.

BOX 42-12 Focus on Pathophysiology

Osteomyelitis

Osteomyelitis is an infection in the bone caused by a variety of microorganisms, most commonly *Staphylococcus aureus,* that are introduced during injury, from the bloodstream, through direct inoculation (chronic infection of skin/soft tissue), or during surgery. Once in the bone, the microorganisms proliferate and spread within the bone shaft, causing an inflammatory response that further destroys the bone. Wound cultures identify the organism and antibiotic sensitivity. Difficult to treat, osteomyelitis requires IV therapy, in general, for 6 weeks. Osteomyelitis may be classified as acute (an infection lasting less than 4 weeks) or chronic (more than 4 weeks). Pain over the affected bone is the dominant finding in osteomyelitis. Palpation of the involved bone usually elicits tenderness over the infected area. Increased warmth, erythema, and swelling may be seen at the affected segment but are not always present. The ESR is commonly elevated, and elevated WBC levels may be seen in acute infections (but not always). The WBC count may be normal in chronic osteomyelitis.

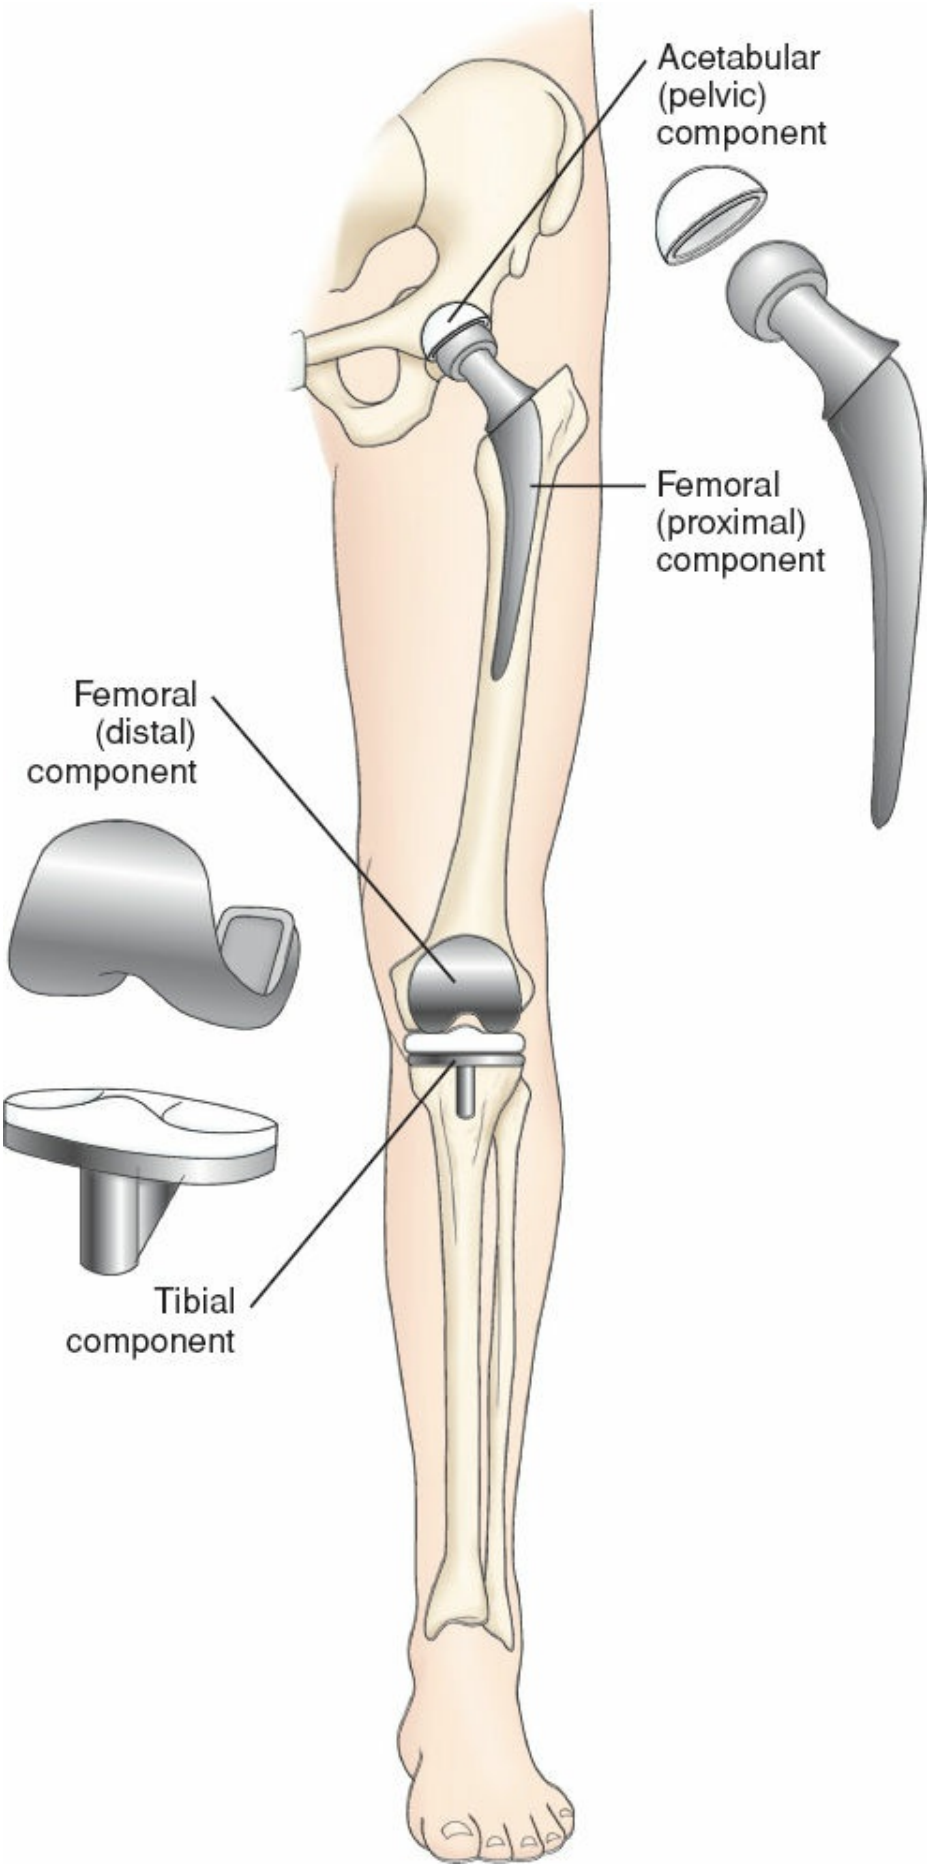
Note: Follow your facility's specific policy and procedure pertaining to skeletal pin care.

The nurse must inspect the pin sites daily for reaction (i.e., normal changes that occur at the pin site after insertion) and infection. Signs of reaction may include redness, warmth, and serous or slightly sanguinous drainage at the site. These signs are expected to subside after 72 hours. Rates of pin tract infections range from 10% to 15%, with deep infection rates of 3.5% to 8.2% (Mitchell et al., 2016). Signs of infection may mirror those of reaction but also include the presence of edema, purulent drainage, erythema, excessive warmth, tenderness, pin loosening, and odor. In addition, the nurse monitors the patient for fever. The frequency of pin care needs to be increased if mechanical looseness of pins or early signs of infection are present. Minor infections may be readily treated with antibiotics,

whereas infections that result in systemic manifestations may additionally warrant pin removal until the infection resolves. When pins are mechanically stable (after 48 to 72 hours), weekly pin site care may be recommended. Crusting may occur at the pin site, and uncertainties currently exist about whether scabs around the pin sites should be removed. Additional research is needed to determine best practice to prevent infection with external fixators. The nurse follows institutional protocol and teaches the patient and family to perform pin-site care prior to discharge from the hospital. Written follow-up instructions that include the signs and symptoms of infection should be provided.

JOINT REPLACEMENT SURGERY

Joint surgery is one of the most frequently performed orthopedic surgeries. Joint disease, disability, or deformity may necessitate surgical intervention to relieve pain, improve stability, and improve function. Conditions contributing to joint degeneration include osteoarthritis (degenerative joint disease), rheumatoid arthritis, trauma, and congenital deformity. As noted previously, some fractures (e.g., femoral neck fracture) may cause disruption of the blood supply and subsequent AVN, and a joint replacement may be elected over an ORIF. Joints frequently replaced include the shoulder, hip, or knee (Fig. 42-15), and finger joints. Less frequently, more complex joints (elbow, wrist, or ankle) are replaced.



Acetabular

FIGURE 42-15 Examples of hip and knee replacement.

Timing of these procedures is important to ensure maximum function. Surgery should be performed before surrounding muscles become contracted and atrophied and serious structural abnormalities occur. The surgeon carefully evaluates the patient so that the most appropriate procedure is performed.

Surgical procedures include excision of damaged and diseased tissue, repair of damaged structures (e.g., ruptured tendon), arthroplasty (replacement of all or part of the joint surfaces), and arthrodesis (immobilizing fusion of a joint).

Most joint replacements consist of metal, ceramic, or polyethylene components. Selection is typically based on the patient's age and activity level as well as the surgeon's preference. Cementless fixation of the femoral and acetabular component has become the standard procedure in the United States. Accurate fitting and the presence of healthy bone with adequate blood supply are important in the use of cementless components. Joint implants may be cemented with a bone-bonding agent, although they usually are reserved for individuals with a life expectancy of 10 years or less (Skinner, Sekiya, Jameel, & McMahon, 2014). Much progress has been made in reducing the prosthesis failure rate through improved techniques, improved materials, and use of bone grafts. The anterior or anterolateral approach for THA (see next section) avoids disruption of the posterior soft tissues and has dislocation rates of less than 1% (McCarthy, McMillan, Busconi, & Pive, 2016). Implant survival rates are 90% to 95% successful at 15 years; however, longevity will vary depending on patient factors, such as weight and activity (Mackenzie & Su, 2016, p. 1830).

With joint replacement, excellent pain relief is obtained in most patients. Return of motion and function depends on preoperative soft tissue condition, soft tissue reactions, and general muscle strength. Early failure of joint replacement is associated with excessive activity and preoperative joint and bone pathology.

Because these are elective procedures, some patients donate their own blood during the weeks preceding their surgery (autologous donation). This blood is used to replace blood lost during surgery. Autologous blood transfusions eliminate many of the risks of transfusion therapy.

TOTAL HIP REPLACEMENT

THA or surgical replacement of the hip joint with an artificial prosthesis, is indicated for idiopathic osteoarthritis, acetabular dysplasia, Paget disease, rheumatoid arthritis, AVN, posttraumatic injury, and other causes.

Nursing Alert
Aspirin and NSAIDs should be discontinued at least 1 week prior to surgery because of the risk of perioperative bleeding.

Preoperative Management

Assessment of the patient and preoperative management are aimed at having the patient in optimal health at the time of surgery. Preoperatively, it is important to evaluate cardiovascular, respiratory, kidney, and liver functions. Additionally, the nurse considers many factors, such as age (over 60 years of age), obesity, preoperative leg edema, a history of any venous thromboemboli, varicose veins, cancer, prolonged immobility, estrogens, and a wide variety of hematologic conditions, as they are indicators of risk for postoperative DVT and PE, the most common causes of postoperative mortality in those undergoing total hip replacement, and every effort is made to prevent them.

Preoperatively, it is important also to assess the neurovascular status of the extremity undergoing joint replacement. Postoperative assessment data are compared with preoperative assessment data to identify changes and deficits. For example, a sensory deficit postoperatively is of concern unless it was also noted preoperatively as nerve palsy can occur as a result of surgery. A plan of nursing care for a patient with a total hip replacement is available online at http://thepoint.lww.com/Honan2e.

Providing Patient Education

Maintenance of the femoral head component in the acetabular cup is essential. The nurse teaches the patient about positioning the leg in abduction, which helps prevent dislocation of the prosthesis. The patient is aware that an abduction splint, a wedge pillow, or pillows will be placed between the knees to keep the hip in abduction if a posterior approach is used. For an anterior approach or anterolateral approach, the patient is instructed to avoid hip extension as well as external rotation beyond neutral. With an anterior THA approach, the hip muscles are left intact, generally leading to a more stable hip, lower complication rates (e.g., lower rate of dislocation, reduced blood loss), earlier restoration of gait, and decreased postoperative restrictions. The nurse should consult with the surgeon regarding the need for specific postoperative hip restrictions. General dislocation precautions include no hip flexion past 90 degrees, avoid hip adduction and internal or external rotation, and do not lie in prone position. In general, hip precautions including raised toilet seats should be employed as they will minimize hip joint flexion in the postoperative period.

Nursing Alert

For total hip replacement surgery (posterior approach) the legs should be slightly abducted. Prevent hip flexion beyond 90 degrees, hip adduction, and internal rotation to avoid dislocation of the hip after joint replacement surgery. For an anterior approach, motions that externally rotate the limb as well as hyperextension and flexion of the hip combined with external rotation are avoided.

Preventing Infection

Preoperative assessment of the patient for infections (including skin, urinary tract, and pulmonary infection) is necessary because of the risk for postoperative infection. Any infection 2 to 4 weeks before planned surgery may result in postponement of surgery.

Preoperative skin preparation frequently begins 1 or 2 days before the surgery. Prophylactic antibiotics are given immediately preoperatively (typically less than 2 hours before the surgery) and continued for 24 hours (Mackenzie & Su, 2016).

Intraoperative Management

Blood is conserved during surgery to minimize loss via a pneumatic tourniquet that produces a "bloodless field." Intraoperative blood salvage with reinfusion is used when a large volume of blood loss is anticipated, and this has shown to substantially reduce the need for allogeneic transfusions (transfusion of blood collected from someone other than the patient) (Xie et al., 2015).

Airborne bacteria that contaminate the wound at the time of surgery cause most deep infections. Therefore, as with any surgery, there is strict adherence to aseptic principles, and the operating area is controlled and made as bacteria-free as possible.

Culture of the joint during surgery, before intraoperative antibiotic therapy is begun, may be important in identifying and treating subsequent infections. If osteomyelitis develops, it is difficult to treat. Persistent infection at the site of the prosthesis usually requires removal of the implant and joint revision, which is a complex procedure. Also, it is not always possible to achieve a functional joint when the reconstruction procedure has to be repeated.

Postoperative Management

Repositioning the Patient and Preventing Dislocation

Depending on the surgical approach, the nurse may turn the patient onto the affected or unaffected extremity as prescribed by the surgeon.

Dislocation is more common with the posterolateral approach and is seen when the hip is in full flexion, adducted (legs together), and internally rotated. For this reason, the patient will have either a triangular abduction wedge placed between the legs or pillows placed between the knees prior to positioning, to keep the affected leg in an abducted position and prevent internal rotation. The pillows between the legs are used when in a supine or side-lying position and when turning. The patient's hip is never flexed more than 90 degrees. To prevent hip flexion, the nurse does not elevate the head of the bed more than 60 degrees. Limited flexion is maintained during transfers and when sitting. When the patient is initially assisted out of bed, an abduction splint or pillows are kept between the legs. The nurse encourages the patient to keep the affected hip in extension, instructing the patient to pivot on the unaffected leg with assistance by the nurse, who protects the affected hip from adduction (together), flexion, internal or external rotation, and excessive weight-bearing.

When the patient is turned onto his side, proper alignment and supported abduction are maintained with pillows or abduction wedge. The nurse ensures that the straps of the abduction wedge are secured before turning the patient onto his unaffected side and that straps do not cause undue pressure on the peroneal nerve or surrounding skin. If the patient needs to use a bedpan, a fracture bedpan is used; the nurse instructs the patient to flex the unaffected hip and use the trapeze to lift the pelvis onto the pan. The patient is also reminded not to flex the affected hip. In addition, the patient is aware that crossing of legs is prohibited. Elevated toilet seats and chairs are suggested, as well as "reaching devices" that will limit hip flexion to less than 90 degrees. Occupational therapists can provide the patient with devices to assist with dressing below the waist.

High-seat (orthopedic) chairs and semireclining wheelchairs may also be used to minimize hip joint flexion. When sitting, the patient's hips should be higher than the knees. The patient's affected leg should not be elevated when sitting. The patient may flex the knee. A cradle boot may be used to prevent leg rotation and to support the heel off the bed, preventing development of a pressure ulcer. In general, the nurse instructs the patient not to sleep on the operative side without consulting the surgeon. Hip precautions should be enforced for 4 or more months after surgery.

Dislocation may occur with positioning that exceeds the limits of the prosthesis. The nurse must recognize dislocation of the prosthesis. Indicators are as follows:

- Increased pain at the surgical site, swelling, and immobilization
- Acute groin pain in the affected hip or increased discomfort
- Shortening of the leg
- Abnormal external or internal rotation
- Restricted ability or inability to move the leg
- Reported "popping" sensation in the hip

If a prosthesis becomes dislocated, the nurse (or the patient, if at home) immediately notifies the surgeon because the hip must be reduced and stabilized promptly so that the leg does not sustain circulatory and nerve damage. After closed reduction, the hip may be stabilized with Buck's traction or a brace to prevent recurrent dislocation. As the muscles and joint capsule heal, the chance of dislocation diminishes. Stresses to the new hip joint should be avoided for the first 3 to 6 months.

Promoting Ambulation

Patients with total hip replacement begin ambulation with a physical therapist, generally within a day after surgery. The nurse and the physical therapist assist the patient in achieving the goal of independent ambulation. At first, the patient may be able to stand for only a brief period because of orthostatic hypotension.

Nursing Alert

Orthostatic hypotension is an abnormal drop in blood pressure on change of position from lying to standing. Approximately 500 to 700 mL of blood momentarily shifts to the lower body when changing position to standing from supine, resulting in decreased venous return and arterial pressure. Complaints of dizziness may be noted. A drop of systolic pressure of 20 mm Hg, a drop in diastolic pressure of 10 mm Hg or more, or an increase in heart rate of 15 bpm within 3 minutes is diagnostic of orthostatic hypotension. It may be related to hypovolemia, dehydration, drug-induced hypotension, or prolonged bed rest. Patients should be encouraged to rise slowly and move their legs prior to rising to facilitate venous return from the extremities.

BOX 42-13 Patient Education

Avoiding Hip Dislocation After Replacement Surgery

Until the hip prosthesis stabilizes after hip replacement surgery, it is necessary to follow instructions for proper positioning so that the prosthesis remains in place. Dislocation of the hip is a serious complication of surgery that causes pain and loss of function and necessitates reduction under anesthesia to correct the dislocation. Desirable positions include abduction, neutral rotation, and flexion of less than 90 degrees. When you are seated, the knees should be lower than the hip.

Methods for avoiding displacement for posterior hip procedures include the following:

- Keep the knees apart at all times.
- Put two pillows between the legs when sleeping.
- Never cross the legs when seated.
- Avoid bending forward when seated in a chair to pick up an object on the floor.
- Avoid internal rotation of the hip.
- Avoid sitting in a low chair or toilet seat to avoid flexing the hip more than 90 degrees.

- Use a high-seated chair and a raised toilet seat; consider handrails by the toilet.
- Limit sitting to 30 minutes at a time—to minimize hip flexion and the risk of prosthetic dislocation and to prevent hip stiffness and flexion contracture.
- Do not flex the hip to put on clothing such as pants, stockings, socks, or shoes. Consider Occupational therapy devices for dressing and reaching.
- Encourage quadriceps setting and ROM exercises, as directed.
- Positions to avoid after total hip replacement are illustrated below.

Affected leg should not cross the center of the body

Hip should not bend
more than 90 degrees

Affected leg should
not turn inward

Specific weight-bearing limits on the prosthesis are determined by the surgeon and are based on the patient's condition, the procedure, and the fixation method. Usually, patients with cemented prostheses can proceed to weight bearing as tolerated. If the patient has a press-fit, cementless, ingrowth prosthesis, weight-bearing immediately after surgery may be limited to minimize micromotion of the prosthesis in the bone. As the patient is able to tolerate more activity, the nurse encourages transferring to a chair several times a day for short periods and walking for progressively greater distances. Refer to Box 42-13 for patient education to prevent hip dislocation.

Monitoring for Complications

Complications that may occur include dislocation of the hip prosthesis, excessive wound drainage, thromboembolism, infection, and heel pressure ulcer. Other complications for which the nurse must monitor include those associated with immobility, heterotopic ossification, AVN, and loosening of the prosthesis.

Monitoring Wound Drainage

If extensive blood loss is anticipated after total joint replacement surgery, an autotransfusion drainage system (in which the drained blood is filtered and reinfused into the patient during the immediate postoperative period) may be used to decrease the need for blood transfusions. Because of the risk of contamination, the blood should be administered within 6 hours of initiation of collection. The nurse should follow institutional protocol.

Fluid and blood accumulating at the surgical site may be drained with a portable suction device (PSD). Traditionally PSD was used to prevent accumulation of fluid, which could contribute to discomfort and provide a site for infection. However, recent research reveals that patients with PSD required transfusions and had longer length of stay; in addition, no differences were observed in pain level, wound-related complications, infection, or early functional outcome than in patients managed postoperatively without drains (Fichman, 2016). If drains are used, typically they are removed by 48 hours after surgery.

Preventing Deep Vein Thrombosis

The risk of venous thromboembolism is particularly great after reconstructive hip surgery. Without prophylaxis, the incidence of documented DVT in the patient with total joint arthroplasty is reported in the range of 40% to 60% (Kakkar & Rushton-Smith, 2013). The peak occurrence is 2 to 14 days after surgery (60% of DVTs occur within 2 weeks); however, patients are at risk until 6 months after the operation (Kakkar & Rushton-Smith, 2013). The risk of DVT can be reduced with short intraoperative time, epidural anesthesia, intraoperative heparin administration, elastic stockings, pneumatic devices, foot flexion-extension exercises, and early ambulation. Therefore, the nurse must institute preventive measures and monitor the patient closely for the development of DVT and PE. Signs of DVT include unilateral calf pain, swelling, and tenderness. Measures to promote circulation and decrease venous stasis are priorities for the patient undergoing hip reconstruction. The nurse encourages the patient to consume adequate amounts of fluids,

to perform ankle and foot exercises hourly while awake, to use elastic stockings and sequential compression devices as prescribed, and to transfer out of bed and ambulate with assistance beginning on the first postoperative day. There is no consensus on appropriate anticoagulation status post-THA; however, low–molecular-weight heparin (e.g., enoxaparin [Lovenox], dalteparin [Fragmin]) or sometimes unfractionated heparin frequently is prescribed as prophylaxis for DVT after hip replacement surgery. If warfarin is administered, the international normalized ratio (INR) should be maintained between 2.0 and 3.0, typically for 21 days (Mackenzie & Su, 2016; McElroy, Innerfield, Cuccurullo, & Rossi, 2015).

Preventing Infection

Infection, a serious complication of total hip replacement, may necessitate removal of the implant. Patients who are elderly, obese, or poorly nourished, and patients who have diabetes, rheumatoid arthritis, concurrent infections (e.g., UTI, dental abscess), or large hematomas are at high risk for infection.

Because total joint infections are so disastrous, all efforts are made to prevent them. Potential sources of infection are avoided. Typically prophylactic antibiotics are prescribed less than 2 hours before surgery and continued for 24 hours. If indwelling urinary catheters or portable wound suction devices are used, they are removed as soon as possible to avoid infection. Prophylactic antibiotics are prescribed if the patient needs any future surgical or invasive procedures, such as tooth extraction or cystoscopic examination.

BOX 42-14 Risk Factors for Delayed Healing

The nurse is aware that patients who present with the following factors are at risk for delayed healing of fractures:

- Extensive local trauma
- Malnutrition
- Bone loss
- Inadequate immobilization
- Space or tissue between bone fragments
- Infection
- Local malignancy
- Metabolic bone disease (e.g., Paget disease)
- Irradiated bone (radiation necrosis)
- Avascular necrosis (AVN)
- Intra-articular fracture (synovial fluid contains fibrolysins, which lyse the initial clot and restrict clot formation)
- Age (elderly people heal more slowly)
- Corticosteroids (inhibit the repair rate)

Acute infections may occur within 3 months after surgery and are associated with

progressive superficial infections or hematomas. Delayed surgical infections may appear 4 to 24 months after surgery and may cause return of discomfort in the hip. Infections occurring more than 2 years after surgery are attributed to the spread of infection through the bloodstream from another site in the body. If an infection occurs, antibiotics are prescribed. Severe infections may require surgical débridement or removal of the prosthesis. Refer to Box 42-14 for risk factors associated with impaired healing.

Teaching the Patient Self-Care

Before the patient prepares to leave the acute care setting, the nurse provides thorough teaching to promote continuity of the therapeutic regimen and active participation in the rehabilitation process. The nurse advises the patient of the importance of the daily exercise program in maintaining the functional motion of the hip joint and strengthening the abductor muscles of the hip, and reminds the patient that it will take time to strengthen and retrain the muscles.

Assistive devices (crutches, walker, or cane) are used for a time. After sufficient muscle tone has developed to permit a normal gait without discomfort, these devices are not necessary. In general, by 3 months, the patient can resume routine ADLs. Frequent walks, swimming, and use of a high rocking chair are excellent for hip exercises. Sexual intercourse can be resumed based upon surgeon recommendation (typically 4 to 6 weeks postoperatively). Sexual positions will depend on surgical approach used for THA and will be individualized based upon the position of the hip that is most unstable.

Assistance in putting on shoes and socks may be needed. The patient should avoid low chairs and maintain restrictions per surgeon's preference. At the present time, weight-bearing restrictions after THA are not standardized and are typically determined by the surgeon's preference. Precautions that minimize hip flexion and risks of prosthetic dislocation, hip stiffness, and flexion contracture are reviewed with the patient and significant others. Other activities to avoid typically include tub baths, jogging, lifting heavy loads, and excessive bending and twisting (e.g., lifting, shoveling snow, forceful turning).

Nursing Alert
The risk of dislocation after THA decreases as time passes without a dislocation. If dislocation occurs, typically it is seen within 6 weeks after surgery and frequently is associated with adhering to postsurgical guidelines.

TOTAL KNEE REPLACEMENT

Total knee replacement surgery is considered for patients who have severe pain and functional disabilities related to destruction of joint surfaces by arthritis (osteoarthritis, AVN, rheumatoid arthritis, posttraumatic arthritis) or bleeding into the joint (e.g., hemarthrosis), such as may result from hemophilia. Metal and acrylic prostheses designed to provide the patient with a functional, painless, stable joint may be used. If the patient's ligaments have weakened, a fully constrained (hinged) or semiconstrained prosthesis may be used to provide joint stability. A nonconstrained prosthesis depends on the patient's ligaments for joint stability.

Postoperative Management

Postoperatively, the knee is dressed with a compression bandage. Ice may be applied to control edema and bleeding. The nurse assesses the neurovascular status of the leg. It is important to encourage active flexion of the foot every hour when the patient is awake. Efforts are directed at preventing complications (thromboembolism, peroneal nerve palsy, infection, limited ROM).

A wound suction drain removes fluid accumulating in the joint. Drainage varies depending on operative event (cement vs. non-cement; use of drains, tourniquets) and patient comorbidities. In general, the surgeon can be expected to remove the drains within 24 hours. If extensive bleeding is anticipated, an autotransfusion drainage system may be used during the immediate postoperative period. The color, type, and amount of drainage are documented, and any excessive drainage or change in characteristics of the drainage is promptly reported to the surgeon.

The use of a CPM device is often dependent on the surgeon's preference. If a CPM machine is used, the patient's leg is placed in the device and ROM movement usually begins on postoperative day 1 at full extension (0 degrees) and 30 degrees of flexion and generally is advanced 5 to 10 degrees per day until 90 degrees of flexion is achieved at approximately 6 weeks postoperatively (McElroy et al., 2015). The physical therapist supervises exercises for strength and ROM, and progression of rehabilitation will be based upon patient tolerance.

The nurse assists the patient to get out of bed on the evening of or the day after surgery. The knee is usually protected with a knee immobilizer (splint, cast, or brace) and is elevated when the patient sits in a chair. The surgeon prescribes weight-bearing limits. Progressive ambulation, using assistive devices and within the prescribed weight-bearing limits, begins on the day after surgery.

After discharge from the hospital, the patient may continue to use the CPM device at home and may undergo physical therapy on an outpatient basis. The overall complication rate of total knee replacement is 8% within the first 6 months postoperatively. Complications include knee stiffness, infection, DVT, poor wound healing, loosening of components, periprosthetic fracture, and nerve injury (McElroy et al., 2015). As with THA, there is no uniform consensus regarding type and duration of anticoagulation therapy after TKA. Medications (warfarin, heparin, aspirin, or enoxaparin) and pneumatic compression devices are often utilized. Patients usually can achieve a pain-free, functional joint and participate more fully in life activities than before the surgery.

AMPUTATION

Amputation is the removal of a body part, usually an extremity. Amputation of a lower extremity is often necessary because of progressive peripheral vascular disease (often a sequela of diabetes mellitus), fulminating gas gangrene, trauma (crushing injuries, burns, frostbite, electrical burns), congenital deformities, chronic osteomyelitis, or malignant tumor. Of all these causes, peripheral vascular disease accounts for 82% of all amputations, with 97% of these in the lower limb (Uustal, 2015). (See Chapter 18 for more information about peripheral vascular disease.) Amputation of an upper extremity occurs less frequently than amputation of a lower extremity and is most often necessary because of either traumatic injury or a malignant tumor. More than 100,000 major amputations occur each year in the United States, and there are currently 1.6 million amputee survivors in the United States, with numbers increasing annually (Uustal, 2015).

Levels of Amputation

Amputation is performed at the most distal point that will heal successfully. The site of amputation is determined by two factors: circulation in the body part and functional usefulness (i.e., meets the requirements for the use of a prosthesis).

The objective of surgery is to conserve as much extremity length as needed to preserve function and possibly to achieve a good prosthetic fit. Preservation of knee and elbow joints is desired. Most amputations involving extremities can be eventually fitted with a prosthesis.

The amputation of toes and portions of the foot causes minor changes in gait and balance. A Syme amputation (modified ankle disarticulation amputation) is the most common ankle procedure and is performed frequently for extensive foot trauma; it produces a painless, durable extremity end that can withstand full weight bearing. Below-knee amputation (BKA) is preferred to above-knee amputation (AKA) because of the importance of the knee joint and the energy requirements for walking. Knee disarticulations are most successful with young, active patients who can develop precise control of the prosthesis. When AKAs are performed, all possible length is preserved, muscles are stabilized and shaped, and hip contractures are prevented for maximum ambulatory potential. Most people who have a hip disarticulation amputation must rely on a wheelchair for mobility.

Complications

Complications that may occur with amputation include hemorrhage, infection, skin breakdown, phantom limb pain, and joint contracture. Because major blood vessels have been severed, massive bleeding may occur. Infection is a risk with all surgical procedures. The risk of infection increases with contaminated wounds after traumatic amputation. Skin irritation caused by the prosthesis may result in skin breakdown. Phantom limb pain is caused by the severing of peripheral nerves. Joint contracture is caused by positioning and a protective flexion withdrawal pattern associated with pain and muscle imbalance.

The 5-year survival rate for patients with BKA due to vascular disease is 48%, and only 22% for patients with AKA, whereas long-term survival rate for patients with traumatic amputation is near normal life expectancy (Uustal, 2015).

Medical and Nursing Management

Dressings vary according to surgeon preference and may include a closed rigid cast dressing, a removable rigid dressing, or a soft dressing. A closed rigid cast dressing is frequently used to provide uniform compression, support soft tissues, control pain, and prevent joint contractures. Care is taken not to constrict circulation.

For the patient with a lower extremity amputation, the plaster cast may be equipped to attach a temporary prosthetic extension (pylon) and an artificial foot. This rigid dressing technique is used as a means of creating a socket for immediate postoperative prosthetic fitting. The length of the prosthesis is tailored to the individual patient. Early minimal weight bearing on the residual limb with a rigid cast dressing and a pylon attached produces little discomfort. The cast is changed in about 10 to 14 days. Elevated body temperature, severe pain, or a loose-fitting cast may necessitate earlier replacement.

A removable rigid dressing may be placed over a soft dressing to control edema, prevent joint flexion contracture, and protect the residual limb from unintentional trauma during transfer activities. This rigid dressing is removed several days after surgery for wound inspection and is then replaced to control edema. The dressing facilitates residual limb shaping.

A soft dressing with or without compression may be used if there is significant wound drainage, and frequent inspection of the residual limb (stump) is desired. An immobilizing splint may be incorporated in the dressing. Stump (wound) hematomas are controlled with wound drainage devices to minimize infection.

Nursing Alert

If the cast or elastic dressing inadvertently comes off, the nurse must immediately wrap the residual limb with an elastic compression bandage. If this is not done, excessive edema will develop in a short time, resulting in a delay in rehabilitation. The nurse notifies the surgeon if a cast dressing comes off so that another cast can be applied promptly.

Promoting Rehabilitation

Patients who require amputation because of severe trauma are usually, but not always, young and healthy, heal rapidly, and are physically able to participate in a vigorous rehabilitation program. Because the amputation is the result of an injury, the patient needs psychological support in accepting the sudden change in body image and in dealing with the stresses of hospitalization, long-term rehabilitation, and modification of lifestyle. Patients who undergo amputation need support as they grieve the loss, and they need time to work through their feelings about their permanent loss and change in body image. Their reactions are unpredictable and can include anger, bitterness, and hostility.

The multidisciplinary rehabilitation team (patient, nurse, clinical nurse specialist, physician, social worker, physical therapist, occupational therapist, psychologist, prosthetist, vocational rehabilitation worker) helps the patient achieve the highest possible level of function and participation in life activities. Prosthetic clinics and amputee support groups facilitate this rehabilitation process. Vocational counseling and job retraining may

be necessary to help patients return to work.

Psychological issues (e.g., denial, withdrawal) may be influenced by the type of support the patient receives from the rehabilitation team and by how quickly ADLs and use of the prosthesis are learned. Knowing the full options and capabilities available with the various prosthetic devices can give the patient a sense of control over the resulting disability.

Minimizing Altered Sensory Perceptions

A person who has had an amputation may experience phantom limb pain soon after surgery or 2 to 3 months later. It occurs more frequently in patients who have had AKAs. As many as 80% of amputees complain of phantom pain, which is often described as sharp and electric or burning pain of the amputated limb, and highly fluctuant (Andersen, Nanos, Pinzur, & Potter, 2015). The pathogenesis of the phantom limb phenomenon is unknown. When a patient describes phantom pains or sensations, the nurse acknowledges these feelings and helps the patient modify these perceptions. Phantom sensations were thought to diminish over time; however, recent research challenges that notion. Richardson, Crawford, Milnes, Bouch, & Kulkarni, (2015) found that phantom pain was associated with sleep loss and social restrictions, and their results challenge the belief that phantom limb pain reduces over time. Further research is warranted on this complex phenomenon, and a multimodal approach that combines both pharmacologic and nonpharmacologic interventions should be considered. Transcutaneous electrical nerve stimulation (TENS), massage, mirror therapy, ultrasound, acupuncture, hypnosis, hot and cold modalities, or local anesthetics may provide some relief for patients. In addition, beta blockers may relieve dull, burning discomfort; antiseizure medications control stabbing and cramping pain; and tricyclic antidepressants are used to modify pain signals and improve mood and coping ability. Newer treatment modalities include virtual reality in an attempt to extinguish maladaptive memory traces of the amputated limb and extinguish the pain (Sano et al., 2015).

Helping the Patient to Achieve Physical Mobility

Proper positioning prevents the development of hip or knee joint contracture in the patient with a lower extremity amputation. Exercises that preserve essential ROM for hip extension and knee extension also should be part of the therapy program. Abduction, external rotation, and flexion of the lower extremity are avoided. Depending on the surgeon's preference, the residual limb may be placed in an extended position or elevated for a brief period after surgery. Prolonged elevation (after initial 24 hours postoperative) is not recommended as flexion contractions are to be avoided.

Nursing Alert
The residual limb should not be placed on a pillow because a flexion contracture of the hip may result.

A physical therapist will develop exercises if indicated for muscle strengthening and to prevent abduction and flexion contractures. The nurse encourages the patient to turn from side to side and to assume a prone position, if possible, to stretch the flexor muscles and to prevent flexion contracture of the hip. The nurse discourages sitting for prolonged periods

to prevent flexion contracture. The legs should remain close together to prevent an abduction deformity. The nurse encourages the patient to use assistive devices (e.g., reachers) to more readily perform self-care activities and to identify what home modifications should be made to perform these activities in the home environment.

Postoperative ROM exercises are started early because contracture deformities develop rapidly. ROM exercises include hip and knee exercises for BKAs and hip exercises for AKAs. It is important that the patient understand the importance of exercising the residual limb.

The upper extremities, trunk, and abdominal muscles are exercised and strengthened. The extensor muscles in the arm and the depressor muscles in the shoulder play an important part in crutch walking. The major problems that can delay prosthetic fitting during this period are (1) flexion deformities, (2) nonshrinkage of the residual limb, and (3) abduction deformities of the hip. In general, fabrication of the temporary prosthesis begins 3 to 4 weeks after amputation. The wearing time should start with only 1 to 2 hours per day and advance by 1 hour daily if tolerated.

Excessive pressure from the prosthesis can cause skin irritation, pain, skin breakdown, and infection. The nurse observes the operative site for erythema and pain. The introduction of gel liner material improves the ability of the skin to tolerate pressures. However, because of sanitation issues associated with gel liners, daily cleansing of the skin and gel liner is essential to prevent maceration of the skin or development of bacterial and fungal infections (Uustal, 2015). The nurse also assesses for systemic indicators of infection (e.g., elevated temperature, leukocytosis [elevated WBCs] with an increase of at least 10% bands on the differential) and promptly reports indications of infection to the surgeon.

CHAPTER REVIEW

Critical Thinking Exercises

1. You volunteer to provide field first aid for your neighborhood's softball league. Common injuries you expect include sprains, strains, and possibly dislocations and fractures. What specific assessment would you make to differentiate these problems? Describe the standard treatment for any of these common musculoskeletal disorders.

2. A 68-year-old man has had a repair of a fracture of his right tibia. During the evening of his second postoperative day, he complains of increasing pain and slight paresthesias of his right toes. Opioid analgesics have only moderately relieved his pain. The night-shift nurse documents her findings and asks you, as the oncoming day-shift nurse, to report these findings to the orthopedic surgeon when he makes his rounds. You assess the patient after report and find that he now describes his right lower leg as "feeling tight" and that he has sensations of "pins and needles." His right lower leg has a capillary refill longer than 3 seconds, and his right toes feel much cooler than the left toes. What additional assessments might you make at this time? What is your priority nursing diagnosis and intervention?

3. Mrs. Y, who is postoperative from total hip repair and has a history of ulcers, is

complaining of abdominal pain. Her hematocrit this morning is 8/24. One unit of packed cells is administered. One hour after the unit has infused, you are asked to draw a repeat H/H. If Mrs. Y does not have any additional sources of blood loss, what do you expect her H/H to rise by in the repeat laboratory work?

NCLEX-Style Review Questions

1. In the immediate postoperative period, which measure would best prevent a DVT?
   a. Adding a multivitamin to the patient's medication
   b. Early ambulation
   c. Measuring intake and output
   d. Lowering the legs below the level of the heart

2. A 22-year-old man is admitted to the emergency department with a crush injury to both lower legs. He was pinned under a car for 3 hours. On admission, his vital signs are stable; he is alert and oriented and complaining of extreme pain in his legs. Popliteal pulses are strong; pedal and posterior tibial pulses are weak. The ankle and feet appear dusky; the skin is tense, but the skin envelope is not broken. X-rays show no broken bones. Based upon these data, what interventions are most appropriate?
   a. Notify the provider and anticipate that a stat $\dot{V}/\dot{Q}$ scan will be performed to rule out fat emboli.
   b. Notify the provider and prepare to set up skin traction to decrease the pressure on the calf muscle.
   c. Notify the provider and anticipate that the provider will measure the pressure in the compartment and possibly perform a fasciotomy if elevated pressure is noted.
   d. Notify the provider and prepare to give IV antibiotics stat to decrease the risk of osteomyelitis.

3. During assessment of a patient admitted to the emergency room after a motor vehicle collision, he becomes semiconscious and continues moaning with pain. His blood pressure has now decreased to 100/42, and his pulse has increased to 122. What is the most immediate life-threatening problem for this patient?
   a. Arrhythmias due to hypokalemia
   b. Hypovolemia
   c. Respiratory depression from pain medication
   d. Fat embolus to the lung

4. A 73-year-old patient is placed in skeletal traction prior to surgery for an ORIF of fractured femur. She develops chest pain, tachypnea, and tachycardia the second day in traction. What additional symptom would indicate her symptoms are related to a fat emboli rather than a pulmonary thromboembolic event?
   a. Hypotension
   b. Restlessness

c. Petechiae of the anterior chest wall
d. Warm, reddened areas in her leg

5. A 23-year-old patient, experienced an open fracture of the left tibia with major soft tissue damage of his lower leg in a bicycle accident. Surgical reduction and fixation of the tibia were performed with debridement of nonviable tissue and drain placement in the damaged soft tissue. Which finding by the nurse would most likely indicate the development of the osteomyelitis?
a. Tachycardia
b. Elevated ESR
c. Numbness in the left leg and toes
d. Muscle spasms around the affected bone

Problems Related to Neurologic Function

A 65-year-old patient presents to the emergency department by ambulance. The paramedics state that his spouse witnessed the sudden onset of confusion, weakness in his right arm and leg, and difficulty speaking (he could not get the right words out). His symptoms occurred 2 hours prior to arrival at the hospital. He has a history of smoking, hypertension, atrial fibrillation, and prior transient ischemic attacks (TIAs). An initial noncontrast head CT was negative for intracerebral hemorrhage. An acute ischemic stroke in the left hemisphere is suspected.

- Discuss emergency management of a stroke when a patient presents with suspected stroke symptoms.
- What sub-type of ischemic stroke is the patient most likely experiencing?
- Discuss nursing considerations for the patient receiving tPA.
- Describe three of the eight standardized performance measures that are considered for a patient with an ischemic stroke.

CHAPTER 43

Nursing Assessment: Neurologic Function

Dawn K. Beland • Donna M. Avanecean

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the structures and functions of the central and peripheral nervous systems.
2. Differentiate between pathologic changes that affect motor control and those that affect sensory pathways.
3. Compare the functioning of the sympathetic and parasympathetic nervous systems.
4. Describe changes in neurologic function associated with aging and their impact on neurologic assessment findings.
5. Describe the significance of physical assessment to the diagnosis of neurologic dysfunction.
6. Describe diagnostic tests used for assessment of suspected neurologic disorders and the related nursing implications.

Nurses in many practice settings encounter patients with altered neurologic function. Disorders of the nervous system can occur at any time during the lifespan and can vary from mild, self-limiting symptoms to devastating, life-threatening disorders. Nurses must be skilled in the assessment of the neurologic system, whether the assessment is generalized or focused on specific areas of function. In either case, assessment requires knowledge of the anatomy and physiology of the nervous system and an understanding of the array of tests and procedures used to diagnose neurologic disorders. Knowledge about the nursing implications and interventions related to assessment and diagnostic testing is also essential.

ANATOMIC AND PHYSIOLOGIC OVERVIEW

The function of the nervous system is control of all motor, sensory, autonomic, cognitive, and behavioral activities. The nervous system consists of two major divisions: the central nervous system (CNS), including the brain and spinal cord; and the peripheral nervous system (PNS), which includes cranial and spinal nerves that lie outside the brain and spinal cord. The PNS can be further divided into the somatic, or voluntary nervous system, and the autonomic, or involuntary nervous system.

Anatomy of the Nervous System

Cells and Neurotransmitters of the Nervous System

Cells of the brain link the motor and sensory pathways, monitor the body's processes, respond to the internal and external environment, maintain homeostasis, and direct all psychological, biologic, and physical activity through complex chemical and electrical messages. The basic functional unit of the brain is the neuron (Fig. 43-1). It is composed of a cell body, a dendrite, and an axon. The dendrite is a branch-type structure with synapses (a gap between two neurons, in which impulses jump from one neuron to another) for receiving electrochemical messages. The axon is a long projection that carries impulses away from the cell body. Nerve cell bodies occurring in clusters are called *ganglia* or *nuclei.* A cluster of cell bodies with the same function is called a *center* (e.g., the respiratory center).

Neurotransmitters communicate messages from one neuron to another or from a neuron to a specific target tissue and are responsible for all types of brain activity. Each neurotransmitter has an affinity for specific receptors in the postsynaptic bulb. When released, neurotransmitters cross the synaptic cleft and bind to receptors in the postsynaptic cell membrane. The action of a neurotransmitter is to potentiate, terminate, or modulate a specific action, and it can either excite or inhibit the activity of the target cell. Usually, multiple neurotransmitters are at work in the neural synapse. Imbalances or deficiencies of a particular neurotransmitter may cause neurologic dysfunction. Major neurotransmitters are described in Table 43-1.

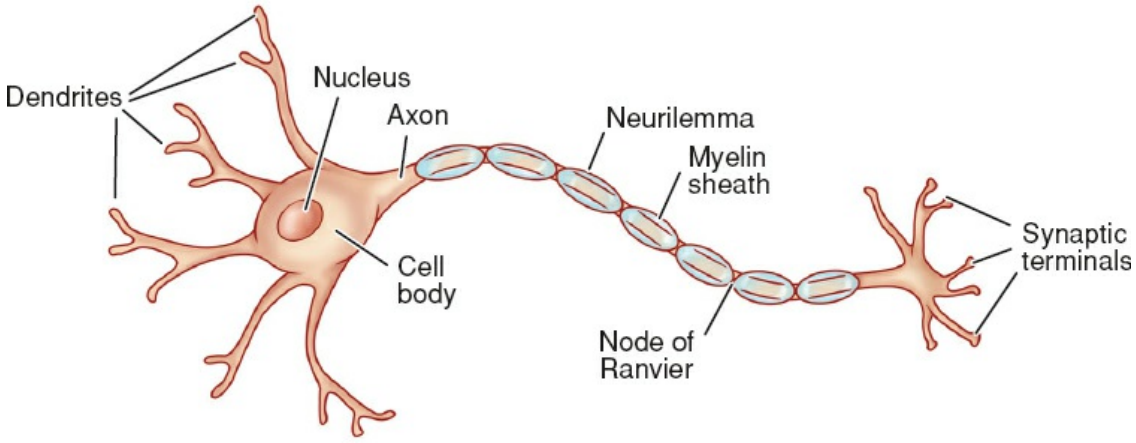

FIGURE 43-1 Neuron.

The Central Nervous System

The Brain

The brain is divided into three major areas: the cerebrum, the brainstem, and the cerebellum. The cerebrum is composed of two hemispheres, the thalamus, the hypothalamus, and the basal ganglia. In addition, connections for the olfactory (cranial nerve I) and optic (cranial nerve II) nerves are found in the cerebrum. The brainstem includes the midbrain, pons, medulla, and connections for cranial nerves III through XII.

The cerebellum is located under the cerebrum and behind the brainstem (Fig. 43-2).

Cerebrum. The cerebrum consists of two hemispheres that are incompletely separated by the great longitudinal fissure. This sulcus (a depression or groove) separates the cerebrum into the right and left hemispheres. The two hemispheres are joined at the lower portion of the fissure by the corpus callosum. The outside surface of the hemispheres has many folded layers or convolutions called *gyri,* which increase the surface area of the brain. The external or outer portion of the cerebrum (the cerebral cortex) is made up of gray matter, approximately 2 to 5 mm in depth. White matter makes up the innermost layer and is composed of nerve fibers and neuroglia (support tissue) that form tracts or pathways connecting various parts of the brain. The cerebral hemispheres are divided into pairs of frontal, parietal, temporal, and occipital lobes. The four lobes are as follows (see Fig. 43-2):

TABLE 43-1 Major Neurotransmitters

Neurotransmitter	Source	Action	Example of Dysfunction
Acetylcholine (major transmitter of the parasympathetic nervous system)	Many areas of the brain; autonomic nervous system	Usually excitatory; parasympathetic effects sometimes inhibitory (stimulation of heart by vagal nerve)	↓ Leads to Myasthenia gravis
Serotonin	Brainstem, hypothalamus, dorsal horn of the spinal cord	Inhibitory, helps control mood and sleep, inhibits pain pathways	↓ Leads to depression
Dopamine	Substantia nigra and basal ganglia	Usually inhibits, affects behavior (attention, emotions) and fine movement	↓ Leads to Parkinson disease
Norepinephrine (major transmitter of the sympathetic nervous system)	Brainstem, hypothalamus, postganglionic neurons of the sympathetic nervous system	Usually excitatory; affects mood and overall activity	Seen rarely
Gamma-aminobutyric acid (GABA)	Spinal cord, cerebellum, basal ganglia, some cortical areas	Inhibitory	↓ Leads to seizures
Enkephalin, endorphin	Nerve terminals in the spine, brainstem, thalamus and hypothalamus, pituitary gland	Excitatory; pleasurable sensation, inhibits pain transmission	Poor pain control

- Frontal: The frontal lobe is the largest lobe in the front of the skull. The major functions are concentration, abstract thought, information storage or memory, and motor function. The motor strip, which lies in the frontal lobe, anterior to the central sulcus, is responsible for muscle movement. Refer to Figure 43-3 for specific locations of control of motor movement. It also contains Broca's area and Wernicke's area (left frontal lobe region in most people), critical for motor control of speech. The frontal lobe is responsible in large part for a person's affect, judgment, personality, emotions, attitudes, and inhibitions, and contributes to the formation of thought processes.
- Parietal: The parietal lobe is the primary sensory cortex, which is located posterior to the motor strip, and is organized topographically similar to the motor strip. This lobe analyzes sensory information such as pressure, vibration, pain, and temperature, and relays the interpretation of this information to the thalamus from the sensory cortex. It is also essential to a person's awareness of the body in space, as well as orientation in space and spatial relations. For example, stereognosis or the ability to perceive an object

using the sense of touch is processed in this area.

- Temporal: The temporal lobes contain the auditory receptive areas located around the temple regions. The interpretive area of the temporal lobe provides integration of visual and auditory areas and plays the most dominant role of any area of the cortex in thinking. Located in the posterior region of the temporal lobe is the area responsible for receptive speech referred to as *Broca's area and Wernicke's area.* For most people, whether right- or left-handed, Broca's area and Wernicke's area. is in the left lobe. Long-term memory recall is also associated with this lobe.
- Occipital: The occipital lobe located in the posterior portion of the cerebral hemispheres is known as the primary visual cortex. The occipital lobe also assists in some visual reflexes, as well as allows for some involuntary eye movements.

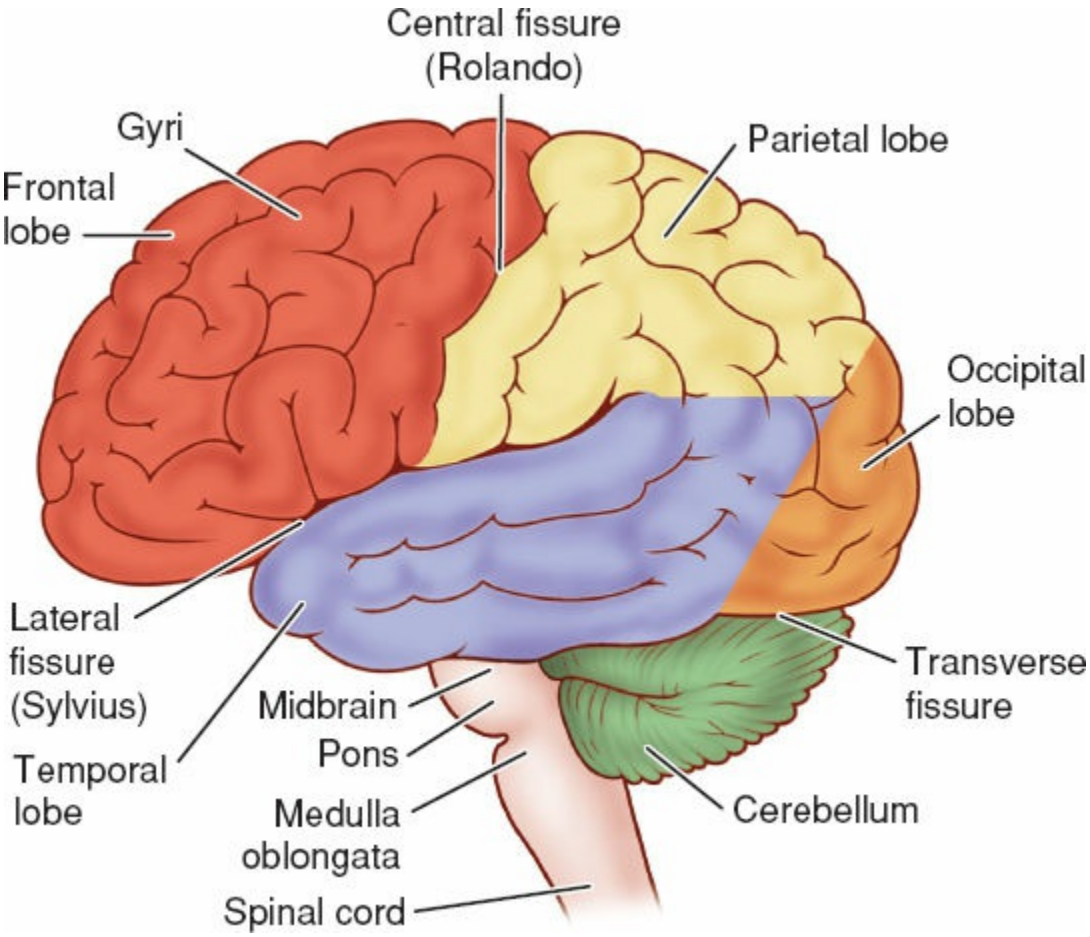

FIGURE 43-2 View of the external surface of the brain showing lobes, cerebellum, and brainstem.

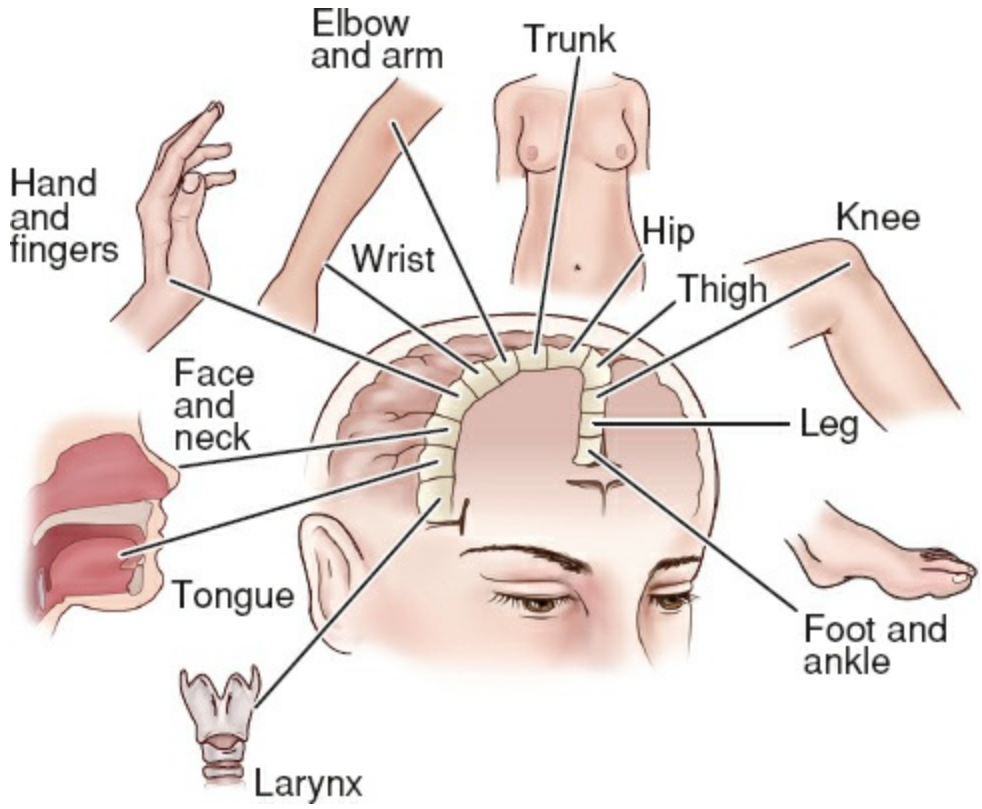

FIGURE 43-3 Diagrammatic representation of the cerebrum showing locations for control of motor movement of various parts of the body.

The corpus callosum (Fig. 43-4) is a thick collection of nerve fibers that connects the two hemispheres of the brain and transmits the information from one side of the brain to the other. Right-handed people and some left-handed people have cerebral dominance on the left side of the brain for verbal, linguistic, arithmetical, calculating, and analytic functions. The nondominant hemisphere is responsible for geometric, spatial, visual, pattern, and musical functions.

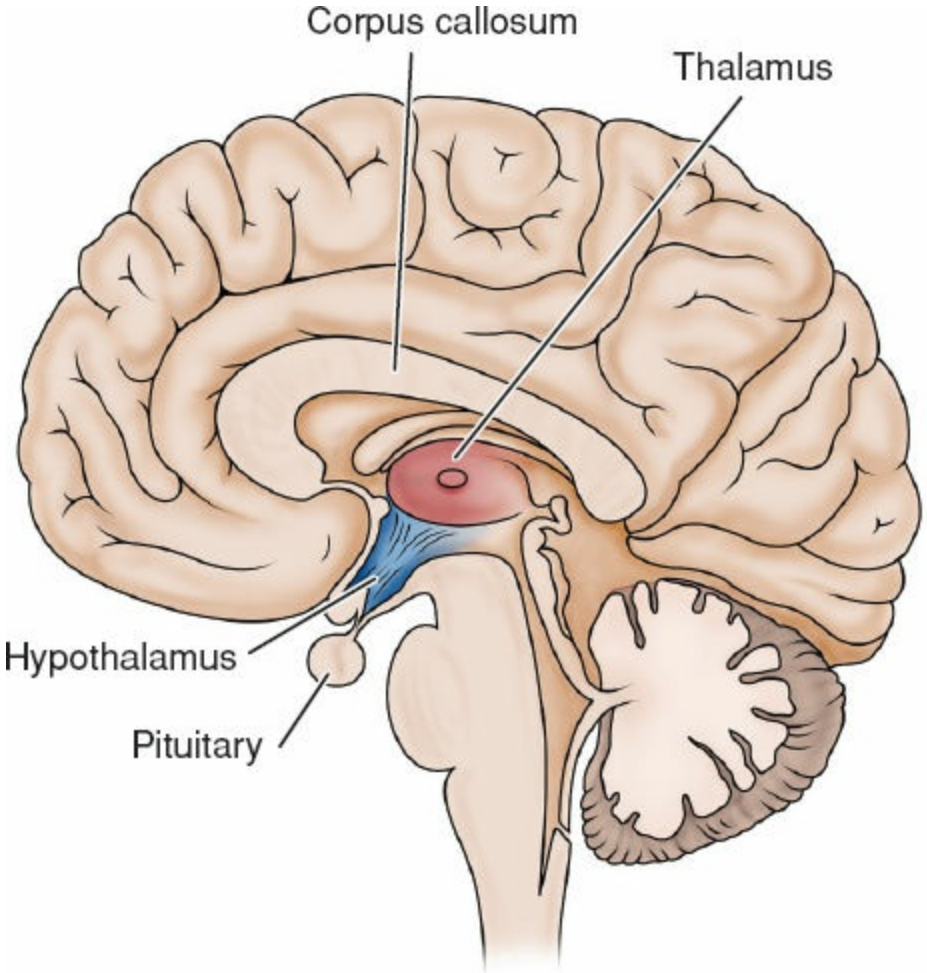

FIGURE 43-4 Medial view of the brain. The brain is divided into the right and left hemisphere, and the two halves are connected by the corpus callosum. This bundle of nerve tissue contains over 200 million axons (nerve fibers that carry electrical impulses from neurons' cell bodies) by rough estimate. This neural tissue facilitates communication between the two sides of the brain (Healthline, 2015).

The basal ganglia are masses of nuclei located deep in the white matter of the cerebral hemispheres and are responsible for control of fine motor movements. The thalamus lies on either side of the third ventricle and acts primarily as a relay station for all sensation except smell. All memory also passes through this section of the brain.

The hypothalamus (see Fig. 43-4) is anterior and inferior to the thalamus and lies next to the third ventricle. It includes the optic chiasm (where the two optic tracts cross) and the mammillary bodies (involved in olfactory reflexes and emotional response to odors). The infundibulum of the hypothalamus connects to the posterior pituitary gland. The hypothalamus, important in the endocrine system, regulates the pituitary secretion of hormones influencing metabolism, reproduction, stress response, and urine production. It works with the pituitary to maintain fluid balance (refer to Chapter 29 for further details). In addition, the hypothalamus, the site of the hunger center, is involved in appetite control. It contains centers that regulate the sleep–wake cycle, blood pressure, aggressive and sexual behavior, and emotional responses (i.e., blushing, rage, depression, panic, and fear). The hypothalamus also controls and regulates the autonomic nervous system and maintains temperature regulation by promoting vasoconstriction or vasodilatation.

The pituitary gland is located in the sella turcica at the base of the brain. The pituitary is

a common site of brain tumors in adults, which are frequently detected by signs and symptoms traced to the pituitary, such as hormonal imbalance or visual disturbances due to pressure on the optic chiasm (see Chapter 31).

Nerve fibers from the cortex converge in each hemisphere and exit in a tight bundle of nerve fibers known as the *internal capsule.* After entering the pons and medulla, each bundle crosses to the corresponding bundle from the opposite side. Although the various cells in the cerebral cortex are quite similar in appearance, their functions vary widely, depending on location.

Brainstem. The brainstem is responsible for automatic functions such as heart rate, breathing, and swallowing. It consists of the midbrain, pons, and medulla oblongata and contains motor and sensory pathways (see Fig. 43-2). The midbrain connects the pons and cerebellum with the cerebral hemispheres and serves as the center for auditory and visual reflexes. Cranial nerves III and IV originate in the midbrain. The pons is situated in front of the cerebellum, between the midbrain and the medulla, and acts as a bridge between the cerebrum, the cerebellum, and the medulla. Cranial nerves V through VIII originate in the pons and connect the brain to the pons. Portions of the pons also control the heart rate, respiration, and blood pressure.

The medulla oblongata contains motor fibers from the brain to the spinal cord and sensory fibers from the spinal cord to the brain. Most of these fibers cross, or *decussate* at this level. Cranial nerves IX through XII originate in the medulla and connect the brain to the medulla. The medulla and pons are essential for respiratory function.

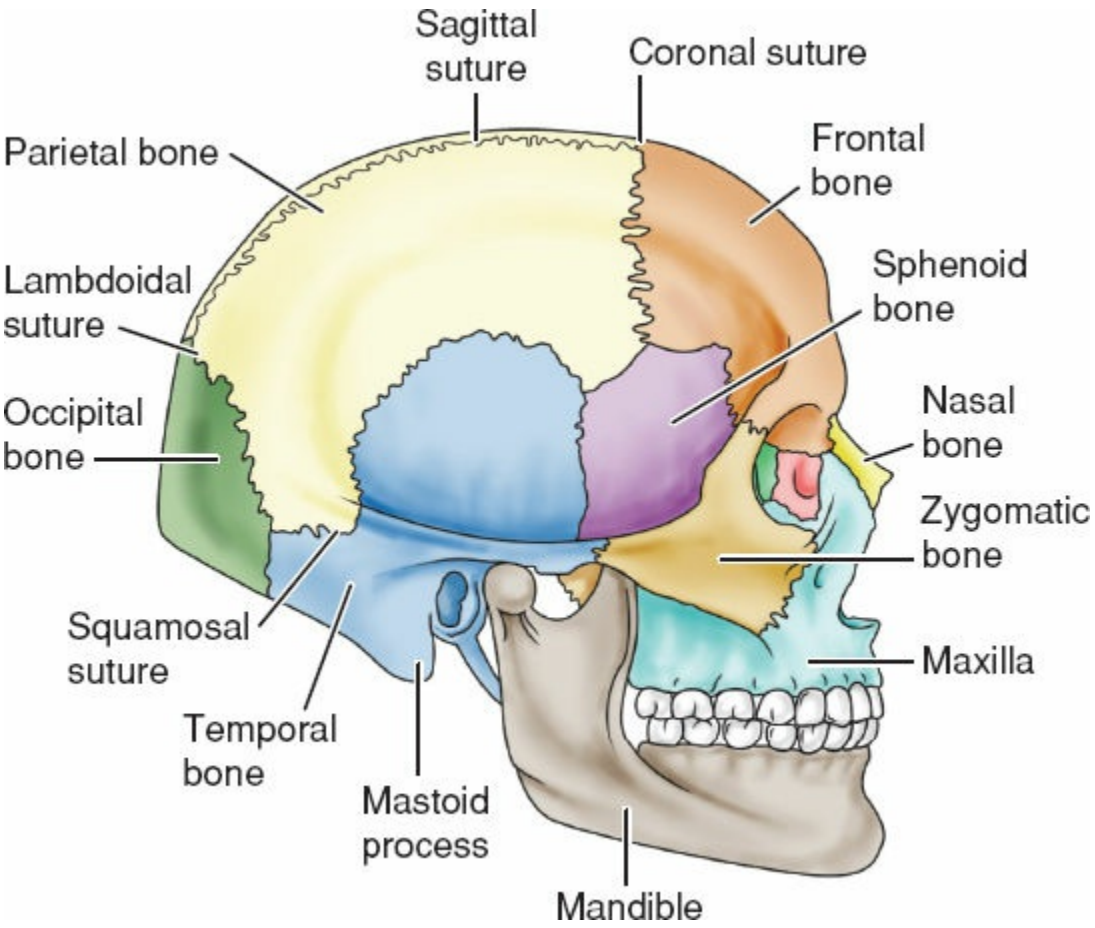

FIGURE 43-5 Bones and sutures of the skull.

Cerebellum. The cerebellum is separated from the cerebral hemispheres by a fold of dura mater, the *tentorium cerebelli.* The cerebellum is largely responsible for coordination of all movement. It also controls fine movement, balance, position (postural) sense or proprioception (awareness of where each part of the body is), and integration of sensory input.

Structures Protecting the Brain

Skull. The brain is contained in a rigid skull, protecting it from injury. The major bones of the skull are the frontal, temporal, parietal, and occipital bones (Fig. 43-5). These bones join at suture lines.

Meninges. The meninges (fibrous connective tissues) cover the brain and spinal cord, and provide protection, support, and nourishment. The three layers of the meninges are the dura, arachnoid, and pia mater (Fig. 43-6). An easy way to remember the layers is to note that the meninges "PAD" the brain (*p*ia, *a*rachnoid, and *d*ura).

The dura mater, the outermost layer, covers the brain and the spinal cord. The dura mater is tough, thick, inelastic, fibrous, and gray. There are four extensions of the dura: the falx cerebri, which separates the two hemispheres in a longitudinal plane; the tentorium, which is an infolding of the dura that forms a tough, membranous shelf between the cerebrum and cerebellum; the falx cerebelli, which lies between the two lateral lobes of the cerebellum; and the diaphragm sellae, which provides a "roof" for the sella turcica. The tentorium supports the hemispheres and separates them from the lower part of the brain. When excess pressure occurs in the cranial cavity, brain tissue may be compressed against the tentorium or displaced downward, a process called *herniation.*

The epidural space, a *potential space* that has the capacity to expand slightly, lies outside the outermost layer of the dura. In the spinal canal, the dura forms a tubular sheath around the spinal cord. This narrow space between the dura mater and the periosteum (lining of the bones) is where local anesthetic can be injected for pain relief.

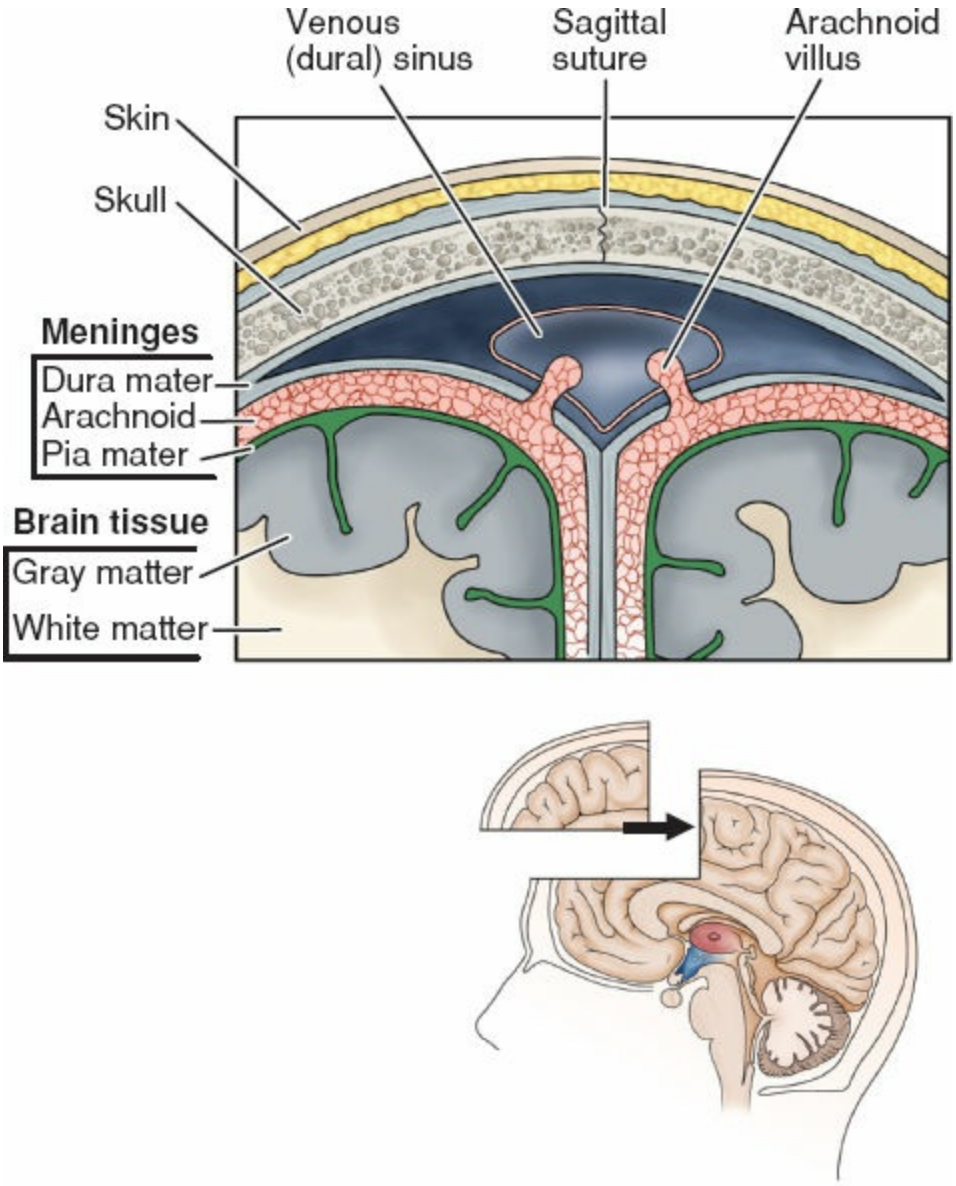

FIGURE 43-6 Meninges and related structures.

The arachnoid, the middle membrane, is an extremely thin, delicate membrane resembling a spider web (hence the name arachnoid). It appears white because it has no blood supply. This membrane has unique finger-like projections, arachnoid villi, which absorb cerebrospinal fluid (CSF). In the normal adult, approximately 500 mL of CSF is produced each day; all but 125 to 150 mL is absorbed by the villi (Hickey, 2014). When blood enters the system (from trauma or hemorrhagic stroke), the villi become obstructed, and hydrocephalus (increased size of ventricles) may result. The subarachnoid space is between the arachnoid and pia layers and contains CSF.

The pia mater, the innermost membrane, is a thin, transparent layer that hugs the brain closely and extends into every fold of the brain's surface. It is highly vascular.

Cerebrospinal Fluid

CSF, a clear and colorless fluid, is produced in the lateral ventricles by the choroid plexus and is circulated around the brain and spinal cord through the ventricular system. There

are four ventricles. The two lateral ventricles, normally containing 25 mL of CSF each, open into the third ventricle at the interventricular foramen or the foramen of Monro. The third and fourth ventricles connect via the aqueduct of Sylvius. The fourth ventricle supplies CSF to the subarachnoid space and down the spinal cord on the dorsal surface. CSF is returned to the brain and then circulated, where it is absorbed by the arachnoid villi.

The composition of CSF is similar to other extracellular fluids (such as blood plasma), but the concentrations of the various constituents differ. The laboratory report of CSF analysis usually contains information on color, specific gravity, protein count, white blood cell (WBC) count, glucose, and other electrolyte levels. Normal CSF contains a minimal number of WBCs and no red blood cells (RBCs). The intracranial pressure (ICP) within the skull results from a combination of brain tissue, blood flow, and CSF. Normal CSF pressure is approximately 5 to 15 mm Hg (Hickey, 2014), while pressures greater than 20 mm Hg indicate increased ICP.

Nursing Alert

In the event of a skull fracture, the nurse should be alert for signs of CSF leakage. Suspect rhinorrhea (leakage of CSF via nares) with fractures involving the cribriform plates of the anterior cranial fossa, while otorrhea (leakage of CSF via ear) is suspected with fractures involving the basilar skull. Depending on the site of the fracture, the patient may present with raccoon eyes (bruising around the eyes) or Battle sign (ecchymosis of the mastoid process of the temporal bone). Leakage of CSF places the patient at risk for meningitis. If a CSF leak is suspected, the nurse is aware that nothing is allowed into the patient's nose or ears (suction or nasogastric catheters, dressings, tissues etc.). See Figure 43-7.

Cerebral Circulation

The cerebral circulation receives approximately 15% of the cardiac output, or 750 mL per minute. The brain does not store nutrients, has a high metabolic demand, and requires high blood flow. The brain's blood pathway is unique because it flows against gravity; its arteries fill from below, and the veins drain from above. The brain has poor collateral blood flow, which results in irreversible tissue damage when blood flow is occluded for even short time periods.

Arteries. Two internal carotid arteries and two vertebral arteries and their extensive system of branches provide blood supply to the brain (Fig. 43-8). The internal carotids arise from the bifurcation of the common carotid and supply much of the anterior circulation. The vertebral arteries branch from the subclavian arteries, flow back and upward on either side of the cervical vertebrae, and enter the cranium through the foramen magnum. The vertebral arteries join to become the basilar artery at the brainstem; then the basilar artery divides to form the two branches of the posterior cerebral arteries. The vertebrobasilar arteries supply most of the posterior circulation of the brain.

The circle of Willis is formed from the branches of the anterior circulation and posterior circulation connected by one anterior communicating artery and two posterior communicating arteries (Fig. 43-9). The arteries of the circle of Willis can provide collateral circulation if one or more of the four vessels supplying it becomes occluded.

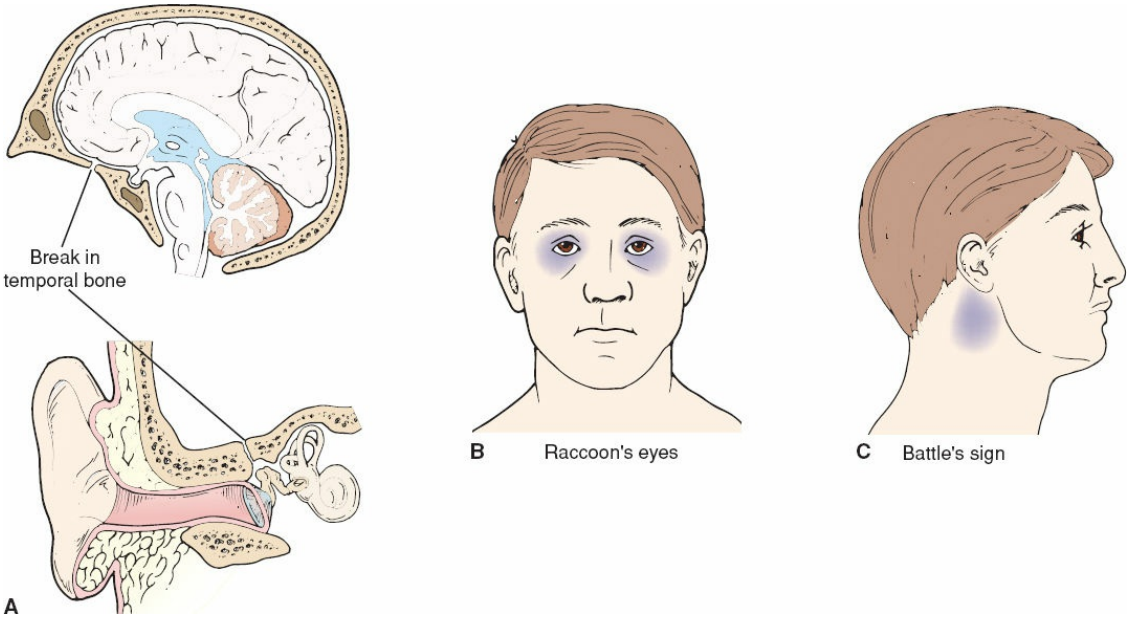

FIGURE 43-7 A. Basilar skull fracture in the temporal bone can cause cerebrospinal fluid (CSF) to leak from the nose or ear. B. Periorbital ecchymosis, called raccoon's eyes. C. Battle sign over the mastoid process. (From Rosdahl, C. B., & Kowalski, M. (2017). *Textbook of basic nursing* (11th ed.). Philadelphia, PA: Wolters Kluwer.)

The arterial bifurcations (branches) along the circle of Willis are frequent sites of aneurysm formation. Aneurysms may be congenital or result from changes in the vessel wall associated with atherosclerotic disease. If an artery with an aneurysm bursts, depending on its size and location, catastrophic effects can be seen. Additionally, if a blood vessel becomes constricted by vasospasm, it may lead to diminished blood flow, causing potential damage to neurons distal to the constriction, leading to cell death. If not aggressively treated, this may result in an ischemic stroke. The effects of the constriction depend on which vessels are involved and the areas these vessels supply.

Veins. Venous drainage for the brain does not follow the arterial circulation, as in other body structures. The veins reach the brain's surface, join larger veins, then cross the subarachnoid space, and empty into the dural sinuses, which are the vascular channels lying within the dura mater (see Fig. 43-6). The network of sinuses empties into the internal jugular vein, returning blood to the heart. Cerebral veins and sinuses are unique because, unlike other veins, they do not have valves to prevent blood from flowing backward and depend on both gravity and blood pressure.

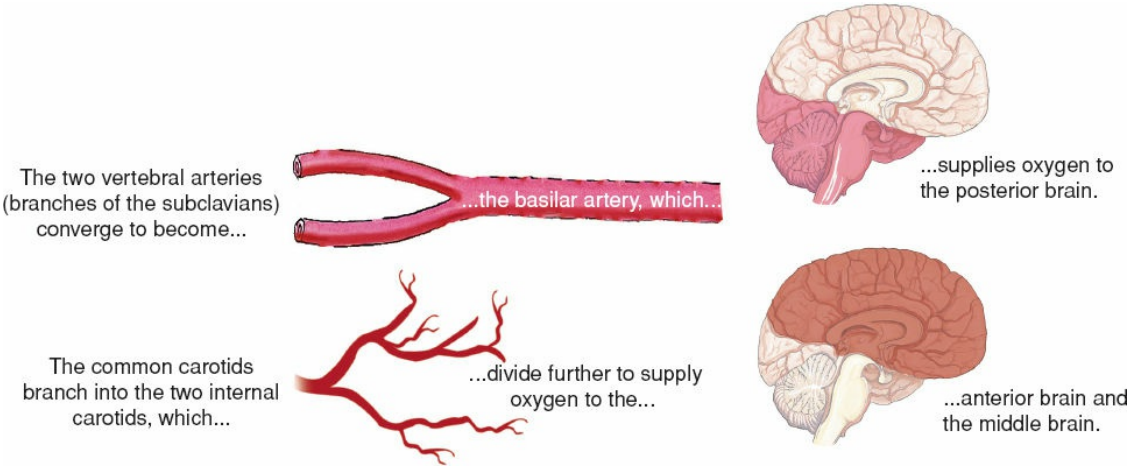

FIGURE 43-8 Arterial circulation to the brain. (From Lippincott. (2009). *Anatomy and physiology made incredibly visual!* (p. 63). Philadelphia, PA: Lippincott Williams & Wilkins.)

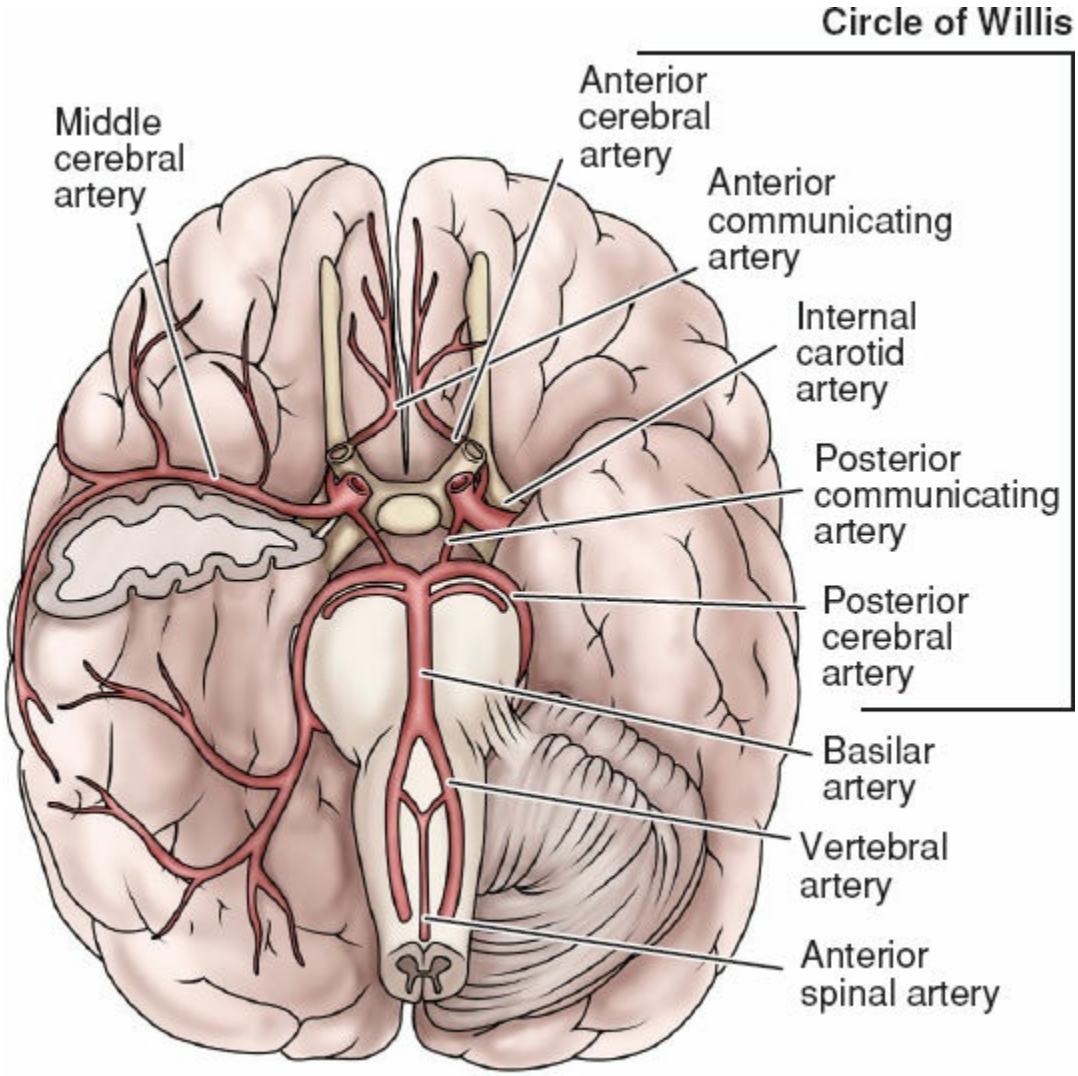

FIGURE 43-9 Arterial blood supply of the brain, including the circle of Willis, as viewed from the ventral surface.

Blood–Brain Barrier

The CNS and its neurons are inaccessible to many substances that circulate in the blood plasma (e.g., dyes, medications, and antibiotics) because of the blood–brain barrier. This barrier is formed by the tight junction of the endothelial cells in the brain's capillaries. All substances entering the CSF must filter through the capillary endothelial cells and astrocytes (Hickey, 2014). The blood–brain barrier has a protective function but can be altered by trauma, cerebral edema, and cerebral hypoxemia; this has implications in the treatment and selection of medication for CNS disorders.

Spinal Cord

The spinal cord and medulla form a continuous structure extending from the cerebral hemispheres and serving as the connection between the brain and the periphery. Approximately 45 cm (18 in) long and about the thickness of a finger, it extends from the foramen magnum at the base of the skull to the lower border of the first lumbar vertebra, where it tapers to a fibrous band called the *conus medullaris.* Continuing below the second lumbar space are the nerve roots that extend beyond the conus, which are called the *cauda equina* because they resemble a horse's tail. Similar to the brain, the spinal cord consists of gray and white matter. Gray matter in the brain is external and white matter is internal; in the spinal cord, gray matter is in the center and is surrounded on all sides by white matter (Fig. 43-10). The spinal cord is an H-shaped structure with nerve cell bodies (gray matter) surrounded by ascending and descending tracts (white matter). The spinal cord is encased by the meninges as in the brain including the pia mater, archnoid, and dura mater.

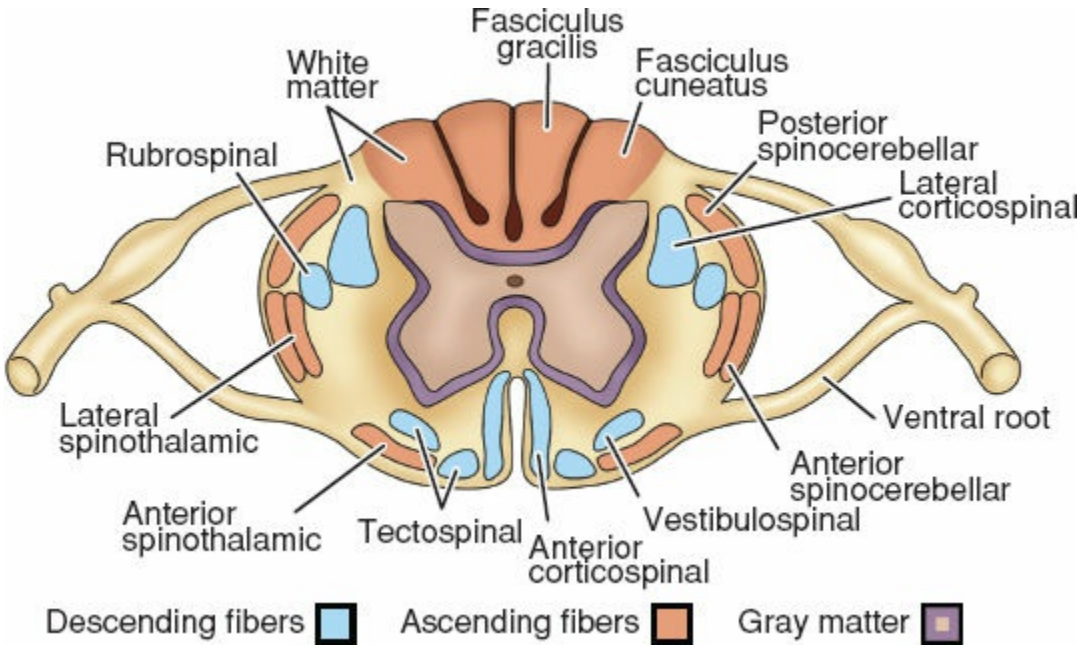

FIGURE 43-10 Cross-sectional diagram of the spinal cord showing major spinal tracts.

Nursing Alert

The nurse understands that the spinal cord extends to L1; therefore, if a lumbar puncture (spinal tap) is to be performed, the site for insertion of the needle will be below L1. Typically the needle is placed in the interspace between L3 and L4 or between L4 and L5, which is a safe distance from the distal spinal cord. The bony landmark for

the L4 spinous process is located at the intersection of the line between the top of the iliac crests and the midline of the lumbar spine.

Sensory and Motor Pathways: The Spinal Tracts. The white matter of the cord is composed of myelinated and unmyelinated nerve fibers. The fast-conducting myelinated fibers form bundles that also contain glial cells. Fiber bundles with a common function are called *tracts.*

There are six ascending tracts (see Fig. 43-10). Two conduct sensation, principally the perception of touch, pressure, vibration, position, and passive motion from the same side of the body. Before reaching the cerebral cortex, these fibers cross to the opposite side in the medulla. The two spinocerebellar tracts conduct sensory impulses from muscle spindles, providing necessary input for coordinated muscle contraction. They ascend essentially uncrossed and terminate in the cerebellum. The last two spinothalamic tracts are responsible for conduction of pain, temperature, proprioception, fine touch, and vibratory sense from the upper body to the brain. They ascend, cross to the opposite side of the brain, and terminate in the thalamus.

There are eight descending tracts. The two corticospinal tracts conduct motor impulses to the anterior horn cells from the opposite side of the brain and control voluntary muscle activity. The three vestibulospinal tracts descend uncrossed and are involved in some autonomic functions (sweating, pupil dilation, and circulation) and involuntary muscle control. The corticobulbar tract conducts impulses responsible for voluntary head and facial muscle movement and crosses at the level of the brainstem. The rubrospinal and reticulospinal tracts conduct impulses involved with involuntary muscle movement.

Vertebral Column. The bones of the vertebral column surround and protect the spinal cord and normally consist of seven cervical, 12 thoracic, and five lumbar vertebrae, as well as the sacrum (a fused mass of five vertebrae), and terminate in the coccyx. Nerve roots exit from the vertebral column through the intervertebral foramina (openings). The vertebrae are separated by disks, except for the first and second cervical, the sacral, and the coccygeal vertebrae. The vertebral body, arch, pedicles, and laminae all encase and protect the spinal cord.

The Peripheral Nervous System

The PNS includes the cranial nerves, the spinal nerves, and the autonomic nervous system.

Cranial Nerves

Twelve pairs of cranial nerves emerge from the lower surface of the brain and pass through the foramina in the skull (Fig. 43-11). Three are entirely sensory (I, II, VIII), five are motor (III, IV, VI, XI, and XII), and four are mixed (V, VII, IX, and X), because they have both sensory and motor functions. Most cranial nerves innervate the head, neck, and special sense structures. Table 43-2 lists the names and primary functions of the cranial nerves.

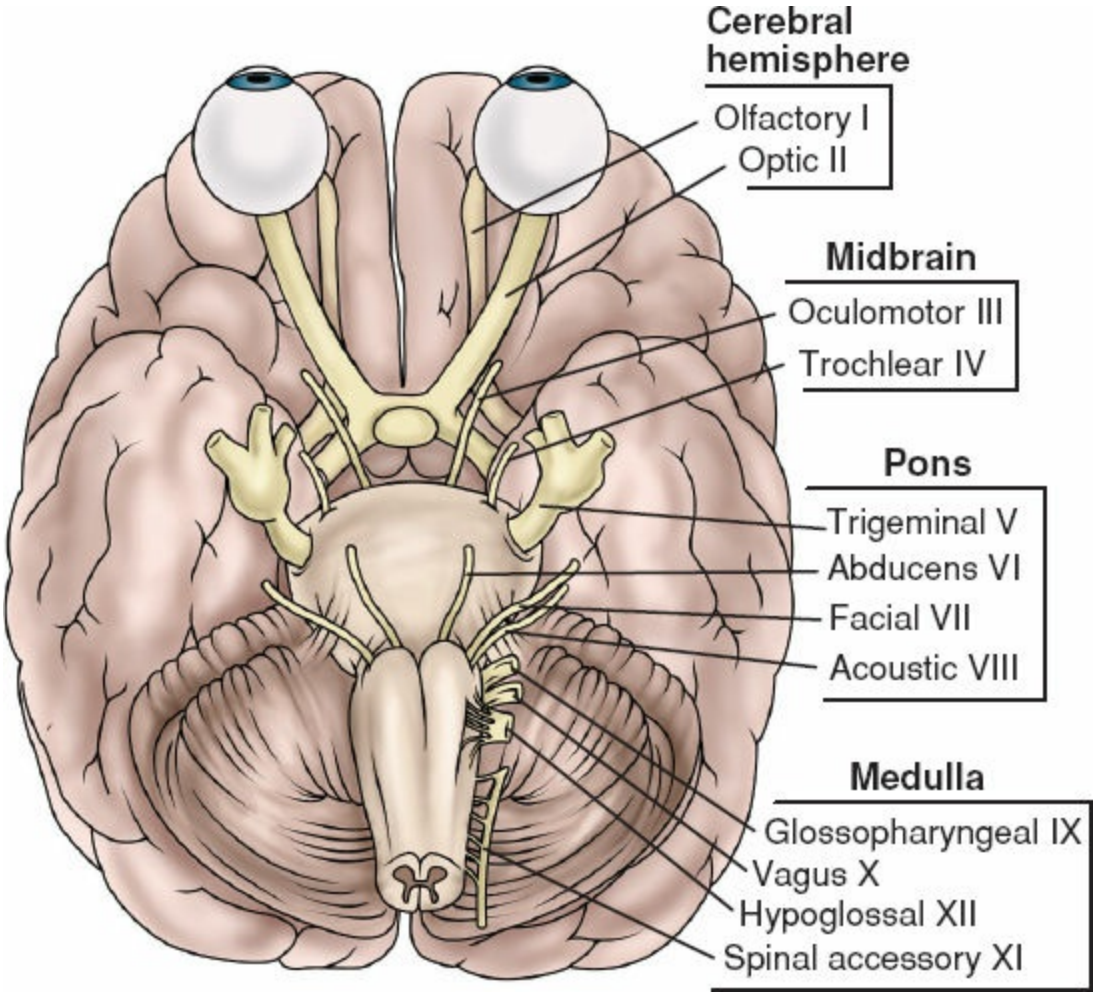

FIGURE 43-11 Diagram of the base of the brain showing entrance or exit of the cranial nerves. The right column shows the anatomic location of the connection of each cranial nerve to the central nervous system.

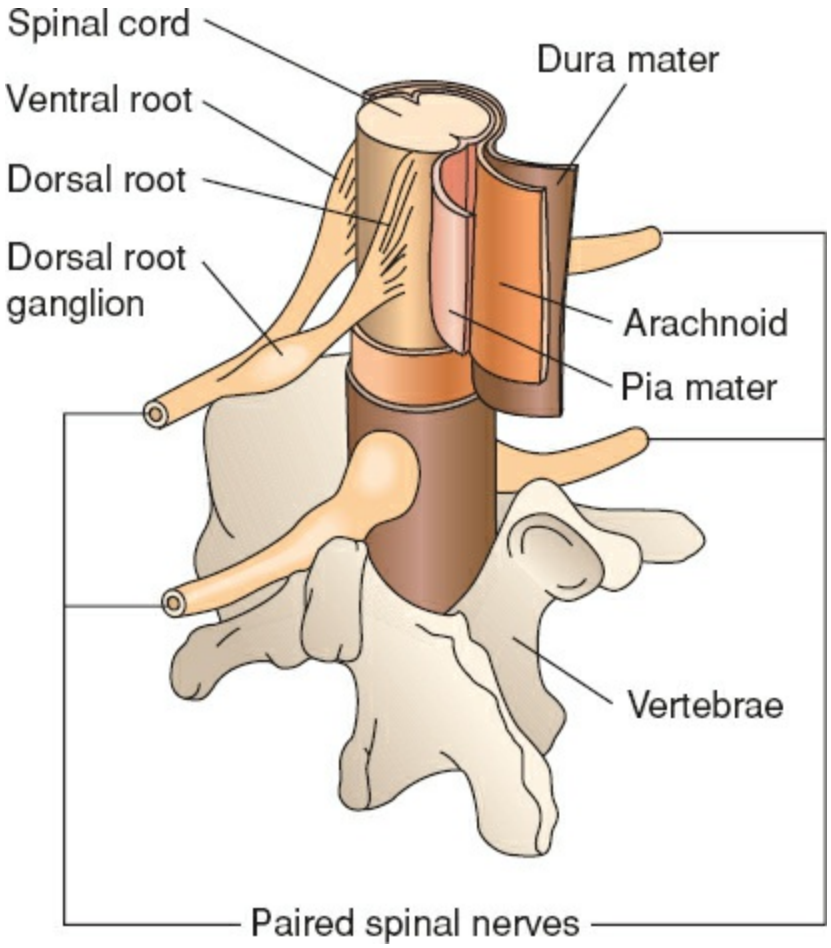

FIGURE 43-12 Spinal cord and meninges. (From Porth, C. M., & Matfin, G. (2009). *Pathology: Concepts of altered health states* (8th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Spinal Nerves

The spinal cord is composed of 31 pairs of spinal nerves: eight cervical, 12 thoracic, five lumbar, five sacral, and one coccygeal. Each spinal nerve has a ventral and dorsal root (Fig. 43-12).

The dorsal roots are sensory and transmit sensory impulses from specific areas of the body known as *dermatomes* (Fig. 43-13) to the dorsal ganglia. The sensory fiber may be somatic, carrying information about pain, temperature, touch, and position sense (proprioception) from the tendons, joints, and body surfaces; or visceral, carrying information from the internal organs.

The ventral roots are motor and transmit impulses from the spinal cord to the body, and these fibers are also either somatic or visceral. The visceral fibers include autonomic fibers that control the cardiac muscles and glandular secretions.

Autonomic Nervous System

The autonomic nervous system regulates activities of internal organs, such as the heart, lungs, blood vessels, digestive organs, and glands. Maintenance and restoration of internal homeostasis is largely the responsibility of the autonomic nervous system. There are two major divisions: the sympathetic nervous system, with predominantly excitatory responses, most notably the "fight-or-flight" response, and the parasympathetic nervous system,

which controls mostly visceral functions, known as "rest-and-digest."

The autonomic nervous system is regulated by centers in the spinal cord, brainstem, and hypothalamus. Its regulatory effects are exerted not on individual cells but on large expanses of tissue and on entire organs. The responses elicited do not occur instantaneously but after a lag period. These responses are sustained far longer than other neurogenic responses to ensure maximal functional efficiency on the part of receptor organs, such as blood vessels. The autonomic nervous system transmits its impulses by way of nerve pathways, enhanced by chemical mediators.

TABLE 43-2 Cranial Nerves

Cranial Nerve (CN)	Type	Assessment	Dysfunction
I (Olfactory)	Sensory	With eyes closed, the patient should be asked to identify two familiar odors (e.g., coffee, tobacco). Each nostril is tested separately. Avoid using strong odors, such as ammonia, as the trigeminal nerve may be stimulated. Testing of this CN is usually deferred.	Inability to identify odor, termed anosmia
II (Optic)	Sensory	Assess visual acuity using a portable eye chart or, if not available, grossly assess vision by having the patient read a card or newspaper from big print to small. Assess visual fields by testing peripheral vision: stand directly in front of the patient. Ask the patient to close one eye and focus on your nose as you assess the patient's ability to see your fingers that are positioned in four visual fields (upper right and left and lower right and left). In combination with CN III, assess the pupils (the light emitted into the pupil begins the process by which constriction is seen; constriction is the function of CN III).	Decreased visual acuity Decreased visual fields
III (Oculomotor)	Motor	CN III controls most extraocular eye movement (EOM), eyelid elevation, and pupillary constriction. To assess EOM, ask the patient to follow your finger through the six cardinal positions (use the letter H as a guide to assess the ability of the eye to move to the left superior, left lateral, left inferior, right superior, right lateral, and right inferior). CN III is responsible for all movements except lateral movement (CN VI) and movement of the eye downward and inward (CN IV). While the patient is looking in the six positions, have him or her hold the position briefly while you assess for nystagmus (rotary oscillation of the eye). Test for pupillary reflexes (constriction of the pupil to light), and inspect the eyelids for ptosis (drooping of the eyelid).	Inability to move the eyes in the visual field described Ptosis of affected eye Nonreactive or dilated pupil

IV (Trochlear)	Motor	This is assessed with EOM as described above. CN IV moves the eye down and in (as if looking toward the nose).	Inability to look down and in
V (Trigeminal)	Mixed	Assess facial sensation, corneal reflex (sensory aspect), and chewing or mastication. Have the patient close the eyes. Touch cotton to the patient's forehead, cheeks, and jaw. Test sensitivity to superficial pain in these same three areas by using the sharp and dull ends of a broken tongue blade. Alternate between the sharp point and the dull end. Patient reports "sharp" or "dull" with each movement. If responses are incorrect, test for temperature sensation. Test tubes of cold and hot water are used alternately. To assess chewing, ask the patient to clench the jaw while you palpate the temporal and masseter muscles. Corneal reflex may be assessed by having the patient look up and away while you brush the cornea with a wisp of cotton; both eyes should blink (Note: use of contact lens decreases this response). Similar to the pupillary reaction (CN II and III), corneal reflexes are a combination CN V and VII.	Absence of corneal reflex Diminished sensation to forehead, maxillary and mandibular region Weakness of muscles responsible for chewing
VI (Abducens)	Motor	Abducens moves the eye laterally (side to side or horizontally) and is assessed with EOMs.	Inability to look laterally, double vision
VII (Facial)	Mixed	Assess for symmetry of facial movement. Ask the patient to smile, raise the eyebrows, keep eyes and lips closed while you try to open them, and puff out the cheeks. Taste is also a function of this CN, although testing is often deferred. The motor response of closing the eye in response to stimuli is assessed with corneal reflex (combination of CN V and VII).	Facial paralysis Facial asymmetry, droop of mouth Absent nasolabial fold Decreased ability to taste
VIII (Acoustic)	Sensory	Assess hearing by rubbing your fingers, placing a ticking watch, or whispering near each ear. Equilibrium can be assessed with the Romberg test and is usually deferred.	Decreased hearing in affected ear
IX (Glossopharyngeal)	Mixed	This CN's function is primarily innervation of the pharynx and tongue, pharyngeal muscles, and swallowing. Ask the patient to open the mouth and say "Ah." Note symmetrical elevation of the upper palate and uvula in the midline position. Assessing for the gag reflex tests this nerve and CN X, as they travel together. To test gag reflex, use a cotton swab or tongue blade to touch the patient's posterior pharynx; note gag response.	Dysphagia Absence of gag reflex
X (Vagus)	Mixed	This CN is assessed by swallowing and gag reflex as noted above. In addition, the quality of the patient's voice is noted.	Hoarse or nasal quality to voice Slurred speech
XI (Spinal accessory)	Motor	Have the patient shrug the shoulders and turn his or her head from side to side; assess the sternocleidomastoid and trapezius muscles for symmetry.	Inability to shrug shoulders
XII (Hypoglossal)	Motor	Inspect the patient's tongue for atrophy at rest. To assess movement of the tongue, have the patient stick out the tongue and move it internally from cheek to cheek.	Tongue weakness

Sympathetic stimuli are mediated by norepinephrine, and parasympathetic impulses are mediated by acetylcholine. Both divisions produce stimulatory and inhibitory effects. Table 43-3 compares sympathetic and parasympathetic effects on different systems of the body.

Motor and Sensory Functions of the Nervous System

Motor System Function

The motor cortex, a vertical band within each cerebral hemisphere, controls the voluntary movements of the body. The exact locations within the brain at which the voluntary movements of the muscles of the face, thumb, hand, arm, trunk, and leg originate are known (see Fig. 43-3). Stimulation of these cells results in muscle contraction. En route to the pons, the motor fibers converge into a tight bundle known as the *internal capsule*. A comparatively small injury to the capsule results in paralysis in more muscles than does a much larger injury to the cortex itself.

Within the medulla, the motor axons from the cortex form the corticospinal or pyramidal tracts. Here, most of the fibers cross (or decussate) to the opposite side. The remaining fibers enter the spinal cord on the same side as the direct pyramidal tract. All of the motor fibers of the spinal nerves represent extensions of the anterior horn cells, with each of these fibers communicating with only one particular muscle fiber. The motor system is complex, and motor function depends on the integrity of the corticospinal tracts, the extrapyramidal system, and cerebellar function.

Upper and Lower Motor Neurons

The voluntary motor system consists of two groups of neurons: upper motor neurons and lower motor neurons. Upper motor neurons originate in the cerebral cortex, the cerebellum, and the brainstem, where they cross over and descend throughout the corticospinal tract. Their fibers make up the descending motor pathways, are located entirely within the CNS, and modulate the activity of the lower motor neurons. Lower motor neurons are located either in the anterior horn of the spinal cord gray matter or within cranial nerve nuclei in the brainstem. Axons of lower motor neurons in both sites extend through peripheral nerves and terminate in skeletal muscle at the myoneural junction. Lower motor neurons are located in both the CNS and the PNS. The clinical features of lesions of upper and lower motor neurons are discussed in Table 43-4.

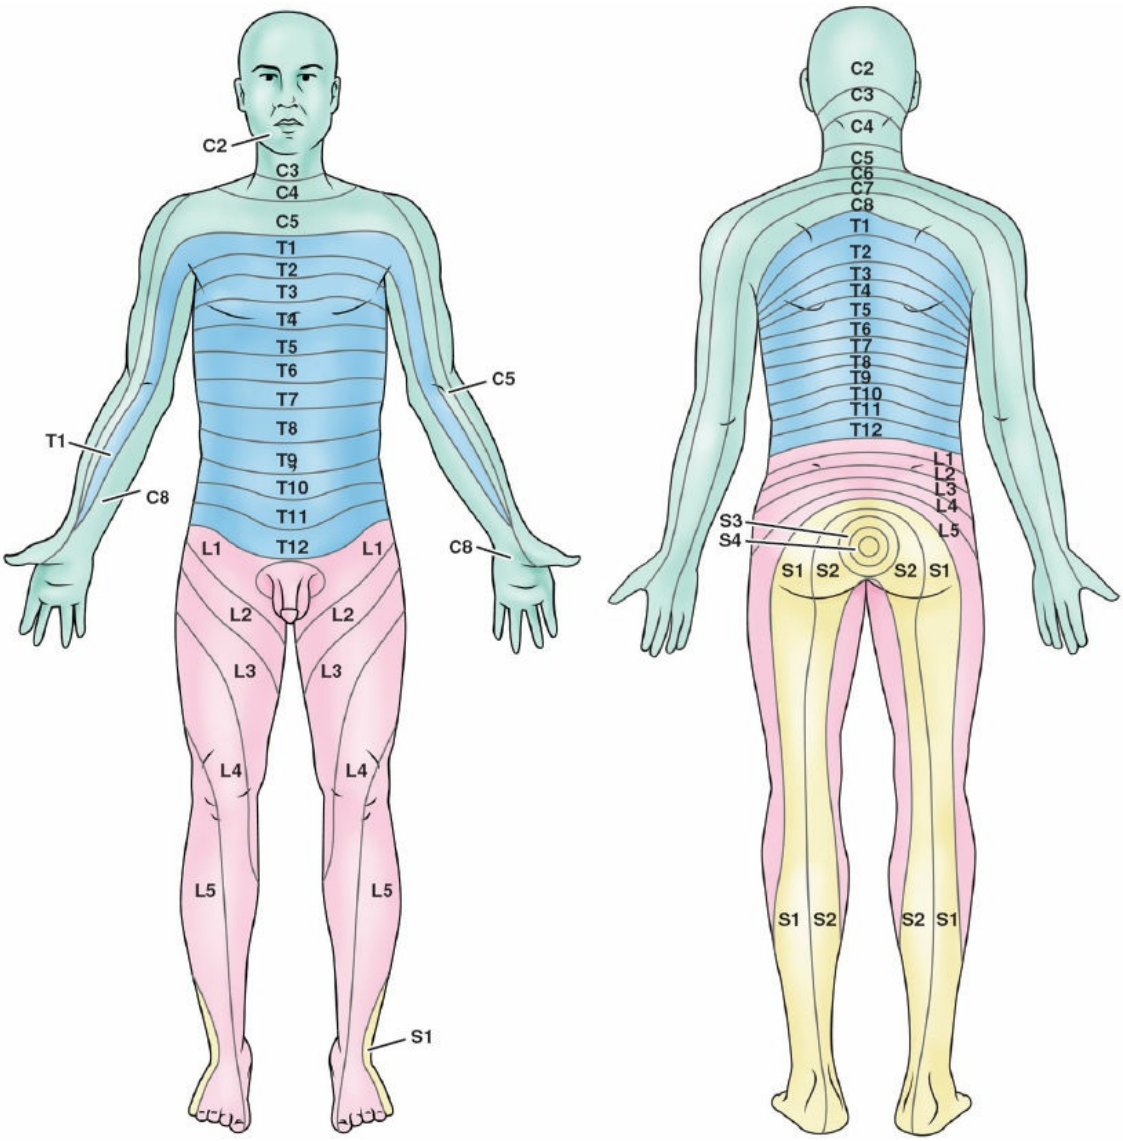

FIGURE 43-13 Dermatome distribution.

Coordination of Movement

The smoothness, accuracy, and strength that characterize muscular movements are attributable to the influence of the cerebellum and the basal ganglia.

The cerebellum (see Fig. 43-2, p. 1252) is responsible for the coordination, balance, and timing of all muscular movements. Through the action of the cerebellum, the contractions of opposing muscle groups are adjusted in relation to each other to maximal mechanical advantage.

The basal ganglia play an important role in planning and coordinating motor movements and posture. Complex neural connections link the basal ganglia with the cerebral cortex. The major effect of these structures is to inhibit unwanted muscular activity; disorders of the basal ganglia result in exaggerated, uncontrolled movements.

Impaired cerebellar function, which may occur as a result of an intracranial injury, cerebrovascular event, or some type of an expanding mass, results in loss of muscle tone, weakness, and fatigue. Cerebellar signs, such as ataxia and incoordination, as well as CSF obstruction and compression of the brainstem may be seen. Signs of increased ICP,

including vomiting, headache, and changes in vital signs and level of consciousness (LOC), are especially common when CSF flow is obstructed.

Destruction or dysfunction of the basal ganglia leads not to paralysis but to muscle rigidity, with disturbances of posture and movement. The patient tends to have involuntary movements. These may take the form of coarse tremors, most often in the upper extremities, particularly in the distal portions; athetosis (movement of a slow, squirming, writhing, twisting type); or chorea (spasmodic, purposeless, irregular, uncoordinated motions of the trunk and the extremities, and facial grimacing). Disorders due to lesions of the basal ganglia include Parkinson disease, Huntington disease, and spasmodic torticollis (a painful condition where neck muscles contract involuntarily, causing the head to twist or turn to one side).

TABLE 43-3 Autonomic Effects of the Nervous System

Structure or Activity	Parasympathetic Effects	Sympathetic Effects
Pupil of the Eye	Constricted	Dilated
Circulatory System		
Rate and force of heartbeat	Decreased	Increased
Blood Vessels		
In heart muscle	Constricted	Dilated
In skeletal muscle	[a]	Dilated
In abdominal viscera and the skin	[a]	Constricted
Blood pressure	Decreased	Increased
Respiratory System		
Bronchioles	Constricted	Dilated
Rate of breathing	Decreased	Increased
Digestive System		
Peristaltic movements of digestive tube	Increased	Decreased
Muscular sphincters of digestive tube	Relaxed	Contracted
Secretion of salivary glands	Thin, watery saliva	Thick, viscid saliva
Secretions of stomach, intestine, and pancreas	Increased	[a]
Conversion of liver glycogen to glucose	[a]	Increased
Genitourinary System		
Urinary bladder Muscle walls	Contracted	Relaxed
Sphincters	Relaxed	Contracted
Muscles of the uterus	Relaxed; variable	Contracted under some conditions; varies with menstrual cycle and pregnancy
Blood vessels of external genitalia	Dilated	[a]
Integumentary System		
Secretion of sweat	[a]	Increased
Pilomotor muscles	[a]	Contracted (gooseflesh)
Adrenal Medulla	[a]	Secretion of epinephrine and norepinephrine

[a]No direct effect.

TABLE 43-4 Comparison of Lesions of the Upper Motor Neurons and Lower Motor Neurons

Upper Motor Neuron Lesions	Lower Motor Neuron Lesions
Loss of voluntary control	Loss of voluntary control
Increased muscle tone	Decreased muscle tone
Muscle spasticity	Flaccid muscle paralysis
No muscle atrophy	Muscle atrophy
Hyperactive and abnormal	Absent or decreased reflexes

Sensory System Function

Integrating Sensory Impulses

The thalamus, a major receiving and transmitting center for the afferent sensory nerves, is a large structure connected to the midbrain (see Fig. 43-4). The thalamus integrates all sensory impulses except olfaction. It plays a role in the conscious awareness of pain and the recognition of variation in temperature and touch. The thalamus is responsible for the sense of movement and position and the ability to recognize the size, shape, and quality of objects.

Receiving Sensory Impulses

Afferent impulses travel from their points of origin to their destinations in the cerebral cortex via the ascending pathways directly, or they may cross at the level of the spinal cord or in the medulla, depending on the type of sensation that is registered. Sensory information may be integrated at the level of the spinal cord or may be relayed to the brain. Knowledge of these pathways is important for neurologic assessment and for understanding symptoms and their relationship to various lesions.

Sensory Losses

Destruction of a sensory nerve results in total loss of sensation in its area of distribution. Transection of the spinal cord yields complete anesthesia below the level of injury. Selective destruction or degeneration of the posterior columns of the spinal cord is responsible for a loss of position and vibratory sense in segments distal to the lesion, without loss of touch, pain, or temperature perception. A lesion, such as a cyst, in the center of the spinal cord causes dissociation of sensation—loss of pain at the level of the lesion. This occurs because the fibers carrying pain and temperature cross within the cord immediately on entering; thus, any lesion that divides the cord longitudinally divides these

fibers. Other sensory fibers ascend the cord for variable distances, some even to the medulla, before crossing, thereby bypassing the lesion and avoiding destruction.

Lesions affecting the posterior spinal nerve roots may cause impairment of tactile sensation, including intermittent severe pain that is referred to the area of distribution. Tingling of the fingers and the toes can be a prominent symptom of spinal cord disease, presumably due to degenerative changes in the sensory fibers that extend to the thalamus (i.e., belonging to the spinothalamic tract).

Gerontologic Considerations

During the normal aging process, the nervous system undergoes many changes, and it is extremely vulnerable to general systemic illness. Changes throughout the nervous system that occur with age vary in degree. Nerve fibers that connect directly to muscles show little decline in function with age, as do simple neurologic functions that involve a number of connections in the spinal cord. Disease in the elderly often makes it difficult to distinguish normal from abnormal changes. It is important for clinicians not to attribute abnormality or dysfunction to aging without appropriate investigation. Pain in the absence of disease, for example, is not a normal part of aging and should be assessed, diagnosed, and treated. Table 43-5 summarizes structural changes.

Structural Changes

A number of alterations occur with increasing age. Brain weight decreases, as does the number of synapses. A loss of neurons occurs in select regions of the brain. Cerebral blood flow and metabolism are reduced. Temperature regulation becomes less efficient. In the PNS, myelin is lost, resulting in a decrease in conduction velocity in some nerves. There is an overall reduction in muscle bulk and the electrical activity within muscles. Taste buds atrophy, and nerve cell fibers in the olfactory bulb degenerate. Nerve cells in the vestibular system of the inner ear, cerebellum, and proprioceptive pathways also degenerate. Deep tendon reflexes can be decreased or, in some cases, absent. Hypothalamic function is modified such that stage IV sleep is reduced. There is an overall slowing of autonomic nervous system responses. Pupillary responses are reduced or may not appear at all in the presence of cataracts.

TABLE 43-5 GERONTOLOGIC CONSIDERATIONS / Age-Related Changes in the Neurologic System

Structural changes	Brain weight decreases Loss of neurons in the brain Reduced cerebral blood flow Decreased myelin, resulting in decreased nerve conduction in some nerves Decrease in muscle bulk Slowing in deep tendon reflexes Overall slowing of the autonomic and sympathetic nervous system Temperature regulation becomes less efficient Reduced pupillary response
Sensory changes	Atrophy of taste buds Degeneration of olfactory bulb Degeneration of nerve cells in vestibular system of inner ear, cerebellum, and proprioceptive pathways Decreased neural transmission leading to difficulty in discriminating important sounds from background noise; hearing loss becomes more common (Walston, 2016) Stage IV sleep is decreased; sleep apnea becomes more common Presence of cataracts Dulling of tactile sensation

Motor Alterations

Changes in motor function often result in a flexed posture, shuffling gait, and rigidity of movement. These changes create difficulties for the older person in maintaining or recovering balance. Strength and agility are diminished, and reaction time and movement time are decreased. Repetitive movements and mild tremors may be noted during an examination and may be of concern to the person. Observation of gait may reveal a wide-based gait with balance difficulties.

Sensory Alterations

Sensory isolation due to visual and hearing loss can cause confusion, anxiety, disorientation, misinterpretation of the environment, and feelings of inadequacy. Sensory alterations may require modification of the home environment, such as large-print reading materials or

sound enhancement for the telephone, as well as extra orientation to new surroundings. Simple explanations of routines, the location of the bathroom, and how to operate the call bell or light are just a few examples of information the elderly patient may need when hospitalized.

Temperature Regulation and Pain Perception

Other manifestations of neurologic changes are related to temperature regulation and pain. The elderly patient may feel cold more readily than heat and may require extra covering when in bed; a room temperature somewhat higher than usual may be desirable. Reaction to painful stimuli may be decreased with age. Because pain is an important warning signal, caution must be used when hot or cold packs are used. The older patient may be burned or suffer frostbite before being aware of any discomfort. Complaints of pain, such as abdominal discomfort or chest pain, may be more serious than the patient's perception might indicate and thus require careful evaluation. Two pain syndromes that are common in the neurologic system in older adults are diabetic neuropathies and postherpetic neuropathies (refer to Chapters 30 and 52 for further information).

Taste and Smell Alterations

The acuity of the taste buds decreases with age; along with an altered olfactory sense, this may cause a decreased appetite and subsequent weight loss. Extra seasoning often increases food intake as long as it does not cause gastric irritation. A decreased sense of smell due to atrophy of olfactory organs may present a safety hazard because elderly people living alone may be unable to detect household gas leaks or fires. Smoke and carbon monoxide detectors, important for all, are critical for the elderly.

Tactile and Visual Alterations

Another neurologic alteration in the elderly patient is the dulling of tactile sensation. There may be difficulty in identifying objects by touch, and because fewer tactile cues are received from the bottom of the feet, the person may become confused about body position and location.

These factors, combined with sensitivity to glare, decreased peripheral vision, and a constricted visual field, may result in disorientation, especially at night when there is little or no light in the room. Because the elderly person takes longer to recover visual sensitivity when moving from a light to dark area, night-lights and a safe and familiar arrangement of furniture are essential.

Mental Status

Mental status is evaluated when obtaining the history. Areas of judgment, intelligence, memory, affect, mood, orientation, speech, and grooming are assessed. Family members who bring the patient to the attention of the health care provider may have noticed changes in the patient's mental status. Drug toxicity should always be suspected as a causative factor when the patient has a change in mental status. Delirium (mental confusion, usually with delusions and hallucinations) is seen in elderly patients who have underlying CNS damage or are experiencing an acute condition, such as infection, adverse medication reaction, or

dehydration. Many elderly patients admitted to the hospital have delirium, and the cause is often reversible and treatable (e.g., drug toxicity, vitamin B deficiency, thyroid disease). Depression may produce impairment of attention and memory. In elderly patients, delirium, which is an acute change in mental status attributable to a treatable medical problem, must be differentiated from dementia, which is a chronic and irreversible deterioration of cognitive status.

Nursing Implications

Nursing care for patients with age-related changes to the nervous system and for patients with long-term neurologic disability who are aging should include the previously described modifications. In addition, the consequences of any neurologic deficit and its impact on overall function, such as activities of daily living, use of assistive devices, and individual coping, should be assessed and considered in planning patient care.

Patient teaching is also affected because the nurse must understand the altered responses and the changing needs of the elderly patient before beginning to teach. When caring for the elderly patient, the nurse adapts activities, such as preoperative teaching, diet therapy, and instruction about new medications, their timing, and doses, to the patient's needs and capabilities. The nurse considers the presence of decline in fine motor movement and failing vision. When using visual materials for teaching or menu selection, adequate lighting without glare, contrasting colors, and large print are used to offset visual difficulties caused by rigidity and opacity of the lens in the eye and slower pupillary reaction.

Even with hearing loss, the elderly patient often hears adequately if the speaker uses a low-pitched, clear voice; shouting only makes it harder for the patient to understand the speaker. Providing auditory and visual cues aids understanding; if the patient has a significant hearing or visual loss, assistive devices, a signer, or a translator may be needed.

Teaching at an unrushed pace and using reinforcement enhances learning and retention. Material should be short, concise, and concrete. Vocabulary is matched to the patient's ability, and terms are clearly defined. The elderly patient requires adequate time to receive and respond to stimuli, learn, and react. These measures allow comprehension, memory, and formation of association and concepts.

ASSESSMENT

Health History

The history-taking portion of the neurologic assessment is critical and, in many cases of neurologic disease, leads to an accurate diagnosis. The initial interview provides an excellent opportunity to systematically explore the patient's current condition and related events while simultaneously observing overall appearance, mental status, posture, movement, and affect. Depending on the patient's condition, the nurse may need to rely on yes-or-no answers to questions, a review of the medical record, or input from the family or a combination of these.

Common Concerns

An important aspect of the neurologic assessment is the history of the present illness. Neurologic disease may be acute or progressive, characterized by symptom-free periods as well as fluctuations in symptoms. The nurse, therefore, asks about the onset, character, severity, location, duration, and frequency of symptoms and signs; associated complaints; precipitating, aggravating, and relieving factors; progression, remission, and exacerbation; and the presence or absence of similar symptoms among family members.

The clinical manifestations of neurologic disease are as varied as the disease processes themselves. Symptoms may be subtle or intense, fluctuating or permanent, inconvenient or devastating. An introduction to some of the most common symptoms associated with neurologic disease is given in this chapter. Detailed discussions regarding how specific symptoms relate to a particular disorder are covered in later chapters in this unit.

Pain

Pain is considered an unpleasant sensory perception and emotional experience associated with actual or potential tissue damage or described in terms of such damage. Therefore pain is considered multidimensional and entirely subjective. Pain can be acute or chronic. In general, acute pain lasts for a relatively short period of time and remits as the pathology resolves. In neurologic disease, this type of pain is often associated with spinal disk disease, trigeminal neuralgia, or other neuropathic pathology (e.g., postherpetic neuralgia or painful neuropathies). In contrast, chronic or persistent pain extends for long periods of time and may represent a low level of pathology. This type of pain can occur with many degenerative and chronic neurologic conditions (e.g., cerebral palsy).

Headache and Migraine

Headache, or cephalalgia, is one of the most common of all human physical complaints. Headache is a symptom rather than a disease entity; it may indicate organic disease (neurologic or other disease), a stress response, vasodilation (migraine), skeletal muscle tension (tension headache), or a combination of factors. A primary headache is one for which no organic cause can be identified. These types of headache include migraine, tension-type, and cluster headaches. Migraine headache is characterized by periodic and recurrent attacks of severe headaches lasting from 4 to 72 hours in adults. The cause of

migraine has not been clearly demonstrated, but it is primarily a vascular disturbance that occurs more commonly in women and has a strong familial tendency. The typical time of onset is at puberty, and the highest prevalence in adults occurs between 25 and 55 years of age. Migraine headaches may occur with or without an aura (a sensation that precedes the headache); however, most patients do not exhibit auras. Migraine with aura affects 5% of the adult population, and 90% of auras are visual. Migraine is more prevalent in white people and in those with a lower socioeconomic status or income (Digre, 2016).

A secondary headache is a symptom associated with an organic cause, such as a brain tumor or an aneurysm. Although most headaches do not indicate serious disease, persistent headaches require further investigation. Serious disorders related to headache include brain tumors, subarachnoid hemorrhage, stroke, severe hypertension, meningitis, and head injuries.

Temporal arteritis is a cause of headache in the older population, reaching its greatest incidence in those older than 70 years of age. Inflammation of the cranial arteries is characterized by a severe headache localized in the region of the temporal arteries. The inflammation may be generalized (in which case temporal arteritis is part of a vascular disease) or focal (in which case only the cranial arteries are involved) and may be associated with visual loss.

Seizures

Seizures are the result of abnormal paroxysmal discharges in the cerebral cortex, which then manifest as an alteration in sensation, behavior, movement, perception, or consciousness. The alteration may be short, such as a blank stare that lasts only a second, or of longer duration, such as a tonic-clonic seizure that can last several minutes. The type of seizure activity is a direct result of the area of the brain affected. Seizures can occur as isolated events, such as when induced by a high fever, alcohol or drug withdrawal, or hypoglycemia. A seizure may also be the first obvious sign of a brain lesion.

Dizziness and Vertigo

Dizziness is an abnormal sensation of imbalance or movement. It is fairly common in the elderly and one of the most common complaints encountered by health professionals. Dizziness can occur as a result of a variety of medical conditions that include viral syndromes, hypotension, cardiac arrhythmia, hypoglycemia, and middle ear infections, to name a few. One difficulty confronting health care providers when assessing dizziness is the vague and varied terms patients use to describe the sensation.

About 50% of all patients with dizziness have vertigo, which is defined as an illusion of movement, usually rotation. Vertigo is usually a manifestation of vestibular dysfunction. It can be so severe as to result in spatial disorientation, light-headedness, loss of equilibrium (staggering), and nausea and vomiting.

Visual Disturbances

Visual defects that cause people to seek health care can range from the decreased visual acuity associated with aging to sudden blindness caused by acute glaucoma. Normal vision depends on functioning visual pathways through the retina and optic chiasm and the radiations into the visual cortex in the occipital lobes. Lesions of the eye itself (e.g.,

cataract), lesions along the pathway (e.g., tumor), or lesions in the visual cortex (from stroke) interfere with normal visual acuity. Abnormalities of eye movement can also compromise vision by causing diplopia or double vision.

Weakness

Weakness, specifically muscle weakness, is a common manifestation of neurologic disease. Weakness frequently coexists with other symptoms of disease and can affect a variety of muscles, causing a wide range of disabilities. Weakness can be sudden and permanent, as in stroke, or progressive, as in many neuromuscular diseases, such as amyotrophic lateral sclerosis (ALS). Any muscle group can be affected.

Abnormal Sensation

Numbness, abnormal sensation, or loss of sensation is a neurologic manifestation of both central and peripheral nerve disease. Altered sensation can affect small or large areas of the body. It is frequently associated with weakness or pain and is potentially disabling. Both numbness and weakness can significantly affect balance and coordination.

History

A review of the medical history, including a system-by-system evaluation, is part of the health history. The nurse should be aware of any history of trauma or falls that may have involved the head or spinal cord.

Family History

The nurse may also use the interview to inquire about any family history of genetic diseases, such as Huntington disease, dystonia, and epilepsy.

Social History

The nurse questions the patient regarding the use of alcohol, medications, and illicit drugs, and assesses for signs and symptoms of withdrawal. Additionally, the nurse is aware that certain agents, such as sedatives, analgesics, or neuromuscular blocking agents, may interfere with an accurate neurologic assessment.

The nurse assesses the impact that any neurologic impairment has on the patient's lifestyle. Issues to consider include the limitations imposed on the patient by any deficit and the patient's role in society, including family and community roles. The plan of care that the nurse develops needs to address and support adaptation to the neurologic deficit and continued function to the extent possible within the patient's support system.

Physical Assessment 

The neurologic examination is a systematic process that includes a variety of clinical tests, observations, and assessments designed to evaluate the neurologic status of a complex system. Although the neurologic examination is often limited to a simple screening, the examiner must be able to conduct a thorough neurologic assessment when the patient's history or other physical findings warrant it. An example of a simple screening tool for patients with head injury is the Glasgow Coma Scale (GCS; refer to Box 45-6 in Chapter 45). A GCS score is based on three patient responses: eye opening, motor response, and verbal response. The patient receives a score for his or her best response in each of these areas, and the three scores are added together. The total score will range from 3 to 15; the higher the number, the better. A score of 8 or lower usually indicates coma.

The brain and spinal cord cannot be examined as directly as other systems of the body. Thus, much of the neurologic examination is an indirect evaluation that assesses the function of the specific body part or parts controlled or innervated by the nervous system. A neurologic assessment is divided into five components: cerebral function, cranial nerves, motor system, sensory system, and reflexes. As in other parts of the physical assessment, the neurologic examination follows a logical sequence and progresses from higher levels of cortical function, such as abstract thinking, to lower levels of function, such as the determination of the integrity of peripheral nerves.

Assessing Cerebral Function

Cerebral abnormalities may cause disturbances in mental status, intellectual functioning, and thought content, and in patterns of emotional behavior. There may also be alterations in perception and motor and language abilities, as well as lifestyle.

Interpretation and documentation of neurologic abnormalities, particularly mental status abnormalities, should be specific and nonjudgmental. Lengthy descriptions and the use of terms such as *inappropriate* or *demented* should be avoided. Terms such as these often mean different things to different people and, therefore, are not useful when describing behavior. The examiner records and reports specific observations regarding level of consciousness (LOC), orientation, emotional state, or thought content, all of which permit comparison by others over time. Analysis and the conclusions that may be drawn from these findings usually depend on the examiner's knowledge of neuroanatomy, neurophysiology, and neuropathology.

Level of Consciousness

The first cue to a change in the neurologic function of a patient may be a change in the LOC, which is evaluated clinically as the patient's ability to respond appropriately to stimuli. It involves both wakefulness and cognition. The nurse compares current findings to previous patient baseline and notifies providers when any deterioration is noted. Rather than use terms like *stuporous* or *obtunded,* it is beneficial to describe the behavior in detail rather than use a broad term.

Nursing Alert

The major source of energy for the brain is glucose. Neurons of the brain are incapable of creating or storing glucose. Therefore, the brain is dependent on blood flow for brain glucose. When blood glucose drops because of insulin administration, patients exhibit signs of decreased mentation, progressing to unconsciousness. If a patient has a history of diabetes or is receiving insulin treatment for other causes, the nurse should perform a glucose fingerstick to assess blood glucose level when a change in the LOC is noted.

Mental Status

An assessment of mental status begins by observing the patient's appearance and behavior, noting dress, grooming, and personal hygiene. Posture, gestures, movements, facial expressions, speech, and motor activity often provide important information about the patient.

Assessing orientation to time, place, and person assists in evaluating mental status. Does the patient know what day it is, what year it is, and where he or she is? Is the patient aware of who the examiner is and of his or her purpose for being in the room?

Assessment of mental status also includes both long- and short-term memory, and the ability to concentrate and attend to tasks asked of them as well. A more detailed mental status assessment may also include assessment of an individual's ability to calculate as well as perform abstract reasoning such as "What would you do if you spotted a fire in your kitchen?"

Perception

The examiner may now consider more specific areas of higher cortical function. Agnosia is the inability to interpret or recognize objects seen through the special senses. The patient may see a pencil but not know what it is called or what to do with it. The patient may even be able to describe it but not interpret its function. The patient may experience auditory or tactile agnosia as well as visual agnosia. Each of the dysfunctions implicates a different part of the cortex (Table 43-6).

Screening for visual and tactile agnosia provides insight into the patient's cortical interpretation ability. The patient is shown a familiar object and asked to identify it by name. Placing a familiar object (e.g., key, coin) in the patient's hand and having him or her identify it with both eyes closed is an easy way to assess tactile interpretation.

Motor Ability

Nurses assess cortical motor integration by asking the patient to perform a skilled act (comb hair, brush teeth). Successful performance requires the ability to understand the activity desired and normal motor strength. Failure signals cerebral dysfunction.

TABLE 43-6 Types of Agnosia and Corresponding Sites of Lesions

Type of Agnosia	Affected Cerebral Area
Visual	Occipital lobe
Auditory	Temporal lobe (lateral and superior portions)
Tactile	Parietal lobe
Body parts and relationships	Parietal lobe (posteroinferior regions)

TABLE 43-7 Types of Aphasia and Region of Brain Involved

Type of Aphasia	Brain Area Involved
Auditory-receptive	Temporal lobe
Visual-receptive	Parietal-occipital area
Expressive speaking	Inferior posterior frontal areas
Expressive writing	Posterior frontal area

Language Ability

The person with normal neurologic function can understand and communicate in spoken and written language. Does the patient answer questions appropriately? Can he or she read a sentence from a newspaper and explain its meaning? Can the patient write his or her name or copy a simple figure that the examiner has drawn? A deficiency in language function is called *aphasia.* Different types of aphasia result from injury to different parts of the brain (Table 43-7).

Unfolding Patient Stories: Marilyn Hughes • Part 2

Recall from Chapter 42 Marilyn Hughes, who came to the hospital after falling on icy stairs. She sustained a left mid shaft tibula-fibula fracture, which requires surgery. Her husband informs the nurse that she also hit her head and did not respond to him for a short time after the fall. Describe the neurologic assessment performed by the nurse. Why should the nurse to report this information promptly to the health care team?

Care for Marilyn and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

Assessing the Cranial Nerves

Refer back to Table 43-2 on page 1258 for assessment of the cranial nerves. Opposite sides of the face and neck are compared throughout the examination. The assessment of multiple cranial nerves may be combined, such as eye movement (CN III, IV, VI) and dysphagia, difficulty swallowing (CN IX, X, XII).

Examining the Motor System

A thorough examination of the motor system includes an assessment of muscle size, tone, and strength as well as coordination and balance. The muscles are inspected, and palpated if necessary, for their size and symmetry. Any evidence of atrophy or involuntary movements (tremors, tics) is noted. Muscle tone (the tension present in a muscle at rest) is evaluated by palpating various muscle groups at rest and during passive movement. Resistance to these movements is assessed and documented. Abnormalities in tone include spasticity (increased muscle tone), rigidity (resistance to passive stretch), and flaccidity.

Strength

Assessing the patient's ability to flex or extend the extremities against resistance tests muscle strength. The function of an individual muscle or group of muscles is evaluated by placing the muscle at a disadvantage. The evaluation of muscle strength compares the sides of the body to each other.

Clinicians use a five-point scale to rate muscle strength:

- 5 indicates full power of contraction against gravity and resistance or normal muscle strength;
- 4 indicates fair but not full strength against gravity and a moderate amount of resistance or slight weakness;
- 3 indicates just sufficient strength to overcome the force of gravity or moderate weakness;
- 2 indicates the ability to move but not to overcome the force of gravity or severe weakness;
- 1 indicates minimal contractile power (weak muscle contraction can be palpated but no movement is noted) or very severe weakness; and
- 0 indicates no movement.

Distal and proximal strength in both upper and lower extremities is recorded.

Nursing Alert

There are occasional situations in which weakness of the upper extremities may be so subtle that the nurse is unsure if weakness is present. In these situations, the pronator drift can help assess for weakness. The patient holds her arms out in front of herself with palms facing the ceiling. The patient is asked to hold the position and close her eyes for approximately 20 seconds. If pronation (turning inward of the palm or the arm) or a downward drift of an arm is noted, the limb is weak. A positive pronator drift is associated with upper motor neurons in the brain and spinal cord that control voluntary movement.

Balance and Coordination

Cerebellar influence on the motor system is reflected in balance control and coordination. Coordination in the upper and lower extremities is tested by having the patient perform rapid, alternating movements and point-to-point testing. Speed, symmetry, and degree of difficulty are noted.

Point-to-point testing for coordination of the upper extremities is accomplished by having the patient touch the examiner's extended finger and then his or her own nose. This is repeated with each arm several times. Coordination in the lower extremities is tested by having the patient run the heel down the anterior surface of the tibia of the other leg. Each leg is tested in turn. Ataxia is defined as incoordination of voluntary muscle action, particularly of the muscle groups used in activities such as walking or reaching for objects. The presence of ataxia or tremors (rhythmic, involuntary movements) during these movements suggests cerebellar disease.

FIGURE 43-14 Deep tendon reflexes: (A) biceps, (B) brachioradialis, (C) triceps, (D) patellar, and (E) ankles. (From Rhoads, J. (2006). *Advanced health assessment and diagnostic reasoning*. Philadelphia, PA: Lippincott Williams & Wilkins.)

The Romberg test is a screening test for balance. The patient stands with feet together and arms at the side, first with eyes open and then with both eyes closed for 20 to 30 seconds. The examiner stands close to reassure the patient of support if he or she begins to fall. Slight swaying is normal, but a loss of balance is abnormal and is considered a positive Romberg test.

Examining the Reflexes

The motor reflexes are involuntary contractions of muscles or muscle groups in response to abrupt stretching near the site of the muscle's insertion. Common reflexes that may be tested include the deep tendon reflexes (biceps, brachioradialis, triceps, patellar, and ankle

reflexes, Fig. 43-14) and superficial or cutaneous reflexes (abdominal reflexes and plantar or Babinski reflex).

Deep Tendon Reflexes

The tendon is struck directly with a reflex hammer or indirectly by striking the examiner's digit with the hammer, which is placed firmly against the patient's tendon. Testing these reflexes enables the examiner to assess involuntary reflex arcs that depend on the presence of afferent stretch receptors, spinal synapses, efferent motor fibers, and a variety of modifying influences from higher levels.

Grading. The absence of reflexes is significant, although ankle jerks (Achilles reflex) may be normally absent in older people. Deep tendon reflex responses are often graded on a scale of 0 to 4+. Box 43-1 depicts how to document reflexes using this scale. As stated previously, scale ratings are highly subjective. Findings can be recorded as a fraction, indicating the scale range (e.g., 2/4). Some examiners prefer to use the terms *present*, *absent*, and *diminished* when describing reflexes.

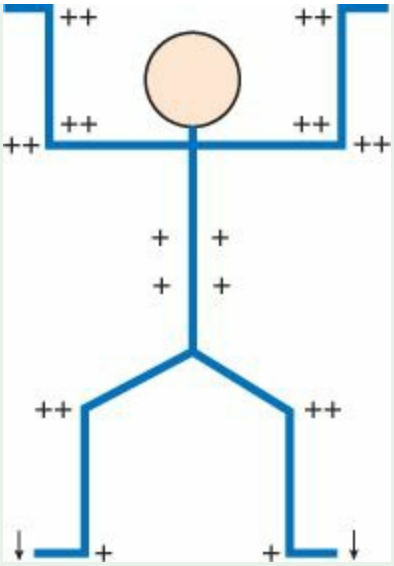
Clonus. When reflexes are very hyperactive, a phenomenon called *clonus* may be elicited. If the foot is abruptly dorsiflexed, it may continue to "beat" two or three times before it settles into a position of rest. Occasionally, with CNS disease, this activity persists, and the foot does not come to rest while the tendon is being stretched but continues the repetitive activity. The unsustained clonus associated with normal but hyperactive reflexes is not considered pathologic. Sustained clonus always indicates the presence of CNS disease and requires further evaluation.

BOX 43-1 Documenting Reflexes

Deep tendon reflexes are graded on a scale of 0 to 4:

0 No response
1+ Diminished (hypoactive)
2+ Normal
3+ Increased (may be interpreted as normal)
4+ Hyperactive (hyperreflexia)

The deep tendon responses and plantar reflexes are commonly recorded on stick figures. The arrow points downward if the plantar response is normal and upward if the response is abnormal.



Superficial Reflexes

The major superficial reflexes include corneal, gag or swallowing, upper/lower abdominal, cremasteric (men only), plantar, and perianal. These reflexes are graded differently than the motor reflexes and are noted to be present (+) or absent (–). Of these, only the corneal, gag, and plantar reflexes are tested commonly.

The corneal reflex is tested carefully using a clean wisp of cotton and lightly touching the outer corner of each eye on the sclera. The reflex is present if the action elicits a blink. Conditions such as a stroke or coma might result in loss of this reflex, either unilaterally or bilaterally. Loss of this reflex indicates the need for eye protection and possible lubrication to prevent corneal damage.

The gag reflex is elicited by gently touching the back of the pharynx with a cotton-tipped applicator; first on one side of the uvula and then the other. Positive response is an equal elevation of the uvula and "gag" with stimulation. Absent response on one or both sides can be seen following a stroke and requires careful evaluation and treatment of the resultant swallowing dysfunction to prevent aspiration of food and fluids.

The plantar reflex, also known as the Babinski reflex, is elicited by stroking the lateral side of the foot with a tongue blade or the handle of a reflex hammer. In a person with an intact CNS, if the lateral aspect of the sole of the foot is stroked, the toes contract and draw together. However, in a person who has CNS disease of the motor system, the toes fan out. This is normal in newborns but in adults, the presence of Babinski indicates brain dysfunction (see Fig. 43-15).

Sensory Examination

The sensory system is even more complex than the motor system because sensory modalities are carried in different tracts located in different portions of the spinal cord. The sensory examination is largely subjective and requires the cooperation of the patient. The examiner should be familiar with dermatomes that represent the distribution of the peripheral nerves that arise from the spinal cord (see Fig. 43-13). Exceptions to this include major destructive lesions of the brain; loss of sensation, which may affect an entire side of

the body; and the neuropathies associated with alcoholism, which occur in a glove-and-stocking distribution (i.e., over the entire hand or foot, in areas traditionally covered by a glove or sock).

FIGURE 43-15 The clinician uses an instrument to stroke the sole of the patient's foot, beginning at the heel and curving upward, causing toe flexion (negative Babinski sign) (A and B). Toes that fan outward (positive Babinski sign) may indicate injury to the brain or spinal nerves. (From Bickley, L. S., & Szilagyi, P. (2003). *Bates' guide to physical examination and history taking* (8th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Assessment of the sensory system involves tests for tactile sensation, superficial pain, vibration, and position sense (proprioception). During the sensory assessment, the patient's eyes are closed. Simple directions and reassurance that the examiner will not hurt or startle the patient encourage cooperation. Comparisons between the left- and right-side findings are documented depending on which modality is found to have a deficit.

Diagnostic Evaluation

Computed Tomography Scanning

Computed tomography (CT) scanning makes use of a narrow x-ray beam to scan the body part in successive layers. The images provide cross-sectional views of the brain, with distinguishing differences in tissue densities of the skull, cortex, subcortical structures, and ventricles. The image is displayed on a monitor and is photographed and stored digitally.

Lesions in the brain are seen as variations in tissue density differing from the surrounding normal brain tissue. Abnormalities of tissue indicate possible tumor masses, brain infarction, displacement of the ventricles, and cortical atrophy. An emergency CT scan is performed in the patient with suspected brain bleed (e.g., subarachnoid hemorrhage) since blood within the basal cisterns is generally evident within the first 24 hours, whereas conventional magnetic resonance imaging (MRI) generally is less sensitive than CT scans for detecting blood (Mayer, 2016).

Procedure

CT scanning is usually performed first without contrast material and then with IV contrast enhancement. The patient lies on an adjustable table with the head held in a fixed position while the scanning system rotates around the head or spine and produces cross-sectional images. The patient must lie perfectly still without talking or moving because motion distorts the image.

CT scanning is noninvasive and painless and has a high degree of sensitivity for detecting lesions. With advances in CT scanning, the number of disorders and injuries that can be diagnosed is increasing.

Nursing Interventions

Essential nursing interventions include preparation for the procedure and patient monitoring. Preparation includes teaching the patient about the need to lie quietly throughout the procedure. A review of relaxation techniques may be helpful for patients with claustrophobia.

Sedation can be used if agitation, restlessness, or confusion will interfere with a successful study. Ongoing patient monitoring during sedation is necessary. If a contrast agent is used, the patient must be assessed before the CT scan for an iodine/shellfish allergy because the contrast agent is iodine-based. An IV line for injection of the contrast agent and a period of fasting (usually 4 hours) are required prior to the study. Patients who receive an IV or inhalation contrast agent are monitored during and after the procedure for allergic reactions, kidney function, and other side effects, including flushing, nausea, and vomiting. Preprocedure hydration, along with the lowest possible dose of contrast for the study, is recommended, since contrast-induced nephropathy is the third most common cause of hospital-acquired kidney failure.

Positron Emission Tomography

Positron emission tomography (PET) is a computer-based nuclear imaging technique that

produces images of actual organ functioning.

Procedure

The patient either inhales a radioactive gas or is injected with a radioactive substance that emits positively charged particles. When these positrons combine with negatively charged electrons (normally found in the body's cells), the resultant gamma rays can be detected by a scanning device that produces a series of two-dimensional views at various levels of the brain. This information is integrated by a computer and gives a composite picture of the brain at work.

PET permits the measurement of blood flow, tissue composition, and brain metabolism and thus indirectly evaluates brain function. The brain is one of the most metabolically active organs, consuming 80% of the glucose the body uses. PET measures this activity in specific areas of the brain and can detect changes in glucose use.

In addition, PET is useful in showing metabolic changes in the brain (Alzheimer disease), locating lesions (brain tumor, epileptogenic lesions), identifying blood flow and oxygen metabolism in patients with strokes, evaluating new therapies for brain tumors, and revealing biochemical abnormalities associated with mental illness. The isotopes used have a very short half-life and are expensive to produce, requiring specialized equipment for production.

Nursing Interventions

Key nursing interventions include patient preparation, which involves explaining the test and teaching the patient about inhalation techniques and the sensations (e.g., dizziness, lightheadedness, and headache) that may occur. The IV injection of the radioactive substance produces similar side effects. Relaxation exercises may reduce anxiety during the test.

Single-Photon Emission Computed Tomography

Procedure

Single-photon emission computed tomography (SPECT) is a three-dimensional imaging technique that uses radionuclides and instruments to detect single photons. It is a perfusion study that captures a moment of cerebral blood flow at the time of injection of a radionuclide. Gamma photons are emitted from a radiopharmaceutical agent administered to the patient and are detected by a rotating gamma camera or cameras; the image is sent to a minicomputer. This approach allows areas behind overlying structures or background to be viewed, greatly increasing the contrast between normal and abnormal tissue. It is relatively inexpensive, and the duration is similar to that of a CT scan.

SPECT is useful in detecting the extent and location of abnormally perfused areas of the brain, thus allowing detection, localization, and sizing of stroke (before it is visible by CT scan); localization of seizure foci in epilepsy; detection of tumor progression; and evaluation of perfusion before and after neurosurgical procedures. Pregnancy and breastfeeding are contraindications to SPECT.

Nursing Interventions

The nursing interventions for SPECT primarily include patient preparation and patient monitoring. Teaching about what to expect before the test can allay anxiety and ensure patient cooperation during the test. Premenopausal women are advised to practice effective contraception before and for several days after testing, and the woman who is breastfeeding is instructed to stop nursing for the time period recommended by the nuclear medicine department.

The nurse may need to accompany and monitor the patient during transport to the nuclear medicine department for the scan. Patients are monitored during and after the procedure for allergic reactions to the radiopharmaceutical agent.

Magnetic Resonance Imaging

Procedure

MRI uses a powerful magnetic field to obtain images of different areas of the body. This diagnostic test involves altering hydrogen ions in the body. Placing the patient into a powerful magnetic field causes the hydrogen nuclei (protons) within the body to align like small magnets in a magnetic field. In combination with radiofrequency pulses, the protons emit signals, which are converted to images. There are two magnet strengths available for clinical use; 1.5 T (most common strength) and 3.0 T. An MRI scan can be performed with or without a contrast agent and can identify a cerebral abnormality earlier and more clearly than other diagnostic tests. It can provide information about the chemical changes within cells, allowing the clinician to monitor a tumor's response to treatment. It is particularly useful in the diagnosis of multiple sclerosis and can describe the activity and extent of disease in the brain and spinal cord. MRI does not involve ionizing radiation. At present, MRI is most valuable in the diagnosis of nonacute conditions because the test may take up to an hour to complete.

There are several MRI scanning techniques, including magnetic resonance angiography (MRA), diffusion-weighted imaging (DWI), perfusion-weighted imaging (PWI), and fluid attenuation inversion recovery (FLAIR). The use of MRA allows visualization of the cerebral vasculature without the administration of an arterial contrast agent, but the clarity of the images is enhanced when a contrast agent is used. If an agent is used, kidney function must be assessed.

Nursing Interventions

Patient preparation should include teaching relaxation techniques and informing the patient that he or she will be able to talk to the staff by means of a microphone located inside the scanner. Many MRI suites provide headphones so that patients can listen to the music of their choice during the procedure.

Before the patient enters the room where the MRI is to be performed, all metal objects and credit cards (the magnetic field can erase them) are removed. This includes medication patches that have a metal backing; these can cause burns if not removed. No metal objects may be brought into the room where the MRI is located; this includes oxygen tanks, traditional ventilators, or even stethoscopes. The magnetic field generated by the unit is so strong that any metal-containing items will be strongly attracted and literally can be pulled away with such force that they fly like projectiles toward the magnet. There is a risk of severe injury and death; furthermore, damage to a very expensive piece of equipment may

occur. A patient history is obtained to determine the presence of any metal objects (e.g., aneurysm clips, orthopedic hardware, pacemakers, artificial heart valves, intrauterine devices). These objects could malfunction, be dislodged, or heat up as they absorb energy. Cochlear implants will be inactivated by MRI; therefore, other imaging procedures are considered.

The patient lies on a flat platform that is moved into a tube housing the magnet. The scanning process is painless, but the patient hears loud thumping of the magnetic coils as the magnetic field is being pulsed. Because the MRI scanner is a narrow tube, patients may experience claustrophobia; sedation may be prescribed in these circumstances. Newer versions of MRI machines (open MRI) are less claustrophobic than the earlier devices and are available in some locations. However, the images produced on these machines are not optimal, and traditional devices are preferable for accurate diagnosis.

Nursing Alert
For patient safety, the nurse must make sure no patient care equipment (e.g., portable oxygen tanks) that contains metal or metal parts enters the room where the MRI is located. The patient must be assessed for the presence of medication patches with foil backing (such as nicotine) that may cause a burn.

Cerebral Angiography

Procedure

Cerebral angiography is an x-ray study of the cerebral circulation with a contrast agent injected into a selected artery. Cerebral angiography is a valuable tool to investigate vascular disease, aneurysms, and arteriovenous malformations and to define their anatomy. It is still considered the gold standard for diagnosing these conditions.

Most cerebral angiograms are performed by threading a catheter through the femoral artery in the groin and up to the desired vessel. After the groin is shaved and prepared, a local anesthetic is administered to prevent pain at the insertion site and to reduce arterial spasm. A catheter is introduced into the femoral artery, flushed with heparinized saline, and filled with contrast agent. Fluoroscopy is used to guide the catheter to the appropriate vessels. During injection of the contrast agent, images are made of the arterial and venous phases of circulation through the brain.

Nursing Interventions

The patient should be well hydrated, and clear liquids are usually permitted up to the time of a regular arteriogram. Before going to the x-ray department, the patient is instructed to void. The locations of the appropriate peripheral pulses are marked with a felt-tip pen. The patient is instructed to remain immobile during the angiogram process and is told to expect a brief feeling of warmth in the face, behind the eyes, or in the jaw, teeth, tongue, and lips, and a metallic taste when the contrast agent is injected.

Nursing care after cerebral angiography includes observation for signs and symptoms of altered cerebral blood flow. In some instances, patients may experience major or minor arterial blockage due to embolism, thrombosis, or hemorrhage, producing a neurologic deficit. Signs of such an occurrence include alterations in the level of responsiveness and consciousness, weakness on one side of the body, motor or sensory deficits, and speech

disturbances. Therefore, it is necessary to observe the patient frequently for these signs and to report them immediately if they occur.

The injection site is observed for hematoma formation (a localized collection of blood), and an ice bag may be applied intermittently to the puncture site to relieve swelling and discomfort. Because a hematoma at the puncture site or embolization to a distant artery affects the peripheral pulses, these pulses are monitored frequently. The color and temperature of the involved extremity are assessed to detect possible embolism (the limb would be cool and pale if arterial perfusion is impaired).

Myelography

Procedure

A myelogram is an x-ray of the spinal subarachnoid space taken after the injection of a contrast agent through a lumbar puncture. It outlines the spinal subarachnoid space and shows any distortion of the spinal cord or spinal dural sac caused by tumors, cysts, herniated vertebral disks, or other lesions. Water-based agents have replaced oil-based agents, and their use has reduced side effects and complications; these agents disperse upward through the CSF. Myelography is performed less frequently today because of the sensitivity of CT and MRI scanning. It is still used occasionally to provide information about the spinal cord and nerve roots (Barbano, 2016).

Nursing Interventions

Because many patients have misconceptions about myelography, the nurse clarifies the explanation given by the provider and answers questions. The patient is informed about what to expect during the procedure and should be aware that changes in position may be made during the procedure. The meal that normally would be eaten before the procedure is omitted. A sedative may be prescribed to help the patient cope with this rather lengthy test. Patient preparation for lumbar puncture is discussed later in this chapter.

After myelography, the patient lies in bed with the head of the bed elevated 30 to 45 degrees. The patient is advised to remain in bed in the recommended position for 3 hours or as prescribed by the provider. The patient is encouraged to drink liberal amounts of fluid for rehydration and replacement of CSF. The blood pressure, pulse, respiratory rate, and temperature are monitored, as well as the patient's ability to void. Untoward signs include headache, fever, stiff neck, photophobia (sensitivity to light), seizures, and signs of chemical or bacterial meningitis.

Noninvasive Carotid Flow Studies

Procedure

Noninvasive carotid flow studies use ultrasound imagery and Doppler measurements of arterial blood flow to evaluate carotid and deep orbital circulation. The graph produced indicates blood velocity. Increased blood velocity can indicate stenosis or partial obstruction. These tests are often obtained before arteriography, which carries a higher risk of stroke or death. Carotid Doppler, carotid ultrasonography, oculoplethysmography, and ophthalmodynamometry are four common noninvasive vascular techniques that permit evaluation of arterial blood flow and detection of arterial stenosis, occlusion, and plaques.

These vascular studies allow noninvasive imaging of extracranial and intracranial circulation.

Nursing Interventions

When a carotid flow study is scheduled, the procedure is described to the patient. The patient is informed that this is a noninvasive test, that a hand-held transducer will be placed over the neck or orbits of the eyes, and that some type of water-soluble jelly is used on the transducer.

Electroencephalography (EEG)

Procedure

An electroencephalogram (EEG) represents a record of the electrical activity generated in the brain. It is obtained through electrodes applied on the scalp or through microelectrodes placed within the brain tissue. It provides a physiologic assessment of cerebral activity.

The EEG is a useful test for diagnosing and evaluating seizure disorders, coma, or organic brain syndrome. Tumors, brain abscesses, blood clots, and infection may cause abnormal patterns in electrical activity. The EEG is also used in making a determination of brain death.

For a baseline recording, the patient lies quietly with both eyes closed. The patient may be asked to hyperventilate for 3 to 4 minutes and then look at a bright, flashing light for photic stimulation. These activation procedures are performed to evoke abnormal electrical discharges, such as seizure potentials. A sleep EEG may be recorded after sedation because some abnormal brain waves are seen only when the patient is asleep.

Nursing Interventions

To increase the chances of recording seizure activity, it is sometimes recommended that the patient be deprived of sleep on the night before the EEG. Antiseizure agents, tranquilizers, stimulants, and depressants should be withheld 24 to 48 hours before an EEG because these medications can alter the EEG wave patterns or mask the abnormal wave patterns of seizure disorders (Hickey, 2014).

The patient is informed that the standard EEG takes 45 to 60 minutes (12 hours for a sleep EEG). The patient is assured that the procedure does not cause an electric shock and that the EEG is a diagnostic test, not a form of treatment. An EEG requires patient cooperation and ability to lie quietly during the test. Sedation is not advisable because it may lower the seizure threshold in patients with a seizure disorder and it alters brain wave activity in all patients. The nurse needs to check with the physician regarding the administration of antiseizure medication prior to testing.

Routine EEGs use a water-soluble lubricant for electrode contact, which at the conclusion of the study can be wiped off and removed by shampooing. Sleep EEGs involve the use of collodion glue for electrode contact, which requires acetone for removal.

Electromyography (EMG)

Procedure

An electromyogram (EMG) is obtained by inserting needle electrodes into the skeletal

muscles to measure changes in the electrical potential of the muscles and the nerves leading to them. The electrical potentials are shown on an oscilloscope and amplified so that both the sound and appearance of the waves can be analyzed and compared simultaneously.

An EMG is useful in determining the presence of neuromuscular disorders and myopathies. It helps distinguish weakness due to neuropathy (functional or pathologic changes in the PNS) from weakness resulting from other causes.

Nursing Interventions

The procedure is explained, and the patient is warned to expect a sensation similar to that of an intramuscular injection as the needle is inserted into the muscle. The muscles examined may ache for a short time after the procedure.

Lumbar Puncture and Examination of Cerebrospinal Fluid

Procedure

A lumbar puncture (spinal tap) is an aseptic procedure carried out by inserting a needle into the lumbar subarachnoid space to withdraw CSF. The test may be performed to obtain CSF for examination, to measure and reduce CSF pressure, to assess for infection, and to determine the presence or absence of blood in the CSF. Antibiotics may be administered intrathecally (into the spinal canal) in certain cases of infection or contrast injected for diagnostic purposes.

The needle is usually inserted into the subarachnoid space between the third and fourth or fourth and fifth lumbar vertebrae. Because the spinal cord divides into a sheaf of nerves at the first lumbar vertebra, insertion of the needle below the level of the third lumbar vertebra prevents puncture of the spinal cord.

A successful lumbar puncture (LP) requires that the patient be relaxed; an anxious patient is tense, and this may increase the pressure reading. CSF pressure with the patient in a lateral recumbent position is normally 70 to 200 mm H_2O. This value is position dependent and will change with a horizontal or sitting position (Fischbach & Dunning, 2014). Pressures of more than 200 mm H_2O are considered abnormal.

An LP may be risky in the presence of an intracranial mass lesion because ICP is decreased by the removal of CSF, and the brain may herniate downward through the tentorium and the foramen magnum. To avoid this complication, a CT scan must be done prior to the procedure for patients with a suspected intracranial mass. Additionally, LPs are avoided in patients on antiplatelet therapy or anticoagulants. See Box 43-2 for nursing guidelines for assisting with a lumbar puncture.

Cerebrospinal Fluid Analysis

The CSF should be clear and colorless. Pink, blood-tinged, or grossly bloody CSF may indicate a subarachnoid hemorrhage. Cloudiness of CSF may be due to increased WBCs or increased protein from microorganisms; whereas xanthochromia (yellow, orange, or brown color) of CNS is usually due to RBC breakdown (Hickey, 2014). Sometimes, with a difficult lumbar puncture, the CSF initially is bloody because of local trauma but then becomes clearer. Usually, specimens are obtained for cell count, culture, and glucose and protein testing. The specimens should be sent to the laboratory immediately because

changes will take place and alter the result if the specimens are allowed to stand.

BOX 43-2 Assisting with a Lumbar Puncture

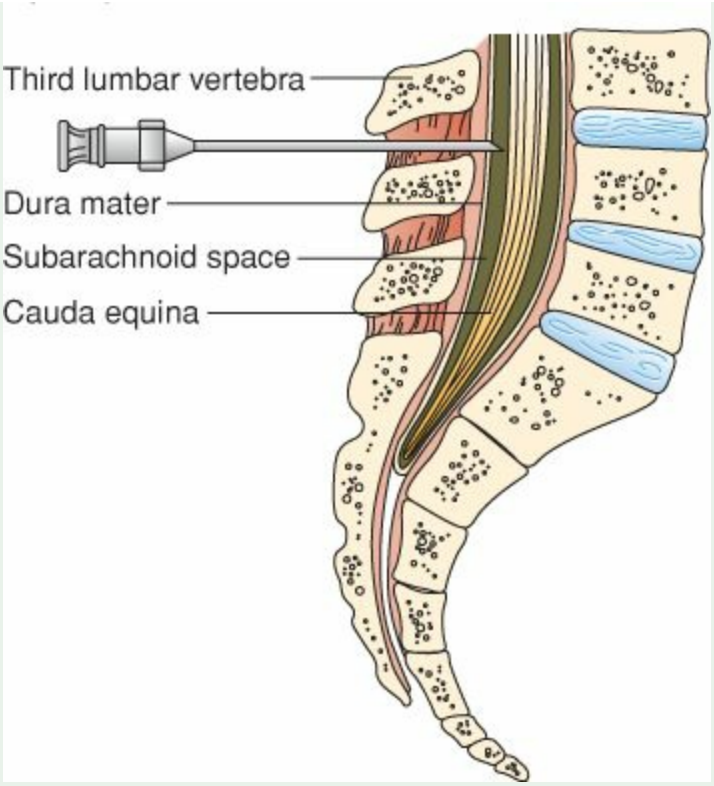
A needle is inserted into the subarachnoid space through the third and fourth or fourth and fifth lumbar interface to withdraw spinal fluid.

Preprocedure

1. Determine whether written consent for the procedure has been obtained.
2. Explain the procedure to the patient and describe sensations that are likely during the procedure (i.e., a sensation of cold as the site is cleansed with solution, a needle prick when local anesthetic is injected).
3. Determine whether the patient has any questions or misconceptions about the procedure; reassure the patient that the needle will not enter the spinal cord or cause paralysis.
4. Instruct the patient to void before the procedure.

Procedure

1. The patient is positioned on one side (knee to chest position) at the edge of the bed or examining table with back toward the provider; the legs are flexed as much as possible to increase the space between the spinous processes of the vertebrae, for easier entry into the subarachnoid space.
2. A small pillow may be placed under the patient's head to maintain the spine in a horizontal position; a pillow may be placed between the legs to prevent the upper leg from rolling forward.
3. The nurse assists the patient to maintain the position to avoid sudden movement, which can produce a traumatic (bloody) tap.
4. The patient is encouraged to relax and is instructed to breathe normally because hyperventilation may lower an elevated pressure.
5. The nurse describes the procedure step by step to the patient as it proceeds.
6. Using an aseptic technique, the provider cleanses the puncture site with an antiseptic solution and drapes the site.
7. The provider injects local anesthetic to numb the puncture site and then inserts a spinal needle into the subarachnoid space through the third and fourth or fourth and fifth lumbar interspace.
8. A specimen of CSF is removed and usually collected in three test tubes, labeled in order of collection. A pressure reading may be obtained. The needle is withdrawn.



9. The provider applies a small dressing to the puncture site.
10. The tubes of CSF are sent to the laboratory immediately.

Postprocedure

Typically patients are instructed to rest in bed for a few hours after a lumbar tap, and fluids are encouraged; however, research reveals no definite differences in the effects of bed rest or hydration of patients. Therefore, the nurse should refer to institutional procedures for postprocedure care.

1. Monitor the patient for complications of lumbar puncture; notify the provider if complications occur:
   a. Common complications: Post–lumbar puncture headache, voiding difficulties, slight elevation of temperature, backache or spasms, stiffness of neck. Typical management of postprocedure headache includes maintaining a supine posture, hydration, and analgesia and/or antiemetics prn; however, the nurse follows institutional procedures until best practices are delineated.
   b. Rare complications: Herniation of intracranial contents, spinal epidural abscess, spinal epidural hematoma, meningitis

Post–Lumbar Puncture Headache

A post–lumbar puncture headache, ranging from mild to severe, may occur a few hours to several days after the procedure. This is the most common complication, occurring in 15% to 30% of patients. It is a throbbing bifrontal or occipital headache, dull and deep in

character. It is particularly severe on sitting or standing but lessens or disappears when the patient lies down.

The headache is caused by CSF leakage at the puncture site. The fluid continues to escape into the tissues by way of the needle track from the spinal canal. It is then absorbed promptly by the lymphatic system. As a result of this leak, the supply of CSF in the cranium is depleted to a point at which it is insufficient to maintain proper mechanical stabilization of the brain. This leakage of CSF allows settling of the brain when the patient assumes an upright position, producing tension and stretching the venous sinuses and pain-sensitive structures. Both traction and pain are lessened and the leakage is reduced when the patient lies down for 4 to 8 hours (Fischbach & Dunning, 2014).

Post–lumbar puncture headache may be avoided if a small-gauge needle is used. The postpuncture headache is usually managed by bed rest, analgesic agents, and hydration. However, the Therapeutics and Technology Assessment Subcommittee of the American Academy of Neurology, along with other groups, noted there is no class I or class II evidence to demonstrate that duration of bed rest, position of bed rest (prone or supine), or increased intake influences incidence of LP headache (Afshinmajd et al., 2014). The nurse should follow hospital standards while best practices are being developed. Occasionally, if the headache persists, an epidural blood patch may be used. Blood is withdrawn from the antecubital vein and injected into the epidural space, usually at the site of the previous spinal puncture. The rationale is that the blood acts as a gelatinous plug to seal the hole in the dura, preventing further loss of CSF.

Other Complications of Lumbar Puncture

Herniation of the intracranial contents, spinal epidural abscess, spinal epidural hematoma, and meningitis are rare but serious complications of lumbar puncture. Other complications include temporary voiding problems, slight elevation of temperature, backache or spasms, and stiffness of the neck.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 68-year-old woman presents to your unit with complaints of weakness, headache, and lethargy. After completing the Glasgow Coma Scale, you are asked to perform assessment of her cranial nerves; identify what will be included in this assessment.

2. A 78-year-old patient with a history of chronic pain is admitted to the hospital to rule out an ischemic stroke and is scheduled for an MRI. Explain why the MRI is indicated and what, if any, precautions must be taken because this patient has chronic pain. What nursing observations and assessments are indicated because of the occurrence of these two disorders? What safety precautions are essential in the MRI suite, and why?

3. You are caring for a patient who is scheduled to undergo a lumbar puncture. How can you best assist and support the patient during the procedure? What laboratory studies would you expect to be ordered on the CSF sample? What postprocedure restrictions

can you expect and prepare the patient for?

NCLEX-Style Review Questions

1. A patient is undergoing a cerebral angiography to rule out an aneurysm. When preparing the patient for the procedure, what would the nurse include in the instructions?
   a. Expect a metallic taste when the contrast agent is injected.
   b. You will need a full bladder prior to the procedure.
   c. Maintain an NPO status.
   d. General sedation will be given prior to procedure.

2. The nurse is assisting with a lumbar puncture. What is the most common complication for which the nurse should monitor the patient following the procedure?
   a. Post–lumbar puncture headache
   b. Herniation of intracranial contents
   c. Spinal epidural abscess
   d. Meningitis

3. A patient is scheduled for an EEG tomorrow. Which piece of information should the nurse provide to the patient prior to the procedure?
   a. Antiseizure medications need to be taken prior to procedure.
   b. Sedation will be given during the procedure.
   c. There is a slight chance of electric shock.
   d. Maintain a sleep-deprived state the night before the procedure.

4. A patient with Parkinson disease is seen in the neurology clinic for treatment. The nurse identifies this disorder as being caused by a lack of which neurotransmitters?
   a. Acetylcholine
   b. Dopamine
   c. Serotonin
   d. Gamma-aminobutyric acid (GABA)

5. The nurse is testing the cranial nerves of a patient diagnosed with myasthenia gravis. The nurse asks the patient to clench his jaw while she palpates the temporal and masseter muscles. The nurse is correctly testing which cranial nerve?
   a. Abducens
   b. Trigeminal
   c. Acoustic
   d. Hypoglossal

CHAPTER 44

Nursing Management: Patients with Oncologic Disorders of the Brain and Spinal Cord

Jill S. Keller

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the different types of brain tumors, including classification, clinical manifestations, diagnosis, and medical and nursing management.
2. Describe the symptoms and effects of increased intracranial pressure.
3. Differentiate between primary and metastatic brain tumors.
4. Describe the different types of spinal cord tumors, including classification, clinical manifestations, diagnosis, and medical and nursing management.
5. Describe the symptoms and effects of spinal cord compression.

PRIMARY BRAIN TUMORS

Primary brain tumors are localized intracranial lesions that begin in the brain and occupy space within the skull. The tumor is an abnormal growth of cells that forms a mass, but it also can grow diffusely. The effects of neoplasms (tumors or lesions) on the central nervous system (CNS), including seizure activity and focal neurologic signs, are caused by the compression or infiltration of tissue, or both. Tumors may be benign or malignant. Benign tumors are usually slow growing but can occur in a vital area, where they can grow large enough to cause serious effects. Malignant tumors can be rapidly growing in nature, can spread into surrounding tissue, and are considered life-threatening. Primary brain tumors rarely spread to other areas of the body.

Oncologic (cancer) disorders of the brain include several types of neoplasms, each with its own biology, prognosis, and treatment options. Because of the unique anatomy and physiology of the CNS, this collection of neoplasms is challenging to diagnose and treat.

Types of Brain Tumors

There are many different types of brain tumors. They are classified into several groups: those originating within brain tissue (e.g., glioma), those arising from the coverings of the brain (e.g., dural meningioma), those developing in or on the cranial nerves (e.g., acoustic neuroma), and metastatic lesions originating from cancer elsewhere in the body. Tumors of the pituitary and pineal glands and of cerebral blood vessels are also considered types of brain tumors. Relevant clinical considerations when developing a plan of treatment includes the location, size, histologic character of the tumor, and if the tumor can be surgically removed.

Gliomas

Gliomas tumors are a type of intracerebral brain neoplasm. Gliomas are divided into many categories. Box 44-1 lists the classification of these and other brain tumors. Glioblastoma multiforme (GBM) is the most common and aggressive malignant brain tumor (Ray, Bonafede, & Mohile, 2014). In most cases, a tissue biopsy, which can be obtained at the time of surgical removal, is needed to confirm the diagnosis. The grade of the tumor is based on cellular density, cell mitosis, and appearance. Usually, these tumors form in the cerebrum and spread by infiltrating the surrounding neural connective tissue. Treatment for this type of tumor may include surgery, radiation therapy, and/or chemotherapy. Total surgical resection is difficult due to the "finger-like tentacles" the tumor produces. The goal of surgery is to remove as much tumor as possible without causing any neurologic damage. Despite treatment, median life expectancy is 14.6 months (American Brain Tumor Association [ABTA], 2014a).

BOX 44-1 Classification of Brain Tumors in Adults

I. Intracerebral tumors
   A. Gliomas—infiltrate any portion of the brain:
      1. Astrocytomas (grades I and II)
      2. Glioblastoma multiforme (astrocytoma grades III and IV)
      3. Oligodendrocytoma (low and high grades)
      4. Ependymoma (grades I to IV)
      5. Medulloblastoma
II. Tumors arising from supporting structures
   A. Meningiomas
   B. Neuromas (acoustic neuroma, schwannoma)
   C. Pituitary adenomas
III. Developmental tumors
   A. Angiomas
   B. Dermoid, epidermoid, teratoma, craniopharyngioma
IV. Metastatic lesions

Meningiomas

Meningiomas represent 36.1% of all primary brain tumors and are the most common brain tumors found in adults. Most are characterized as a benign, encapsulated, slow-growing tumor that occurs in people over 60 years of age and found twice as often in women as in men (ABTA, 2014e). These tumors grow on the membrane covering of the brain, called the meninges. Grade I meningiomas are the most common type and can be cured by surgery. Due to the slow-growing nature of this tumor, it is not uncommon that people die unaware they have a meningioma. Grades II and III are less common and grow quickly. They can spread to the brain and spinal cord. These tumors have a poorer prognosis and usually cannot be completely resected. Manifestations depend on the area involved and are the result of compression rather than invasion of brain tissue (National Cancer Institute [NCI], 2015). In some cases this type of tumor can run in families that have the neurofibromatosis syndrome (genetic disorders that cause tumors to grow along various types of nerves and/or nonnervous tissues) that can increase their risk for developing a brain tumor (American Cancer Society [ACS], 2015).

Acoustic Neuromas

An acoustic neuroma (vestibular schwannoma) is a benign tumor of the eighth cranial nerve, the cranial nerve most responsible for hearing and balance. It usually arises within the internal auditory meatus. An acoustic neuroma is a slow-growing tumor and attains considerable size before it is correctly diagnosed. The patient usually experiences loss of hearing, tinnitus, episodes of vertigo, and staggering gait. As the tumor becomes larger, painful sensations of the face may occur on the same side, as a result of the tumor's compression of the fifth cranial nerve (trigeminal nerve) resulting in facial numbness (paresthesia) and pain. Diagnosis is suggested by unilateral sensorineural hearing loss; the Weber and Rinne test may be useful in assessing asymmetric hearing loss (refer to Chapter 48). Most acoustic neuromas can be surgically removed or are suitable for stereotactic radiotherapy. When patients present with small tumors with limited symptomatology, treatment options may include observation over time since some tumors may not progress and may shrink in size.

Pituitary Adenomas

Pituitary tumors represent 12–19% of all primary brain tumors (ABTA, 2017). They are slow growing in nature. A majority of these tumors are benign but, in rare cases, may be malignant. Pituitary tumors are classified as nonfunctioning and functioning. Nonfunctioning tumors do not produce hormones. Functioning tumors can produce one or more hormones, normally by the anterior pituitary. Increase may be seen in prolactin hormone, growth hormone, adrenocorticotropic hormone (ACTH), or thyroid-stimulating hormone. Females are more affected than males, and these tumors are rarely seen in the pediatric population (Lopes, 2013). Endocrine disorders resulting from these tumors are discussed in Chapter 31.

Pressure from a pituitary adenoma may be exerted on the optic nerves, optic chiasm, optic tracts, hypothalamus, or the third ventricle. Headache is a common symptom; there

can also be visual dysfunction, hypothalamic disorders (diabetes insipidus, sleep disturbances, and changes in appetite), and increased intracranial pressure (ICP). Advances in transsphenoidal surgery and stereotactic radiotherapy help to normalize hormonal secretion and relieve symptoms and compression on surrounding structures (Melmed & Jameson, 2015).

Angiomas

Brain angiomas (masses composed largely of abnormal blood vessels) are found either in the brain or on its surface. They occur most often in the cerebellum. Some persist throughout life asymptomatically, while others cause symptoms of a brain tumor, such as seizures and headaches. Occasionally, the diagnosis is suggested by the presence of another angioma somewhere in the head or by a bruit (an abnormal sound) that is audible over the skull. Because the walls of the blood vessels in angiomas are thin, affected patients are at risk for hemorrhagic stroke. In fact, cerebral hemorrhage in people younger than 40 years of age should suggest the possibility of an angioma.

Cerebral Metastases

Metastatic disease is the ability for a malignant cell to travel through the circulation and reestablish itself in a second site. Primary sites of cancer that commonly metastasize to the brain include the lung, breast, and gastrointestinal tract as well as melanoma. Primary lung cancer accounts for 50% of all brain metastases (Tse, 2014a).

Risk Factors

The incidence of brain tumors appears to have increased in the past few decades. Epidemiologic data suggest that this is due to more aggressive and more accurate diagnosis rather than to an actual rise in incidence. Better access to care and an increase in the aging population may contribute to the increase in rates. An estimated 68,470 new cases of primary brain (nonmalignant and malignant) and CNS tumors were diagnosed in 2015. Of those tumors, 23,180 will be primary malignant brain tumors. The incidence rate for primary brain and CNS tumors is higher in males than females (Central Brain Tumor Registry of the United States [CBTRUS], 2014).

The cause of most primary brain tumors is unknown. The only known risk factors are exposure to ionizing radiation and cancer-causing chemicals. Additional possible risk factors that require further investigation include nonionizing consumption of nitrates, cigarette smoking, cell phone use, and exposure to residential power lines (ABTA, 2014a).

There has been some suggestion that there are particular genetic risk factors for certain types of brain tumors. Neurofibromatosis type 1 (NF1), also known as von Recklinghausen disease, is a genetic disorder linked to brain and spinal cord tumors. People with this disorder are at higher risk for schwannomas, meningiomas, and types of gliomas and neurofibromas (benign tumor). Neurofibromatosis type 2 (NF2) is less common and related to acoustic neuromas. People with a condition called tuberous sclerosis are at risk for low-grade astrocytomas (tumors that arise from astrocytes—star-shaped cells that make up the supportive tissue of the brain) and other benign tumors on the body. Li-Fraumeni syndrome increases the risk for developing gliomas, and von Hippel–Lindau disease may cause tumors in the blood vessels of the brain and spinal cord as well as other areas of the body. Other inherited conditions include Gorlin syndrome, Turcot syndrome, and Cowden syndrome (ACS, 2015). However, the cause of the vast majority of brain tumors remains elusive.

Clinical Manifestations

Brain tumors can produce focal (localized) or generalized neurologic symptoms. Symptoms reflect brain invasion, compression by the mass on adjacent structures, or increased ICP. The patient can experience seizures, nausea and vomiting, cognitive impairment, and visual disturbances. Additionally, specific signs and symptoms result from tumors that interfere with functions in specific brain regions. These focal symptoms may also include weakness, sensory loss, aphasia, visual dysfunction, and other manifestations related to specific neurologic dysfunction because of localized involvement. Figure 44-1 indicates common tumor sites in the brain.

Increased Intracranial Pressure

Symptoms of increased ICP, which is discussed in Chapter 45, result from compression of the brain by the enlarging tumor or edema. Vasogenic (cerebral) edema plays a major role in symptoms related to an increase in mass. Edema can exceed the mass itself, creating increased pressure and disrupting flow of blood or cerebral spinal fluid. Symptoms often include headache, nausea with or without vomiting, papilledema (edema of the optic disk), and visual changes (Gucalp & Dutcher, 2015). Personality changes and a variety of focal deficits, including motor, sensory, and cranial nerve dysfunction, are common. The nurse remains alert for changes in the patient's level of consciousness (LOC) and notifies the primary care provider of any alterations in mental status. Late signs associated with rising ICP related to the vital signs are termed Cushing triad; those signs may include hypertension with a widening pulse pressure (the difference between systolic and diastolic pressure), bradycardia, and respiratory depression.

Headache

Headache, although not always present, is most common in the early morning and improves during the day. Pain is made worse by coughing, straining, or sudden movement. Headache is thought to be caused by the tumor's invading, compressing, or distorting the pain-sensitive structures or by edema that accompanies the tumor. Thus, headaches are related to intracerebral edema and increasing ICP (ABTA, 2014b). Headaches are usually described as deep or expanding or as dull but unrelenting. Location of the headache can correlate to the area of the tumor. Progressive headaches are more common in glioblastoma and secreting pituitary adenomas tumors (Nelson & Taylor, 2014).

Nursing Alert
The nurse is aware that headaches in the morning are suggestive of a tumor. When the patient complains of a headache, the nurse assesses the patient's temperature. The nurse knows that fever with headache is associated with an infectious process, such as meningitis or encephalitis, whereas headache without fever may be associated with a tumor or intracerebral bleeding.

Personality Changes

The location, pressure, and degree of infiltration of the tumor, and edema, if present, influence the changes in personality and mental status. Changes may be subtle with the patient sleeping more, losing interest in activities, and having difficulty with memory. These symptoms may be confused with depression (Wong & Wu, 2016). It is not uncommon for the short-term memory to be affected while still retaining long-term thoughts.

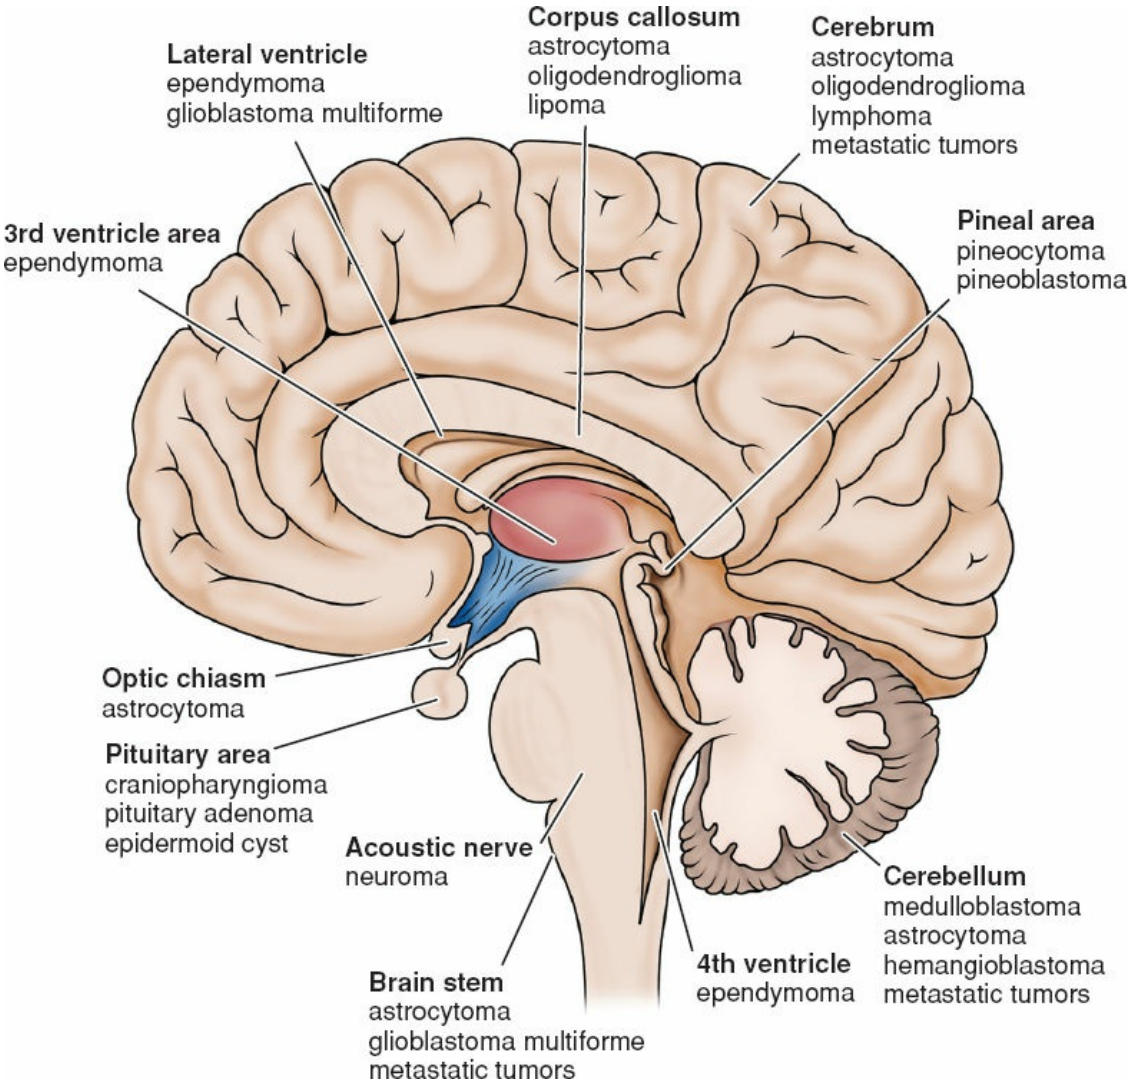

FIGURE 44-1 Common brain tumor sites.

Fatigue

Fatigue is a symptom experienced by patients with both malignant and nonmalignant brain tumors. Etiology of fatigue can be multifactorial. The tumor itself, surgery, medications, chemotherapy, and radiation may all contribute to increased fatigue. Patients may complain of a constant feeling of exhaustion, weakness, and lack of energy. It is also important to identify underlying conditions, such as stress, anxiety, and depression, which may play a role in fatigue (ABTA, 2014c).

Vomiting

Vomiting, seldom related to food intake, is usually the result of irritation of the vagal centers in the medulla. Forceful vomiting is described as *projectile vomiting.*

Visual Disturbances

Papilledema is associated with visual disturbances, such as decreased visual acuity, diplopia (double vision), and visual field deficits.

New Onset of Seizures

Seizures are a common symptom among patients with brain tumors due to abnormal electrical activity in the brain. They may present upon initial diagnosis or during the course of the disease process. Approximately 60% of patients with brain tumors have seizures during their illness (ABTA, 2014d). The type and frequency of seizure vary, related to tumor size, site, and type. Seizures can be characterized as simple partial, complex partial, and secondary generalized seizures (Vecht, Kerkhof, & Duran-Pena, 2014). Figure 44-2 presents an algorithm for initial evaluation of seizures.

Localized Symptoms

Common focal, or localized, symptoms include muscle weakness, sensory loss, aphasia, and visual changes (Wong & Wu, 2016). When specific regions of the brain are affected, additional local signs and symptoms occur, such as motor abnormalities, changes in hearing, alterations in cognition, and language disturbances. The progression of the signs and symptoms is important because it indicates tumor growth and expansion. For example, if a tumor is present in the cerebellar area, the nurse might expect to see changes in balance and coordination. Figure 44-3 reviews specific cerebral structures and function.

Assessment and Diagnostic Findings

The history of the illness as well as the manner and time frame in which the symptoms evolved are key components in the diagnosis of a brain tumor. A neurologic examination can be helpful in indicating the areas of the CNS that are involved. To assist in identifying the precise location of the lesion, a battery of tests may need to be performed.

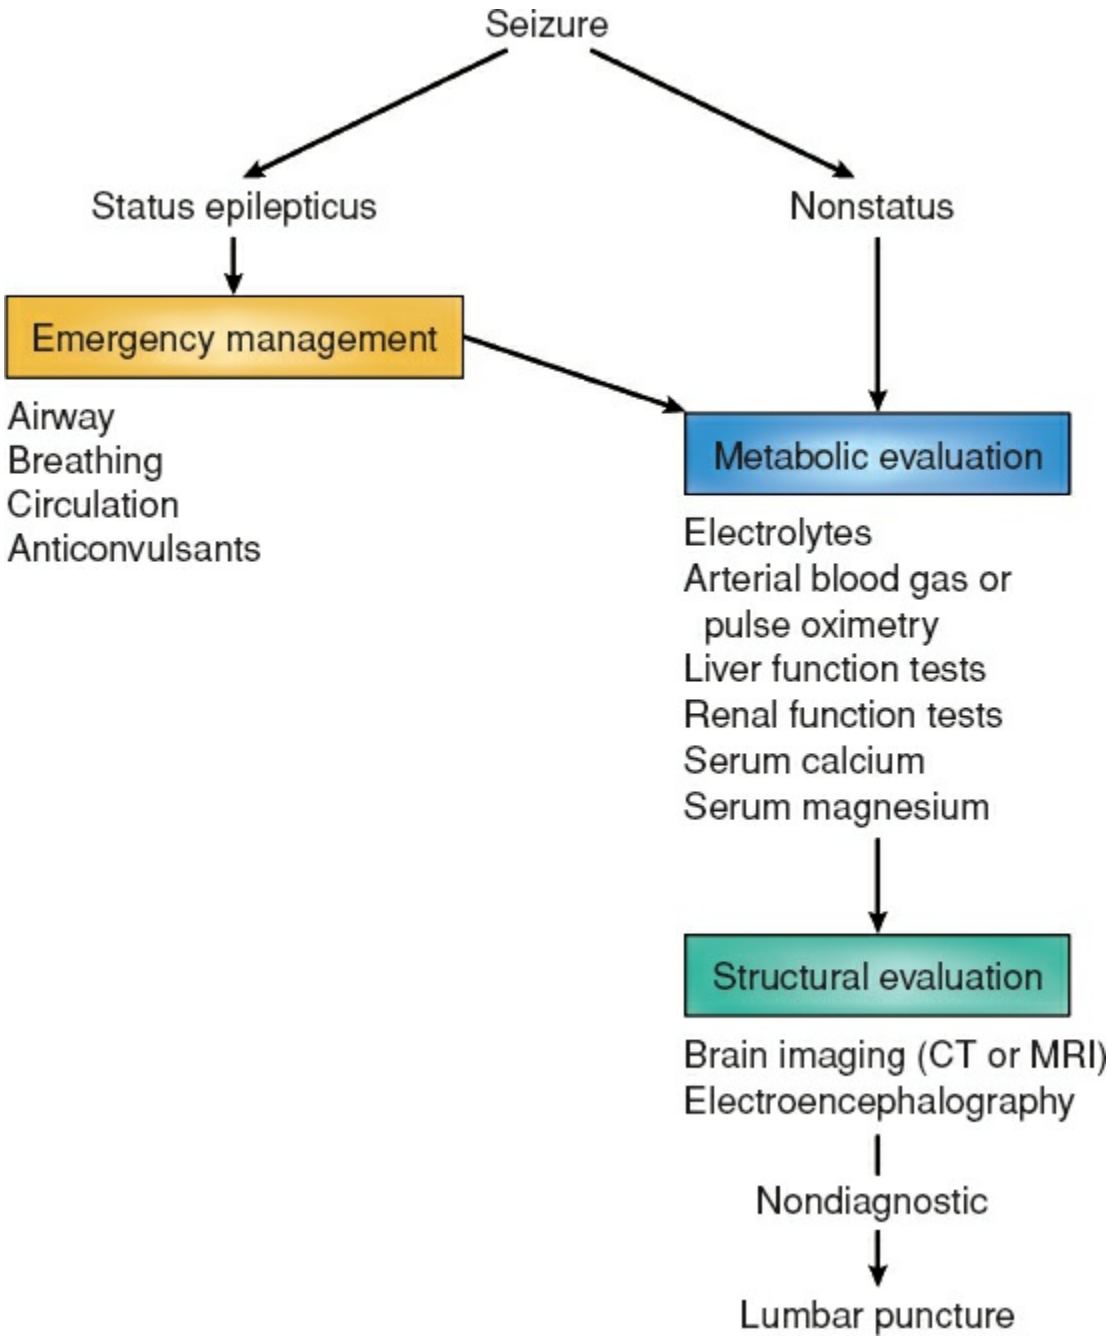

FIGURE 44-2 Algorithm for initial evaluation of patients with suspected brain tumor based on type of seizure in presenting symptoms. (From Hickey, J. (2015). *The clinical practice of neurological and neurosurgical nursing*. Philadelphia, PA: Lippincott Williams & Wilkins.)

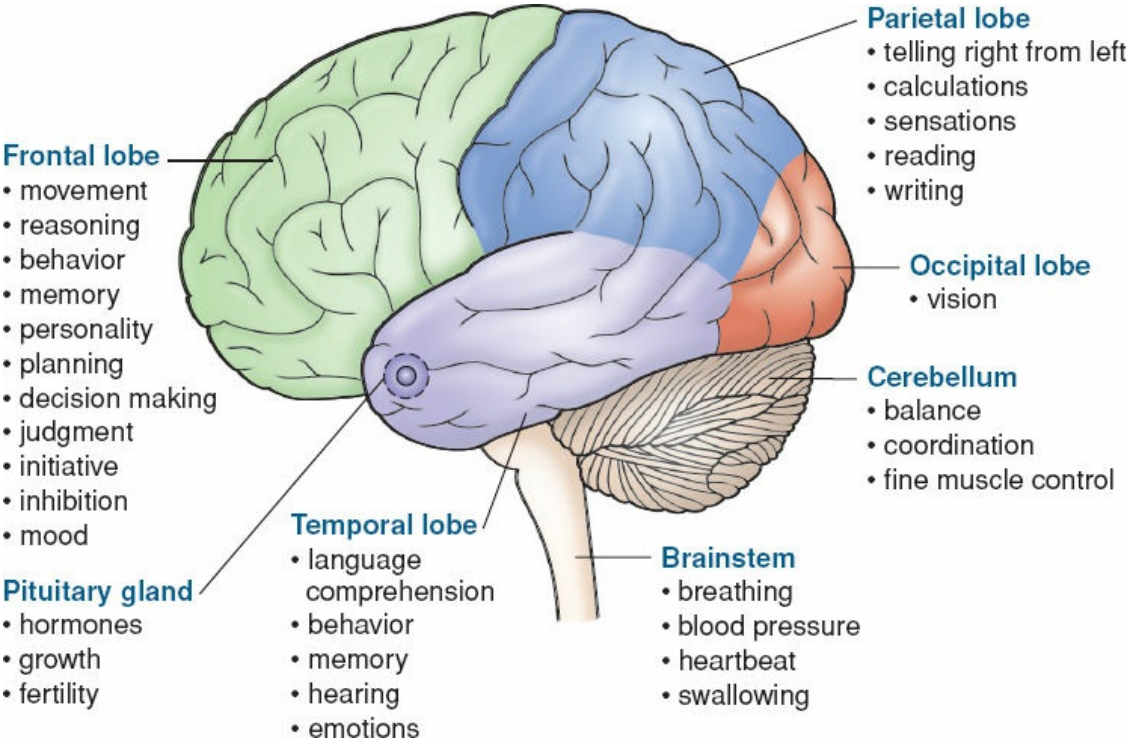

FIGURE 44-3 Brain structures and their function. (Adapted with permission from National Brain Tumor Society. (2010). *The essential guide to brain tumors*, p. 9, Retrieved from http://www.braintumor.org/patients-family-friends/about-brain-tumors/publications/essentialguide.pdf.)

Magnetic resonance imaging (MRI) is the gold standard for detecting brain tumors (McDonald & McMullen, 2015), particularly smaller lesions, and tumors in the brainstem and pituitary regions, where bone is thick (Fig. 44-4). Computed tomography (CT), enhanced by a contrast agent, can give specific information concerning the number, size, and density of the lesions and the extent of secondary cerebral edema. CT can also provide information about the ventricular system (the communicating network of cavities filled with CSF and located within the brain parenchyma).

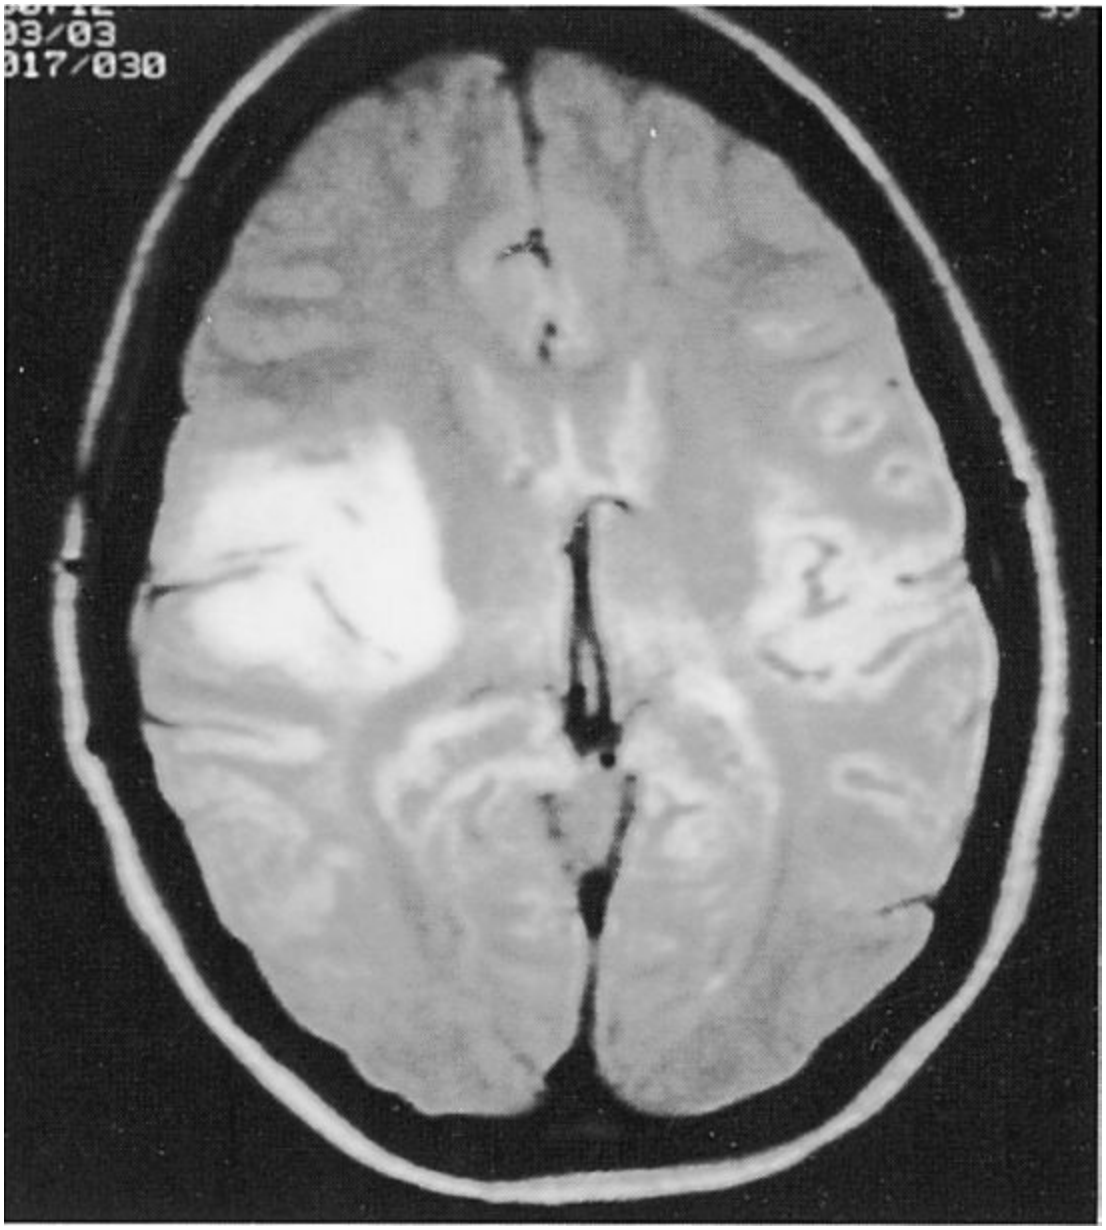

FIGURE 44-4 Low-grade glioma. Magnetic resonance imaging (MRI) of the brain shows an abnormal density in the right temporal lobe. (Courtesy of the Hospital of the University of Pennsylvania, Nuclear Medicine Section, Philadelphia, PA.)

Positron emission tomography (PET), which measures the brain's activity rather than simply its structure, is useful in differentiating tumor from scar tissue or radiation necrosis. Computer-assisted stereotactic (three-dimensional) biopsy is being used to diagnose deep-seated brain tumors. Cerebral angiography provides visualization of cerebral blood vessels and can localize most cerebral tumors.

Cytologic studies of the CSF may be performed to detect malignant cells because CNS tumors can shed cells into the CSF.

Medical Management of Primary Brain Tumors

A variety of medical treatment modalities, including chemotherapy and external-beam radiation therapy, radiosurgery, or radiotherapy are used alone or in combination with surgical resection (Etame, 2014). Depending on the type and the extent of the tumor, medical treatments may be done for symptom management purposes rather than to cure the patient of a brain tumor. This type of medical management is referred to as *palliative care* and will help improve the patient's quality of life when cure is not possible.

Surgical Management

Surgical intervention provides the best outcome for most brain tumor types. The objective of surgical management is removal of part of or the entire tumor without increasing the neurologic deficit. The surgical approach depends on the type of tumor, its location, and its accessibility. Options include stereotactic biopsy, open biopsy, craniotomy with debulking (surgical removal of part of a malignant tumor that cannot be excised completely), and subtotal or complete resection (National Comprehensive Cancer Network [NCCN], 2015).

Radiation Therapy

Radiation therapy, the cornerstone of treatment for many brain tumors, decreases the incidence of recurrence of incompletely resected tumors. External-beam radiation therapy may be used alone or in combination with surgical resection. Stereotactic radiosurgery may be performed to deep, inaccessible tumors, often in a single session. Precise localization of the tumor is accomplished by the stereotactic approach and by minute measurements and precise positioning of the patient either through the use of Gamma Knife or CyberKnife (McDonald & McMullen, 2015). Gamma Knife is a form of stereotactic radiosurgery, where precise beams of radiation produce a targeted approach of concentrated radiation for the brain, head, and neck, whereas CyberKnife is used to treat cancer anywhere on the body.

Pharmacologic Therapy and Chemotherapy

Chemotherapy may be given intravenously, orally, or intrathecally (injected directly into the subarachnoid space). The newer oral chemotherapy agent temozolomide (Temodar) is often part of the systemic therapy because of its ability to pass through the blood–brain barrier (NCCN, 2015). Chemotherapy that is given by intrathecal injection bypasses the blood–brain barrier. Other chemotherapy agents are usually given as salvage therapy (treatment given after initial cancer treatments have failed). Newer targeted therapies work differently than chemotherapy and affect the way a cell functions. Immunotherapy agents, such as bevacizumab (Avastin) and everolimus (Afinitor), may be used to treat some brain and spinal cord tumors (ACS, 2015). Corticosteroids are used during treatment to reduce cerebral edema and to reduce the side effects of treatment, such as nausea and vomiting. They are also helpful in relieving headache and alterations in LOC. Anticonvulsant agents are used to treat seizures if they occur. Special consideration is given when managing

seizures, related to a potential serious interaction between seizure medications and antineoplastic agents. Newer antiseizure agents are now available with fewer drug interactions and plasma concentrations of drug levels are not required (McDonald & McMullen, 2015). Patients with brain tumors are at a higher risk for the development of deep vein thrombosis (DVT) and pulmonary embolism (PE). Careful consideration is taken when prescribing anticoagulant therapy due to the risk of CNS hemorrhage.

Pain is managed by means of a stepped progression with regard to the dosing, delivery method, and type of analgesic agents needed for relief. Headache is often a common complaint of pain in this population of patients. If the patient has severe pain, morphine can be infused into the epidural catheter placed as near as possible to the spinal segment where the pain is projected. Small doses of morphine are administered at prescribed intervals (refer to Chapter 7).

Medical Management of Metastatic Brain Cancer

The treatment of metastatic brain cancer is palliative and involves eliminating or reducing serious symptoms. Even when palliation is the goal, distressing signs and symptoms can be relieved, thereby improving the quality of life for both patient and family. The therapeutic approach includes radiation therapy, surgery (usually for a single intracranial metastasis), and chemotherapy. GammaKnife radiosurgery is considered if three or fewer lesions are present. Survival rates vary, depending on the type and extent of the tumor at the time of diagnosis. The overall prognosis is poor in most cases.

Nursing Management

The effects of increased ICP caused by the tumor mass are reviewed in Chapter 45. The nurse performs neurologic checks, monitors vital signs, maintains a neurologic flow chart, spaces nursing interventions to prevent a rapid increase in ICP, and reorients the patient when necessary to person, time, and place. Patients with changes in cognition caused by their lesions require frequent reorientation and the use of orienting devices (e.g., personal possessions, photographs, lists, and a clock). Supervision of and assistance with self-care, ongoing monitoring, and interventions for prevention of injury may be required. Patients who have seizures are carefully monitored and protected from injury. Box 44-2 explores the emotional impact of being diagnosed with an aggressive brain tumor.

BOX 44-2 Family Caregivers of Patients with a High-Grade Glioma

A Qualitative Study of Their Lived Experience and Needs Related to Professional Care

Coolbrandt, A., Sterckx, W., Clement, P., Borgenon, S., Decruyenaere, M., de Vleeschouwer, S., … de Casterle, B. D. (2015). Family caregivers of patients with a high-grade glioma: A qualitative study of their lived experience and needs related to professional care. *Cancer Nursing*, *38*(5), 406–413.

Purpose

To look at what caregivers of patients with high-grade glioma experienced and their needs for professional help.

Design

The work was based on a qualitative study using the Grounded Theory to help understand how caregivers experience caring for a patient with high-grade gliomas. Caregivers were chosen from a university hospital between February and July 2011 and again between April and November 2012. Caregivers were caring for patients who received chemotherapy and/or radiation therapy or who were in the monitor stage after treatment. Seventeen caregivers participated initially, but one withdrew due to the death of the patient. Semistructured interviews took place at the hospital or in the home. Topics of discussion included diagnosis, symptoms, relationships, support, caregiving tasks, the future, communication, and information. Interviews were audiotaped and transcribed.

Findings

Caregivers reported disbelief and powerlessness. Many reported they felt this way due to the way the diagnosis was communicated to them. Lack of support during diagnosis added to their stress. Life as they knew it was lost. They noted feelings of being socially deprived as they assumed the role of caregiver. At the same time caregivers reported loss of control of their own life as well. Witnessing physical and cognitive decline was painful for the caregiver to watch. Many developed irritation when they became tired. A sense of loneliness was expressed as the relationship with the patient was no longer the same. Caregivers developed anxiety and uncertainty regarding the future but at the same time tried to remain hopeful. Despite the struggle, caregivers remained completely

committed to continuing to give care until the end. They did express that they got little or no professional help on how to care for a patient with a brain tumor and felt they made decisions on their own. They felt that professional help was not available (nights, 24 hours a day). Those who did accept help were fairly positive. Multiple caregivers felt unprepared to care for the patient but stated no one ever questioned the demands on them. When the patient was satisfied, caregivers became more confident, but when the patient could no longer express his or her feelings, once again the caregiver became less confident.

Caregivers did express the need for information on how to care for the patient and side effects of treatment. Follow-up visits were often with a physician in training and did not allow for the opportunity to ask questions. At home caregivers felt that they had no one to turn to. Caregivers wanted professionals to share their goals for the patient in order to provide the best care possible.

Nursing Implications

This study will help nurses caring for patients with brain tumors understand the difficulties the caregivers experience. Nurses are a resource of information to both the patient and the caregivers. Working with home care agencies and asking for social work consultation can provide a benefit in the care of the patient and the caregiver. Nurses need to be aware of the family structure and identify needs for additional assistance.

The nursing process for patients undergoing neurosurgery is discussed in Chapter 45. The patient with a brain tumor may be at increased risk for aspiration due to cranial nerve dysfunction. If the patient is at risk for aspiration, he or she should be placed in a side-lying position with HOB elevated 10 to 30 degrees. The nurse must ensure that suction equipment is at the bedside. Preoperatively, the gag reflex and ability to swallow are evaluated by gently touching each side of the posterior pharyngeal wall with a cotton swab or suction catheter and noting the strength of the gag. The nurse expects to observe a simultaneous elevation of the uvula and "gag" with stimulation of the posterior pharynx. Function should be reassessed postoperatively because changes can occur because of alterations in cranial nerves IX (glossopharyngeal) and X (vagus) or the pons or medulla. If the gag reflex is impaired, the health care provider is notified and food and fluid are withheld until evaluation of swallowing is determined.

SPINAL CORD TUMORS

Primary spinal tumors are rare. Tumors within the spine are classified according to their anatomic relation to the spinal cord. Intramedullary tumors arise from within the spinal cord. Intradural–extramedullary tumors are within or under the spinal dura but not on the actual spinal cord. Extradural tumors are located outside the dura and often involve the vertebral bodies. These tumors may be either primary or metastatic in nature (Welch, Schiff, & Gerszten, 2015). Spinal tumors causing cord compression are considered a neurologic emergency.

Metastatic Spinal Cord Tumors

Cancer can spread to the spinal cord. The three most common cancers that metastasize to the spinal cord are lung, breast, and those of the gastrointestinal tract. It is the third most common site for metastases behind the lung and liver (Tse, 2014b). Cancer can invade the bone, causing vertebral metastases.

Spinal Cord Compression

Spinal cord compression (SCC) occurs because of tumor extension into the epidural space. The cord can be compressed at any area of the spine, resulting in permanent paralysis if not treated. Patients with myeloma or lymphoma, as well as those with breast, lung, and prostate cancer are at an increased risk for developing SCC.

SCC is considered a medical emergency and requires immediate treatment to prevent permanent neurologic damage. The treatment goal is to relieve cord compression with the use of IV steroids, such as dexamethasone (Decadron), to reduce edema. Additionally, chemotherapy, radiation, or surgery to debulk the tumor is expected to preserve neurologic function. Early intervention is the key to prevent loss of function.

Assessment and Diagnostic Findings

Initial symptoms may present as radicular pain (pain that radiates along the dermatome [sensory distribution] of a nerve), weakness, sphincter dysfunction, and sensory changes. The nurse is alert for early complaints of back pain, which occurs in the region of the tumor. The pain typically increases when the patient is in the prone position. Symmetrical extremity weakness also may be present. Ataxia with back pain should always be a concern for patients with SCC. If left untreated, motor weakness and sensory deficits can progress to paralysis. Neurologic examination and diagnostic studies are used to make the diagnosis. Neurologic examination includes assessment of pain, loss of reflexes above the tumor level, progressive loss of sensation or motor function, and the presence of weakness and paralysis. These changes in neurologic function are related to the mass exerting pressure and compression of the nerve roots or spinal cord. Late symptoms include bladder and bowel dysfunction (urinary incontinence or retention; fecal incontinence or constipation). The patient's ambulatory status is also an important prognostic indicator. MRI is the most commonly used diagnostic tool, detecting epidural SCC and metastases (Schiff, 2015).

Medical Management

Treatment of spinal cord tumors depends on the type, location of the tumor, the presenting symptoms, and physical status of the patient. Surgical intervention, if appropriate, is the primary treatment for most tumors. Other treatment modalities include partial removal of the tumor with decompression of the spinal cord. For metastatic lesions of the spine, radiation therapy can be used to decrease the size of the tumor. Chemotherapy options are limited due to the blood–brain barrier. Dexamethasone is used temporarily to reduce edema and improve neurologic function until other treatments can take effect.

Tumor removal is desirable but not always possible. The goal is to remove as much tumor as possible while sparing uninvolved portions of the spinal cord to avoid neurologic damage. Microsurgical techniques have improved the prognosis for patients with intramedullary tumors. Prognosis is related to the degree of neurologic impairment at the time of surgery, the speed with which symptoms occurred, and the origin of the tumor. Patients with extensive neurologic deficits before surgery usually do not make significant functional recovery, even after successful tumor removal.

Palliative care may be an option for the medical management of some patients. Relief from symptoms and pain control are the goals of care. Patients may receive palliative treatments, such as radiation, and then transition into hospice care when supportive treatments fail to control tumor growth. Other integrative therapies (complementary/alternative) may be incorporated into part of the patient's treatment plan.

Nursing Management

Providing Preoperative Care

The objectives of preoperative care include recognition of neurologic changes through ongoing assessments, pain control, and the management of altered activities of daily living (ADLs). The nurse assesses for weakness, muscle wasting, spasticity, sensory changes, bowel and bladder dysfunction, and potential respiratory problems, especially if a cervical tumor is present. The patient is also evaluated for coagulation deficiencies. Postoperative pain management strategies are discussed with the patient before surgery.

Assessing the Patient Postoperatively

The patient is monitored for deterioration in neurologic status. A sudden onset of neurologic deficit is an ominous sign and may be due to vertebral collapse associated with spinal cord infarction. Frequent neurologic checks are carried out, with emphasis on movement, strength, and sensation of the upper and lower extremities. Staining of the dressing may indicate leakage of CSF from the surgical site, which may lead to serious infection or to an inflammatory reaction in the surrounding tissues that can cause severe pain in the postoperative period (refer to Chapter 43 for evaluation of CSF leakage).

Managing Pain

The prescribed medication should be administered in adequate amounts and at appropriate intervals to relieve pain and prevent its recurrence. Early symptoms of spinal cord tumors include stiffness and pain that continues to worsen. Pain and bone pain at night is the hallmark of spinal metastasis. Pain may increase in the recumbent position (Welch et al., 2015).

The bed is usually kept flat initially. However the head of the bed position will depend on the specific surgical procedure and the surgeon's preference (Hickey, 2015, p. 312). The nurse turns the patient as a unit, keeping shoulders and hips aligned and the back straight. The side-lying position is usually the most comfortable because this position imposes the least pressure on the surgical site. Placement of a pillow between the knees of the patient in a side-lying position helps to prevent extreme knee flexion.

Promoting Home and Community-Based Care

In preparation for discharge, the patient is assessed for the ability to function independently in the home and for the availability of resources, such as family members, to assist in caregiving. Safety is a key component when arranging for home care. Patients with residual sensory involvement are cautioned about the dangers of extremes in temperature. They should be alerted to the dangers of heating devices (e.g., hot water bottles, heating pads, space heaters). The patient is taught to check skin integrity daily. Patients with impaired motor function related to motor weakness or paralysis may require training in ADLs and safe use of assistive devices, such as a cane, walker, or wheelchair.

The patient and family members are educated about pain management strategies, bowel and bladder management, and assessment for signs and symptoms of neurologic

dysfunction, which should be reported promptly.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 48-year-old man is married with two young children and has been newly diagnosed with a metastatic spinal cord tumor. The patient is scheduled to have surgery to debulk the tumor. What nursing assessments should be performed preoperatively? What postoperative nursing assessments should be performed? What assessments would alert the nurse of possible complications? What interventions can the nurse do to provide comfort pre- and postoperatively?

2. A 60-year-old patient with a history of lymphoma who has developed a new onset of low back pain is seen in the clinic. What pertinent questions should the nurse ask the patient that would aid in identifying the cause of the pain? Describe what nursing assessment is the priority. Identify deficits that would indicate that this is an urgent condition and why. What type of medication do you anticipate will be prescribed for this patient?

3. A 50-year-old patient has been recently diagnosed with a glioblastoma brain tumor. He had surgery several weeks ago and is now receiving chemotherapy. He is complaining of feeling exhausted and unable to do his normal work at home. What resources would you use to identify current guidelines for treatment of fatigue? How would this information help you develop a plan to educate your patient in lifestyle changes?

NCLEX-Style Review Questions

1. A patient admitted to the emergency room has a history of a spinal tumor. Which sign and symptom should alert the nurse to the possibility of SCC?
   a. Seizures
   b. Headache
   c. Back pain
   d. Diplopia

2. A patient with a decreased LOC and an absent gag reflex was just admitted to the neurologic unit. In what position should the nurse place the patient?
   a. Prone
   b. Head of bed should be elevated 45 to 90 degrees
   c. Flat
   d. Side lying with head of bed elevated 10 to 30 degrees

3. What is a late sign of rising ICP?
   a. Papilledema
   b. Change in the LOC

c. Vomiting
d. Hypertension

4. A patient with a brain tumor is receiving palliative care. What does the nurse understand to be true about palliative care? *Select all that apply.*
   a. Providing comfort care
   b. Early identification of spiritual needs to the patient
   c. Management of symptoms
   d. Does not include pain management
   e. Is not an option with a patient with a brain tumor

5. A patient has just been admitted to the hospital with a diagnosis of brain tumor. She makes a comment that drinking alcohol has caused her brain tumor. What does the nurse understand to be a cause of brain tumor?
   a. Smoking
   b. Ionizing radiation
   c. Diet high in fat
   d. Exposure to the sun

CHAPTER 45

Nursing Management: Patients with Neurologic Trauma

Tara Driesen Jennings

Learning Objectives

After reading this chapter, you will be able to:

1. Differentiate patients with head injuries according to mechanism of injury, clinical signs and symptoms, diagnostic testing, and treatment options.
2. Describe the multiple needs of the patient with altered level of consciousness.
3. Identify the early and late clinical manifestations of increased intracranial pressure (ICP).
4. Describe the management of the patient with increased ICP.
5. Identify the population at risk for spinal cord injury (SCI).
6. Identify common complications and management of complications in patients with SCI.
7. Use the nursing process as a framework for care of patients with SCI.

Trauma involving the central nervous system often can be life-threatening. Even when it is not life-threatening, brain and spinal cord injuries (SCIs) can result in major physical and psychological dysfunction and can alter the patient's life completely. Neurologic trauma affects the patient, the family, the health care system, and society as a whole because of its major sequelae and the costs of acute and long-term care of patients with trauma to the brain and spinal cord.

Ongoing assessment of the patient's neurologic function and health needs, identification of problems, mutual goal setting, development and implementation of care plans (including teaching, counseling, and coordinating activities), and evaluation of the outcomes of care are nursing actions integral to the recovery of the patient with neurologic trauma. The nurse also collaborates with other members of the health care team to provide essential care, offer a variety of solutions to problems, help the patient and family gain control of their lives, and explore the educational and supportive resources available in the community. The goals are to achieve as high a level of function as possible and to enhance the quality of life for the patient with neurologic trauma and his or her family.

HEAD INJURIES

Head injury is a broad classification that includes injury to the scalp, skull, or brain. It is the most common cause of death from trauma in the United States. Approximately 1.4 million people receive treatment for head injuries every year (National Institute of Neurological Disorders and Stroke [NINDS], 2015). Of these, 1.1 million are treated and released by the emergency room, 230,000 are hospitalized, 80,000 have permanent disabilities, 60,000 develop seizure disorders, and 50,000 people die (Dawodu, 2015). Traumatic brain injury (TBI) is the most serious form of head injury. The most common causes of TBI are falls (40.5%), motor vehicle accidents (14.3%), collisions with stationary or moving objects (15.5%), and assaults (10.7%) (CDC, 2015). Males between 15 and 24 years of age are at highest risk for TBI. The very young (children under 5 years of age) and the very old (adults over 75 years of age) are also at increased risk. An estimated 5.3 million Americans today are living with a disability as a result of a TBI (Brain Trauma Foundation, 2007; CDC, 2015). Despite advances in care, only 40% of patients with severe TBI have good outcomes (Seemann, 2014). Patients with TBI often have long-lasting chronic comorbidities, including neuroendocrine abnormalities, neuropsychiatric disease, insomnia, and chronic pain (Bay & Chartier, 2014). The best approach to head injury is an emphasis on prevention (Box 45-1).

Pathophysiology

Research has shown that not all brain damage occurs at the moment of impact. Damage to the brain from traumatic injury takes two forms: primary injury and secondary injury. Primary injury is the initial damage to the brain that results from the traumatic event. This may include contusions, lacerations, and torn blood vessels due to impact, acceleration/deceleration, or penetration by a foreign object (Porth & Matfin, 2013). Secondary injury evolves over the ensuing hours and days after the initial injury and can be due to cerebral edema, ischemia, seizures, infection, hyperthermia, hypovolemia, and hypoxia (Loane, Stoica, & Faden, 2015).

BOX 45-1 Health Promotion

Preventing Head and Spinal Cord Injuries

- Advise drivers to obey traffic laws and to avoid speeding or driving when under the influence of drugs or alcohol.
- Advise all drivers and passengers to wear seat belts and shoulder harnesses.
- Caution passengers against riding in the back of pickup trucks.
- Advise motorcyclists, scooter riders, bicyclists, skateboarders, and roller-bladers to wear helmets.
- Promote educational programs that are directed toward prevention of violence and suicide in the community.
- Provide water safety instruction.
- Teach patients steps that can be taken to prevent falls, particularly in the elderly.
- Advise athletes to use protective devices. Recommend that coaches be educated in proper coaching techniques.
- Advise owners of firearms to keep them locked in a secure area where children cannot access them.
- Advise drivers to pay attention to the road and not be a distracted driver; advise against looking away from the road to eat, read, or text while driving.

An injured brain is different from other injured body areas because of its unique characteristics. It resides within the skull, which is a rigid, closed compartment (Hickey, 2014). Unlike other areas of the body, the confines of the skull do not allow for the expansion of cranial contents. Any bleeding or swelling within the skull increases the volume of contents and therefore can cause increased intracranial pressure (ICP). If the increased pressure is high enough, it can cause herniation of the brain through or against the rigid structures of the skull. This causes restriction of blood flow to the brain, with resultant ischemia, infarction, irreversible brain damage, and, eventually, brain death (Box 45-2).

Skull Fractures

A skull fracture is a break in the continuity of the skull caused by forceful trauma. It may occur with or without damage to the brain. Skull fractures can be classified as simple, comminuted, depressed, or basilar. A simple (linear) fracture is a break in the continuity of the bone. A comminuted skull fracture refers to a splintered fracture line. When bone fragments are embedded into brain tissue, the fracture is depressed. A fracture of the base of the skull is called a basilar or basal skull fracture (Fig. 45-1) (Porth & Matfin, 2013). A fracture may be open, indicating a scalp laceration or tear in the dura, or closed, in which case the dura is intact.

Clinical Manifestations

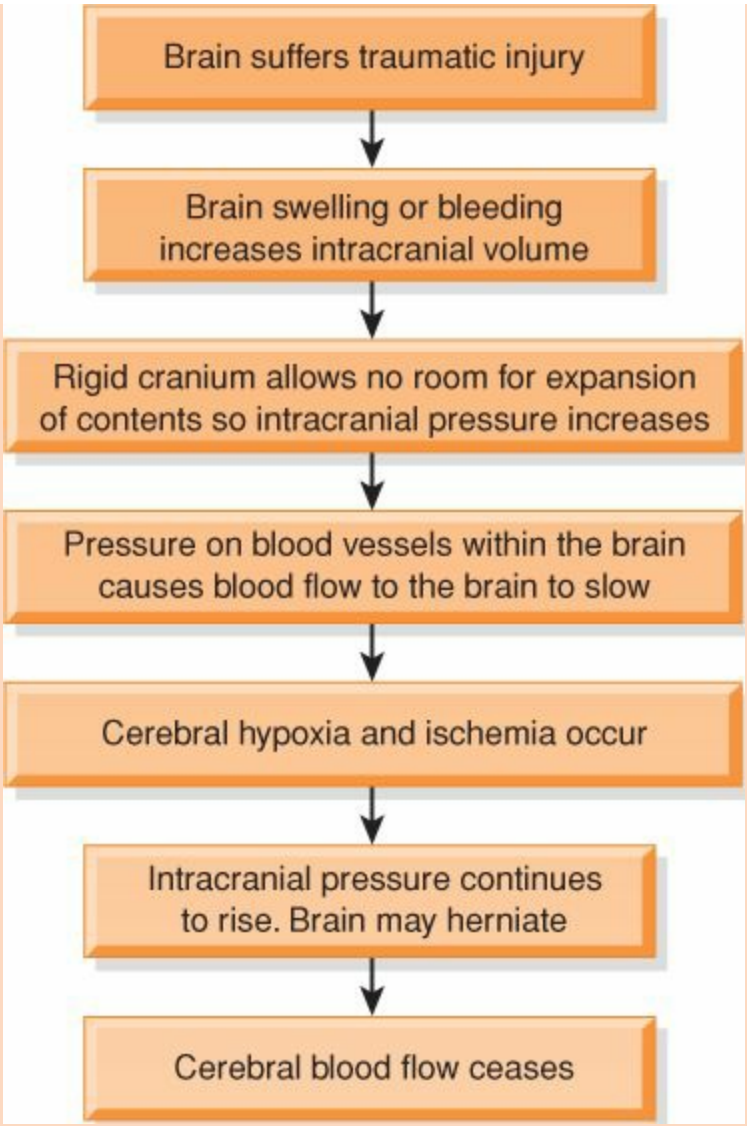
The symptoms, apart from those of the local injury, depend on the severity and the distribution of the underlying brain injury. Persistent, localized pain suggests that a fracture is present. Fractures of the cranial vault may or may not produce swelling in the region of the fracture.

Fractures of the base of the skull tend to traverse the paranasal sinus of the frontal bone or the middle ear located in the temporal bone. Therefore, they frequently produce hemorrhage from the nose, pharynx, or ears, and blood may appear under the conjunctiva. An area of ecchymosis (bruising) that may be seen over the mastoid (Battle sign), develops 12 to 24 hours after injury (Hickey, 2014). Basilar skull fractures are suspected when cerebrospinal fluid (CSF) escapes from the ears (CSF otorrhea) and the nose (CSF rhinorrhea). A halo sign (a blood stain surrounded by a yellowish stain) may be seen on bed linens or on the head dressing and is highly suggestive of a CSF leak. Drainage of CSF is a serious problem because meningeal infection, abscess formation, and osteomyelitis can occur if organisms gain access to the cranial contents via the nose, ear, or sinus through a tear in the dura.

BOX 45-2 Focus on Pathophysiology

Traumatic Brain Injury

When the brain is injured, there is no room for swelling within the rigid cranial vault. Any bleeding or swelling causes an increase in the amount of intracranial contents, which, in turn, increases intracranial pressure (ICP). The increased pressure causes vasoconstriction and a decrease in blood flow to the brain. This causes hypoxia and ischemia of brain tissue. If ICP continues to rise, eventually the brain will herniate, causing brain death.



Brain suffers traumatic injury
Brain swelling or bleeding increases intracranial volume
Rigid cranium allows no room for expansion of contents so intracranial pressure increases
Pressure on blood vessels within the brain causes blood flow to the brain to slow
Cerebral hypoxia and ischemia occur
Intracranial pressure continues to rise. Brain may herniate
Cerebral blood flow ceases

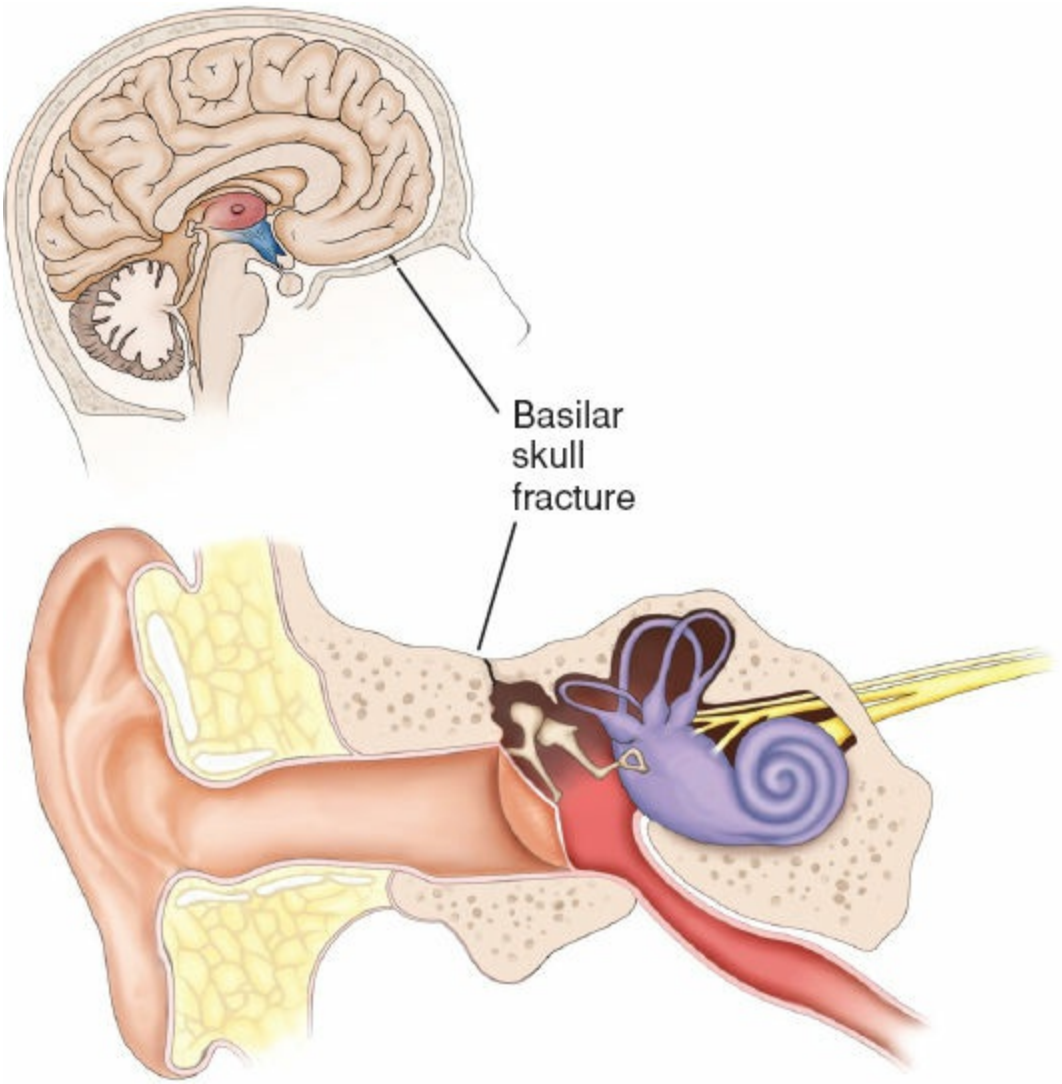


FIGURE 45-1 Basilar skull fractures allow cerebrospinal fluid to leak from the nose and ears. (Adapted from Hickey, J. V. (2014). *The clinical practice of neurological and neurosurgical nursing* (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Assessment and Diagnostic Findings

Radiologic examination confirms the presence and extent of a skull fracture (Porth & Matfin, 2013). A rapid physical examination and evaluation of neurologic status detects obvious brain injuries, and a computed tomography (CT) scan uses high-speed x-ray scanning to detect less apparent abnormalities.

Magnetic resonance imaging (MRI) is used to evaluate patients with head injury when a more accurate picture of the anatomic nature of the injury is warranted and when the patient is stable enough to undergo this longer diagnostic procedure. See Chapter 43 for further discussion of CT and MRI.

Medical and Nursing Management

Nondepressed skull fractures generally do not require surgical treatment; however, close observation of the patient is essential. Nursing personnel may observe the patient in the hospital, but if no underlying brain injury is present, the patient may be allowed to return home. If the patient is discharged home, specific instructions must be given to the family.

Depressed skull fractures usually require surgery, particularly if contaminated or deformed fractures are present. Large defects can be repaired immediately with bone or artificial grafts; if significant cerebral edema is present, repair of the defect may be delayed for 3 to 6 months. Penetrating wounds require surgical débridement to remove foreign bodies and devitalized brain tissue and to control hemorrhage. IV antibiotic treatment is instituted immediately, particularly with a dural laceration, and blood products are administered if indicated.

As stated previously, fractures of the base of the skull are serious because they are usually open (involving the paranasal sinuses or the middle or external ear). CSF leakage is present in 15% to 20% of patients with skull base fractures (Neville et al., 2014). Clear fluid that is draining from the nose or ears should be collected and tested for glucose. If the drainage is CSF, it will be positive for glucose. Suspicion of a CSF leak should be reported immediately to the provider.

The patient who is conscious is cautioned not to blow his or her nose if there is a CSF leak as this can worsen the leak. The head is elevated 30 degrees to reduce ICP and promote spontaneous closure of the leak (Hickey, 2014). Early detection of a CSF leak may help avoid complications, including meningitis or pneumocephalus (air within the cranial vault). The patient with a basal skull fracture should not have the nose suctioned. If a nasogastric tube is required for patient management, it should be inserted orally. Tears of the dura (protective covering directly on top of the brain) are commonly seen in basal skull fractures. A suction catheter or nasogastric tube is a potential source of infection and may lead to the development of meningitis. Early CSF rhinorrhea (resolving within 3 to 5 days) usually does not require surgery. Late-onset (7 or more days after the initial injury) and persistent CSF rhinorrhea usually requires surgical intervention to prevent development of meningitis. CSF otorrhea typically does not require surgical treatment as 85% of CSF leaks through the ears stop spontaneously (Mateo, Savage, & Jimenez, 2012).

Nursing Alert

Any patient with extensive facial fractures or suspected basilar skull fracture may also have a fracture of the cribriform plate (portion of the ethmoid bone that separates the roof of the nose from the cranial cavity). Attempted intubation with a nasogastric tube or nasotracheal tube or suctioning is prohibited to avoid intracranial penetration of the brain with the tube or catheter.

BRAIN INJURY

The most important consideration in any head injury is whether or not the brain is injured. Even seemingly minor injury can cause significant brain damage secondary to obstructed blood flow and decreased tissue perfusion. The brain cannot store oxygen or glucose to any significant degree. Because neurons need an uninterrupted blood supply to obtain these nutrients, irreversible brain damage and cell death occur if the blood supply is interrupted for even a few minutes. Clinical manifestations of brain injury (injury to the brain that is severe enough to interfere with normal functioning) are listed in Box 45-3. Closed (blunt) brain injury occurs when the head accelerates and then rapidly decelerates or collides with another object (i.e., a wall, the dashboard of a car) and brain tissue is damaged but there is no opening through the skull and dura. Open brain injury occurs when an object penetrates the skull, enters the brain, and damages the soft brain tissue in its path (penetrating injury), or when blunt trauma to the head is so severe that it opens the scalp, skull, and dura to expose the brain.

BOX 45-3 Focused Assessment

Traumatic Brain Injury

Be on alert for the following signs and symptoms:

- Altered level of consciousness (LOC)
- Confusion
- Pupillary abnormalities (changes in shape, size, and response to light)
- Sudden onset of neurologic deficits
- Changes in vital signs (altered respiratory pattern, widened pulse pressure, bradycardia, tachycardia, hypothermia, or hyperthermia)
- Vision and hearing impairment
- Sensory dysfunction
- Headache
- Seizures

Types of Brain Injury

Concussion

A concussion (also referred to as a mild TBI) involves an alteration in mental status that results from trauma and may or may not involve loss of consciousness. This typically lasts no longer than 24 hours and may include symptoms such as headache, nausea, vomiting, photophobia (sensitivity to light), amnesia, and blurry vision (McClain, 2015).

Treatment involves observing the patient for symptoms, including headache, dizziness, lethargy, irritability, anxiety, photophobia, phonophobia (fear of sound or of speaking aloud), difficulty concentrating, and memory difficulties. The occurrence of these symptoms after the injury is referred to as *postconcussive syndrome* (Barlow et al., 2014). Giving the patient information, explanations, and encouragement may reduce some of the problems associated with postconcussive syndrome. The patient is advised to resume normal activities slowly; the exact recovery time is not known (McClain, 2015). Once the patient is discharged home, he or she should be closely observed for the next 24 hours and awakened every 2 hours in order to detect any changes in mental status. Box 45-4 provides complete instructions to be given to the patient and the family. Neuroimaging (CT and MRI) is generally not indicated in concussion.

Contusion

A cerebral contusion is a more severe injury than concussion, involving bruising of the brain, with possible surface hemorrhage. The patient is unconscious for more than a few seconds or minutes. Clinical signs and symptoms depend on the size of the contusion and the amount of associated swelling of the brain (cerebral edema). The patient may lie motionless, with a faint pulse, shallow respirations, and cool, pale skin. The patient may be aroused with effort but soon slips back into unconsciousness. Blood pressure and temperature are subnormal, and the clinical picture is somewhat similar to that of shock. Patients may recover consciousness but pass into a stage of cerebral irritability. In this stage, the patient is conscious and easily disturbed by any form of stimulation, such as noises, light, and voices; he or she may become hyperactive at times.

Nursing Alert
When the patient begins to emerge from unconsciousness, every measure that is available and appropriate for calming and quieting the patient should be used. Any form of restraint is likely to be countered with resistance, leading to self-injury or to a dangerous increase in ICP. Therefore, physical restraints should be avoided, if possible.

Gradually, the pulse, respirations, temperature, and other body functions return to normal, but full recovery can be delayed for months. Residual headache and vertigo are common, and impaired mental function or seizures may occur as a result of irreparable cerebral damage.

BOX 45-4 Patient and Family Education

Teaching Guidelines Following Concussion

Once the patient is discharged home, he or she should be closely observed for the next 24 hours and awakened every 2 hours. The patient and family are instructed to observe for the following signs and symptoms and to notify the provider (or bring the patient to the emergency department) if they occur:

- Difficulty in awakening
- Difficulty speaking
- Confusion
- Seizures
- Severe headache
- Vomiting
- Weakness on one side of the body

The patient should also avoid playing contact sports, driving, drinking alcohol, and using heavy machinery until cleared by a health care provider.

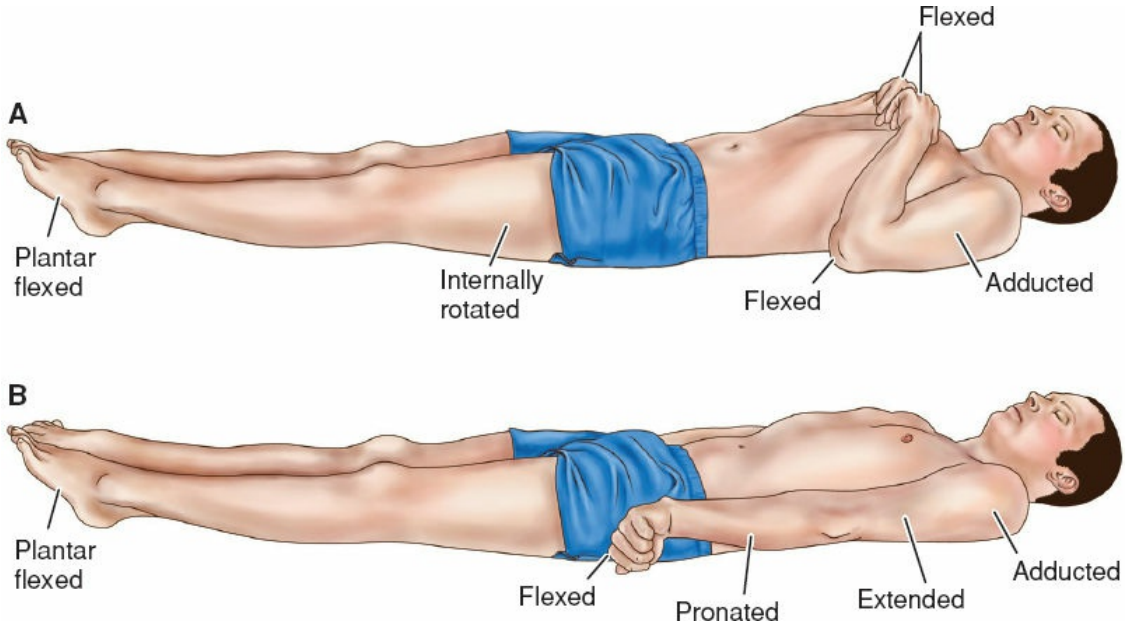

FIGURE 45-2 Abnormal posture response to stimuli. A. Decorticate posturing, involving adduction and flexion of the upper extremities, internal rotation of the lower extremities, and plantar flexion of the feet. B. Decerebrate posturing, involving extension and outward rotation of upper extremities and plantar flexion of the feet.

Diffuse Axonal Injury

Diffuse axonal injury involves widespread damage to axons in the cerebral hemispheres, corpus callosum, and brainstem. It can be seen with mild, moderate, or severe head trauma. The patient experiences immediate coma, global cerebral edema, decorticate and decerebrate rigidity, or *posturing* (Fig. 45-2). Decorticate posturing involves abnormal flexion of the upper extremities and extension of the lower extremities and indicates damage to the upper midbrain; decerebrate posturing involves extreme extension of the

upper and lower extremities and indicates severe damage to the brain at the lower midbrain and upper pons (Hickey, 2014). Diagnosis of diffuse axonal injury is made by clinical signs in conjunction with a CT or MRI scan. These tests are usually normal; a definitive diagnosis can be made only at autopsy. Recovery depends on the severity of the axonal injury.

Intracranial Hemorrhage (Intracranial Hematoma)

Hematomas (collections of blood) that develop within the cranial vault are the most serious type of brain injury (Hickey, 2014). A hematoma may be epidural (above the dura), subdural (below the dura), or intracerebral (within the brain) (Fig. 45-3). Major symptoms are frequently delayed until the hematoma is large enough to cause distortion of the brain and increased ICP. The signs and symptoms of cerebral ischemia resulting from compression by a hematoma are variable and depend on the speed with which vital areas are affected and the area that is injured (American Association of Neuroscience Nurses [AANN], 2012).

Epidural Hematoma (Extradural Hematoma or Hemorrhage)

After a head injury, blood may collect in the epidural (extradural) space between the skull and the dura. This can result from a skull fracture that causes a rupture or laceration of the middle meningeal artery, the artery that runs between the dura and the skull, inferior to a thin portion of temporal bone. Hemorrhage from this artery causes a rapid increase in pressure on the brain.

Symptoms are caused by the expanding hematoma. Usually a momentary loss of consciousness occurs at the time of injury, followed by an interval of apparent recovery (lucid interval). Although the lucid interval is considered a classic characteristic of an epidural hematoma, no lucid interval has been reported in many patients with this lesion (Hickey, 2014), and, therefore, it should not be considered a critical defining criterion. During the lucid interval, compensation for the expanding hematoma takes place by rapid absorption of CSF and decreased intravascular volume, both of which help maintain a normal ICP. When these mechanisms can no longer compensate, even a small increase in the volume of the hematoma produces a marked elevation in ICP. Then, often suddenly, signs of compression appear (usually deterioration of consciousness and signs of focal neurologic deficits, such as dilation and fixation of a pupil or paralysis of an extremity), and the patient's condition deteriorates rapidly.

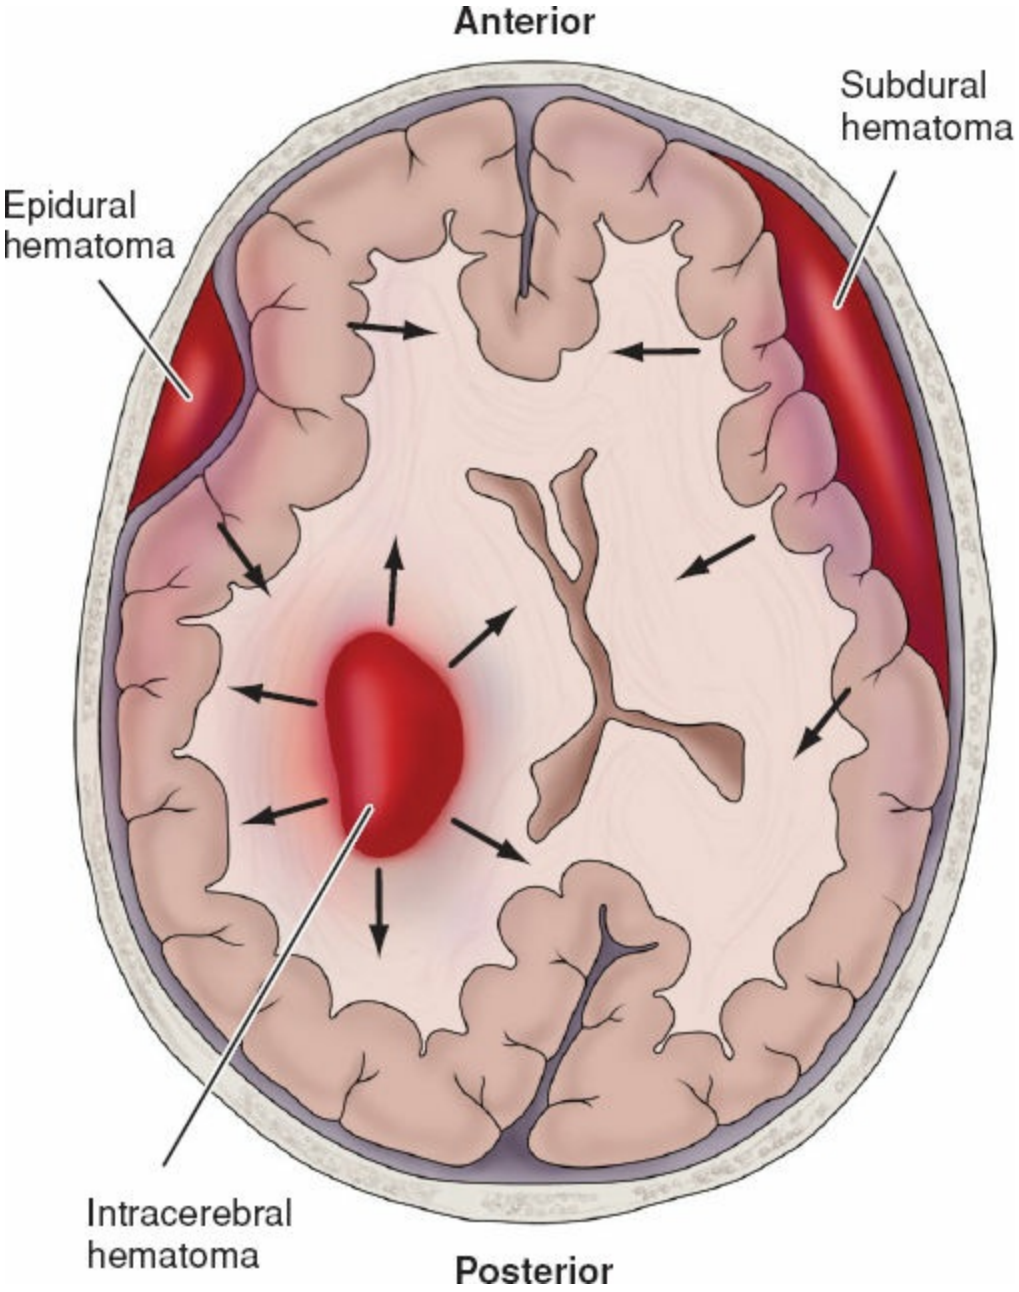

FIGURE 45-3 Location of epidural, subdural, and intracerebral hematomas.

An epidural hematoma is considered an extreme emergency; marked neurologic deficit and respiratory arrest can occur within minutes. Treatment consists of making openings through the skull (burr holes) to decrease ICP emergently, remove the clot, and control the bleeding. A craniotomy (surgical procedure that removes of part of the skull to gain access to the brain) may be required to remove the clot and control the bleeding. A drain may be inserted after creation of burr holes or a craniotomy to prevent reaccumulation of blood.

Subdural Hematoma

A subdural hematoma (SDH) is a collection of blood between the dura and the brain, a space normally occupied by a thin cushion of CSF (see Fig. 45-3). The most common cause of SDH is trauma, but it can also occur as a result of coagulopathies (bleeding disorders) or rupture of an aneurysm. The elderly are at increased risk for subdural

hemorrhage secondary to whole brain atrophy, which causes traction on fragile bridging veins and also allows more free space for bleeding (Hickey, 2014). Box 45-5 is a discussion of the elderly and SDHs. SDHs can be acute, subacute, or chronic, depending on when the bleed occurred.

Acute and Subacute Subdural Hematoma. Acute SDHs are associated with major head injury involving contusion or laceration. Clinical symptoms develop over 24 to 48 hours. Signs and symptoms include changes in the level of consciousness (LOC), changes in the reactivity of the pupils, and hemiparesis (weakness on one side of the body). There may be minor or even no symptoms, with small collections of blood. Coma, increasing blood pressure, decreasing heart rate, and slowing respiratory rate are all signs of a rapidly expanding mass requiring immediate intervention.

Subacute SDHs are the result of less severe contusions and head trauma. Clinical manifestations usually appear between 48 hours and 2 weeks after the injury. Signs and symptoms are similar to those of an acute SDH.

If the patient can be transported rapidly to the hospital, an immediate surgery may be performed to open the dura, allowing the subdural clot to be evacuated. Successful outcome also depends on the control of ICP and careful monitoring of respiratory function. The mortality rate for patients with acute or subacute SDH is high because of associated brain damage (Hickey, 2014).

BOX 45-5 Gerontologic Considerations

Subdural Hematomas

Subdural hematomas (SDHs) are more common in the elderly, occurring most often in patients in their 60s and 70s. SDHs represent a reversible cause of dementia so their detection is vital to accurate diagnosis of dementia in the older adult.

Older adults are more prone to developing SDHs due to cerebral atrophy. This causes fragile bridging veins, which run between the dura and the brain, to tear as the atrophied brain pulls away from the dura. Trauma is the leading cause of SDHs and will often be so trivial that the older adult does not remember it occurring. Alcoholics and patients taking anticoagulation are also at increased risk for developing an SDH.

Common presenting symptoms of SDHs in the older adult are gait disturbance, headache, aphasia (inability to speak), altered mental status, and hemiparesis (weakness on one side of the body). The initial presentation of an SDH is often very subtle, with the patient becoming confused and easily agitated. Diagnosis is made by obtaining a CT scan. Treatment typically consists of surgical evacuation of the hematoma.

When caring for the older adult, it is important to consider the risk for development of an SDH. SDHs represent a common cause of reversible dementia that is easily overlooked due to the subtlety of presenting signs and symptoms.

Chronic Subdural Hematoma. Chronic SDHs can develop from seemingly minor head injuries and are seen most frequently in the elderly. The time between injury and onset of symptoms can be lengthy (i.e., 3 weeks to many months) so the actual injury may be forgotten.

The treatment of a chronic SDH typically consists of surgical evacuation of the clot if the patient is symptomatic and the bleed is at least 1 cm in size. Smaller bleeds are monitored until the body has fully reabsorbed the blood (Hickey, 2014).

Intracerebral Hemorrhage and Hematoma

Intracerebral hemorrhage (ICH) is bleeding into the parenchyma of the brain. It is commonly seen in head injuries when force is exerted to the head over a small area (e.g., bullet wounds and stab injuries). These hemorrhages within the brain may also result from:

- Systemic hypertension, which causes degeneration and rupture of a vessel
- Rupture of a saccular aneurysm
- Vascular anomalies
- Intracranial tumors
- Bleeding disorders, such as leukemia, hemophilia, aplastic anemia, and thrombocytopenia
- Complications of anticoagulant therapy

The onset may be insidious, beginning with the development of neurologic deficits followed by headache. Management includes supportive care, control of ICP, and careful administration of fluids, electrolytes, and antihypertensive medications. Surgical intervention by craniotomy permits removal of the blood clot and control of hemorrhage but may not be possible because of the inaccessible location of the bleeding or the lack of a clearly circumscribed area of blood that can be removed. Decompressive craniectomies that are performed up to 24 hours after the initial injury have been shown to improve outcomes. These procedures are performed to allow for swelling of the brain, which decreases ICP. The earlier the craniectomy can be done, the greater benefit it can have for the patient (Takeuchi et al., 2013).

Management of Brain Injuries

Assessment and diagnosis of the extent of injury are accomplished by the initial physical and neurologic examinations. CT and MRI are the primary neuroimaging diagnostic tools of choice and are useful in evaluating the brain structure.

Cervical spine injuries occur in 1.7% to 8% of patients with TBI. Patients at highest risk for cervical spine injury are those involved in motorcycle accidents, those with lower scores on the Glasgow Coma Scale (GCS) (score of 8 or less), and those with skull base fractures (Tomoko, Faul, & Sasser, 2013). The patient is transported from the scene of the injury on a board with the head and neck maintained in alignment with the axis of the body. A hard cervical collar should be applied and maintained until cervical spine x-rays have been obtained and the absence of cervical SCI is documented.

All therapy is directed toward preserving brain homeostasis and preventing secondary brain injury. Common causes of secondary injury include cerebral edema, hypotension, and respiratory depression. Treatments to prevent secondary injury include stabilization of cardiovascular and respiratory function to maintain adequate cerebral perfusion, control of hemorrhage and hypovolemia, and maintenance of optimal blood gas values.

Nursing Alert

Any patient with a head injury is presumed to have a cervical spine injury until such injury is ruled out; therefore, immobilization of the spine via cervical collar, spinal backboard, and the avoidance of movement is essential.

ALTERED LEVEL OF CONSCIOUSNESS AND INCREASED INTRACRANIAL PRESSURE

An altered level of consciousness (LOC) is apparent in the patient who is not oriented, does not follow commands, or needs persistent stimuli to achieve a state of alertness. LOC is gauged on a continuum, with a normal state of alertness and full cognition (consciousness) on one end and coma on the other end. Coma is a clinical state of unarousable unresponsiveness in which there are no purposeful responses to internal or external stimuli, although nonpurposeful responses to painful stimuli and brainstem reflexes may be present (Hickey, 2014). The duration of coma is usually limited to 2 to 4 weeks. *Persistent vegetative state* is a condition in which the unresponsive patient resumes sleep–wake cycles after coma but is devoid of cognitive or affective mental function. Locked-in syndrome results from a lesion affecting the pons or midbrain and results in tetraplegia (formerly called quadriplegia) and inability to speak, but vertical eye movements and lid elevation typically remain intact and are used to indicate responsiveness (Hickey, 2014). The LOC is the most important indicator of the patient's condition.

The volume of the rigid cranial vault is approximately 1,700 mL, containing brain tissue (1,400 mL, or 80%), intravascular blood (150 mL, or 10%), and CSF (150 mL, or 10%). The volume and pressure of these three components are usually in a state of equilibrium, and together they produce the ICP. An alteration in LOC may be the result of increased ICP. Increased ICP is explained by the Monro-Kellie hypothesis. The Monro-Kellie hypothesis states that because of the limited space for expansion within the skull, an increase in any one of the components causes a change in the volume of the others. Because brain tissue has limited space to expand, compensation typically is accomplished by increasing absorption or diminishing production of CSF or decreasing cerebral blood volume. Without such changes, ICP will begin to rise. ICP is usually measured in the lateral ventricles, with normal pressure being 5 to 15 mm Hg. Treatment of increased ICP is generally initiated at a pressure of 20 mm Hg (Hickey, 2014).

Pathophysiology

Altered LOC is not a disorder itself; rather, it is the result of multiple pathophysiologic phenomena. The cause may be neurologic (head injury, stroke), toxicologic (drug overdose, alcohol intoxication), or metabolic (liver or kidney failure, diabetic ketoacidosis). Increased ICP affects many patients with acute neurologic conditions. This is because pathologic conditions alter the relationship between intracranial volume and ICP. Elevated ICP is most commonly associated with head injury, although it may also be seen in other neurologic conditions, including brain tumors and subarachnoid hemorrhages. Increased ICP from any cause decreases cerebral perfusion, stimulates further swelling (edema), and may shift brain tissue through openings in the rigid dura, resulting in herniation (Fig. 45-4). The herniated brain tissue exerts pressure on the brain area into which it has shifted, which interferes with the blood supply in that area. Cessation of cerebral blood flow results in cerebral ischemia, infarction, and brain death. Herniation is often a dire, and frequently fatal, event (Hickey, 2014).

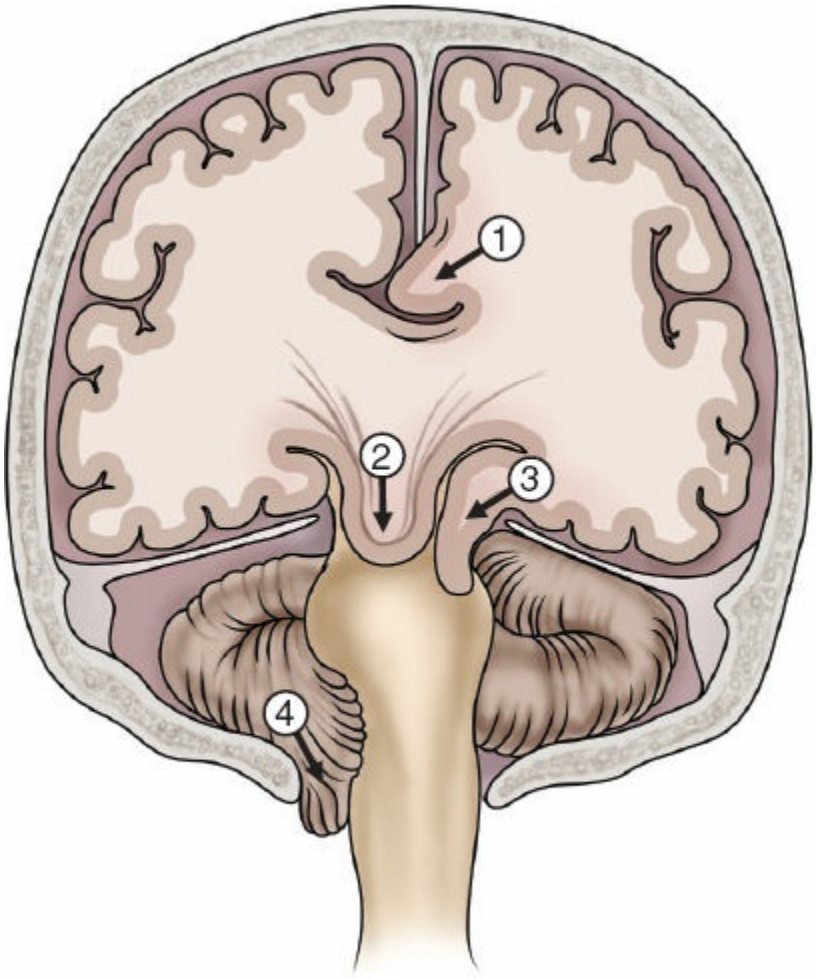

FIGURE 45-4 Brain with intracranial shifts from supratentorial lesions. (1) Herniation of the cingulate gyrus under the falx cerebri. (2) Central transtentorial herniation. (3) Uncal herniation of the temporal lobe into the tentorial notch. (4) Infratentorial herniation of the cerebral tonsils. (Adapted from Porth, C. M., & Matfin, G. (2013). *Pathophysiology: Concepts of altered health states* (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Increased ICP may significantly reduce cerebral blood flow, resulting in ischemia and cell death. In the early stages of cerebral ischemia, the vasomotor centers are stimulated and the systemic pressure rises to maintain cerebral blood flow. This is typically accompanied by a slow, bounding pulse and respiratory irregularities. These changes in blood pressure, pulse, and respiration are important clinically because they suggest increased ICP.

Cerebral edema is defined as an abnormal accumulation of water or fluid in the intracellular space, extracellular space, or both, and is associated with an increase in the volume of brain tissue. Edema can occur in any part of the brain. As brain tissue swells within the rigid skull, several mechanisms attempt to compensate for the increasing ICP. These compensatory mechanisms include autoregulation and decreased production and flow of CSF. Autoregulation refers to the brain's ability to change the diameter of its blood vessels automatically to maintain a constant cerebral blood flow during alterations in systemic blood pressure. This mechanism may be impaired in patients who are experiencing a pathologic and sustained increase in ICP.

A clinical phenomenon known as the Cushing response (or Cushing reflex) is seen when cerebral blood flow decreases significantly. When ischemic, the vasomotor center triggers an increase in arterial pressure in an effort to overcome the increased ICP. A sympathetically mediated response causes an increase in the systolic blood pressure, with a widening of the pulse pressure and cardiac slowing. It is a late sign requiring immediate intervention; however, perfusion may be recoverable if the Cushing response is treated rapidly.

At a certain point, the brain's ability to autoregulate becomes ineffective and decompensation (ischemia and infarction) begins. When this occurs, the patient exhibits significant changes in mental status and vital signs. The bradycardia, hypertension, and bradypnea associated with this deterioration are known as Cushing triad, a grave sign. At this point, herniation of the brainstem and occlusion of the cerebral blood flow occur if therapeutic intervention is not initiated immediately.

Clinical Manifestations

Alterations in LOC occur along a continuum, and the clinical manifestations depend on where the patient is along this continuum. As the patient's state of alertness and consciousness decreases, changes will ultimately occur in the pupillary response, eye opening response, verbal response, and motor response. However, initial alterations in LOC may be reflected by subtle behavioral changes, such as restlessness or increased anxiety. The pupils, normally round and briskly reactive to light, become sluggish (response is slower); as the patient becomes comatose, the pupils become fixed (no response to light). The patient in a coma does not open the eyes, respond verbally, or move the extremities in response to a request to do so.

It is important to be familiar with the patient's baseline status as many early signs of increased ICP are subtle; they include sudden onset of restlessness (without apparent cause), confusion, and increasing drowsiness. As ICP increases, the patient becomes stuporous, reacting only to loud or painful stimuli. At this stage, serious impairment of brain circulation is likely taking place, and immediate intervention is required. As neurologic function deteriorates further, the patient becomes comatose and exhibits decorticate and decerebrate posturing or flaccidity (see Fig. 45-2). If the coma is profound, with the patient exhibiting fixed and dilated pupils and impaired or absent respiration, death is usually inevitable.

Assessment and Diagnostic Findings

The patient with an altered LOC is at risk for alterations in every body system. A complete assessment is performed, with particular attention to the neurologic system. The neurologic examination should be as complete as the LOC allows (AANN, 2014a). It includes an evaluation of mental status, cranial nerve function, cerebellar function (balance and coordination), reflexes, and motor and sensory function.

LOC, a sensitive indicator of neurologic function, can be assessed based on the criteria in the GCS, which include eye opening (E), verbal response (V), and motor response (M). The patient's responses are rated on a scale from 3 to 15. Box 45-6 provides the complete scoring of the GCS. The severity of TBI can be classified based upon the score on the GCS. A score of 13 to 15 is classified as mild TBI, 9 to 12 is moderate TBI, and 3 to 8 is severe TBI (Goldberg, Rojanasarntikul, & Jagoda, 2015; Hickey, 2014). A score of 3 indicates severe impairment of neurologic function, deep coma, brain death, or pharmacologic inhibition of the neurologic response; a score of 8 or less typically indicates an unconscious patient; a score of 15 indicates a fully alert and oriented patient.

BOX 45-6 Focused Assessment

Glasgow Coma Scale

The Glasgow Coma Scale (GCS) is a tool for assessing a patient's response to stimuli. Scores range from 3 (deep coma) to 15 (normal).

Eye opening response	Spontaneous	4
	To voice	3
	To pain	2
	None	1
Best verbal response	Oriented	5
	Confused	4
	Inappropriate words	3
	Incomprehensible sounds	2
	None	1
Best motor response	Obeys command	6
	Localizes pain	5
	Withdraws	4
	Flexion	3
	Extension	2
	None	1
Total		3 to 15

The patient's orientation is assessed by asking the patient to identify his or her full name, where he or she is, and the day, month, or season, and what happened to them (person, time, place, and situation). Other questions such as "Who is the president?" may

be helpful in determining the patient's processing of information in the environment. Verbal response cannot be evaluated if the patient is intubated or has a tracheostomy; this should be clearly documented.

Alertness is measured by the patient's ability to open the eyes spontaneously or in response to a vocal or noxious stimulus (pressure or pain). Patients with severe neurologic dysfunction cannot do this. The nurse assesses for periorbital edema (swelling around the eyes) or trauma, which may prevent the patient from opening the eyes, and documents any such condition that interferes with eye opening.

Motor response includes spontaneous, purposeful movement (e.g., the awake patient can move all four extremities with equal strength on command), movement only in response to painful stimuli, or abnormal posturing. If the patient is not responding to commands, the motor response is tested by applying a painful stimulus, using the least amount of pressure to elicit a possible response. Suggestions include using central pressure such as a sternal rub or squeezing the muscle masses and tendons. Central stimulation produces an overall body response, compared to peripheral stimulation via nail bed pressure, which can elicit a reflex response, which is not a true indicator of motor activity (Hickey, 2014; Noah, 2004). If the patient attempts to push away or withdraw, the response is recorded as purposeful or appropriate ("patient withdraws to painful stimuli"). This response is considered purposeful if the patient can cross the midline from one side of the body to the other in response to painful stimuli. An inappropriate or nonpurposeful response is random and aimless. Movement of only one side is suggestive of hemiparesis, while withdrawal suggests purposeful behavior. The motor response cannot be elicited if pharmacologic paralyzing agents have been administered to the patient. These must be suspended and time must elapse for the effects to wear off before attempting to elicit a motor response.

In addition to LOC, the nurse monitors parameters such as respiratory status, pupillary response, and vital signs on an ongoing basis. Table 45-1 summarizes the assessment and the clinical significance of the findings. Body functions (circulation, respiration, elimination, fluid and electrolyte balance) are examined in a systematic and ongoing manner.

If the patient is comatose and has localized signs, such as abnormal pupillary and motor responses, it is assumed that neurologic disease is present until proven otherwise. If the patient is comatose but pupillary light reflexes are preserved, a toxic or metabolic disorder is suspected. Common laboratory testing and diagnostic procedures performed on patients with decreased LOC and increased ICP are listed in Table 45-2.

Medical and Nursing Management

The first priority of treatment for the patient with altered LOC is to obtain and maintain a patent airway. The patient may be orally or nasally intubated (unless basilar skull fracture or facial trauma is suspected), or a tracheostomy may be performed. Until the ability of the patient to breathe on his or her own is determined, a mechanical ventilator is used to maintain adequate oxygenation and ventilation. The circulatory status (blood pressure, heart rate) is monitored to ensure adequate perfusion to the body and brain. An IV catheter is inserted to provide access for IV fluids and medications.

Increased ICP is a true emergency and must be treated promptly. Invasive monitoring of ICP is an important component of management. Immediate management to relieve increased ICP requires decreasing cerebral edema, lowering the volume of CSF, and decreasing cerebral blood volume while maintaining cerebral perfusion. These goals are accomplished by administering osmotic diuretics, restricting fluids, draining CSF, controlling fever, maintaining systemic blood pressure and oxygenation, and reducing cellular metabolic demands. Corticosteroids are not recommended in cases of increased ICP resulting from TBI (Hickey, 2014). In patients with severe TBI, there was a significant reduction in mortality when clinicians closely followed the guidelines from the Brain Trauma Foundation for control of both ICP and cerebral perfusion pressure (CPP) (Gerber, Chiu, Carney, Hartl, & Ghajar, 2013).

TABLE 45-1 Nursing Assessment of the Unconscious Patient

Examination	Clinical Assessment	Clinical Significance
Level of responsiveness or consciousness	Eye opening; verbal and motor responses; pupils (size, equality, reaction to light)	Obeying commands is a favorable response and demonstrates a return to consciousness.
Pattern of respiration	Respiratory pattern	Disturbances of respiratory center of brain may result in various respiratory patterns.
	Cheyne–Stokes respiration	Suggests lesions deep in both hemispheres; area of basal ganglia and upper brainstem
	Hyperventilation	Suggests onset of metabolic problem or brainstem damage
	Ataxic respiration with irregularity in depth/rate	Ominous sign of damage to medullary center
Eyes		
Pupils (size, equality, reaction to light)	Equal, normally reactive pupils	Suggests that coma is toxic or metabolic in origin
	Equal or unequal diameter	Helps determine location of lesion
	Progressive dilation	Indicates increasing intracranial pressure
	Fixed dilated pupils	Indicates injury at level of midbrain
Eye movements	Normally, eyes should move from side to side.	Functional and structural integrity of brainstem is assessed by inspection of extraocular movements; usually absent in deep coma
Corneal reflex	When cornea is touched with a wisp of clean cotton, blink response is normal	Tests cranial nerves V and VII; helps determine location of lesion if unilateral; absent in deep coma
Facial symmetry	Asymmetry (sagging, decrease in wrinkles)	Sign of paralysis
Swallowing reflex	Drooling versus spontaneous swallowing	Absent in coma Paralysis of cranial nerves IX, X, and XII
Neck	Stiff neck	Subarachnoid hemorrhage, meningitis
	Absence of spontaneous neck movement	Fracture or dislocation of cervical spine
Response of extremity to noxious stimuli	Firm pressure on a joint of the upper and lower extremity	Asymmetric response in paralysis
	Observe spontaneous movements	Absent in deep coma
Deep tendon reflexes	Tap patellar and biceps tendons.	Brisk response may have localizing value Asymmetric response in paralysis No response in deep coma
Pathologic reflexes	Firm pressure with blunt object on sole of foot, moving along lateral margin and crossing to the ball of foot	Flexion of the toes, especially the great toe, is normal except in newborn Dorsiflexion of toes (especially great toe) indicates contralateral pathology of corticospinal tract (Babinski reflex) Helps determine location of lesion in brain
Abnormal posture	Observation for posturing (spontaneous or in response to noxious stimuli)	Deep extensive brain lesion
	Flaccidity with absence of motor response	Seen with cerebral hemisphere pathology and in metabolic depression of brain function
	Decorticate posture (flexion and internal rotation of forearms and hands)	Decorticate posturing indicates damage to the upper midbrain
	Decerebrate posture (extension and external rotation)	Decerebrate posturing indicates deeper and more severe dysfunction than does decorticate posturing; implies brain pathology; poor prognostic sign

TABLE 45-2 Laboratory and Diagnostic Tests for Patients with Traumatic Brain Injury

Test	Normal Values	Critical Values	Nursing Implications
Complete blood count	WBC: 4.5–10.5 (×1,000/mm^3) WBC for Black adults: 3.2–10.0 (×1,000/mm^3) HCT: women: 36–48%; men: 42–52%	WBC: >10.5 (×1,000/mm^3) HCT: <32%	Assess for any signs or symptoms of infection with increased WBC; assess for any signs or symptoms of occult bleeding with decreased HCT.
Glucose	70–110 mg/dL	>150 mg/dL	Hyperglycemia may worsen outcomes; administer insulin if glucose is elevated.
Serum osmolality	278–300 mOsm/L	≥320 mOsm/L	Osmolality should not exceed 320 mOsm/L to prevent kidney failure in patients receiving mannitol.
Serum sodium	135–145 mEq/L	<130 mEq/L or >145 mEq/L	Hyponatremia may indicate cerebral salt wasting or SIADH. Hypernatremia may indicate diabetes insipidus or be due to mannitol therapy.
Urine specific gravity	1.005–1.015	<1.005 or >1.015	Low specific gravity can mean diabetes insipidus while a high level may mean SIADH.
Chest radiograph	Negative for pneumonia or infiltrate	Presence of pneumonia or infiltrate	Ventilated patients are prone to aspiration and development of pneumonias.
Head CT without contrast	Negative for acute hemorrhage	Positive for epidural, subdural, or intracerebral hemorrhage	Observe for any signs or symptoms of intracranial bleeding.
Serum potassium	3.5–5.0 mEq/L	<3.5 mEq/L	Hypokalemia may be a consequence of mannitol therapy.
Magnesium	1.8–2.6 mg/dL	<1.8 mg/dL	Hypomagnesemia may lower the seizure threshold and cause secondary brain injury; low levels should be corrected.

WBC, white blood cell count; HCT, hematocrit; SIADH, syndrome of inappropriate antidiuretic hormone.

Monitoring Intracranial Pressure

Nursing management focuses on detecting early signs of increasing ICP because medical interventions are usually ineffective once later signs develop. Frequent neurologic assessments and documentation and analysis of trends will reveal the subtle changes that may indicate increasing ICP.

Detecting Early Indications of Increasing Intracranial Pressure

The nurse assesses for and immediately reports any of the following early signs or symptoms of increasing ICP:

- Disorientation, restlessness, increased respiratory effort, purposeless movements, and mental confusion; these are early clinical indications of increasing ICP because the brain cells responsible for cognition are extremely sensitive to decreased oxygenation.
- Pupillary changes and impaired extraocular movements; these occur as the increasing pressure displaces the brain against the oculomotor and optic nerves (cranial nerves II, III, IV, and VI), which arise from the midbrain and brainstem (see Chapter 43).
- Weakness in one extremity or on one side of the body; this occurs as increasing ICP compresses the pyramidal tracts, which control motor function.
- Headache that is constant, increasing in intensity, and aggravated by movement or

straining; this occurs as increasing ICP causes pressure and stretching of venous and arterial vessels in the base of the brain.

Nursing Alert
The earliest sign of increasing ICP is a change in LOC. Any changes in LOC should be reported immediately.

Detecting Later Indications of Increasing Intracranial Pressure

As ICP increases, the patient's condition worsens and the following signs and symptoms may be observed:

- LOC continues to deteriorate until the patient is comatose.
- Respiratory rate decreases or becomes erratic, blood pressure and temperature increase. The pulse pressure widens and the pulse fluctuates rapidly, varying from bradycardia to tachycardia.
- Altered respiratory patterns develop, including Cheyne–Stokes breathing (rhythmic waxing and waning of rate and depth of respirations alternating with brief periods of apnea) and ataxic breathing (irregular breathing with a random sequence of deep and shallow breaths).
- Projectile vomiting may occur with increased pressure on the reflex center in the medulla.
- Hemiplegia or decorticate or decerebrate posturing may develop as pressure on the brainstem increases; bilateral flaccidity occurs before death.
- Loss of brainstem reflexes, including pupillary, corneal, gag, and swallowing reflexes, which is an ominous sign of impending death.

Because clinical assessment is not always a reliable guide in recognizing increased ICP, especially in comatose patients, monitoring of ICP is an essential part of management (Hickey, 2014). ICP is monitored closely for continuous elevation or significant increase over baseline. The trend of ICP measurements over time is an important indication of the patient's underlying status. Vital signs are assessed when an increase in ICP is noted.

ICP can be monitored with the use of an intraventricular catheter (ventriculostomy) or a subarachnoid bolt or screw (Fig. 45-5). When a ventriculostomy is used for monitoring ICP, a fine-bore catheter is inserted into a lateral ventricle, preferably in the nondominant hemisphere of the brain (Hickey, 2014). The catheter is connected by a fluid-filled system to a transducer, which records the pressure in the form of an electrical impulse. In addition to obtaining continuous ICP recordings, the ventricular catheter allows CSF to drain, particularly during acute increases in pressure. The ventriculostomy can also be used to drain blood from the ventricle. Continuous drainage of CSF under pressure control is an effective method of treating intracranial hypertension. Complications associated with its use include infection, meningitis, ventricular collapse, occlusion of the catheter by brain tissue or blood, and problems with the monitoring system (AANN, 2014a). CSF drainage is frequently performed because the removal of CSF with a ventriculostomy drain can dramatically reduce ICP and restore cerebral perfusion. Caution should be used in draining CSF, however, because excessive drainage may result in collapse of the ventricles and

herniation.

The subarachnoid bolt or screw is a hollow device that is inserted through the skull and dura mater into the cranial subarachnoid space (Hickey, 2014). It has the advantage of not requiring a ventricular puncture. The subarachnoid bolt is attached to a pressure transducer, and the output is recorded on an oscilloscope. This technique also has the advantage of avoiding complications from brain shift and small ventricle size. One disadvantage to using a subarachnoid bolt is the inability to obtain CSF for analysis or drainage purposes. Complications include infection and blockage of the bolt by clot or brain tissue, which leads to a loss of pressure tracing and a decrease in accuracy at high ICP readings.

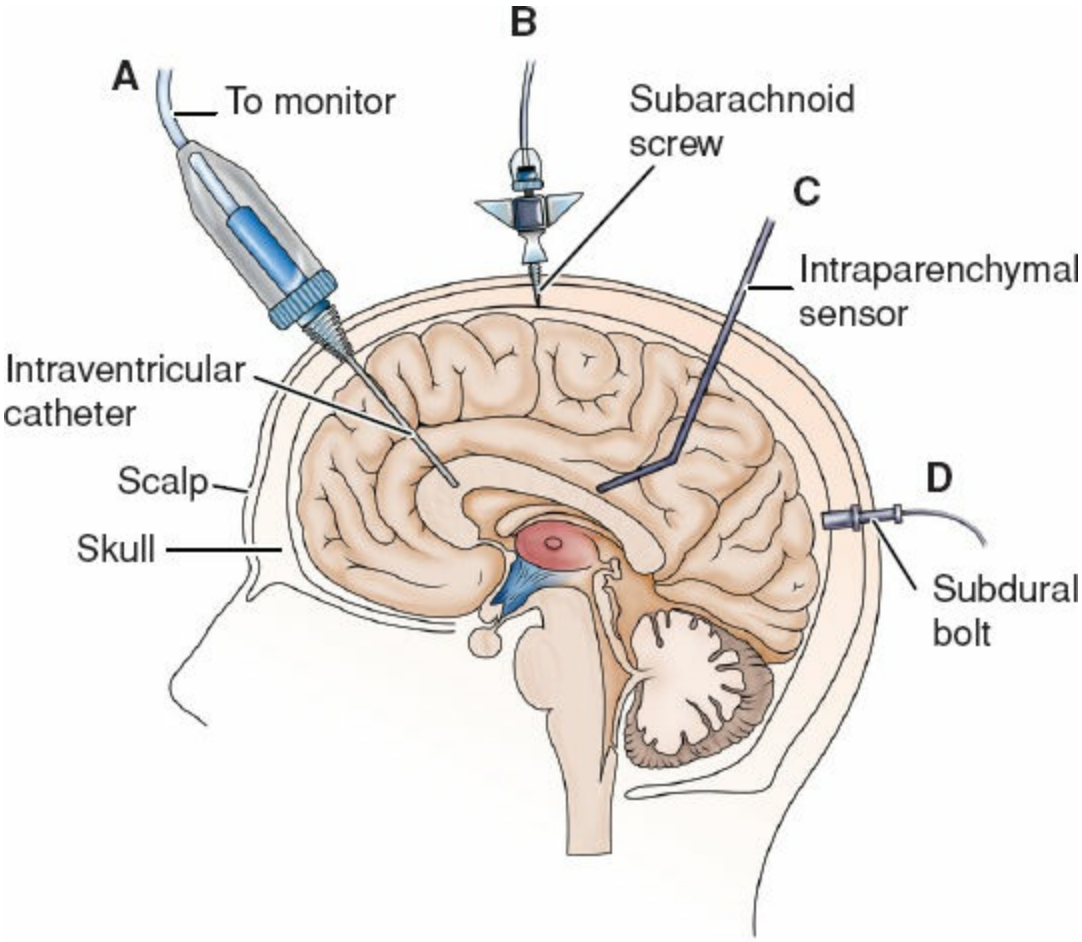

FIGURE 45-5 Intracranial pressure monitoring. A device may be placed in (A) the ventricle, (B) the subarachnoid space, (C) the intraparenchymal space, or (D) the subdural space.

While ICP monitoring is only performed in an ICU setting, CSF drainage may be carried out in the operating room, emergency room, or intensive care unit. A ventriculostomy without the ICP monitoring catheter is known as an *external ventricular drain* (EVD). Box 45-7 provides guidelines on nursing care of the EVD.

Monitoring and Managing Complications

Potential complications for the patient with altered LOC include respiratory failure, pneumonia, pressure ulcers, and aspiration. Respiratory failure may develop shortly after

the patient becomes unconscious. If the patient cannot maintain effective respirations, insertion of an airway and mechanical ventilation is initiated to provide adequate ventilation and to protect the airway. Pneumonia is common in patients receiving mechanical ventilation and in those who cannot maintain and clear the airway. The patient with altered LOC is subject to all the complications associated with immobility, such as pressure ulcers, venous stasis, musculoskeletal deterioration, and disturbed gastrointestinal functioning. Aspiration of gastric contents or feedings may occur, precipitating the development of aspiration pneumonia or airway occlusion.

Endocrine abnormalities, including diabetes insipidus and syndrome of inappropriate antidiuretic hormone (SIADH), are common complications of TBI. Diabetes insipidus is the result of decreased secretion of antidiuretic hormone (ADH). The patient has excessive urine output, decreased urine osmolality, and serum hyperosmolarity. Therapy consists of administration of fluids, electrolyte replacement, and vasopressin (desmopressin, DDAVP) therapy. SIADH is the result of increased secretion of ADH. The patient becomes volume-overloaded, urine output diminishes, and serum sodium concentration becomes dilute (sodium is less than 134 mEq/L). Treatment of SIADH includes fluid restriction (typically less than 1 L/day with no free water), which is usually sufficient to correct the hyponatremia. Severe cases call for judicious administration of a 3% hypertonic saline solution. If hypertonic saline is administered, usually it is necessary to administer furosemide (Lasix) simultaneously to reduce intravascular volume via diuresis. Hyponatremia presents commonly with a change in mental status ranging from mild confusion to coma; seizures are associated with low sodium levels (less than 115 mEq/L). The more quickly this problem has developed, the more profound the signs and symptoms. Aggressive management may be required to correct hyponatremia as delaying treatment may result in irreversible brain damage. However, overcorrection of the sodium level predisposes the patient to central pontine myelinolysis, a disorder in which the white matter of the pons loses myelin (the protective sheath surrounding nerves); this results in tetraplegia with cranial nerve deficits (Luzzio, 2013). To prevent this complication, the nurse monitors results of sodium levels (initially, these may be ordered hourly) and the patient's response to hypertonic saline treatment. As a general guideline, the plasma sodium concentration should probably be raised by no more than 10 mEq during the first 24 hours.

BOX 45-7 GUIDELINES FOR NURSING CARE

Caring for an External Ventricular Drain (EVD)

Nurses in a variety of acute care settings may receive patients who have an external ventricular drain (EVD) in place to drain off excess CSF. The nurse is responsible for maintaining the EVD while monitoring for any signs or symptoms of infection or CSF leak.

Equipment

- Carpenter's level
- Sterile gloves

- Sterile 4 × 4 gauze pad
- Transparent dressing large enough to cover the gauze (e.g., Tegaderm)

Implementation

NURSING ACTION	RATIONALE
1. Position the head of the bed at 30 degrees with the patient's head and neck in the midline position, taking care to avoid neck flexion.	1. Positioning the head of the bed at 30 degree helps promote venous return, which will assist in keeping ICP within normal limits. Keeping the head and neck in the midline position while avoiding flexion will help prevent any increases in ICP.
2. Using the carpenter's level, set the collection bag even with the external auditory meatus (EAM) of the ear at the level that has been ordered by the physician (measured in centimeters either above or below the EAM).	2. The EAM is level with the foramen of Monro. A level below the EAM will increase drainage of CSF, while a level above the EAM will decrease drainage of CSF.
3. Documentation should include the position of the collection bag, the amount of CSF drainage, and the color and quality of the CSF (clear, cloudy, bloody, etc.).	3. Proper documentation of where the collection bag is placed and the amount of drainage is important for the neurosurgeons to evaluate when to make adjustments to the level and when the EVD is no longer needed. Any change in quality of the CSF may indicate infection or bleeding into the ventricles, which should be reported immediately.
4. If the patient needs to be turned, the head of the bed needs to be adjusted, or when the patient needs to be moved out of bed, the drainage system should be turned off until it can be returned to the ordered position. Once the patient is back in bed and the system has been re-leveled, the drainage system may be opened again.	4. If the drainage system is not turned off and the patient's head is moved, CSF may be forcefully pulled out of the ventricles, potentially causing herniation of the brain.
5. The EVD should always be handled with sterile technique when changing the dressing covering the insertion site. The dressing consists of a sterile 4 × 4 gauze pad that is folded in order to fully cover the insertion site and then covered with a transparent dressing. The insertion site should be monitored for any signs or symptoms of infection and should be kept clean and dry. If the dressing becomes damp, it should be changed and the provider should be notified.	5. The EVD is a closed, sterile system. Risk for infection is high and all precautions should be taken to prevent any infection from entering the brain. The gauze needs to be covered with a clear dressing so that the gauze may be readily inspected for the presence of dampness and blood. If the dressing becomes damp with fluid, the fluid is presumed to be CSF. Presence of a damp dressing may indicate a CSF leak.

EAM, external auditory meatus; EVD, external ventricular drain; ICP, intracranial pressure; CSF, cerebrospinal fluid.

Because the unconscious patient's protective reflexes are impaired, the quality of nursing care provided literally may mean the difference between life and death. The nurse must assume responsibility for the patient until the basic reflexes (coughing, blinking, and swallowing) return and the patient becomes conscious and oriented. Therefore, the major nursing goal is to compensate for the absence of these protective reflexes.

Potential complications include cerebral edema, high fever, alterations in blood pressure and oxygenation, increased metabolic demand, and seizures. The nurse must maintain oral hygiene, monitor for the presence of pressure ulcers, avoid any complications associated with the eyes (eye care discussed later in this chapter), monitor urinary output and bowel function, and assess nutritional status. The nurse must always remember to be the patient's advocate, as an unconscious patient cannot advocate for him- or herself.

Decreasing Cerebral Edema: Osmotic Diuretics, Fluid Restriction, and Hypothermia

Cerebral edema is the leading cause of secondary brain injury (Kahle, Walcott, & Simard, 2014). Osmotic diuretics, such as mannitol, may be administered to dehydrate the brain tissue and reduce cerebral edema. Osmotic diuretics work by creating a gradient that draws water across intact membranes, thereby reducing the volume of the swollen brain. Secondarily, they reduce blood viscosity and hematocrit and enhance cerebral blood flow

(Rickard, Smith, Newell, Bailey, & Mann, 2014). If the patient is receiving osmotic diuretics, serum osmolality should be determined to assess hydration status.

Drug Alert!
Mannitol becomes ineffective when the serum osmolality exceeds 320 mOsm.

Nursing Alert
The serum osmolality is calculated with the following formula:

2 × sodium + glucose/18 + Blood Urea Nitrogen (BUN)/2.8

If a patient's serum sodium is 140 mEq/L, blood sugar is 80 mg/dL, and BUN is 10 mg/dL; then the calculated serum osmolality is

280 (sodium) + 4.4 (glucose) + 3.5 (BUN), for a calculated serum osmolality of 288 mOsm/kg.

Hypertonic saline is another medication that works to reduce cerebral edema. While mannitol is considered the gold standard in reducing increased ICP, hypertonic saline is gaining popularity as an effective osmotic diuretic. Optimal concentration, dosing, timing, and duration of hypertonic saline has yet to be determined (Rickard et al., 2014). The nurse follows institutional policies for hypertonic saline administration.

Another method for decreasing cerebral edema is fluid restriction. Limiting overall fluid intake leads to dehydration and hemoconcentration, which draws fluid across the osmotic gradient and decreases cerebral edema. Fluid needs are met initially by administering the required IV fluids.

Drug Alert!
Hypotonic fluids (e.g., 0.45% NaCl, D_5W) should be avoided in patients with TBI as those fluids can cause an increase in cerebral edema.

Researchers have long hypothesized that lowering body temperature decreases cerebral edema by reducing the oxygen and metabolic requirements of the brain, thus protecting the brain from continued ischemia. If body metabolism can be reduced by lowering the body temperature, the collateral circulation in the brain may be able to provide an adequate blood supply to the brain. The effect of hypothermia on ICP requires more study; thus far, induced hypothermia has not consistently been shown to be beneficial for patients with brain injury. Current literature suggests it is beneficial but only when maintained for at least 48 hours. Inducing and maintaining hypothermia is a major clinical treatment that requires knowledge and skilled nursing observation and management (Crossley et al., 2014).

Controlling Fever

High fever in the unconscious patient may be caused by infection of the respiratory or urinary tract, drug reactions, or damage to the hypothalamic temperature-regulating center. Approximately one fifth to one half of fevers are never explained, despite extensive workup. Because of damage to the temperature center in the brain or severe intracranial infection,

unconscious patients often develop very high temperatures. Such temperature elevations must be controlled because the increased metabolic demands of the brain can exceed cerebral circulation and oxygenation, resulting in cerebral deterioration (Hickey, 2014). Studies have shown that fever within the first week of injury is associated with poor outcomes and should be treated aggressively (Titus, Furones, Atkins, & Dietrich, 2015). Persistent hyperthermia with no identified clinical source of infection indicates brainstem damage and a poor prognosis.

Strategies for reducing fever include:

- Removing all bedding over the patient (with the possible exception of a light sheet or small drape)
- Administering acetaminophen as prescribed
- Giving cool sponge baths and allowing a fan to blow over the patient to increase surface cooling
- Using a hypothermia blanket

Frequent temperature monitoring is indicated to assess the patient's response to the therapy and to prevent an excessive decrease in temperature and shivering, which increases heat production and cerebral oxygen consumption.

Nursing Alert

If an automatic hyperthermia/hypothermia blanket is used for patient care, the nurse understands that the unit directly and continually monitors the patient's temperature by means of a thermistor probe (e.g., rectal, skin) and alternates heating and cooling cycles as necessary to achieve and maintain the desired body temperature. The nurse inserts the thermistor probe into the patient's rectum or axilla and tapes it in place to prevent accidental dislodgment. If dislodged, the thermistor will be monitoring room temperature rather than the patient's temperature and will warm the patient to the desired temperature. The probe should be checked at frequent intervals to ensure correct placement.

Maintaining Blood Pressure, Oxygenation, and Hyperventilation

Patients with TBI may sustain a secondary insult if they become hypotensive or hypoxic. Due to ethical reasons, no randomized controlled trials have been done to study the effects of hypotension and hypoxia. However, a growing body of evidence shows deleterious effects if the patient experiences either of these conditions. It is recommended that systolic blood pressure be maintained at greater than 90 mm Hg and oxygen saturation be maintained at greater than 90% (Brain Trauma Foundation, 2007; Hickey, 2014).

Hyperventilation, which results in vasoconstriction, was previously used in patients with increased ICP. Research has demonstrated that hyperventilation may not be as beneficial as once thought (Brain Trauma Foundation, 2007). The reduction in partial pressure of carbon dioxide ($PaCO_2$) may result in hypoxia, ischemia, and an increase in cerebral lactate levels (Hickey, 2014). Hyperventilation is an option for patients with ICP who are unresponsive to conventional therapies, but it should be used cautiously and should be avoided for the first 24 hours following the initial injury (Brain Trauma Foundation, 2007).

Pathophysiology Alert

Carbon dioxide (CO_2) is a potent vasodilator or vasoconstrictor. A normal PCO_2 is 35 to 45 mm Hg. As the patient hypoventilates, the PCO_2 rises (hypercarbia), which causes vasodilation. Likewise, as the patient hyperventilates, the PCO_2 decreases (hypocarbia), which causes vasoconstriction. It seems reasonable that hyperventilation would cause vasoconstriction and, therefore, decrease cerebral blood flow with a resulting decrease in ICP. However, on review, when the PCO_2 was lowered to 25 mm Hg, ischemia of the brain and increased mortality was seen. Therefore, moderate hyperventilation where the target PCO_2 is 30 to 35 mm Hg may be recommended as a temporary measure until definitive treatment is instituted. In general, normocarbia is preferred.

Reducing Metabolic Demands

Cellular metabolic demands may be reduced through the administration of high doses of barbiturates if the patient is unresponsive to conventional treatment. The mechanism by which barbiturates decrease ICP and protect the brain is through inhibition of free radicals, alterations in vascular tone, and suppression of metabolism (Hickey, 2014). Use of high-dose barbiturates should be reserved for patients with refractory increased ICP who do not respond to other medical or surgical treatments. Barbiturates should not be used as prophylaxis to prevent increased ICP (Brain Trauma Foundation, 2007).

Another method of reducing cellular metabolic demand and improving oxygenation is the administration of pharmacologic paralyzing agents, such as pancuronium, vecuronium, and cisatracurium. The patient who receives these agents cannot move; this decreases the metabolic demands and results in a decrease in cerebral oxygen demand. Because the patient cannot respond or report pain, sedation and analgesia must be provided because the paralyzing agents do not provide either.

Patients receiving high doses of barbiturates or pharmacologic paralyzing agents require continuous cardiac monitoring, endotracheal intubation, mechanical ventilation, ICP monitoring, and arterial pressure monitoring.

The ability to perform serial neurologic assessments is lost with the use of barbiturates or paralyzing agents. Therefore, other monitoring tools are needed to assess the patient's status and response to therapy. Important parameters that must be assessed include ICP, blood pressure, heart rate, respiratory rate, and response to ventilator therapy (e.g., "bucking" or "fighting" the ventilator). Refer to Chapters 10 and 55 for ventilator considerations. Potential complications include hypotension due to decreased sympathetic tone and myocardial depression (Hickey, 2014).

Seizure Prophylaxis

Patients with severe TBI are at risk for developing seizures. Seizures that develop after head injury are known as posttraumatic seizures (PTS) and are classified according to when they occur. If they occur within 7 days of injury, they are known as early PTS; if they occur more than 7 days after the injury, they are known as late PTS (Szaflarski, Nazzal, & Dreer, 2014). Box 45-8 lists risk factors for developing PTS. There is evidence to support the use of prophylactic anticonvulsants only for early PTS. It is not recommended that patients be started on seizure prophylaxis more than 1 week after the injury if they have not had any

seizures. If the patient develops late PTS, the seizures should be managed in the same way as new-onset seizures (Szaflarski et al., 2014). See Chapter 46 for further discussion on management of seizures.

BOX 45-8 Risk Factors for Developing Posttraumatic Seizures (PTS)

- Depressed skull fracture
- Penetrating head wound
- Epidural, subdural, or intracerebral hemorrhage
- GCS score below 10
- Cortical contusion

Providing Mouth Care

To provide care, the mouth is inspected for dryness, inflammation, and crusting. The unconscious patient requires conscientious oral care because there is a risk of parotitis (inflammation of the salivary glands) if the mouth is not kept scrupulously clean (refer to Chapter 22). The mouth is cleansed and rinsed carefully to remove secretions and crusts and to keep the mucous membranes moist. A thin coating of petrolatum on the lips prevents drying, cracking, and encrustations. If the patient has an endotracheal tube, the tube should be moved to the opposite side of the mouth daily to prevent ulceration of the mouth and lips.

Nursing Alert
Oral care in patients at risk for increased ICP has been shown to be safe. However, this should be done with caution in patients who already have elevated ICP as oral interventions may cause modest increases in ICP (McNett & Olson, 2013).

Maintaining Skin and Joint Integrity

Preventing skin breakdown requires continuing nursing assessment and intervention. Special attention is given to unconscious patients because they cannot respond to external stimuli. Assessment includes a regular schedule of turning to avoid pressure, which can cause breakdown and necrosis of the skin. Turning also provides kinesthetic (sensation of movement), proprioceptive (awareness of position), and vestibular (equilibrium) stimulation. After turning, the patient is carefully repositioned to prevent ischemic necrosis over pressure areas.

Preserving Corneal Integrity

Unconscious patients may have their eyes open and have inadequate or absent corneal reflexes. The cornea may become irritated, dried out, or scratched, leading to ulceration. The eyes may be cleansed with cotton balls moistened with sterile normal saline to remove debris and discharge (Hickey, 2014). If artificial tears are prescribed, they may be instilled every 1 to 2 hours. Periorbital edema often occurs after cranial surgery. Cold compresses may be prescribed, and care must be exerted to avoid contact with the cornea. Eye patches

should be used cautiously because of the potential for corneal abrasion from contact with the patch.

Managing Nutritional Needs

If the patient does not recover quickly and sufficiently enough to take adequate fluids and calories by mouth, a nasogastric tube or gastrostomy tube is inserted for the administration of enteral feedings. A nutritionist should be involved in the care of the unconscious patient. The nutritionist will determine the patient's caloric needs and will make recommendations for the amount and type of tube feeding that is appropriate. Daily intake and output should be recorded, as well as daily weights to ensure the patient has adequate caloric intake (Hickey, 2014). Box 45-9 gives nutritional considerations of the patient with decreased LOC and increased ICP.

Preventing Urinary Retention

The patient with an altered LOC is often incontinent or has urinary retention. The bladder is palpated or scanned at intervals to determine whether urinary retention is present. If the patient is not voiding, an indwelling urinary catheter is inserted and connected to a closed drainage system. A catheter may also be inserted during the acute phase of illness to monitor urinary output. Because catheters are a major factor in causing urinary tract infection (UTI), the patient is observed for fever, leukocytosis (increased WBCs), and cloudy urine. The urinary catheter is usually removed if the patient has a stable cardiovascular system and if no diuresis, sepsis, or voiding dysfunction existed before the onset of coma. An intermittent catheterization program may be initiated to ensure complete emptying of the bladder at intervals, if indicated.

BOX 45-9

Nutrition Alert 

Nutritional Support Following Traumatic Brain Injury

- Patients with traumatic brain injury (TBI) have increased metabolic expenditure so they have high caloric needs.
- Full nutritional support should be begun no later than 72 hours after the injury to achieve full caloric replacement by postinjury day 7.
- Protein should comprise 15% of total calories.
- When feedings are initiated, glucose levels should be closely monitored as hyperglycemia is associated with worse outcomes.
- Consultation with a dietician is recommended to provide optimal nutritional support.

Promoting Bowel Function

The abdomen is assessed for distention by listening for bowel sounds and measuring the

girth of the abdomen with a tape measure. There is a risk for diarrhea from infection, antibiotics, hyperosmolar fluids and enteral feedings.

Immobility and lack of dietary fiber can cause constipation. The nurse monitors the number and consistency of bowel movements and performs a rectal examination for signs of fecal impaction. Stool softeners may be prescribed and can be administered with tube feedings. To facilitate bowel emptying, a glycerin suppository may be indicated. The patient may require an enema every other day to empty the lower colon (Hickey, 2014).

Nursing Alert

The nurse is aware that straining during bowel movement increases intra-abdominal and/or intrathoracic pressure, which impedes venous return and increases ICP. Therefore a bowel program is initiated to prevent constipation.

Protecting the Patient

Care should be taken to prevent injury from invasive lines and equipment, and other potential sources of injury should be identified, such as restraints, tight dressings, environmental irritants, damp bedding or dressings, and tubes and drains.

Protection also includes protecting the patient's dignity during altered LOC. Simple measures, such as providing privacy and speaking to the patient during nursing care activities, preserve the patient's dignity. Not speaking negatively about the patient's condition or prognosis is also important because patients in a light coma may be able to hear. The patient who is comatose has an increased need for advocacy, and the nurse is responsible for seeing that these advocacy needs are met (Hickey, 2014).

New Therapies

Despite many years of extensive research, no new therapies have been shown to improve outcomes after TBI. Research into this area continues to be important as over 5 million Americans currently have some form of disability related to TBI with an estimated annual cost in the United States around $76 billion (Wright et al., 2014). The hormone progesterone initially showed clinical benefit in two phase II randomized controlled trials. However, a large phase III randomized clinical trial did not show any difference between treatment with progesterone and treatment with placebo. The use of progesterone in treatment for TBI is no longer recommended (Skolnick et al., 2014).

Intracranial Surgery

Decompressive craniectomy is a surgical procedure that can be used to help relieve increased ICP. A decompressive craniectomy involves removal of a bone flap from the skull to allow expansion of the brain. The bone flap is then implanted into the abdomen, so the bone remains viable. Once cerebral edema has decreased, the bone flap is replaced back on the skull. No randomized controlled trials have investigated the utility of decompressive craniectomy, although studies have suggested it is helpful (Hickey, 2014).

BRAIN DEATH

When a patient has sustained a severe neurologic injury incompatible with life, the diagnosis of brain death should be considered. Often, it is the nurse who will first notice signs of decompensation and will begin the process of determining if the patient meets criteria for brain death. Approximately 5% to 10% of patients in ICUs who are comatose will be declared brain dead (Hickey, 2014).

Brain death was formally defined by the Ad Hoc Committee at Harvard Medical School in 1968 as an "irreversible coma." In 1981, the President's Commission for the Study of Ethical Problems in Medicine and Biomedical and Behavioral Research published *Guidelines for the Determination of Death.* These guidelines clarified that patients who are considered brain dead must have confirmation of cessation of all brain function resulting from an irreversible cause. Reversible conditions, such as shock, hypothermia, and drug intoxication, must be excluded prior to diagnosis. This study served as the basis for the Uniform Death and Determination Act (UDDA), which is now recognized by all 50 states. The UDDA states that death will be determined with accepted medical standards and that death will indicate irreversible loss of all brain function.

The most recent practice parameters come from the Quality Standards Subcommittee of the American Academy of Neurology (2010) and include three cardinal findings: coma or unresponsiveness, absence of brainstem reflexes, and apnea. The current criteria for brain death are: the condition is irreversible with a known cause; the patient is not under the effects of a CNS depressant or a paralytic; no evidence of electrolyte, severe acid–base, or endocrine abnormality; the patient has apnea; the patient has no brainstem reflexes; the core body temperature is greater than 90°F (36°C); systolic blood pressure is at least 100 mm Hg; and there is neuroimaging evidence of catastrophic CNS damage.

The nurse may assist in the clinical examination for determination of brain death and in the process of organ procurement. Often, there will be a meeting among the attending physician, nurse, social worker, and representative of the organ procurement organization to inform the family of the organ donation process. The family will often look to the nurse for answers about organ donation and an explanation of questions related to the determination of brain death (Jackson, Willmarth-Stec, & Shutter, 2015; Miller, 2015).

SPINAL CORD INJURY

Spinal cord injury (SCI) is a major health problem. An estimated 276,000 people in the United States live each day with a disability from SCI, and an estimated 12,500 new injuries occur each year (National Spinal Cord Injury Statistical Center [NSCISC], 2014). Males account for 79% of SCI in a reported national database (NSCISC, 2014). Young people between 16 and 30 years of age account for more than half of the new SCIs each year. The most common cause of SCI is motor vehicle accidents, which account for 38% of SCI. Violence-related injuries account for 14% of SCIs, with falls causing 30%, and sports-related injuries causing 9% of SCIs (NSCISC, 2014). The frequency of associated injuries and medical complications in SCI is high. The frequency with which these risk factors are associated with SCI serves to emphasize the importance of primary prevention. The same interventions suggested earlier in this chapter for head injury prevention serve to decrease the incidence of SCI as well (see Box 45-1, p. 1288).

Pathophysiology

Damage to the spinal cord ranges from transient concussion (from which the patient fully recovers) to contusion, laceration, and compression of the cord substance (either alone or in combination), to complete transection (severing) of the cord (which renders the patient paralyzed below the level of the injury).

SCIs, like head injuries, can be separated into two categories: primary injuries and secondary injuries (Porth & Matfin, 2013). Primary injuries are the result of the initial insult or trauma and are usually permanent. Secondary injuries are usually the result of a contusion or tear injury, in which the nerve fibers begin to swell and disintegrate. A secondary chain of events produces ischemia, hypoxia, edema, and hemorrhagic lesions, which in turn result in destruction of myelin and axons (Hickey, 2014). These secondary reactions, believed to be the principal causes of spinal cord degeneration at the level of injury, are now thought to be reversible during the first 4 to 6 hours after injury. Therefore, if the cord has not suffered irreparable damage, some method of early treatment is needed to prevent partial damage from developing into total and permanent damage (Hickey, 2014) (see later discussion).

The vertebrae most frequently involved in SCI are the fifth, sixth, and seventh cervical (neck) vertebrae (C5 to C7), the twelfth thoracic vertebra (T12), and the first lumbar vertebra (L1). These vertebrae are most susceptible because there is a greater range of mobility in the vertebral column in these areas (Porth & Matfin, 2013).

Clinical Manifestations

Manifestations of SCI depend on the type and level of injury (Box 45-10). Incomplete spinal cord lesions (the sensory or motor fibers, or both, are preserved below the lesion) are classified according to the area of spinal cord damage: central, lateral, anterior, or peripheral. The American Spinal Injury Association (ASIA) provides another standard classification of SCI according to the degree of sensory and motor function present after injury (Box 45-11). *Neurologic level* refers to the lowest level at which sensory and motor functions are normal. A motor complete SCI (ASIA Grades A and B) involves no motor function below the neurologic level. ASIA Grade A involves no sensory or motor function all the way down to the sacral segments, S4 and S5. ASIA Grade B involves preserved sensory but not motor function below the neurologic level and includes preservation of the sacral segments S4 and S5. A motor incomplete SCI (ASIA Grades C and D) involves preservation of motor function below the neurologic level. ASIA Grade C involves preserved motor function below the neurologic level with at least half of the key muscles having a grade of less than 3 (see Chapter 43 for discussion of grading muscle strength). ASIA Grade D involves preserved motor function below the neurologic level with at least half of the key muscles having a grade of 3 or greater. A complete spinal cord lesion (total loss of sensation and voluntary muscle control below the lesion) can result in paraplegia (paralysis of the lower body) or tetraplegia (formerly quadriplegia—paralysis of all four extremities). Complete SCIs also include loss of all spinal reflexes below the level of the lesion, loss of the ability to perspire below the level of the lesion, dysfunction of the bowel and bladder, and absence of visceral and somatic sensations below the level of the lesion (Hickey, 2014).

If conscious, the patient usually complains of acute pain in the back or neck, which may radiate along the involved nerve. However, absence of pain does not rule out spinal injury, and a careful assessment of the spine should be conducted if the mechanism of injury has involved significant force (i.e., concomitant head injury).

Respiratory dysfunction is related to the level of injury. The muscles contributing to respiration are the abdominals and intercostals (T1 to T11) and the diaphragm (C3 to C5). In high cervical cord injury, acute respiratory failure is the leading cause of death. Functional abilities by level of injury are described in Table 45-3.

Nursing Alert
Ascending edema of the spinal cord in the acute phase of the injury may cause respiratory difficulty that requires immediate intervention. Therefore, the patient's respiratory status must be monitored frequently.

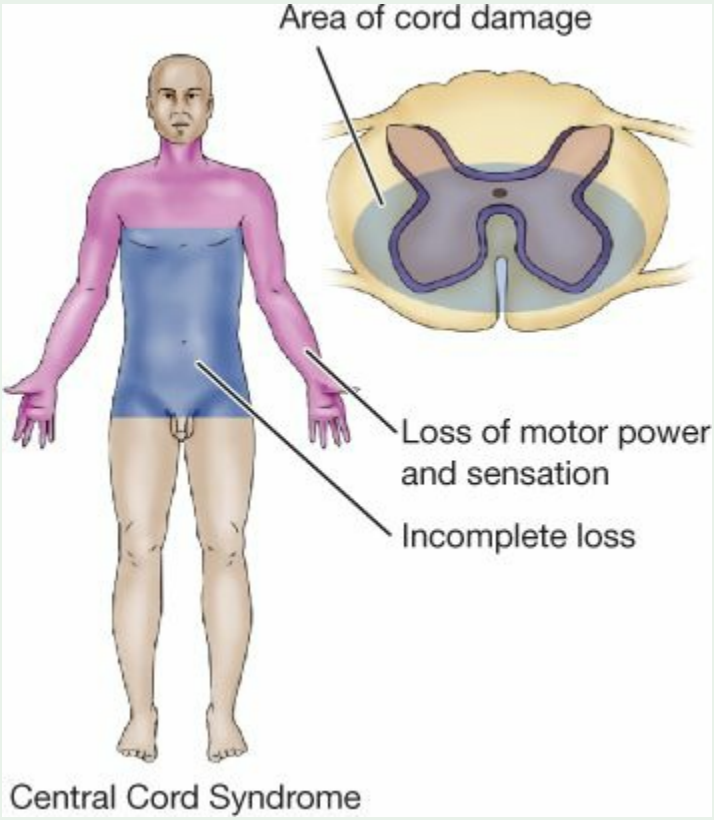
Assessment and Diagnostic Findings

A detailed neurologic examination is performed. Diagnostic x-rays (lateral cervical spine x-rays) and CT are usually performed initially. An MRI may be ordered as further workup if a ligamentous injury is suspected because significant spinal cord damage may exist even in the absence of bony injury. An assessment is made for other injuries because spinal trauma often is accompanied by concomitant injuries, commonly to the head and chest. Continuous cardiac monitoring may be indicated if an SCI is suspected because bradycardia and asystole are common in patients with acute SCIs.

BOX 45-10 Effects of Spinal Cord Injuries (SCI)

Central Cord Syndrome

- Characteristics: Motor deficits (in the upper extremities compared to the lower extremities; sensory loss varies but is more pronounced in the upper extremities); bowel/bladder dysfunction is variable, or function may be completely preserved.
- Cause: Injury or edema of the central cord, usually of the cervical area. May be caused by hyperextension injuries.

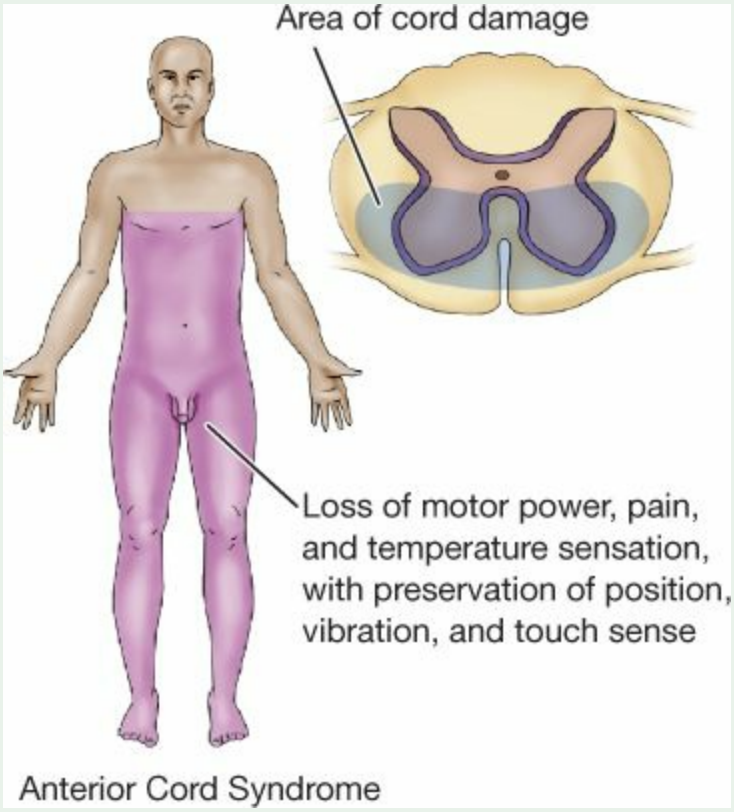


Anterior Cord Syndrome

- Characteristics: Loss of pain, temperature, and motor function are noted below the

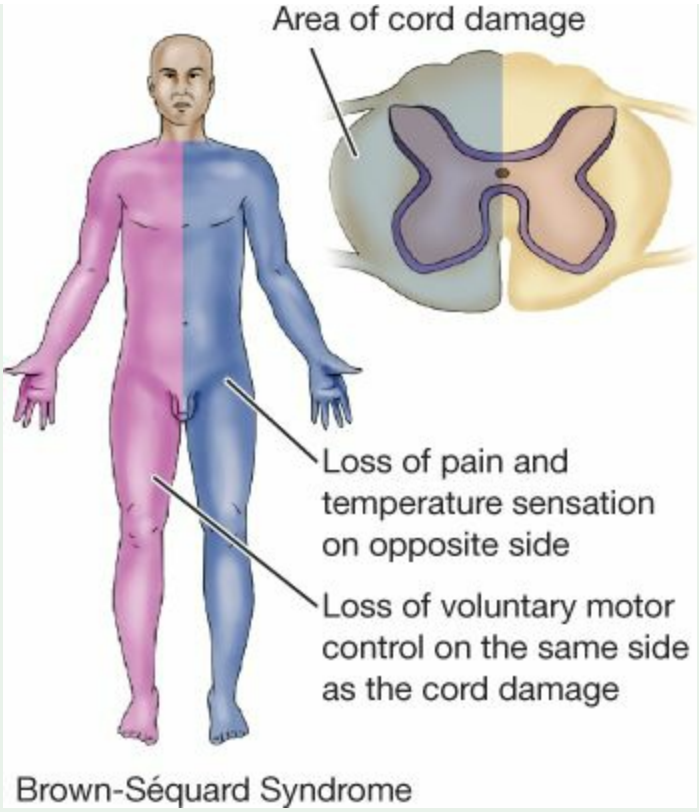
level of the lesion; light touch, position, and vibration sensations remain intact.

- Cause: The syndrome may be caused by acute disk herniation or hyperflexion injuries associated with fracture-dislocation of vertebra. It also may occur as a result of injury to the anterior spinal artery, which supplies the anterior two thirds of the spinal cord.



Brown-Séquard Syndrome (Lateral Cord Syndrome)

- Characteristics: Ipsilateral paralysis or paresis is noted, together with ipsilateral loss of touch, pressure, and vibration and contralateral loss of pain and temperature.
- Cause: The lesion is caused by a transverse hemisection of the cord (half of the cord is transected from north to south), usually as a result of a knife or missile injury, fracture-dislocation of a unilateral articular process, or possibly an acute ruptured disk.



Adapted from Hickey, L. (2014). The clinical practice of neurological and neurosurgical nursing (7th ed., pp. 423–425). Philadelphia, PA: Lippincott Williams & Wilkins.

Emergency Management

The immediate management at the scene of the injury is critical because improper handling of the patient can cause further damage and loss of neurologic function. Any patient who is involved in a motor vehicle accident, a diving or contact sports injury, a fall, or any direct trauma to the head and neck should be considered to have an SCI until such an injury has been ruled out. Initial care should include rapid assessment, immobilization, extrication, stabilization or control of life-threatening injuries, and transportation to the most appropriate medical facility (Ropper, Neal, & Theodore, 2015).

BOX 45-11 ASIA Impairment Scale

A = Complete: No motor or sensory function is preserved in the sacral segments S4–S5.
B = Incomplete: Sensory but not motor function is preserved below the neurologic level, and includes the sacral segments S4 to S5.
C = Incomplete: Motor function is preserved below the neurologic level, and more than half of key muscles below the neurologic level have a muscle grade of less than 3.
D = Incomplete: Motor function is preserved below the neurologic level, and at least half of key muscles below the neurologic level have a muscle grade of 3 or greater.
E = Normal: Motor and sensory function are normal.

Used with permission of American Spinal Injury Association.

At the scene of the injury, the patient should be immobilized on a spinal (back) board, with head and neck in a neutral position, to prevent an incomplete injury from becoming complete. Up to 25% of SCIs occur after the initial insult, during either transit to a care facility or during the early course of treatment (Hadley et al., 2013). One member of the team must assume control of the patient's head to prevent flexion, rotation, or extension; this is done by placing the hands on both sides of the patient's head at about ear level to limit movement and maintain alignment while a spinal board or cervical immobilizing device is applied. If possible, at least four people should slide the patient carefully onto a board for transfer to the hospital. Any twisting movement may irreversibly damage the spinal cord by causing a bony fragment of the vertebra to cut into, crush, or sever the cord completely (Hickey, 2014). While spine immobilization is necessary, it may lead to worse outcomes in patients with penetrating trauma as immobilization may delay other lifesaving treatments (Ropper et al., 2015).

TABLE 45-3 Functional Abilities by Level of Spinal Cord Injury

Injury Level	Segmental Sensorimotor Function	Dressing, Eating	Elimination	Mobility[a]
C1	Little or no sensation or control of head and neck; no diaphragm control; requires continuous ventilation	Dependent	Dependent	Limited. Voice or sip-n-puff controlled electric wheelchair
C2–C3	Head and neck sensation; some neck control; independent of mechanical ventilation for short periods	Dependent	Dependent	Same as for C1
C4	Good head and neck sensation and motor control; some shoulder elevation; diaphragm movement	Dependent, may be able to eat with adaptive sling	Dependent	Limited to voice, mouth, head, chin, or shoulder-controlled electric wheelchair
C5	Full head and neck control; shoulder strength; elbow flexion	Independent with assistance	Maximal assistance	Electric or modified manual wheelchair, needs transfer assistance
C6	Fully innervated shoulder; wrist extension or dorsiflexion	Independent or with minimal assistance	Independent or with minimal assistance	Independent in transfers and wheelchair
C7–C8	Full elbow extension; wrist plantar flexion; some finger control	Independent	Independent	Independent; manual wheelchair
T1–T5	Full hand and finger control; use of intercostal and thoracic muscles	Independent	Independent	Independent; manual wheelchair
T6–T10	Abdominal muscle control, partial to good balance with trunk muscles	Independent	Independent	Independent; manual wheelchair
T11–L5	Hip flexors, hip abductors (L1–L3); knee extension (L2–L4); knee flexion and ankle dorsiflexion (L4–L5)	Independent	Independent	Short distance to full ambulation with assistance
S1–S5	Full leg, foot, and ankle control; innervation of perineal muscles for bowel, bladder, and sexual function (S2–S4)	Independent	Normal to impaired bowel and bladder function	Ambulate independently with or without assistance

[a]Assistance refers to adaptive equipment, setup, or physical assistance.
From Porth, C. M., & Matfin, G. (2013). *Pathophysiology: Concepts of altered health states* (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

The standard of care is that the patient is referred to a regional spinal injury or trauma center because of the multidisciplinary personnel and support services required to counteract the destructive changes that occur in the first 24 hours after injury. During treatment in the emergency and x-ray departments, the patient is kept on the transfer board. The patient must always be maintained in an extended position. No part of the body should be twisted or turned, nor should the patient be allowed to sit up. Once the extent of the injury has been determined, the patient may be placed on a rotating bed or in a cervical collar. Later, if SCI and bone instability have been ruled out, the patient may be moved to a conventional bed or the collar may be removed without harm. If a rotating bed is needed but not available, the patient should be placed in a hard cervical collar and on a firm mattress.

Medical and Nursing Management

The goals of management are to prevent further SCI and to observe for symptoms of progressive neurologic deficits. Many changes in the treatment of SCI have occurred during the past 20 years. Treatments such as hypothermia, corticosteroids, and naloxone were investigated and used during the 1980s; of these, high-dose corticosteroids had shown the most promise, but their use has become controversial. In the National Acute Spinal Cord Injury Studies (NASCIS) done in 1990 and 1997, the administration of high-dose corticosteroids, specifically methylprednisolone (Solu-Medrol), was found to improve motor and sensory outcomes at 6 weeks, 6 months, and 1 year if given within 8 hours after injury (Hadley et al., 2013). In 2001, The American Association of Neurological Surgeons/Congress of Neurological Surgeons conducted a review of available literature and noted that treatment for either 24 or 48 hours was recommended as an option. They noted, however, that there was more evidence to suggest harmful side effects than there was evidence that suggested clinical benefit (Hadley et al., 2013). Currently, there is no Class I or II evidence to support the benefits of methylprednisolone; and there is Class I, II, and III evidence that use of high-dose steroids is associated with harmful side effects, up to and including death. There also has not been any benefit seen from administration of the biologic agent Syngen (GM-1 ganglioside) and its use is not recommended (Hurlbert et al., 2013).

Biologic agents are currently being investigated for the acute and chronic phases of SCI. Cell-based therapies, including stem cells, have theoretical benefits, but while trials so far have not consistently shown efficacy, they do seem to be relatively safe (Robbins, Kumar, Vaccaro, & Behrend, 2015).

Nonsurgical Management

Treatment of SCI attempts to achieve decompression, stabilization, and realignment of the spinal cord while preserving or improving neurologic function (Hickey, 2014). Cervical fractures are reduced, and the cervical spine is aligned with some form of skeletal traction, such as skeletal tongs or calipers, or with use of the halo device. A variety of skeletal tongs are available, all of which involve fixation in the skull in some manner. The Gardner-Wells tongs require no predrilled holes in the skull. Crutchfield and Vinke tongs are inserted through holes made in the skull with a special drill under local anesthesia.

A halo device may be used initially with traction, or may be applied after removal of the tongs. It consists of a stainless-steel halo ring that is fixed to the skull by four pins. The ring is attached to a removable halo vest, a device that suspends the weight of the unit circumferentially around the chest. A metal frame connects the ring to the chest. Halo devices provide immobilization of the cervical spine while allowing early ambulation (Fig. 45-6). Refer to Chapter 42 for nursing responsibilities related to pin care.

FIGURE 45-6 Halo vest.

Thoracic and lumbar injuries are usually treated with surgical intervention followed by immobilization with a fitted brace. Traction is not indicated either before or after surgery, due to the relative stability of the spine in these regions.

Surgical Management

Surgery is indicated in any of the following instances:

- Compression of the cord
- Fragmented or unstable vertebral body
- Penetrating wound to the spinal cord
- Bone fragments in the spinal canal
- Deterioration of the patient's neurologic status

Surgery is performed to decompress the spinal cord, reduce the spinal fracture or dislocation, or to stabilize the spinal column. Laminectomy is the most common surgical procedure used to decompress or stabilize the spinal column. A laminectomy involves excision of the lamina (a portion of the posterior arch) and spinous processes of a vertebra. Various techniques (i.e., fusion or fixation) are used to create a stable spinal column (Hickey, 2014).

Monitoring and Managing Acute Complications of Spinal Cord Injury

Spinal and Neurogenic Shock

The spinal shock associated with SCI reflects a sudden depression of reflex activity in the spinal cord (areflexia) below the level of injury. The muscles innervated by the part of the spinal cord segment below the level of the lesion are without sensation, paralyzed, and flaccid. In particular, the reflexes that initiate bladder and bowel function are affected. Bowel distention and paralytic ileus can be caused by depression of the reflexes and are treated with intestinal decompression by insertion of a nasogastric tube (Hickey, 2014).

Neurogenic shock develops due to the loss of autonomic nervous system function below the level of the lesion (Hickey, 2014). The vital organs are affected, causing the blood pressure and heart rate to decrease. This loss of sympathetic innervation causes a variety of other clinical manifestations, including a decrease in cardiac output, venous pooling in the extremities, and peripheral vasodilation, resulting in mild hypotension, bradycardia, and warm skin. In addition, the patient does not perspire on the paralyzed portions of the body because sympathetic activity is blocked; therefore, close observation is required for early detection of an abrupt onset of fever. Further details on neurogenic shock may be found in Chapter 54.

Deep Vein Thrombosis

Thrombophlebitis, inflammation of a vein related to deep vein thrombosis (DVT), is a relatively common potential complication of immobility and is common in patients with SCI (Chung, Lin, Chang, Sung, & Kao, 2014). DVT occurs in a high percentage of patients with SCI, placing them at risk for pulmonary embolism (PE), which is the third most common cause of death in patients with SCI (Chung et al., 2014). The patient must be assessed for symptoms of both DVT and PE. A low-grade fever may be the first sign of DVT. Manifestations of PE include pleuritic chest pain, anxiety, and shortness of breath.

Thigh and calf measurements should be made daily at consistent sites. The patient is evaluated for the presence of DVT if the circumference of one extremity increases significantly. Diagnostic studies used to detect DVT and PE include Doppler ultrasound, radiocontrast venography, ventilation/perfusion lung scans (Hickey, 2014), a computed tomographic pulmonary angiography (CTPA) (Weitz, 2016), or spiral CT.

Anticoagulation therapy to prevent DVT and PE is initiated once head injury and other

systemic injuries have been ruled out and there is low risk for bleeding. There is strong evidence to support the use of low–molecular-weight heparin as well as unfractionated heparin. This may be followed by long-term oral anticoagulation with a vitamin K antagonist (i.e., warfarin) or subcutaneous fractionated heparin injections (Chung et al., 2014). In a review of the literature on treatments for thromboembolism, low–molecular-weight heparin was shown to be more effective at preventing DVT and had fewer bleeding complications than fractionated heparin. However, full-dose enoxaparin should be used with caution as it can lead to compartment syndrome and even limb amputation (Yeung & Formal, 2015). Anticoagulant therapy should be continued for at least 6 to 12 weeks after injury.

Nonpharmacologic measures, including elastic compression stockings or pneumatic compression devices, as well as range-of-motion exercises, are important preventive measures that work to reduce venous pooling and promote venous return. Compression devices should be used for 2 weeks following injury. In some cases, permanent indwelling filters may be placed in the vena cava to prevent emboli (dislodged clots) from migrating to the lungs and causing PE in patients who have developed clots despite receiving anticoagulation (Sarosiek, Crowther, & Sloan, 2013).

Orthostatic Hypotension

For the first 2 weeks following SCI, blood pressure tends to be unstable and quite low. It gradually returns to preinjury levels, but periodic episodes of severe orthostatic hypotension frequently interfere with efforts to mobilize the patient. Orthostatic hypotension is defined as a drop in systolic blood pressure of at least 20 mm Hg or a drop in diastolic pressure of at least 10 mm Hg, regardless of the patient's symptoms (Shen, Huang, Yuan, Zhang, & Li, 2014). Patients with SCI are prone to orthostatic hypotension during position changes due to a loss of reflex vasoconstriction and pooling of blood in the lower extremities and abdominal viscera. This results in decreased venous return to the heart and decreased cardiac output. To compensate, patients develop reflex tachycardia, although this is rarely sufficient to raise blood pressure enough to return to normal levels (Shen et al., 2014). Orthostatic hypotension is a particularly common problem for patients with lesions above T7 and those with tetraplegia (Hickey, 2014).

A number of techniques can be used to reduce the frequency of hypotensive episodes. Close monitoring of vital signs before and during position changes is essential. Vasopressor medication can be used to treat the profound vasodilation. Elastic compression stockings should be applied to improve venous return from the lower extremities. Abdominal binders may also be used to encourage venous return and provide diaphragmatic support when the patient is upright. Activity should be planned in advance, and adequate time should be allowed for a slow progression of position changes from recumbent to sitting and upright.

Autonomic Dysreflexia

Autonomic dysreflexia, also known as autonomic hyperreflexia, sympathetic storming, or autonomic dysfunction syndrome (ADS), is an acute emergency that occurs as a result of exaggerated autonomic responses to stimuli that are harmless in normal people. It only occurs after spinal shock has resolved in patients with cord lesions above T6. This syndrome is characterized by a severe, pounding headache with paroxysmal hypertension,

profuse diaphoresis (most often of the forehead), nausea, nasal congestion, and bradycardia (Hickey, 2014). The sudden increase in blood pressure may cause a rupture of one or more cerebral blood vessels or lead to increased ICP. Autonomic dysreflexia is more commonly seen in patients with complete SCIs and in the chronic stages of SCI (Richa, 2014).

A number of stimuli may trigger this reflex: distended bladder (the most common cause); distention or contraction of the visceral organs, especially the bowel (from constipation, impaction); or stimulation of the skin (tactile, pain, thermal stimuli, pressure ulcer). Because this is an emergency situation, the objectives are to remove the triggering stimulus and to avoid the potentially serious complications.

The following measures are carried out:

- The head of the bed is raised, and the patient is placed immediately in a sitting position to lower blood pressure.
- Rapid assessment is performed to identify and alleviate the cause.
- The bladder is emptied immediately via a urinary catheter. If an indwelling catheter is not patent, it is irrigated or replaced with another catheter.
- The rectum is examined for a fecal mass. If one is present, a topical anesthetic such as lidocaine may be inserted 10 to 15 minutes before the mass is removed because visceral distention or contraction can worsen autonomic dysreflexia. The nurse observes for symptoms of flushing, sweating, nasal congestion, and headache while performing a digital examination and ceases the procedure if symptoms appear and assesses blood pressure.
- The skin is examined for any areas of pressure, irritation, or broken skin.
- Any other stimulus that could be the triggering event, such as an object next to the skin or a draft of cold air, must be removed.
- If these measures do not relieve the hypertension and excruciating headache, a ganglionic blocking agent (hydralazine hydrochloride [Apresoline]) is prescribed and administered slowly by the IV route.
- The medical record or chart is labeled with a clearly visible note about the risk for autonomic dysreflexia.
- The patient is instructed about prevention and management measures.
- Any patient with a lesion above the T6 segment is informed that such an episode is possible and may occur even years after the initial injury.

NURSING PROCESS

The Patient with Acute Spinal Cord Injury

ASSESSMENT

The breathing pattern is observed, the strength of the cough is assessed, and the lungs are auscultated because paralysis of abdominal and respiratory muscles diminishes coughing and makes clearing of bronchial and pharyngeal secretions difficult.

The patient is monitored closely for any changes in motor or sensory function and for symptoms of progressive neurologic damage. In the early stages of SCI, determining whether the cord has been severed may be very difficult because signs and symptoms of cord edema are indistinguishable from those of cord transection. Edema of the spinal cord may occur with any severe cord injury and may further compromise spinal cord function.

Motor and sensory functions are assessed through careful neurologic examination. These findings are usually recorded on a flow sheet so that changes in the baseline neurologic status can be monitored closely and accurately. The ASIA classification is commonly used to describe level of function for SCI patients. Box 45-10 gives examples of the effects of altered spinal cord function. At the minimum:

- Motor ability is tested by asking the patient to spread the fingers, squeeze the examiner's hand, and move the toes or turn the feet.
- Sensation is evaluated by gently pinching the skin or touching it lightly with an object such as a tongue blade, starting at shoulder level and working down both sides of the extremities. The patient should have both eyes closed so that the examination reveals true findings, not what the patient hopes to feel. The patient is asked where the sensation is felt.
- Any decrease in neurologic function is reported immediately.

The patient is also assessed for spinal shock, urinary retention, overdistention of the bladder, and paralytic ileus.

DIAGNOSIS

NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Ineffective breathing patterns related to weakness or paralysis of abdominal and intercostal muscles and inability to clear secretions
- Ineffective airway clearance related to weakness of intercostal muscles
- Impaired bed and physical mobility related to motor and sensory impairments
- Disturbed sensory perception related to motor and sensory impairment
- Risk for impaired skin integrity related to immobility and sensory loss
- Impaired urinary elimination related to inability to void spontaneously
- Constipation related to presence of atonic bowel as a result of autonomic disruption
- Acute pain and discomfort related to treatment and prolonged immobility

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Potential complications that may develop in patients with SCI include:

- DVT/PE (thrombophlebitis)
- Orthostatic hypotension
- Autonomic dysreflexia

PLANNING AND GOALS

The goals for the patient may include improved breathing pattern and airway clearance, improved mobility, improved sensory and perceptual awareness, maintenance of skin integrity, relief of urinary retention, improved bowel function, promotion of comfort, and absence of complications.

NURSING INTERVENTIONS

PROMOTING ADEQUATE BREATHING AND AIRWAY CLEARANCE

Oxygen is administered to maintain a normal saturation level because hypoxemia can create or worsen a neurologic deficit of the spinal cord. If endotracheal intubation is necessary, extreme care is taken to avoid flexing or extending the patient's neck, which can result in extension of a cervical injury.

Possible impending respiratory failure is detected by observing the patient, noting rate and depth of respirations, assessing lung sounds, accessory muscle use, monitoring oxygen saturation through pulse oximetry, and monitoring arterial blood gas values. Early and vigorous attention to clearing bronchial and pharyngeal secretions can prevent retention of secretions and atelectasis. Suctioning may be indicated, but caution must be used because this procedure can stimulate the vagus nerve, producing bradycardia, which can result in cardiac arrest.

If the patient cannot cough effectively because of decreased inspiratory volume and inability to generate sufficient expiratory pressure, chest physical therapy and assisted coughing may be indicated.

IMPROVING MOBILITY

Proper body alignment is maintained at all times. The patient is repositioned frequently and is assisted out of bed as soon as the spinal column is stabilized. The feet are prone to footdrop; therefore, various types of splints are used to prevent it. When used, the splints are removed and reapplied every 2 hours. Trochanter rolls, applied from the crest of the ileum to the midthigh of both legs, help prevent external rotation of the hip joints.

Patients with lesions above the midthoracic level have loss of sympathetic control of peripheral vasoconstrictor activity, leading to hypotension. These patients may tolerate changes in position poorly and require monitoring of blood pressure when positions are changed. Usually, the patient is turned every 2 hours by log rolling. Log rolling ensures proper spinal alignment during turning of the patient. The patient should not be turned

unless the spine is stable and the provider has indicated that it is safe to do so.

Contractures develop rapidly with immobility and muscle paralysis. A joint that is immobilized too long becomes fixed as a result of contractures of the tendon and joint capsule. Atrophy of the extremities results from disuse. Contractures and other complications may be prevented by range-of-motion exercises that help preserve joint motion and stimulate circulation. Passive range-of-motion exercises should be implemented as soon as possible after injury.

PROMOTING ADAPTATION TO SENSORY AND PERCEPTUAL ALTERATIONS

The nurse assists the patient to compensate for sensory and perceptual alterations that occur with SCI. The intact senses above the level of the injury are stimulated through touch, aromas, flavorful food and beverages, conversation, and music. Additional strategies include the following:

- Providing prism glasses to enable the patient to see from the supine position
- Encouraging use of hearing aids, if indicated, to enable the patient to hear conversations and environmental sounds
- Providing emotional support to the patient
- Teaching the patient strategies to compensate for or cope with these deficits

MAINTAINING SKIN INTEGRITY

Because patients with SCI are immobilized and have loss of sensation below the level of the lesion, they have the highest prevalence of pressure ulcers in the United States. Up to 66% of patients with spinal cord disorders will develop pressure ulcers. Patients with higher-level SCIs are more likely to develop pressure ulcers than patients with lower-level SCIs (Kruger, Pires, Ngann, Sterling, & Rubayi, 2013). The most common sites for pressure ulcers are over the ischial tuberosity, the greater trochanter, the sacrum, the gluteal region, and the occiput (back of the head). Patients who wear cervical collars for prolonged periods may develop breakdown from the pressure of the collar under the chin, on the shoulders, and at the occiput. The nurse follows institutional policy regarding collar care, which typically may require changing of pads every 24 hours and inspecting and cleaning the skin every shift. In patients with SCI, pressure-relieving cushions (e.g., Roho wheelchair cushions) and bed support surfaces are used to lessen the risk of developing pressure ulcer. The nurse is aware that doughnut-shaped devices are NOT to be used because of the reduced blood flow associated with them.

The patient is repositioned every 2 hours, and careful inspection of the skin is made every time the patient is turned. The skin over pressure points is assessed for redness or breakdown. The patient's skin should be kept clean by washing with a mild soap, rinsing well, and blotting dry. Pressure-sensitive areas should be kept well-lubricated and soft with hand cream or lotion.

MAINTAINING URINARY ELIMINATION

Immediately after SCI, the urinary bladder may become atonic and is unable to contract by reflex activity. Urinary retention typically results. Because the patient has no sensation of bladder distention, overstretching of the bladder and detrusor muscle may occur, delaying the return of bladder function.

Intermittent catheterization is carried out to avoid overdistention of the bladder and UTI. If this is not feasible, an indwelling catheter is inserted temporarily. At an early stage, family members are shown how to carry out intermittent catheterization and are encouraged to participate in this facet of care because they will be involved in long-term follow-up and must be able to recognize complications so that treatment can be instituted.

The patient is taught to record fluid intake, voiding pattern, characteristics of urine, and any unusual sensations that may occur. The management of a neurogenic bladder (bladder dysfunction that results from a disorder or dysfunction of the nervous system) is discussed in detail in Chapter 28.

IMPROVING BOWEL FUNCTION

Immediately after SCI, a paralytic ileus may develop due to neurogenic paralysis of the bowel; therefore, a nasogastric tube is often required to relieve distention and to prevent vomiting and aspiration.

Bowel activity usually returns within the first week following the injury. As soon as bowel sounds are heard on auscultation, the patient is given a high-calorie, high-protein, high-fiber diet, with the amount of food gradually increased. The nurse administers prescribed stool softeners to counteract the effects of immobility and analgesic agents. A bowel regimen is instituted as early as possible. The types of bowel dysfunction most commonly seen in patients with SCI are constipation, fecal incontinence, and fecal impaction. Of these, fecal impaction is the most common and is reported in about 39% of patients (Pan, Liu, Li, Zhang, & Lu, 2014).

PROVIDING COMFORT MEASURES

A patient who has had pins, tongs, or calipers placed for cervical stabilization may have a headache or discomfort for several days after the pins are inserted. Patients initially may be bothered by the rather startling appearance of these devices, but usually they readily adapt to it because the device provides comfort for the unstable neck. The patient may complain of being caged in and of noise created by any object coming in contact with the steel frame of a halo device, but he or she can be reassured that adaptation to this will occur.

The areas around the four pin sites of a halo device are cleaned daily and observed for redness, drainage, and pain. The pins are observed for loosening, which may contribute to infection. If one of the pins becomes detached, the head is stabilized in a neutral position by one person, while another notifies the neurosurgeon. A torque screwdriver should be readily available in case the screws on the frame need tightening.

The skin under the halo vest is inspected for excessive perspiration, redness, and skin blistering, especially on the bony prominences. The vest is opened at the sides to allow the torso to be washed. The liner of the vest should not become wet because dampness causes skin excoriation. The liner should be changed periodically to promote hygiene and good skin care. If the patient is to be discharged with the vest, detailed instructions must be given to the family, with time allowed for them to demonstrate the necessary skills of halo vest care.

PROMOTING HOME AND COMMUNITY-BASED CARE

Teaching Patient Self-Care. In most cases, patients with SCI (i.e., patients with tetraplegia or paraplegia) need long-term rehabilitation. The process begins during hospitalization, as acute symptoms begin to subside or come under better control and the overall deficits and long-term effects of the injury become clear. The goals begin to shift from merely surviving the injury to learning strategies necessary to cope with the alterations that the injury imposes on activities of daily living (ADLs). The emphasis shifts from ensuring that the patient is stable and free of complications to specific assessment and planning designed to meet the patient's rehabilitation needs. Patient teaching may initially focus on the injury and its effects on mobility, dressing, and bowel, bladder, and sexual function. As the patient and family acknowledge the consequences of the injury and the resulting disability, the focus of teaching broadens to address issues necessary for carrying out the tasks of daily living and taking charge of their lives. Teaching begins in the acute phase and continues throughout rehabilitation. Interventions are aimed at increasing function, improving adjustment, increasing social integration, and reducing social stigma (Delparte, Chau, Mills, & Burns, 2014).

Caring for the patient with SCI at home may at first seem a daunting task to the family. They will require dedicated nursing support to gradually assume full care of the patient. Although maintaining function and preventing complications will remain important, goals regarding self-care and preparation for discharge will assist in a smooth transition to rehabilitation and eventually to the community.

Continuing Care. The ultimate goal of the rehabilitation process is independence. The nurse becomes a support to both the patient and the family, assisting them to assume responsibility for increasing aspects of patient care and management. Care for the patient with SCI involves members of all the health care disciplines, which may include nursing, medicine, rehabilitation, respiratory therapy, physical and occupational therapy, case management, and social services. The nurse often serves as coordinator of the management team and as a liaison with rehabilitation centers and home care agencies (Hickey, 2014). The patient and family often require assistance in dealing with the psychological impact of the injury and its consequences; referral to a psychiatric clinical nurse specialist or other mental health care professional is often helpful. Box 45-12 discusses the higher incidence in depression with SCI and recognition of the importance of assessment of the patient's psychological state early in the rehabilitative process, as early

intervention improves long-term patient satisfaction (Hickey, 2014).

As more patients survive acute SCI, they face the changes associated with aging with a disability. Therefore, teaching in the home and community focuses on health promotion and addresses the need to minimize risk factors that increase the risk of mortality. Some risk factors that have been identified include cardiovascular disease, diabetes, psychiatric disorders, and alcohol or substance abuse (Hwang, Zebracki, Chlan, & Vogel, 2014). Home care nurses and others who have contact with patients with SCI are in a position to teach patients about healthy lifestyles, remind them of the need for health screenings, and make referrals as appropriate. Assisting patients to identify accessible health care providers, clinical facilities, and imaging centers may increase the likelihood that they will participate in health screening (van Wyk, Backwell, & Townson, 2015).

EVALUATION

EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Demonstrates improvement in gas exchange and clearance of secretions, as evidenced by normal breath sounds on auscultation:
    a. Breathes easily without shortness of breath
    b. Performs hourly deep-breathing exercises, coughs effectively, and clears pulmonary secretions
    c. Is free of respiratory infection (i.e., has normal temperature, respiratory rate, and pulse, normal breath sounds, absence of purulent sputum)
2. Moves within limits of the dysfunction and demonstrates completion of exercises within functional limitations
3. Demonstrates adaptation to sensory and perceptual alterations:
    a. Uses assistive devices (i.e., prism glasses, hearing aids, computers) as indicated
    b. Describes sensory and perceptual alterations as a consequence of injury
4. Demonstrates optimal skin integrity:
    a. Exhibits normal skin turgor; skin is free of reddened areas or breakdown
    b. Participates in skin care and monitoring procedures within functional limitations
5. Regains control of urinary bladder function:
    a. Exhibits no signs of UTI (i.e., has normal temperature; voids clear, dilute urine)
    b. Has adequate fluid intake
    c. Participates in bladder training program within functional limitations
6. Regains control of bowel function:
    a. Reports regular pattern of bowel movement
    b. Consumes adequate dietary fiber and oral fluids
    c. Participates in bowel training program within functional limitations
7. Reports absence of pain and discomfort

8. Is free of complications:
    a. Demonstrates no signs of DVT or PE
    b. Exhibits no manifestations of PE (i.e., no chest pain or shortness of breath; arterial blood gas values are within normal limits)
    c. Maintains blood pressure within normal limits
    d. Reports no lightheadedness with position changes
    e. Exhibits no manifestations of autonomic dysreflexia (i.e., absence of headache, diaphoresis, nasal congestion, or bradycardia)

BOX 45-12 Nursing Research

Bridging the Gap to Evidence-Based Practice

Williams, R., & Murray, A. (2015). Prevalence of depression after spinal cord injury: A meta-analysis. *Archives of Physical Medicine and Rehabilitation*, *96*(1), 133–140.

Purpose

To use meta-analysis to synthesize point prevalence estimates of depressive disorder diagnoses for people who have sustained a spinal cord injury (SCI).

Design

Data Sources searched PsycINFO, PubMed, the Cumulative Index to Nursing and Allied Health Literature (CINAHL), and Dissertation Abstracts International (DAI) for studies examining depression after SCI through 2013. A manual search of the reference sections of included studies was also completed. Nineteen studies, containing 35,676 subjects and 21 effect size estimates, were included in this meta-analysis. All the studies contained people with SCI; used a diagnostic measure of depression (i.e., an unstructured, semi-structured, or structured clinical interview, and/or a clinician diagnosis); and provided a diagnosis of major or minor depressive episodes for the subjects in the study.

Findings

The mean prevalence estimate of depression diagnosis after SCI was 22.2%, with a lower-bound estimate of 18.7% and an upper-bound estimate of 26.3%. Data collection method, *Diagnostic and Statistical Manual of Mental Disorders* version, and diagnostic composition significantly predicted variation in observed effect size estimates, with primary data collection studies having lower estimates compared with secondary data analysis studies; studies using *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition; diagnostic criteria having higher estimates compared with studies using *Diagnostic and Statistical Manual of Mental Disorders*, Third Edition; and samples comprising individuals diagnosed only with major depression having lower prevalence estimates.

Nursing Implications

The existing data on depression after SCI indicate that the prevalence of depression after SCI is substantially greater than that in the general medical population. These results underscore the importance of continued research on measuring depression in

people with SCI and on treatments for depression after SCI. Since nursing is actively involved in patient care, assessment of the patient's psychological state and referral is crucial as early intervention improves long-term patient satisfaction.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 70-year-old patient was brought to the emergency department after he fell and hit his head and was unconscious for about 2 minutes. He now seems alert and oriented. What type of injury has he most likely sustained? What discharge instructions are warranted for this patient's family or caregiver? How would you modify your discharge instructions if the patient lives alone?

2. Your 25-year-old patient with a TBI has early signs of increased ICP. Describe the medical management you would anticipate to control the ICP and the nursing measures that are indicated. How would you determine whether your interventions were effective in alleviating the increased ICP? What is the evidence base for these interventions?

3. A 47-year-old man with paraplegia secondary to SCI, diabetes, and obesity is admitted. For what complications is he at risk? What interventions would be appropriate to prevent these complications?

NCLEX-Style Review Questions

1. The nurse assesses the LOC of a patient who suffered a head injury and determines that the patient's GCS score is 15. Which of the following responses did the nurse assess to determine the GCS score? *Select all that apply.*
   a. Spontaneous eye opening
   b. Tachycardia, hypotension, bradycardia
   c. Ability to follow commands
   d. Unequal pupil size
   e. Orientation to person, place, and time

2. A patient sustained a C6 SCI 4 hours ago. What nursing diagnosis is a priority?
   a. Urinary retention
   b. Risk for impaired skin integrity
   c. Ineffective breathing pattern
   d. Powerlessness

3. The nurse notices clear fluid draining from the nose of a patient who sustained a head injury 2 hours ago. This may indicate the presence of what condition?
   a. Cerebral concussion
   b. Basal skull fracture

c. Brain tumor
d. Sinus infection

4. A patient is admitted with a closed head injury that was sustained in a motorcycle accident. The patient has been showing an upward trend in ICP measurements. What is the first priority action that the nurse should take with this patient?
   a. Administer 100 mg of IV pentobarbital as ordered
   b. Increase the ventilator settings to a respiratory rate of 20 breaths/min
   c. Administer 20 g of IV mannitol as ordered
   d. Reposition the patient to avoid neck flexion

5. Which interventions should the nurse's plan of care include to help prevent autonomic dysreflexia in a patient with SCI? *Select all that apply*.
   a. Check for fecal impactions.
   b. Monitor blood pressure for hypotension.
   c. Check the urinary drainage system for any obstruction.
   d. Monitor bowel movements.
   e. Instruct the patient to wear a medic alert bracelet.

Nursing Management: Patients with Neurologic Disorders

Cynthia Bautista

Learning Objectives

After reading this chapter, you will be able to:

1. Identify the various types and causes of seizures.
2. Use the nursing process to develop a plan of care for the patient experiencing seizures.
3. Differentiate among the infectious disorders of the nervous system according to causes, manifestations, medical care, and nursing management.
4. Describe the pathophysiology, clinical manifestations, and medical and nursing management of multiple sclerosis, myasthenia gravis, and Guillain–Barré syndrome.
5. Describe neuromuscular disorders and their manifestations and indicated nursing interventions.
6. Use the nursing process as a framework for care of patients with degenerative neurologic disorders.

SEIZURE DISORDERS

SEIZURES, EPILEPSY, AND STATUS EPILEPTICUS

Seizures are abnormal discharges in the brain for a single event of which results in an abrupt and temporary altered cerebral function state (England & Plueger, 2014). A part or all of the brain may be involved. The term *ictal* refers to an actual seizure or *ictal event.*

Epilepsy is a disease that meets any of the following conditions: (1) at least two unprovoked seizures occurring more than 24 hours apart; (2) one unprovoked seizure and probability of further seizures; (3) diagnosis of an epilepsy syndrome (Fisher et al., 2014). Epileptic syndromes are classified by specific patterns of clinical features, including age at onset, family history, and seizure type.

Status epilepticus is continuous seizure activity for more than 5 minutes or two or more sequential seizures without full recovery of consciousness between seizures (England & Plueger, 2014). Seizures that last longer than 5 to 10 minutes are less likely to stop without intervention. Status epilepticus is a neurologic emergency and can be life-threatening.

Nursing Alert

Not all seizures imply epilepsy. Although seizures are the cardinal symptom of epilepsy, seizures also occur as a manifestation of an underlying treatable problem, such as hyponatremia or high fever. Once the cause is identified and treated, the seizures cease. Epilepsy is a disease, and refers to recurrent, unpredictable, and unprovoked seizures.

Pathophysiology of Seizures

Messages from the body are carried by the neurons (nerve cells) of the brain by means of discharges of electrochemical energy that sweep along them. These impulses occur in bursts whenever a nerve cell has a task to perform. Sometimes, these cells or groups of cells continue firing after a task is finished. During the period of unwanted discharges, parts of the body controlled by the errant cells may perform erratically. Seizures require three conditions: (1) excitable neurons; (2) increase in excitatory glutaminergic activity (relates to the action of glutamate or to neural or metabolic pathways in which it functions as a transmitter) through recurrent connections to spread the discharge; and (3) reduction in activity of normal inhibitory GABA projection (GABA is an amino acid that is the major inhibitory neurotransmitter in the vertebrate gray matter) (England & Plueger, 2014). When there is an imbalance between inhibition and excitation within the central nervous system (CNS), seizures occur.

Nursing Alert

Anyone can have a seizure. Although we all have a unique threshold for seizures, an imbalance in that threshold can provoke a seizure. In fact, 10% of Americans will have a seizure in their lifetime. It is a matter of imbalance in excitatory activity in the CNS or a reduction in inhibitory activity.

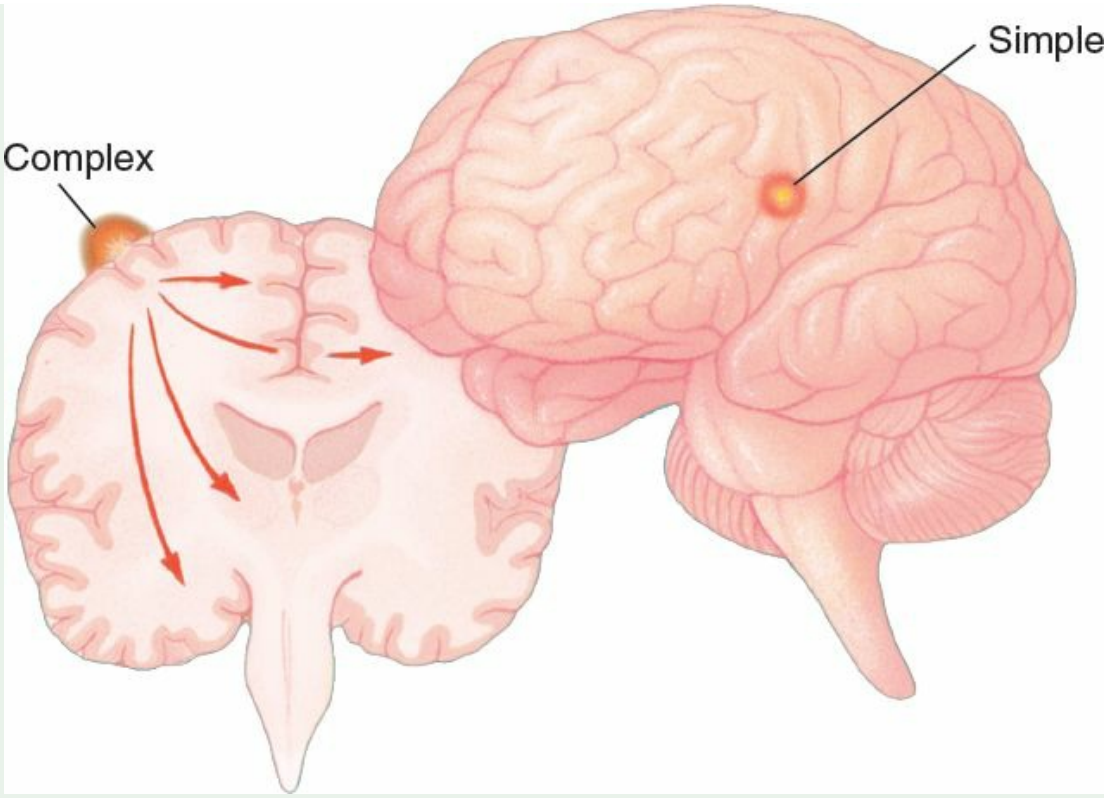
BOX 46-1 Classification of Seizures

Focal Seizures (seizure activity starts in one area of the brain)

- *Focal*—retains awareness: There is no impairment of consciousness, similar to simple partial seizures, may have movement of body parts, may experience an aura.
- *Focal*—altered awareness: There is impairment of consciousness, similar to complex partial seizures, this can spread to both hemispheres of brain.

Partial Seizures

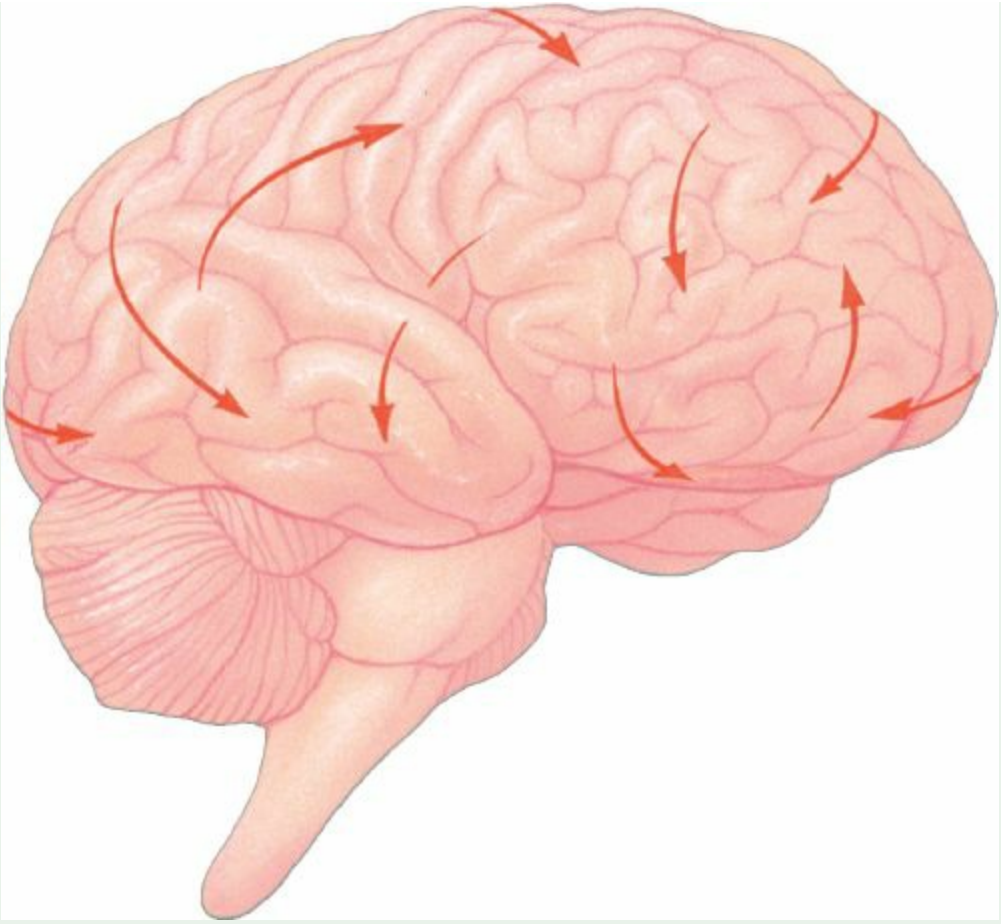
These seizures begin in a part of one hemisphere, generally in the temporal or frontal lobe. The two types of partial seizures, called simple and complex, are based on whether a person remains fully conscious during a seizure.



Unknown Seizures (insufficient evidence to classify as focal, generalized, or both)

Generalized Seizures (seizure activity involves both hemispheres of the brain)

Generalized Seizures
These seizures affect both hemispheres of the brain at the same time. Abnormal activity is not focused in one specific area and there generally is no aura at the start.



- *Tonic–clonic seizures:* Generalized seizures that affect the entire brain; they begin with rigidity (tonic phase), followed by repetitive clonic activity of all extremities characterized by stiffening or jerking of the body.
- *Tonic seizures:* Seizures characterized by muscle stiffening, dilation of the pupils, and altered respiratory patterns; the body becomes stiff and the person may fall backward. The seizure usually lasts less than 1 minute, and recovery is rapid.
- *Clonic seizures:* Characterized by jerking movements, which involve muscles on both sides of the body
- *Absence seizures:* Short episodes of staring and loss of awareness
- *Atonic seizures:* Sudden loss of muscle tone, resulting in falls or a "drop" to the ground, with rapid recovery
- *Myoclonic seizure:* Characterized by jerking (myoclonic) movements of a muscle or muscle group, without loss of consciousness

The international classification of seizures differentiates between two main types: focal or partial seizures, which begin in one part of the brain, and generalized seizures, which involve electrical discharges in the whole brain (see Box 46-1). However, it is understood that not all seizures or syndromes fit neatly into these classifications, and patients may have more than one type of seizure.

The specific causes of seizures are varied and can be categorized as idiopathic (genetic, developmental defects) and acquired. Causes of acquired seizures include:

- Cerebrovascular disease
- Hypoxemia of any cause, including vascular insufficiency
- Fever (childhood)
- Head injury
- Hypertension
- CNS infections
- Metabolic and toxic conditions (e.g., kidney failure, hyponatremia, hypocalcemia, hypoglycemia, pesticides)
- Brain tumor
- Drug and alcohol withdrawal; drug toxicity
- Allergies
- Alzheimer disease (see discussion later in this chapter on pp. 1343–1347)

Clinical Manifestations and Assessment

The initial pattern of the seizures indicates the region of the brain in which the seizure originates (see Box 46-1). In focal seizures in which the patient retains awareness, only a finger or hand may shake, or the mouth may jerk uncontrollably. The person may talk unintelligibly, may be dizzy, and may experience unusual or unpleasant sights, sounds, odors, or tastes but without loss of consciousness.

In focal seizures with altered awareness, the person either remains motionless or moves automatically but inappropriately for time and place, or he or she may experience excessive emotions of fear, anger, elation, or irritability. Whatever the manifestations, the person does not remember the episode when it is over.

Generalized seizures involve both hemispheres of the brain, causing both sides of the body to react. Intense rigidity of the entire body may occur, followed by alternating muscle relaxation and contraction (generalized tonic–clonic contraction). The simultaneous contractions of the diaphragm and chest muscles may produce a characteristic epileptic cry. The patient may chew the tongue or bite the inner cheek, and the patient may be incontinent of urine and feces. After 1 or 2 minutes, the convulsive movements begin to subside; the patient relaxes and lies in deep coma, breathing noisily. The respirations at this point are chiefly abdominal. In the postictal (after the seizure) state, the patient is often confused and hard to arouse and may sleep for hours. Many patients report headache, sore muscles, extremity weakness, fatigue, and depression (Bazil & Pedley, 2015).

A medical history is taken, including previous seizure history, alcohol and drug use, medication use, allergy status, and family history. The patient is also questioned about illnesses or head injuries that may have affected the brain. Women should be questioned about their last menstrual period (increase in seizure frequency is noted during menses) and pregnancy status (fetal anomaly is two times higher in women taking antiepileptic medications). The patient is asked about common triggers associated with seizures, which can be olfactory (particular odors), visual (flashing lights), or auditory (certain types of music) in nature, or related to fatigue, sleep deprivation, hypoglycemia, emotional stress, electrical shock, febrile illness, alcohol consumption, certain drugs, drinking too much water, constipation, and hyperventilation (England & Plueger, 2014).

In addition to physical and neurologic evaluations, diagnostic examinations include biochemical, hematologic, and serologic studies. Imaging studies, such as magnetic resonance imaging (MRI), computed tomography (CT) scan, single-photon emission computed tomography (SPECT), and positron emission tomography (PET) may be used to detect lesions, such as focal abnormalities, cerebrovascular abnormalities, and cerebral degenerative changes (Nettina, 2014). The SPECT is useful for identifying the epileptogenic zone so that the area in the brain giving rise to seizures can be removed surgically.

The EEG furnishes diagnostic evidence for a substantial proportion of patients with epilepsy and assists in classifying the type of seizure (Nettina, 2014). Abnormalities in the EEG usually continue between seizures or, if not apparent, may be elicited by hyperventilation or during sleep. Microelectrodes (depth electrodes) can be inserted deep in the brain to probe the action of single brain cells. Some people with clinical seizures have normal EEGs, whereas others who have never had seizures have abnormal EEGs. Telemetry

and computerized equipment are used to monitor electrical brain activity while the patient pursues his or her normal activities and to store the readings on computer tapes for analysis. Video recording of seizures taken simultaneously with EEG telemetry is useful in determining the type of seizure as well as its duration and magnitude.

Medical and Nursing Management

The goals of treatment are to stop the seizures as quickly as possible, to ensure adequate cerebral oxygenation, and to maintain the patient in a seizure-free state. In the case of prolonged seizures, as in status epilepticus, the nurse recalls the standard ABCs (airway, breathing, and circulation) of emergency management. An airway and adequate oxygenation are established if the patient shows signs of airway obstruction. Oxygen is administered as ordered via nasal cannula, or intubation may be required, and oxygen is administered via the artificial airway and monitored by pulse oximetry. Suctioning of the airway may also be required. An IV line is established, and IV lorazepam (Ativan), diazepam (Valium), or midazolam (Versed) is administered slowly in an attempt to halt seizures immediately. The IV line is closely monitored because it may become dislodged during seizures. Antiepileptic drugs (AEDs) (levetiracetam, phenytoin, phenobarbital) are administered later to maintain a seizure-free state. In general, a single drug is used to control the seizures. Termed *monotherapy*, the selected drug is determined by the type of seizure, and the dose is increased until symptoms resolve, maximal dose is required, or signs of drug toxicity emerge, at which time alternative therapeutic agents are considered.

Nursing Alert
Phenytoin (Dilantin), if ordered intravenously, must be administered slowly because of its effect on the myocardium and the potential for arrhythmia development. In addition, it is irritating to the vein; thus, the nurse observes for the development of phlebitis. The rate of administration is no faster than 50 mg/min in normal saline solution, since the drug precipitates in D_5W. If the pre-existing solution contained dextrose, the nurse flushes the IV line with normal saline before administering the medication. Many AEDs are highly bound to plasma protein, and the nurse is aware that only the unbound, or "free," serum concentration is available for use by the body. Patients on high-protein tube feedings (see Chapter 22) may require higher dosages to maintain therapeutic blood levels, while those with hypoalbuminemia because of malnutrition, burns, or liver or kidney disease may require alternative dosing to prevent phenytoin toxicity. Therapeutic range for phenytoin is 10 to 20 mg/L (Lassiter & Henkel, 2014).

Blood samples are obtained to monitor serum electrolytes, glucose, blood cell count, and toxicology/drug screen, and levels of drugs, such as phenobarbital or phenytoin, may be monitored if the patient has been treated with the medication. If the serum concentration of the AED is below therapeutic levels, it suggests that the patient was not taking the medication, the dosage was too low, or factors such as pharmacokinetics of the medication may be involved. EEG monitoring may be useful in determining the nature of the seizure activity. Vital signs and neurologic signs are monitored on a continuing basis. An IV infusion of dextrose is administered if the seizure is caused by hypoglycemia. If initial treatment is unsuccessful, general anesthesia with a short-acting barbiturate may be used. Cardiac involvement or respiratory depression may be life-threatening. The potential for postictal cerebral edema also exists. This varies in clinical presentation and may include deterioration in neurologic signs, ranging from drowsiness to coma, as well as nausea,

vomiting, sluggish pupillary response, cardiac arrhythmias, and altered respiratory patterns. The nurse initiates ongoing assessment and monitoring of respiratory and cardiac function because of the risk for delayed depression of respiration and blood pressure secondary to administration of AEDs and sedatives to halt the seizures. Nursing assessment also includes monitoring and documenting the seizure activity and the patient's responsiveness.

A person who has received long-term antiepileptic therapy has a significant risk for fractures resulting from bone disease (osteoporosis, osteomalacia, and hyperparathyroidism), a side effect of therapy. Therefore, during seizures, the patient is protected from injury with the use of seizure precautions, which include placing the bed in a low position, raising the bedside rails, and not letting the patient get up and ambulate without someone's assistance. The patient's room should have suction and oxygen available at the bedside if needed (England & Plueger, 2014). No effort should be made to restrain seizure activity. The patient having seizures can inadvertently injure nearby people, so nurses should protect themselves. Other nursing interventions for the person having seizures are presented in Box 46-2.

During a Seizure

A major responsibility of the nurse is to observe and record the sequence of signs. Before and during a seizure, the patient is assessed and the following items are documented:

- The circumstances before the seizure (visual, auditory, or olfactory stimuli; tactile stimuli; emotional or psychological disturbances; sleep; hyperventilation)
- The occurrence of an aura (a premonitory or warning sensation that can be visual, auditory, gustatory, visceral, or olfactory) that is experienced at the beginning of a seizure and remembered (England & Plueger, 2014)
- The first thing the patient exhibits in the seizure—in what part of the body the movement or stiffness begins, conjugate gaze position (term that denotes both eyes working in unison), and the position of the head at the beginning of the seizure. This information gives clues to the location of the seizure's origin in the brain. (In recording, it is important to state whether the beginning of the seizure was observed).
- The type of movements in the part of the body involved
- The areas of the body involved (turn back bedding to expose patient)
- The size of both pupils and whether the patient's eyes are open
- Whether the patient's eyes or head are/is turned to one side (eyes look away from the side of the seizure)
- The presence or absence of automatisms (involuntary motor activity, such as lip smacking or repeated swallowing)
- Incontinence of urine or stool
- Duration of each phase of the seizure
- Unconsciousness, if present, and its duration
- Any obvious paralysis or weakness of the patient's arms or legs after the seizure
- Inability to speak after the seizure
- Movements at the end of the seizure

- Whether or not the patient sleeps afterward
- Cognitive status (confused or not confused) after the seizure

In addition to providing data about the seizure, nursing care is directed at preventing injury and supporting the patient, not only physically but also psychologically. Steps to prevent or minimize injury are presented in Box 46-2.

After a Seizure

After a patient has a seizure, the nurse's role is to document the events leading to and occurring during and after the seizure and to prevent complications (e.g., aspiration, injury). The patient is at risk for hypoxia, vomiting, and pulmonary aspiration. To prevent complications, the patient is placed in the side-lying position to facilitate drainage of oral secretions, and suctioning is performed, if needed, to maintain a patent airway and prevent aspiration (see Box 46-2). Seizure precautions are maintained, including having available functioning suction equipment with a suction catheter. The bed is placed in a low position with two to three side rails up, if necessary, to prevent injury to the patient. The patient may be drowsy and may wish to sleep after the seizure; he or she may not remember events leading up to the seizure and for a short time thereafter.

Pharmacologic Therapy

Although many medications are available to control seizures, the nurse stresses that the treatment is not curative. The objective is to achieve seizure control with minimal side effects. Medications are selected on the basis of the patient's type of seizure and the effectiveness and safety of the medications. If properly prescribed and taken, medications control seizures in 70% to 80% of patients with seizures (Lowenstein, 2014), although approximately 65% of patients with epilepsy are resistant to AEDs (England & Plueger, 2014). In these situations, surgery may reduce seizure frequency or provide complete seizure control.

BOX 46-2 GUIDELINES FOR NURSING CARE

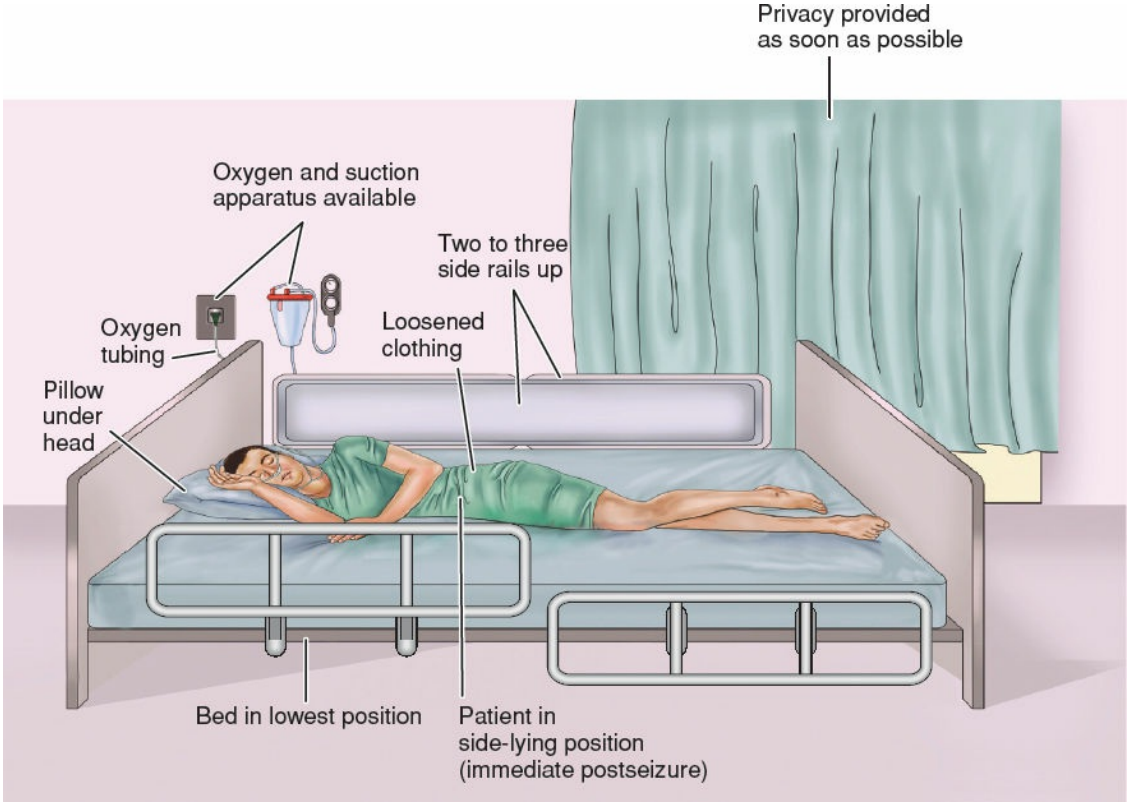
Nursing Care During a Seizure

- Provide privacy and protect the patient from curious onlookers. (The patient who has an *aura* [warning of an impending seizure] may have time to seek a safe, private place.)
- Ease the patient to the floor, if possible.
- Protect the head with a pad to prevent injury (from striking a hard surface).
- Loosen constrictive clothing, remove eyeglasses.
- Push aside any furniture that may injure the patient during the seizure.
- If the patient is in bed, remove extra pillows and raise the side rails.
- *Do not attempt to pry open the patient's jaws if they are clenched in a spasm or to insert anything.* Broken teeth and injury to the lips and tongue may result from such an action.
- No attempt should be made to restrain the patient during the seizure because muscular contractions are strong and restraint can produce injury.

- If possible, place the patient on one side to facilitate drainage of saliva and mucus. If suction is available, use it if necessary to clear secretions.

Nursing Care After the Seizure

- Keep the patient on one side to prevent aspiration. Make sure the airway is patent.
- There is usually a period of confusion after a tonic–clonic seizure.
- A short apneic period may occur during or immediately after a generalized seizure.
- The patient, on awakening, should be reoriented to the environment.
- If the patient becomes agitated after a seizure (postictal), use calm persuasion.



Treatment usually starts with a single medication. The starting dose and the rate at which the dosage is increased depend on the occurrence of side effects. The medication levels in the blood are monitored because the rate of drug absorption varies among patients. Changing to another medication may be necessary if seizure control is not achieved or if toxicity makes it impossible to increase the dosage. The medication may need to be adjusted because of concurrent illness, weight changes, or increases in stress. Stopping these medications without provider's knowledge can cause seizures to occur with greater frequency or can precipitate the development of status epilepticus (England & Plueger, 2014).

TABLE 46-1 Major Antiseizure Medications

Medication	Dose-Related Side Effects	Toxic Effects
Carbamazepine (Tegretol)	Dizziness, drowsiness, unsteadiness, nausea and vomiting, diplopia, mild leukopenia	Severe skin rash, blood dyscrasias, hepatitis
Clonazepam (Klonopin)	Drowsiness, behavior changes, headache, hirsutism, alopecia, palpitations	Hepatotoxicity, thrombocytopenia, bone marrow failure, ataxia
Ethosuximide (Zarontin)	Nausea and vomiting, headache, gastric distress	Skin rash, blood dyscrasias, hepatitis, systemic lupus erythematosus (SLE)
Gabapentin (Neurotonin)	Dizziness, drowsiness, somnolence, fatigue, ataxia, weight gain, nausea	Leukopenia, hepatotoxicity
Lamotrigine (Lamictal)	Drowsiness, tremor, nausea, ataxia, dizziness, headache, weight gain	Severe rash (Stevens-Johnson syndrome)
Levetiracetam (Keppra)	Somnolence, dizziness, fatigue	Unknown
Oxcarbazepine (Trileptal)	Dizziness, somnolence, double vision, fatigue, nausea, vomiting, loss of coordination, abnormal vision, abdominal pain, tremor, abnormal gait	Hepatotoxicity
Phenobarbital (Luminal)	Sedation, irritability, diplopia, ataxia	Skin rash, anemia
Phenytoin (Dilantin)	Visual problems, hirsutism, gingival hyperplasia, arrhythmias, dysarthria, nystagmus	Severe skin reaction, peripheral neuropathy, ataxia, drowsiness, blood dyscrasias
Primidone (Mysoline)	Lethargy, irritability, diplopia, ataxia, impotence	Skin rash
Tiagabine (Gabitril)	Dizziness, fatigue, nervousness, tremor, difficulty concentrating, dysarthria, weak or buckling knees, abdominal pain	Unknown
Topiramate (Topamax)	Fatigue, somnolence, confusion, ataxia, anorexia, depression, weight loss	Nephrolithiasis
Valproate (Depakote, Depakene)	Nausea and vomiting, weight gain, hair loss, tremor, menstrual irregularities	Hepatotoxicity, skin rash, blood dyscrasias, nephritis
Zonisamide (Zonegran, Excegran)	Somnolence, dizziness, anorexia, headache, nausea, agitation, rash	Leukopenia, hepatotoxicity

Side effects of AEDs may be divided into three groups: (1) idiosyncratic or allergic disorders, which manifest primarily as skin reactions; (2) acute toxicity, which may occur when the medication is initially prescribed; and (3) chronic toxicity, which occurs late in the course of therapy.

The manifestations of drug toxicity are variable, and any organ system may be involved. Gingival hyperplasia (swollen and tender gums) can be associated with long-term use of phenytoin (Dilantin), for example (Lassiter & Henkel, 2014). Periodic physical and dental examinations and laboratory tests are performed for patients receiving medications that are known to have hematopoietic, genitourinary, or hepatic effects. Table 46-1 lists the medications in current use.

Surgical Management

Surgery is indicated for patients whose epilepsy results from intracranial tumors, abscesses, cysts, or vascular anomalies. Some patients have intractable seizure disorders that do not respond to medication. A focal (localized or limited) atrophic process may occur secondary to trauma, inflammation, stroke, or anoxia. If the seizures originate in a reasonably well-circumscribed area of the brain that can be excised without producing significant neurologic deficits, the removal of the area (termed a *lobectomy*) generating the seizures may produce long-term control and improvement (Lowenstein, 2014).

Epilepsy surgery has been aided by several advances, including microsurgical techniques,

EEGs with depth electrodes, improved illumination and hemostasis, and the introduction of neuroleptanalgesic agents (droperidol and fentanyl). These techniques, combined with use of local anesthetic agents, enable the neurosurgeon to perform surgery on an alert and cooperative patient. Using special testing devices, electrocortical mapping, and the patient's responses to stimulation, the boundaries of the epileptogenic focus (the abnormal area of the brain) are determined. The abnormal epileptogenic focus is then excised (lobectomy) (England & Plueger, 2014). Resection surgery significantly reduces the incidence of seizures in patients with refractory epilepsy; however, more research is needed to determine the effect of surgery on quality of life, anxiety, and depression, all issues for these patients.

As an adjunct to medication in adolescents and adults with focal seizures, a vagal nerve stimulator may be implanted under the clavicle. The device is connected to the vagus nerve in the cervical area, where it delivers electrical signals to the brain to control and reduce seizure activity (England & Plueger, 2014). An external programming system is used by the physician to change stimulator settings. Patients can turn the stimulator on and off with a magnet. This can be performed as an outpatient surgical procedure.

Gerontologic Considerations

Elderly people (65 years of age and older) have a high incidence of new-onset epilepsy (England & Plueger, 2014). Cerebrovascular disease is the leading cause of seizures in the elderly, but head trauma, dementia, infection, alcoholism, and aging are also associated risk factors (Correll & Bazil, 2014). Treatment depends on the underlying cause. Because many elderly people have chronic health problems, they may be taking other medications that can interact with medications prescribed for seizure control. In addition, the absorption, distribution, metabolism, and excretion of medications are altered in the elderly as a result of age-related changes in kidney and liver function. Therefore, elderly patients must be monitored closely for adverse and toxic effects of AEDs and for osteoporosis. The cost of AEDs can lead to poor adherence to the prescribed regimen in elderly patients on fixed incomes.

NURSING PROCESS

The Patient with Epilepsy and Seizures

ASSESSMENT

The nurse elicits information about the patient's seizure history. The patient is asked about the factors or events that may precipitate the seizures. Alcohol and illicit drug intake is documented. The nurse determines whether the patient has an aura before an epileptic seizure, which may indicate the origin of the seizure (e.g., seeing a flashing light may indicate that the seizure originated in the occipital lobe). Observation and assessment during and after a seizure assist in identifying the type of seizure and its management.

The effects of epilepsy on the patient's lifestyle are assessed. What limitations are imposed by the seizure disorder? Does the patient have a recreational program? Social contacts? Is the patient working, and is it a positive or stressful experience? What coping mechanisms are used?

DIAGNOSIS

NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Risk for injury related to seizure activity
- Fear related to the possibility of seizures
- Ineffective individual coping related to stresses imposed by epilepsy
- Deficient knowledge related to epilepsy and its control

COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

The major potential complications for patients with epilepsy are status epilepticus and medication side effects (toxicity).

PLANNING AND GOALS

Goals for the patient may include prevention of injury, control of seizures, achievement of a satisfactory psychosocial adjustment, acquisition of knowledge and understanding about the condition, and absence of complications.

NURSING INTERVENTIONS

PREVENTING INJURY

Injury prevention for the patient with seizures is a priority. If the type of seizure the patient is having places him or her at risk for injury, the patient should be lowered gently to the floor (if not in bed), and any potentially harmful items nearby (e.g., furniture, eyeglasses) should be removed. The patient should never be restrained or forced into a position, nor should anyone attempt to insert anything into the patient's mouth once a seizure has begun, as protecting the airway is a priority. Place a pillow under the patient's head to cushion it. Patients for whom seizure precautions are instituted should have the bed in the lowest position and side rails raised when in bed.

Nursing Alert
Since 50% of deaths associated with epilepsy are accidental (drowning, trauma, burns, choking), the nurse reviews safety issues with the patient, such as never swimming alone, taking showers rather than baths, and avoiding activities that could cause harm if the patient were to have a seizure.

REDUCING FEAR OF SEIZURES

Fear that a seizure may occur unexpectedly can be reduced by the patient's adherence to the prescribed treatment regimen. Cooperation of the patient and family and their trust in the prescribed regimen are essential for control of seizures. The nurse emphasizes that the prescribed AED must be taken on a continuing basis and that drug dependence or addiction does not occur. Periodic monitoring is necessary to ensure the adequacy of the treatment regimen, to prevent side effects, and to monitor for drug resistance.

In an effort to control seizures, factors that may precipitate them are identified, such as emotional disturbances, new environmental stressors, onset of menstruation in female patients, hypoglycemia, or fever. Online programs, such as SeizureTracker.com and "My

seizure event diary," are available for patients to document their seizure activity. The patient is encouraged to follow a regular and moderate routine in lifestyle, diet (avoiding excessive stimulants), exercise, and rest (sleep deprivation may lower the seizure threshold). Moderate activity is therapeutic, but excessive exercise should be avoided. An additional dietary intervention, referred to as the *ketogenic diet,* has been suggested for control of seizures in some patients. This diet is high-fat and protein and low-carbohydrate. Effects of this diet are seen quickly. Because of the high-fat component of this diet and limited replacement of essential nutrients, compliance with this diet is difficult (Klein, Tyrlikova, & Mathews, 2014; Ye, Li, Jiang, Sun, & Liu, 2015).

Photic stimulation (bright flickering lights, television viewing) may precipitate seizures; wearing dark glasses or covering one eye may be preventive. Tension states (anxiety, frustration) induce seizures in some patients. Classes in stress management may be of value. Because seizures are known to occur with alcohol intake, alcoholic beverages should be avoided.

IMPROVING COPING MECHANISMS

The social, psychological, and behavioral problems that frequently accompany epilepsy can be more of a disability than the actual seizures. Epilepsy may be accompanied by feelings of stigmatization, alienation, depression, and uncertainty. The patient must cope with the constant fear of a seizure and the psychological consequences. Adults face potential issues such as the burden of finding employment, restrictions on the ability to drive, concerns about relationships and childbearing, insurance problems, and legal barriers. Alcohol abuse may complicate matters. Family reactions may vary from outright rejection of the person with epilepsy to overprotection. As a result, many people with epilepsy are at risk for psychological and behavioral problems.

Nursing Alert
Patients with epilepsy have a depression incidence that is nearly five times higher than that of the general population as well as a higher suicide rate (England & Plueger, 2014). Thus, all patients with epilepsy should be screened for depression.

Counseling assists the patient and family to understand the condition and the limitations it imposes. Social and recreational opportunities are necessary for good mental health. Nurses can improve the quality of life for patients with epilepsy by teaching them and their families about symptoms and their management.

PROVIDING PATIENT AND FAMILY EDUCATION

Perhaps the most valuable facets of care contributed by the nurse to the person with epilepsy are education and efforts to modify the attitudes of the patient and family toward the disorder. The person who experiences seizures may consider every seizure a potential source of humiliation and shame. This may result in anxiety, depression, hostility, and secrecy on the part of the patient and family. Ongoing education and encouragement

should be given to patients to enable them to overcome these reactions. The patient with epilepsy should carry an emergency medical identification card or wear a medical information bracelet. The patient and family need to be educated about medications as well as care during a seizure.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Status epilepticus, the major complication, was described previously. Another complication is the toxicity of AEDs. The patient and family are instructed about side effects and are given specific guidelines to assess and report signs and symptoms that indicate medication toxicity. Many AEDs require careful monitoring for therapeutic levels. The patient should plan to have serum drug levels assessed at regular intervals. Many known drug interactions occur with AEDs. A complete pharmacologic profile should be reviewed with the patient to avoid interactions that either potentiate or inhibit the effectiveness of the medications.

EVALUATION

EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Sustains no injury during seizure activity:
    a. Complies with treatment regimen and identifies the hazards of stopping the medication
    b. Patient and family can identify appropriate care during seizure.
2. Indicates a decrease in fear
3. Displays effective individual coping
4. Exhibits knowledge and understanding of epilepsy:
    a. Identifies the side effects of AEDs
    b. Avoids factors or situations that may precipitate seizures (e.g., flickering lights, hyperventilation, alcohol)
    c. Follows a healthy lifestyle by getting adequate sleep and eating meals at regular times to avoid hypoglycemia
5. Absence of complications

INFECTIOUS NEUROLOGIC DISORDERS

MENINGITIS

Meningitis is an inflammation of the meninges, which are the protective membranes covering the brain and spinal cord. Bacterial or viral infections are the primary causes of meningitis, but it also can be caused by a fungus or parasite. Because of this inflammation close to the brain and spinal cord, meningitis can be life-threatening.

Bacterial Meningitis

Bacterial meningitis is caused by bacteria; commonly, *Streptococcus pneumoniae* and *Neisseria meningitidis* (meningococcus) are infecting organisms. *Haemophilus influenzae* was once a common cause of meningitis in children, but because of vaccination, infection with this organism is now rare in the United States. However, it is still a concern for those not immunized for *H. influenzae.* Outbreaks of *N. meningitidis* infection are most likely to occur in dense community groups, such as college campuses and military installations. Although infections occur year round, incidence of outbreaks is reduced in the summer (VanDemark & Hickey, 2014). Factors that increase the risk for bacterial meningitis include tobacco use and viral upper respiratory infection because they increase the amount of droplet production. Otitis media and mastoiditis increase the risk for bacterial meningitis because the bacteria can cross the epithelial membrane and enter the subarachnoid space. Patients who are immunosuppressed are at risk for the development of bacterial meningitis (organ transplant, diabetes, cancer, asplenia [spleen removed], chronic steroid therapy, HIV infection, malnutrition, etc.), as well as patients who are very young (less than 2 months of age) and the elderly. A study by Fernandes et al. (2014) found that patients admitted with acute bacterial meningitis in the intensive care unit with low Glasgow Coma Scale scores or no signs of fever were at high risk for unfavorable outcomes.

Pathophysiology

The brain is protected by the skull, meninges, and the blood–brain barrier. Any violation to these defenses by a pathogen can result in meningitis. Meningeal infections generally originate in one of two ways: through the bloodstream as a consequence of other infections of the heart, lung, or viscera; or by direct spread, such as might occur after a traumatic injury to the facial bones, infection in the skull or spine, sinusitis, otitis, brain abscess, or secondary to invasive procedures, such as lumbar puncture or ventricular shunting procedures.

Nursing Alert
Given the risk of bacterial meningitis in patients with traumatic injuries, prophylactic antibiotics are administered to patients who present with cerebrospinal fluid (CSF) escaping from the ears (CSF otorrhea) and the nose (CSF rhinorrhea) as is seen in basal skull fractures, dural tears, and compound skull fractures.

Once the causative organism enters the bloodstream, it crosses the blood–brain barrier and proliferates in the CSF. The host immune response disrupts the cellular integrity of the microorganism and the breakdown products (cell wall fragments and lipopolysaccharides [LPS]), which enhances the inflammatory response in the involved meninges. Part of this response is the recruitment of neutrophils to the inflammatory site, resulting in thickening (an increase in viscosity) of the CSF. Because the cranial vault contains little room for expansion, the inflammation may cause increased intracranial pressure (ICP). CSF circulates through the subarachnoid space, where inflammatory cellular materials from the affected meningeal tissue enter and accumulate. The thickened CSF can interfere with CSF

absorption, resulting in hydrocephalus. CSF studies demonstrate decreased glucose, increased protein levels, and increased white blood cell count (Bloch, 2014).

The prognosis for bacterial meningitis depends on the causative organism, the severity of the infection and illness, and the timeliness of treatment. Acute fulminant presentation may include adrenal damage, circulatory collapse, and widespread hemorrhages (Waterhouse–Friderichsen syndrome). This syndrome is the result of endothelial damage and vascular necrosis caused by the bacteria. Complications include visual impairment, deafness, seizures, paralysis, hydrocephalus, and septic shock.

Clinical Manifestations and Assessment

Headache and fever are frequently the initial symptoms. Fever tends to remain high throughout the course of the illness. An altered level of consciousness (LOC) is frequently seen; however one third of patients present with normal mentation (Bloch, 2014). Meningeal irritation results in a number of other well-recognized signs common to all types of meningitis:

- *Nuchal rigidity (stiff neck):* This is an early sign seen in 30% to 70% of patients (Bloch, 2014). Any attempts at flexion of the head are difficult because of spasms in the muscles of the neck. With the patient in supine position, the head is gently flexed forward and assessed for rigidity.
- *Positive Kernig sign:* When the patient is lying supine with the hip flexed to a 90-degree angle, resistance to passive extension of the knee is a positive Kernig sign (Fig. 46-1A). This pain is caused by inflammation of the meninges and spinal roots.
- *Positive Brudzinski sign:* When the patient's neck is flexed (after ruling out cervical trauma or injury), flexion of the knees and hips is produced; when the lower extremity of one side is passively flexed, a similar movement is seen in the opposite extremity (see Fig. 46-1B). This sign is caused by exudate that is irritating the root of the lumbar region (VanDemark & Hickey, 2014).
- *Photophobia (extreme sensitivity to light):* This finding is common, although the cause is unclear.

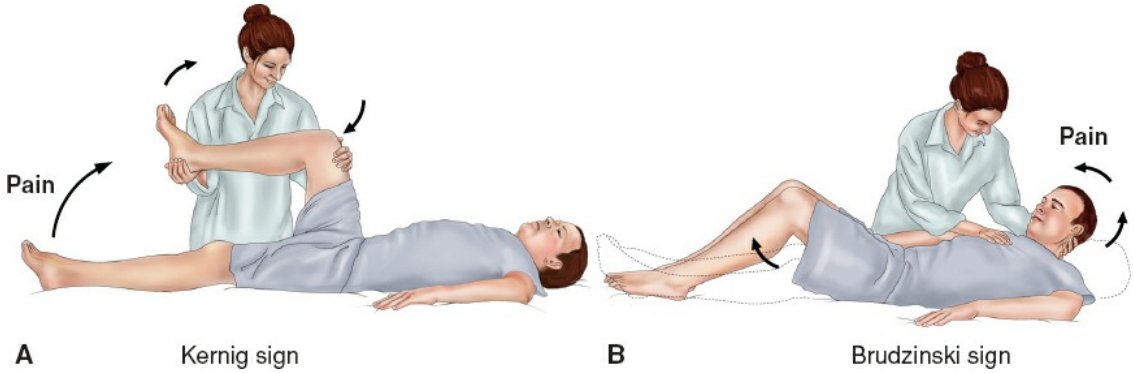


FIGURE 46-1 Testing for meningeal irritation. A. Kernig sign. B. Brudzinski sign.

Nursing Alert

The classic triad of symptoms of bacterial meningitis is stiff neck/nuchal rigidity, altered LOC,

and fever, although all these symptoms are not found routinely. However, 95% of patients with bacterial meningitis suffer from two of the following four symptoms: headache, fever, stiff neck/nuchal rigidity, and altered LOC.

A rash can be a striking feature of *N. meningitidis* infection, occurring in about half of patients with this type of meningitis. Skin lesions develop, ranging from a petechial rash with purpuric lesions to large areas of ecchymosis.

Disorientation and memory impairment are common early in the course of the illness. The changes depend on the severity of the infection, as well as the individual response to the physiologic processes. As the illness progresses, lethargy, unresponsiveness, and coma may develop. Within the first week, seizures occur in 40% to 50% of patients with bacterial meningitis (VanDemark & Hickey, 2014).

ICP increases secondary to the accumulation of purulent exudate and cerebral edema. The initial signs of increased ICP include decreased LOC and focal motor deficits. Vomiting is a frequent finding associated with rising ICP. If ICP is not controlled, the uncus of the temporal lobe may herniate through the tentorium, causing pressure on the brainstem. Brainstem herniation is a life-threatening event that causes cranial nerve dysfunction and depresses the centers of vital functions, such as the medulla. Refer to Chapter 45 to review vital sign changes termed *Cushing's response*. An acute fulminant infection can occur in patients with meningococcal meningitis, producing signs of overwhelming septicemia: an abrupt onset of high fever, extensive purpuric lesions (over the face and extremities), shock, and signs of disseminated intravascular coagulopathy (DIC). Refer to Chapter 20 for details of DIC. Some patients develop hyponatremia or Syndrome of Inappropriate Antidiuretic Hormone (SIADH, refer to Chapter 31). Death may occur within a few hours after onset of the infection.

Nursing Alert
The nurse recognizes that with fever, tachycardia (increased heart rate) and tachypnea (increased respiratory rate [RR]) are expected. If bradycardia and decreased RR are seen, the nurse should consider ICP as an etiology for the decreased HR and RR.

If the clinical presentation suggests meningitis, diagnostic testing is conducted to identify the causative organism. Bacterial culture and Gram staining of CSF and blood are the "gold standard" for definitive diagnosis. These cultures should be obtained immediately when there is a suspicion of bacterial meningitis (Fischbach & Dunning, 2014). CT scanning is useful for detection of abscesses and lesions that may have provided a route for the bacteria.

Medical and Nursing Management

Successful outcomes depend on the early administration of antibiotics that cross the blood–brain barrier into the subarachnoid space in sufficient concentration to halt the multiplication of bacteria. Penicillin antibiotics (e.g., ampicillin, piperacillin) or one of the cephalosporins (e.g., ceftriaxone sodium, cefotaxime sodium) may be used. Vancomycin hydrochloride alone or in combination with rifampin may be used if resistant strains of

bacteria are identified. High doses of the appropriate antibiotic are administered IV.

Nursing Alert

The nurse understands the difference between empiric antimicrobial therapy versus culture-documented therapy. Empiric therapy refers to selection of an antibiotic based upon the "most likely" suspected organism, while considering variables such as the patient's age, predisposing conditions, geographical region, etc. Empiric therapy is initiated immediately after collecting the culture specimens. Premature initiation of antimicrobial therapy before cultures are obtained can suppress bacterial growth and impede the diagnosis. While culture-documented therapy will detail this patient's organism and specific sensitivities and/or resistance to certain antibiotics, there is a lapse of 24 to 72 hours before culture results are returned.

The use of dexamethasone as an adjunct therapy in the treatment of acute bacterial meningitis and in pneumococcal meningitis, if administered before the first dose of antibiotic, has been considered. However, recent results of a meta-analysis did not demonstrate significant reduction in death or neurologic disability in patients with steroid use (Brouwer, McIntyre, Prasad, & van de Beek, 2015).

Dehydration and shock are treated with fluid volume expanders. Seizures, which may occur early in the course of the disease, are controlled with phenytoin (Dilantin). Some providers may prophylactically use anticonvulsants and histamine-2-receptor antagonists or proton pump inhibitors (PPI) to prevent GI bleeding. Increased ICP is treated as necessary (see Chapter 45).

The patient with bacterial meningitis is critically ill; therefore, many of the nursing interventions are collaborative with the health care provider, respiratory therapist, and other members of the health care team. The patient's safety and well-being depend on sound nursing judgment.

Neurologic status and vital signs are continually assessed. Pulse oximetry and arterial blood gas (ABG) values are used to quickly identify the need for respiratory support if increasing ICP compromises the patient's LOC. Insertion of a cuffed endotracheal tube (or tracheotomy) and mechanical ventilation may be necessary to maintain adequate tissue oxygenation.

Blood pressure should be monitored to assess for incipient shock, which precedes cardiac or respiratory failure. Rapid IV fluid replacement may be prescribed, but care is taken to prevent fluid overload. Fever also increases the workload of the heart and cerebral metabolism. ICP will increase in response to increased cerebral metabolic demands. Therefore, measures are taken to reduce body temperature as quickly as possible.

Other important components of nursing care include the following measures:

- Protecting the patient from injury secondary to seizure activity or altered LOC
- Monitoring daily body weight; serum electrolytes; and urine volume, specific gravity, and osmolality, especially if SIADH is suspected (refer to Chapter 31).
- Preventing complications associated with immobility, such as pressure ulcers and pneumonia
- Instituting infection control precautions until 24 hours after initiation of antibiotic

therapy (oral and nasal discharge is considered infectious)

Any sudden, critical illness can be devastating to the family. Because the patient's condition is often critical and the prognosis guarded, the family needs to be informed about the patient's condition. Periodic family visits are essential to facilitate coping of the patient and family. An important aspect of the nurse's role is to support the family and assist them in identifying others who can be supportive of them during the crisis.

Nursing Alert

Since bacterial meningitis is a contagious disease, isolation precautions must be instituted and will depend on the organism and patient status.

Viral Meningitis

Pathophysiology

Viral meningitis, also known as acute aseptic meningitis or acute benign lymphocytic meningitis, is more common than bacterial meningitis. The most common causes are enteroviruses (coxsackievirus, poliovirus, and echovirus). Patients with HIV can present with acute aseptic meningitis. In most cases no specific organism is identified. Children are most often affected, but all age groups can be affected.

Clinical Manifestations and Assessment

Viral meningitis usually starts with a headache, low-grade fever, stiff neck, photophobia, malaise, and symptoms of an upper respiratory viral illness, which are similar to bacterial meningitis. However, altered mental status and seizure activity are not associated with this disorder. Assess patient for a recent systemic viral infection. Patient may receive a CT scan to look for increased ICP. A lumbar puncture should be performed, and the CSF will be clear; results will show increased protein and WBC count as well as normal glucose level but will be free of any bacterial organism.

Medical and Nursing Management

Viral meningitis is managed based on the patient's symptoms and supportive nursing care. Patients may need to be hospitalized because of their discomfort and severe vomiting. Supportive care can include bed rest with head of bed (HOB) elevated 30 degrees and the patient's head in neutral alignment (improves venous drainage), a dark quiet environment, fever management, monitoring fluid intake, and pain management. Recovery should occur within 10 days.

ENCEPHALITIS

Encephalitis is an acute inflammatory process of the brain tissue (cerebral cortex) secondary to viruses, bacteria, fungi, or parasites. Viruses are the most common cause of encephalitis in the United States, and herpes simplex virus (HSV) is the most common of these. There are two HSVs, HSV-1 and HSV-2 (VanDemark & Hickey, 2014). HSV-1 typically affects children and adults. HSV-2 most commonly affects neonates whose mother was infected during pregnancy (Nettina, 2014).

Herpes Simplex Encephalitis

Pathophysiology

HSV-1 causes encephalitis by following a retrograde intraneuronal path to the brain. The olfactory and trigeminal nerves are the paths most commonly involved. A latent virus in brain tissue may reactivate and result in encephalitis. The invading organism causes cerebral edema and petechial hemorrhages of the brain and can directly invade the brain, damaging neurons (VanDemark & Hickey, 2014).

Clinical Manifestations and Assessment

Initial symptoms include fever, headache, stiff neck, and confusion. Focal neurologic symptoms reflect the areas of cerebral inflammation and necrosis and include behavioral changes, focal seizures, dysphasia, hemiparesis, and altered LOC. Patients may also have auditory and visual hallucinations (VanDemark & Hickey, 2014).

Neuroimaging studies, EEG, and CSF examination are used to diagnose HSV encephalitis. The EEG demonstrates periodic high-voltage spikes originating in the temporal lobe, and MRI may reveal temporal lobe edema. Lumbar puncture often reveals a high opening pressure and low-glucose and high-protein levels in CSF samples. Viral cultures are almost always negative. The polymerase chain reaction (PCR) is the standard test for early diagnosis of HSV-1 encephalitis. The validity of PCR is very high between the third and tenth days after symptom onset.

Medical and Nursing Management

Acyclovir (Zovirax), an antiviral agent, is the medication of choice in the treatment of HSV. Studies have indicated that early administration of acyclovir improves the prognosis associated with HSV-1 encephalitis and reduces a mortality rate of 60% to 70% down to 30% if treatment is initiated before the onset of coma (VanDemark & Hickey, 2014). To prevent relapse, treatment should continue for up to 3 weeks. Slow IV administration over at least 1 hour, along with adequate hydration, may prevent crystallization of the medication in the renal tubules, which would be reflected by a rising serum creatinine and blood urea nitrogen (BUN). Assessment of neurologic function is key to monitoring the progression of disease. Comfort measures to reduce headache include dimming the lights, limiting noise, and administering analgesic agents. Opioid analgesic medications may mask neurologic symptoms; therefore, they are used cautiously. Focal seizures and altered LOC require care directed at injury prevention and safety. Nursing care addressing patient and family anxieties is ongoing throughout the illness. Monitoring of blood chemistry test results and hourly urinary output will alert the nurse to the presence of renal complications related to acyclovir therapy.

Arboviral Encephalitis

Arthropod vectors transmit several types of viruses that cause encephalitis. The primary vector in North America is the mosquito. In cases of West Nile virus, humans are the secondary host; birds are the primary host (refer to Fig. 46-2). Arbovirus infection (transmitted by arthropod vectors) occurs in specific geographic areas during the summer or early fall when the vectors are most active. West Nile virus, the most common type of arboviral encephalitis, was first observed in New York City in 1999 (Jubelt, 2015). The elderly are primarily affected (Jubelt, 2015). The St. Louis arbovirus is seen in the western United States, and the elderly are affected more frequently.

Pathophysiology

Viral replication occurs at the site of the mosquito bite. The host immune response attempts to control viral replication. If the immune response is inadequate, viremia will ensue. The virus gains access to the CNS via the cerebral capillaries, resulting in encephalitis. It spreads from neuron to neuron, predominantly affecting the cortical gray matter, the brainstem, and the thalamus. Meningeal exudates compound the clinical presentation by irritating the meninges and increasing ICP.

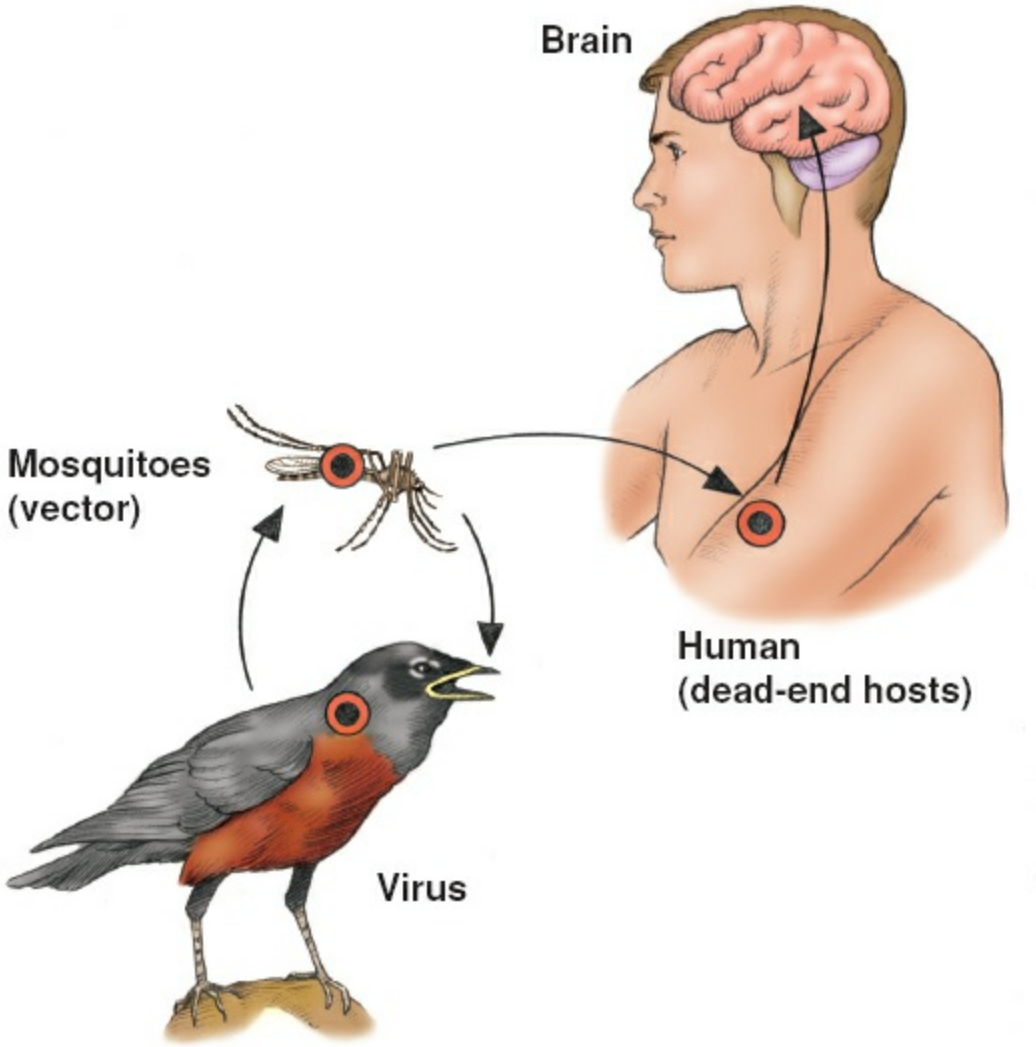

FIGURE 46-2 Transmission routes of West Nile virus. Birds are the reservoir of the West Nile virus, but they are unable to spread it. Mosquitoes serve as the vectors, spreading it from bird to bird and from birds to people. Humans are believed to be "dead-end hosts" because the virus can live and cause illness in humans. (Used with permission from Lippincott's Nursing Advisor.)

Clinical Manifestations and Assessment

An arboviral encephalitis begins with early flu-like symptoms, but specific neurologic manifestations depend on the viral type. After a brief febrile prodrome, neurologic symptoms will reflect the area of the brain that is involved. For example, if meninges are involved, patients can present with nuchal rigidity and headache. A unique clinical feature of St. Louis encephalitis is the development of SIADH with hyponatremia in 25% to 33% of affected patients (Jubelt, 2015). (SIADH is detailed in Chapter 31.) Signs and symptoms specific to West Nile encephalitis include a maculopapular or morbilliform rash (erythematous [red] rash resembling that of measles consisting of macules and papules [or maculopapular]) on the neck, trunk, arms, and legs, and flaccid paralysis. Both West Nile and St. Louis encephalitis can result in parkinsonian-like movements, reflecting inflammation of the basal ganglia.

Neuroimaging and CSF evaluation are useful in the diagnosis of arboviral encephalitis. MRI demonstrates inflammation of the basal ganglia in cases of St. Louis encephalitis and

inflammation in the periventricular area in cases of West Nile encephalitis. Immunoglobulin M antibodies to West Nile virus are observed in serum and CSF (Davis & Pirio Richardson, 2015). Serum cultures are not useful because the viremia is brief.

Medical and Nursing Management

No specific medication for arboviral encephalitis exists. Medical management is aimed at controlling the seizures and the increased ICP and supporting respiratory function. If the patient is very ill, hospitalization may be required. The nurse carefully assesses neurologic status and identifies improvement or deterioration in the patient's condition. Injury prevention is key in light of the potential for falls and seizures. Arboviral encephalitis may result in death or lifelong residual health issues, such as neurologic deficits and seizures. The family will need support and teaching to cope with these outcomes.

Public education addressing the prevention of arboviral encephalitis is a key nursing role. Clothing that provides coverage and applying Environmental Protection Agency (EPA)–approved insect repellents containing permethrin or another EPA-registered repellent to clothes will give extra protection. This should be used in high-risk areas to decrease mosquito and tick bites. Avoidance of outdoor activities and control of the mosquito vector are important for control of the disease. Screens should be in good repair in the home, and standing water, such as in birdbaths, should be removed or avoided. Blood donation centers screen all blood for West Nile virus. Cases of West Nile virus are reported to the Centers for Disease Control and Prevention (CDC). People must be warned not to handle a dead bird if found and to call the local health department for instructions on reporting and disposing of the body.

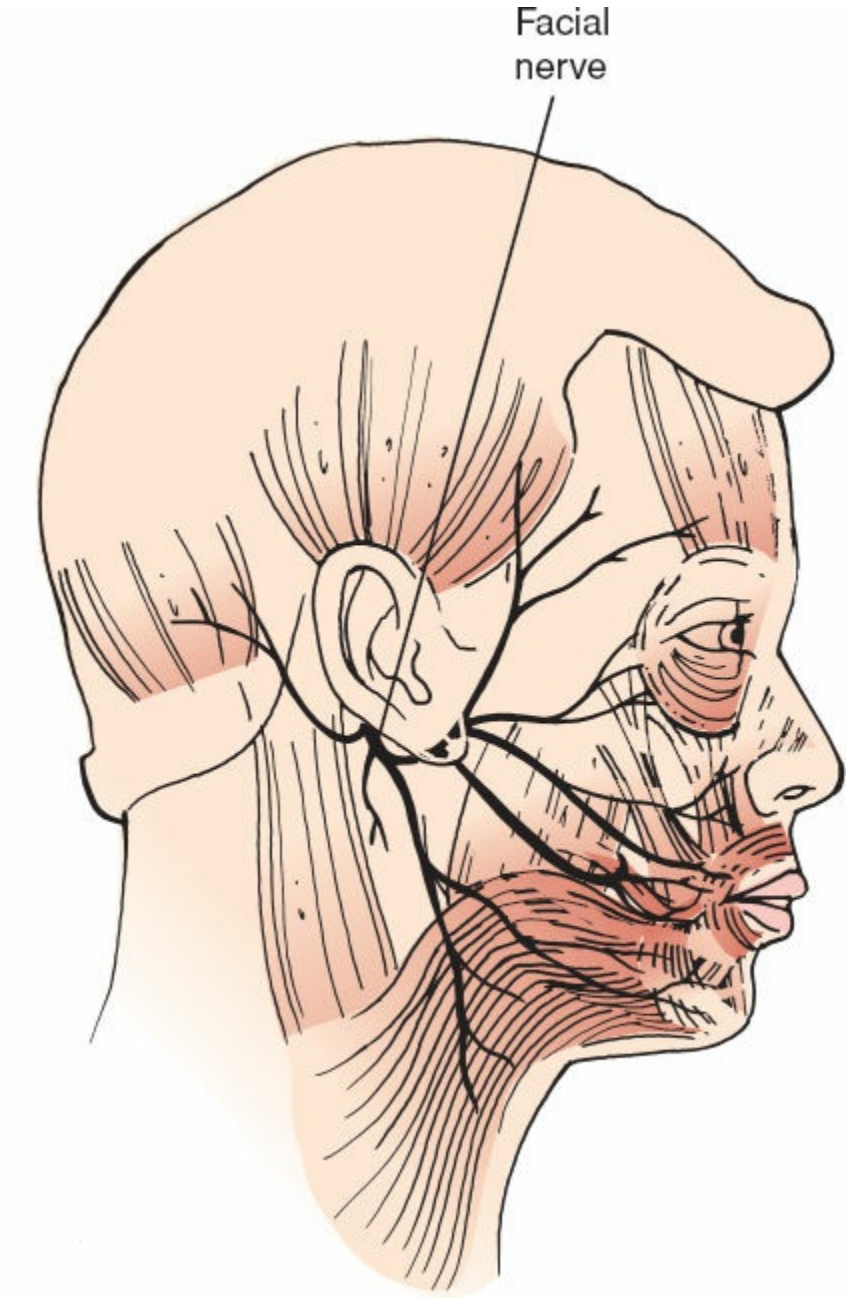

FIGURE 46-3 Distribution of the facial nerve.

BELL'S PALSY

Bell's palsy (facial paralysis) is caused by unilateral inflammation of the seventh cranial nerve, which results in weakness or paralysis of the facial muscles on the ipsilateral, or same side, of the affected facial nerve (Fig. 46-3).

Pathophysiology

Although the cause is unknown, theories about causes include vascular ischemia, viral disease (herpes simplex, herpes zoster), Lyme disease, autoimmune disease, or a combination of all of these factors. Bell's palsy may be a type of pressure paralysis. The inflamed, edematous nerve becomes compressed to the point of damage, or its blood supply is occluded, producing ischemic necrosis of the nerve.

Clinical Manifestations and Assessment

The face is distorted from paralysis of the facial muscles; there are increased lacrimation (tearing) and painful sensations in the face, behind the ear, and in the eye of the affected side. The ear pain may precede the paralysis by 24 to 48 hours. The patient may experience speech difficulties and may be unable to eat on the affected side because of weakness or paralysis of the facial muscles. A disturbance of taste is a common finding. When asking the patient to show his or her teeth and smile, weakness of the involved nerve will be noted, there will be an absence of wrinkling on the forehead, the affected side will appear mask-like.

Medical and Nursing Management

Corticosteroid therapy (prednisone) may be prescribed to reduce inflammation and edema; this reduces vascular compression and permits restoration of blood circulation to the nerve. Early administration of corticosteroid therapy appears to diminish the severity of the disease, relieve the pain, and prevent or minimize denervation. Prednisone may be combined with Acyclovir to improve facial function (Nettina, 2014).

Facial pain is controlled with analgesic agents. Heat may be applied to the involved side of the face to promote comfort and blood flow through the muscles. Electrical stimulation may be applied to the face to prevent muscle atrophy.

While the paralysis lasts, nursing care involves protection of the eye from injury. Frequently, the eye does not close completely and the blink reflex is diminished, so the eye is vulnerable to injury from dust and foreign particles. Corneal irritation, corneal abrasion, and ulceration may occur. Distortion of the lower lid alters the proper drainage of tears. To prevent injury, the eye may be covered with a protective shield at night. The eye patch may abrade the cornea, however, because there is some difficulty in keeping the partially paralyzed eyelids closed. Eye ointment may be applied at bedtime to promote adherence of the eyelids to prevent injury during sleep. Artificial tears are typically instilled to maintain eye lubrication. The patient can be taught to close the paralyzed eyelid manually before going to sleep. Wrap-around sunglasses or goggles may be worn during the day to decrease normal evaporation from the eye.

NEURODEGENERATIVE AND NEUROMUSCULAR DISORDERS

MULTIPLE SCLEROSIS

Multiple sclerosis (MS), the leading cause of nontraumatic disability in young adults, is an immune-mediated, progressive demyelinating disease of the CNS. *Demyelination* refers to the destruction of myelin, the fatty and proteinaceous material that surrounds certain nerve fibers in the brain and spinal cord; it results in impaired transmission of nerve impulses (Fig. 46-4). MS may occur at any age but typically manifests in young adults between the ages of 20 and 40 years; it affects women more frequently than men and rarely affects those over 60 years (Riley & Tullman, 2015).

The etiology of MS is unknown and may result from complex interactions between environmental factors and genetically susceptible individuals that trigger an abnormal immune response that damages the myelin sheath, oligodendrocytes, axons, and neurons (Riley & Tullman, 2015). Evidence for a genetic predisposition is seen in an increased risk for Caucasians of northern European ancestry and a decreased risk in others (e.g., Native Americans) (Riley & Tullman, 2015). Researchers found that some environmental exposure (i.e., biomarker of Epstein–Barr virus, infectious mononucleosis, smoking) may play a role in the development of MS (Belbasis, Bellou, Evangelou, Ioannidis, & Tzoulaki, 2015).

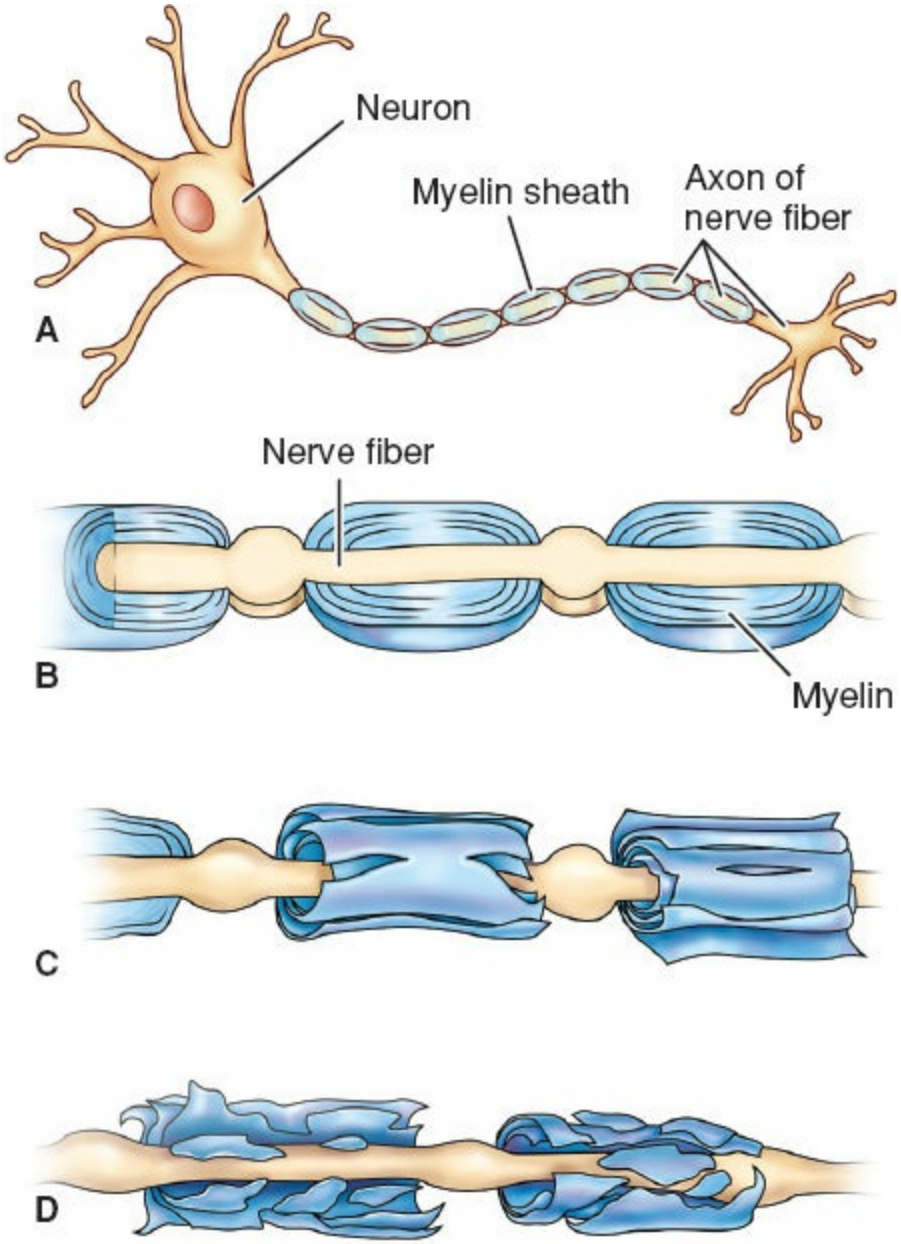

FIGURE 46-4 The process of demyelination. (A) and (B) depict a normal nerve cell and axon with myelin. (C) and (D) show the slow disintegration of myelin, resulting in a disruption in axon function.

Pathophysiology

Sensitized T cells typically cross the blood–brain barrier; their function is to check the CNS for antigens and then leave. B cells and monocytes are also activated; B cells secrete antibodies against myelin. In MS, the sensitized T cells remain in the CNS and promote the infiltration of other agents that damage the immune system. The immune system attack leads to inflammation that damages myelin (which normally insulates the axon and speeds the conduction of impulses along the axon) and the oligodendroglial cells that produce myelin in the CNS.

Demyelination interrupts the flow of nerve impulses and results in a variety of manifestations, depending on the nerves affected. Plaques appear on demyelinated axons, further interrupting the transmission of impulses. Demyelinated axons are scattered irregularly throughout the CNS. The areas most frequently affected are the optic nerves, chiasm, and tracts; the cerebrum; the brainstem and cerebellum; and the spinal cord. Eventually, the axons themselves begin to degenerate, resulting in permanent and irreversible damage (Riley & Tullman, 2015).

Clinical Manifestations and Assessment

The course of MS may assume many different patterns (Fig. 46-5). Between 85% and 90% of patients with MS have a relapsing-remitting (RR) course. With each relapse, recovery is usually complete; however, residual deficits may occur and accumulate over time, contributing to functional decline. Approximately 40% of those with the RR course of MS progress to a secondary progressive course, in which disease progression occurs with or without relapses. About 10% to 15% of patients have a primary progressive course, in which disabling symptoms steadily increase, with rare plateaus and temporary improvement (Riley & Tillman, 2015). Primary progressive MS may result in quadriparesis, cognitive dysfunction, visual loss, and brainstem syndromes. The least common presentation is the progressive relapsing form of MS, which occurs in approximately 5% of patients and is characterized by relapses with continuous disabling progression between exacerbations (Hauser & Goodin, 2014).

The signs and symptoms of MS are varied and multiple, reflecting the location of the lesion (plaque) or combination of lesions. The primary symptoms most commonly reported are unilateral visual loss, typically preceded or accompanied by orbital pain that increases with eye movement (acute optic neuritis), fatigue, depression, weakness, limb (typically legs) numbness, difficulty in coordination, loss of balance, and pain. Visual disturbances due to lesions in the optic nerves or their connections may also include blurring of vision, diplopia (double vision), nystagmus (rotary oscillation of the eyes), patchy blindness (scotoma), and total blindness.

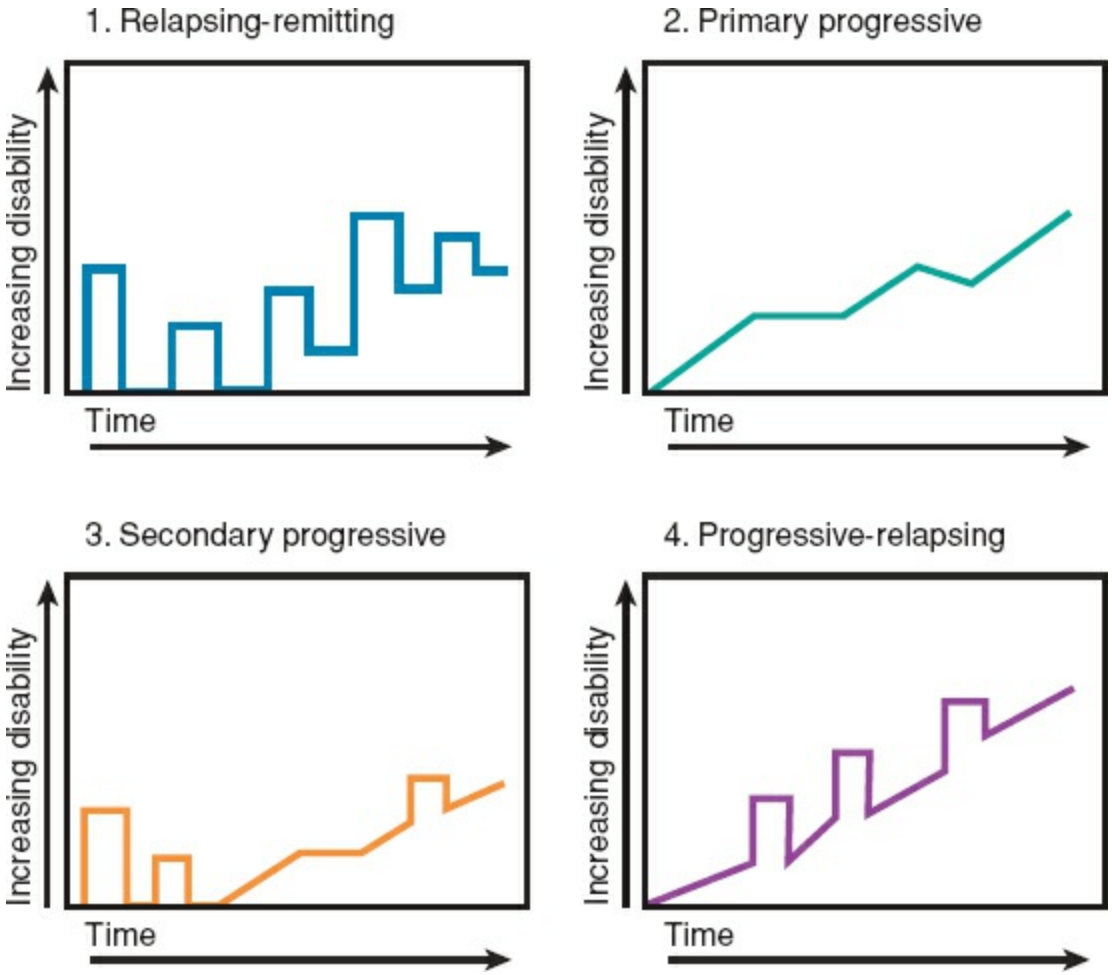

FIGURE 46-5 Types and courses of multiple sclerosis (MS). 1. Relapsing-remitting (RR) MS is characterized by clearly acute attacks with full recovery or with sequelae and residual deficit upon recovery. Periods between disease relapses are characterized by lack of disease progression. 2. Primary progressive (PP) MS is characterized by disease showing progression of disability from onset, without plateaus and temporary minor improvements. 3. Secondary progress (SP) MS begins with an initial RR course, followed by progression of variable rate, which may also include occasional relapses and minor remissions. 4. Progressive-relapsing (PR) MS shows progression from onset but with clear acute relapses with or without recovery. (From Lublin, F. D., & Reingold, S. C. (1996). Defining the clinical course of multiple sclerosis: Results of an international survey. *Neurology*, *46*(64), 907–911. Used with permission from Lippincott Williams & Wilkins.)

Fatigue, defined as a subjective lack of physical or mental energy that interferes with desired activity, is one of the more common symptoms of MS; it is typically worse in the afternoon hours. Depression, heat, anemia, deconditioning, and medication may contribute to fatigue. The etiology of MS-related fatigue is poorly understood; there appears to be no association between fatigue and disease course (Riley & Tillman, 2015).

Like fatigue, pain is a symptom that can contribute to social isolation. Approximately 70% of patients with MS report pain at some point (Riley & Tillman, 2015). Lesions on the sensory pathways cause pain. Lhermitte sign is described as an electrical sensation that is felt down the arms, back, or lower trunk when the patient flexes the neck. It is theorized this acute pain sensation is related to sclerotic plaques on the dorsal nerve roots (Weigel & Hickey, 2014). Many people with MS need daily analgesics. In some cases, pain is managed with opioids, antiseizure medication, or antidepressants. Rarely, surgery may be needed to

interrupt pain pathways.

Additional sensory manifestations include paresthesias (abnormal skin sensations, such as tingling, itching, or burning), dysesthesias (unpleasant, abnormal sense of touch), and loss of proprioception (ability to sense the position, location, orientation, and movement of the body and its parts). An objective sensory loss (position, vibration, shape, texture) is noted in 50% of patients with MS (Weigel & Hickey, 2014). Among perimenopausal women, those with MS are more likely to have pain related to osteoporosis. In addition to estrogen loss, immobility and corticosteroid therapy play a role in the development of osteoporosis among women with MS. Bone mineral density (BMD) testing is recommended for this high-risk group (refer to Chapter 40). Diagnosis and treatment of osteoporosis are discussed in Chapter 41.

Spasticity (muscle hypertonicity) of the extremities (usually the legs) and loss of the abdominal reflexes result from involvement of the main motor pathways (pyramidal tracts) of the spinal cord. The spasticity often occurs with painful spasms, which interfere with mobility, sleep, and activities of daily living (ADLs). Gait abnormalities are common and are usually a result of ataxia, weakness, or spasticity. Disruption of the sensory axons may produce sensory dysfunction (paresthesias, pain). Cognitive and psychosocial problems may reflect frontal or parietal lobe involvement. Some degree of cognitive impairment (e.g., memory loss, decreased concentration) occurs in about 65% of patients, but severe cognitive changes with dementia (progressive organic mental disorder) are rare.

Involvement of the cerebellum or basal ganglia can produce ataxia (impaired coordination of movements) and tremor. Loss of the control connections between the cortex and the basal ganglia may occur and cause emotional lability and euphoria. Bladder, bowel, and sexual dysfunctions are common. Bladder dysfunction (urinary urgency, frequency, nocturia, and urge incontinence) affects approximately 75% of patients, and in approximately 15% of these, symptoms can be severe enough to socially isolate the patient (Riley & Tillman, 2015).

Secondary complications of MS include urinary tract infections, constipation, pressure ulcers, contracture deformities, dependent pedal edema, pneumonia, reactive depression, and decreased bone density. Emotional, social, marital, economic, and vocational problems may also be a consequence of the disease.

Exacerbations and remissions are characteristic of MS. During exacerbations, new symptoms appear and existing ones worsen; during remissions, symptoms decrease or disappear. Fifteen years after onset, only 20% of patients have no functional limitation (Hauser & Goodin, 2014). Precipitation of symptoms may occur with the following events: periods of emotional and physical stress; cold or humid, hot weather; hot baths; overheating; fever; fatigue; and pregnancy (Weigel & Hickey, 2014). There is no single test for the diagnosis of MS. Diagnosis is established based upon clinical examination, results from MRI ("bright spots" of demyelinated lesions or plaques are easily seen in white matter) and evoked potential studies (EPS), and examination of CSF. Approximately 95% of MS patients' MRI studies reveal abnormalities. Electrophoresis of CSF identifies the presence of oligoclonal banding. EPS can help define the extent of the disease process and monitor changes.

Medical and Nursing Management

No cure exists for MS. The goals of treatment are to treat acute exacerbations, delay the progression of the disease, and manage chronic symptoms. Many patients with MS have a stable disease course and require only intermittent treatment, whereas others experience steady progression of their disease. Symptoms requiring intervention include spasticity, fatigue, bladder dysfunction, and ataxia. Management strategies target the various motor and sensory symptoms and effects of immobility that can occur.

Disease-Modifying Therapies

The disease-modifying medications reduce the frequency of relapse, the duration of relapse, and the number and size of plaques observed on MRI. All of the medications require injection.

Interferon beta-1a (Rebif) and interferon beta-1b (Betaseron) are administered subcutaneously (SQ), and another preparation of interferon beta-1a, Avonex, is administered intramuscularly (IM) once a week. Side effects of all the interferon beta medications include flu-like symptoms, which may be minimized by administration at bedtime, and can be managed with acetaminophen and ibuprofen; these side effects may resolve after a few months. Additional side effects include injection site reaction (seen less frequently with IM preparations), thrombocytopenia, anemia, leukopenia, potential liver damage, fetal abnormalities, and depression. For optimal control of disability, disease-modifying medications should be started early in the course of the disease.

Nursing Alert
MS does not affect fertility or carrying a pregnancy to term. Interestingly women with MS typically do not have relapses during pregnancy; however, there is a relapse incidence of 20% to 40% in the first 3 months after delivery. The relapse does not impact the risk of long-term disability. Research efforts on the effects of hormones and circulating protein on MS may shed light on the course of MS.

Glatiramer acetate (Copaxone) reduces the rate of relapse in the RR course of MS. It decreases the number of plaques noted on MRI and increases the time between relapses. Copaxone is administered SQ daily. It acts by increasing the antigen-specific suppressor T cells. Side effects and injection site reactions are rare. Copaxone is an option for those with an RR course; however, it may take 6 months for evidence of an immune response to appear.

IV methylprednisolone, the key agent in treating acute relapse in the RR course, shortens the duration of relapse. It exerts anti-inflammatory effects by acting on T cells and cytokines. One gram is administered IV daily for 3 to 5 days, with or without an oral taper of prednisone (Riley & Tullman, 2015). Side effects include mood swings, weight gain, and electrolyte imbalances.

Symptom Management

Medications are also prescribed for management of specific symptoms. Baclofen (Lioresal), a gamma-aminobutyric acid (GABA) agonist, is the medication of choice for treating spasticity. It can be administered orally or by intrathecal injection. Benzodiazepines (Valium), tizanidine (Zanaflex), and dantrolene (Dantrium) may also be used to treat spasticity. Patients with disabling spasms and contractures may require nerve blocks or surgical intervention. Fatigue that interferes with ADLs may be treated with amantadine (Symmetrel), pemoline (Cylert), or fluoxetine (Prozac). Ataxia is a chronic problem most resistant to treatment. Medications used to treat ataxia include beta-adrenergic blockers (Inderal), antiseizure agents (Neurontin), and benzodiazepines (Klonopin).

Bladder and bowel problems are often among the most difficult ones for patients, and a variety of medications (anticholinergics, alpha-adrenergic blockers, antispasmodic agents) may be prescribed. Nonpharmacologic strategies also assist in establishing effective bowel and bladder elimination (discussed shortly).

Urinary tract infection is often superimposed on the underlying neurologic dysfunction. Ascorbic acid (vitamin C) may be prescribed to acidify the urine, making bacterial growth less likely. Antibiotics are prescribed when appropriate.

Antidepressants may be prescribed since 25% to 50% of patients with MS are depressed, and the suicide rate is significantly higher than in the general population (Weigel & Hickey, 2014).

An individualized program of physical therapy, rehabilitation, and education is combined with emotional support. An educational plan of care is developed to enable the person with MS to deal with the physiologic, social, and psychological problems that accompany chronic disease.

Promoting Physical Mobility

Relaxation and coordination exercises promote muscle efficiency. Progressive resistive exercises are used to strengthen weak muscles because diminishing muscle strength is often significant in MS.

Exercises. Walking improves the gait and particularly helps with the problem of the loss of the sense of position of the legs and feet. If certain muscle groups are irreversibly affected, other muscles can be trained to compensate. Instruction in the use of assistive devices may be needed to ensure their safe and correct use. Weighted canes, walkers, or limb bracelets may be of value.

Minimizing Spasticity and Contractures. Muscle spasticity is common and, in its later stages, is characterized by severe adductor spasm of the hips, with flexor spasm of the hips and knees. Without relief, fibrous contractures of these joints will occur. Warm packs may be beneficial, but hot baths should be avoided because of risk for burn injury secondary to sensory loss and increasing symptoms that may occur with elevation of the body temperature.

Daily exercises for muscle stretching are prescribed to minimize joint contractures. Special attention is given to the hamstrings, gastrocnemius muscles, hip adductors, biceps, and wrist and finger flexors. Muscle spasticity is common and interferes with normal function. A stretch–hold–relax routine is helpful for relaxing and treating muscle spasticity.

Swimming and stationary bicycling are useful, and progressive weight bearing can relieve spasticity in the legs. The patient should not be hurried in any of these activities because this often increases spasticity.

Activity and Rest. The patient is encouraged to work and exercise to a point just short of fatigue. Very strenuous physical exercise is not advisable because it raises the body temperature and may aggravate symptoms. The patient is advised to take frequent short rest periods, preferably lying down. Extreme fatigue may contribute to the exacerbation of symptoms.

Minimizing Effects of Immobility. Because of the decrease in physical activity that often occurs with MS, complications associated with immobility, including pressure ulcers, expiratory muscle weakness, and accumulation of bronchial secretions, need to be considered and steps taken to prevent them. Measures to prevent such complications include assessing and maintaining skin integrity and having the patient perform coughing and deep-breathing exercises.

Preventing Injury

If motor dysfunction causes coordination problems and clumsiness, or if ataxia is apparent, the patient is at risk for falling. To overcome this disability, the patient is taught to walk with feet apart to widen the base of support and to increase walking stability. If the loss of sense of position occurs, the patient is taught to watch the feet while walking. Gait training may require assistive devices (walker, cane, braces, crutches, parallel bars) and instruction about their use by a physical therapist. If the gait remains inefficient, a wheelchair or motorized scooter may be the solution. The occupational therapist is a valuable resource person in suggesting and securing aids to promote independence. The patient is trained in transfer and ADLs.

Because sensory loss may occur in addition to motor loss, pressure ulcers are a continuing threat to skin integrity. The need to use a wheelchair continuously increases the risk. See Chapter 52 for a discussion of the prevention and treatment of pressure ulcers.

Enhancing Bladder and Bowel Control

In general, bladder symptoms fall into the following categories: (1) inability to store urine (hyperreflexic, uninhibited); (2) inability to empty the bladder (hyporeflexic, hypotonic); and (3) a mixture of both types. The patient with urinary frequency, urgency, or incontinence requires special support. The sensation of the need to void must be heeded immediately so the bedpan or urinal should be readily available. A voiding time schedule is set up (every 1.5 to 2 hours initially, with gradual lengthening of the interval). The patient is instructed to drink a measured amount of fluid every 2 hours and then attempt to void 30 minutes after drinking. Use of a timer or wristwatch with an alarm may be helpful for the patient who does not have enough sensation to signal the need to empty the bladder. The nurse encourages the patient to take the prescribed medications to treat bladder spasticity because this allows greater independence. Intermittent self-catheterization has been successful in maintaining bladder control in patients with MS. If a female patient has permanent urinary incontinence, urinary diversion procedures may be considered. The

male patient may wear a condom appliance for urine collection.

Bowel problems include constipation, fecal impaction, and incontinence. Adequate fluids, dietary fiber, and a bowel-training program are frequently effective in solving these problems.

Enhancing Communication and Managing Swallowing Difficulties

If the cranial nerves that control the mechanisms of speech and swallowing are affected, dysarthrias (defects of articulation) marked by slurring, low volume of speech, and difficulties in phonation may occur. Dysphagia (difficulty swallowing) may also occur. A speech therapist evaluates speech and swallowing and instructs the patient, family, and health team members about strategies to compensate for speech and swallowing problems. The nurse reinforces this instruction and encourages the patient and family to adhere to the plan. Impaired swallowing increases the patient's risk for aspiration; therefore, strategies are needed to reduce that risk. Such strategies include having suction apparatus available, performing careful feeding, and ensuring proper positioning for eating. Refer to Chapters 9 and 10 for information related to aspiration.

Improving Sensory and Cognitive Function

Measures may be taken if visual defects or changes in cognitive status occur.

Vision. The cranial nerves affecting vision may be affected by MS. An eye patch or a covered eyeglass lens may be used to block the visual impulses of one eye if the patient has diplopia (double vision). Prism glasses may be helpful for patients who are confined to bed and have difficulty reading in the supine position. People who are unable to read regular-print materials are eligible for the free "talking book" services of the Library of Congress or may obtain large-print or audio books from local libraries.

Cognition and Emotional Responses. Cognitive impairment and emotional lability occur early in MS in some patients and may impose numerous stresses on the patient and family. Some patients with MS are forgetful and easily distracted.

Patients adapt to illness in a variety of ways, including denial, depression, withdrawal, and hostility. Emotional support assists patients and their families to adapt to the changes and uncertainties associated with MS and to cope with the disruption in their lives. The patient is assisted to set meaningful and realistic goals, to remain as active as possible, and to keep up social interests and activities. Hobbies may help the patient's morale and provide satisfying interests if the disease progresses to the stage at which formerly enjoyed activities can no longer be pursued.

The family should be made aware of the nature and degree of cognitive impairment. The environment is kept structured, and lists and other memory aids are used to help the patient with cognitive changes to maintain a daily routine. The occupational therapist can be helpful in formulating a structured daily routine.

Strengthening Coping Mechanisms. The diagnosis of MS is always distressing to the patient and family. They need to know that no two patients with MS have identical symptoms or courses of illness. Although some patients do experience significant disability

early, others have a near-normal lifespan with minimal disability. Some families, however, face overwhelming frustrations and problems. MS affects people who are often in a productive stage of life and concerned about career and family responsibilities. Family conflict, disintegration, separation, and divorce are not uncommon. Often, very young family members assume the responsibility of caring for a parent with MS. Nursing interventions in this area include alleviating stress and making appropriate referrals for counseling and support to minimize the adverse effects of dealing with chronic illness.

The nurse, mindful of these complex problems, initiates home care and coordinates a network of services, including social services, speech therapy, physical therapy, and homemaker services. To strengthen the patient's coping skills, as much information as possible is provided. Patients need an updated list of available assistive devices, services, and resources.

Coping through problem-solving involves helping the patient define the problem and develop alternatives for its management. Careful planning and maintaining flexibility and a hopeful attitude are useful for psychological and physical adaptation.

Improving Home Management

MS can affect every facet of daily living. Certain abilities are often impossible to regain after they are lost. Physical function may vary from day to day. Modifications that allow independence in home management should be implemented (e.g., assistive eating devices, raised toilet seat, bathing aids, telephone modifications, long-handled comb, tongs, modified clothing). Exposure to heat increases fatigue and muscle weakness so air conditioning is recommended in at least one room. Exposure to extreme cold may increase spasticity.

Promoting Sexual Functioning

Patients with MS and their partners face problems that interfere with sexual activity, both as a direct consequence of nerve damage and also from psychological reactions to the disease. Easy fatigability, conflicts arising from dependency and depression, emotional lability and loss of self-esteem compound the problem. Erectile and ejaculatory disorders in men and orgasmic dysfunction and adductor spasms of the thigh muscles in women can make sexual intercourse difficult or impossible. Bladder and bowel incontinence and urinary tract infections add to the difficulties.

An experienced sexual counselor helps bring into focus the patient's or partner's sexual resources and suggests relevant information and supportive therapy. Sharing and communicating feelings, planning for sexual activity (to minimize the effects of fatigue), and exploring alternative methods of sexual expression may open up a wide range of sexual enjoyment and experiences.

MYASTHENIA GRAVIS

Myasthenia gravis (MG), an autoimmune disorder affecting the neuromuscular junction, is characterized by fatigability and degrees of muscle weakness of the voluntary muscles. According to the Myasthenia Gravis Foundation of America, the prevalence of MG in the

United States is estimated to be approximately 20 per 100,000 people. MG occurs in both men and women at older ages; however before 40 years of age, the disease is three times more common in women (Penn & Rowland, 2015). A women's average age of onset is 28 years of age whereas the men's average age of onset is 42 years of age (Fowler, Herrington, Koopman, & Ricci, 2013).

Pathophysiology

Normally, a chemical impulse precipitates the release of acetylcholine from vesicles on the nerve terminal at the neuromuscular junction. The acetylcholine attaches to receptor sites on the motor endplate and stimulates muscle contraction. Continuous binding of acetylcholine to the receptor site is required for muscular contraction to be sustained.

In MG, there is a reduction in the number of acetylcholine receptor sites because antibodies directed at the acetylcholine receptor sites impair transmission of impulses across the neuromuscular junction. Therefore, fewer receptors are available for stimulation, resulting in voluntary muscle weakness that escalates with continued activity (Fig. 46-6). Abnormalities of the thymus (located behind the sternum) are found in 80% of patients with MG (Nettina, 2014).

Clinical Manifestations and Assessment

The initial manifestation of MG usually involves the ocular muscles. Diplopia (double vision) and ptosis (drooping of the eyelids) are common. However, the majority of patients also experience weakness of the muscles of the face and throat (bulbar symptoms) and generalized weakness. Weakness of the facial muscles results in a bland facial expression. Laryngeal involvement produces dysphonia (voice impairment) and increases the patient's risk for choking and aspiration. Generalized weakness affects all the extremities and the intercostal muscles, resulting in decreasing vital capacity and respiratory failure. MG is purely a motor disorder with no effect on sensation or coordination.

The hallmark of MG is fluctuating muscle weakness, which intensifies with activity, such as exercise, and improves with rest (Koopman & Hickey, 2014).

An acetylcholinesterase test is used to diagnose MG. The acetylcholinesterase inhibitor stops the breakdown of acetylcholine, thereby increasing availability at the neuromuscular junction. The drug used is edrophonium chloride (Tensilon) because it has a rapid onset of 30 seconds and a short duration of 5 minutes (Koopman & Hickey, 2014). Immediate improvement in muscle strength after administration of this agent represents a positive test and usually confirms the diagnosis.

An ice-pack test can help differentiate MG from other causes of ptosis. An ice pack is applied over the patient's closed eyes for 2 minutes. Improvement of the ptosis that is sustained for several minutes is considered a positive ice-pack test and is suggestive of MG. The rationale behind this test is that by cooling the tissues, which include skeletal muscle fibers, the activity of the acetylcholinesterases are inhibited. This test has the advantage of being noninvasive and inexpensive; however, not all patients with MG present with ptosis.

The presence of acetylcholine receptor antibodies is identified in serum. Repetitive nerve stimulation demonstrates a decrease in successive action potentials. The thymus gland may be enlarged in MG, and a CT scan of the mediastinum is performed to detect thymoma or hyperplasia of the thymus.

Medical and Nursing Management

Management of MG is directed at improving function and reducing and removing circulating antibodies. Therapeutic modalities include administration of anticholinesterase medications and immunosuppressive therapy, plasmapheresis, intravenous immunoglobulin, and thymectomy.

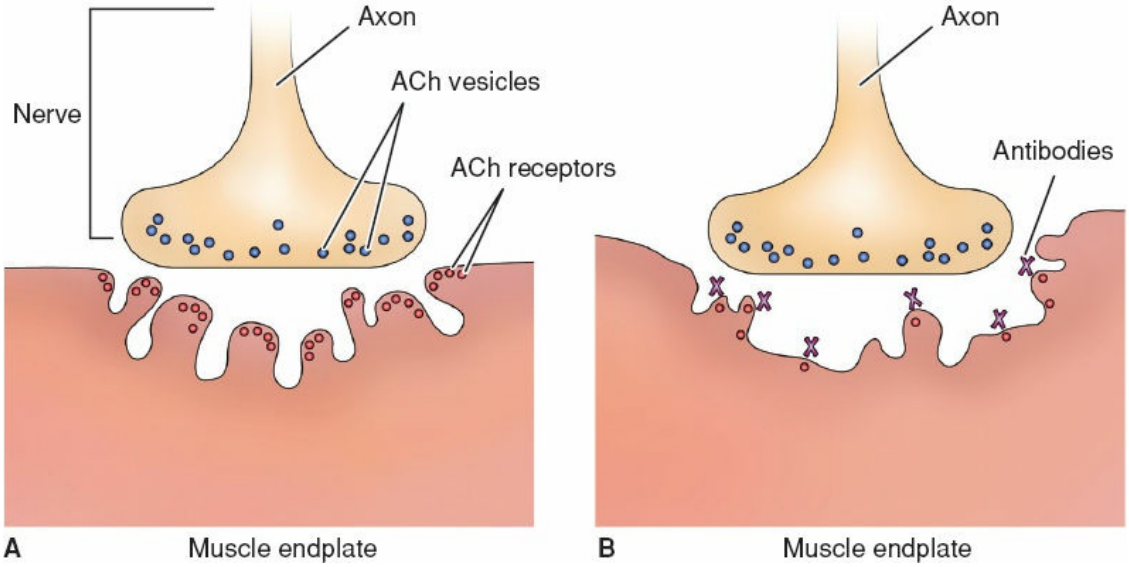

FIGURE 46-6 Myasthenia gravis (MG). A. Normal acetylcholine (ACh) receptor site. B. ACh receptor site in MG.

Pharmacologic Therapy

Pyridostigmine bromide (Mestinon), an anticholinesterase medication, is the first line of therapy. It provides symptomatic relief by inhibiting the breakdown of acetylcholine and increasing the relative concentration of available acetylcholine at the neuromuscular junction. The dosage is gradually increased to a daily maximum and is administered in divided doses (usually four times a day). The most common adverse effects are gastrointestinal discomfort, increased bronchial and oral secretions, and muscle fasciculations and cramps (Koopman & Hickey, 2014). Pyridostigmine tends to have fewer side effects than other anticholinesterase medications (Box 46-3).

If pyridostigmine bromide does not improve muscle strength and control fatigue, the next agents used are immunosuppressant agents. The goal of immunosuppressive therapy is to reduce production of the antibody. Corticosteroids suppress the patient's immune response, decreasing the amount of antibody production, and this correlates with clinical improvement. An initial dose of prednisone is given daily; as symptoms improve, the medication is tapered and a maintenance alternative-day dosing schedule may be considered. Since long-term steroids carry substantial risks for a variety of dose-dependent side effects (diabetes, osteoporosis, hypertension), this treatment is usually reserved for patients with ocular symptoms. As the corticosteroid dosage is gradually increased, the anticholinesterase dosage is lowered. Cytotoxic medications are used to treat MG if there is inadequate response to steroids. Azathioprine (Imuran), an immunosuppressive drug,

inhibits T lymphocytes and reduces acetylcholine receptor antibody levels. Therapeutic effects may not be evident for 3 to 12 months. Leukopenia and hepatotoxicity are serious adverse effects so monthly evaluation of liver enzymes and white blood cell count is necessary.

BOX 46-3 Potential Adverse Effects of Anticholinesterase Medications

Central Nervous System
Irritability
Anxiety
Insomnia
Headache
Dysarthria
Syncope
Seizures
Coma
Diaphoresis

Respiratory
Bronchial relaxation
Increased bronchial secretions

Cardiovascular
Tachycardia
Hypotension

Gastrointestinal
Abdominal cramps
Nausea
Vomiting
Diarrhea
Anorexia
Increased salivation

Skeletal Muscles
Fasciculations
Spasms
Weakness

Genitourinary
Frequency
Urgency

Integumentary
Rash
Flushing

Nursing Alert
Prophylactic treatment for osteoporosis and careful follow-up for other side effects is mandatory in all patients managed with long-term prednisone.

A number of medications are contraindicated for patients with MG because they exacerbate the symptoms. The health care provider and the patient should weigh risks and benefits before any new medications are prescribed, including antibiotics, cardiovascular medications, antiseizure and psychotropic medications, morphine, quinine and related agents, beta blockers, and nonprescription medications.

Nursing Alert
The patient's dentist should be advised of the diagnosis of MG, and Procaine (Novocain) should be avoided. Since neuromuscular blocking agents may have a very prolonged effect in patients with MG, any anesthetic medication should be evaluated by the primary care provider to ensure it is not capable of exaggerating myasthenic weakness (Fowler et al., 2013).

Plasmapheresis/Intravenous Immunoglobulin

Plasmapheresis (plasma exchange) is a technique used to treat exacerbations of MG. The patient's plasma and plasma components are removed through a centrally placed large-bore double-lumen catheter. The blood cells and antibody-containing plasma are separated, after which the cells and a plasma substitute are reinfused. Plasma exchange produces a temporary reduction in the level of circulating antibodies. The typical course of plasmapheresis consists of daily or alternate-day treatment, and the number of treatments is determined by the patient's response. IV immunoglobulin (IVIG) treatment involves the administration of pooled human gamma globulin, which usually produces a relatively quick and short-term relief of MG weakness. Although IVIG is easier than plasmapheresis to administer, the response to plasmapheresis is more rapid. No treatments cure MG because they do not stop the production of the acetylcholine receptor antibodies.

Surgical Management

Thymectomy (surgical removal of the thymus gland) can produce antigen-specific immunosuppression and result in clinical improvement. The procedure results in either partial or complete remission. The entire gland must be removed for optimal clinical outcomes; therefore, surgeons prefer the trans-sternal surgical approach. After surgery, the patient is monitored in an intensive care unit, with special attention to respiratory function. The patient is weaned from mechanical ventilation after thorough respiratory assessment. Thymectomy leads to improvement in almost all patients, but it may take months before the patient sees any benefit from the procedure.

Nursing Management

Because MG is a chronic disease and most patients are seen on an outpatient basis, much of the nursing care focuses on patient and family teaching. Educational topics for outpatient self-care include medication management, energy conservation, strategies to help with ocular manifestations, and prevention and management of complications.

Medication management is a crucial component of ongoing care. Understanding the actions of the medications and taking them on schedule is emphasized, as are the consequences of delaying medication and the signs and symptoms of myasthenic and cholinergic crises. The patient can determine the best times for daily dosing by keeping a diary to determine fluctuation of symptoms and to learn when the medication is wearing off. The medication schedule can then be manipulated to maximize strength throughout the day.

Nursing Alert

Maintenance of stable blood levels of anticholinesterase medications is imperative to stabilize muscle strength. Therefore, the anticholinesterase medications must be administered on time. Any delay in administration of medications may exacerbate muscle weakness and make it impossible for the patient to take medications orally.

To minimize the risk of aspiration, mealtimes should coincide with the peak effects of anticholinesterase medication. In addition, rest before meals is encouraged, to reduce muscle fatigue. The patient is advised to sit upright during meals, with the neck slightly flexed to facilitate swallowing. Soft foods in gravy or sauces can be swallowed more easily; if choking occurs frequently, the nurse can suggest puréed food with a pudding-like consistency. Suction should be available at home, with the patient and family instructed in its use. Supplemental feedings may be necessary in some patients to ensure adequate nutrition.

Impaired vision results from ptosis of one or both eyelids, decreased eye movement, or double vision. To prevent corneal damage when the eyelids do not close completely, many providers may instruct the patient to tape or patch the eyes closed for short intervals and to regularly instill artificial tears. If taping is done, it is important to ensure the lid covers the eye to prevent corneal abrasion from the tape or patch. Patients who wear eyeglasses can have "crutches" attached to help lift the eyelids. Patching of one eye can help with double vision.

The patient is reminded of the importance of maintaining health promotion practices and of following health care screening recommendations. Factors that exacerbate symptoms and potentially cause crisis should be noted and avoided: emotional stress, infections (particularly respiratory infections), vigorous physical activity, some medications, and high environmental temperature.

The patient is also taught strategies to conserve energy. To do this, the nurse helps the patient identify the optimal times for rest throughout the day. If the patient lives in a two-story home, the nurse can suggest that frequently used items (e.g., hygiene products, cleaning products, snacks) be kept on each floor to minimize travel between floors. The patient is encouraged to apply for a handicapped license plate to minimize walking from parking spaces, and to schedule activities to coincide with peak energy and strength levels.

Patients are encouraged to wear a medical alert bracelet identifying them as having MG. The Myasthenia Gravis Foundation of America provides support groups, services, and educational materials for patients, families, and health care providers (www.myasthenia.org).

Complications

Cholinergic Crisis

A cholinergic crisis, which is essentially a problem of overmedication, results in severe generalized muscle weakness, respiratory impairment, and excessive pulmonary secretions that may result in respiratory failure. Weak respiratory muscles do not support inhalation. An inadequate cough and an impaired gag reflex, caused by bulbar weakness, result in poor airway clearance and risk of aspiration. Bulbar weakness specifically involves the muscles of the jaw, face, palate, pharynx, larynx, tongue, glossopharyngeal nerve (IX), vagus nerve (X), and hypoglossal nerve (XII). A downward trend of two respiratory function tests, the negative inspiratory force and vital capacity, is the first clinical sign of respiratory compromise.

Nursing Alert

The phrase bulbar weakness refers to weakness and fatigue in the neck and jaw, and it is named for the nerves that originate from the bulblike part of the brainstem, the medulla. The nurse anticipates the patient will have difficulty talking, chewing, swallowing, and holding the head erect. Patients should be assessed for their ability to communicate, to tolerate oral intake, and to determine their aspiration risk. A marked decrease in oxygen saturation (as measured by pulse oximetry), tachypnea (increased respiration rate), and coughing to a lesser extent after oral intake suggests aspiration. Weakness of the respiratory musculature can lessen the ability to cough.

Endotracheal intubation and mechanical ventilation may be needed. Cholinesterase inhibitors are stopped when respiratory failure occurs and gradually restarted after the patient demonstrates improvement. Nutritional support may be needed if the patient is intubated for a long period.

Myasthenic Crisis

Myasthenic crisis is a sudden, temporary exacerbation of symptoms of MG. A common precipitating event for myasthenic crisis is an infection. Respiratory distress and varying degrees of dysphagia (difficulty swallowing), dysarthria (difficulty speaking), eyelid ptosis, diplopia, and prominent muscle weakness are symptoms of myasthenic crisis.

Providing ventilatory assistance takes precedence in the immediate management of the patient with myasthenic crisis. Ongoing assessment for respiratory failure is essential. The nurse assesses the respiratory rate and depth, breath sounds, and oxygen saturation and monitors pulmonary function parameters (vital capacity and negative inspiratory force) to detect pulmonary problems before respiratory dysfunction progresses. ABG analysis is performed as needed. Endotracheal intubation and mechanical ventilation may be needed.

If the abdominal, intercostal, and pharyngeal muscles are severely weak, the patient cannot cough, take deep breaths, or clear secretions. Chest physiotherapy, including postural drainage to mobilize secretions and suctioning to remove secretions, may have to be performed frequently. (Postural drainage should not be performed for 30 minutes after

feeding.)

Several strategies and supportive measures should be performed during this crisis, including monitoring of laboratory work, input and output, and daily weight, along with vigilant pulmonary assessments. If the patient cannot swallow, nasogastric tube feedings may be prescribed. Sedatives and tranquilizers are avoided because they aggravate hypoxia and hypercapnia and can cause respiratory and cardiac depression.

GUILLAIN–BARRÉ SYNDROME

Guillain–Barré syndrome (GBS) is an autoimmune attack on the peripheral nerve myelin. The result is acute, rapid, segmental demyelination of peripheral nerves and some cranial nerves, producing ascending weakness with dyskinesia (inability to execute voluntary movements), hyporeflexia, and paresthesias (numbness). An antecedent event (most often a viral infection) precipitates clinical presentation. *Campylobacter jejuni*, cytomegalovirus, Epstein–Barr virus, *Mycoplasma pneumoniae, H. influenzae*, and HIV are the most common infectious agents associated with the development of GBS. In a few instances, the patient reports receiving a vaccination prior to the onset of GBS (Hickey, 2014a).

In North America, approximately 1.0 to 2.0 cases of GBS occur for every 100,000 people each year. GBS affects people of all ages and races and females slightly more than men. Given the relationship of GBS to colds and flu-like illnesses, it is expected that GBS would occur more frequently in the fall and winter when these infections are more likely (Hickey, 2014a).

Pathophysiology

Myelin is a complex substance that covers nerves, providing insulation and speeding the conduction of impulses from the cell body to the dendrites. The cell that produces myelin in the peripheral nervous system is the Schwann cell. In GBS, the Schwann cell is spared, allowing for remyelination in the recovery phase of the disease.

GBS is the result of a cell-mediated and humoral immune attack on peripheral nerve myelin proteins that causes inflammatory demyelination. The immune system cannot distinguish between the two proteins and attacks and destroys peripheral nerve myelin. The exact location of the immune attack within the peripheral nervous system is the ganglioside GM1b. With the autoimmune attack, there is an influx of macrophages and other immune-mediated agents that attack myelin, cause inflammation and destruction, and leave the axon unable to support nerve conduction (Fig. 46-7).

Clinical Manifestations and Assessment

GBS typically begins with muscle weakness and diminished reflexes of the lower extremities. Hyporeflexia and weakness may progress to tetraplegia (paralysis of all four limbs). Demyelination of the nerves that innervate the diaphragm and intercostal muscles results in neuromuscular respiratory failure. Sensory symptoms include paresthesias of the hands and feet and pain related to the demyelination of sensory fibers.

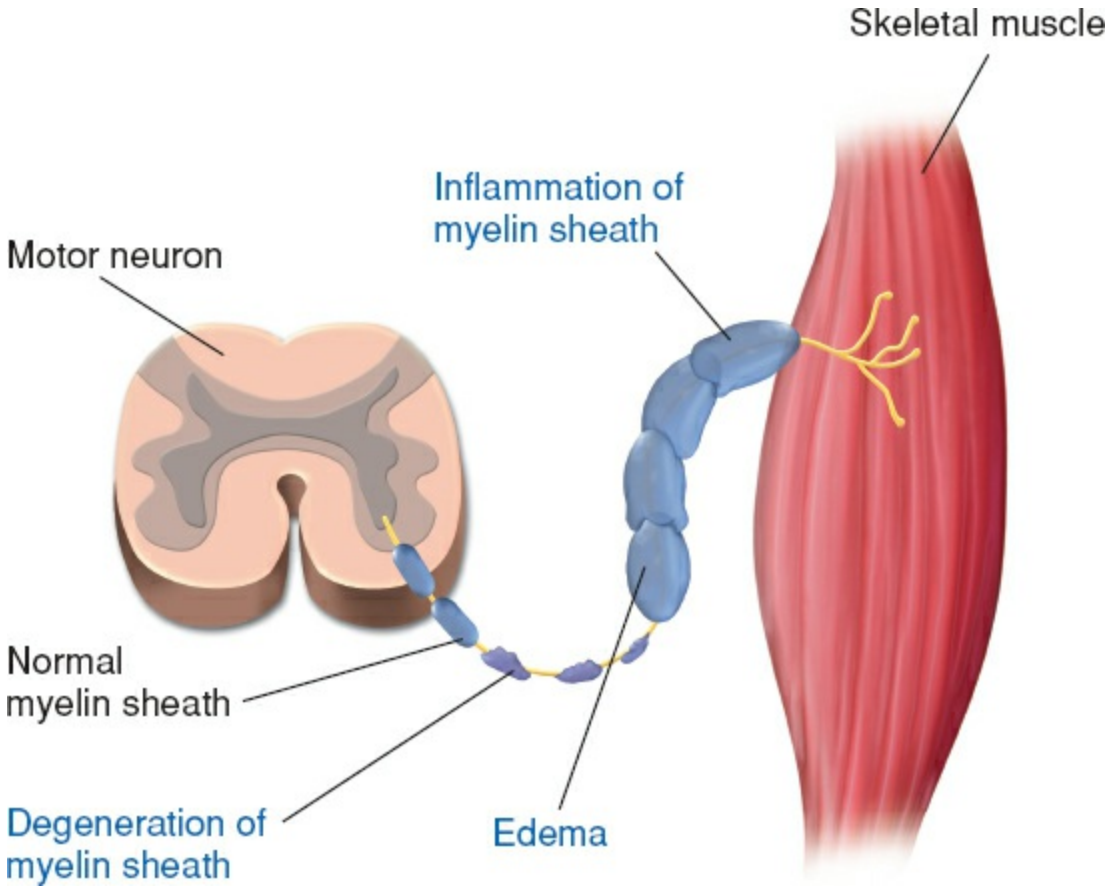

FIGURE 46-7 Peripheral nerve demyelination. (Used with permission from *ACC atlas of pathophysiology*. (2001). Philadelphia, PA: Lippincott Williams & Wilkins.)

The antecedent event usually occurs 2 weeks before symptoms begin. Weakness usually begins in the legs and progresses upward. Maximum weakness, the *plateau,* varies in length but usually includes neuromuscular respiratory failure and bulbar weakness. The duration of the symptoms is variable; complete functional recovery may take up to 2 years (Hickey, 2014a). Any residual symptoms are permanent and reflect axonal damage from demyelination.

Cranial nerve demyelination can result in a variety of clinical manifestations. Optic nerve demyelination may result in blindness. Bulbar muscle weakness related to demyelination of the glossopharyngeal and vagus nerves results in the inability to swallow or clear secretions. Vagus nerve demyelination results in autonomic dysfunction, manifested by instability of the cardiovascular system. The presentation is variable and may include tachycardia, bradycardia, hypertension, or orthostatic hypotension. The symptoms

of autonomic dysfunction occur and resolve rapidly. GBS does not affect cognitive function or LOC.

Although the classic clinical features include areflexia and ascending weakness, variation in presentation occurs. There may be a sensory presentation, with progressive sensory symptoms, an atypical axonal destruction, or the Miller–Fisher variant, which includes paralysis of the ocular muscles, ataxia, and areflexia (Hickey, 2014a).

The patient presents with symmetric weakness, diminished reflexes, and upward progression of motor weakness. Changes in vital capacity and negative inspiratory force are assessed to identify impending neuromuscular respiratory failure. Serum laboratory tests are not useful in the diagnosis. However, elevated protein levels are detected in CSF evaluation, without an increase in other cells. EPSs demonstrate a progressive loss of nerve conduction velocity.

Medical and Nursing Management

Because of the possibility of rapid progression and neuromuscular respiratory failure, GBS is a medical emergency, requiring management in an intensive care unit. After baseline values are identified, assessment of changes in muscle strength and respiratory function alert the clinician to the physical and respiratory needs of the patient. Respiratory therapy or mechanical ventilation may be necessary to support pulmonary function and adequate oxygenation. Some clinicians recommend elective intubation before the onset of extreme respiratory muscle fatigue. Mechanical ventilation may be required for an extended period. The patient is weaned from mechanical ventilation after the respiratory muscles can again support spontaneous respiration and maintain adequate tissue oxygenation.

Other interventions are aimed at preventing the complications of immobility. These may include the use of anticoagulant agents and thigh-high elastic compression stockings or sequential compression boots to prevent thrombosis and pulmonary emboli (PE).

Plasmapheresis and IVIG are used to affect directly the peripheral nerve myelin antibody level. Both therapies decrease circulating antibody levels and reduce the amount of time the patient is immobilized and dependent on mechanical ventilation. The cardiovascular risks posed by autonomic dysfunction require continuous electrocardiographic (ECG) monitoring. Tachycardia and hypertension are treated with short-acting medications, such as alpha-adrenergic blocking agents. The use of short-acting agents is important because autonomic dysfunction is very labile. Hypotension is managed by increasing the amount of IV fluid administered.

Maintaining Respiratory Function

Respiratory function can be maximized with incentive spirometry and chest physiotherapy. Monitoring for changes in vital capacity and negative inspiratory force are key to early intervention for neuromuscular respiratory failure. Mechanical ventilation is required if the vital capacity falls, making spontaneous breathing impossible and tissue oxygenation inadequate.

Nursing Alert

To evaluate respiratory muscle strength, maximal inspiratory pressures (MIP) are obtained using a handheld or electronic device that can be attached to an endotracheal tube (if needed), or the patient can place the device around his or her lips. The patient exhales the residual volume and then inhales with maximal force. A normal MIP is usually more negative than −75 cm H_2O; when the value is less negative than −20 or −30 cm H_2O, weaning from mechanical ventilation may be difficult, and values less positive than 60 cm H_2O suggest cough insufficiency (Stoller & Hill, 2016). This simple bedside test also can be used to monitor deterioration or improvement of the strength of the diaphragm and other inspiratory muscles. Respiratory therapy personnel perform this test.

Parameters for determining the appropriate time to begin mechanical ventilation include a vital capacity of less than 15 mL/kg. The potential need for mechanical ventilation should

be discussed with the patient and family on admission, to provide time for psychological preparation and decision-making. Intubation and mechanical ventilation will result in less anxiety if it is initiated on a nonemergency basis to a well-informed patient. The patient may require mechanical ventilation for a long period.

Bulbar weakness that impairs the ability to swallow and clear secretions is another factor in the development of respiratory failure in the patient with GBS. Suctioning may be needed to maintain a clear airway.

The nurse assesses the blood pressure and heart rate frequently to identify autonomic dysfunction so that interventions can be initiated quickly if needed. Medications are administered for clinically significant symptoms.

Enhancing Physical Mobility

Nursing interventions to enhance physical mobility and prevent the complications of immobility are key to the function and survival of these patients. The paralyzed extremities are supported in functional positions, and passive range-of-motion (ROM) exercises are performed at least twice daily. Deep venous thrombosis (DVT) and PE are threats to the patient who is paralyzed. Nursing interventions are aimed at preventing DVT. ROM exercises, position changes, anticoagulation, the use of thigh-high elastic compression stockings or sequential compression boots, and adequate hydration decrease the risk for DVT.

Padding may be placed over bony prominences, such as the elbows and heels, to reduce the risk for pressure ulcers. The need for consistent position changes every 2 hours cannot be overemphasized. The nurse evaluates laboratory test results that may indicate malnutrition or dehydration, both of which increase the risk for pressure ulcers. The nurse collaborates with the provider and dietitian to develop a plan to meet the patient's nutritional and hydration needs.

Providing Adequate Nutrition

Paralytic ileus may result from insufficient parasympathetic activity. In this event, the nurse administers IV fluids and parenteral nutrition as prescribed and monitors for the return of bowel sounds and bowel function. If the patient cannot swallow due to bulbar paralysis (immobility of muscles), a gastrostomy tube may be placed to administer nutrients. The nurse carefully assesses the return of the gag reflex and bowel sounds before resuming oral nutrition.

Improving Communication

Because of paralysis, the patient cannot talk, laugh, or cry and therefore has no method for communicating needs or expressing emotion. Establishing some form of communication with picture cards or an eye blink system provides a means of communication. Collaboration with the speech therapist may be helpful in developing a communication mechanism that is most effective for a specific patient.

Decreasing Fear and Anxiety

The patient and family are faced with a sudden, potentially life-threatening disease, and

anxiety and fear are constant themes for them. The impact of disease on the family depends on the patient's role within the family. Referral to a support group may provide information and support to the patient and family.

The family may feel helpless in caring for the patient. Mechanical ventilation and monitoring devices may frighten and intimidate them. Family members often want to participate in physical care; with instruction and support by the nurse, they should be allowed to do so.

In addition to fear, the patient may experience isolation, loneliness, and lack of control. Nursing interventions that increase the patient's sense of control include providing information about the condition, emphasizing a positive appraisal of coping resources, and teaching relaxation exercises and distraction techniques. The positive attitude and atmosphere of the multidisciplinary team are important to promote a sense of well-being.

Diversional activities are encouraged to decrease loneliness and isolation. Encouraging visitors, engaging visitors or volunteers to read to the patient, listening to music or books on tape, and watching television are ways to alleviate the patient's sense of isolation.

Complications

Thorough assessment of respiratory function at regular and frequent intervals is essential because respiratory insufficiency and subsequent failure due to weakness or paralysis of the intercostal muscles and diaphragm may develop quickly. In addition to the respiratory rate and the quality of respirations, vital capacity is monitored frequently and at regular intervals so that respiratory insufficiency can be anticipated. Decreasing vital capacity associated with weakness of the muscles used in swallowing, which causes difficulty in both coughing and swallowing, indicates impending respiratory failure. Signs and symptoms include breathlessness while speaking, shallow and irregular breathing, use of accessory muscles, tachycardia, and changes in respiratory pattern.

Parameters for determining the onset of respiratory failure are established on admission, allowing intubation and the initiation of mechanical ventilation on a nonemergent basis. This also allows the patient to be prepared for the procedure in a controlled manner, which reduces anxiety and complications.

Other complications include cardiac arrhythmias, which necessitate ECG monitoring; transient hypertension; orthostatic hypotension; DVT; PE; urinary retention; and other threats to any patient who is immobilized and paralyzed. These require monitoring and attention to prevent them and prompt treatment if indicated.

PARKINSON DISEASE

Parkinson disease (PD) is a slowly progressing neurologic movement disorder that eventually leads to disability. The degenerative or idiopathic form is the most common; there is also a secondary form with a known or suspected cause. Although the cause of most cases is unknown, causative factors include genetics, atherosclerosis, excessive accumulation of oxygen-free radicals, viral infections, head trauma, chronic use of antipsychotic medications, and some environmental exposures. Parkinsonian symptoms usually first appear in the fifth decade of life, with diagnosis typically in the sixth and seventh decades of life; however, cases have been diagnosed as early as 30 years of age. It is the second most common neurodegenerative disease. PD affects men more frequently than women.

Pathophysiology

PD is associated with decreased levels of dopamine resulting from destruction of pigmented neuronal cells in the substantia nigra in the basal ganglia region of the brain. Fibers or neuronal pathways project from the substantia nigra to the corpus striatum, where neurotransmitters are key to the control of complex body movements. Through the neurotransmitters acetylcholine (excitatory) and dopamine (inhibitory), striatal neurons relay messages to the higher motor centers that control and refine motor movements. The loss of dopamine stores in this area of the brain results in more excitatory neurotransmitters than inhibitory neurotransmitters, leading to an imbalance that affects voluntary movement. Clinical symptoms do not appear until 60% of the pigmented neurons are lost and the striatal dopamine level is decreased by 80%. Cellular degeneration impairs the extrapyramidal tracts that control semiautomatic functions and coordinated movements; motor cells of the motor cortex and the pyramidal tracts are not affected.

Clinical Manifestations and Assessment

PD has a gradual onset, and symptoms progress slowly over a chronic, prolonged course. The cardinal signs are T-R-A-P: Tremor, Rigidity of muscles, Akinesia/Bradykinesia (without or decreased body movement), and Postural disturbances (gait and balance disorders).

Tremor

The most common reason why individuals seek medical evaluation is the presence of a resting tremor. Resting tremor characteristically disappears with purposeful movement but is evident when the extremities are motionless. The tremor may manifest as a rhythmic, slow-turning motion (pronation–supination) of the forearm and the hand and a motion of the thumb against the fingers as if rolling a pill between the fingers. Tremor is present while the patient is at rest; it increases when the patient is walking, concentrating, or feeling anxious.

Rigidity

Resistance to passive limb movement characterizes muscle rigidity. *Cogwheel rigidity* is characterized by jerky rhythmic tone on passive muscle stretching (Mastrianni, Barton, Shannon, Gilman, & Shakkotai, 2014). Involuntary stiffness of the passive extremity increases when another extremity is engaged in voluntary active movement. Early in the disease, the patient may complain of shoulder pain due to rigidity.

Akinesia/Bradykinesia

Akinesia means a lack of movement, and *bradykinesia* means a slowness of initiation and execution of movement. Patients may take longer to complete activities and have difficulty initiating movement, such as rising from a sitting position or turning in bed.

Postural Disturbances

A loss of postural reflexes occurs, and the patient stands with the head bent forward and walks with a propulsive gait. The posture is caused by the forward flexion of the neck, hips, knees, and elbows. The patient may walk faster and faster, trying to move the feet forward under the body's center of gravity (shuffling gait). Difficulty in pivoting that causes loss of balance (either forward or backward) places the patient at risk for falls.

Other Manifestations

The effect of PD on the basal ganglia often produces autonomic symptoms that include excessive and uncontrolled sweating, paroxysmal flushing, orthostatic hypotension, gastric and urinary retention, constipation, and sexual dysfunction. Cognitive and psychiatric changes are often interrelated and may be predictive of one another. Depression is common; whether it is a reaction to the disorder or is related to a biochemical abnormality is uncertain. Cognitive changes may appear in the form of judgment, reasoning, decision

making, and memory deficits, although intellect is not usually affected. A number of psychiatric manifestations (personality changes, psychosis, dementia, and acute confusion) are common in elderly patients with PD.

Patients with PD experience sleep disturbances. This may be related to depression, dementia, or medications. Auditory and visual hallucinations have also been reported in PD and may be associated with depression, dementia, lack of sleep, or adverse effects of medications.

Hypokinesia (abnormally diminished movement) is also common and may appear after the tremor. The *freezing phenomenon* refers to a transient inability to perform active movement and is thought to be an extreme form of bradykinesia. Additionally, the patient tends to shuffle and exhibits a decreased arm swing. As dexterity declines, micrographia (small handwriting) develops. The face becomes increasingly mask-like and expressionless, and the frequency of blinking decreases. Dysphonia (soft, low-pitched, and less audible speech) may occur due to weakness of the muscles responsible for speech and paralysis of the soft palate, resulting in a nasal-sounding speech. In many cases, the patient develops dysphagia, begins to drool, and is at risk for choking and aspiration.

Complications associated with PD are common and are typically related to disorders of movement. As the disease progresses, patients are at risk for respiratory and urinary tract infection, skin breakdown, and injury from falls. The adverse effects of medications used to treat the symptoms are associated with numerous complications, such as dyskinesia (impairment of voluntary movements resulting in fragmented or jerky motions) and orthostatic hypotension.

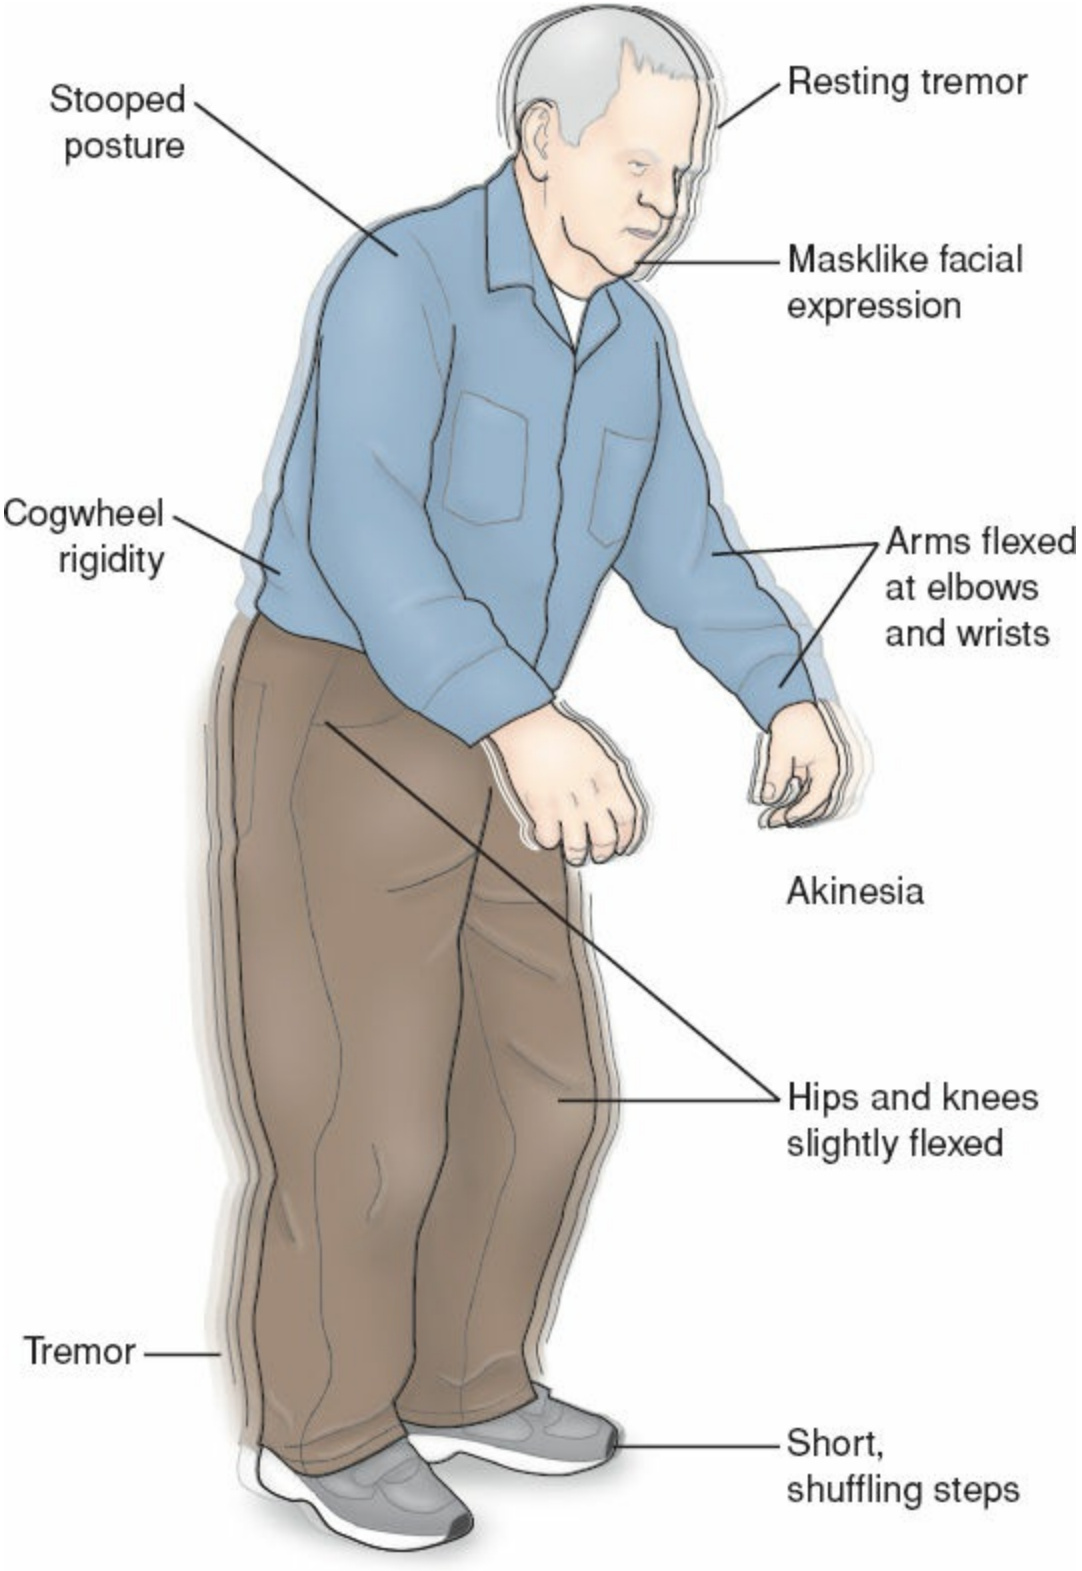

FIGURE 46-8 The clinical features of Parkinson disease: TRAP (Tremor, Rigidity, Akinesia/Bradykinesia, and Postural disturbances). (Adapted from Timby, B. (2010). *Introductory medical-surgical nursing* (10th ed., p. 535). Philadelphia, PA: Lippincott Williams & Wilkins.)

Early diagnosis can be difficult because patients rarely are able to pinpoint when the symptoms started. Often, a family member notices a change, such as stooped posture, a stiff arm, a slight limp, tremor, or slow, small handwriting. The medical history, presenting

symptoms, neurologic examination, and response to pharmacologic management are carefully evaluated when making the diagnosis. Currently, the disease is diagnosed clinically from the patient's history and the presence of two of the four cardinal manifestations: tremor, rigidity, akinesia/bradykinesia, and postural disturbances (Fig. 46-8).

Medical and Nursing Management

Treatment is directed at controlling symptoms and maintaining functional independence. Care is individualized for each patient based on presenting symptoms and social, occupational, and emotional needs. Pharmacologic management is the mainstay of treatment, although advances in research have led to increased surgical options. Patients are usually cared for at home and are admitted to the hospital only for complications or to initiate new treatments.

Antiparkinsonian Medications

Levodopa (Larodopa) is the most effective agent and the mainstay of treatment. Levodopa is converted to dopamine in the basal ganglia, producing symptom relief. The beneficial effects of levodopa are most pronounced in the first few years of treatment. Benefits begin to wane and adverse effects become more severe over time. Confusion, hallucinations, depression, and sleep alterations are associated with prolonged use. Levodopa is usually administered in combination with carbidopa (Sinemet), an amino acid decarboxylase inhibitor, which helps to maximize the beneficial effects of levodopa.

Within 5 to 10 years, most patients develop a response to the medication characterized by dyskinesia (abnormal involuntary movements), including facial grimacing, rhythmic jerking movements of the hands, head bobbing, chewing and smacking movements, and involuntary movements of the trunk and extremities. The patient may experience an on–off syndrome, in which sudden periods of near-immobility ("off effect") are followed by a sudden return of effectiveness of the medication ("on effect"). Refer to Table 46-2 for additional medical therapies.

Drug Alert!
MAO-B inhibitors may offer some neuroprotective benefits that could postpone the need for levodopa. Since MAO-B is an enzyme that breaks down dopamine, a medication that helps to block the breakdown of dopamine in the brain makes more dopamine available and reduces some of the motor symptoms of PD. When used together with other medications, MAO-B inhibitors may reduce "off" effect and extend "on" effect as described previously. The patient must be educated to avoid an interaction with products containing tyramine (red wine, aged cheese) since sudden and severe hypertension can occur.

Deep Brain Stimulation

Deep brain stimulation is the delivery of high-frequency electrical stimulation to a select targeted area in the brain (Fig. 46-9). A CT scan or MRI determines the target area. Unilateral and/or bilateral deep brain stimulation of the subthalamic nucleus or globus pallidus (the site where most of the degenerative changes of PD occurs) improves the symptoms of PD, and early use (when motor complications are developing) results in

significant benefit compared to traditional medical treatment (Lang, 2016). In deep brain stimulation, one or more electrodes is placed in specific areas of the brain and connected to a pulse generator that is implanted in a subcutaneous subclavicular or abdominal pouch. The battery-powered pulse generator sends high-frequency electrical impulses through a wire placed under the skin to a lead anchored to the skull. The electrode blocks nerve pathways in the brain that cause tremors. Deep brain stimulation usually results in patients being at their best for longer periods of the day than they were with medication alone.

TABLE 46-2 Antiparkinsonian Medications

Anticholinergic Therapy Trihexyphenidyl hydrochloride (Artane) Benztropine mesylate (Cogentin)	Used for controlling tremor by counteracting the action of the neurotransmitter acetylcholine; often poorly tolerated in elderly patients. Intraocular pressure must be closely monitored; these medications are contraindicated in patients with narrow-angle glaucoma. Patients with benign prostate hyperplasia (BPH) are monitored for signs of urinary retention.
Antiviral Therapy Amantadine hydrochloride (Symmetrel)	Used for symptoms related to akinesia, as well as tremor. A low incidence of side effects is seen but can include psychiatric disturbances (mood changes, confusion, depression, hallucinations), lower extremity edema, orthostatic hypotension, congestive heart failure, nausea, epigastric distress, urinary retention, headache, and visual impairment.
Dopamine Agonists Bromocriptine mesylate (Parlodel) Pergolide (Permax) Ropinirole hydrochloride (Requip) Pramipexole (Mirapex)	Useful in postponing the initiation of carbidopa or levodopa therapy or added to the medication regimen after carbidopa or levodopa loses effectiveness. Adverse reactions to these medications include nausea, vomiting, diarrhea, lightheadedness, hypotension, impotence, and psychiatric effects. Requip and Mirapex do not have the potentially serious adverse effects of pergolide and bromocriptine mesylate.
Monoamine Oxidase Inhibitors (MAOIs) Selegiline (Eldepryl) Rasagiline (Azilect) Zydis selegiline HCl (Zelapar)	Used in combination with a dopamine agonist to delay the use of carbidopa or levodopa therapy. Adverse effects are similar to those of levodopa.
Catechol-O-Methyltransferase (COMT) Inhibitors Entacapone (Comtan) Tolcapone (Tasmar)	When given in combination with carbidopa or levodopa, they can increase the duration of action. COMT inhibitors block an enzyme that metabolizes levodopa, making more levodopa available for conversion to dopamine in the brain.
Antidepressants	
Tricyclic antidepressants	Used to treat depression; dosing is lower in patients with Parkinson disease, typically one third to one half of the usual dosage.
Amitriptyline hydrochloride (Elavil)	Used for anticholinergic and antidepressant effects
Serotonin reuptake inhibitors (SRIs) Fluoxetine hydrochloride (Prozac)	Effective for treating depression but may aggravate symptoms of Parkinson disease.
Atypical antidepressants Bupropion hydrochloride (Wellbutrin)	Effective for treating depression but may aggravate symptoms of Parkinson disease.

Improving Mobility

A progressive program of daily exercise will increase muscle strength, improve coordination and dexterity, reduce muscular rigidity, and prevent contractures that occur when muscles are not used. Walking, riding a stationary bicycle, swimming, and gardening are all exercises that help maintain joint mobility. Stretching (stretch–hold–relax) and ROM exercises promote joint flexibility. Postural exercises are important to counter the tendency of the head and neck to be drawn forward and down. A physical therapist may be helpful in developing an individualized exercise program and can provide instruction to the patient and caregiver on exercising safely. Faithful adherence to an exercise and walking program

helps to delay the progress of the disease. Warm baths and massage, in addition to passive and active exercises, help relax muscles and relieve painful muscle spasms that accompany rigidity.

Balance may be adversely affected because of the rigidity of the arms (arm swinging is necessary in normal walking). Special walking techniques must be learned to offset the shuffling gait and the tendency to lean forward. The patient is taught to concentrate on walking erect, to watch the horizon, and to use a wide-based gait (i.e., walking with the feet separated). A conscious effort must be made to swing the arms, raise the feet while walking, and use a heel–toe placement of the feet with long strides. The patient is advised to practice walking to marching music or to the sound of a ticking metronome because this provides sensory reinforcement. Breathing exercises while walking helps to move the rib cage and to aerate parts of the lungs. Frequent rest periods aid in preventing frustration and fatigue.

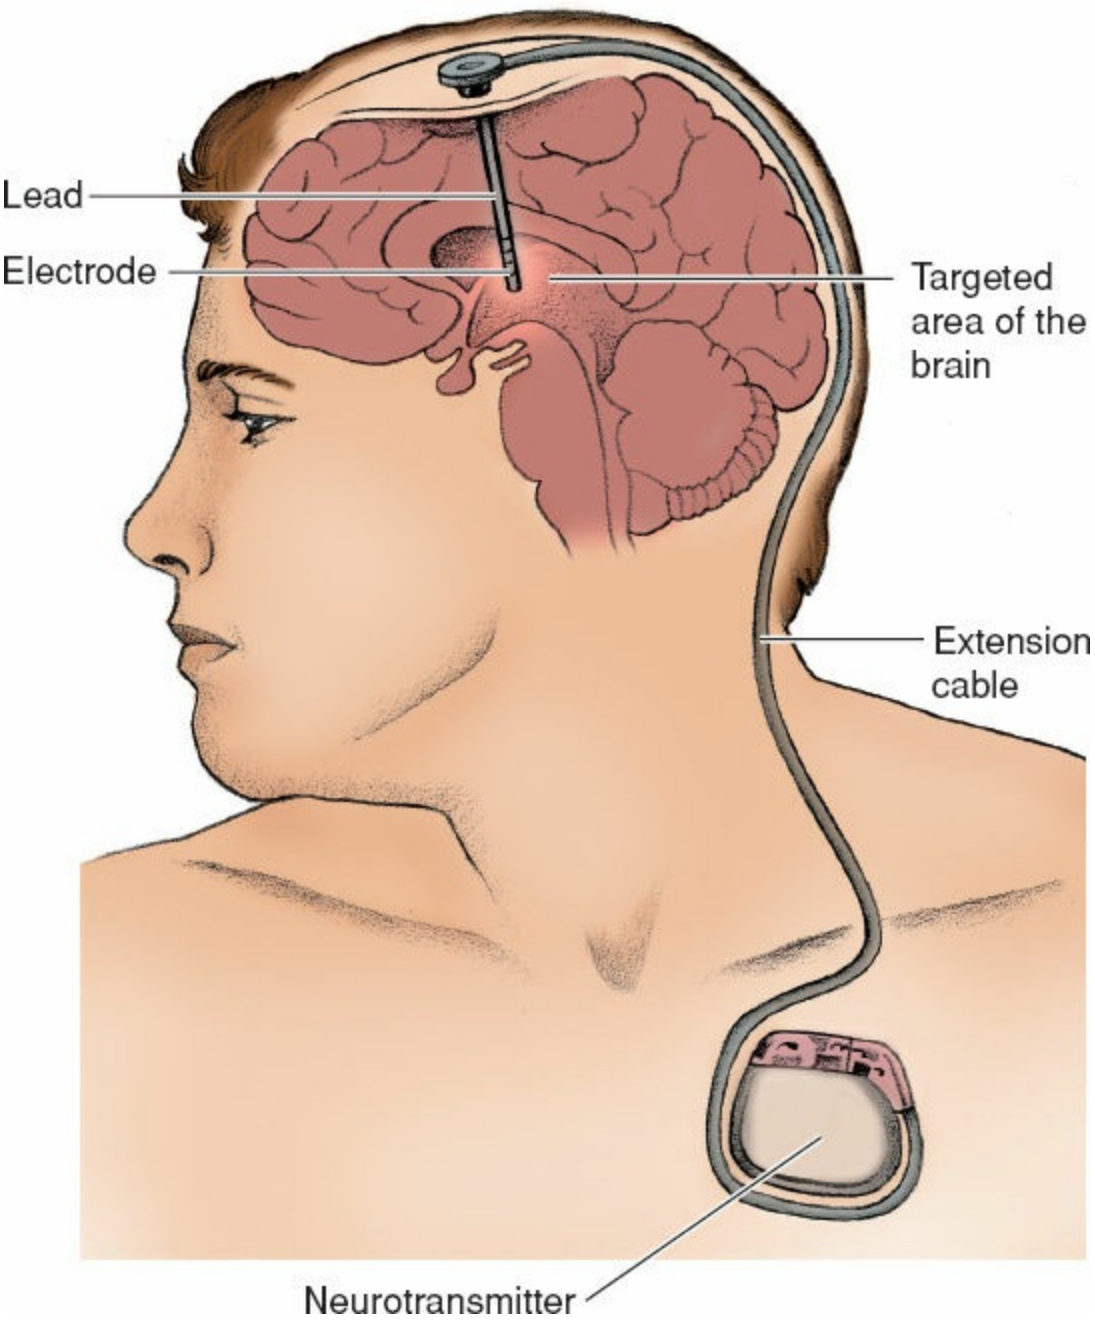

FIGURE 46-9 Deep brain stimulation. The deep brain stimulation system consists of the stimulating lead (which is implanted to the desired target), the extension cable (which is tunneled under the scalp and soft tissues of the neck to the anterior chest wall), and the pulse generator (which is the programmable source of the electrical impulses). This illustration shows the placement of the stimulator in the patient's body. (Used with permission from Lippincott's Nursing Advisor by Lippincott Williams & Wilkins.)

Enhancing Self-Care Activities

Environmental modifications are necessary to compensate for functional disabilities (removing scatter rugs, installing bathroom handrails, ensuring good lighting, etc.). Patients may have severe mobility problems that make normal activities impossible. Adaptive or assistive devices may be useful. A hospital bed at home with bedside rails, an overbed frame with a trapeze, or a rope tied to the foot of the bed can provide assistance in pulling up without help. An occupational therapist can evaluate the patient's needs in the home, make recommendations regarding adaptive devices, and teach the patient and caregiver how to improvise.

Improving Bowel Elimination

The patient may have severe problems with constipation. Among the factors causing constipation are weakness of the muscles used in defecation, lack of exercise, inadequate fluid intake, and decreased autonomic nervous system activity. The medications used for the treatment of the disease also inhibit normal intestinal secretions. A regular bowel routine may be established by encouraging the patient to set a specific time of day to sit on the toilet without distractions, consciously increase fluid intake, and eat foods with moderate fiber content. Laxatives should be avoided. A raised toilet seat is useful because the patient has difficulty in moving from a standing to a sitting position.

Improving Nutrition

Patients may have difficulty maintaining their weight. Eating becomes a very slow process, requiring concentration due to a dry mouth from medications and difficulty chewing and swallowing. These patients are at risk for aspiration because of impaired swallowing and the accumulation of saliva. They may be unaware that they are aspirating; subsequently, bronchopneumonia may develop.

Monitoring weight on a weekly basis indicates whether caloric intake is adequate. Supplemental feedings increase caloric intake. As the disease progresses, a nasogastric tube or percutaneous endoscopic gastroscopy may be necessary to maintain adequate nutrition. A dietitian can be consulted regarding nutritional needs.

An electric warming tray keeps food hot and allows the patient to rest during the prolonged time that it may take to eat. Special utensils also assist at mealtime. A plate that is stabilized, a nonspill cup, and eating utensils with built-up handles are useful self-help devices. The occupational therapist can assist in identifying appropriate adaptive devices.

Enhancing Swallowing

Swallowing difficulties are common in PD, and may be associated with poor head control, tongue tremor, hesitancy in initiating swallowing, difficulty in shaping food into a bolus,

and disturbances in pharyngeal motility. To offset these problems, the patient should sit in an upright position during mealtime. A semisolid diet with thick liquids is easier to swallow than solids; thin liquids should be avoided. Thinking through the swallowing sequence is helpful. The patient is taught to place the food on the tongue, close the lips and teeth, lift the tongue up and then back, and swallow. The patient is encouraged to chew first on one side of the mouth and then on the other. To control the buildup of saliva, the patient is reminded to hold the head upright and make a conscious effort to swallow.

Improving Communication

Speech disorders are present in most patients with PD. Their low-pitched, monotonous, soft speech requires that they make a conscious effort to speak slowly, with deliberate attention to what they are saying. The patient is reminded to face the listener, exaggerate the pronunciation of words, speak in short sentences, and take a few deep breaths before speaking. A speech therapist may be helpful in designing speech improvement exercises and assisting the family and health care personnel to develop and use a method of communication that meets the patient's needs. A small electronic amplifier is helpful if the patient has difficulty being heard.

Supporting Coping Abilities

Support can be given by encouraging the patient and pointing out that activities will be maintained through active participation. A combination of physiotherapy, psychotherapy, medication therapy, and support group participation may help reduce the depression that often occurs.

Patients often feel embarrassed, apathetic, inadequate, bored, and lonely. These feelings may be due, in part, to physical slowness and the great effort that even small tasks require. The patient is assisted and encouraged to set achievable goals (e.g., improvement of mobility).

Because PD can lead to withdrawal and depression, patients must be active participants in their therapeutic program, including social and recreational events. A planned program of activity throughout the day prevents too much daytime sleeping as well as disinterest and apathy.

Every effort should be made to encourage patients to carry out the tasks involved in meeting their own daily needs and to remain independent. Doing things for the patient merely to save time undermines the basic goal of improving coping abilities and promoting a positive self-concept.

ALZHEIMER DISEASE

Alzheimer disease (AD) is the most common type of dementia. This disease is a progressive, irreversible, degenerative neurologic disease that begins insidiously and is characterized by gradual losses of cognitive function and disturbances in behavior and affect. Although AD can occur in people as young as 40 years of age, it is uncommon before 65 years of age. AD can be classified into two types: familial, or early-onset AD, and sporadic, or late-onset AD. Familial AD is rare, accounting for only 5% to 10% of all cases, and is frequently associated

with genetic mutations (four susceptible genes have been identified). It occurs in middle-aged adults. If family members have at least one other relative with AD, then there is a familial component, which nonspecifically includes both environmental triggers and genetic determinants. Sporadic AD generally occurs in people older than 65 years of age, and it has no obvious pattern of inheritance.

Pathophysiology

Specific neuropathologic and biochemical changes are found in patients with AD. These include neurofibrillary tangles (tangled masses of nonfunctioning neurons) and senile or neuritic plaques (deposits of amyloid protein, part of a larger protein called amyloid precursor protein [APP]) in the brain. The neuronal damage occurs primarily in the cerebral cortex and results in brain atrophy. Similar changes are found in the normal brain tissue of older adults, but to a lesser extent. Cells that use the neurotransmitter acetylcholine are those principally affected by AD. Biochemically, the enzyme active in producing acetylcholine, which is specifically involved in memory processing, is decreased.

Clinical Manifestations and Assessment

In the early stages of AD, forgetfulness and subtle memory loss occur. Patients may experience small difficulties in work or social activities but have adequate cognitive function to hide the loss and function independently. Depression may occur. With further progression of AD, the deficits can no longer be concealed. Forgetfulness is manifested in many daily actions; patients may lose their ability to recognize familiar faces, places, and objects, and they may become lost in a familiar environment. They may repeat the same stories because they forget that they have already told them. Trying to reason with people with AD and using reality orientation only increases their anxiety without increasing function. Conversation becomes difficult, and word-finding difficulties occur. The ability to formulate concepts and think abstractly disappears; for example, a patient can interpret a proverb only in concrete terms. Patients are often unable to recognize the consequences of their actions and, therefore, will exhibit impulsive behavior. For example, on a hot day, a patient may decide to wade in the city fountain fully clothed. Patients have difficulty with everyday activities, such as operating simple appliances and handling money.

Personality changes are also usually evident. Patients may become depressed, suspicious, paranoid, hostile, and even combative. Progression of the disease intensifies the symptoms: speaking skills deteriorate to nonsense syllables, agitation and physical activity increase, and patients may wander at night. Eventually, assistance is needed for most ADLs, including eating and toileting, because dysphagia and incontinence develop. The late stages, in which patients are usually immobile and require total care, may last months or years. Occasionally, patients may recognize family members or caregivers. Death occurs as a result of complications, such as pneumonia, malnutrition, or dehydration.

A definitive diagnosis of AD is made based on meeting the clinical criteria and histologic evidence based on examination of brain tissue obtained from biopsy or autopsy. The most important goal is to rule out other causes of dementia or reversible causes of confusion, such as other types of dementia, depression, delirium, alcohol or drug abuse, or inappropriate drug dosage or drug toxicity. Refer to Table 46-3 for a summary of differences between AD and delirium.

The health history—including medical history, family history, social and cultural history, and medication history—and the physical examination, including functional and mental health status, are essential to the diagnosis of probable AD. Diagnostic tests, including complete blood count, chemistry profile, and vitamin B_{12} and thyroid hormone levels, as well as screening with EEG, CT, MRI, and examination of the CSF may all refute or support a diagnosis of probable AD.

Depression can closely mimic early-stage AD and coexists in many patients. A depression scale is helpful in screening for underlying depression. Tests of cognitive function, such as the Mini-Mental Status Examination and the clock-drawing test, are useful for screening. CT scans and MRIs of the brain are useful for excluding hematoma, brain tumor, stroke, normal-pressure hydrocephalus, and atrophy but are not reliable in making a definitive diagnosis of AD. Infections, physiologic disturbances such as hypothyroidism, PD, and vitamin B_{12} deficiency can cause cognitive impairment that may be misdiagnosed as AD. Biochemical abnormalities can be excluded through examination

of the blood and CSF, but the findings are not sufficiently specific to make the diagnosis. AD is a diagnosis of exclusion, and a diagnosis of probable AD is made when the medical history, physical examination, and laboratory tests have excluded all known causes of other dementias.

TABLE 46-3 Summary of Differences Between Alzheimer Disease and Delirium

	Alzheimer Disease (AD)	Delirium
Etiology	Familial (genetic [chromosomes 1, 14, 21]) Sporadic	Drug toxicity and interactions; acute disease; trauma; chronic disease exacerbation Fluid and electrolyte disorder
Risk factors	Advanced age; genetics (apoE4 gene)	Preexisting cognitive impairment
Occurrence	50–60% of dementias	20% of hospitalized older people
Onset	Slow, progressive	Rapid, acute onset A harbinger of acute medical illness (e.g., pneumonia, urinary tract infection, myocardial infarction, pain)
Age of onset (years)	Early onset AD: 30–65 years of age Late onset AD: 65+ years of age Most commonly: 85+ years of age	Any age but predominantly in older people (over 65 years of age) (Fong, Tulebaev, & Inouye, 2009).
Gender	Males and females equally	Males and females equally
Course	Chronic, irreversible; progressive, regular, downhill	Acute
Duration	2–20 years	Lasts 1 day to 1 month
Symptom progress	Onset insidious. *Early:* Mild and subtle *Middle and late:* Intensified Progression to death (infection or malnutrition)	Symptoms are fully reversible with adequate treatment; can progress to chronicity or death if underlying condition is ignored.
Mood	Early depression (30%)	Variable
Speech/language	Speech remains intact until late in disease *Early:* Mild anomia (cannot name objects); deficits progress until speech lacks meaning; echoes and repeats words and sounds; mutism	Fluctuating; often cannot concentrate long enough to speak
Physical signs	*Early:* No motor deficits *Middle:* Apraxia (70%) (cannot perform purposeful movement) *Late:* Dysarthria (impaired speech) *End stage:* Loss of all voluntary activity; positive neurologic signs	Signs and symptoms of underlying disease
Orientation	Becomes lost in familiar places (topographic disorientation) Has difficulty drawing three-dimensional objects (visual and spatial disorientation) Disorientation to time, place, and person—with disease progression	May fluctuate between lucidity and complete disorientation to time, place, and person

Memory	Loss is an early sign of AD; loss of recent memory is soon followed by progressive decline in remote memory as well	Impaired recent and remote memory; may fluctuate between lucidity and confusion
Personality	Apathy, indifference, irritability Early disease—social behavior intact; hides cognitive deficits Advanced disease—disengages from activity and relationships; suspicious; paranoid delusions caused by memory loss; aggressive; catastrophic reactions	Fluctuating; cannot focus attention to converse; alarmed by symptoms (when lucid); hallucinations; paranoid
Functional status, activities of daily living	Poor judgment in everyday activities; has progressive decline in ability to handle money, use telephone, function in home and workplace	Impaired
Attention span	Distractable; short attention span	Highly impaired; cannot maintain or shift attention
Psychomotor activity	Wandering, hyperactivity, pacing, restlessness, agitation	Variable; alternates between high agitation, hyperactivity, restlessness, and lethargy
Sleep–wake cycle	Often impaired; wandering and agitation at nighttime	Takes brief naps throughout day and night

Medical and Nursing Management

The primary goal in the medical management of AD is to manage the cognitive and behavioral symptoms. There is no cure and no way to slow the progression of the disease. Cholinesterase inhibitors, such as donepezil hydrochloride (Aricept), rivastigmine tartrate (Exelon), and galantamine hydrobromide (Reminyl), enhance acetylcholine uptake in the brain, thus maintaining memory skills for a period of time. The drug memantine (Namenda) is an N-methyl-D-aspartate receptor antagonist that is thought to interfere with glutaminergic overstimulation. Cognitive ability improves within 6 to 12 months of therapy, but cessation of the medications results in cognitive decline commensurate with disease progression.

Behavioral problems, such as agitation and psychosis, can be managed by behavioral and psychosocial therapies. Providing an environment that is controlled and stable can help with behavior problems. Pharmacologic treatment for psychosis in patients with AD can be complicated due to a black box warning by the FDA that both conventional and atypical antipsychotics can increase the risk of death (Madhusoodanan & Ting, 2014). Assessment and diagnosis of depression should occur during the initial evaluation. Associated depression can be treated with antidepressants.

Nursing interventions for AD are aimed at promoting patient function and independence for as long as possible. Other important goals include promoting the patient's physical safety, promoting independence in self-care activities, reducing anxiety and agitation, improving communication, providing for socialization and intimacy, promoting adequate nutrition, promoting balanced activity and rest, and supporting and educating family caregivers.

Supporting Cognitive Function

Because dementia of any type is degenerative and progressive, patients display a decline in cognitive function over time. In the early phase of AD, minimal cueing and guidance may be all that are needed for the patient to function fairly independently for a number of years. However, as the patient's cognitive ability declines, family members must provide more and more assistance and supervision. A calm, predictable environment helps people with AD interpret their surroundings and activities. Environmental stimuli are limited, and a regular routine is established. A quiet, pleasant manner of speaking, clear and simple explanations, and use of memory aids and cues help minimize confusion and disorientation and give patients a sense of security. Prominently displayed clocks and calendars may enhance orientation to time. Color-coding the doorway may help patients who have difficulty locating their room. Active participation may help patients maintain cognitive, functional, and social interaction abilities for a longer period.

Promoting Physical Safety

A safe home environment allows the patient to move about as freely as possible and relieves the family of constant worry about safety. To prevent falls and other injuries, all obvious hazards are removed and hand rails are installed. A hazard-free environment allows the patient maximum independence and a sense of autonomy. Adequate lighting, especially in

halls, stairs, and bathrooms, is necessary. Night lights are helpful, particularly if the patient has increased confusion at night (sundowning). Driving is prohibited, and smoking is allowed only with supervision. The patient may have a short attention span and be forgetful. Wandering behavior can often be reduced by gentle persuasion or distraction. Restraints should be avoided because they increase agitation. Doors leading from the house must be secured. Outside the home, all activities must be supervised to protect the patient, and the patient should wear an identification bracelet or neck chain in case he or she becomes separated from the caregiver.

Promoting Independence in Self-Care Activities

Pathophysiologic changes in the brain make it difficult for people with AD to maintain physical independence. Patients should be assisted to remain functionally independent for as long as possible. One way to do this is to simplify daily activities by organizing them into short, achievable steps so that the patient experiences a sense of accomplishment. Frequently, occupational therapists can suggest ways to simplify tasks or recommend adaptive equipment. Direct patient supervision is sometimes necessary, but maintaining personal dignity and autonomy is important for people with AD, who should be encouraged to make choices when appropriate and to participate in self-care activities as much as possible.

Reducing Anxiety and Agitation

Despite profound cognitive losses, patients are sometimes aware of their diminishing abilities. Patients need constant emotional support that reinforces a positive self-image. When losses of skills occur, goals are adjusted to fit the patient's declining ability.

The environment should be kept familiar and noise-free. Excitement and confusion can be upsetting and may precipitate a combative, agitated state known as a *catastrophic reaction* (overreaction to excessive stimulation). The patient may respond by screaming, crying, or becoming abusive (physically or verbally); this may be the person's only way of expressing an inability to cope with the environment. When this occurs, it is important to remain calm and unhurried. Forcing the patient to proceed with the activity only increases the agitation. It is better to postpone the activity until later, even to another day. Frequently, the patient quickly forgets what triggered the reaction. Measures such as moving to a familiar environment, listening to music, stroking, rocking, or distraction may quiet the patient. Structuring activity is also helpful. Becoming familiar with a particular patient's predicted responses to certain stressors helps caregivers avoid similar situations.

Many older people with AD who have progressed to the late stages of the disease typically reside in nursing homes and are predominantly cared for by nurses' aides. Dementia education for caregivers is essential to minimize patient agitation and can be effectively taught by advanced practice nurses.

Improving Communication

To promote the patient's interpretation of messages, the nurse should remain unhurried and reduce noises and distractions. Use of clear, easy-to-understand sentences to convey messages is essential because patients frequently forget the meaning of words or have

difficulty organizing and expressing thoughts. In the earlier stages of AD, lists and simple written instructions that serve as reminders may be helpful. In later stages, the patient may be able to point to an object or use nonverbal language to communicate. Tactile stimuli, such as hugs or hand pats, are usually interpreted as signs of affection, concern, and security.

Providing for Socialization and Intimacy Needs

Because socialization with friends can be comforting, visits, letters, and phone calls are encouraged. Visits should be brief and nonstressful; limiting visitors to one or two at a time helps reduce overstimulation. Recreation is important, and people with AD are encouraged to enjoy simple activities. Realistic goals for activities that provide satisfaction are appropriate. Hobbies and activities, such as walking, exercising, and socializing, can improve the quality of life. The nonjudgmental friendliness of a pet may provide stimulation, comfort, and contentment. Care of plants or of a pet can also be satisfying and an outlet for energy.

AD does not eliminate the need for intimacy. Patients and their spouses may continue to enjoy sexual activity. Spouses should be encouraged to talk about any sexual concerns, and sexual counseling may be necessary. Simple expressions of love, such as touching and holding, are often meaningful.

Promoting Adequate Nutrition

Mealtime can be a pleasant social occasion or a time of upset and distress, and it should be kept simple and calm, without confrontations. Patients prefer familiar foods that look appetizing and taste good. To avoid any "playing" with food, one dish is offered at a time. Food is cut into small pieces to prevent choking. Liquids may be easier to swallow if they are converted to gelatin. Hot food and beverages are served warm, and the temperature of the foods should be checked to prevent burns.

When lack of coordination interferes with self-feeding, adaptive equipment is helpful. Some patients may do well eating with a spoon or with their fingers. If this is the case, an apron or a smock, rather than a bib, is used to protect clothing. As deficits progress, it may be necessary to feed the patient. Forgetfulness, disinterest, dental problems, lack of coordination, overstimulation, and choking may all serve as barriers to good nutrition and hydration.

Promoting Balanced Activity and Rest

Many patients with AD exhibit sleep disturbances, wandering, and behaviors that may be considered inappropriate. These behaviors are most likely to occur when there are unmet underlying physical or psychological needs. Caregivers must identify the needs of patients who are exhibiting these behaviors because further health decline may occur if the source of the problem is not corrected. Adequate sleep and physical exercise are essential. If sleep is interrupted or the patient cannot fall asleep, music, warm milk, or a back rub may help the patient to relax. During the day, patients should be encouraged to participate in exercise because a regular pattern of activity and rest enhances nighttime sleep. Long periods of daytime sleeping are discouraged.

Caregiver Burden

The emotional burden on the families of patients with AD is enormous. The physical health of the patient is often very stable, and the mental degeneration is gradual. Family members are faced with numerous difficult decisions (e.g., when the patient should stop driving, when to assume responsibility for the patient's financial affairs). Aggression and hostility exhibited by the patient are often misunderstood by families or caregivers, who feel unappreciated, frustrated, and angry. Feelings of guilt, nervousness, and worry contribute to caregiver fatigue, depression, and family dysfunction.

In some cases, caregivers themselves can become so fatigued as a result of the stress of caregiving that self-neglect or neglect or abuse of the patient can occur. This has been documented in home situations as well as in institutions. Respite care is a commonly provided service in which caregivers can get away from the home for short periods while someone else tends to the needs of the patient.

AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS) is a degenerative disease characterized by the loss of both upper and lower motor neurons. As motor neuron cells die, the muscle fibers that they supply undergo atrophic changes. Causes of ALS include multiple genetic and environmental factors (Hickey, 2014b). It is estimated that 90% of cases of ALS occur sporadically, but 5% to 10% are familial, usually with an autosomal dominant mode of inheritance (Shaw, 2016).

Clinical Manifestations and Assessment

Clinical manifestations depend on the location of the affected motor neurons because specific neurons activate specific muscle fibers. The chief symptoms are fatigue and limb weakness. There is a gradual onset of asymmetric, progressive weakness. Upper extremity onset causes reduced dexterity, and lower extremity symptoms may be tripping, falling, and changes in gait (Hickey, 2014b). Spasticity usually is present, and the deep tendon stretch reflexes become brisk and overactive. Usually, the function of the anal and bladder sphincters remains intact because the spinal nerves that control muscles of the rectum and urinary bladder are not affected.

In about 25% of patients, weakness starts in the muscles supplied by the cranial nerves, and difficulty in talking, swallowing, and, ultimately, breathing occurs. When the patient ingests liquids, soft palate and upper esophageal weakness cause the liquid to be regurgitated through the nose. Weakness of the posterior tongue and palate impairs the ability to laugh, cough, or even blow the nose. If bulbar muscles are impaired, speaking and swallowing are progressively difficult, and aspiration becomes a risk. The voice assumes a nasal sound, and articulation becomes so disrupted that speech is unintelligible. Some emotional lability may be present, but intellectual function is not impaired. Eventually, respiratory function is compromised.

The prognosis generally is based on the area of CNS involvement and the speed with which the disease progresses. Death usually occurs as a result of infection, respiratory failure, or aspiration.

ALS is diagnosed on the basis of the signs and symptoms because no clinical or laboratory tests are specific for this disease. An electromyogram (EMG) will demonstrate fibrillations, which are signs of denervation, muscle wasting, and atrophy (Shaw, 2016). An MRI scan may show high signal intensity in the corticospinal tracts; this differentiates ALS from a multifocal motor neuropathy.

Medical and Nursing Management

No specific therapy exists for ALS. The main focus of management is on interventions to maintain or improve function, well-being, and quality of life.

Most patients with ALS are managed at home and in the community, with hospitalization for acute problems. The most common reasons for hospitalization are dehydration and malnutrition, pneumonia, and respiratory failure; recognizing these problems at an early stage in the illness allows for the development of preventive strategies.

Riluzole (Rilutek), a glutamate antagonist, is the only drug approved by the FDA. A dose of 100 mg/day (50 mg BID) provides a modest improvement in the survival rate (additional 3 months of survival) (Shaw, 2016). The action of riluzole is not clear, but its pharmacologic properties suggest that it may have a neuroprotective effect in the early stages of ALS. Liver function tests should be monitored at baseline and monthly.

Symptomatic treatment and rehabilitative measures are employed to support the patient. Baclofen (Lioresal), dantrolene sodium (Dantrium), or diazepam (Valium) may be useful for patients troubled by spasticity, which causes pain and interferes with self-care.

A patient experiencing problems with aspiration and swallowing may require enteral feeding. The American Academy of Neurology practice guidelines suggest the placement of a percutaneous endoscopic gastrostomy tube before the forced vital capacity drops below 50% of the predicted value.

Nursing Alert

The nurse observes for paradoxical movement of the abdominal wall during inspiration, SOB, and orthopnea, which may be associated with diaphragmatic weakness. Complaints of interrupted sleep, morning headaches, anorexia, and daytime somnolence may reflect nocturnal retention of carbon dioxide.

Respiratory management is guided by the results of vital capacity and negative inspiratory force parameters that are measured at regular intervals. The use of noninvasive positive-pressure ventilation (NIPPV) is started as indicated by these measurements. As the disease progresses, the NIPPV will become inadequate, and, if the decision is made to have life prolonged with advanced technology, the patient can proceed to tracheotomy and invasive ventilation (Shaw, 2016).

Decisions about life-support measures are made by the patient and family and should be based on a thorough understanding of the disease, the prognosis, and the implications of initiating such therapy. Patients are encouraged to complete an advance directive or "living will" to preserve their autonomy in decision-making.

DEGENERATIVE DISK DISEASE

Low back pain is a significant public health disorder in the United States, although its prevalence is difficult to quantify. Acute low back pain lasts less than 3 months, whereas chronic or degenerative disease has a duration of 3 months or longer. It is estimated that disk disease, such as protrusion, accounts for only 5% of all low back problems, whereas

degenerative changes are commonly associated with low back pain.

Pathophysiology

The intervertebral disk is a cartilaginous plate that forms a cushion between the vertebral bodies (see Fig. 46-10A). This tough, fibrous material is incorporated in a capsule. A ball-like cushion in the center of the disk is called the *nucleus pulposus.* In herniation of the intervertebral disk (ruptured disk), the nucleus of the disk protrudes into the annulus (the fibrous ring around the disk), with subsequent nerve compression. Protrusion or rupture of the nucleus pulposus usually is preceded by degenerative changes that occur with aging. Loss of protein polysaccharides in the disk decreases the water content of the nucleus pulposus. The development of radiating cracks in the annulus weakens resistance to nucleus herniation. After trauma (falls and repeated minor stresses such as lifting incorrectly), the cartilage may be injured.

For most patients, the immediate symptoms of trauma are short-lived, and those resulting from injury to the disk do not appear for months or years. Then, with degeneration in the disk, the capsule pushes back into the spinal canal, or it may rupture and allow the nucleus pulposus to be pushed back against the dural sac or against a spinal nerve as it emerges from the spinal column (see Fig. 46-10B). This sequence produces pain due to radiculopathy (pressure in the area of distribution of the involved nerve endings). Continued pressure may produce degenerative changes in the involved nerve, such as changes in sensation and deep tendon reflexes.

Clinical Manifestations and Assessment

Common clinical manifestations are pain, motor and sensory deficits, and alterations of reflexes. A neurologic examination is carried out to determine whether motor, sensory, or reflex impairment from root compression is present and to provide a baseline for future assessment.

MRI has become the diagnostic tool of choice for localizing even small disk protrusions, particularly for lumbar spine disease. If the clinical symptoms are not consistent with the pathology seen on MRI, then CT scanning and myelography are performed. EMG may be used to localize the specific spinal nerve roots involved.

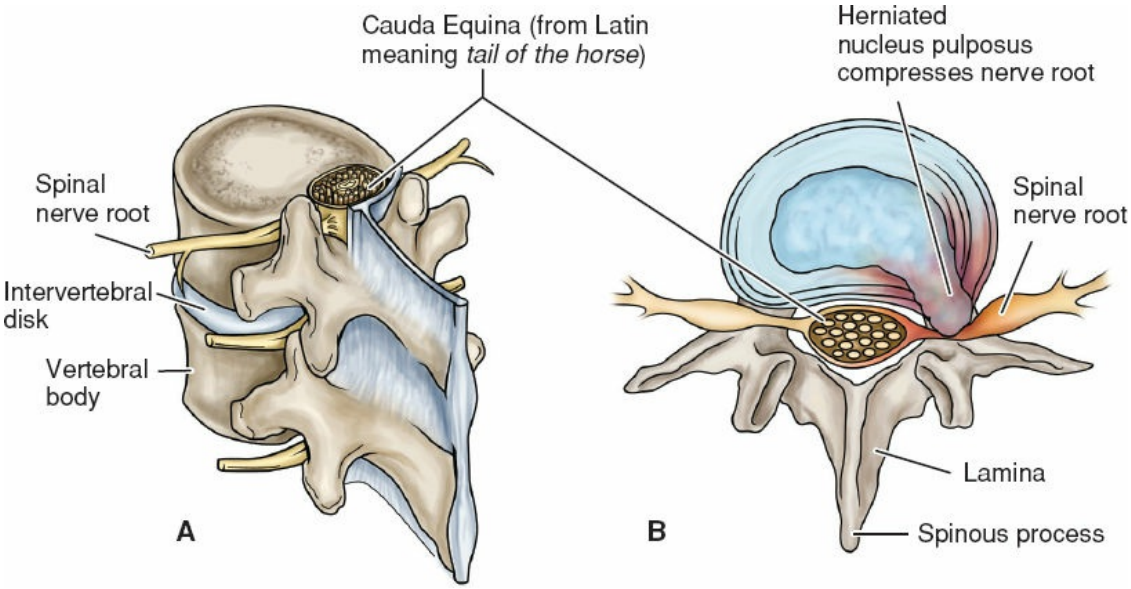

FIGURE 46-10 A. Normal lumbar spine vertebrae, invertebral disks, and spinal nerve root. B. Ruptured vertebral disk.

Medical and Nursing Management

Most cases may improve with conservative treatment consisting of 1 to 2 days of bed rest, nonsteroidal anti-inflammatory drugs (NSAIDs), exercise regimens, epidural steroids, and patient education (Strayer & Hickey, 2014).

Surgery is usually indicated if the degenerative disk is causing compression on the spinal cord or if the patient has radiculopathy that fails conservative treatment. The most common procedure is a decompression laminectomy, which is the removal of the laminar portion of the vertebrae to gain access to the spinal cord.

INTERVERTEBRAL DISK HERNIATION

CERVICAL SPINE

The cervical spine is subjected to stresses that result from disk degeneration (due to aging, occupational stresses) and spondylosis (degenerative changes occurring in a disk and adjacent vertebral bodies with bulging and, occasionally, herniation). Cervical disk degeneration may lead to lesions that can cause damage to the spinal cord and its roots.

Clinical Manifestations and Assessment

A cervical disk herniation usually occurs at the C5–C6 and C6–C7 interspaces. Pain and stiffness may occur in the neck, the top of the shoulders, and the region of the scapulae. Sometimes patients interpret these signs as symptoms of heart trouble or bursitis. Pain may also occur in the upper extremities and head, accompanied by paresthesia (tingling or a "pins and needles" sensation) and numbness of the upper extremities. Cervical MRI usually confirms the diagnosis.

Medical and Nursing Management

The goals of treatment are to rest and immobilize the cervical spine to give the soft tissues time to heal and to reduce inflammation in the supporting tissues and the affected nerve roots in the cervical spine. Bed rest (usually 1 to 2 days) is important because it eliminates the stress of gravity and relieves the cervical spine of the need to support the head. It also reduces inflammation and edema in soft tissues around the disk, relieving pressure on the nerve roots. Proper positioning on a firm mattress may bring dramatic relief from pain.

The cervical spine may be rested and immobilized by a cervical collar. A collar allows maximal opening of the intervertebral foramina and holds the head in a neutral or slightly flexed position. The patient may have to wear the collar 24 hours a day during the acute phase. The skin under the collar is inspected for irritation. After the patient is free of pain, cervical isometric exercises are begun to strengthen the neck muscles.

Analgesic agents are often necessary to manage pain (NSAIDs, acetaminophen). Narcotics are reserved for severe pain (e.g., hydrocodone/tylenol). Sedatives may be administered to control the anxiety that is often associated with cervical disk disease. Muscle relaxants (cyclobenzaprine [Flexeril], methocarbamol [Robaxin], metaxalone [Skelaxin]) are administered to interrupt muscle spasm and to promote comfort. NSAIDs (aspirin, ibuprofen [Motrin, Advil], naproxen [Naprosyn, Anaprox]) or corticosteroids are prescribed to treat the inflammation that usually occurs in the affected nerve roots and supporting tissues. Occasionally, a corticosteroid is injected into the epidural space for relief of radicular (spinal nerve root) pain. Hot, moist compresses (for 10 to 20 minutes) applied to the back of the neck several times daily increase blood flow to the muscles and help relax the patient and reduce muscle spasm.

Surgical excision of the herniated disk may be necessary if there is a significant neurologic deficit, progression of the deficit, evidence of cord compression, or pain that either worsens or fails to improve. A cervical discectomy, with or without fusion, may be performed to alleviate symptoms. An anterior surgical approach may be used through a transverse incision to remove disk material that has herniated into the spinal canal and foramina, or a posterior approach may be used at the appropriate level of the cervical spine. Potential complications with the anterior approach include carotid or vertebral artery injury, recurrent laryngeal nerve dysfunction, esophageal perforation, and airway obstruction. Complications of the posterior approach include damage to the nerve root or the spinal cord due to retraction or contusion of either of these structures, resulting in weakness of muscles supplied by the nerve root or cord.

Microsurgery, such as endoscopic microdiscectomy, may be performed in selected patients through a small incision and using magnification techniques. The patient who undergoes microsurgery usually has less tissue trauma and pain and consequently a shorter hospital stay than after conventional surgical approaches.

Nursing Alert

Although NSAIDs are often prescribed for cervical disk herniation, when surgery involving bone fusion is considered, NSAIDs are often discontinued because they can interfere with bone healing. The nurse should collaborate with the health care

provider to instruct the patient to avoid these drugs prior to and after surgery.

LUMBAR SPINE

The most common site of lumbar disk herniation occurs at the L4–L5 or L5–S1 levels (Strayer & Hickey, 2014). A herniated lumbar disk causes low back pain accompanied by varying degrees of motor and sensory impairment.

Clinical Manifestations and Assessment

The patient complains of low back pain with muscle spasms, followed by radiation of the pain into one hip and down into the leg (sciatica). Pain is aggravated by actions that increase intraspinal fluid pressure, such as bending, lifting, or straining (as in sneezing or coughing), and usually is relieved by bed rest. Usually there is some type of postural deformity because pain causes an alteration of the normal spinal mechanics. If the patient lies on the back and attempts to raise a leg in a straight position, pain radiates into the leg; this maneuver, called the *straight leg–raising test*, stretches the sciatic nerve. Additional signs include muscle weakness, alterations in tendon reflexes, and sensory loss.

The diagnosis of lumbar disk disease is based on the history and physical findings and the use of imaging techniques, such as MRI, CT, and myelography. Although MRI has largely replaced myelography (fluoroscopy and an injection of contrast material to evaluate the spinal cord, nerve roots and spinal lining), myelography still may be used occasionally to provide information about the spinal cord and nerve roots.

Medical and Nursing Management

The objectives of treatment are to relieve pain, slow disease progression, and increase the patient's functional ability. Bed rest for patients with severe pain in the lumbar region is limited to a short course (2 days or less), followed by resumption of light activity (Strayer & Hickey, 2014).

Strategies for increasing the patient's functional ability include weight reduction, physical therapy, and biofeedback. Mobilization, walking short distances, is recommended. When symptoms subside, stretching, strengthening, and exercise programs should be initiated.

Because muscle spasm is prominent during the acute phase, muscle relaxants are used. NSAIDs and systemic corticosteroids may be administered to counter the inflammation that usually occurs in the supporting tissues and the affected nerve roots. Moist heat and massage help to relax muscles.

Most patients fear surgery on any part of the spine and therefore need explanations about the surgery and reassurance that it will not weaken the back. When data are being collected for the health history, any reports of pain, paresthesia, or muscle spasm are recorded to provide a baseline for comparison after surgery. Preoperative assessment also includes an evaluation of movement of the extremities, as well as bladder and bowel function. To facilitate the postoperative turning procedure, the patient is taught to turn as a unit (called *logrolling*) as part of the preoperative preparation (Fig. 46-11). Before surgery, the patient is also encouraged to take deep breaths, cough, and perform muscle-setting exercises to maintain muscle tone.

FIGURE 46-11 Before the patient undergoes spinal surgery, the logrolling technique that will be used for turning the patient should be demonstrated. The patient's arms will be crossed and the spine aligned. To avoid twisting the spine, the patient's head, shoulders, knees, and hips are turned at the

same time that the patient rolls over like a log. When in a side-lying position, the patient's back, buttocks, and legs are supported with pillows.

In the lumbar region, surgical treatment includes lumbar disk excision through a posterolateral laminotomy and the techniques of microdiscectomy and percutaneous discectomy. In microdiscectomy, an operating microscope is used to visualize the offending disk and compressed nerve roots; it permits a small incision (2.5 cm [1 in]) and minimal blood loss and takes about 30 minutes of operating time. In general, the hospital stay is short, and the patient makes a rapid recovery. Percutaneous discectomy is an alternative treatment for herniated intervertebral disks of the lumbar spine. One approach in current use is through a 2.5-cm (1-in) incision just above the iliac crest. A tube, trocar, or cannula is inserted under x-ray guidance through the retroperitoneal space to the involved disk space. Special instruments are used to remove the disk. The operating time is about 15 minutes. Blood loss and postoperative pain are minimal, and usually the patient is discharged within 2 days after surgery. The disadvantage of this procedure is the possibility of damage to structures in the surgical pathway.

Complications that could occur after surgery include herniation relapse, arachnoiditis (inflammation of the arachnoid), neuritis (inflammation of a nerve), or failed disk syndrome (generalized term to describe continued pain after surgery). Herniation relapse may occur at the same level or elsewhere so the patient may become a candidate for another disk procedure. Arachnoiditis may occur after surgery (and after myelography [if used]); it involves an insidious onset of diffuse, frequently burning pain in the lower back, radiating into the buttocks. Disk excision can leave adhesions and scarring around the spinal nerves and dura, which then produce inflammatory changes that create chronic neuritis and neurofibrosis. Disk surgery may relieve pressure on the spinal nerves, but it does not reverse the effects of neural injury and scarring and the pain that results.

Because postoperative neurologic deficits may occur from nerve root injury, the motor strength and sensation of the lower extremities are evaluated at specified intervals, along with the color and temperature of the legs and sensation of the toes. Assessing the patient after surgery, the nurse checks vital signs frequently, and the wound is inspected for hemorrhage because vascular injury is a complication of disk surgery. It is important to assess for urinary retention, another sign of neurologic deterioration.

In discectomy with fusion, the patient has an additional surgical incision if bone fragments were taken from the iliac crest or fibula to serve as wedges in the spine. The recovery period is longer than for those patients who underwent discectomy without spinal fusion because bony union must take place.

To position the patient, a pillow is placed under the head, and the knee rest is elevated slightly to relax the back muscles. When the patient is lying on one side, however, extreme knee flexion must be avoided. The patient is encouraged to move from side to side to relieve pressure and is reassured that no injury will result from moving. When the patient is ready to turn, the bed is placed in a flat position and a pillow is placed between the patient's legs. The patient turns as a unit (logrolls) without twisting the back. To get out of bed, the patient lies on one side while pushing up to a sitting position. At the same time, the nurse or family member eases the patient's legs over the side of the bed. Coming to a sitting or standing posture is accomplished in one long, smooth motion. Most patients walk to the bathroom on the same day as the surgery. Sitting is discouraged except for

defecation.

CHAPTER REVIEW

Critical Thinking Exercises

1. Your 40-year-old patient has MG. Her condition has been stable and she has been able to manage without assistance, but she reports increasing weakness and fatigue. What nursing assessments and interventions are warranted for her? What discharge plans are indicated if she is to return home to the care of her family? How would your discharge planning change if she lived alone in an apartment on the third floor of a building without an elevator?

2. Your patient has been admitted to the intensive care unit with a diagnosis of possible Guillain–Barré syndrome. Identify the priorities of assessment for this patient and the nursing and medical interventions that you would anticipate. What medications should you have readily available for this patient?

3. A 50-year-old man newly diagnosed with Parkinson disease asks what type of medication he will be given. What are the possible medications that will be used to treat his disease, and the long-term effects of each? How would your discharge teaching targeted toward medications be modified if the patient lives alone?

NCLEX-Style Review Questions

1. While assessing a client with Parkinson disease, the nurse identifies bradykinesia when the client exhibits which symptom?
   a. Muscle flaccidity
   b. An intention tremor
   c. Paralysis of the limbs
   d. Slow spontaneous movement

2. What is the most common initial symptom that a nurse might expect a client with MS to complain about?
   a. Diarrhea
   b. Headaches
   c. Skin infections
   d. Visual disturbances

3. A client who has GB asks, "Will I ever get better?" Which response would be the most appropriate answer by the nurse?
   a. "You'll notice your strength will improve each day."
   b. "We are doing everything we can to provide the best care."
   c. "You seem concerned about getting better. What do you think?"

d. "Your chances for recovery are very good, but recovery is slow."

4. What manifestations will the nurse observe in the patient undergoing a tonic–clonic seizure?
   a. Jerking in one extremity that spreads gradually to adjacent areas
   b. Vacant staring and abrupt cessation of all activity
   c. Facial grimaces, patting motions, and lip smacking
   d. Loss of consciousness, body stiffening, and violent muscle contractions

5. The nurse knows that the signs and symptoms of meningeal irritation include which of the following? Select all that apply.
   a. Nuchal rigidity and headache
   b. Kernig and Brudzinski signs
   c. Aphasia and motor weakness
   d. Photophobia
   e. Ptosis

CHAPTER 47

Nursing Management: Patients with Cerebrovascular Disorders

Karin V. Nyström

Learning Objectives

After reading this chapter you will be able to:

1. Describe the incidence and epidemiology of stroke.
2. Identify mechanisms that affect cerebral blood flow.
3. Describe the pathophysiology of ischemic and hemorrhagic stroke, and transient ischemic attack.
4. Identify risk factors and manifestations of stroke syndromes.
5. Describe collaborative care, drug therapy, and nutritional considerations for patients who have had a stroke.
6. Describe the acute care, rehabilitation, and drug and nutritional considerations for patients recovering from stroke.

Cerebrovascular disorder is an umbrella term that refers to abnormalities of the central nervous system (CNS) affecting normal blood supply to the brain and/or spinal cord. There are many vascular abnormalities affecting cerebral blood flow, but the most common cerebrovascular disorder is stroke. The nurse should be well prepared to recognize stroke symptoms be able to care for patients admitted to an acute care facility with a stroke, and identify the common comorbidities that accompany stroke syndromes. The neurologic condition may be the patient's primary health problem or a secondary diagnosis. As such, nurses must be able to develop a care plan for a stroke patient's recovery that considers both neurologic deficits and potential complications associated with those deficits during both acute recovery and rehabilitation. Additionally, the care plan should include important stroke prevention strategies, such as pharmacotherapies and lifestyle changes applicable to patients who have had a stroke and other patient populations at risk for a cerebrovascular event.

STROKE

It was more than 2,000 years ago that Hippocrates recognized stroke and coined the term "apoplexy" (meaning "struck down with violence" in Greek), which characterized sudden body changes that are manifested in patients who have a stroke, such as unilateral paralysis (Nilsen, 2010). It has been only within the last century that clinicians have understood the pathophysiologic mechanisms to describe stroke types and the potential etiologies of these cerebrovascular disorders. Although patients may present with the sudden onset of neurologic symptoms, usually the etiology of this syndrome is related to chronic disease. An organized and expeditious approach to the management of patients during the acute stroke phase becomes key to reducing the leading adult disability in the United States (2016 stroke statistics).

Incidence

Stroke is currently the fifth leading cause of death in the United States, behind heart disease, cancer, chronic respiratory diseases, and accidents (Centers for Disease Control and Prevention [CDC], 2016). Approximately 800,000 people experience a stroke each year in the United States; 600,000 of these are first events, and approximately 200,000 are recurrent strokes. With about 5 million stroke survivors alive today, stroke is the leading cause of serious, long-term adult disability in the United States (Lloyd-Jones, Brown et al., 2010; AHA, 2015). It is estimated that approximately 90% of stroke survivors are left with some residual deficit. The financial impact of stroke is profound, with estimated direct and indirect costs totaling $33 billion (Mozaffarian, 2015). Although strokes can affect people of all ages, older men are more likely to have strokes and older women more frequently tend to die from their stroke. African Americans have a risk for an ischemic stroke that is three times higher than Caucasians; and Asian patients are at higher risk for a hemorrhagic stroke. These patients are in the same category of populations at higher risk for cardiac events and other vascular diseases. There is also a geographic distinction in this country such that Americans living in the southeastern United States have a higher incidence of stroke—thereby nicknaming this region the "stroke belt."

Despite the numerous national campaign efforts (American Heart/Stroke Association [AHA/ASA], 2017; Payne, Fang, Fogle et al., 2010) to increase stroke awareness over the past three decades, several studies have shown that a majority of people cannot name many of the typical stroke symptoms or do not consider calling 911 in the event that they or a family member are experiencing stroke symptoms (Fussman, Rafferty, Lyon-Callo et al., 2012). Delays in recognizing stroke symptom and in activating the Emergency Medical System limit treatment options and lead to worsening long-term recovery outcomes. The AHA/ASA responded to this gap in awareness and adopted the Stroke Chain of Survival (similar to the Heart Chain of Survival established for cardiac care), implementing a prompt pre-hospital and acute care approach to the evaluation of patients with acute stroke symptoms. Also known as the "7 D's," these components highlight key areas in the recognition and evaluation of a patient suspected of having a stroke to reinforce an efficient method for a rapid approach to acute stroke care (Box 47-1).

Strokes continue to be one of the most common neurologic emergencies, and both community hospitals and large tertiary referral medical centers see a high volume of patients admitted with a stroke-related neurologic diagnosis or patients at risk for stroke. Hospitals today are charged with implementing systems of care to treat stroke patients in the acute phase of their illness and to direct patients and their families to the appropriate rehabilitative program to optimize recovery and functional outcome (Schwamm et al. 2013).

BOX 47-1 Stroke Chain of Survival: The 7 D's

1. *Detection* of the onset of signs and symptoms of acute stroke. Early recognition of the hallmark signs and symptoms of acute stroke is critical to improved patient outcomes.

2. *Dispatch* of Emergency Medical Services (EMS) by telephoning 911. This communication activates EMS systems and ensures prompt EMS response.
3. *Delivery* of the patient to a medical facility. Patients should be transported to a stroke hospital or other facility capable of providing acute stroke care, and advanced prehospital notification should be given to the selected medical facility.
4. *Door* of the emergency department (ED). Immediately upon arrival, the patient should undergo general and neurologic assessment in the ED.
5. *Data* collection, including computer tomography (CT) scan and serial neurologic examinations, along with reviews of the patient's file for potential fibrinolytics (tPA) exclusions.
6. *Decision* regarding stroke treatment. If the patient remains a candidate for tissue plasminogen activator (tPA) therapy, review risks and benefits with the patient and family.
7. *Drug* administration as appropriate and postadministration monitoring.

Certified Stroke Centers

In 2003, the Joint Commission launched a disease-specific care certification program for medical facilities committed to using evidence-based clinical practice guidelines for best stroke care. The Joint Commission's Primary Stroke Center certification program was developed in collaboration with the ASA and was based on the 2000 Brain Attack Coalition's "Recommendations for the Establishment of Primary Stroke Centers." In 2011, an update to the recommendation for the establishment of Primary Stroke Centers as an approach to acute stroke care was published to improve the medical care of stroke patients and included criteria such as an acute stroke team, a dedicated stroke unit, written care protocols, supporting laboratory and imaging services, and mandatory continuing education related to strokes (Alberts, Latchaw, & Jagoda, 2011). These recommendations followed the 1996 U.S. Food and Drug Administration (FDA) approval of intravenous tissue plasminogen activator (tPA) for the treatment of acute ischemic stroke (NINDS & Stroke rtPA Stroke Study Work Group, 1995). In the past 20 years, intravenous thrombolytic therapy with alteplase (recombinant tissue-type plasminogen activator or rtPA) has shown to improve outcomes in patients with acute ischemic stroke if treated within 3 to 4.5 hours from stroke onset and when additional eligibility criteria (discussed later in the chapter) are met. Certified stroke centers are mandated to collect data on a series of specific practice components, including selected performance measures to monitor and improve the quality of stroke care. These measures apply to patients hospitalized with either an ischemic or hemorrhagic stroke. Currently, eight stroke performance activities have been endorsed by the National Quality Forum and are supported by The Joint Commission. Although not inclusive of all important aspects of acute stroke care, initial data from these metrics support the efforts to improve quality of care and to predict functional outcome (Smith, Saver, & Alexander, 2014). Table 47-1 outlines the specific stroke performance measures and applicable stroke types.

In the last decade, stroke certification options have expanded to include Acute Stroke Ready Hospital (for small facilities equipped to stabilize and treat acute stroke patients prior to transferring to a higher level of care), Thrombectomy-capable Stroke Center (for facilities that meet Primary Stroke Center criteria and have the capability to perform thrombectomy procedures), and Comprehensive Stroke Centers (for facilities capable of managing multiple complex stroke patients across the disease trajectory). Certified Comprehensive Stroke Centers are required to report their compliance with the eight Primary Stroke Center measures as well as an additional eight measures (Comprehensive Stroke Center-specific) that reflect care and outcomes for patients who undergo specific treatment interventions. Today, there are nearly 2,000 hospitals certified as Primary Stroke Centers and over 100 hospitals certified as Comprehensive Stroke Centers (Gorelick, 2013). Nursing staff working at a certified stroke center will be familiar with evidence-based stroke protocols and will have specific education requirements to maintain their stroke expertise.

TABLE 47-1 Stroke Performance Measures

Stroke Performance Measures	Stroke Type
Deep venous thrombosis (DVT) prophylaxis: • Nonambulatory patients should start receiving DVT prophylaxis by the end of day 2	Ischemic stroke Hemorrhagic stroke
Discharged on antithrombotic therapy: • Patients prescribed antithrombotic therapy at discharge	Ischemic stroke
Discharged on anticoagulation for patients in atrial fibrillation: • Patients with atrial fibrillation discharged on anticoagulation	Ischemic stroke
Thrombolytic therapy administered: • Patients with acute ischemic stroke who arrive at the hospital within 120 minutes of time last known well and for whom IV tissue plasminogen activator (tPA) was initiated at this hospital within 180 minutes of last known well	Ischemic stroke
Antithrombotic medication by the end of hospital day 2: • Patients received antithrombotic therapy by the end of hospital day 2	Ischemic stroke
Discharged on cholesterol-reducing medication: • Patients with low-density lipoproteins (LDL) above 100 or LDL not measured or on cholesterol-reducer before admission are discharged on cholesterol-reducing drugs	Ischemic stroke
Stroke education: • Patients and caregivers were given education or educational materials prior to discharge to address personal risk factors, stroke warning signs, activation of emergency medical services, need for follow-up after discharge, and medications prescribed	Ischemic stroke Hemorrhagic stroke
Assessed for rehabilitation: • Patients were assessed for rehabilitation	Ischemic stroke Hemorrhagic stroke

Pathophysiology

Stroke is a heterogeneous syndrome characterized by the onset of one or more focal neurologic deficits (corresponding to the affected area of the brain) caused by reduced cerebral blood flow that leads to brain cell death and functional disability. The two major stroke types that cause an interruption in cerebral blood flow are an occluded artery that deprives blood flow to part of the brain supplied by that blood vessel (called an *ischemic stroke*, Fig. 47-1), or a ruptured artery resulting in bleeding in or around the brain (called a *hemorrhagic stroke*, Fig. 47-2). Hemorrhagic strokes are further subdivided based on the specific intracranial space that is filled with blood: an intraparenchymal hemorrhage (blood within the brain tissue), and a subarachnoid hemorrhage (SAH) (blood occupying the subarachnoid space). Ischemic strokes account for about 85% of all stroke syndromes. Hemorrhagic strokes account for the remaining 15% (Table 47-2). Regardless of stroke type or mechanism, the concept that "time is brain" has become the mainstay for directing a rapid clinical diagnosis and acute treatment options if patients present within a specific time window from the onset of symptoms.

Although patients suffering from an ischemic or hemorrhagic stroke may present with similar neurologic deficits, initial brain imaging (i.e., noncontrast head CT) will identify the presence of a hemorrhage; any area of ischemia due to an occluded artery typically will be visible only after 4 to 6 hours from symptom onset. Therefore the rapid diagnosis of an acute ischemic stroke is considered a clinical diagnosis and is based on the patient's presenting symptoms and clinical examination. Treatment options and management will vary depending on stroke type.

Ischemic Stroke

Normally, the brain receives approximately 15% of the total cardiac output. Cerebral blood flow is calculated to be 50 to 55 mL of blood per 100 g of brain tissue per minute. For patients who experience an ischemic stroke, disruption of blood flow in or to the brain due to an obstruction of a blood vessel initiates a complex series of circulatory and metabolic events referred to as the *ischemic cascade*. The ischemic cascade begins when cerebral blood flow decreases to less than 25 mL/100 g/min. At this point, neurons are no longer able to maintain aerobic respiration. The cell's mitochondria must then switch to anaerobic metabolism, generating large amounts of lactic acid and glutamate, causing a change in pH. This switch to anaerobic metabolism also renders the neuron incapable of producing sufficient quantities of adenosine triphosphate (ATP) to fuel cell depolarization processes. The cell membrane pumps that maintain electrolyte balances begin to fail, and the cells cease to function (Fig. 47-3). Cell death at the site of occlusion is referred to as the *core infarct*. The surrounding area of affected brain tissue in which blood flow has been reduced is referred to as the *ischemic penumbra*. In selected patients, the penumbra, or stunned brain tissue, is deemed salvageable with early treatment, such as with thrombolysis (*administration of intravenous alteplase or IV tPA*) or with clot retrieval (using a catheter-based intra-arterial approach to extract the clot); see Figure 47-4. Specific inclusion and exclusion criteria for the use of these treatment options assist the clinicians in identifying

patients that would have the best outcomes after acute stroke.

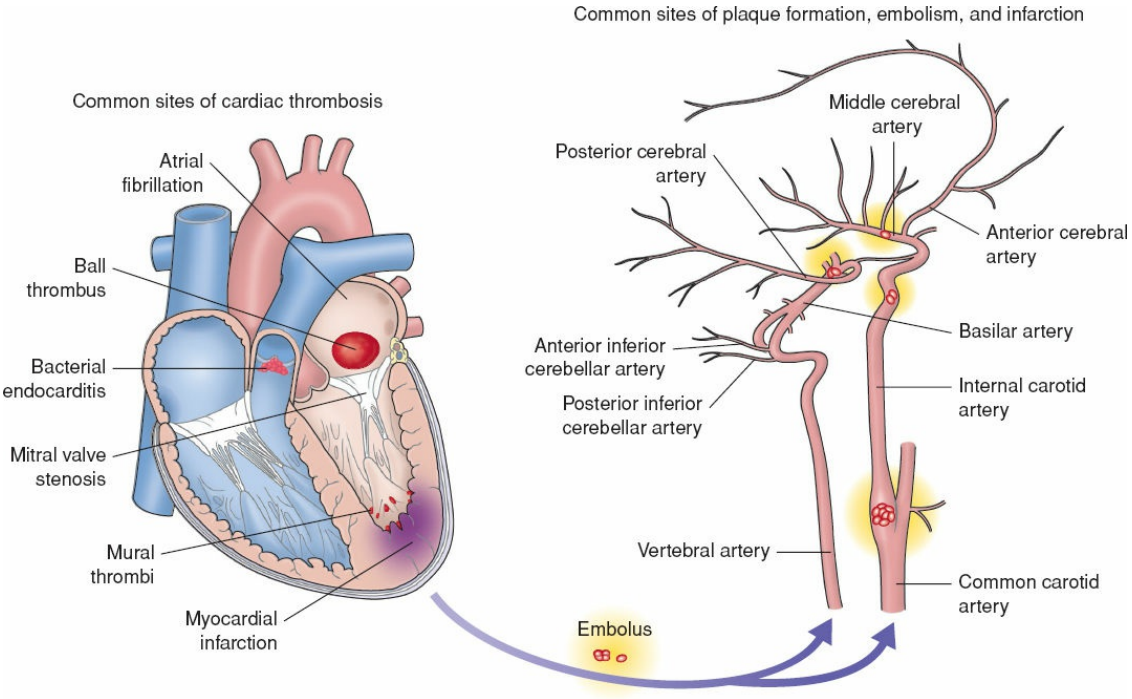

FIGURE 47-1 Ischemic stroke.

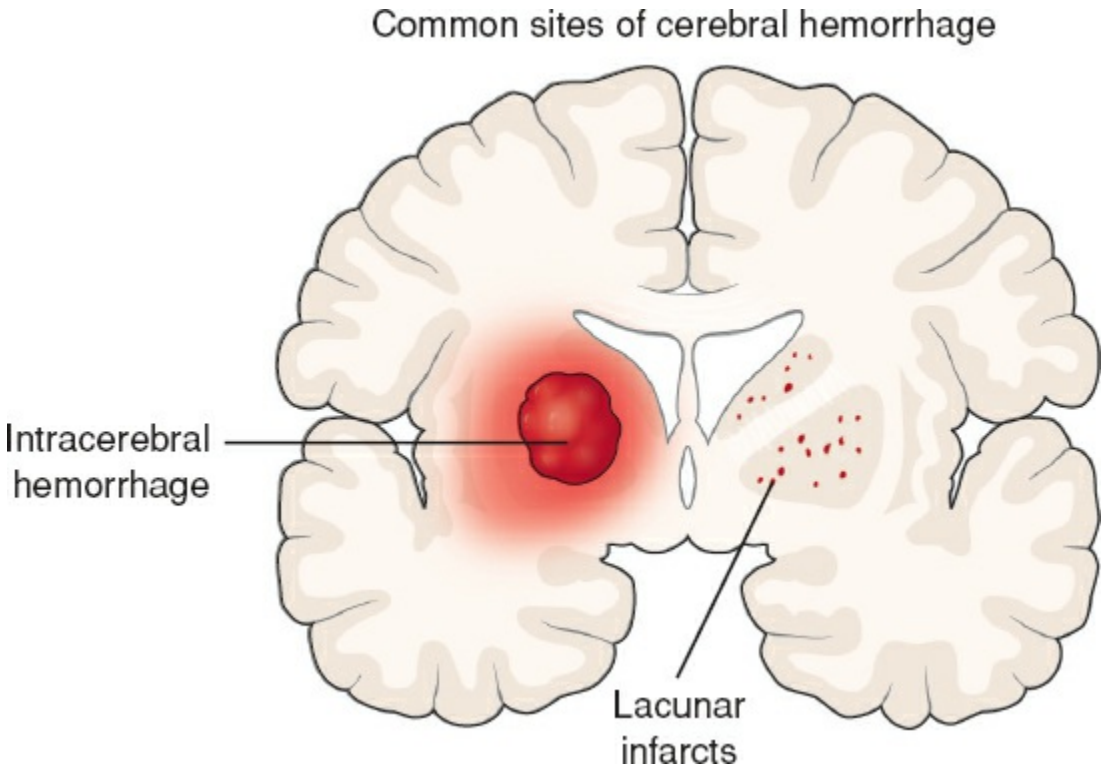

FIGURE 47-2 Common sites of cerebral hemorrhage.

Ischemic strokes are further divided into five subtypes according to a mechanism-based classification system: large-artery thrombotic strokes (representing 20% of ischemic strokes); small, penetrating artery thrombotic strokes (25%); cardio embolic strokes (20%);

cryptogenic strokes (strokes that cannot be attributable to any specific cause) (30%); and "other" (5%). Each stroke subtype has a characteristic pathophysiologic course, but these types have overlapping clinical features. This subtyping directs both therapeutic interventions and long-term prognosis.

Large-artery thrombotic strokes are caused by atherosclerotic plaques in the large blood vessels of the brain. Thrombus formation and occlusion can occur at the site of the atherosclerosis and result in ischemia and infarction (tissue death).

TABLE 47-2 Comparison of Major Types of Stroke

Facet	Ischemic	Hemorrhagic
Causes	Large-artery thrombosis Small, penetrating artery thrombosis Cardiogenic embolic Cryptogenic (no known cause) Other	Intracerebral hemorrhage Subarachnoid hemorrhage Cerebral aneurysm Arteriovenous malformation
Main presenting symptoms	Numbness or weakness of the face, arm, or leg, especially on one side of the body	"Exploding headache" Decreased level of consciousness
Additional symptoms	Slurred speech, or difficulty with word finding or comprehension	Nausea/vomiting; visual changes; seizures

Many of these symptoms occur with either stroke type.

Small, penetrating artery thrombotic strokes that affect one or more vessels and cause reduced blood flow are the most common type of ischemic stroke, typically caused by longstanding hypertension, hyperlipidemia, or diabetes. Small artery thrombotic strokes are frequently referred to as *lacunar strokes* or *lacunes* because of the small cavities that are created after the death of infarcted brain tissue.

Cardio embolic strokes are associated with cardiac arrhythmias, such as atrial fibrillation, but can also be associated with valvular heart disease or left ventricular thrombus (as depicted in Fig. 47-1). Emboli originating from the heart that circulate to the cerebral vasculature, most commonly via the left middle cerebral artery, cause ischemia and subsequent infarction.

The last two classifications of ischemic strokes are cryptogenic strokes, which have no identified cause, and strokes-from other-causes, such as illicit drug use (cocaine), coagulopathies, migraine, or spontaneous dissection of the carotid or vertebral arteries. Differentiating stroke etiologies directs specific treatment and secondary prevention strategies.

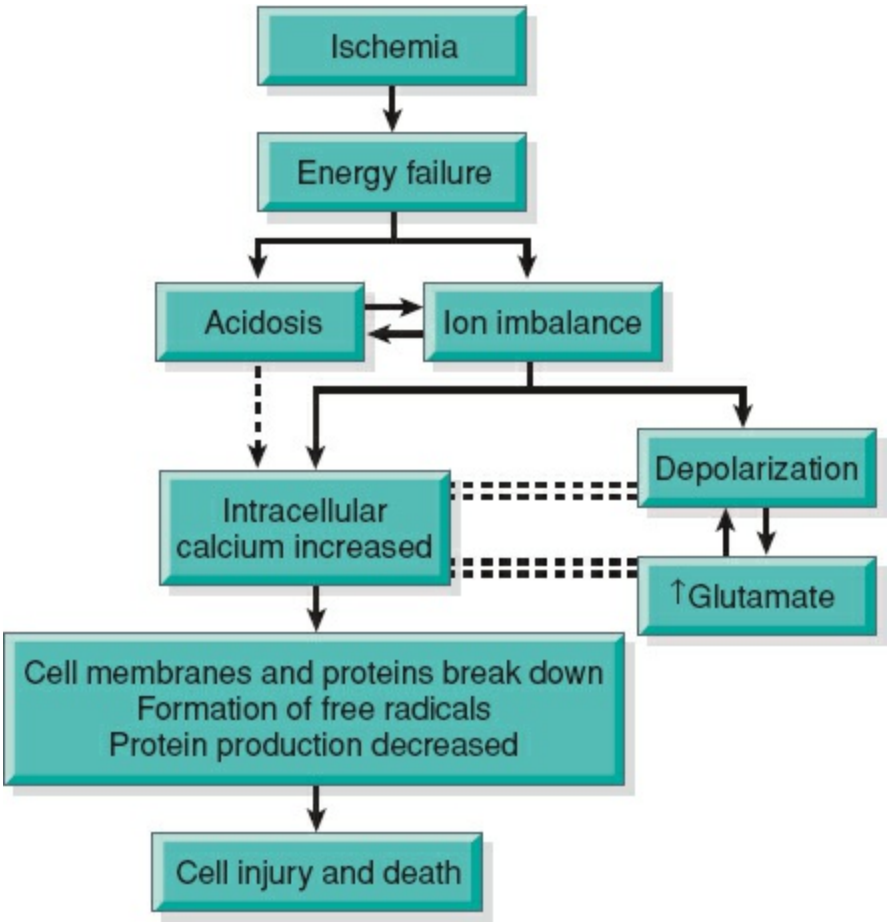

FIGURE 47-3 Processes contributing to ischemic brain cell injury. Courtesy of the National Stroke Association, Englewood, Colorado.

Transient Ischemic Attacks

A transient ischemic attack, or TIA (sometimes referred to as a "mini-stroke"), has traditionally been defined as a brief episode of neurologic dysfunction resulting from focal cerebral ischemia not associated with permanent cerebral infarction. A TIA involves the same pathophysiologic mechanism outlined in the ischemic cascade, but symptoms are transient (persisting less than 24 hours) and there is no evidence of cerebral tissue infarction on follow-up brain imaging studies. TIAs have often been referred to as a warning stroke since the causative process is likely to recur (causing cerebral infarction) if no interventions are undertaken. With the advent of better brain imaging techniques, and recognizing that TIAs typically resolve within 60 minutes, a new definition for a TIA was adopted. It has now been operationally defined as a brief episode of neurologic dysfunction caused by focal brain or retinal ischemia, with clinical symptoms typically lasting less than 1 hour, and without evidence of acute infarction (Livesay & Hickey, 2014). The corollary is that persistent clinical signs or characteristic imaging abnormalities change the definition to include ischemic infarction. For the purposes of this chapter, ischemic stroke and TIA are considered one disease process that mandates the same evaluative detail in determining cause, implementing a care plan, and supporting secondary stroke prevention measures (Kernan, Ovbiagele, Black et al., 2014).

Patients diagnosed with a TIA are at a higher risk for a subsequent stroke (Thacker,

2010). Clinicians use a scoring system to determine which TIA patients warrant a more urgent evaluation and possible hospital admission based on selected clinical features. As outlined in Figure 47-5, older patients with elevated blood pressure and multiple symptoms of a longer duration were more likely to have a stroke at the 2-day, 7-day, and 9-day periods, thereby requiring a more urgent evaluation and initiation of secondary stroke prevention therapy.

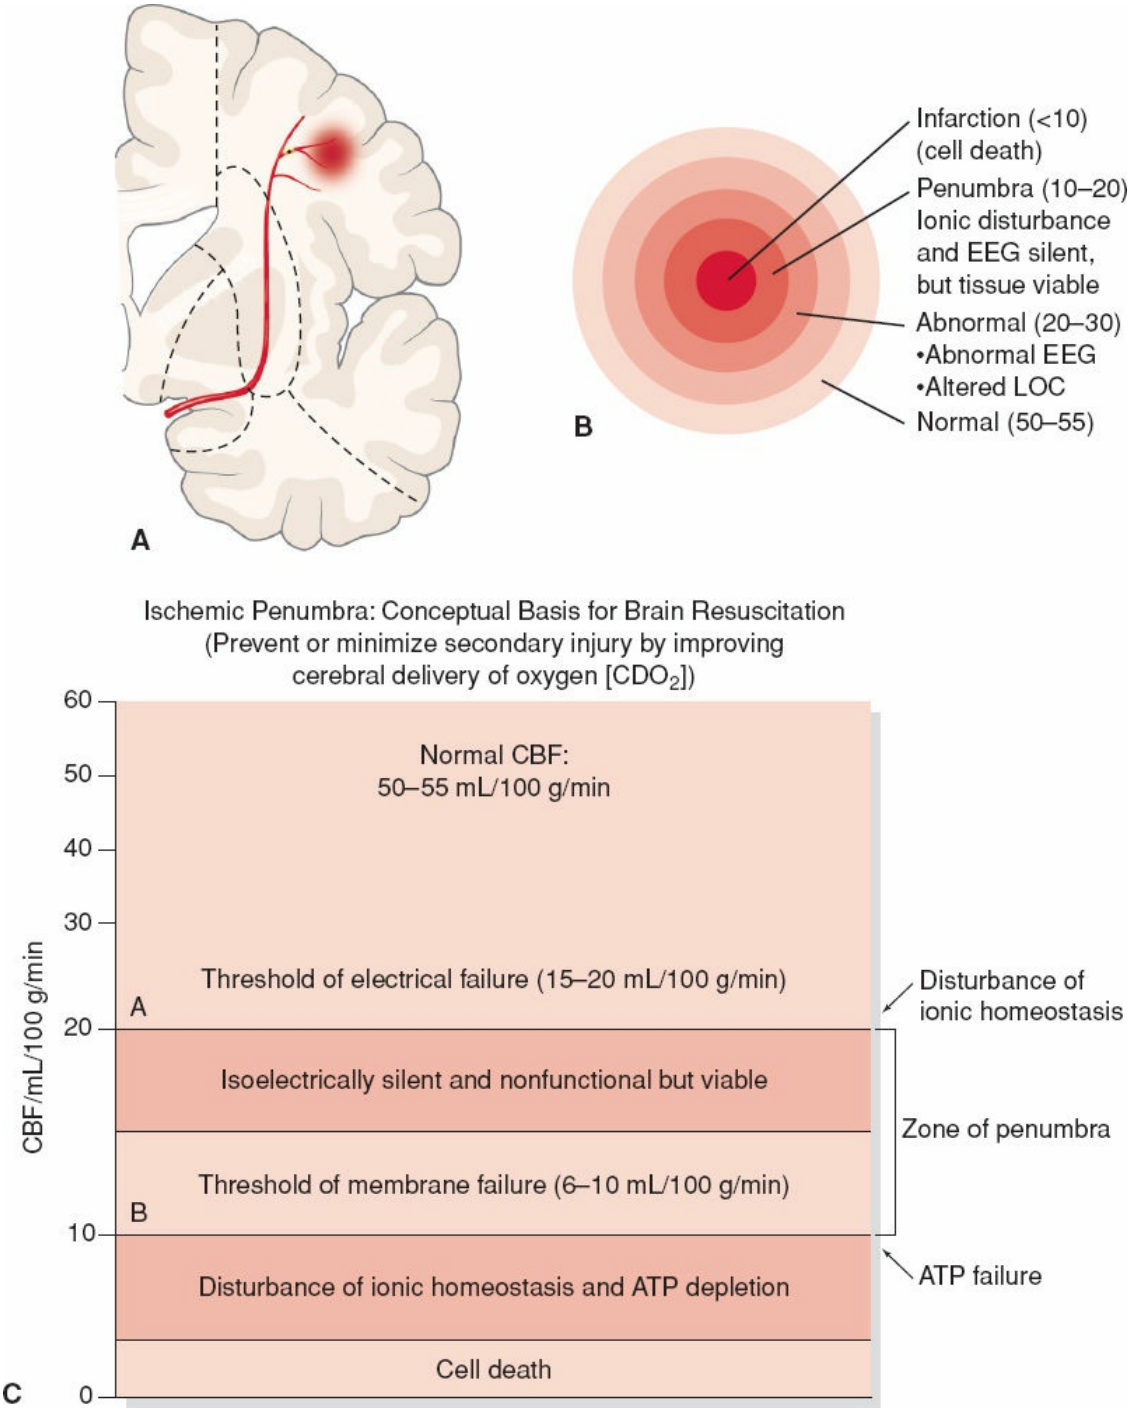

FIGURE 47-4 Cerebral blood supply during ischemic events. A. See distribution of middle cerebral artery and occlusion of a branch. Note area of infarction and surrounding penumbra with viable but nonfunctional cells. These cells will become either infarcted or recover, depending on treatment. B. Ischemic penumbra: normal cerebral blood flow (CBF) = 50 to 55 mL/100 g/min. Variations in CBF are noted. Penumbra is the critical area that may be salvageable with appropriate treatment, or cell death will occur if adequate CBF is not restored. C. Ischemic penumbra: conceptual basis for brain resuscitation. ATP, adenosine triphosphate; EEG, electroencephalogram; LOC, level of consciousness. (Adapted from Hickey, J. V. (2014). *The clinical practice of neurological and neurosurgical nursing* (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Hemorrhagic Strokes

Hemorrhagic strokes refer to bleeding into the brain tissue (parenchyma), the ventricles, or the subarachnoid space. Normal brain metabolism is disrupted when blood outside the vasculature forms a mass that compresses adjacent brain tissue, causing increased intracranial pressure (ICP), secondary hemorrhage, and further ischemia. In cases where there is significant blood volume in the brain tissue, a condition referred to as *herniation* can occur in which brain tissue is subjected to increased pressure and moves across structures within the skull. If blood extends into the ventricles, it can cause acute hydrocephalus (increase in the amount of cerebral spinal fluid in the brain). These events can impair level of consciousness (LOC) and lead to coma and death.

Hemorrhagic stroke can further be divided into subtypes: intracerebral hemorrhage (ICH) and subarachnoid hemorrhage (SAH). ICH can occur with bleeding into any of the spaces within the cranium, including subarachnoid, epidural, and subdural spaces. Bleeding into the subdural and epidural spaces is primarily associated with trauma. Conversely, SAH, which is bleeding into the subarachnoid space, is associated primarily with hemorrhage due to intracranial aneurysms (commonly in the *vessels that make up* the Circle of Willis), trauma, or arteriovenous malformations (AVMs). An AVM is caused by an abnormality during embryonal development that leads to a tangle of arteries and veins in the brain that lacks a capillary bed. The absence of a capillary bed causes higher pressure within the arterioles to be transmitted directly to the veins. This anomaly leads to dilation of both arteries and veins and, if the pressure increases, possible rupture. AVM is a common cause of hemorrhagic stroke in younger patients.

Risk Factor	Points	Score
Age ≥ 60 years	1	
Blood pressure Systolic BP ≥ 140 mm Hg *OR* Diastolic BP ≥ 90 mm Hg	1	
Clinical features of TIA *(choose one)* Unilateral weakness with or without speech impairment *OR* Speech impairment without unilateral weakness	2 1	
Duration TIA duration ≥ 60 minutes TIA duration 10–59 minutes	2 1	
Diabetes	1	
***Total ABCD²* score**	0–7	

Using the ABCD² Score

Higher ABCD² scores are associated with greater risk of stroke during the 2, 7, 30, and 90 days after a TIA (Figure). The authors of the ABCD² score made the following recommendations for hospital observation[1]:

ABCD² Score	2-day Stroke Risk (%)	Comment
0–3	1.0	Hospital observation may be unnecessary without another indication (e.g., new atrial fibrillation)
4–5	4.1	Hospital observation justified in most situations
6–7	8.1	Hospital observation worthwhile

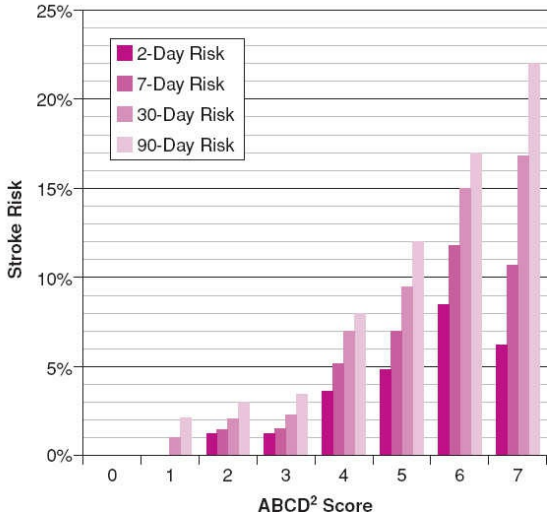

FIGURE 47-5 Transient ischemic attack (TIA): Prognosis and key management considerations. MR, magnetic resonance; TIA, transient ischemic attack. (Used with permission from Johnston, S. C., Rothwell, P. M., Huynh-Huynh, M. N., Giles, M. F., Elkins, J. S., & Sidney, S. (2007). Validation and refinement of scores to predict very early stroke risk after transient ischemic attack. *Lancet*, *369*, 283–292; Johnston, S. C., Nguyen-Huynh, M. N., Schwarz, M. E., Fuller, K., Williams, C. E., Josephson, S. A., … Albers, G. W. (2006). National Stroke Association guidelines for the management of transient ischemic attacks. *Annals of Neurology*, *60*, 301–313.)

Primary ICH from a spontaneous rupture of small arteries or arterioles accounts for approximately 80% of hemorrhagic strokes and is caused chiefly by uncontrolled hypertension. Blood can accumulate outside the vessels and into the intracranial space over minutes to hours. Symptom presentation can vary from mild deficits to acute loss of consciousness. Because the brain is enclosed in a rigid structure, hemorrhage can dramatically increase ICP, causing shifts in the content volume within the skull and eventual herniation (and a higher mortality rate) if not acutely treated. ICH occurs most commonly in the cerebral lobes, basal ganglia, thalamus, brainstem (the pons), and cerebellum. Occasionally, bleeding ruptures the wall of the lateral ventricle and causes intraventricular hemorrhage, which is frequently fatal.

ICH can also occur in the setting of an ischemic stroke, when the infarcted tissue becomes susceptible to leaking blood vessels. ICH is also associated with AVMs, intracranial aneurysms, intracranial neoplasms, and with certain medications, such as anticoagulants or abuse of cocaine or amphetamines (Hickey & Livesay, 2014). Cerebral

amyloid angiopathy (a condition in which amyloid [fibrous proteins] deposits accumulate inside the walls of arteries in the brain, causing vessel wall breakdown) can predispose patients to cerebral hemorrhage. Amyloid deposits are often seen in conjunction with dementia. Characteristic lobar hemorrhages on magnetic resonance imaging (MRI) may be diagnostic in the absence of a brain tissue biopsy when combined with patient history and clinical presentation (Hickey & Livesay, 2014). An intracranial (cerebral) aneurysm is a dilation of the wall of a cerebral artery. These vessel abnormalities may be due to atherosclerosis, which results in vessel wall weakness but also may be due to a congenital defect of the vessel wall, hypertensive vascular disease, head trauma, or advancing age. The cerebral arteries most commonly affected by an aneurysm are the internal carotid artery (ICA), anterior cerebral artery (ACA), anterior communicating artery (ACoA), posterior communicating artery (PCoA), posterior cerebral artery (PCA), and middle cerebral artery (MCA).

Risk Factors

The conditions or risk factors that predispose patients to stroke are diverse and are similar to risk factors for cardiac and peripheral vascular disease. Although some risk factors are applicable to a specific stroke type, most can apply to both ischemic and hemorrhagic strokes. Identifying patient-specific stroke risk factors is part of the patient and family education process during primary stroke prevention and during stroke recovery.

Modifiable Risk Factors

Modifiable risk factors are those that can be altered through lifestyle changes and medical treatment. Common modifiable stroke risk factors include hypertension, smoking and second-hand smoke exposure, diabetes, dyslipidemia, atrial fibrillation, diet (including excessive salt, high alcohol consumption), obesity, sleep apnea, and lack of exercise.

Hypertension is the most important risk factor for both ischemic and hemorrhagic stroke, and, despite the numerous treatment options, it remains underrecognized and undertreated in most communities. In the acute stroke phase, blood pressure is generally liberalized to allow for improved cerebral blood flow, but the general practice in the stroke recovery phase is to achieve normotension, defined as less than 140 mm Hg systolic and less than 90 mm Hg diastolic (JNC 8).

Smoking and second-hand smoke are prevalent among all age groups and pose an increased stroke risk among women who smoke and who are on oral contraceptives. Smoking cessation programs (counseling and nicotine replacement) have been included as part of the post-stroke care plan for all patients identified as current smokers (CDC, 2015).

Diabetes independently increases stroke risk and contributes to the increased prevalence of hypertension and dyslipidemia. Glycemic control alone has not been shown to reduce stroke risk, but in combination with blood pressure and lipid management, patients with diabetes can lower their overall risk (ASA, 2014).

Atrial fibrillation is the most frequently diagnosed arrhythmia in the United States. If left untreated, it puts patients at higher risk for suffering from an ischemic stroke. Approximately 15% to 20% of ischemic strokes can be attributed to atrial fibrillation. Screening for atrial fibrillation in patients over 40 years of age has been recommended since anticoagulation and rate/rhythm control can reduce stroke risk by up to 68% (ACC guidelines for afib-2014).

Obstructive sleep apnea (OSA) is an independent risk factor for stroke, and the mechanism of cause is yet to be elucidated. It has been proposed that intermittent hypoxemia (due to intermittent cessation of breathing) may cause surges in blood pressure with release of vasoconstrictive substances, such as endothelin; additionally increased levels of inflammatory biomarkers are seen in sleep-disordered breathing (Ifergane, Ovanyan, Toledano, et al., 2016). Patients with OSA have a greater functional impairment and higher mortality rates than patients without OSA during an acute stroke. Continuous positive airway pressure (CPAP) treatment is associated with decreased mortality and better functional recovery after stroke (Ifergane, Ovanyan, Toledano, et al., 2016, p. 1207).

Nonmodifiable Risk Factors

Nonmodifiable risk factors are important to highlight from both a primary and secondary stroke prevention standpoint because, while they cannot be changed, stroke risk factors can be identified in a patient's medical profile, and associated modifiable risk factors can be aggressively treated. Having a family history of stroke increases the chance of stroke and can be attributed to genetic influences as well as cultural/environmental influences. Genetic testing is not generally recommended unless there is a suspicion of a rare genetic condition or when other more common causes for stroke cannot be identified. Older age is a risk factor for stroke, and for both ischemic and hemorrhagic strokes the risk doubles every 10 years after 55 years of age. Men tend to have a higher risk for stroke and a higher age-specific stroke incidence rate, but more women tend to die from stroke.

Race and ethnicity impact stroke risk among specific populations. Blacks and Hispanics have a higher incidence of both ischemic and hemorrhagic stroke, and contributing factors may be the higher incidence of diabetes and hypertension in these groups (Livesay & Hickey, 2014).

Clinical Manifestations and Assessment

Common Symptoms

Stroke syndromes produce a wide variety of neurologic deficits, depending on the location in the brain that is affected, the specific blood vessels that are obstructed, the size and area of underperfused brain tissue, and the amount of collateral (secondary or accessory) blood flow to the affected area. The AHA/ASA advises the public to be aware of the symptoms of stroke and to call 911 immediately. The most common symptoms of stroke include:

- Sudden numbness or weakness of the face, arm, or leg, especially on one side of the body
- Sudden trouble speaking or understanding speech
- Sudden visual disturbances
- Difficulty walking, dizziness, or loss of balance or coordination
- Sudden, severe headache

There are additional, less commonly recognized stroke symptoms that also put patients at risk for disabling and devastating outcomes. These include: sudden, unexplained fall; onset of nausea and vomiting; and acute changes in mentation, such as confusion or disorientation. These symptoms have been associated more commonly with strokes that occur in the posterior circulation leading to infarctions in the cerebellum (Arch et al., 2015).

The clinician should be able to correlate commonly presenting neurologic deficits with the location(s) in the brain affected by ischemia or hemorrhage. Box 47-2 compares the symptoms and behaviors seen in patients with right hemispheric strokes with those seen in patients with left hemispheric strokes. Acute neurologic deficits are not stroke-type specific. Patients with a hemorrhagic or ischemic stroke can present with similar neurologic deficits, thus making expedited brain imaging an important aspect of the stroke workup.

Many of the same motor, sensory, cranial nerve, cognitive, and other functions that are disrupted after ischemic stroke are also altered after a hemorrhagic stroke. For patients with cerebral hemorrhages, the most common presenting symptom is a severe headache. Other symptoms that can be observed are vomiting, a slow or sudden change in LOC, or focal seizures. Patients with a ruptured AVM will typically present with a sudden severe headache and sudden loss of consciousness. There may be posterior neck or spine pain associated with the headache. If there is a slow leakage of blood that leads to formation of a clot at the site of rupture, the patient may show little neurologic deficit. In cases in which severe bleeding occurs, there can be extensive cerebral injury, and the patient may progress to coma and death. Symptoms are described in detail in the following sections.

BOX 47-2 Focused Assessment

Left and Right Hemispheric Strokes

Be alert for the following signs and symptoms:

Left hemispheric stroke:

- Paralysis or weakness on right side of body
- Right visual field deficit
- Aphasia (expressive, receptive, or global)
- Altered intellectual ability
- Slow, cautious behavior

Right hemispheric stroke:

- Paralysis or weakness on left side of body
- Left visual field deficit
- Spatial-perceptual deficits
- Increased distractibility
- Impulsive behavior and poor judgment
- Lack of awareness of deficits

Motor Loss

The most common motor dysfunction resulting from stroke is hemiparesis, or weakness of one side of the body. Upper and lower motor neurons play a role in mediating muscle and tendon reflex activity. Because the upper motor neurons decussate (cross over from one hemisphere to the other), a disturbance of voluntary motor control on one side of the body may reflect damage to the upper motor neurons on the opposite side of the brain. Motor loss can range from a mild or subtle weakness in an isolated muscle group (such as the muscles controlling wrist flexion) to a dense paresis or plegia in which there are multiple muscle groups affecting multiple limbs rendering a patient unable to sit, stand, or walk.

Communication Loss

Language and communication may also be affected by stroke. While there are several specific areas in the brain responsible for the production and comprehension of speech, a majority of patients have their language center in the left hemisphere. Dysfunctions of language and communication related to cerebral injury include:

- *Dysarthria:* Difficulty in articulating speech, caused by paralysis of the muscles responsible for producing speech; also referring to slurred speech.
- *Dysphasia or aphasia:* Partial or complete impairment of language resulting from brain injury, affecting spoken language and comprehension.
- Aphasias can be further defined as (1) Expressive aphasia, in which the patient has difficulty producing speech and (2) Receptive aphasia, in which the patient has difficulty comprehending speech.
- *Apraxia:* Inability to put sounds and syllables together in the correct order to form words, to produce speech.

Visual Disturbances

Visual-perceptual dysfunctions are caused by disturbances of the primary sensory pathways between the eye and visual cortex. Although there are numerous forms of visual impairment that include diplopia, impaired acuity, and abnormal eye movement, the most common visual impairment after stroke is visual field loss. Homonymous hemianopsia (loss of half of the visual field) may occur from stroke and may be temporary or permanent. Disturbances in visual–spatial relations (perceiving the relationship of two or more objects in spatial areas) are frequently seen in patients with right hemispheric damage.

Dysphagia

Dysphagia is one of the most common complications after stroke, leading to problems such as aspiration pneumonia, dehydration, and poor nutrition. It can occur in up to 75% of patients and can prolong hospitalization and overall recovery. Swallowing is a complex process that allows for the transfer of food or fluids from the mouth to the stomach. The swallowing process occurs in four stages using six cranial nerves (trigeminal [CN V], facial [CN VII], glossopharyngeal [CN IIX], vagus [CN X], spinal accessory [CN XI], and hypoglossal [CN XII]). Multiple bedside dysphagia screening tools have been developed to assess patients suspected of having a stroke who are at risk for aspiration prior to administering medications or food. These tools include a clinical assessment of the patient's LOC and ability to swallow (various consistencies, such as thin liquids). Usually these assessments are performed by nurses with a "pass/fail" option for the patient. A patient who fails the assessment is referred to a speech and language pathologist for a formal swallow study, such as videofluoroscopy (VFS) or a fiberoptic endoscopic evaluation of swallowing (FEES).

Sensory Loss

The sensory losses from stroke may range from a slight impairment of touch, to more severe or total loss of sensation, with loss of proprioception (ability to perceive the position and motion of body parts), as well as difficulty in interpreting visual, tactile, and auditory stimuli. *Agnosias* describe the inability to recognize previously familiar objects perceived by one or more of the senses.

Cognitive Impairment and Psychological Effects

If damage has occurred to the frontal lobe, learning capacity, memory, or other higher cortical intellectual functions may be impaired. Such dysfunction may be reflected in a limited attention span, difficulties in comprehension, forgetfulness, and a lack of motivation.

A common sequela is depression, and this may be exaggerated by the patient's natural response to this catastrophic event. Emotional lability, hostility, frustration, resentment, lack of cooperation, and other psychological problems may occur at some point during the recovery period and should be part of a screening process post-stroke.

Acute Stroke Assessment

As a result of the more recent clinical trials in stroke treatment that demonstrated a positive outcome, the concept of defining and performing an acute stroke assessment has now become a standard approach to clinical care in both the pre-hospital field setting as well as

the "stroke ready" emergency departments. The Emergency Nurses Association and the American College of Emergency Physicians recommend stroke patients be considered an ESI Level 2 emergency (see Chapter 56 for an explanation of the five-level Emergency Severity Index [ESI]), meaning that the suspected stroke patient "needs immediate assessment," the same as for an unstable trauma patient or a critical-care cardiac patient.

Nurses in the pre-hospital setting or at triage in an emergency department should be familiar with the pre-hospital screening and assessments that are done by members of the EMS team so that they can relay this information to the stroke team prior to arrival. (For a detailed explanation of the pre-hospital care for stroke patients, refer to Interactions within Stroke Systems of Care: A Policy Statement from the American Heart Association/American Stroke Association Expert Panel on Emergency Medical Services Systems and the Stroke Council [Higgashida, Alberts, Alexander, et al., 2013].)

Acute stroke care can be divided into two phases: the hyperacute phase (the first 24 hours of care) and the acute phase (acute care during the hospitalization). Nurses involved in the initial triage process are corresponding with EMS either to confirm a patient suspected of having a stroke is being transported to their facility or to address the immediate needs of a patient who may "walk in" to the emergency department.

Several algorithms have been developed for the hyperacute phase for the initial workup of a patient presenting with acute stroke symptoms as a template to expedite the diagnostic workup (Fig. 47-6). For patients arriving by ambulance (with prenotification by the paramedics that a suspected stroke patient is en route) or by car, the triage nurse will confirm the presenting stroke symptoms and the time the patient was last known to be at his or her baseline. Many of the same motor, sensory, cranial nerve, and cognitive functions are disrupted in both ischemic and hemorrhagic strokes; however, changes in LOC, vomiting, sudden severe headache, and seizure are frequently associated with hemorrhagic strokes.

Specifically, triaging includes eliciting a detailed history and determining time of onset of the patient's symptoms. When the time of symptom onset is not definitive, the time the patient was last known to be at baseline becomes the default time of onset. Determining the time of the onset of symptoms becomes important since drug treatment options and interventional procedures for clot retrieval for an ischemic stroke are time dependent. Vital signs and other key clinical information (e.g., current medications or recent prior surgeries) also will be obtained. This information also may trigger the staff to activate a stroke code at the receiving facility so that the team is prepared to expedite a rapid evaluation.

Figure 47-7 depicts a typical acute stroke protocol.

Diagnostic Evaluation

The diagnosis of an acute stroke is made by history, a precise neurologic examination, and rapid neuroimaging. An initial noncontrast head CT scan is performed to assess for the presence of intraparenchymal blood. Ischemia will not be readily visible on initial CT scan when it is performed within the first few hours after symptom onset; however, evidence of bleeding (hemorrhage) will almost always be visible. Clinicians will also consider the location of the hematoma, the size and presence of blood in the ventricular system, and evidence of increased ICP. Additional diagnostic testing is done to determine if the hemorrhage is due to a ruptured intracranial aneurysm or AVM.

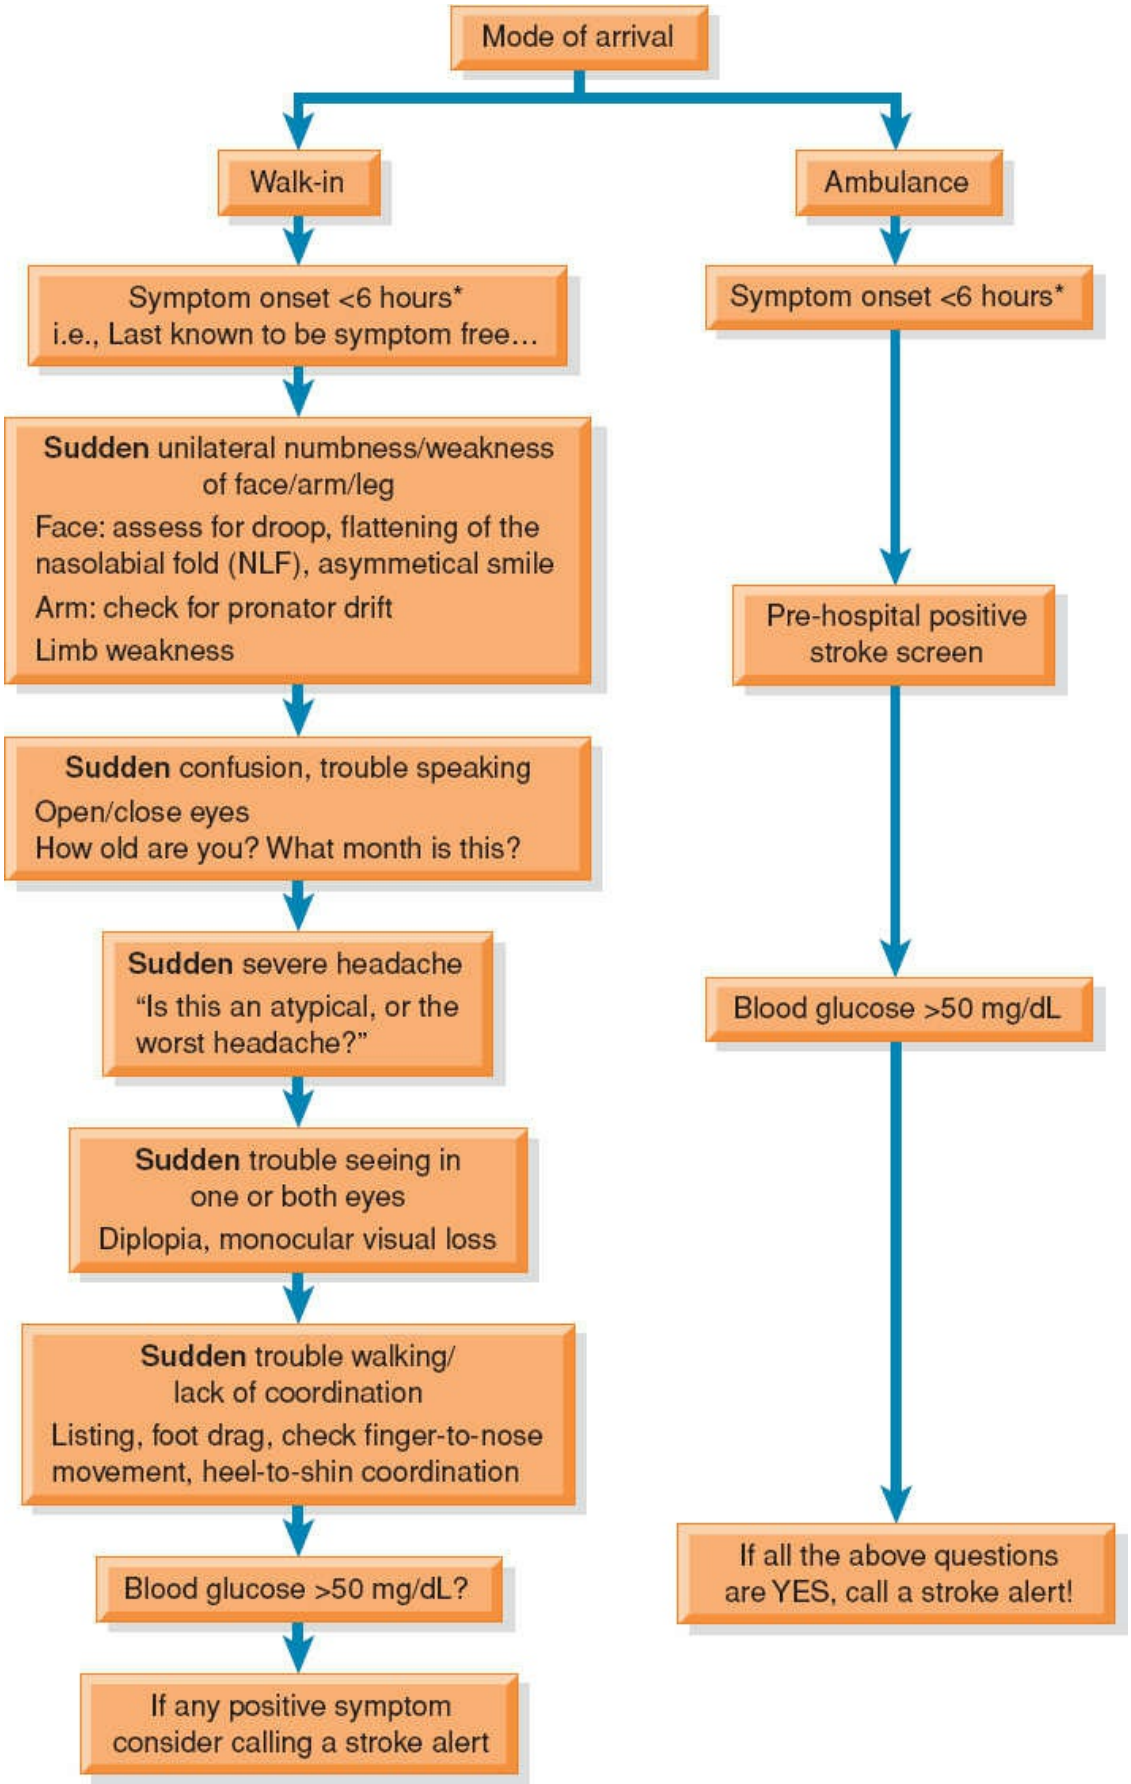

FIGURE 47-6 Triage stroke screen. *While intravenous tPA treatment is administered to eligible patients within 3 to 4.5 hours of symptom onset, patients are frequently evaluated within 6 to 12 hours

of symptom onset to determine eligibility for neurointerventional treatment procedures.

Although both CT scan and MRI are acceptable initial studies, most facilities have ready access to rapid CT imaging to rule out hemorrhage. Given that "minutes matter" when treatment for brain injury is time dependent, rapid imaging procedures should be part of the evaluation. Both CT and MRI will aid in determining stroke type, size, and location of the infarct or hematoma, any swelling and shift in brain tissue, presence of blood in the ventricles, and presence of hydrocephalus. It is a common practice at most institutions to also acquire intracranial and extracranial vessel imaging (computed tomography angiography [CTA] and magnetic resonance angiography [MRA]) to look for evidence of a significant vessel stenosis, in situ clot, or dissection of a vessel wall that could explain the patient's presenting symptoms and direct treatment options for the patient with acute stroke.

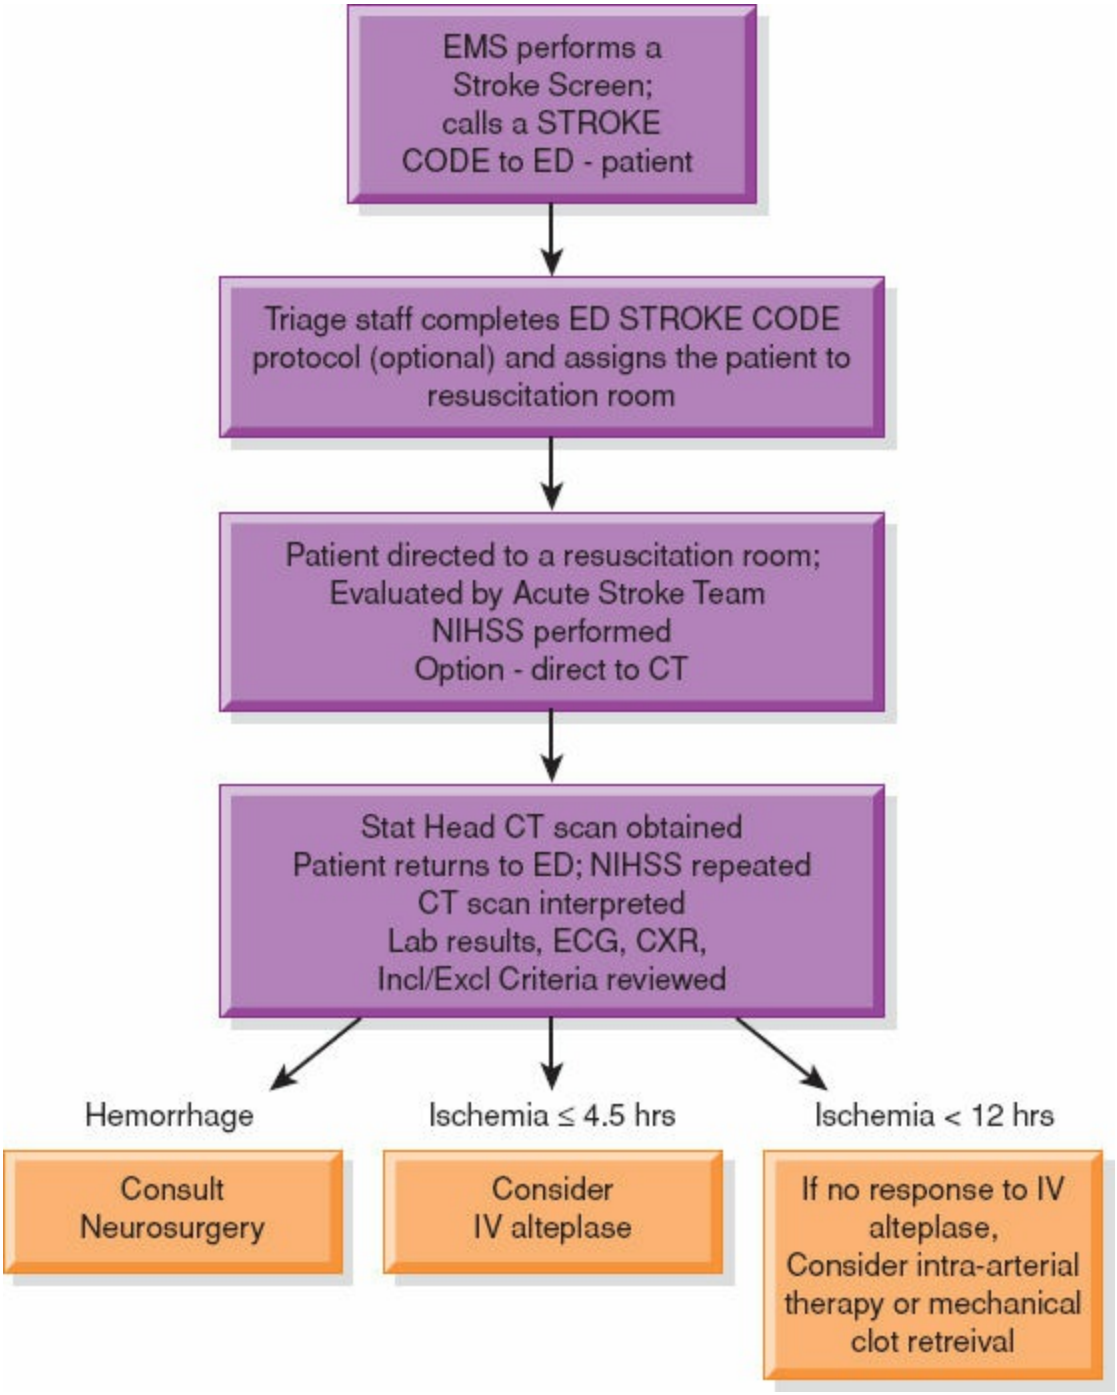

FIGURE 47-7 Acute Stroke Protocol. EMS, Emergency Medical Services; ED, emergency department; CXR, chest x-ray.

Although patients who present with TIA-type symptoms are usually symptom-free by the time they arrive in the emergency department, they undergo the same diagnostic workup as those patients whose symptoms are ongoing since their presenting symptoms may be predictive of an evolving stroke.

Routine blood chemistries, coagulation studies, blood cell counts, cardiac rhythm status, and IV access are also obtained as part of the initial evaluation. Key laboratory results (such as the platelet count, glucose, and coagulation profile) will direct decision-making regarding treatment options, such as thrombolysis. Table 47-3 details a variety of diagnostic tests or

procedures that are commonly recommended.

The Clinical Examination

The neurologic examination is perceived as a complicated and often poorly performed examination. For clinicians working in acute care (and specifically in the emergency department), a more focused standardized neurologic examination has been a recommended practice in identifying and quantifying the presenting deficits and in facilitating communication among the team members. A standard examination is also an efficient way to assess the patient suspected of having a stroke rapidly during the first minutes after arrival.

The National Institutes of Health Stroke Scale (NIHSS) has become an accepted assessment tool to quantify stroke severity and to assess patient outcome after stroke treatment (Table 47-4). The NIHSS is a 42-point assessment scale, with 0 indicating no neurologic deficits and 42 indicating the worst possible score. It focuses on six major areas of the neurologic examination: (1) LOC, (2) visual function, (3) motor function, (4) sensation and neglect (failure to pay attention to stimuli on one side of the body), (5) cerebellar function, and (6) language. The NIHSS was initially used by stroke teams but is now a standard assessment used by nursing to follow the stroke patient's neurologic deficits and to document stroke severity. It enables the examiner to rapidly determine the severity and possible location of the stroke. While it focuses on cerebral ischemia corresponding to abnormalities affecting the anterior circulation, this scale often misses deficits in territories in the brain dependent on posterior circulation. Because this examination relies heavily on responses to questions and directions, the assessment score becomes less specific in those patients who have a markedly depressed LOC or who have lost language. However, it allows clinicians to communicate findings using a standardized assessment tool. Certification in the use of this assessment tool is available online through the ASA training center and is often a requirement (part of orientation) for nurses working in the neurosciences domain. The NIHSS has become a standard assessment tool on nursing flow sheets for periodic assessments, during handoffs, at discharge, and when there is a neurologic change (or worsening) that warrants an urgent evaluation.

Medical Management

Treatment for Acute Ischemic Stroke: Reperfusion Therapies

The initial expedited diagnostic workup and treatment of ischemic stroke are driven by time-dependent pharmacologic and clot retrieval device treatment options. This follows the concept that "Time is Brain," that says for every minute that a stroke occurs and is not treated, nearly two million brain cells are destroyed. Thrombolysis with recombinant tPA (alteplase) is currently the only FDA-approved drug for acute ischemic stroke within a 3-hour window of symptom onset. Alteplase binds to fibrin and converts plasminogen to plasmin, which is responsible for clot breakdown. Results from the 1995 NINDS trial demonstrated a significant improvement in functional outcome at 3 months post-stroke in those patients who received tPA within 3 hours after symptom onset (NINDS & Stroke rtPA Stroke Study Work Group, 1995).

Results from the 2008 European Cooperative Acute Stroke Study (ECASS 3) demonstrated clinically significant improvement in functional outcome in selected patients who received treatment up to 4.5 hours after symptom onset (Hacke, Kaste, Bluhmi, et al., 2008). Specifically, patients who are under 80 years of age, who have no history of stroke or diabetes, who are not on anticoagulation therapy, and who do not have a severe stroke score of 25 or more are deemed significantly likely to benefit from thrombolysis using this extended time window (Livesay & Hickey, 2014, p. 525). This change in practice has afforded more patients the option for treatment and a better functional outcome after stroke. Stroke centers generally outline their approach to treatment according to the most current ASA guidelines. Once a hemorrhage has been ruled out and the clinical diagnosis of ischemic stroke is made, the acute stroke team must review the eligibility criteria for alteplase administration. For a complete list of inclusion and exclusion criteria for IV thrombolysis, see Figure 47-7.

TABLE 47-3 Diagnostic Procedures for Transient Ischemic Attacks (TIAs) and Stroke

Diagnostic Procedure	Information Provided
Computed tomography (CT) scan without contrast	Important diagnostic test to quickly assess for the presence of blood (hemorrhage), which will preclude treatment with antithrombotics
CT scan with contrast	Useful to rule out lesions that may mimic ischemia, especially when symptoms are related to hemispheric deficits; hypodense areas on CT scan suggest infarction
Magnetic resonance imaging (MRI)	Offers soft tissue contrast discrimination with superior demarcation of mass lesion from surrounding structures, including areas of ischemia and infarction; good visualization of vascular structures; useful for diagnosis of stroke in first 72 hours; a diffusion-weighted MRI can show ischemia in first few hours
Magnetic resonance angiography (MRA)	Less available and higher cost; noninvasive imaging of the carotid, vertebral, basilar, and major intracranial and extracranial arteries to determine occlusion; useful for clot visualization
Carotid ultrasonography	Noninvasive imaging; widely used initial diagnostic in patients with carotid territory symptoms for whom carotid endarterectomy (CEA) is considered
Transcranial Doppler (TCD)	Noninvasive monitoring of blood flow velocities of the major cerebral and carotid arteries to assess degree of stenoses; may be included as part of the stroke workup
Cerebral angiography	Ordered for patients to define precisely the percentage of occlusion and in patients with unusual presentation with aneurysm, vasculitis, and high-grade stenosis
Transthoracic echocardiography (TTE)	Helpful to identify cardioembolic sources; TTE is particularly helpful for diagnosing left ventricular thrombi, left atrial myxomas, and thrombi that protrude into the atrial cavity; they are less reliable for small tumors, laminated thrombi, and thrombi limited to the left or right atrium
Transesophageal echocardiography (TEE)	Benefit of TEE is in greater sensitivity for source of cardioembolic (except ventricular disease); TEE provides better visualization of cardiac structures, especially those at greater depth from chest wall and lesions of the atria (atrial appendage thrombi associated with atrial fibrillation), interatrial septum defects (patent foramen ovale, atrial septal defects), mitral valvular vegetation, and atherosclerotic disease of ascending aortic arch
Electrocardiogram (ECG); 12-lead is recommended initially	12-lead ECG recommended immediately because of the high incidence of heart disease in patients with stroke; ECG also useful when cardiogenic embolic stroke or concurrent coronary artery disease is suspected and to evaluate for atrial fibrillation
Ambulatory ECG monitoring	Reserved for patients who have suspicious palpitations, arrhythmias, or enlarged left atrium
Prothrombotic states	Protein C, protein S, antithrombin III, thrombin time, hemoglobin, electrophoresis, anticardiolipin antibody, lupus anticoagulant, and syphilis serology

Nurses are often responsible for administering alteplase, and some facilities expect nurses to mix and prepare the medication for administration. It is a weight-based medication and dosed at 0.9 mg/kg, with a maximum dose of 90 mg. Ten percent of the calculated dose is administered as an IV bolus over 1 minute. The remaining dose (90%) is administered over 1 hour via an infusion pump. Since bleeding is the most common side effect of alteplase, the patient is closely monitored for any suspected bleeding (at IV insertion sites, gums, urine/stools, and intracranially by assessing changes in LOC). Patients are also monitored for angioedema (oral/lingual swelling) and anaphylaxis (allergic reaction) to the medication.

TABLE 47-4 Summary of National Institutes of Health Stroke Scale (NIHSS)

Category	Description	Score
1a. Level of consciousness (LOC)	Alert Arousable by minor stimulation Obtunded, strong stimulation to attend Unresponsive, or reflex responses only	0 1 2 3
1b. LOC questions (month, age)	Answers both correctly Answers one correctly Both incorrect	0 1 2
1c. LOC, commands (open, close eyes; make fist, let go)	Obeys both correctly Obeys one correctly Both incorrect	0 1 2
2. Best gaze (eyes open—patient follows examiner's finger or face)	Normal Partial gaze palsy Forced deviation	0 1 2
3. Visual (introduce visual stimulus/threat to patient's visual field quadrants)	No visual loss Partial hemianopsia Complete hemianopsia Bilateral hemianopsia	0 1 2 3
4. Facial palsy (show teeth, raise eyebrows and squeeze eyes shut)	Normal Minor loss Partial loss Complete loss	0 1 2 3
5a. Motor; arm—left (elevate extremity to 90 degrees for 10 seconds and score drift/movement)	No drift Drift but maintains in air Unable to maintain in air No effort against gravity No movement Amputation, joint fusion (explain)	0 1 2 3 4 N/A
5b. Motor; arm—right (elevate extremity to 90 degrees for 10 seconds and score drift/movement)	No drift Drift but maintains in air Unable to maintain in air No effort against gravity No movement Amputation, joint fusion (explain)	0 1 2 3 4 N/A
6a. Motor; leg—left (elevate extremity to 30 degrees for 5 seconds and score drift/movement)	No drift Drift but maintains in air Unable to maintain in air No effort against gravity No movement Amputation, joint fusion (explain)	0 1 2 3 4 N/A
6b. Motor; leg—right (elevate extremity to 30 degrees for 5 seconds and score drift/movement)	No drift Drift but maintains in air Unable to maintain in air No effort against gravity No movement Amputation, joint fusion (explain)	0 1 2 3 4 N/A
7. Limb ataxia (finger-to-nose and heel-to-shin testing)	Absent Present in one limb Present in two limbs	0 1 2
8. Sensory (pin prick to face, arm, trunk, and leg—compare side to side)	Normal Mild to moderate loss Severe to total loss	0 1 2

9. Best language (name items, describe a picture and read sentences)	No aphasia Mild to moderate aphasia Severe aphasia Mute	0 1 2 3
10. Dysarthria (evaluate speech clarity by having patient repeat words)	Normal Mild to moderate dysarthria Severe dysarthria, mostly unintelligible or worse Intubated or other physical barrier	0 1 2 N/A
11. Extinction and inattention (use information from prior testing to score)	No abnormality Visual, tactile, auditory, or other extinction to bilateral simultaneous stimulation Profound hemi-attention or extinction to more than one modality.	0 1 2
Total score

During the hyperacute phase of a suspected acute stroke, ongoing assessments and meticulous documentation of the patient's neurologic and hemodynamic status are essential, regardless of stroke type and whether or not the patient was a candidate for IV treatment.

Following the publication of several major trials in 2014 and 2015 for treatment of acute ischemic stroke, intra-arterial therapies for acute ischemic stroke were recommended as a standard-of-care option for selected patients with large vessel occlusions. The use of a clot-retrieval device (thrombectomy) with and without intra-arterial alteplase (typically within 6 hours of when patient was last known well) was shown to have a benefit in recanalizing the stenosed or occluded vessel and also demonstrated a statistically significantly improved functional outcome. These procedures have now become an accepted option for patients who present to facilities who support neurointerventional services (Goyal, Menon, & Van Zwam, 2016). Many Primary Stroke Centers, Thrombectomy-capable Stroke Centers, and Comprehensive Stroke Centers have the capability to perform thrombectomies, and patients require postprocedure intensive care monitoring similar to care provided following IV thrombolysis. For a more detailed explanation regarding the management of stroke patients who undergo these procedures, see the Current Treatment Options in Cardiovascular Medicine (2014) article, Intra-arterial Treatment for Acute Ischemic Stroke: the Continued Evolution.

Acute Stroke Recovery Care

Table 47-5 summarizes the nursing care for thrombolysis and nonthrombolysis treatments for patients with acute ischemic stroke. Post-stroke management addresses blood pressure parameters, oxygenation, body temperature, and hyperglycemia. Additionally, there are directives for neurologic assessments, deep vein thrombosis (DVT) prophylaxis, body temperature and oxygen status, cardiac monitoring and screening for impaired swallowing prior to oral intake.

Secondary Stroke Prevention

Once the patient has had a stroke, the patient is at increased risk for a second event. This risk is dependent on the etiology of the index stroke and the steps taken to prevent a recurrent stroke. Once the likely etiology of an ischemic stroke is determined, effective

secondary stroke prevention will include the selection of the appropriate antithrombotic medication. The use of antithrombotic agents is a primary focus for secondary stroke prevention.

For patients whose stroke is thought to be cardiogenic embolic (from atrial fibrillation), warfarin or one of the newer anticoagulants is the most effective treatment to reduce stroke risk. For all other ischemic stroke types, antiplatelet treatment is recommended and can comprise one of several medications, including aspirin (at doses of 81 to 325 mg), clopidogrel (75 mg daily), and low-dose aspirin in combination with extended-release dipyridamole (50/200 mg). Additionally, based on the results of several studies, the use of statins for secondary (and primary) stroke prevention is recommended. A lipid profile is reviewed, and the current goal is for the LDL (low-density lipoprotein) to be less than 70 mg/dL. In general, patients are prescribed a high-dose statin (such as atorvastatin) to achieve the goal LDL. Statins also have shown to have an anti-inflammatory effect, which provides further secondary stroke prevention in the first few months after the event.

Acute Hemorrhagic Stroke

During the hyperacute phase, the management of patients with an intracranial hemorrhage focuses on airway, breathing, and circulation (ABCs), with particular attention paid to the patient's LOC. Immediate complications of a hemorrhage include extension of bleeding causing increased ICP, acute hydrocephalus, potential for herniation, and secondary brain injury. Any evidence of deterioration and ICP (refer to Chapter 45) is reported immediately to the health care team. For patients with a hemorrhage, the Glasgow Coma Scale (GCS) is also used as part of ongoing patient assessment. For patients with a GCS score of 8 or less, immediate intubation is indicated. Monitoring of peripheral oxygenation is expected with a pulse oximeter. Nurses will be directed to elevate the head of bed to 30 degrees, monitor sedation if instituted, and prepare for one or more of the following treatment options: anticoagulation reversal if patient is on anticoagulant, hyperventilation (hypocapnia temporarily causes vascular constriction, resulting in reduced blood flow in vessels not involved with the injury), placement of a ventricular catheter for CSF drainage, administration of mannitol—all to reduce elevated ICP. Because hyperthermia (temperature above 37.5°C) is associated with a poorer prognosis following acute stroke, the nurse monitors the patient's temperature and is prepared to initiate measures to prevent and control fever collaboratively with the health care team. Additionally, because aspiration is a significant risk, patients should be maintained NPO until they are screened for dysphagia (Livesay & Hickey, 2014).

TABLE 47-5 Schedule of Neurologic Assessment and Vital Signs and Other Acute Care Assessments in Thrombolysis-Treated and Nonthrombolysis-Treated Patients

Thrombolysis-Treated Patients	Nonthrombolysis-Treated Patients
Neurologic assessment and vital signs (except temperature) every 15 minutes during alteplase infusion, then every 30 minutes for 6 hours, and then every 60 minutes for 16 hours (total of 24 hours) Note: Frequency of blood pressure (BP) assessments may need to be increased if systolic BP stays greater than 180 mm Hg or diastolic BP stays greater than 105 mm Hg during the first 24 hours. Temperature every 4 hours or as required. Treat temperatures > 99.6°F with acetaminophen as ordered.	In intensive care unit (ICU), every hour with neurologic checks or more frequently if necessary. In a non-ICU setting, depending on patient's condition and neurologic assessments; at a minimum check neurologic assessment and vital signs every 4 hours
After 24 hours, call physician if systolic BP greater than 185 or less than 110 mm Hg; diastolic BP greater than 105 or less than 60 mm Hg; pulse less than 50 or greater than 110 per minute; respirations 24 per minute; temperature over 99.6°F; or for worsening of stroke symptoms or other decline in neurologic status	Call physician for further treatment based on physician and institutional preferences/guidelines: Systolic BP above 220 or below 110 mm Hg; diastolic BP above 120 or below 60 mm Hg; pulse below 50 or above 110 per minute; temperature above 99.6°F; respirations 24 per minute; or for worsening of stroke symptoms or other decline in neurologic status
For O_2 saturation below 94%, give O_2 by cannula at 2–3 L/min	For O_2 saturation below 94%, give O_2 by cannula at 2–3 L/min
Monitor for major and minor bleeding complications	N/A
Continuous cardiac monitoring up to 72 hours or more	Continuous cardiac monitoring for 24–48 hours
Measure intake and output	Measure intake and output
Activity – as ordered by the physician	Activity – as ordered by the physician
IV fluids normal saline (NS) at 75–100 mL/hr	IV fluids NS at 75–100 mL/hr
No heparin, warfarin, aspirin, clopidogrel, or aspirin/extended-release dipyridamole for 24 hours, then start antithrombotic as ordered	Antithrombotics should be ordered before the end of hospital day #2
Brain CT or MRI after rtPA therapy	Repeat brain CT scan or MRI may be ordered 24–48 hours after stroke or as needed

Comprehensive overview of nursing and interdisciplinary care of the acute ischemic stroke patient: A scientific statement from the American Heart Association. *Stroke*, *40*, 2911–2944. © 2009 American Heart Association, Inc.

Clinicians will report an ICH score early in the assessment of a patient with an intracranial hemorrhage to determine prognosis. The scale in Figure 47-8 reviews specific patient-related characteristics to devise a score that is associated with risk for mortality within the first 30 days after hemorrhage. Components of the ICH score include the GCS score, hemorrhage volume, the presence of infratentorial hemorrhage, location of the hemorrhage, and patient age. The higher scores (5 and 6) predict a 100% mortality and, as such, will assist with decisions related to goals of care (Hemphill, Bonovich, Besmertis, et al., 2001).

GCS	
3–4	2 pts
5–12	1 pt
13–15	0 pts
ICH volume	
≥ 30 cm^3	1 pt
< 30 cm^3	0 pts
IVH	
Yes	1 pt
No	0 pts
Location	
Infratentorial	1 pt
Supratentorial	0 pts
Age	
≥ 80 yrs	1 pt
< 80 yrs	0 pts

ICH score	Mortality
0	No mortality
1	13%
2	26%
3	72%
4	97%
5	100%
6	100%

FIGURE 47-8 Determination of the intracerebral hemorrhage (ICH) score and risk of mortality. GCS, Glasgow Coma Scale; ICH, intracerebral hemorrhage; IVH, intraventricular hemorrhage. (Hemphill, J. C., Bonovich, D. C., Besmertis, L., Manley, G. T., & Johnston, S. C. (2001). The ICH score: A simple reliable grading scale for intracerebral hemorrhage. *Stroke*, *32*, 891–897.)

Concept Mastery Alert

For nonthrombolysis-treated patients, antithrombotics should be administered before the end of Day #2.

Surgical evacuation of intracranial bleeding is also considered in selected cases that require immediate intervention and when neurosurgical services are available. Depending on the location and volume of the intracerebral bleed, the degree of neurologic deterioration, and the presence of hydrocephalus and ventricular obstruction, patients may undergo a craniotomy and evacuation of the hematoma. Antihypertensive medications and antiepileptic medications are also mainstays of acute therapy to control bleeding and potential seizures. Blood pressure goals are ordered based on individual patient profiles. Current clinical trials are underway to determine target blood pressure ranges in ischemic stroke; however, generally treatment is avoided unless the systolic BP is greater than 220 mm Hg or diastolic BP is greater than 120 mm Hg (Livesay & Hickey, 2014, p. 525). Pain, fever, and hyperglycemia are addressed in the first 24 hours to reduce further cerebral

injury (Livesay & Hickey, 2014).

For patients with a known ruptured aneurysm and subsequent SAH, the 2015 AHA guidelines for SAH describe both surgical clipping and endovascular coiling as beneficial options to reduce the risk of rebleeding. Surgical clipping involves a craniotomy and placement of a clip at the neck of the artery to close the rupture site. Coiling is an endovascular procedure using a catheter that is accessed from the femoral artery and directed through the vasculature to the location of the aneurysm. Multiple coils are then dispensed through the catheter and packed into the dome of the aneurysm to promote clotting and close the aneurysm. The choice of aneurysm treatment depends on the overall health of the patient, the nature and location of the aneurysm, and the available resources at the hospital. Clinicians also use an assessment scoring tool called the Hunt and Hess Score (Fig. 47-9) to grade patients with SAH to predict surgical mortality. Based on headache quality, focal deficit, and LOC, the patient with a higher score will portend a poor prognosis. Because this score depends on evolving and sometimes fluctuating symptoms, this score can change from what was recorded during the patient's initial admission.

Stroke care in the acute phase is typically designated as the time during which the patient has been admitted to the hospital. The hospital stay can vary from a few days to many weeks, depending on the nature and severity of the stroke, and deficits and complications associated with recovery. In addition to monitoring for potential complications associated with stroke such as deconditioning, aspiration, infection, bowel and bladder dysfunction, and inability to perform self-care, care plans should include an early initiation of rehabilitation to improve functional outcome.

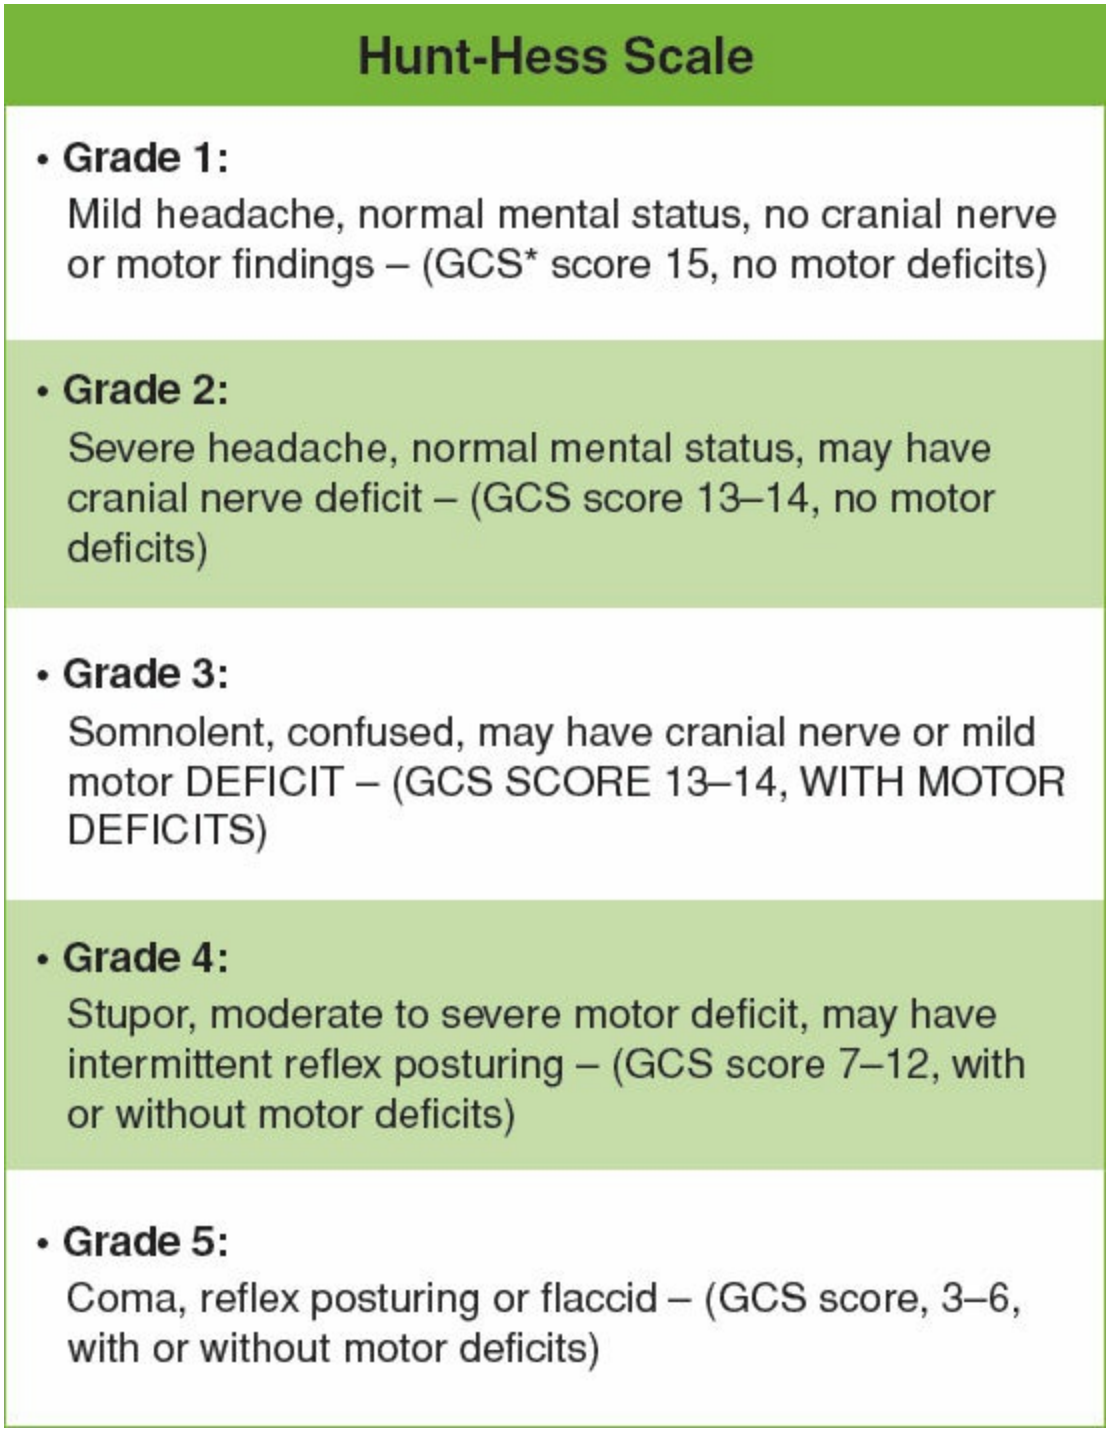

FIGURE 47-9 HUNT-HESS scores. (Hunt, W. E., & Hess, R. M. (1968). Surgical risk as related to time of intervention in the repair of intracranial aneurysms. *Journal of Neurosurgery*, *28*(1), 14–20.)

Stroke Rehabilitation

The potential for recovery after stroke extends beyond the hospital admission and beyond the time spent in an acute or subacute care facility. Although rehabilitation planning begins on the day of hospital admission, nursing interventions and collaboration with the multidisciplinary rehabilitation team continue throughout the patient's recovery. It is important to understand what the patient was like before the stroke. A history of other illnesses, behavioral characteristics, activities of daily living (ADLs), and neurologic scores (such as the modified Rankin scale) will provide information to develop a realistic plan for recovery. The World Health Organization's International Classification of Functioning (ICF) has been included as one of the five sections outlined in the AHA's Guidelines for Adult Stroke Rehabilitation and Recovery (Winstein, Stein, Arena, et al., 2016). The three components of the model include:

1. The pathophysiologic processes directly related to the stroke and its associated comorbidities
2. The impact this condition has on the individual
3. Contextual variables, such as each survivor's personal and environmental resources

The major goals for the patient (and family) should include all efforts to return the patient to his or her premorbid functioning. Depending on the location of the initial brain injury, patients are assessed for rehabilitative needs to improve mobility, communication, cognition, coordination, balance, and pain relief (from contractures). Potential complications such as aspiration, incontinence, skin breakdown, falls, depression, and disruption of family dynamics are targets for prevention.

Prevention

In a healthy population, risk factors are identified and addressed in a primordial and primary prevention program. *Primordial prevention* refers to strategies designed to decrease the development of disease risk factors (e.g., efforts to decrease the development of obesity, increase exercise, and provide a well-balanced diet). Primordial prevention encompasses the entire population and is not limited to individuals with recognized risk factors for stroke or other cardiovascular diseases (Schwamm, Pancioli, Acker, et al., 2005). *Primary prevention* refers to the treatment of established disease risk factors but for those patients who have not yet had an event. The 2014 Guidelines for the Primary Prevention of Stroke provide a comprehensive overview of established and emerging modifiable and nonmodifiable stroke risk factors (Meschia, Bushnell, Boden-Albala, et al., 2014).

For patients who have had a stroke, risk factor modification is a critical part of the secondary prevention plan. Stroke education for patients and their families addresses the possible causes of stroke, identifies potential stroke risk factors, reinforces compliance with medications, and discusses pertinent lifestyle changes to reduce stroke risk. The 2014 guidelines for the prevention of subsequent stroke after stroke or TIA highlight the following key risk factors: hypertension, diabetes, dyslipidemia, smoking, alcohol consumption, obesity, and sedentary activity. Patient education has become a standard performance measure for practice at certified primary stroke centers.

Optimal medical therapy includes prescribing an antiplatelet medication (such as aspirin, clopidogrel, or aspirin/extended-release dipyridamole), a statin (such as atorvastatin or simvastatin), and an antihypertensive (thiazide diuretic, angiotensin-converting enzyme [ACE] inhibitor or beta blocker). For those patients with paroxysmal or permanent atrial fibrillation, anticoagulation (with warfarin or other anticoagulant) is also recommended (Furie, Kasner, Adams, et al., 2011).

For those patients who have had a hemorrhagic stroke, blood pressure control is critical. The issue of whether to start or resume antithrombotic therapy is highly dependent on the nature and severity of the hemorrhage and the risk for a subsequent thrombotic event (as in the case of a patient with atrial fibrillation or with a mechanical heart valve).

For patients with symptoms of TIA or stroke thought to be caused by significant carotid artery stenosis (70% to 99%), a carotid endarterectomy (CEA) may be recommended. A CEA is the removal of an atherosclerotic plaque or thrombus from the ICA to prevent recurrent stroke. Carotid angioplasty and stenting is an alternative (less invasive) procedure and performed in selected patients when surgery poses a higher risk and the endovascular approach poses a low perioperative complication risk. These procedures are generally recommended once the patient is hemodynamically stable and usually within the first 2 weeks following their event.

In preparation for discharge, teaching patients and families about what to expect within a home or rehabilitation facility will be a focus for nursing, the rehabilitation staff, and the discharge planner. Resources in the community, such as support groups, regional and national heart and stroke associations, and hospital-based social work support should also be part of the discharge materials.

NURSING PROCESS

The Patient with a Stroke

ASSESSMENT

A nursing flow sheet is maintained for the documentation of a complete neurologic assessment.

A systems approach to examining and documenting findings should include a mental status evaluation (orientation, affect, perception, memory, attention span, speech, and language), motor control, swallowing ability, hydration status, fluid output, skin integrity, and activity level. The ongoing nursing assessment continues to focus on alterations in cognition and functional impairment and directs the appropriate nursing diagnoses.

DIAGNOSIS

Appropriate nursing diagnoses may include:

- Altered hemodynamics related to cardiac arrhythmias, hyper-/hypotension, fluid/electrolyte imbalances
- Impaired physical mobility related to hemiparesis, sensory loss, loss of balance or coordination, or visual field deficit
- Impaired verbal communication related to dysarthria, aphasia, altered cognition
- Impaired swallowing/risk for aspiration related to inability to protect airway or altered LOC
- Risk for infection related to smoking history, invasive lines, Foley catheter, nasogastric (NG) tube
- Risk for ineffective peripheral tissue perfusion related to risk for DVT/immobility
- High risk for injury related to visual field, motor, or perception deficits
- Knowledge deficit related to lack of awareness of stroke risk factors, secondary stroke prevention medications, potential lifestyle changes, physical and occupational therapies

PLANNING

Although rehabilitation begins on the day of admission, the process is intensified during convalescence and requires a coordinated team effort. It is helpful for the team to know the patient's baseline function, medical history, mental and emotional state, behavioral

characteristics, and ADLs. Additionally, clinicians should be knowledgeable about the relative importance of predictors of stroke outcome (age, comorbidities such as diabetes, and presenting NIHSS score) in order to provide stroke survivors and their families with a realistic recovery trajectory. For example, the NIHSS score is used commonly to communicate the severity of symptoms associated with stroke and is often conducted on admission, at 24 hours and at discharge; other institutions will collect the NIHSS score every shift and use the score to communicate patient status (Livesay & Hickey, 2014). Refer to Table 47-4 for the NIHSS scale.

A commonly used assessment scale for measuring disability as it relates to the patient's dependence with daily activities after stroke is the modified Rankin scale. A 0–6 scale is used to describe the trajectory from "zero" or "no symptoms—able to perform all usual activities" to "five" or "severe disability—bedridden and requiring constant 24-hour care." A score of "six" refers to "death." This tool has been adopted by clinicians, rehabilitation specialists, and researchers to determine pre-stroke capabilities as well as short- and long-term post-stroke degree of disability (Wilson, Hareendran, & Grant, 2002). See Figure 47-10.

The major goals for the patient (and family) may include improved mobility, avoidance of shoulder pain, achievement of self-care, relief of sensory and perceptual deprivation, prevention of aspiration, continence of bowel and bladder, improved thought processes, optimization of communication, maintaining skin integrity, restored family functioning, improved sexual function, and absence of complications.

Modified Rankin Scale (MRS)	
0	No symptoms
1	No significant disability, despite symptoms; able to perform all usual duties and activities
2	Slight disability; unable to perform all previous activities but able to look after own affairs without assistance
3	Moderate disability; requires some help, but able to walk without assistance
4	Moderately severe disability; unable to walk without assistance and unable to attend to own bodily needs without assistance
5	Severe disability; bedridden, incontinent, and requires constant nursing care and attention
6	Death

FIGURE 47-10 Modified Rankin scale. (Rankin, J. (1957). Cerebral vascular accidents in patients over the age of 60. *Scottish Medical Journal*, *2*, 200–215; Bonita, R., & Beaglehole, R. (1988). Modification of Rankin Scale: Recovery of motor function after stroke. *Stroke*, *19*(12), 1497–1500.)

NURSING INTERVENTIONS

Nursing care has a significant impact on the patient's recovery. Often, many body systems are impaired as a result of the stroke, and conscientious care and timely interventions can prevent debilitating complications. During and after the acute phase, nursing interventions include a comprehensive approach to physical care and fostering recovery by listening to the patient and asking questions to elicit the meaning of the stroke experience.

IMPROVING MOBILITY AND PREVENTING JOINT DEFORMITIES

When control of the voluntary muscles is lost, the strong flexor muscles exert control over

the extensors. The arm tends to adduct (adductor muscles are stronger than abductors) and to rotate internally. The elbow and the wrist tend to flex, the affected leg tends to rotate externally at the hip joint and flex at the knee, and the foot at the ankle joint supinates and tends toward plantar flexion.

Correct positioning is important to prevent contractures; measures are used to relieve pressure, assist in maintaining good body alignment, and prevent compressive neuropathies, especially of the ulnar and peroneal nerves. Because flexor muscles are stronger than extensor muscles, a posterior splint applied at night to the affected extremity may prevent flexion and maintain correct positioning during sleep. If splints are in place, the nurse assesses the skin for evidence of impaired circulation, sensation, and/or mobility, as well as any evidence of altered skin integrity.

Nursing Alert

Positioning after stroke remains controversial (Hunter et al., 2011; Olavarria et al., 2014). In the acute phase, the goal is to optimize cerebral perfusion and so having the head of bed flat (supine) will enhance blood flow to the brain. The supine position is generally reserved for conscious patients without evidence of dysphagia since they are at low risk for aspiration and can control secretions. The unconscious patient or a patient at risk for aspiration is positioned in side-lying position with the head of the bed elevated 10 to 30 degrees to facilitate the drainage of secretions from the mouth (Livesay & Hickey, 2014). Practices for patient positioning are institution-specific and are outlined in stroke recovery care protocols. In general, most practices include an HOB order of 30 to 45 degrees.

Preventing Shoulder Adduction. To prevent adduction of the affected shoulder while the patient is in bed, a pillow is placed in the axilla when there is limited external rotation; this keeps the arm away from the chest. A pillow is placed under the arm, and the arm is placed in a neutral (slightly flexed) position, with distal joints positioned higher than the more proximal joints (i.e., the elbow is positioned higher than the shoulder and the wrist higher than the elbow). This helps to prevent edema and the resultant joint fibrosis that will limit range of motion (ROM) if the patient regains control of the arm.

Positioning the Hand and Fingers. The fingers are positioned so that they are barely flexed. The hand is placed in slight supination (palm faces upward), which is its most functional position. If the upper extremity is flaccid, a splint can be used to support the wrist and hand in a functional position. Every effort is made to prevent hand edema.

Spasticity, particularly in the hand, can be a disabling complication after stroke. Researchers have reported that repeated intramuscular injections of botulinum toxin A into wrist and finger muscles significantly reduced upper limb spasticity after stroke and improved upper limb motor function for a period of 3 months; however, the evidence on whether botulinum toxin A injections are useful for improving upper limb capacity is lacking (Kwakkel & Meskers, 2015; Tsuchiya, Morita, & Hara, 2016).

Mirror therapy has also demonstrated improvement in motor functions and ADLs that persisted after 6 months. In this therapy, the patient watches a mirror as movements with

the unaffected hand are performed, leaving the impression that his or her affected hand is moving. This therapy is purported to induce neuroplasticity changes in the primary motor cortex that support recovery (Radajewska, 2016).

Establishing an Exercise Program. The affected extremities are exercised passively and put through a full ROM four or five times a day to maintain joint mobility, regain motor control, prevent contractures in the paralyzed extremity, prevent further deterioration of the neuromuscular system, and enhance circulation. Repetition of an activity forms new pathways in the CNS and therefore encourages new patterns of motion. At first, the extremities are usually flaccid. If tightness occurs in any area, the ROM exercises should be performed more frequently. Regularity in exercise is most important. Improvement in muscle strength and maintenance of ROM can be achieved only through daily exercise.

The patient is encouraged and reminded to exercise the unaffected side at intervals throughout the day. It is helpful to develop a written schedule to remind the patient of the exercise activities. The nurse supervises and supports the patient during these activities. The patient can be taught to put the unaffected leg under the affected one to assist in moving it when turning and exercising. Flexibility, strengthening, coordination, endurance, and balancing exercises prepare the patient for ambulation. Quadriceps muscle setting and gluteal setting exercises are started early to improve the muscle strength needed for walking; these are performed at least five times daily for 10 minutes at a time.

Preparing for Ambulation. As soon as possible, the patient is assisted out of bed. Usually, an active rehabilitation program is started as soon as the patient regains consciousness. The patient is first taught to maintain balance while sitting and then to learn to balance while standing. If the patient has difficulty in achieving standing balance, a tilt table, which slowly brings the patient to an upright position, can be used. If orthostatic hypotension is a problem, the nurse can gradually elevate the head of the bed and assess blood pressure, pulse, skin color, and any complaints of dizziness or lightheadedness. If hypotension, tachycardia, paleness, diaphoresis, dizziness, or lightheadedness are noted, the head of the bed may be lowered until the symptoms resolve.

The patient is usually ready to walk as soon as standing balance is achieved. Parallel bars are useful in these first efforts. A chair or wheelchair should be readily available in case the patient suddenly becomes fatigued or feels dizzy.

The training periods for ambulation should be short and frequent. As the patient gains strength and confidence, an adjustable cane can be used for support. In general, a three- or four-pronged cane provides a stable support in the early phases of rehabilitation.

PREVENTING SHOULDER PAIN

As many as 70% of stroke patients suffer pain in the shoulder that prevents them from regaining full ROM, and 88% will have some level of upper extremity dysfunction (Winstein, 2016). Shoulder function is essential in achieving balance and performing

transfers and self-care activities. Three problems can occur: painful shoulder, subluxation (partial dislocation) of the shoulder, and shoulder–hand syndrome or reflex sympathetic dystrophy syndrome (RSDS), which features pain (often "burning"); tenderness; vasoconstrictive-related coldness of the affected extremity; trophic changes of hair, nails, skin; and swelling.

A flaccid shoulder joint may be overstretched by the use of excessive force in turning the patient or from overstrenuous arm and shoulder movement. To prevent shoulder pain, the nurse should never lift the patient by the flaccid shoulder or pull on the affected arm or shoulder. If the arm is paralyzed, subluxation at the shoulder can occur as a result of overstretching of the joint capsule and musculature by the force of gravity when the patient sits or stands in the early stages after a stroke. This results in severe pain. Shoulder–hand syndrome (painful shoulder and generalized swelling of the hand) can cause a frozen shoulder and ultimately atrophy of subcutaneous tissues. When a shoulder becomes stiff, it is usually painful.

Many shoulder problems can be prevented by proper patient movement and positioning. The flaccid arm is positioned on a table or with pillows while the patient is seated. Some clinicians advocate the use of a properly worn sling when the patient first becomes ambulatory to prevent the paralyzed upper extremity from dangling without support. ROM exercises are important in preventing painful shoulder. Overly strenuous arm movements are avoided. The patient is instructed to interlace the fingers, place the palms together, and push the clasped hands slowly forward to bring the scapulae forward; he or she then raises both hands above the head. This is repeated throughout the day. The patient is instructed to flex the affected wrist at intervals and move all the joints of the affected fingers. He or she is encouraged to touch, stroke, rub, and look at both hands. Pushing the heel of the hand firmly down on a surface is useful. Elevation of the arm and hand is also important in preventing dependent edema of the hand. When dressing, the sequence of weaker arm, head, followed by stronger arm is followed (Winstein, 2016). Patients with continuing pain after attempted movement and positioning may require the addition of analgesia to their treatment program.

Medications are helpful in the management of post-stroke pain. Opioids are generally prescribed for acute pain but may be considered for patients with chronic pain. If prescribed, the nurse assesses for side effects, tolerance, dependency, and abuse. Adjuvant drugs, such as antidepressants, anticonvulsants, and anxiolytics, may also be considered. Tricyclic antidepressants are often prescribed for neuropathic pain, while anticonvulsants are used for their ability to stabilize neuronal membranes. Gabapentin (Neurontin) is becoming a first-line drug for neuropathic pain (Livesay & Hickey, 2014). The antiseizure medication lamotrigine (Lamictal) has been found to be effective for post-stroke pain. Topical analgesics, such as lidocaine cream or patch, may also be considered.

ENHANCING SELF-CARE

As soon as the patient can sit up, personal hygiene activities are encouraged. The patient is helped to set realistic goals; if feasible, a new task is added daily. The first step is to carry

out all self-care activities on the unaffected side. Such activities as combing the hair, brushing the teeth, shaving with an electric razor, bathing, and eating can be carried out with one hand and are suitable for self-care. Although the patient may feel awkward at first, the various motor skills can be learned by repetition, and the unaffected side will become stronger with use. The nurse must be sure that the patient does not neglect the affected side. Assistive devices will help make up for some of the patient's deficits. For example, a small towel is easier to control while drying after bathing, and boxed paper tissues are easier to use than a roll of toilet tissue.

Return of functional ability is important to the patient recovering after a stroke. An early baseline assessment of functional ability with an instrument such as the Functional Independence Measure (FIM™) is important in team planning and goal setting for the patient. The FIM™ is a widely used instrument in stroke rehabilitation and provides valuable information about motor, social, and cognitive function (Livesay & Hickey, 2014). The patient's morale will improve if ambulatory activities are carried out in street clothes. The family is instructed to bring in clothing that is preferably a size larger than that normally worn. Clothing fitted with front or side fasteners or Velcro closures is the most suitable. The patient has better balance if most of the dressing activities are carried out while seated.

Perceptual problems may make it difficult for the patient to dress without assistance because of an inability to match the clothing to the body parts. To assist the patient, the nurse can take steps to keep the environment organized and uncluttered, because the patient with a perceptual problem is easily distracted. The patient has to make many compensatory movements when dressing; these can produce fatigue and painful twisting of the intercostal muscles. Support and encouragement are provided to prevent the patient from becoming overly fatigued and discouraged. Even with intensive training, not all patients can achieve independence in dressing.

MANAGING SENSORY-PERCEPTUAL DIFFICULTIES

Patients with a decreased field of vision should be approached on the side where visual perception is intact. All visual stimuli (e.g., clock, calendar, television) should be placed on this side. The patient can be taught to turn the head in the direction of the defective visual field to compensate for this loss. The nurse should make eye contact with the patient and draw his or her attention to the affected side by encouraging the patient to move the head. The nurse may also want to stand at a position that encourages the patient to move or turn to visualize who is in the room. Increasing the natural or artificial lighting in the room and providing eyeglasses are important aids to increasing vision.

The patient with homonymous hemianopsia (loss of half of the visual field) turns away from the affected side of the body and tends to neglect that side and the space on that side; this is called *amorphosynthesis.* In such instances, the patient cannot see food on half of the tray, and only half of the room is visible. It is important for the nurse to constantly remind the patient of the other side of the body, to maintain alignment of the extremities, and, if possible, to place the extremities where the patient can see them.

ASSISTING WITH NUTRITION

Stroke can result in swallowing problems (dysphagia). Patients must be observed for paroxysms of coughing, food dribbling out of or pooling in one side of the mouth, food retained for long periods in the mouth, or nasal regurgitation when swallowing liquids. Swallowing difficulties place the patient at risk for aspiration, pneumonia, dehydration, and malnutrition. A speech therapist will evaluate the patient's gag reflexes and ability to swallow. A validated, nurse-directed dysphagia screening assessment has been recommended as part of post-stroke care to identify a patient's swallowing difficulty. A speech therapist may be consulted for patients who fail an initial screen and require a more formal evaluation. Even if swallowing function is partially impaired, it may return in some patients over time, or the patient may be taught alternative swallowing techniques, advised to take smaller boluses of food, place food on the unaffected side of the patient's mouth, and taught about types of foods that are easier to swallow. The patient may be started on a thick liquid or puréed diet because these foods are easier to swallow than thin liquids. Having the patient sit upright, preferably out of bed in a chair, and instructing him or her to tuck the chin toward the chest as he or she swallows will help prevent aspiration. The diet may be advanced as the patient becomes more proficient at swallowing. If the patient cannot resume oral intake, a gastrointestinal feeding tube will be placed for ongoing tube feedings.

Enteral tubes can be either nasogastric (placed in the stomach) or nasoenteric (placed in the duodenum) to reduce the risk of aspiration. For long-term feedings, a gastrostomy tube is preferred. Refer to Chapter 22 for details on enteral feeding. Nursing responsibilities in feeding include elevating the head of the bed at least 30 degrees to prevent aspiration, checking the position of the tube before feeding, assessing residuals, and ensuring that the cuff of the tracheostomy tube (if in place) is inflated.

ATTAINING BOWEL AND BLADDER CONTROL

After a stroke, the patient may have transient urinary incontinence due to confusion, inability to communicate needs, and inability to use the urinal or bedpan because of impaired motor and postural control. Occasionally, after a stroke, the bladder becomes atonic, with impaired sensation in response to bladder filling. Sometimes control of the external urinary sphincter is lost or diminished. During this period, intermittent catheterization with sterile technique is carried out. After muscle tone increases and deep tendon reflexes return, bladder tone increases and spasticity of the bladder may develop. Because the patient's sense of awareness is clouded, persistent urinary incontinence or urinary retention may be symptomatic of bilateral brain damage. The voiding pattern is analyzed, and the urinal or bedpan is offered on a pattern or schedule. The upright posture and standing position are helpful for male patients during this aspect of rehabilitation.

Patients may have problems with bowel control, particularly constipation. Unless contraindicated, a high-fiber diet and adequate fluid intake (2 to 3 L/day) should be provided and a regular time (usually after breakfast) should be established for toileting.

IMPROVING THOUGHT PROCESSES

After a stroke, patients may experience changes in cognition and behavior and may exhibit periods of emotional lability. These changes are usually associated with injury to the right hemisphere. Often they are transient and, with aggressive rehabilitation, patients can recover.

Screening for these problems is typically incorporated into the initial rehabilitation assessment and then repeated after discharge. Often a neuropsychologist will be consulted to perform formal neuropsychological testing to make recommendations for the appropriate follow-up treatment. A treatment program for addressing any identified deficit is established in collaboration with the patient's neurologist and primary care provider.

The role of the nurse is supportive. The nurse reviews the results of neuropsychological testing, observes the patient's performance and progress, gives positive feedback, and, most importantly, conveys an attitude of confidence and hope. Interventions capitalize on the patient's strengths and remaining abilities while attempting to improve performance of affected functions. Other interventions are similar to those for improving cognitive functioning after a head injury.

IMPROVING COMMUNICATION

Aphasia, which impairs the patient's ability to express him- or herself and to understand what is being said, may become apparent in various ways. The cortical area that is responsible for integrating the myriad pathways required for the comprehension and formulation of language is called the *Broca area.* It is located in a convolution adjoining the middle cerebral artery. This area is responsible for control of the combinations of muscular movements needed to speak each word. Patients who are paralyzed on the right side (due to damage or injury to the left side of the brain) cannot speak, whereas those paralyzed on the left side are less likely to have speech disturbances. The speech therapist assesses the communication needs of the stroke patient, describes the precise deficit, and suggests the best overall method of communication. Most language intervention strategies can be tailored for the individual patient. The patient is expected to take an active part in establishing goals.

Nursing interventions include strategies to make the atmosphere conducive to communication. This includes being sensitive to the patient's reactions and needs and responding to them in an appropriate manner. A consistent schedule, routines, and repetition help the patient to function despite significant deficits. A written copy of the daily schedule, a folder of personal information (birth date, address, names of relatives), checklists, and an audio-taped list help improve the patient's memory and concentration. The patient may also benefit from a communication board, which has pictures of common needs and phrases. When talking with the patient, it is important for the nurse to gain the patient's attention, speak slowly, and keep the language of instruction consistent. One instruction is given at a time, and time is allowed for the patient to process what has been said. The use of gestures may enhance comprehension. In working

with the patient with aphasia, the nurse must remember to talk to the patient during care activities. This provides social contact for the patient.

MAINTAINING SKIN INTEGRITY

The patient who has had a stroke may be at risk for skin and tissue breakdown because of altered sensation and inability to respond to pressure and discomfort by turning and moving. Preventing skin and tissue breakdown requires frequent assessment of the skin, with emphasis on bony areas and dependent parts of the body. During the acute phase, a specialty bed (e.g., low-air-loss bed) may be used until the patient can move independently or assist in moving.

A regular turning schedule (at least every 2 hours) must be adhered to even if pressure-relieving devices are used to prevent tissue and skin breakdown. When the patient is positioned or turned, care must be used to minimize shear and friction forces that may tear the skin and expose the patent to additional sources for infection. The patient's skin must be kept clean and dry; gentle massage of healthy (non-reddened) skin and adequate nutrition are other factors that help to maintain normal skin and tissue integrity.

IMPROVING FAMILY COPING

Family members play an important role in the patient's recovery. Family members are encouraged to participate in counseling and to use support systems that will help with the emotional and physical stress of caring for the patient. Involving others in the patient's care and teaching stress management techniques and methods for maintaining personal health also facilitate family coping.

The family may have difficulty accepting the patient's disability and may be unrealistic in their expectations. They are given information about the expected outcomes and are counseled to avoid doing activities for the patient that he or she can do. They are assured that their love and interest are part of the patient's therapy.

The family needs to be informed that the rehabilitation of the hemiplegic patient requires many months and that progress may be slow. The gains made by the patient in the hospital or rehabilitation unit must be maintained. All caregivers should approach the patient with a supportive and optimistic attitude, focusing on the patient's remaining abilities. The rehabilitation team, the medical and nursing team, the patient, and the family must all be involved in developing attainable goals for the patient at home.

Most relatives of patients with stroke handle the physical changes better than the emotional aspects of care. The family should be prepared to expect occasional episodes of emotional lability. The patient may laugh or cry easily and may be irritable and demanding or depressed and confused. The nurse can explain to the family that the patient's laughter does not necessarily connote happiness, nor does crying reflect sadness, and that emotional lability usually improves with time.

HELPING THE PATIENT COPE WITH SEXUAL DYSFUNCTION

Sexual functioning can be altered by stroke. Sexual dysfunction after stroke is

multifactorial. There may be medical reasons for the dysfunction (neurologic and cognitive deficits, previous diseases, medications), as well as various psychosocial factors. A stroke can potentially be such a catastrophic illness that the patient experiences loss of self-esteem and value as a sexual being. These psychosocial factors play an important role in determining sexual drive, activity, and satisfaction after a stroke.

Nurses in the rehabilitation setting play a crucial role in beginning a dialogue between the patient and his or her partner about sexuality after a stroke. In-depth assessments to determine sexual history before and after the stroke should be followed by appropriate interventions. Interventions for the patient and partner focus on providing relevant information, education, reassurance, adjustment of medications, counseling regarding coping skills, suggestions for alternative sexual positions, and a means of sexual expression and satisfaction.

PROVIDING PATIENT EDUCATION AND PREPARING THE PATIENT FOR THE HOME

Patient and family education is a fundamental component of rehabilitation. The nurse provides teaching about stroke, its causes and prevention, and the rehabilitation process. In both acute care and rehabilitation facilities, the focus is on teaching the patient to resume as much self-care as possible. This may entail using assistive devices or modifying the home environment to help the patient live with a disability. Families are also encouraged to take part in being assessed for their role as caregiver and their readiness to accept the additional responsibilities associated with a family member with both physical and cognitive disabilities.

An occupational therapist may be helpful in assessing the home environment and recommending modifications to help the patient become more independent. For example, a shower is more convenient than a tub for the patient with hemiplegia because most patients do not gain sufficient strength to get up and down from a tub. Sitting on a stool of medium height with rubber suction tips allows the patient to wash with greater ease. A long-handled bath brush with a soap container is helpful to the patient who has only one functional hand. If a shower is not available, a stool may be placed in the tub and a portable shower hose attached to the faucet. Handrails may be attached alongside the bathtub and the toilet. Other assistive devices include special utensils for eating, grooming, dressing, and writing.

A program of physical therapy can be beneficial in the home environment. One technique that was shown to result in a reduction in motor impairment concentrates on enhanced exercise of the affected limb. Another technique that showed positive outcomes uses sensorimotor training of the upper limb and the wrist.

Depression is a common and serious problem after stroke. Counseling and antidepressant therapy may help if depression dominates the patient's life. As progress is made in the rehabilitation program, some problems will diminish. The family can help by continuing to support the patient and by giving positive reinforcement for the progress that is being made.

Community-based stroke support groups may allow the patient and family to learn from others with similar problems and to share their experiences. Support groups take the form of in-person meetings as well as web-based support programs. The patient is encouraged to continue hobbies and recreational and leisure interests and to maintain contact with friends to prevent social isolation. Patients should be supported to keep active, adhere to the exercise program, and remain as self-sufficient as possible.

The nurse should recognize the potential effects of caregiving on the family. Not all families have the adaptive coping skills and adequate psychological functioning necessary for the long-term care of another person. The patient's spouse may be elderly, with his or her own health concerns; in some instances, the patient may have been the provider of care to the spouse. Even healthy caregivers may find it difficult to maintain a schedule that includes being available around the clock.

Depressed caregivers are more likely to resort to physical or emotional abuse of the patient and are more likely to place the patient in a nursing home. Respite care (planned short-term care to relieve the family from having to provide continuous 24-hour care) may be available from an adult day care center. Some hospitals also offer weekend respite care that can provide caregivers with needed time for themselves. The nurse encourages the family to arrange for such services and provides information to assist them.

The nurse involved in home and continuing care also needs to remind the patient and family of the need for continuing health promotion and screening practices. Patients who have not been involved in these practices in the past are educated about their importance and are referred to appropriate health care providers, if indicated.

EVALUATION

Expected patient outcomes may include the following:

1. Demonstrates intact neurologic status and normal vital signs and respiratory patterns:
    a. Normal mental status examination, intact cognitive process
    b. Normal speech patterns and language function
    c. Normal/equal strength, movement, and sensation of all four extremities
2. Understands diagnostic procedures and treatment plan:
    a. Review of current and new medications
    b. Proposed physical and occupational therapies
    c. Achieves self-care; uses adaptive equipment
3. Arranges for follow-up appointments with stroke neurologist or primary care provider

CHAPTER REVIEW

Critical Thinking Exercises

1. A 74-year-old man presents to the emergency department with confusion, right-sided weakness, and difficulty getting his words out. He scores an 8 on the NIHSS. His

symptoms started 1 hour prior to admission. His head CT scan shows no evidence of a bleed. He weighs 78 kg. What are the inclusion criteria for administering IV alteplase? What is the FDA-approved time-frame for administering alteplase? How is alteplase dosed?

2. An 80-year-old woman is admitted to the hospital with a large SAH and undergoes a coiling procedure for a ruptured aneurysm. What nursing measures should be implemented to prevent rebleeding during her hospital stay?

3. A 48-year-old man with a history of hypertension, dyslipidemia, coronary artery disease, and smoking is admitted to the hospital with a 2-day history of nausea and vertigo. His hospital workup revealed an ischemic stroke in the right cerebellum. What medications might he be sent home with? What risk factor modifications will be recommended? What additional teaching will be important to emphasize his need to seek medical care?

NCLEX-Style Review Questions

1. A patient being cared for on the neurologic unit has a diagnosis of acute ischemic stroke. It has affected the left hemisphere of the patient's brain. The nurse would expect to assess which deficit in this patient?
   a. Left side of body weakness
   b. Aphasia
   c. Left field visual deficit
   d. Lack of awareness of deficits

2. A patient diagnosed with a stroke is experiencing slurred speech. The nurse would accurately document this finding as which clinical manifestation of stroke?
   a. Aphasia
   b. Dysphasia
   c. Dysarthria
   d. Apraxia

3. A 73-year-old patient has been diagnosed with ischemic stroke following diagnostic studies. Which medication must be given within a 4.5-hour window of symptom onset to be effective in lysing a clot?
   a. Heparin
   b. Coumadin
   c. Plavix
   d. Alteplase

4. What would the nurse expect to document in a patient diagnosed with a right hemispheric stroke?
   a. Aphasia
   b. Slow, cautious behavior

c. Right visual field deficit
d. Impulsive behavior

5. What initial diagnostic test is recommended to assess for a cerebral bleed?
a. MRI
b. Noncontrast CT
c. CT with contrast
d. Cerebral angiography

Problems Related to Sensorineural Function

A patient with hearing loss in both ears is being seen in the hearing clinic. She sustained the hearing loss in a traumatic accident. The health care provider is giving her information about a cochlear implant.

- What are the criteria that have to be met to receive a cochlear implant?

- What does the surgical procedure involve?
- What does the rehabilitation period consist of?

CHAPTER 48

Nursing Assessment: Sensorineural Function

Linda S. Dune • Lynn S. Bickley • Peter G. Szilagyi

Learning Objectives

After reading this chapter, you will be able to:

1. Identify eye structures and describe their functions.
2. Describe assessment components for the eye.
3. Identify diagnostic tests for assessment of vision and evaluation of visual disabilities.
4. Identify ear structures and describe their functions.
5. Describe assessment components for the ear.
6. Describe methods used to assess hearing and diagnose hearing and balance disorders.

THE EYE

The eye is a sensitive, highly specialized sense organ subject to various disorders, many of which lead to impaired vision. Impaired vision may affect a person's independence in self-care, work and lifestyle choices, sense of self-esteem, safety, ability to interact with society and the environment, and overall quality of life.

Although most people with eye disorders are treated in an ambulatory care setting, many patients receiving health care have an eye disease as a comorbid condition. In addition to understanding the prevention, treatment, and consequences of eye disorders, nurses in all settings assess visual acuity in those at risk, refer patients to eye care specialists as appropriate, implement measures to prevent further visual loss, and help patients adapt to impaired vision.

ANATOMIC AND PHYSIOLOGIC OVERVIEW

Unlike most organs of the body, the eye is available for external examination, and its anatomy is more easily assessed than many other body parts (Fig. 48-1). The eyeball, or globe, sits in a protective bony structure known as the *orbit*. The optic nerve and the ophthalmic artery enter the orbit at its apex through the optic foramen. The eyeball is moved through all fields of gaze by the extraocular muscles. The four rectus muscles and two oblique muscles (Fig. 48-2) are innervated by cranial nerves (CN) III, IV, and VI. Normally, the movements of the two eyes are coordinated, and the brain perceives a single image.

External Eye

The eyelids, composed of thin elastic skin that covers striated and smooth muscles, protect the anterior portion of the eye. The eyelids contain multiple glands, including sebaceous, sweat, and accessory lacrimal glands, and they are lined with conjunctival material. The upper lid normally covers the uppermost portion of the iris and is innervated by the oculomotor nerve (CN III). The lid margins contain meibomian glands, which produce an oil-like substance as a constituent of tears that helps to prevent dry eyes in the inferior and superior puncta, and the eyelashes. The triangular spaces formed by the junction of the eyelids are known as the *inner* or *medial canthus* and the *outer* or *lateral canthus.*

Tears are vital to eye health. They protect the cornea and sclera with lubrication, nutritional support, moisture, and protection from microbes. Tears also contain immunoglobulins that contribute to the increase in tearing during allergic responses. A healthy tear is composed of three layers: lipoid, aqueous, and mucoid. If there is a defect in the composition of any of these layers, the integrity of the cornea may be compromised. Tears are secreted in response to reflex or emotional stimuli. With every blink of the eyes, the lids wash the cornea and conjunctiva with tears.

Nursing Alert
In the absence of the patient's corneal reflex, the nurse must protect the patient's affected eye from injury by lubricating it with artificial tears to prevent drying.

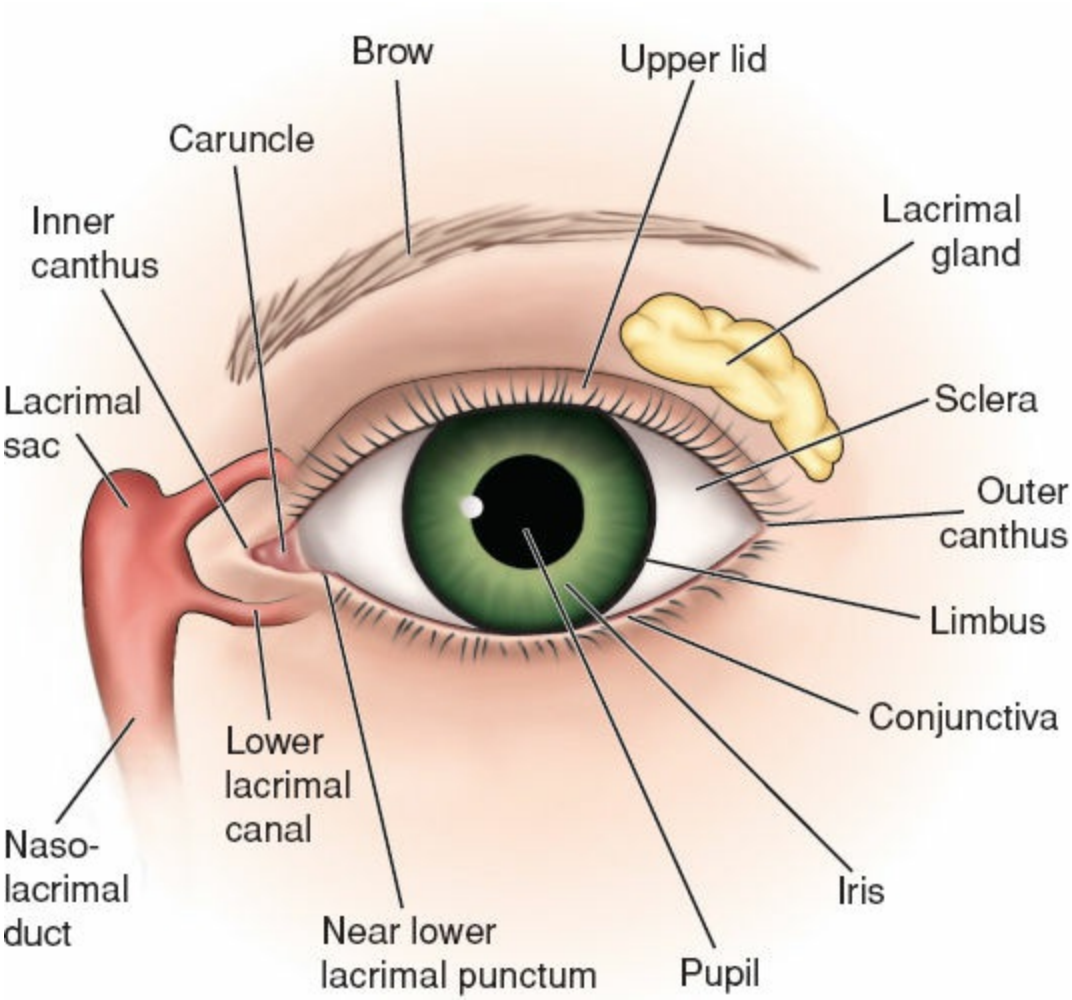

FIGURE 48-1 External structures of the eye and position of the lacrimal structures.

Nursing Alert

The lacrimal apparatus are located in the eyelid and inner canthus and are essential for tear formation and drainage needed to lubricate the eyes. The lacrimal apparatus, within the inner canthus, contains a tiny fold of mucous membrane that can be blocked by debris when providing eye care (Bickley, 2013). When cleaning the eyes, in order to remove crusting or drainage, the nurse moves from inner to outer canthus. Use only one cotton ball or pledget (small compress) for each eye to remove debris and prevent it from entering the lacrimal duct.

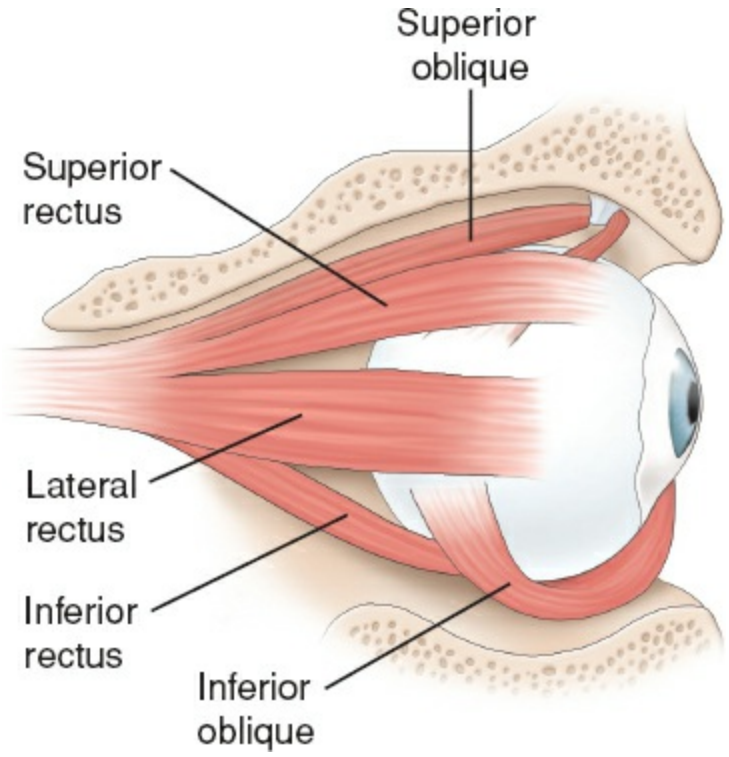

FIGURE 48-2 The extraocular muscles responsible for eye movement. The medial rectus muscle (not shown) is responsible for opposing the movement of the lateral rectus muscle.

Internal Eye

The conjunctiva, a mucous membrane, provides a barrier to the external environment and nourishes the eye. The goblet cells of the conjunctiva secrete lubricating mucus. The bulbar conjunctiva covers the sclera, whereas the palpebral conjunctiva lines the inner surface of the upper and lower eyelids. The junction of the two portions is known as the *fornix*.

The sclera, commonly known as the white of the eye, is a dense, fibrous structure that helps maintain the shape of the eyeball and protects the intraocular contents from trauma (Fig. 48-3). The sclera may have a slightly bluish tinge in young children, a dull white color in adults, a slightly yellowish color in the elderly, or a muddy brown color in African Americans; all are variations of normal. Externally, it is overlaid with conjunctiva, which is a thin, transparent mucous membrane that contains fine blood vessels. The conjunctiva meets the cornea at the limbus on the outermost edge of the iris.

The cornea (Fig. 48-4) is a transparent, avascular, domelike structure that covers the iris, pupil, and anterior chamber. It is the most anterior portion of the eyeball and is the main refracting surface of the eye. The epithelial cells of the cornea are capable of rapid replication and are completely replaced every 7 days. Behind the cornea lies the anterior chamber, filled with a continually replenished supply of clear aqueous humor, which nourishes the cornea. The aqueous humor is produced by the ciliary body, and its production is dependent on a normal intraocular pressure (IOP) of 10 to 21 mm Hg.

The uvea consists of the iris, the ciliary body, and the choroid. The iris, or colored part of the eye, is a highly vascularized, pigmented collection of fibers surrounding the pupil. The pupil is a space that dilates and constricts in response to light. Normal pupils are round and constrict symmetrically when exposed to bright, direct light or for accommodation to objects that are near. Dilation and constriction are controlled by the sphincter and dilator pupillae muscles. The dilator muscles are controlled by the sympathetic nervous system, whereas the sphincter muscles are controlled by the parasympathetic nervous system.

Nursing Alert
Approximately 20% of the population may have pupils that are slightly unequal in size but respond equally to light. The term for unequal pupils is physiologic anisocoria, and it can be a benign variant (usually less than 1 mm difference between pupils) or a manifestation of disease, pathologic anisocoria (at least 1 mm difference) (American Association for Pediatric Ophthalmology and Strabismus [AAPOS, 2015]).

Directly behind the pupil and iris lies the lens, a colorless and almost completely transparent biconvex structure. It is avascular and has no nerve or pain fibers. The lens enables focusing for near vision and refocusing for distance vision. The ability to focus and refocus is called accommodation. The lens is suspended behind the iris by zonules (string-like fibers) and is connected to the ciliary body. The ciliary body controls accommodation through the zonular fibers and the ciliary muscles (Fig. 48-4). The aqueous humor is anterior to the lens; posterior to the lens is the vitreous humor. The posterior chamber is a small space between the vitreous and the iris. The ciliary body in the posterior chamber

produces aqueous fluid. This aqueous fluid flows from the posterior chamber into the anterior chamber, from which it drains through the trabecular meshwork into the canal of Schlemm.

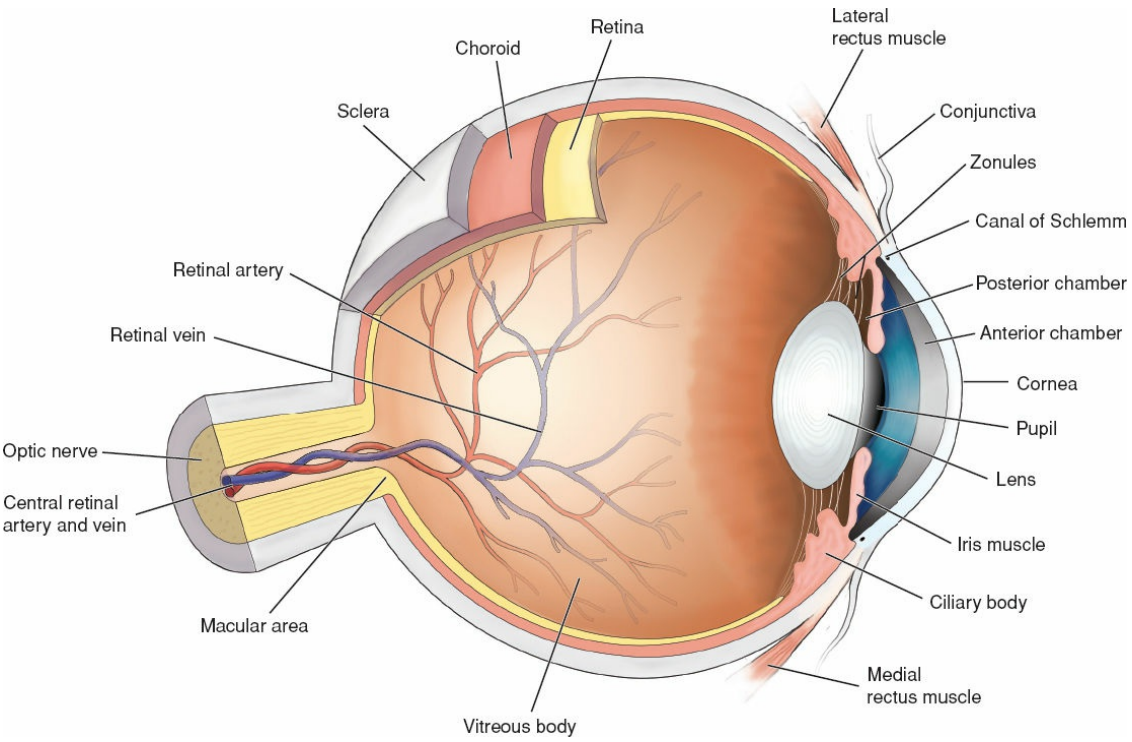

FIGURE 48-3 Three-dimensional cross-section of the eye.

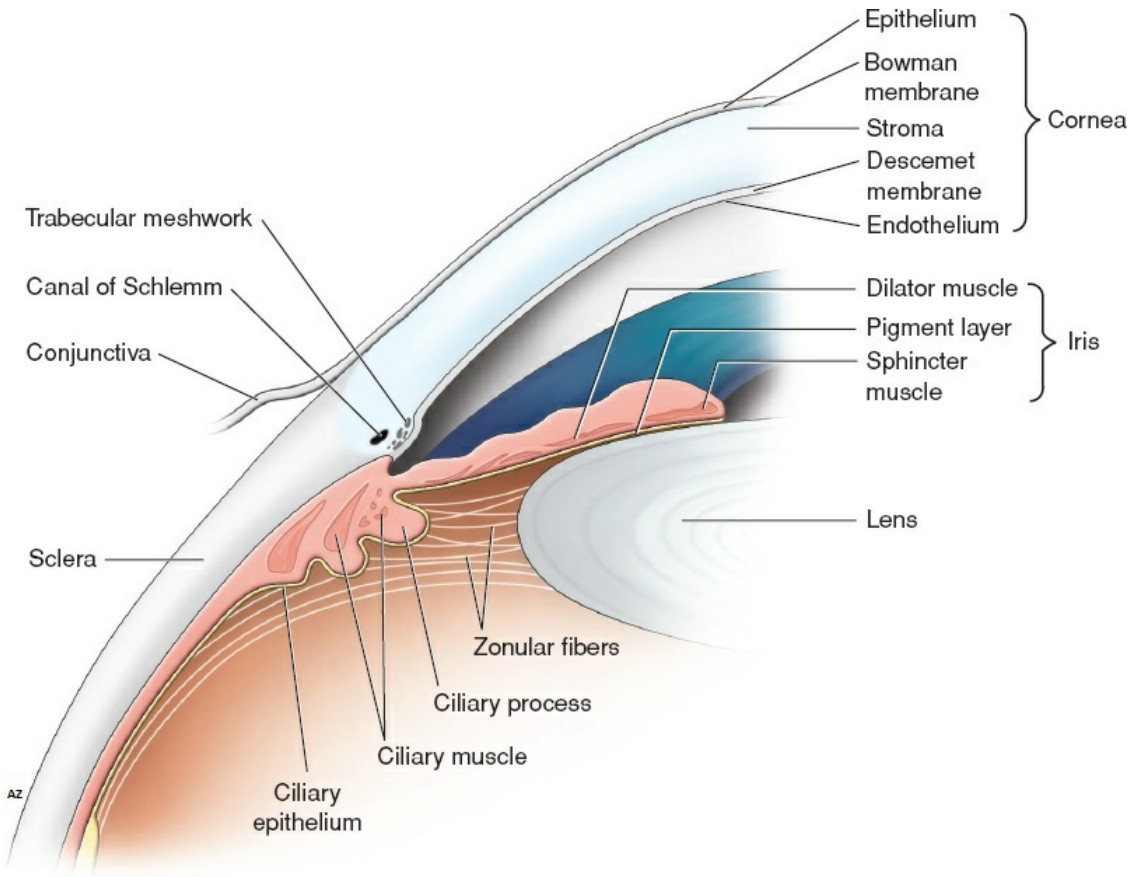

FIGURE 48-4 Internal structures of the eye. (Redrawn from American Society of Ophthalmic Registered Nurses. (2008). *Core curriculum for ophthalmic nursing*. Dubuque, IA: Kendall/Hall Publishing.)

The choroid lies between the retina and the sclera. It is avascular tissue, supplying blood to the portion of the sensory retina closest to it.

The ocular fundus is the largest chamber of the eye and contains the vitreous humor, a clear, gelatinous substance, composed mostly of water and encapsulated by a hyaloid membrane. The vitreous humor occupies about two thirds of the eye's volume and helps maintain the shape of the eye. The vitreous humor is in continuous contact with the retina and is attached to the retina by scattered collagenous filaments. The innermost surface of the fundus is the retina. The retina is composed of 10 microscopic layers and has the consistency of wet tissue paper. It is neural tissue, an extension of the optic nerve. Viewed through the pupil, the landmarks of the retina are the optic disc, the retinal vessels, and the macula. The point of entrance of the optic nerve into the retina is the optic disc. The optic disc is pink; it is oval or circular and has sharp margins. In the disc, a physiologic depression or cup is present centrally, with the retinal blood vessels emanating from it. The retinal tissues arise from the optic disc and line the inner surface of the vitreous chamber. The retinal vessels also enter the eye through the optic nerve, branching out through the retina and forming superior and inferior branches. The macula is the area of the retina responsible for central vision. The rest of the retina is responsible for peripheral vision. In the center of the macula is the most sensitive area, the fovea, which is avascular and surrounded by the superior and inferior vascular arcades (arches of blood vessels). Two important layers of the retina are the retinal pigment epithelium (RPE) and the sensory retina. A single layer of cells constitutes the RPE, and these cells have numerous functions, including the absorption of light. The sensory retina contains the photoreceptor cells: rods and cones. These are long, narrow cells shaped like rods or cones. The rods are mainly responsible for night vision or vision in low light, whereas the cones provide the best vision for bright light, color vision, and fine detail. Cones are distributed throughout the retina, with their greatest concentration in the fovea. Rods are absent in the fovea (Grossman & Porth, 2014).

Vision

Visual acuity depends on a healthy, functioning eyeball and an intact visual pathway (Fig. 48-5). This pathway includes the retina, optic nerve, optic chiasm, optic tracks, lateral geniculate bodies, optic radiations, and the visual cortex area of the brain. The pathway is an extension of the central nervous system (CNS). The funduscopic examination allows the only direct visualization of arteries, veins, and the CNS.

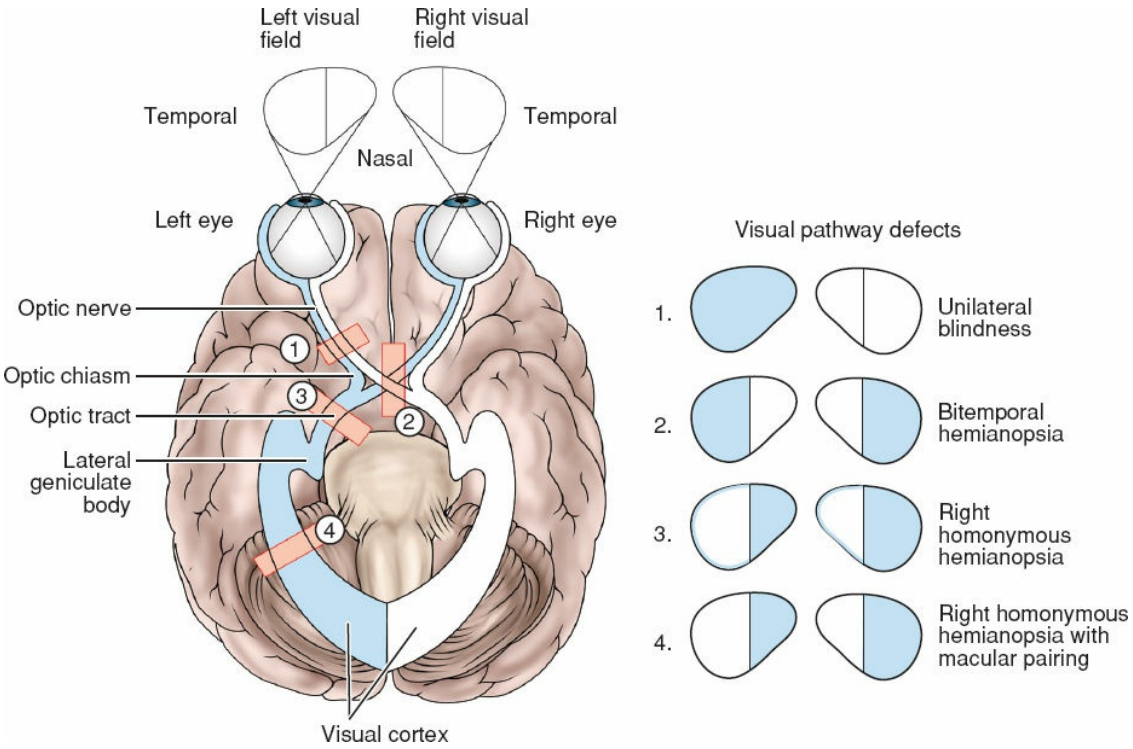

FIGURE 48-5 The visual pathway. (Redrawn from Fuller, J., & Schaller-Ayers, J. (2000). *Health assessment: A nursing approach* (3rd ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

The optic nerve is also known as the second cranial nerve (CN II). Its purpose is to transmit impulses from the retina to the occipital lobe of the brain. The optic nerve head, or optic disc, is the physiologic blind spot in each eye. The optic nerve leaves the eye and then meets the optic nerve from the other eye at the optic chiasm. The chiasm is the anatomic point at which the nasal fibers from the nasal retina of each eye cross to the opposite side of the brain. The nerve fibers from the temporal retina of each eye remain uncrossed. Fibers from the right half of each eye, which would be the left visual field, carry impulses to the right occipital lobe. Fibers from the left half of each eye, or the right visual field, carry impulses to the left occipital lobe. Beyond the chiasm, these fibers are known as the *optic tract.* The optic tract continues on to the lateral geniculate body, which leads to the optic radiations and then to the cortex of the occipital lobe of the brain.

Gerontologic Considerations

The eye undergoes many changes as the body ages. All cells formed throughout life are retained by the lens, which makes the cell structure of the lens susceptible to the degenerative effects of aging. The lens continues to grow throughout life, laying down fibers in concentric rings. As the body ages, the gel-like characteristics of the vitreous humor are gradually lost, and various cells and fibers cast shadows that the patient perceives as "floaters." The vitreous humor shrinks and shifts with age. Other age-related changes are summarized in Table 48-1.

TABLE 48-1 GERONTOLOGIC CONSIDERATIONS / Age-Related Changes in the Eye

Component	Structural Change	Functional Change	History and Physical Findings
Dry eye	Dysfunction of meibomian glands	Discomfort and pain with possible vision changes	Patient complains of vision changes, itching, burning, scratching sensation proportional to increased computer screen time.
Eyelids and lacrimal structures	Loss of skin elasticity and orbital fat, decreased muscle tone; wrinkles develop	Lid margins turn in, causing lashes to irritate cornea and conjunctiva (entropion); or lid margins may turn out, resulting in increased corneal exposure (ectropion)	Patient reports burning, foreign-body sensation, increased tearing (epiphora); injection, inflammation, and ulceration may occur.
Refractive changes; presbyopia	Loss of accommodative power in the lens with age	Reading materials must be held at increasing distance in order to focus.	Patient reports, "Arms are too short!;" need for increased light; reading glasses or bifocals needed.
Cataract	Opacities in the normally crystalline lens	Interference with the focus of a sharp image on the retina	Patient reports increased glare, decreased vision, changes in color values (blue and yellow especially affected).
Posterior vitreous detachment	Liquefaction and shrinkage of vitreous body	May lead to retinal tears and detachment	Patient reports light flashes, cobwebs, floaters.
Age-related macular degeneration (AMD)	Drusen (yellowish aging spots in the retina) appear and coalesce in the macula. Abnormal choroidal blood vessels may lead to formation of fibrotic disciform scars in the macula.	Central vision is affected; onset is more gradual in dry AMD, more rapid in wet AMD; distortion and loss of central vision may occur	Patient reports reading vision is affected; words may be missing letters, faded areas appear on the page, straight lines may appear wavy; drusen, pigmentary changes in retina; abnormal submacular choroidal vessels.
Low vision	Vision difficulties even with corrective lenses	Vision less than 20/40 with corrective lenses with the best correction possible	Patient reports progressive vision loss in near and far vision with light sensitivity and difficulty seeing at night.

Chader & Taylor, 2013.

ASSESSMENT

Health History

The nurse, through careful questioning, elicits the necessary information that can lead to the diagnosis of an ophthalmic condition.

Common Complaints

Common symptoms include changes in vision, pain or discomfort, and discharge. For each of the symptoms, the nurse asks:

- Are both eyes affected?
- Is this a recurrence of a previous condition?
- How has the patient self-treated?
- How is the patient affected by the symptom(s)?
- What makes the symptoms improve or worsen?
- What is the duration of the problem?

Changes in Vision

The nurse asks about changes in vision, including diminished visual acuity and blurred, distorted, or double vision. Changes in vision can be associated with problems such as myopia (distant objects appear blurred or nearsightedness), hyperopia (farsightedness), presbyopia (diminished ability to focus on near objects with age, a form of farsightedness), cataracts (opacity of the lens), glaucoma (abnormally high IOP that can damage the optic nerve), aging, diabetes, hypertension, cranial tumors, head trauma, or increased intracranial pressure (ICP).

Pain or Discomfort

The nurse inquires about the type of pain (sharp or dull) and whether it is worse when blinking. Pain while blinking might be present in superficial trauma events, such as corneal abrasions, corneal lacerations, or presence of a foreign body. Discomfort may include itching or a foreign-body sensation. This sensation of the presence of a foreign body is often present in diseases associated with conjunctival irritation. Conjunctival irritation may be found in conditions such as dry eye, bacterial or viral infections (pink eye), and irritation and allergic reactions (Bickley, 2013).

Discharge

It is important to note the color, consistency, and odor of any discharge. Eye discharge commonly results from inflammation or infection of the conjunctiva. Manifestations of other non-eye disorders may have eye discharge, such as erythema multiforme major (Stevens–Johnson syndrome), herpes zoster, and psoriasis vulgaris (refer to Chapter 52).

Past History

The nurse asks if this is a recurrence of a previous condition and notes the presence of any systemic diseases and medications used in their treatment. Medications for medical disorders cause thousands of eye disorders as side effects. For example, if long-term steroids are administered for arthritis, cataracts may develop. The nurse also inquires about concurrent ophthalmic conditions and any history of ophthalmic surgery.

Family History

The nurse asks whether any family members have had the same symptoms or condition, such as glaucoma, refraction disorders, and allergies.

Social History

In ophthalmology, the well-being of the patient physically, emotionally, financially, socially, and spiritually can be at risk when vision is threatened. The patient may equate a decrease in visual acuity with a loss of independence. The loss of a driver's license may force a patient to relocate or give up or change careers.

Major goals should include the preservation of vision and the prevention of further visual loss in patients who have already experienced some degree of loss. Lines of communication must be kept open so that the patient is comfortable exploring all treatment options to promote rehabilitation.

Physical Assessment

Visual Acuity Assessment

Following the health history, the patient's visual acuity is assessed. Most people are familiar with the standard Snellen chart. It is composed of a series of progressively smaller rows of letters and is used to test distance vision. The patient is positioned at the prescribed distance, usually 20 ft, from the chart and is asked to read the smallest line visible. The patient should wear distance correction (eyeglasses or contact lenses) if required, and each eye should be tested separately. A card should be provided to cover one eye to prevent the patient from trying to view the chart between the fingers. The fraction 20/20 is considered the standard of normal vision. The numerator denotes the distance between the patient and the chart, whereas the denominator quantifies the distance at which a normal eye can read the line of letters. A person whose vision is 20/200 can read print from 20 ft away that a person with 20/20 vision can read at 200 ft (Bickley, 2013). Most people can see the letters on the line designated as 20/20 from a distance of 20 ft.

If the patient cannot read the 20/20 line, he or she is given a pinhole occluder and asked to read again using the eye in question. The patient should be encouraged to read every letter possible. Specific visual acuities are then recorded for each eye. If the patient reads all five letters from the 20/20 line with the right eye and three letters of the 20/15 line with the left eye, the examiner records right eye 20/20, left eye 20/15-2. (Note: Medical abbreviations in the past used the terms OD and OS to represent right and left eyes, respectively; however, those abbreviations are no longer recommended because misinterpretation has resulted in harmful medication errors.)

If the patient cannot read the largest letter on the chart (the 20/200 line), the patient should be moved toward the chart or the chart moved toward the patient until the patient can identify the largest letter on the chart. If the patient can recognize only the letter E on the top line at a distance of 10 ft, the visual acuity would be recorded as 10/200. If the patient cannot see the letter E at any distance, the examiner should determine if the patient can count fingers. The examiner holds up a random number of fingers and asks the patient to count the number he or she sees. If the patient correctly identifies the number of fingers at 3 ft, the examiner would record "counts fingers/3 ft."

If the patient cannot count fingers, the examiner raises one hand up and down or moves it side to side and asks in which direction the hand is moving. This level of vision is known as hand motion. A patient who can perceive only light is described as having light perception. The vision of a patient who cannot perceive light is described as no light perception.

Near vision testing is performed to identify the need for reading glasses. Presbyopia is the term used for impaired near vision and is often found in middle-aged and older persons. A specially designed handheld card is held 14 in away from the patient's eyes, and the patient is asked to read the chart. Presbyopic people are commonly able to read the chart when it is held farther away.

External Eye Examination

After the visual acuity has been recorded, an external eye examination is performed. While standing directly in front of the patient, the nurse notes the position of the eyelids and alignment of the eyes. Commonly, the upper 2 mm of the iris are covered by the upper lid. The patient is examined for ptosis (drooping eyelid) and for lid retraction (too much of the eye exposed). Sometimes, the upper or lower lid turns out, referred to as *ectropion*, affecting closure. Additionally, the eyelid may invert; this is termed *entropion* and causes irritation of the eye. The lid margins and lashes should have no edema, erythema, or lesions. The examiner looks for scaling or crusting, and the sclera is inspected. A normal sclera is opaque and white (except as noted earlier). Lesions on the conjunctiva, discharge, and tearing or blinking are noted.

The pupils are inspected for size, shape, and symmetry. A normal pupil is black in color, round in shape, and symmetrical. Pupil size ranges between 2 and 8 mm depending on extremes of light. In room lighting, usual pupil size is 3 to 5 mm. The room should be darkened so that the pupils can be examined. The nurse checks pupillary response with a penlight to determine if the pupils are equally reactive and regular. The patient is asked to stare at a target; each eye is covered and uncovered quickly while the examiner looks for any shift in gaze. Recall that pupillary inequality of less than 1 mm may be detected in 20% to 40% of normal people (AAPOS, 2015). An artificial eye will have anisocoria. Other notable irregularity may be the result of trauma, previous surgery, or disease.

The pupillary response to light is determined by shining a bright light obliquely into each pupil. Pupils are assessed for *direct reaction*, in which the pupil tested with light constricts, and for *consensual reaction*, in which the pupil of the opposite eye also constricts. The nurse is aware that the pupil of a blind eye will not constrict; however, if a direct light is reflected on the "good eye," a consensual light reaction may be noted in the impaired eye. Obviously, there will be no reaction with a prosthetic eye.

The examiner also observes for nystagmus (i.e., oscillating movement of the eyeball). The extraocular movements (EOMs) of the eyes are tested by having the patient follow the examiner's finger, pencil, or a hand light through the six cardinal directions of gaze, a wide H pattern (i.e., up, down, right, left, and both diagonals). Normal EOMs should produce conjugate movements of the eyes in each direction. This is especially important when screening patients for ocular trauma or for neurologic disorders.

Diagnostic Evaluation

Direct Ophthalmoscopy

A direct ophthalmoscope is a handheld instrument enabling magnification of the cornea, lens, and retina. The patient is normally given mydriatic drops to dilate the pupils and assist in the examination of vision. Contraindications to the use of mydriatic drops include head injury or narrow-angle glaucoma. The patient is given a target to gaze at. The examiner holds the ophthalmoscope in the right hand and uses the right eye to examine the patient's right eye. The examiner switches to the left hand and left eye when examining the patient's left eye. During this examination, the room should be darkened, and the examiner should be about 15 in away from the patient and 15 degrees lateral to the patient's line of vision. The patient should be relaxed and able to keep both eyes open and steady.

The examiner shines the light on the patient's pupil to examine the fundus (Fig. 48-6). The fundus of the eye is the interior structure opposite the lens that includes the retina, optic disc, macula, fovea, and posterior pole. A normal orange glow is observed as light is applied to the pupil, known as the red reflex. Absence of the red reflex may indicate lens opacity, which is consistent with a cataract, detached retina, or retinoblastoma in children. When the fundus is examined, the vasculature comes into focus first. The examiner focuses on a large vessel and then follows it as it becomes larger in diameter, leading to the optic disc. The central depression in the disc is known as the *cup.* The normal cup is about one third the size of the disc. The size of the physiologic optic cup should be estimated and the disc margins described as sharp or blurred. The periphery of the retina is examined by having the patient shift his or her gaze. The last area of the fundus to be examined is the macula, because this area is the most sensitive to light.

FIGURE 48-6 Normal fundus.

The healthy fundus should be free of any lesions. The examiner looks for intraretinal hemorrhages, which may appear as red smudges or, if the patient has hypertension, may look somewhat flame-shaped. A yellow lipid may be present in the retina of patients with hypercholesterolemia or diabetes. The examiner looks for microaneurysms, which look like little red dots, and nevi. *Drusen* (small, hyaline, globular growths), commonly found in macular degeneration, appear as yellowish areas with indistinct edges. The examiner should sketch the fundus and document any abnormalities.

Amsler Grid

The Amsler grid is a test often used for patients with macular problems, such as macular degeneration. It consists of a geometric grid of identical squares with a central fixation point. The grid should be viewed by the patient wearing normal reading glasses. Each eye is tested separately. The patient is instructed to stare at the central fixation spot on the grid and report any distortion in the squares of the grid itself. Patients with macular problems typically note that some of the squares may look wavy, blurred, or distorted. Patients with age-related macular degeneration are commonly given these Amsler grids to take home. The patient is encouraged to check them frequently, as often as daily, to detect any early signs of distortion that may indicate the development of a neovascular choroidal membrane, an advanced stage of macular degeneration characterized by the growth of abnormal choroidal vessels.

Tonometry

Tonometry measures IOP by determining the amount of force or pressure necessary to indent or flatten (applanate) a small anterior area of the globe of the eye. High readings indicate high pressure; low readings indicate low pressure. The procedure is noninvasive and usually painless. A topical anesthetic eye drop is instilled into the lower conjunctival sac, and the tonometer is then used to measure the IOP. Air-puff tonometry may also be done but is not as reliable as a direct contact method (Farhood, 2013).

Two of the most commonly used tonometers are the applanation tonometer and the Tono-Pen. The applanation tonometer is generally used by the more skilled examiner. A drop of fluorescein dye and an anesthetic drop are instilled in the eye. The applanation tip is pressed against the cornea and the examiner, looking through the slit lamp, obtains the IOP reading. The Tono-Pen is a portable, battery-operated, handheld tonometer that is commonly used in many clinical settings. A disposable cover is placed over the tip of the instrument, and it is held against the anesthetized cornea for a few seconds. The tension reading is displayed in a liquid crystal display window.

Perimetry Testing

Perimetry testing evaluates the field of vision. A *visual field* is the area or extent of physical space visible to an eye in a given position. It has a three-dimensional contour representing areas of relative retinal sensitivity; visual acuity is sharpest at the very top of the field and declines progressively toward the periphery. It is most helpful in detecting central scotomas (blind areas in the visual field) in macular degeneration and the peripheral field defects in glaucoma and retinitis pigmentosa.

The two methods of perimetric testing are manual and automated perimetry. Manual perimetry involves the use of moving (kinetic) or stationary (static) stimuli or targets. An example of kinetic manual perimetry is the tangent screen. A tangent screen is a black felt material mounted on a wall that has a series of concentric circles bisected by straight lines emanating from the center. It tests the central 30 degrees of the visual field. Automated perimetry uses stationary targets, which are more difficult to detect than moving targets. In this test, a computer projects light randomly in different areas of a hollow dome while the patient looks through a telescopic opening and depresses a button whenever the light stimulus is detected. Automated perimetry is more accurate than manual perimetry.

Slit-Lamp Examination

The slit lamp is a binocular microscope mounted on a table. This instrument enables the user to examine the eye with magnification of 10 to 40 times the actual image. The illumination can be varied from a broad to a narrow beam of light for different parts of the eye. For example, by varying the width and intensity of the light, the anterior chamber can be examined for signs of inflammation. Cataracts may be evaluated by changing the angle of the light. When a handheld lens, such as a three-mirror lens, is used with the slit lamp, the angle of the anterior chamber may be examined, as may the ocular fundus.

Color Vision Testing

The ability to differentiate colors has a dramatic effect on the activities of daily living. For example, the inability to differentiate between red and green can compromise traffic safety. Some careers (e.g., commercial art, color photography, airline pilot, electrician) may be closed to people with significant color deficiencies. Color discrimination allows visualization of a broad spectrum of color. The photoreceptor cells responsible for color vision are the cones, and the greatest area of color sensitivity is in the macula, the area of densest cone concentration. A defect or deficiency in the cones (red, blue, or green) will result in abnormal color vision. There are three basic types of color blindness: red–green, which is the most common deficiency; blue; and total color blindness, also known as *achromatopsia*.

A screening test, such as the polychromatic plates, can be used to establish whether a person's color vision is within normal range. Color vision deficits can be inherited. For example, red–green color deficiencies are inherited in an X-linked manner, affecting approximately 8% of men and 0.5% of women. Acquired color vision losses may be caused by chronic illness (e.g., diabetes, macular degeneration, glaucoma), medications (e.g., digitalis), trauma, industrial toxins, or aging (e.g., cataracts). A simple test, such as asking a patient if the red top on a bottle of eye drops appears redder to one eye than the other, can be an effective tool. A difference in the perception of the intensity of the color red between the two eyes can be a symptom of a neurologic problem and may provide information about the location of the lesion.

Ultrasonography

Lesions in the globe or the orbit may not be directly visible and are evaluated by ultrasonography. Ultrasonography is a very valuable diagnostic technique, especially when

the view of the retina is obscured by opaque media, such as cataract or hemorrhage. Ultrasonography can be used to identify orbital tumors, retinal detachment, and changes in tissue composition.

Special techniques can also be used to calculate the power for an intraocular lens implant and to obtain more anatomic information, showing cross-sectional images. Vitreous hemorrhage, retinal detachment, and tumors can be evaluated with minimal discomfort for the patient. Three-dimensional images can be created, and the entire ultrasound examination can be recorded for later use.

Fluorescein Angiography

Fluorescein angiography evaluates clinically significant macular edema, documents macular capillary nonperfusion, and identifies retinal and choroidal neovascularization (growth of abnormal new blood vessels) in age-related macular degeneration. It is an invasive procedure in which fluorescein dye is injected, usually into an antecubital vein. Within 10 to 15 seconds, this dye can be seen coursing through the retinal vessels. Over a 10-minute period, serial black-and-white photographs are taken of the retinal vasculature. The dye may impart a gold tone to the skin of some patients, and urine may turn deep yellow or orange. This discoloration usually disappears in 24 hours.

Nursing Alert
When the nurse administers eye medications, pressure is applied to the inner canthus while placing the medication on the conjunctival sac to prevent systemic absorption.

THE EAR

The ear is a sensory organ with dual functions—hearing and balance. The sense of hearing is essential for normal development and maintenance of speech, as well as for the ability to communicate with others. Balance, or equilibrium, is essential for maintaining body movement, position, and coordination.

ANATOMIC AND PHYSIOLOGIC OVERVIEW

External Ear

The external ear includes the auricle (pinna) and the external auditory canal (Fig. 48-7). The external ear is separated from the middle ear by a disc-like structure called the tympanic membrane (eardrum). The auricle, attached to the side of the head by skin, is composed mainly of cartilage, except for the fat and subcutaneous tissue in the earlobe. The auricle collects the sound waves and directs vibrations into the external auditory canal.

The external auditory canal is approximately 2.5 cm long. The external auditory canal ends at the tympanic membrane. The skin of the canal contains hair, sebaceous glands, and ceruminous glands, which secrete a brown, waxlike substance called cerumen (earwax). The ear's self-cleaning mechanism moves old skin cells and cerumen to the outer part of the ear.

Middle Ear

The middle ear, an air-filled cavity, includes the tympanic membrane laterally and the otic capsule medially. The middle ear is connected by the eustachian tube to the nasopharynx and is continuous with air-filled cells in the adjacent mastoid portion of the temporal bone. Normally, the eustachian tube is closed, but it opens when the person performs a Valsalva maneuver, yawns, or swallows. It drains normal and abnormal secretions of the middle ear and equalizes pressure in the middle ear with that of the atmosphere.

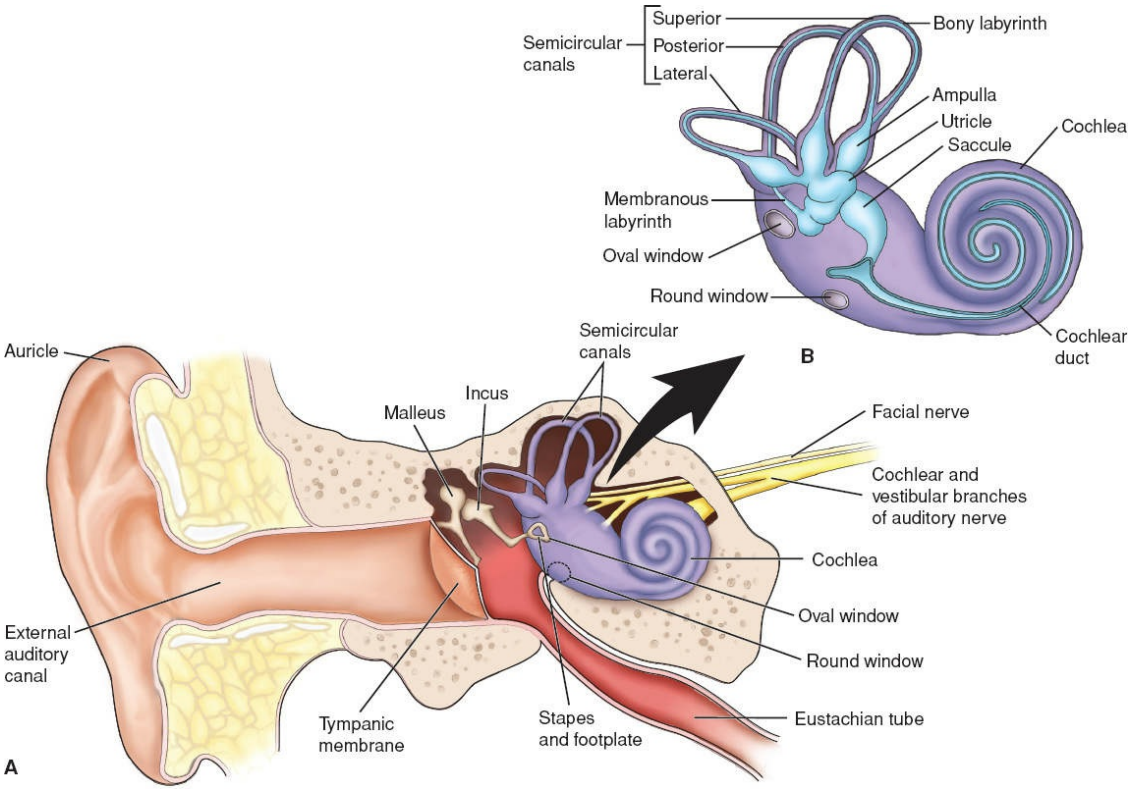

Figure 48-7 A. Anatomy of the ear. B. The inner ear.

The tympanic membrane (eardrum), about 1 cm in diameter and very thin, is normally pearly gray and translucent. The tympanic membrane protects the middle ear and conducts sound vibrations from the external canal to the ossicles. Figure 48-8 illustrates the distinguishing landmarks of the tympanic membrane.

The middle ear contains the three smallest bones (the ossicles) of the body: the malleus, the incus, and the stapes. The ossicles, which are held in place by joints, muscles, and ligaments, assist in the transmission of sound. Two small fenestrae (oval and round windows), located in the medial wall of the middle ear, separate the middle ear from the inner ear. The footplate of the stapes sits in the oval window, secured by a fibrous annulus (ring-shaped structure). The footplate transmits sound to the inner ear. The round window, covered by a thin membrane, provides an exit for sound vibrations (see Fig. 48-7).

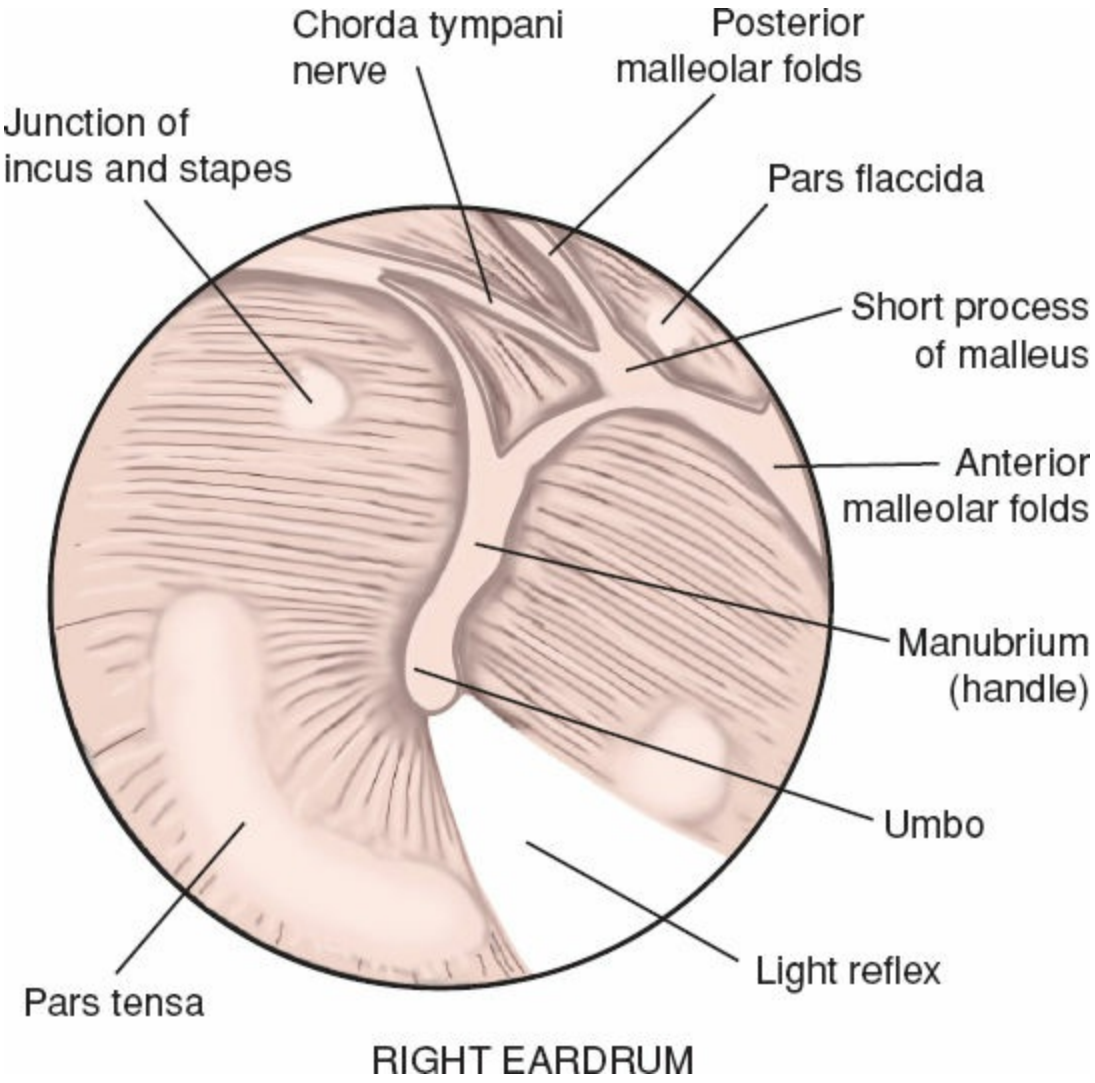

FIGURE 48-8 The tympanic membrane.

TABLE 48-2 GERONTOLOGIC CONSIDERATIONS / Age-Related Changes in the Ear

Component	Structural Change	Functional Change	History and Physical Findings
Atrophy of the external ears	Pinna loses flexibility	Thinning and drying of ear canal	Pinna longer and thinner with dry cerumen in external ear canal
Hardening of cerumen	Dryer, thicker cerumen	Earwax accumulates	Visible earwax and conductive hearing impairment
Thickening of the eardrum	Stiffness of eardrum	Impaired transmission of sound	Mild hearing impairment
Change in vestibulospinal reflex	Loss of vestibular afferents and neurons	Progressive imbalance and increased falls	Balance and gait tests provoke symptoms of dizziness and postural instability
Degeneration of organ of Corti (presbycusis)	Loss of cochlear pathway neurons, atrophy of vascular cochlear tissue	Loss of ability to discriminate words or comprehend conversations	Decreased ability to hear high frequencies or to interpret consonant sounds

Inner Ear

The inner ear is housed deep within the temporal bone. The organs for hearing (cochlea) and balance (semicircular canals), as well as CN VII (facial nerve) and CN VIII (vestibulocochlear nerve), are all part of this complex anatomy (see Fig. 48-7). The three semicircular canals—posterior, superior, and lateral, which lie at 90-degree angles to one another—contain sensory receptor organs, arranged to detect rotational movement. These receptor end organs are stimulated by changes in the rate or direction of a person's movement.

The organ of Corti, also called the *end organ for hearing,* transforms mechanical energy into neural activity and separates sounds into different frequencies. This electrochemical impulse travels through the acoustic nerve to the temporal cortex of the brain to be interpreted as meaningful sound. In the internal auditory canal, the cochlear (acoustic) nerve joins the vestibular nerve to become the vestibulocochlear nerve (CN VIII).

Hearing

Hearing is conducted over two pathways: air and bone (Fig. 48-9). Sounds transmitted by air conduction travel over the air-filled external and middle ear through the vibration of the tympanic membrane and ossicles. Sounds transmitted by bone conduction travel directly through bone to the inner ear, bypassing the tympanic membrane and ossicles. Normally, air conduction is the more efficient pathway. However, a defect in the tympanic membrane or interruption of the ossicular chain disrupts normal air conduction, which results in a conductive hearing loss.

Balance and Equilibrium

Body balance is maintained by the cooperation of the muscles and joints of the body (proprioceptive system), the eyes (visual system), and the labyrinth (vestibular system). These areas send their information about equilibrium, or balance, to the brain (cerebellar system) for coordination and perception in the cerebral cortex. The vestibular apparatus of the inner ear provides feedback regarding the movements and the position of the head and body in space.

Gerontologic Considerations

Hearing loss is a common finding in the geriatric population, with a full third of those over 60 years of age demonstrating detectable hearing deficits (Fioretti, Poli, Varakliotis, & Eibenstein, 2014). The term *presbycusis* refers to hearing loss associated with degenerative changes. Table 48-2 summarizes age-related changes.

ASSESSMENT

Assessment of the ear includes a health history and physical assessment.

Health History

The nurse should include questions about hearing loss, hearing aids, medications, itching, ear drainage, tinnitus (sensation of noise such as ringing or roaring), vertigo (sensation of motion), ear pain, and environmental exposure to loud or continuous noises in the health history.

Common Complaints

The nurse needs to explore common ear complaints, such as changes in hearing acuity, earache, drainage, and tinnitus. A common complaint of ear pain is associated with a variety of disorders including cerumen impaction, acute external otitis, acute mastoiditis, acute otitis media, and foreign bodies. Impaction of cerumen can cause otalgia (a sensation of fullness or pain in the ear), with or without a hearing loss. If, on manipulation of the auricle, the patient complains of pain, the nurse suspects the etiology of the pain is acute external otitis. Tenderness on palpation in the area of the mastoid may indicate acute mastoiditis or inflammation of the posterior auricular node. Acute otitis media, an acute infection of the middle ear, can occur at any age, although it is seen most commonly in children. Symptoms vary with the severity of the infection. In adults, complaints of pain are usually unilateral, and the pain is relieved after spontaneous perforation or therapeutic incision of the tympanic membrane.

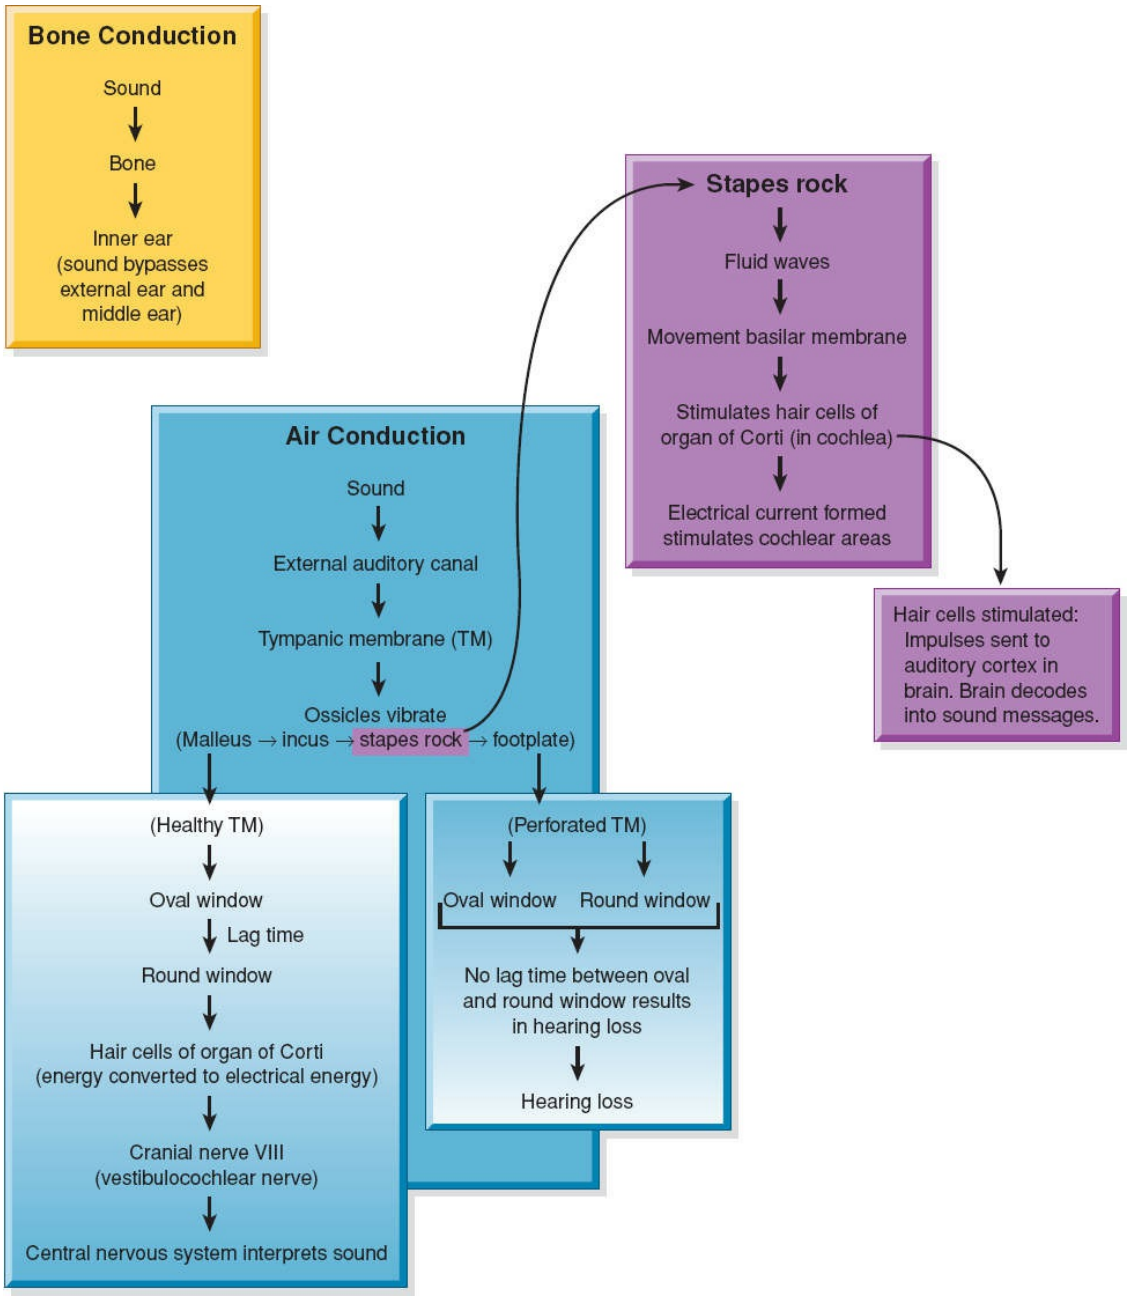

FIGURE 48-9 Bone conduction compared to air conduction.

Tinnitus is another common symptom of an underlying disorder of the ear that is associated with hearing impairment and loss, ototoxic substances (see Chapter 50), and a variety of hearing disorders (otosclerosis, Ménière disease, acoustic neuroma) and systemic disorders (thyroid disease, neurologic disorders). Tinnitus may range from mild to severe and is frequently described as a roaring, buzzing, or hissing sound in one or both ears. Refer to Chapter 50 for further details.

Past History

A history of infections affecting the ear may indicate a hearing loss caused by diseases of the tympanic membranes. Medications can alter auditory function so each agent should be evaluated for potential effects on ear disorders. Some common ototoxic medications

include antibiotics, diuretics, and nonsteroidal anti-inflammatory agents (NSAIDs). Surgical approaches that may have been performed to improve a patient's auditory function must be explored. If used, it is necessary to evaluate the patient's experience with hearing aids in the past. The effectiveness of previous therapies will determine the patient's decisions on ear interventions.

Exposure to loud noises should also be explored. Other related conditions associated with hearing loss include head trauma, brain tumors, multiple sclerosis, and vascular disorders, such as hypertension and arteriosclerosis.

Family History

Many cases of hearing loss are inherited; hereditary disorders of the ear include Hallgren disease, Alport syndrome, Refsum disease, and Treacher Collins disease. Some of these disorders are associated with other organ disorders, such as kidney disease.

Social History

The presence of social problems must be explored with the patient with a hearing loss. Patients with decreased hearing may withdraw from situations in which communication skills are needed. They may become depressed and unable to continue in their chosen professions. Explore the patient's ability to work and engage in social interactions. Data regarding the age at onset and severity of hearing loss will help the nurse understand the personal impact of hearing loss.

Physical Assessment

Physical assessment includes inspection and palpation of the external ear, inspection of the internal ear, and hearing evaluation.

Inspection and Palpation of the External Ear

Inspection of the external ear is a simple procedure but often overlooked. The external ear is examined by inspection and direct palpation; the auricle and surrounding tissues should be inspected for deformities, lesions, and discharge, as well as size, symmetry, and angle of attachment to the head. If manipulation of the auricle is painful, acute external otitis is suspected. Tenderness on palpation in the area of the mastoid may indicate acute mastoiditis or inflammation of the posterior auricular node. Because the ear is exposed to the sunlight, the nurse should examine the shell of the ear for lesions. Any lesion lasting over 2 weeks should be referred to a skin care specialist for evaluation of skin cancer. The nurse uses the opportunity to inform patients to apply sunscreen to exposed skin including the ears.

Inspection of the Internal Ear

The tympanic membrane is inspected with an otoscope and indirect palpation with a pneumatic otoscope. To examine the external auditory canal and tympanic membrane, the otoscope should be held in the examiner's right hand, in a pencil-hold position, with the examiner's hand braced against the patient's face (Fig. 48-10). Using the opposite hand, the auricle is grasped and gently pulled back to straighten the canal in the adult. If the canal is not straightened with this technique, the tympanic membrane is more difficult to visualize because the canal obstructs the view. The speculum is slowly inserted into the ear canal, with the examiner's eye held close to the magnifying lens of the otoscope to visualize the canal and tympanic membrane. The external auditory canal is examined for discharge, inflammation, or a foreign body.

The position and color of the membrane and any unusual markings or deviations from normal are documented (see Fig. 48-8). If the tympanic membrane cannot be visualized because of cerumen, the cerumen may be removed by gently irrigating the external canal with warm water (unless contraindicated). If adherent cerumen is present, a small amount of mineral oil or over-the-counter cerumen softener may be instilled within the ear canal, and the patient is instructed to return for subsequent removal of the cerumen and inspection of the ear.

Evaluation of Gross Auditory Acuity

A general estimate of hearing can be made by assessing the patient's ability to hear a whispered phrase or a ticking watch, testing one ear at a time. The Weber and Rinne tests may be used to distinguish conductive loss from sensorineural loss when hearing is impaired.

Whisper Test

To exclude one ear from the testing, the examiner covers the untested ear with the palm of the hand. Then the examiner whispers softly from a distance of 1 or 2 ft from the unoccluded ear and out of the patient's sight. The patient with normal hearing acuity can correctly repeat what was whispered.

Weber Test

The Weber test uses bone conduction to test lateralization of sound. A tuning fork (ideally, 512 Hz), set in motion, is placed on the patient's head or forehead (Fig. 48-11). A person with normal hearing hears the sound equally in both ears or describes the sound as centered in the middle of the head. The Weber test is useful for detecting unilateral hearing loss (Table 48-3).

Rinne Test

In the Rinne test, the examiner shifts the stem of a vibrating tuning fork between two positions: against the mastoid bone (for bone conduction), and, when the sound is no longer audible, then the position is shifted 2 in from the opening of the ear canal (for air conduction). As the position changes, the patient is asked to indicate which tone is louder or when the tone is no longer audible. The Rinne test is useful for distinguishing between conductive and sensorineural hearing loss (Table 48-3).

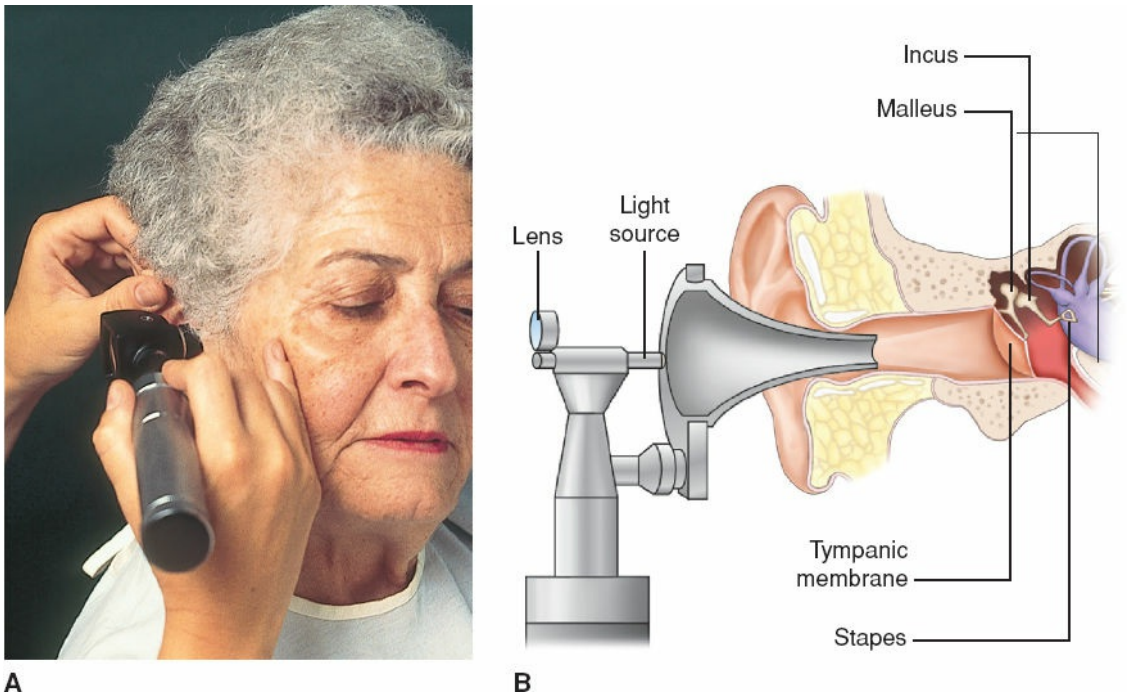

FIGURE 48-10 Proper technique for examining the ear. A. Hold the otoscope in the right or left hand, in a "pencil-hold" position. B. Steady the hand against the patient's head to avoid inserting the otoscope too far into the external canal.

Diagnostic Evaluation

Many diagnostic procedures are available to measure the auditory and vestibular systems indirectly. These tests are usually performed by an audiologist whose clinical competence is certified by the American Speech-Language-Hearing Association.

Audiometry

In detecting hearing loss, audiometry is the single most important diagnostic instrument. Audiometric testing is of two kinds: *pure-tone audiometry*, in which the sound stimulus consists of a pure or musical tone (the louder the tone before the patient perceives it, the greater the hearing loss), and *speech audiometry*, in which the spoken word is used to determine the ability to hear and discriminate sounds and words. Responses are plotted on a graph known as an *audiogram*, which differentiates conductive from sensorineural hearing loss.

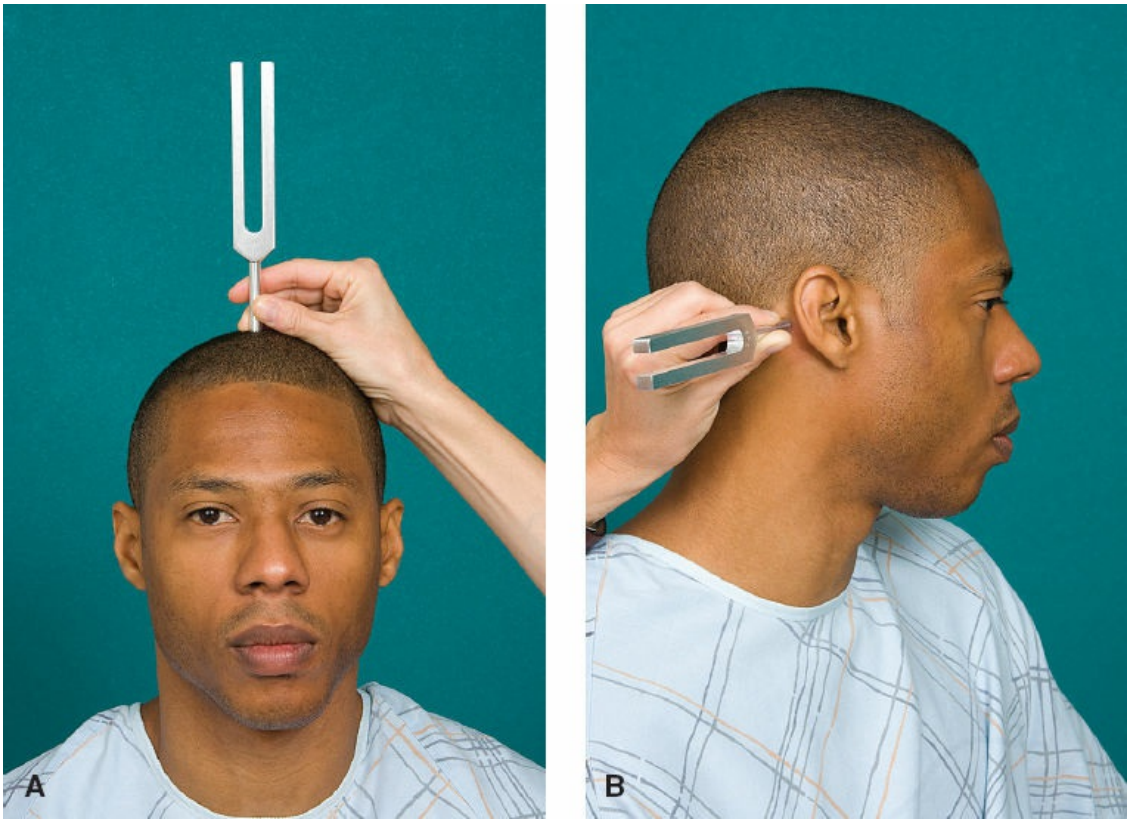

FIGURE 48-11 A. The Weber test assesses bone conduction of sound. B. The Rinne test assesses both air and bone conduction of sound.

TABLE 48-3 Comparison of Weber and Rinne Tests

Hearing Status	Weber	Rinne
Normal hearing	Sound is heard equally in both ears.	Air conduction is audible longer than bone conduction.
Conductive hearing loss	Sound heard best in affected ear (hearing loss).	Sound heard as long or longer in affected ear (hearing loss).
Sensorineural hearing loss	Sound heard best in normal hearing ear.	Air conduction is audible longer than bone conduction in affected ear.

When evaluating hearing, three characteristics are important: frequency, pitch, and intensity. *Frequency* refers to the number of sound waves emanating from a source per second, measured as cycles per second, or Hertz (Hz). The normal human ear perceives sounds ranging in frequency from 20 to 20,000 Hz. *Pitch* is the term used to describe frequency; a tone with 100 Hz is considered of low pitch, and a tone of 10,000 Hz is considered of high pitch. The unit for measuring loudness (*intensity* of sound) is the decibel (dB), the pressure exerted by sound. Hearing loss is measured in decibels, a logarithmic function of intensity that is not easily converted into a percentage. The critical level of loudness is approximately 30 dB. The shuffling of papers in quiet surroundings is about 15 dB. Table 48-4 classifies hearing loss based on decibel level.

Tympanogram

A tympanogram or impedance audiometry is used to evaluate the tympanic membrane and status of the middle ear. This test measures middle ear muscle reflex to sound stimulation (movement of the tympanic membrane) and the compliance of the tympanic membrane by changing the air pressure in the sealed ear canal. Compliance is impaired with middle ear disease, such as fluid accumulation in the middle ear or rupture of the tympanic membrane.

TABLE 48-4 Severity of Hearing Loss

Loss in Decibels	Interpretation
0–15	Normal hearing
>15–25	Slight hearing loss
>25–40	Mild hearing loss
>40–55	Moderate hearing loss
>55–70	Moderate to severe hearing loss
>70–90	Severe hearing loss
>90	Profound hearing loss

Auditory Brainstem Response

The auditory brainstem response is a detectable electrical potential from CN VIII and the ascending auditory pathways of the brainstem in response to sound stimulation. Electrodes are placed on the patient's forehead. Acoustic stimuli (e.g., clicks) are made in the ear. The resulting electrophysiologic measurements can determine at which decibel level a patient hears and whether there are any impairments along the nerve pathways (e.g., tumor on CN VIII).

Electronystagmography

Electronystagmography is the measurement and graphic recording of the changes in electrical potentials created by eye movements during spontaneous, positional, or calorically evoked nystagmus. It is also used to assess the oculomotor and vestibular systems and their corresponding interaction. It helps diagnose conditions such as Ménière disease and tumors of the internal auditory canal or posterior fossa. Vestibular suppressants, such as sedatives, tranquilizers, antihistamines, and alcohol, are withheld for 24 hours before testing. Prior to the test, the procedure is explained to the patient.

Platform Posturography

Platform posturography is used to investigate postural control capabilities, such as vertigo. It can be used to evaluate if a person's vertigo is becoming worse or to evaluate the person's response to treatment. The integration of visual, vestibular, and proprioceptive cues (i.e., sensory integration) with motor response output and coordination of the lower limbs is tested. The patient stands on a platform, surrounded by a screen, and different conditions, such as a moving platform with a moving screen or a stationary platform with a moving screen, are presented. The responses from the patient on six different conditions are measured and indicate which of the anatomic systems may be impaired. Preparation for the testing is the same as for electronystagmography.

Sinusoidal Harmonic Acceleration

Sinusoidal harmonic acceleration, or a rotary chair, is used to assess the vestibulo-ocular system by analyzing compensatory eye movements in response to the clockwise and counterclockwise rotation of the chair. Although such testing cannot identify the side of the lesion in unilateral disease, it helps identify disease (e.g., Ménière disease and tumors of the auditory canal) and evaluate the course of recovery. The same patient preparation is required as for electronystagmography.

Middle Ear Endoscopy

With endoscopes of very small diameters and acute angles, the ear can be examined by an endoscopist specializing in otolaryngology. Middle ear endoscopy is performed safely and effectively as an office procedure to evaluate suspected perilymphatic fistula, new-onset conductive hearing loss, the anatomy of the round window before transtympanic treatment of Ménière disease, and the tympanic cavity before ear surgery to treat chronic middle ear and mastoid infections.

The tympanic membrane is anesthetized topically for about 10 minutes before the procedure. Then, the external auditory canal is irrigated with sterile normal saline solution.

With the aid of a microscope, a tympanotomy is created with a laser beam or a myringotomy knife so that the endoscope can be inserted into the middle ear cavity. Video and photo documentation can be accomplished through the scope.

CHAPTER REVIEW

Critical Thinking Exercises

1. An 82-year-old woman who lives at home with her daughter is scheduled for a posturography. She cooks for the family and frequently cooks for and visits older ill friends in the local extended-care facilities. She is very active and walks on her treadmill three times per week. She plans on her usual work at evening church services after her posturography. What should you instruct her regarding preprocedure planning for her examination?

2. A 24-year-old woman was transported to the emergency department after sustaining a corneal irritation from chemical exposure. Following the health history, the patient's visual acuity was assessed. Visual acuity test was to be done by Snellen chart. The patient was positioned 20 ft from the chart and was asked to read the smallest line visible. She was not able to see the chart with the affected eye. She started crying and reported that she used to be able to see perfectly from both eyes. What further assessment is needed at this time? How would you explain this finding to the patient?

NCLEX-Style Review Questions

1. What information from a health history collected from a 70-year-old should be further evaluated as a sign of presbycusis?
   a. "I haven't been going out with friends."
   b. "I am a retired truck driver."
   c. "My hobby is caring for livestock."
   d. "I watch television in the evening with my wife."

2. The nurse assesses a patient who is complaining of an earache. What assessment finding would the nurse expect?
   a. Blue tympanic membrane
   b. Cerumen buildup
   c. Mastoid tenderness
   d. Tympanic retraction

3. A 45-year-old man reports that he is experiencing trouble with close vision that is becoming progressively worse. The nurse explains the reason for the problem. What statement shows that the patient understands the explanation?
   a. "This is a sign that I might have hypertension."
   b. "I might be having early signs of presbyopia."

c. "So you think I might have had some kind of eye trauma?"
d. "Which one of my medications caused this?"

4. A patient arrives at a minor emergency center complaining of eye pain after an animal scratch incident. What would the nurse expect to find during the assessment?
   a. An injury to the opposite eye
   b. Pain while blinking
   c. Bleeding from the tear duct
   d. Change in distance vision

5. A patient is being evaluated for conductive versus sensorineural hearing loss. The nurse is performing the Rinne test. What result would the nurse expect to see if the patient has sensorineural hearing loss?
   a. Sound is heard equally in both ears.
   b. Air conduction is equal to bone conduction in the affected ear.
   c. Air conduction is longer than bone conduction in the affected ear.
   d. Air conduction is shorter than bone conduction in the affected ear.

CHAPTER 49

Nursing Management: Patients with Eye and Vision Disorders

Carolynn Spera Bruno

Learning Objectives

After reading this chapter, you will be able to:

1. Define low vision and blindness, and differentiate between functional and visual impairment.
2. List and describe assessment and management strategies for low vision.
3. Demonstrate orientation and mobility techniques for patients with low vision in a hospital setting.
4. Discuss assessment and management of glaucoma.
5. Discuss assessment and management of cataracts.
6. Discuss assessment and management of retinal disorders.
7. Discuss assessment and management of eye trauma.
8. Discuss assessment and management of infectious and inflammatory eye disorders.
9. Demonstrate the instillation of eye drops and ointment.
10. Discuss the postoperative management and discharge instructions of patients undergoing ocular surgery.

Patients admitted to medical surgical units may have acute conditions affecting the eye or comorbidities associated with visual impairment. Many of the leading causes of visual impairment are associated with aging (e.g., cataracts, glaucoma, macular degeneration), and two thirds of the population with impaired vision are older than 65 years of age. Younger people are also at risk for eye disorders, particularly traumatic injuries. Understanding the prevention, treatment, and consequences of eye disorders, nurses in all settings assess visual acuity in those at risk (e.g., patients who are elderly, those with diabetes or AIDS), refer patients to eye care specialists as appropriate, implement measures to prevent further visual loss, and help patients adapt to impaired vision.

IMPAIRED VISION

More than one million Americans are legally blind and 12 million are visually impaired (Centers for Disease Control and Prevention [CDC], 2017). Chief causes of visual impairment or blindness include diabetic retinopathy and age-related eye diseases (i.e., cataracts, macular degeneration, and glaucoma). In 2013, the World Health Organization (WHO) stated in their Global Action Plan 2014–2019 that 80% of all causes of visual impairment can be prevented. Given that the population rates among the aged demographic are increasing dramatically along with the recognition that many eye disorders often are undiagnosed, it is essential for nurses to screen for visual impairment and provide education and appropriate resources to their patients.

Refractive Errors, Low Vision, and Blindness

In refractive errors, vision is impaired because a shortened or elongated eyeball prevents light rays from focusing sharply on the retina. Blurred vision from refractive error can be corrected with eyeglasses or contact lenses. The appropriate eyeglass or contact lens is determined by refraction. Ophthalmic refraction consists of placing various types of lenses in front of the patient's eyes to determine which lens best improves the patient's vision.

The depth of the eyeball is important in determining refractive error. Patients for whom the visual image focuses precisely on the macula and who do not need eyeglasses or contact lenses are said to have emmetropia (normal vision). People who have myopia are said to be nearsighted. They have deeper eyeballs; thus, the distant visual image focuses in front of, or short of, the retina. People who are myopic experience blurred distance vision. When people have a shorter depth to their eyes, the visual image focuses beyond the retina; the eyes are shallower and are called *hyperopic.* People with hyperopia are farsighted. These patients experience near vision blurriness, whereas their distance vision is excellent.

Another important cause of refractive error is astigmatism, an irregularity in the curve of the cornea. Because astigmatism causes a distortion of the visual image, acuity of both distance and near vision can be decreased. Hard or soft toric contact lenses may be used to correct astigmatic errors, in place of eyeglasses.

Ophthalmology has entered the era of customized vision correction, in its desire to achieve "super-normal vision." A new method of measuring refractive error is called *wavefront technology.* The most promising application for this technology is wavefront-guided refractive surgery.

Low vision is a general term describing visual impairment that requires patients to use devices and strategies in addition to corrective lenses to perform visual tasks. Low vision is defined as a best corrected visual acuity (BCVA) of 20/70 to 20/200.

Blindness is defined as a BCVA that can range from 20/400 to no light perception (NLP). The clinical definition of absolute blindness is the absence of light perception. Legal blindness is a condition of impaired vision in which a person has a BCVA that does not exceed 20/200 in the better eye or whose widest visual field diameter is 20 degrees or less. This definition neither equates with functional ability nor classifies the degrees of visual impairment. Legal blindness ranges from an inability to perceive light to having some vision remaining. A person who meets the criteria for legal blindness may be eligible for government financial assistance, such as social security disability benefits. Nurses may make social service referral for follow-up.

Impaired vision is often accompanied by difficulty in performing functional activities. People with visual acuity of 20/80 to 20/100 and a visual field restriction of 60 degrees to greater than 20 degrees can read at a nearly normal level with optical aids. Their visual orientation is near normal but requires increased scanning of the environment (i.e., systematic use of head and eye movements). In patients with a visual acuity range of 20/200 to 20/400 and a visual field restriction of 20 degrees to greater than 10 degrees, these persons can read slowly with optical aids. In this setting, visual orientation is slow necessitating constant scanning of the environment. People in this category may have the ability to negotiate their environment without auxiliary aids. This ability is termed "travel vision." People with hand motion vision or no vision may benefit from the use of mobility

devices (e.g., cane, guide dog) and should be encouraged to learn Braille and to use computer aids.

The most common causes of blindness and visual impairment among adults 40 years of age or older are diabetic retinopathy (refer to Chapter 30), macular degeneration, glaucoma, and cataracts (discussed later in this chapter) (Baloh & Jen, 2016). Macular degeneration is more prevalent among Caucasians, whereas glaucoma is more prevalent among African Americans. Age-related changes in the eye are discussed in Chapter 48.

Clinical Manifestations and Assessment

The assessment of low vision includes a thorough history and the examination of distance and near visual acuity, visual field, contrast sensitivity, glare, color perception, and refraction (see Chapter 48). Specially designed, low-vision visual acuity charts are used to evaluate patients.

During history taking, the underlying cause, course, and duration of the patient's visual impairment are identified. Patients with retinitis pigmentosa, for example, have a genetic abnormality. Patients with diabetic macular edema typically experience fluctuating visual acuity. Deterioration of the central portion of the retina causes macular degeneration and central acuity problems. Risk factors of age-related macular degeneration (AMD) include being 50+ years of age, smoking, and family history, and there is a higher incidence among Caucasians than African Americans or Hispanics/Latinos (National Eye Institute [NEI], 2015). Patients with macular degeneration may experience scotomas (partial or complete visual field cuts surrounded by intact visual fields). Central acuity problems cause difficulty in performing activities that require seeing fine details, such as reading. People with peripheral field defects have more difficulties with mobility. The patient's customary activities of daily living (ADLs), medication regimen, habits (e.g., smoking), acceptance of the physical limitations brought about by the visual impairment, and realistic expectations of low-vision aids must be identified and included in the plan of care, including provision of guidelines for safety and referrals to social services.

Contrast-sensitivity testing measures visual acuity in different degrees of contrast. The initial test may take the form of simply turning on the lights while testing the distance acuity. If the patient can read better with the lights on, the patient can benefit from magnification. Glare testing enables the examiner to obtain a more realistic evaluation of the patient's ability to function in his or her environment. Glare can reduce a person's ability to see, especially in patients with cataracts. Devices that test glare are calibrated to imitate certain objects that create glare, such as a car's headlights at night.

Medical Management

Managing patients with low vision involves magnification and image enhancement through the use of low-vision aids and strategies, and referrals to social services and community agencies serving those with visual impairment. Since macular degeneration is irreversible, goals are to optimize the patient's remaining vision, whether central or peripheral, and assist the patient to perform customary activities. Low-vision aids include optical and nonoptical devices (Table 49-1). The optical devices include convex lens aids, such as magnifiers and spectacles; telescopic devices; antireflective lenses that diminish glare; and electronic reading systems, such as closed-circuit television and computers with large print. Continuing advances in computer software provide very useful products for patients with low vision. Scanners and the appropriate software enable the user to scan printed material and have it read by computer voice or to enlarge the print for reading. Magnifiers can be handheld or attached to a stand with or without illumination. Telescopic devices can be spectacle telescopes or clip-on or handheld loupes.

TABLE 49-1 Activities Affected by Visual Impairment with Suggestions for Low-Vision Aids

Activity	Optical Aids	Nonoptical Aids
Shopping	Hand magnifier	Lighting, color cues
Fixing a snack	Spectacle magnifier	Color cues, consistent storage plan
Eating out	Hand magnifier	Flashlight, portable lamp
Identifying money	Spectacle, spectacle-mounted or hand magnifier	Arrange paper money in wallet compartments or fold banknotes of different denominations differently
Reading print	Spectacle, spectacle-mounted, dome, hand, or stand magnifier Closed-circuit television	Lighting, high-contrast print, large print, reading slit stand magnifier, electronic books
Writing	Hand magnifier	Lighting, bold-tip pen, black ink
Using a telephone	Telescope hand magnifier	Large print dial or touch tone buttons, hand-printed directory
Crossing streets	Telescope	Cane, ask directions
Finding taxis and bus signs	Telescope	Ask for assistance
Reading medication labels	Hand magnifier	Color codes, large print
Reading stove dials	Hand magnifier	Color codes, raised dots
Adjusting the thermostat	Hand magnifier	Enlarged print model

Adapted from Riordan-Eva, P., & Cunningham, E. (Eds.). (2012). *Vaughan & Asbury's general ophthalmology* (18th ed.). New York: McGraw-Hill Companies.

The Internet continues to expand, and a telephone system has been developed that allows access to the Internet and e-mail using voice commands (Box 49-1).

Referrals to community agencies may be necessary for patients with low vision who live

alone and cannot self-administer their medications. Community agencies, such as the Lighthouse National Center for Vision and Aging, offer services to patients with low vision that include training in independent living skills, the provision of occupational and recreational activities, and a wide variety of assistive devices for vision enhancement and orientation and mobility.

BOX 49-1 Web Access for the Visually Impaired

People with impaired vision need not be left behind in the computer age. Various technologies are available. A list of general equipment needs follows:

- *Computer:* Software specifically developed for people with visual impairment
- *Internet service provider* (e.g., AOL, Netscape, Earthlink, Comcast)
- *Screen-reader program:* Converts text on the computer screen to synthesized speech (e.g., JAWS for Windows, Windows Eyes, Slimware Window Bridge, ProTalk 32, Hal Screen Reader, WinVision, outSPOKEN for Windows)
- *Browser program to navigate the World Wide Web* (e.g., Microsoft Internet Explorer, IBM Home Page Reader)

Nursing Management

Coping with blindness involves three types of adaptation: emotional, physical, and social. The emotional adjustment to blindness or severe visual impairment determines the success of the physical and social adjustments of the patient. Successful emotional adjustment means acceptance of blindness or severe visual impairment.

Promoting Coping Efforts

Effective coping may not occur until the patient recognizes the permanence of the blindness. Clinging to false hopes of regaining vision hampers effective adaptation to blindness. A patient who is newly blind and his or her family members (especially those who live with the patient) undergo the various steps of grieving: denial, anger, loss bargaining, depression, and resolution and acceptance (Kübler-Ross, 1969). The ability to accept the changes that must come with visual loss and willingness to adapt to those changes influence the successful rehabilitation of the patient who is blind. Additional aspects to consider are value changes, independence–dependence conflicts, coping with stigma, and learning to function in social settings without visual cues and landmarks.

Promoting Spatial Orientation and Mobility

A person who is blind or severely visually impaired requires strategies for adapting to the environment. ADLs, such as walking to a chair from a bed, require spatial concepts. A patient whose visual impairment results from a chronic progressive eye disorder, such as glaucoma, has better cognitive mapping skills than does the patient who becomes blind suddenly. Patients with progressive eye disorders develop the use of spatial and topographic concepts early and gradually; hence, remembering a room layout is easier for them. Patients who become blind suddenly have more difficulty in adjusting, and emotional and behavioral issues of coping with blindness may hinder their learning. These patients require intensive emotional and physical support.

In the hospital, the bedside table and the call button must always be within reach. The parts of the call button are explained, and the patient is taught to touch and press the buttons or dials until the activity is mastered. The patient must be familiarized with the location of the telephone, water pitcher, and other objects on the bedside table. The food tray's composition is likened to the face of a clock; for example, the main plate may be described as being at 12 o'clock or the coffee cup at 3 o'clock. All articles and furniture must remain in the same positions throughout the patient's hospitalization. Introduction of hospital personnel should be made upon entering and departure from the patient's room.

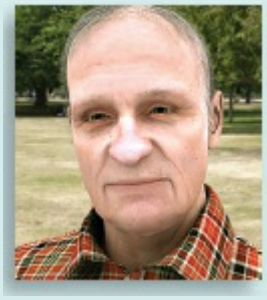
The nurse should be aware of the importance of techniques in providing physical assistance, encouraging independence, and ensuring safety. Specific guidelines for interacting with the patient with vision loss are presented in Box 49-2. The readiness of the patient and his or her family to learn must be assessed before initiating orientation and mobility training.

Promoting Home and Community-Based Care

The nurse, social worker, family, and others collaborate to assess the patient's home condition and support system. If available, a low-vision specialist or occupational therapist should be consulted, particularly for patients for whom identifying and administering medications pose problems. Contact information for some private and nonprofit services is included in the Internet Resources for this chapter available at http://thepoint.lww.com/Honan2e.

Other interventions that are appropriate for some people with low vision or blindness include Braille and guide dogs. Guide dogs, also known as Seeing-Eye dogs, are dogs that are specially bred and raised and then rigorously trained to assist people who are blind. The guide dog is a constant companion to the person who is blind (also referred to as the animal's handler) and is allowed on airplanes and in restaurants, stores, hotels, and other public places. A guide dog in harness is a working dog and should not be approached without permission of the handler. With the assistance of the guide dog, the person who is blind can be extremely mobile and accomplish normal activities both within and outside of the home and workplace.

Unfolding Patient Stories: Vernon Watkins • Part 2



Recall from Chapter 5 Vernon Watkins, who came to the emergency department with severe abdominal pain and underwent a hemicolectomy for a bowel perforation. During postoperative care the nurse determines that he has poor vision. What measures can the nurse take to maintain a safe environment for a patient with visual impairment? How will the discovery of impaired vision impact the nursing plan of care, discharge planning, and delivery of patient education?

Care for Vernon and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

GLAUCOMA

Glaucoma is a group of ocular conditions characterized by optic nerve damage. The optic nerve damage is related to the intraocular pressure (IOP) caused by congestion of aqueous humor in the eye. Ranges of pressures have been considered "normal," but they may be associated with visual loss in some patients. While the average IOP is generally at or below 21 mm Hg, exceptions to this normal value exist. Genetic disposition and central corneal

thickness have been implicated in causing ocular hypertension (OHT), a major precursor to glaucoma (Yanoff & Cameron, 2016). Glaucoma is one of the leading causes of irreversible blindness in the world and is the leading cause of blindness among adults in the United States. There is no cure for glaucoma; research is aimed at identifying risk factors and preventing vision loss and blindness.

BOX 49-2 Guidelines for Interacting with People Who Are Blind or Have Low Vision

- Remember that the only difference between you and people who are blind or have low vision is that they are not able to see through their eyes what you are able to see through yours.
- Do not be uncomfortable when in the company of a person who is blind or has low vision. Talk with the person as you would talk with any other individual, honestly and without pity; do not be concerned about using words like "see" and "look." There is no need to raise your voice unless the person asks you to do so.
- Identify yourself as you approach the person and before you make physical contact. Tell the person your name and your role. If another person approaches, introduce him or her. When you leave the room, be sure to tell the person that you are leaving and if anyone else remains in the room.
- It is appropriate to touch the person's hand or arm lightly to indicate that you are about to speak.
- When talking, face the person and speak directly to him or her using a normal tone of voice.
- Be specific when communicating direction. Mention a specific distance or use clock cues when possible (e.g., walk left about 2 yards; walk about 20 ft to the right; the telephone is at 2 o'clock). Avoid using phrases such as "over there."
- When you offer to assist someone, allow the person to hold onto your arm just above the elbow and to walk a half-step behind you.
- When offering the person a seat, place the person's hand on the back or the arm of the seat.
- When you are about to go up or down a flight of stairs, tell the person, and place his or her hand on the banister.
- Make sure that the environment is free of obstacles; close doors and cabinets so they are not in the path.
- Offer to read written information, such as a menu.
- If you serve food to the person, use clock cues to specify where everything is on the plate.
- When the person who is blind or who has low vision is a patient in a health care facility:

    - Make sure all objects the person will need are close at hand.
    - Identify the location of objects that the person may need (e.g., "The call light is near your right hand"; "The telephone is on the table on the left side of your bed.")
    - Remove obstacles that may be in the person's pathway and could cause a fall.
    - Place all assistive devices the person uses close at hand; let the person feel the devices so that he or she knows their location.
- Do not distract the service animal unless the owner has given permission.
- Ask the person, "How can I help you?" At some times, the person needs help, but at other times help may not be needed.

This material is adapted from and based in part on *Achieving Physical and Communication Accessibility,* a publication of the National Center for Access Unlimited; *Community Access Facts,* an Adaptive Environments Center publication; and *The Ten Commandments of Interacting with People with Mental Health Disabilities,* a publication of The Ability Center of Greater Toledo.

Pathophysiology

Aqueous humor flows between the iris and the lens, nourishing the cornea and lens. Most (90%) of the fluid then flows out of the anterior chamber, draining through the spongy trabecular meshwork into the canal of Schlemm and the episcleral veins (Fig. 49-1). About 10% of the aqueous fluid exits through the ciliary body into the suprachoroidal space and then drains into the venous circulation of the ciliary body, choroid, and sclera. Unimpeded outflow of aqueous fluid depends on an intact drainage system and an open angle (about 45 degrees) between the iris and the cornea. A narrower angle places the iris closer to the trabecular meshwork, diminishing the angle. The amount of aqueous humor produced tends to decrease with age, in systemic diseases such as diabetes, and in ocular inflammatory conditions.

IOP is determined by the rate of aqueous production, the resistance encountered by the aqueous humor as it flows out of the passages, and the venous pressure of the episcleral veins that drain into the anterior ciliary vein. When aqueous fluid production and drainage are in balance, the IOP is between 10 and 21 mm Hg. When aqueous fluid is inhibited from flowing out, pressure builds up within the eye. Fluctuations in IOP occur with time of day, exertion, diet, and medications. IOP tends to increase with blinking, tight lid squeezing, and upward gazing. Systemic conditions, such as hypertension, and intraocular conditions, such as uveitis and retinal detachment, have been associated with elevated IOP.

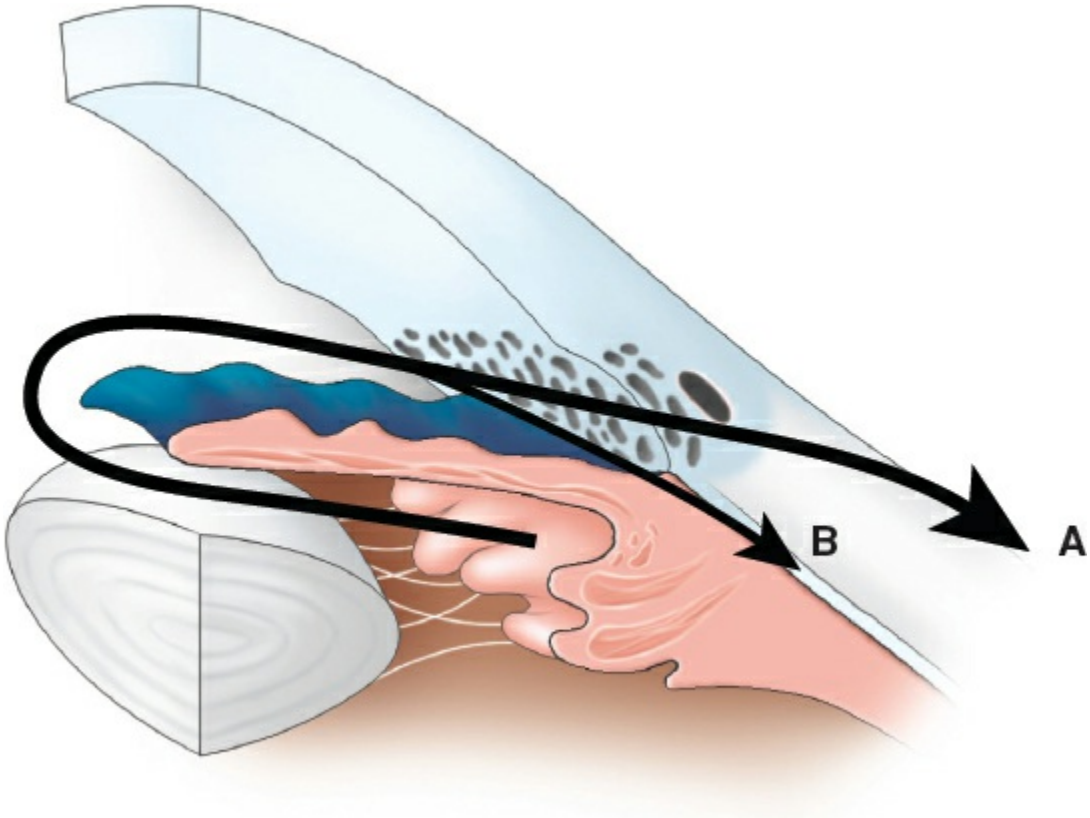


FIGURE 49-1 Normal outflow of aqueous humor. A. Trabecular meshwork. B. Uveoscleral route. (From Kanski, J. J. (2011). *Clinical ophthalmology*. Oxford: Butterworth-Heinemann Ltd.)

BOX 49-3 Progression of Glaucoma

1. Initiating events
   Precipitating factors include illness, emotional stress, congenital narrow angles, long-term use of corticosteroids, and use of mydriatics (i.e., medications causing pupillary dilation).

↓

2. Structural alterations in the aqueous outflow system
   Tissue and cellular changes caused by factors that affect aqueous humor dynamics lead to structural alterations.

↓

3. Functional alterations
   Conditions such as increased IOP or impaired blood flow create functional changes.

↓

4. Optic nerve damage
   Atrophy of the optic nerve is characterized by loss of nerve fibers and blood supply. This fourth stage inevitably progresses to the fifth stage.

↓

5. Visual loss
   Progressive loss of vision is characterized by visual field defects.

There are two accepted theories regarding how increased IOP damages the optic nerve in glaucoma. The direct mechanical theory suggests that high IOP damages the retinal layer as it passes through the optic nerve head. The indirect ischemic theory suggests that high IOP compresses the microcirculation in the optic nerve head, resulting in cell injury and death. Some glaucomas appear as exclusively mechanical, and some are exclusively ischemic types. Typically, most cases are a combination of both. Regardless of the cause of damage, glaucomatous changes typically evolve through clearly discernible stages (Box 49-3).

Classification of Glaucoma

There are several types of glaucoma. Although glaucoma classification is changing as knowledge increases, current clinical forms of glaucoma are identified as open-angle glaucoma, angle-closure glaucoma (also called pupillary block), congenital glaucoma, and glaucoma associated with other conditions, such as developmental anomalies or corticosteroid use. Glaucoma can be primary or secondary, depending on whether associated factors contribute to the rise in IOP. The two common clinical forms of glaucoma encountered in adults are open-angle and angle-closure glaucoma. These are differentiated by mechanisms that cause impaired aqueous outflow. Table 49-2 summarizes the characteristics of the different types of open-angle and angle-closure glaucoma.

Risk Factors

It is estimated that at least 2.7 million Americans have glaucoma (Prevent Blindness in America, 2012). Glaucoma is more prevalent among people older than 40 years of age, and the incidence increases with age. It is also more prevalent among men than women and in African American and Asian populations. Inflammatory processes, such as uveitis, may cause glaucoma in about 10% to 30% of the population (Sarodia, Kulkarni, & Barton, 2016). Uveitic glaucoma (UG) is a secondary glaucoma associated with high IOP and optic nerve damage. There are multiple mechanisms of IOP, which pose significant challenge when treating UG. Glaucoma associated with uveitis results in cellular debris and protein leakage out of the blood vessels into clear, aqueous fluid, blocking drainage. Initially the angle between the iris and cornea may be open. As IOP rises, the iris can bow forward, sticking to the lens, cornea, or sclera, which closes the angle of the anterior chamber. Management often requires both an ophthalmologist specializing in glaucoma in addition to a rheumatologist (Munoz-Negrete, Moreno-Montanes, Hernandez-Martinez, & Rebolleda, 2015) (Box 49-4).

Clinical Manifestations and Assessment

Glaucoma is often called the "silent thief of sight" because most patients are unaware that they have the disease until they have experienced visual changes and vision loss. The patient may not seek health care until he or she experiences blurred vision or "halos" around lights, difficulty focusing, difficulty adjusting eyes in low lighting, loss of peripheral vision, aching or discomfort around the eyes, and headache.

The purpose of a glaucoma workup is to establish the diagnostic category, assess the optic nerve damage, and formulate a treatment plan. The patient's ocular and medical history must be detailed to investigate the history of predisposing factors. Diagnostic examination to detect and manage glaucoma includes the following tests: tonometry to measure the IOP, ophthalmoscopy to inspect the optic nerve, gonioscopy to examine the filtration angle of the anterior chamber, perimetry to assess the visual fields, and pachymetry to measure the thickness of the cornea, which influences IOP readings.

The changes in the optic nerve related to glaucoma are pallor and cupping of the optic nerve disc. The pallor of the optic nerve is caused by a lack of blood supply that results from cellular destruction. Cupping is characterized by exaggerated bending of the blood vessels as they cross the optic disc, resulting in an enlarged optic cup that appears more basin-like compared with a normal cup. The progression of cupping in glaucoma is caused by the gradual loss of retinal nerve fibers accompanied by the loss of blood supply, resulting in increased pallor of the optic disc.

TABLE 49-2 Glaucoma Types, Clinical Manifestation, and Treatment

Types of Glaucoma	Clinical Manifestations	Treatment
Open-Angle Glaucoma		
Usually bilateral, but one eye may be affected more severely than the other. In all three types of open-angle glaucoma, the anterior chamber angle is open and appears normal.		
Chronic open-angle glaucoma (COAG)	Optic nerve damage, visual field defects, IOP >21 mm Hg May have fluctuating IOPs. Usually no symptoms but possible ocular pain, headache, and halos	Decrease IOP 20–50%. Additional topical and oral agents added as necessary. If medical treatment is unsuccessful, laser trabeculoplasty (LT) can decrease IOP by 20%. Glaucoma filtering surgery if continued optic nerve damage despite medication therapy and LT.
Normal tension glaucoma	IOP ≤21 mm Hg; optic nerve damage, visual field defects	Treatment similar to COAG, however, the best management for normal tension glaucoma is yet to be established. Goal is to lower the IOP by at least 30%.
Ocular hypertension	Elevated IOP Possible ocular pain or headache	Decrease IOP by at least 20%
Angle-Closure (Pupillary Block) Glaucoma		
Obstruction in aqueous humor outflow due to the complete or partial closure of the angle from the forward shift of the peripheral iris to the trabecula. The obstruction results in an increased IOP.		
Acute angle-closure glaucoma (AACG)	Rapidly progressive visual impairment, periocular pain, conjunctival hyperemia, and congestion Pain may be associated with nausea, vomiting, bradycardia, and profuse sweating. Reduced central visual acuity, severely elevated IOP, corneal edema Pupil is vertically oval, fixed in a semi-dilated position, and unreactive to light and accommodation	Ocular emergency, requiring administration of hyperosmotics, acetazolamide, and topical ocular hypotensive agents, such as pilocarpine and beta blockers (betaxolol). Possible laser incision in the iris (iridotomy) to release blocked aqueous and reduce IOP Other eye is also treated with pilocarpine eye drops and/or surgical management to avoid a similar spontaneous attack.
Subacute angle-closure glaucoma	Transient blurring of vision, halos around lights; temporal headaches and/or ocular pain; pupil may be semi-dilated	Prophylactic peripheral laser iridotomy Can lead to acute or chronic angle-closure glaucoma if untreated
Chronic angle-closure glaucoma	Progression of glaucomatous cupping and significant visual field loss; IOP may be normal or elevated; ocular pain and headache	Management is similar to that for COAG: includes laser iridotomy and medications.
Other Types of Glaucoma		
Uveitic glaucoma	IOP ≥ 21 mm Hg; optic nerve damage, visual field defects	Decrease IOP; medical treatment or surgery may be necessary

BOX 49-4 Risk Factors for Glaucoma

- Family history of glaucoma
- African American race
- Older age (over 60 years of age)
- Diabetes mellitus
- Cardiovascular disease
- Migraine syndromes
- Nearsightedness (myopia)
- Eye trauma
- Prolonged use of topical or systemic corticosteroids

As the damage to the optic nerve increases, visual perception in the area is lost. The localized areas of visual loss (i.e., scotomas) represent loss of retinal sensitivity and are measured and mapped by perimetry. In patients with glaucoma, there is a distinct pattern

that differs from other ocular diseases and is useful in establishing its diagnosis. Figure 49-2 shows the progression of visual field defects caused by glaucoma.

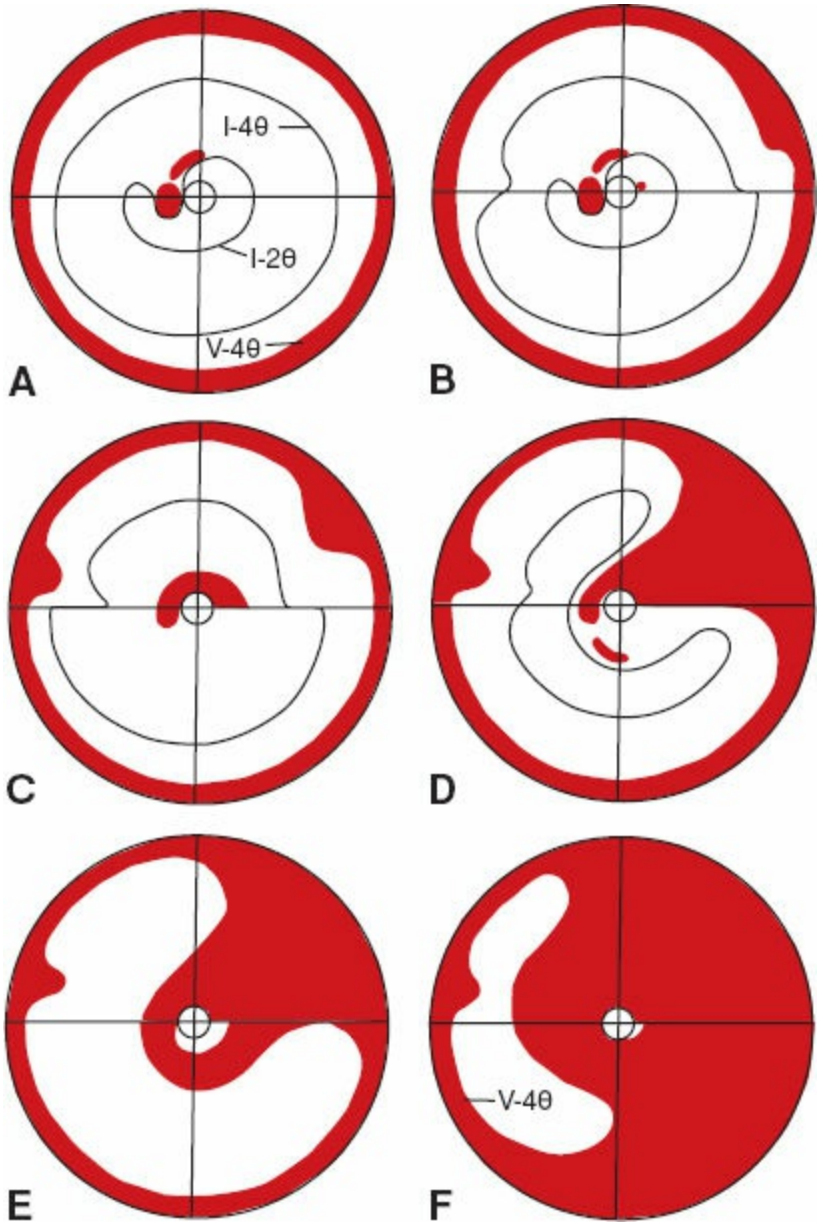

FIGURE 49-2 Progression of glaucomatous visual field defects. A central scotoma at 10 to 20 degrees of fixation near the blind spot is the initial significant finding (A, B). As the glaucoma progresses, the scotomas enlarge and deepen, resulting in peripheral vision loss. C. Defect within 5 degrees of fixation point nasally. D. Peripheral involvement enlarges. E. Ringlike scotoma. F. Eventually, vision is lost. The resulting "island of vision" becomes the characteristic visual field appearance of glaucoma and correlates with the "tunnel vision," in which peripheral vision is lost. (From Kanski, J. J. (2011). *Clinical ophthalmology*. Oxford: Butterworth-Heinemann Ltd.)

Medical Management

The aim of all glaucoma treatment is prevention of damage to the optic nerve. Lifelong therapy is almost always necessary because glaucoma cannot be cured. Treatment focuses on pharmacologic therapy, laser procedures, surgery, or a combination of these approaches, all of which have potential complications and side effects. The object is to achieve the greatest benefit at the least risk, cost, and inconvenience to the patient. Although treatment cannot reverse damage to the optic nerve, further damage can be controlled. The goal is to maintain an IOP within a range unlikely to cause further damage.

The initial target for IOP among patients with elevated IOP and those with low-tension glaucoma with progressive visual field loss is typically set at 30% lower than the current pressure. The patient is monitored for changes in the appearance of the optic nerve. If there is evidence of progressive damage, the target IOP is lowered again until the optic nerve shows stability.

Medical management of glaucoma relies on systemic and topical ocular medications that lower IOP. Periodic follow-up examinations are essential to monitor IOP, the appearance of the optic nerve, the visual fields, and side effects of medications. Therapy takes into account the patient's health and stage of glaucoma. Comfort, affordability, convenience, lifestyle, and personality are factors to consider in the patient's adherence to the medical regimen.

The patient is usually started on the lowest dose of topical medication and then advanced to increased concentrations until the desired IOP level is reached and maintained. Because of their efficacy, minimal dosing (can be used once each day), and low cost, beta blockers are the preferred initial topical medications. Beta blockers decrease the production of aqueous humor with resultant decrease in IOP. One eye is treated first, with the other eye used as a control in determining the efficacy of the medication; once efficacy has been established, treatment of the other eye is started. If the IOP is elevated in both eyes, both are treated. When results are not satisfactory, a new medication is substituted. The main markers of the efficacy of the medication in glaucoma control are lowering of the IOP to the target pressure, appearance of the optic nerve head, and less deterioration of the visual field.

Surgical management for glaucoma includes several procedures. In laser trabeculoplasty, burns are applied to the inner surface of the trabecular meshwork to open the intratrabecular spaces and widen the canal of Schlemm, thereby promoting outflow of aqueous humor and decreasing IOP. Laser iridotomy, used for pupillary block glaucoma, is an opening made in the iris to eliminate the pupillary block. Laser iridotomy is contraindicated in patients with corneal edema, which interferes with laser targeting and strength.

Filtering procedures for chronic glaucoma are used to create an opening or fistula in the trabecular meshwork to drain aqueous humor from the anterior chamber to the subconjunctival space into a bleb (blister-like fluid collection), thereby bypassing the usual drainage structures. This allows the aqueous humor to flow and exit by different routes (i.e., absorption by the conjunctival vessels or mixing with tears). Trabeculectomy is the standard filtering technique used to remove part of the trabecular meshwork. Complications include hemorrhage, an extremely low (hypotony) or elevated IOP, uveitis,

cataracts, bleb failure, bleb leak, and endophthalmitis. Unlike other surgical procedures, the filtering procedure's goal in glaucoma treatment is to achieve incomplete healing of the surgical wound.

Nursing Management

Teaching Patients Self-Care

The medical and surgical management of patients with glaucoma slows the progression of glaucoma but does not cure it. The lifelong therapeutic regimen mandates patient education. The nature of the disease and the importance of strict adherence to the medication regimen must be included in a teaching plan to help ensure compliance. A thorough patient interview is essential to determine systemic conditions, current systemic and ocular medications, family history, and problems with compliance to glaucoma medications. The effects of glaucoma-control medications on vision must also be explained. Miotics and sympathomimetics decrease the size of the pupil, facilitating the outflow of aqueous humor and decreasing the IOP, but they may also result in altered focus; therefore, patients need to be cautious in navigating their surroundings.

BOX 49-5 Patient Education

Managing Glaucoma

- Know your IOP measurement and the desired range.
- Be informed about the extent of your vision loss and optic nerve damage.
- Keep a record of your eye pressure measurements and visual field test results to monitor your own progress.
- Review all your medications (including over-the-counter and herbal medications) with your ophthalmologist, and mention any side effects each time you visit.
- Ask about potential side effects and drug interactions of your eye medications.
- Ask whether generic or less costly forms of your eye medications are available.
- Review the dosing schedule with your ophthalmologist and inform him or her if you have trouble following the schedule.
- Participate in the decision-making process. Let your provider know what dosing schedule works for you and other preferences regarding your eye care.
- Have the nurse observe you instilling eye medication to determine whether you are administering it properly.
- Be aware that glaucoma medications can cause adverse effects if used inappropriately. Eye drops are to be administered as prescribed, not when eyes feel irritated.
- Ask your ophthalmologist to send a report to your provider after each appointment.
- Keep all follow-up appointments.

Nurses in all settings encounter patients with glaucoma. Even patients with longstanding disease and those with glaucoma as a secondary diagnosis should be assessed for knowledge level and compliance with the therapeutic regimen. Box 49-5 contains points to review with patients with glaucoma.

Continuing Care

For the patient with severe glaucoma and impaired function, referral to services that assist the patient in performing ADLs may be needed. The loss of peripheral vision can impact mobility, and patients may benefit from low vision and rehabilitation services. Patients who meet the criteria for legal blindness should be offered referrals to agencies that can assist them in obtaining federal assistance.

Reassurance and emotional support are important aspects of care. A lifelong disease involving possible loss of sight has psychological, physical, social, and vocational ramifications. The family must be integrated into the plan of care, and because the disease has a familial tendency, family members should be encouraged to undergo examinations at least once every 2 years to detect glaucoma early.

CATARACTS

A cataract is a lens opacity or cloudiness (Fig. 49-3). Cataracts rank behind only arthritis and heart disease as a leading cause of disability in older adults. In fact, cataracts are the most common cause of treatable blindness. It is estimated the prevalence for cataract is 17.2%, with higher rates (77%) appreciated among Caucasian woman over 80 years of age (Klein & Klein, 2013). It is estimated that more than 30 million Americans will develop cataracts by the year 2020 (Ferri, 2016).

Pathophysiology

Cataracts can develop in one or both eyes at any age for a variety of causes (Box 49-6). Visual impairment normally progresses at the same rate in both eyes over many years or in a matter of months. The three most common types of senile (age-related) cataracts are defined by their location in the lens: nuclear, cortical, and posterior subcapsular. The extent of visual impairment depends on their size, density, and location in the lens. More than one type can be present in one eye.

A nuclear cataract is caused by central opacity in the lens and has a substantial genetic component. It is associated with myopia (i.e., nearsightedness), which worsens when the cataract progresses. If dense, the cataract severely blurs vision. Periodic changes in prescription eyeglasses help manage this condition.

A cortical cataract involves the anterior, posterior, or equatorial cortex of the lens. A cataract in the equator or periphery of the cortex does not interfere with the passage of light through the center of the lens and has little effect on vision. Cortical cataracts progress at a highly variable rate. Vision is worse in very bright light.

Posterior subcapsular cataracts occur in front of the posterior capsule. This type typically develops in younger people and, in some cases, is associated with prolonged corticosteroid use, diabetes, or ocular trauma. Near vision is diminished, and the eye is increasingly sensitive to glare from bright light (e.g., sunlight, headlights).

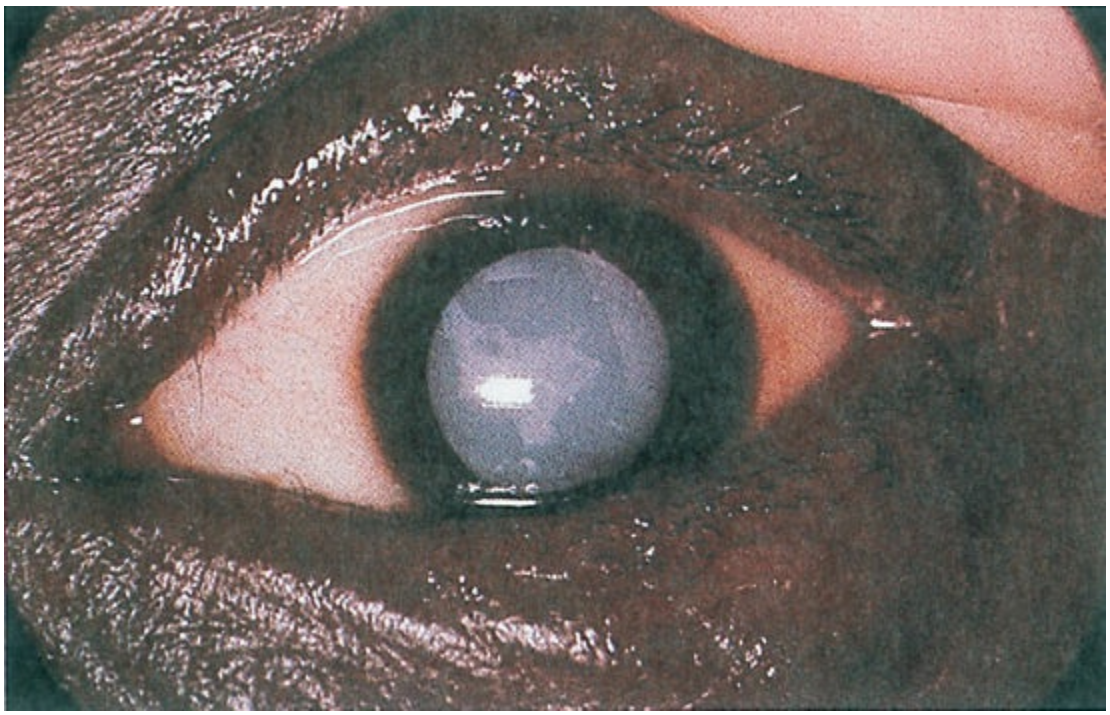

FIGURE 49-3 A cataract is a cloudy or opaque lens. On visual inspection, the lens appears gray or milky. (From Rubin, E., & Strayer, D. S. (Eds.). (2014). *Rubin's pathology* (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

BOX 49-6 Risk Factors for Cataract Formation

Aging:

- Loss of lens transparency
- Clumping or aggregation of lens protein (which leads to light scattering)
- Accumulation of a yellow-brown pigment due to the breakdown of lens protein
- Decreased oxygen uptake
- Increase in sodium and calcium
- Decrease in levels of vitamin C, protein, and glutathione (an antioxidant)

Associated ocular conditions:

- Retinitis pigmentosa
- Myopia
- Retinal detachment and retinal surgery
- Infection (e.g., herpes zoster, uveitis)

Toxic factors:

- Corticosteroids, especially at high doses and in long-term use
- Alkaline chemical eye burns, poisoning
- Cigarette smoking
- Calcium, copper, iron, gold, silver, and mercury, which tend to deposit in the pupillary area of the lens

Nutritional factors:

- Reduced levels of antioxidants
- Poor nutrition
- Obesity

Physical factors:

- Dehydration associated with chronic diarrhea, use of purgatives in anorexia nervosa, and use of hyperbaric oxygenation
- Blunt trauma, perforation of the lens with a sharp object or foreign body, electric shock
- Ultraviolet radiation in sunlight and x-ray

Systemic diseases and syndromes:

- Diabetes mellitus
- Down syndrome
- Disorders related to lipid metabolism
- Kidney disorders
- Musculoskeletal disorders

Clinical Manifestations and Assessment

Painless, blurry vision is characteristic of cataracts. The person perceives that surroundings are dimmer, as if his or her glasses need cleaning. Light scattering is common, and the person experiences reduced contrast sensitivity, sensitivity to glare, and reduced visual acuity. Other effects include myopic shift, astigmatism, monocular diplopia (double vision), color shift (the aging lens becomes progressively more absorbent at the blue end of the spectrum), brunescens (color values shift to yellow-brown), and reduced light transmission.

Decreased visual acuity is directly proportionate to cataract density. The Snellen visual acuity test, ophthalmoscopy, and slit-lamp biomicroscopic examination are used to establish the degree of cataract formation. The degree of lens opacity does not always correlate with the patient's functional status. Some patients can perform normal activities despite clinically significant cataracts. Others with less lens opacification have a disproportionate decrease in visual acuity; hence, visual acuity is one measure of visual impairment and needs to be considered along with other visual screening techniques and assessments.

Medical Management

Nonsurgical Management

Nonsurgical (medications, eyedrops, eyeglasses) treatment has not been found as curative for people with cataracts nor does it prevent age-related cataracts. Cigarette smoking, long-term use of corticosteroids, especially at high doses, sunlight and ionizing radiation, diabetes, obesity, and eye injuries can increase the risk for cataracts. In the early stages of cataract development, glasses, contact lenses, strong bifocals, or magnifying lenses may improve vision.

Surgical Management

Surgical management of cataracts is considered when reduced vision interferes with normal activities. In deciding when cataract surgery is to be performed, the patient's functional and visual status should be a primary consideration. Surgery is performed on an outpatient basis and usually takes less than 1 hour. Although complications from cataract surgery are uncommon, they can have significant effects on vision. Restoration of visual function through a safe and minimally invasive procedure is the surgical goal.

When both eyes have cataracts, one eye is treated first, with at least several weeks, preferably months, separating the two procedures. Because cataract surgery is performed to improve visual functioning, the delay for the other eye gives time for the patient and the surgeon to evaluate whether the results from the first surgery are adequate to preclude the need for a second operation.

Intracapsular Cataract Extraction

In intracapsular cataract extraction, the entire lens (i.e., nucleus, cortex, and capsule) is removed and fine sutures are used to close the incision. From the late 1800s until the 1970s, it was the technique of choice for cataract extraction. It is infrequently performed today but is still indicated when there is a need to remove the entire lens, such as with a subluxated cataract (i.e., partially or completely dislocated lens).

Extracapsular Cataract Extraction

The extracapsular cataract extraction technique involves smaller incisional wounds (less trauma to the eye) and maintains the posterior capsule of the lens, thus reducing postoperative complications, particularly aphakic retinal detachment and cystoid macular edema. A portion of the anterior capsule is removed, allowing extraction of the lens nucleus and cortex. The posterior capsule and zonular support are left intact. An intact zonular–capsular diaphragm provides the needed safe anchor for the posterior chamber intraocular lens (IOL). After the pupil has been dilated and the surgeon has made a small incision on the upper edge of the cornea, a viscoelastic substance (clear gel) is injected into the space between the cornea and the lens. This prevents the space from collapsing and facilitates insertion of the IOL.

Phacoemulsification

This method of extracapsular surgery uses an ultrasonic device that liquefies the nucleus and cortex, which are then suctioned out through a tube. The posterior capsule is left intact. Because the incision is even smaller than the standard extracapsular cataract extraction, the wound heals more rapidly, and there is early stabilization of refractive error and less astigmatism. Hardware and software advances in ultrasonic technology—including modern phaco needles that are used to cut and aspirate the cataract—permit safe and efficient removal of nearly all cataracts through a clear cornea incision. With increasing frequency, self-sealing (sutureless) clear corneal incisions (temporal part of the cornea) are performed with phacoemulsification, minimizing postoperative astigmatism and thus decreasing bleeding and subconjunctival hemorrhage and speeding recovery of visual acuity.

Lens Replacement

After removal of the crystalline lens, the patient is considered to have aphakia (i.e., without a lens). The lens, which focuses light on the retina, must be replaced for the patient to see clearly. There are three lens replacement options: aphakic eyeglasses, contact lenses, and IOL implants.

Aphakic glasses, although effective, are rarely used. Objects are magnified by 25%, making them appear closer than they actually are. This magnification creates distortion. Peripheral vision is also limited, and binocular vision (i.e., ability of both eyes to focus on one object and fuse the two images into one) is impossible if the other eye is phakic (normal).

Contact lenses provide patients with almost normal vision, but because contact lenses need to be removed occasionally, the patient also needs a pair of aphakic glasses. Contact lenses are not advised for patients who have difficulty inserting, removing, and cleaning them. Frequent handling and improper disinfection increase the risk for infection.

Insertion of IOLs during cataract surgery is the usual approach to lens replacement. After cataract extraction, or phacoemulsification, the surgeon implants an IOL. Extracapsular cataract extraction and posterior chamber IOLs are associated with a relatively low incidence of complications (e.g., hyphema [bleeding into the anterior chamber of the eye], macular edema, secondary glaucoma, damage to the corneal endothelium). IOL implantation is contraindicated in patients with recurrent uveitis, proliferative diabetic retinopathy, neovascular glaucoma, or rubeosis iridis.

The most common IOL is the single-focus lens. Eyeglasses are still needed for distant or close vision because the single-focus lens, unlike the natural lens of the eye, cannot alter its shape to bring objects at different distances into focus. Multifocal IOLs reduce the need for eyeglasses, but patients can experience halos and glare. In the future, aging patients may benefit from a combined surgical approach using customized IOLs and refractive surgery for a customized vision correction.

Toxic Anterior Segment Syndrome

Also known as toxic endothelial cell destruction or sterile endophthalmitis, toxic anterior segment syndrome is a noninfectious inflammation caused by a toxic agent after an uncomplicated and uneventful surgery. This disorder is a complication of anterior chamber surgery that often occurs acutely and is characterized by widespread corneal edema and disseminated breakdown of the blood–aqueous barrier and the presence of fibrin and

exudate noted in the anterior chamber (Dotan, Kaiserman, Kremer, Ehrlich, & Bahar, 2014).

Toxic anterior segment syndrome is characterized by corneal edema less than 24 hours after surgery and an accumulation of white cells in the anterior chamber of the eye. Like the classic endophthalmitis, the symptoms include reduction in visual acuity and pain. In the absence of microorganism growth, improvement has occurred with topical steroid treatment alone.

Nursing Management

The patient with cataracts should receive the usual preoperative care for ambulatory surgical patients undergoing eye surgery.

Providing Preoperative Care

It has been common practice to withhold any anticoagulant therapy (e.g., aspirin, warfarin [Coumadin]) to reduce the risk for retrobulbar hemorrhage (after retrobulbar injection) for 5 to 7 days before surgery. Dilating drops are administered every 10 minutes for four doses at least 1 hour before surgery. Additional dilating drops may be administered in the operating room (immediately before surgery) if the affected eye is not fully dilated. Antibiotic, corticosteroid, and anti-inflammatory drops may be administered prophylactically to prevent postoperative infection and inflammation.

BOX 49-7 Patient Education

Intraocular Lens Implant

- Wear glasses or metal eye shield at all times following surgery, as instructed by the provider.
- Always wash hands before touching or cleaning the postoperative eye.
- Clean the postoperative eye with a clean tissue; wipe the closed eye with a single gesture from the inner canthus outward.
- Bathe or shower; shampoo hair cautiously or seek assistance.
- Avoid lying on the side of the affected eye the night after surgery.
- Keep activity light (e.g., walking, reading, watching television). Resume the following activities only as directed by the surgeon: driving, sexual activity, unusually strenuous activity.
- Remember not to lift, push, or pull objects heavier than 15 lb.
- Avoid bending or stooping for an extended period.
- Be careful when climbing or descending stairs.
- Know when to contact the surgeon.[a]

[a]Contact the surgeon immediately if any of the following problems occur before the next appointment: (1) vision changes; (2) continuous flashing lights appear to the affected eye; (3) redness, swelling, or pain increase in the eye; (4) the amount or type of eye drainage changes; (5) the eye is injured in any way; (6) significant pain is not relieved by acetaminophen.

Providing Postoperative Care

After recovery from anesthesia, the patient receives verbal and written instructions about how to protect the eye, administer medications, recognize signs of complications, and obtain emergency care. Box 49-7 identifies activities to be avoided. The nurse also explains

that there should be minimal discomfort after surgery and instructs the patient to take a mild analgesic agent, such as acetaminophen, as needed. Antibiotic, anti-inflammatory, and corticosteroid eye drops or ointments are prescribed postoperatively.

Teaching Patients Self-Care

To prevent accidental rubbing or poking of the eye, the patient wears a protective eye patch for 24 hours after surgery, followed by eyeglasses worn during the day and a metal shield worn at night for 1 to 4 weeks. The nurse instructs the patient and family in applying and caring for the eye shield. Sunglasses should be worn while outdoors during the day because the eye is sensitive to light.

Slight morning discharge, some redness, and a scratchy feeling may be expected for a few days. A clean, damp washcloth may be used to remove slight morning eye discharge. Because cataract surgery increases the risk for retinal detachment, the patient must know to notify the surgeon if new floaters (dots) in vision, flashing lights, decrease in vision, pain, or increase in redness occurs.

Continuing Care

The eye patch is removed after the first follow-up appointment. The patient may experience blurring of vision for several days to weeks. Sutures, if used, are left in the eye but alter the curvature of the cornea, resulting in temporary blurring and some astigmatism. Vision gradually improves as the eye heals. Patients with IOL implants have functional vision on the first day after surgery. Vision is stabilized when the eye is completely healed, usually within 6 to 12 weeks, when final corrective prescription is completed. Visual correction is needed for any remaining nearsightedness or farsightedness (even in patients with IOL implants).

RETINAL DISORDERS

Although the retina is composed of multiple microscopic layers, the two innermost layers, the sensory retina and the retinal pigment epithelium (RPE), are the most susceptible to common retinal disorders. As the film in a camera captures an image, the retina, the neural tissue of the eye, performs the same function. The rods and cones, the photoreceptor cells, are found in the sensory layer of the retina. Beneath the sensory layer lies the RPE, the pigmented layer. When the rods and cones are stimulated by light, an electrical impulse is generated, and the image is transmitted to the brain.

RETINAL DETACHMENT

Retinal detachment refers to the separation of the RPE from the sensory layer. The four types of retinal detachment are rhegmatogenous, traction, a combination of rhegmatogenous and traction, and exudative. Rhegmatogenous detachment is the most common form. In this condition, a hole or tear develops in the sensory retina, allowing some of the liquid vitreous to seep through the sensory retina and detach it from the RPE (Fig. 49-4). People at risk for this type of detachment include those with high myopia or aphakia (absence of lens) after cataract surgery. Trauma may also play a role in rhegmatogenous retinal detachment. Between 5% and 10% of all rhegmatogenous retinal detachments are associated with proliferative retinopathy, a retinopathy associated with diabetic neovascularization (see Chapter 30).

Tension, or a pulling force, is responsible for traction retinal detachment. An ophthalmologist must ascertain all of the areas of retinal break and identify and release the scars or bands of fibrous material providing traction on the retina. In general, patients with this condition have developed fibrous scar tissue from conditions such as diabetic retinopathy, vitreous hemorrhage, or the retinopathy of prematurity. The hemorrhages and fibrous proliferation associated with these conditions exert a pulling force on the delicate retina.

Patients can have both rhegmatogenous and traction retinal detachment. Exudative retinal detachments are the result of the production of a serous fluid under the retina from the choroid. Conditions such as uveitis and macular degeneration may cause the production of this serous fluid.

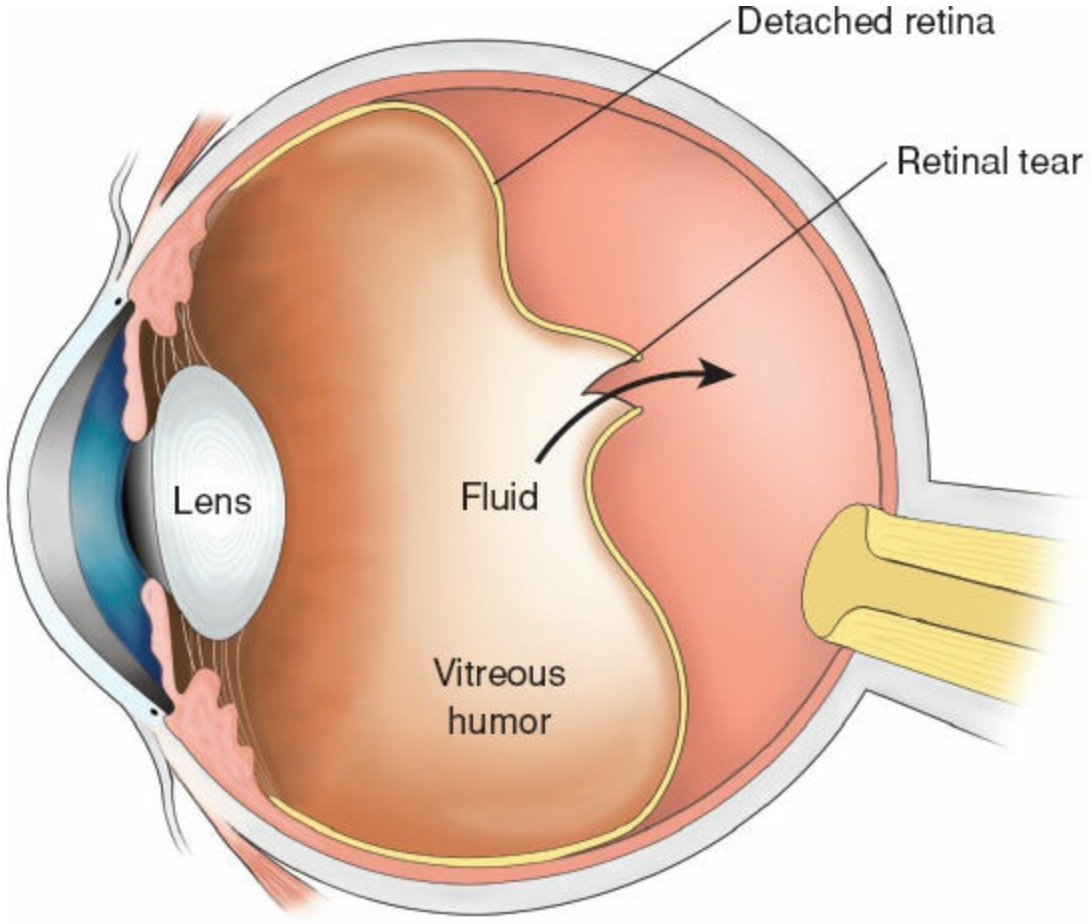

FIGURE 49-4 Rhegmatogenous detachment: the most common form of retinal detachment.

Clinical Manifestations and Assessment

Patients may report the sensation of a shade or curtain coming across the vision of one eye, cobwebs, bright flashing lights, or the sudden onset of a great number of floaters. Patients do not complain of pain.

After visual acuity is determined, the patient must have a dilated fundus examination using an indirect ophthalmoscope as well as slit-lamp biomicroscopy. Stereo fundus photography and fluorescein angiography are commonly used during the evaluation.

Increasingly, optical coherence tomography and ultrasound are used for the complete retinal assessment, especially if the view is obscured by a dense cataract or vitreal hemorrhage. All retinal breaks, all fibrous bands that may be causing traction on the retina, and all degenerative changes must be identified.

Medical Management

In rhegmatogenous detachment, an attempt is made to surgically reattach the sensory retina to the RPE. In traction detachment, the source of traction must be removed and the sensory retina reattached. New surgical techniques, as well as advances in instrumentation, have led to an increased rate of success of surgical reattachment and better visual outcomes. The most commonly used surgical interventions are the scleral buckle, the pars plana vitrectomy, and pneumatic retinopexy. The scleral buckle is a procedure in which a piece of silicone plastic or sponge is sewn onto the sclera at the site of the retinal tear. The buckle holds the retina against the sclera until scarring seals the tear (Fig. 49-5).

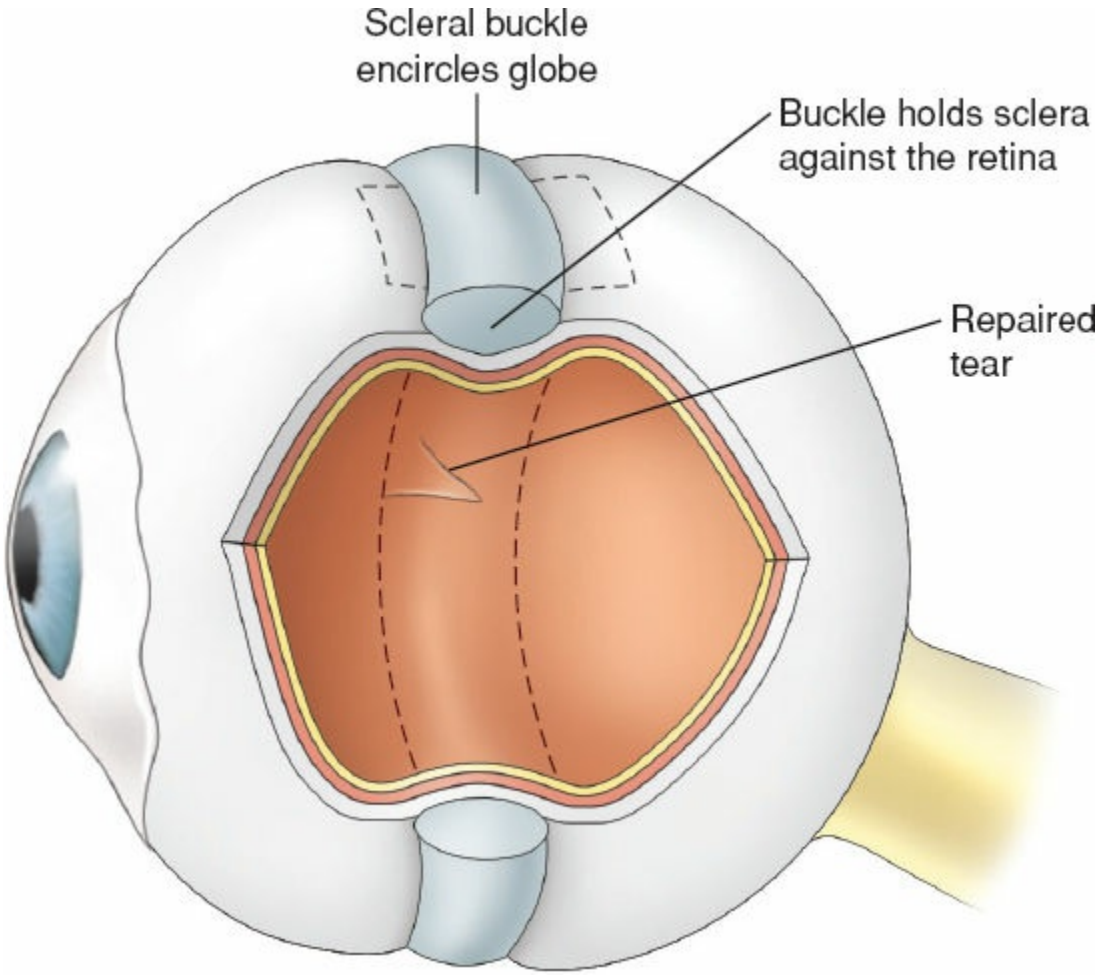

FIGURE 49-5 Scleral buckle.

Nursing Management

For the most part, nursing interventions consist of educating the patient and providing supportive care.

Promoting Comfort

Following surgery, patients will require assistance with meals and walking. While some procedures require a hospital stay, many scleral buckling procedures are performed on an outpatient basis. The nurse should advise patients to avoid heavy lifting or strenuous activity that could increase intraocular pressure. Reading may be restricted until the surgeon gives permission. Patients wear sunglasses during the day and an eye patch at night. Patients often report pain, erythema, and a scratchy sensation after surgery. Ice packs may be applied to counter any edema associated with the conjunctiva. If a vitrectomy was performed with scleral buckling, patients are required to sleep with their head elevated. Air travel must be avoided until the gas bubble, injected during surgery into the vitreous cavity to position the retina, is absorbed. Driving may be restricted until vision stabilizes. Reevaluation of vision and the need for corrective lenses is performed 6 to 8 weeks postoperatively.

Teaching About Complications

Postoperative complications may include increased IOP, endophthalmitis (inflammation of the internal layer of the eye), development of other retinal detachments, development of cataracts, and loss of turgor of the eye. Patients must be taught the signs and symptoms of complications, particularly of increasing IOP and postoperative infection, such as eye pain, sudden change in vision, fever, lid swelling, or conjunctival and/or corneal injection (redness). Excessive pain, swelling, and bleeding must be reported immediately to the surgeon.

MACULAR DEGENERATION

Macular degeneration is the leading cause of severe, irreversible vision loss in people over 60 years of age, affecting an estimated 8.7% of the world population. The prevalence is projected to reach 196 million people by 2020 and 288 million by 2040 (Wong et al., 2014). Commonly called AMD, it is characterized by tiny, yellowish spots called drusen (Fig. 49-6) beneath the retina. Most people older than 60 years of age have at least a few small drusen. There is a wide range of visual loss in patients with macular degeneration, but most patients do not experience total blindness. Central vision is generally the most affected, with most patients retaining peripheral vision (Fig. 49-7). There are two types of AMD, commonly known as the dry type and wet type.

Pathophysiology

Approximately 90% of people with AMD have the dry or nonexudative type, which has an insidious onset and leads to a mild to moderate loss of vision, although peripheral vision is

preserved. In dry AMD, the outer layers of the retina slowly break down (Fig. 49-8). With this breakdown comes the appearance of drusen. When the drusen occur outside of the macular area, patients generally have no symptoms. When the drusen occur within the macula, however, there is a gradual blurring of vision that patients may notice when they try to read. There is no known treatment that can cure this type of AMD.

Wet or exudative AMD is characterized by choroidal neovascularization (CNV), new growth of blood vessels beneath the retina, which causes severe vision loss in 90% of AMD cases (Normando, Tilley, Guo, & Cordeiro, 2013). Wet AMD may have an abrupt onset. The affected vessels can leak fluid and blood, elevating the retina. Patients report that straight lines appear crooked and distorted, or that letters in words appear broken. Some patients can be treated with the argon laser to stop the leakage from these vessels. However, this treatment is not ideal because vision may be affected by the laser treatment and abnormal vessels often grow back after treatment.

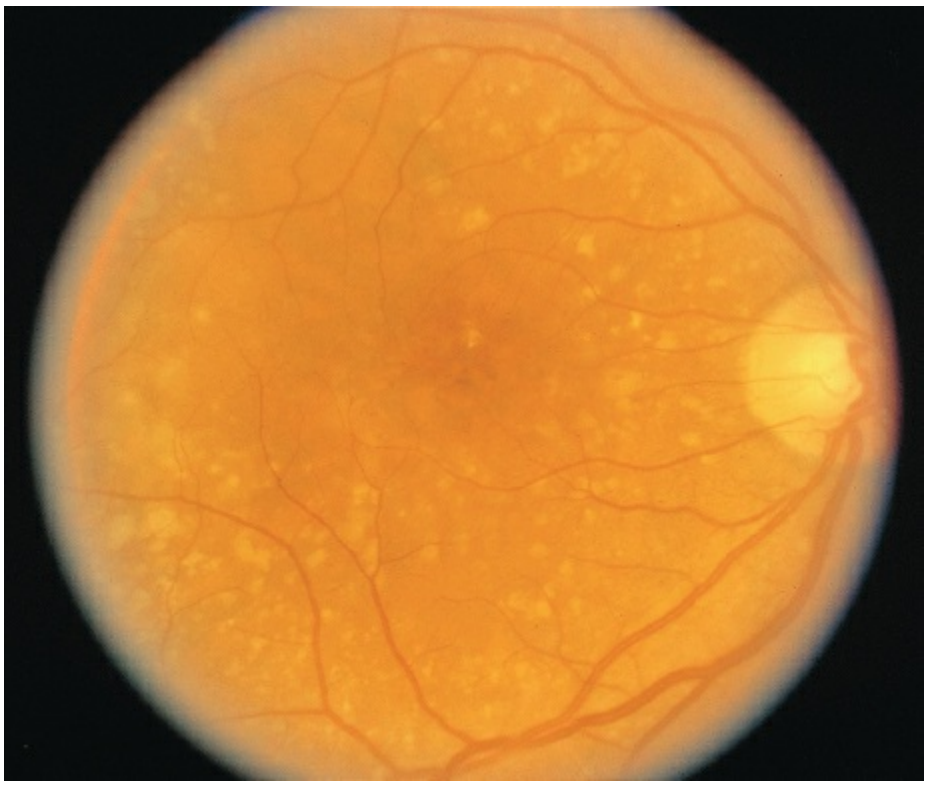

FIGURE 49-6 Retina showing drusen and age-related macular degeneration (AMD).

FIGURE 49-7 A. Normal vision. B. Visual loss associated with macular degeneration. (Photos courtesy of the National Eye Institute/National Institutes of Health.)

Medical Management

Visual loss from CNV lesions in AMD is a growing problem. With the growth of these new vessels from the choriocapillary layer, fibrous tissue develops that can, over months, destroy central vision. Laser treatment has been used to close these abnormal vessels, but the very process of photocoagulation carries with it some level of retinal destruction, albeit less than the natural scarring that would occur in the untreated eye.

Photodynamic therapy (PDT) has been developed in an attempt to ameliorate the CNV while causing minimal damage to the retina. Studies have shown that PDT can reduce the risk of visual loss for certain groups of patients who have classic subfoveal CNV due to macular degeneration. PDT is a two-step process. Verteporfin, a photosensitive dye, is infused IV over 10 minutes. Fifteen minutes after the start of the infusion, a diode laser is used to treat the abnormal network of vessels. The dye within the vessels takes up the energy of the diode laser but the surrounding retina does not, thus avoiding damage to adjacent areas. Multiple treatments may be necessary over time.

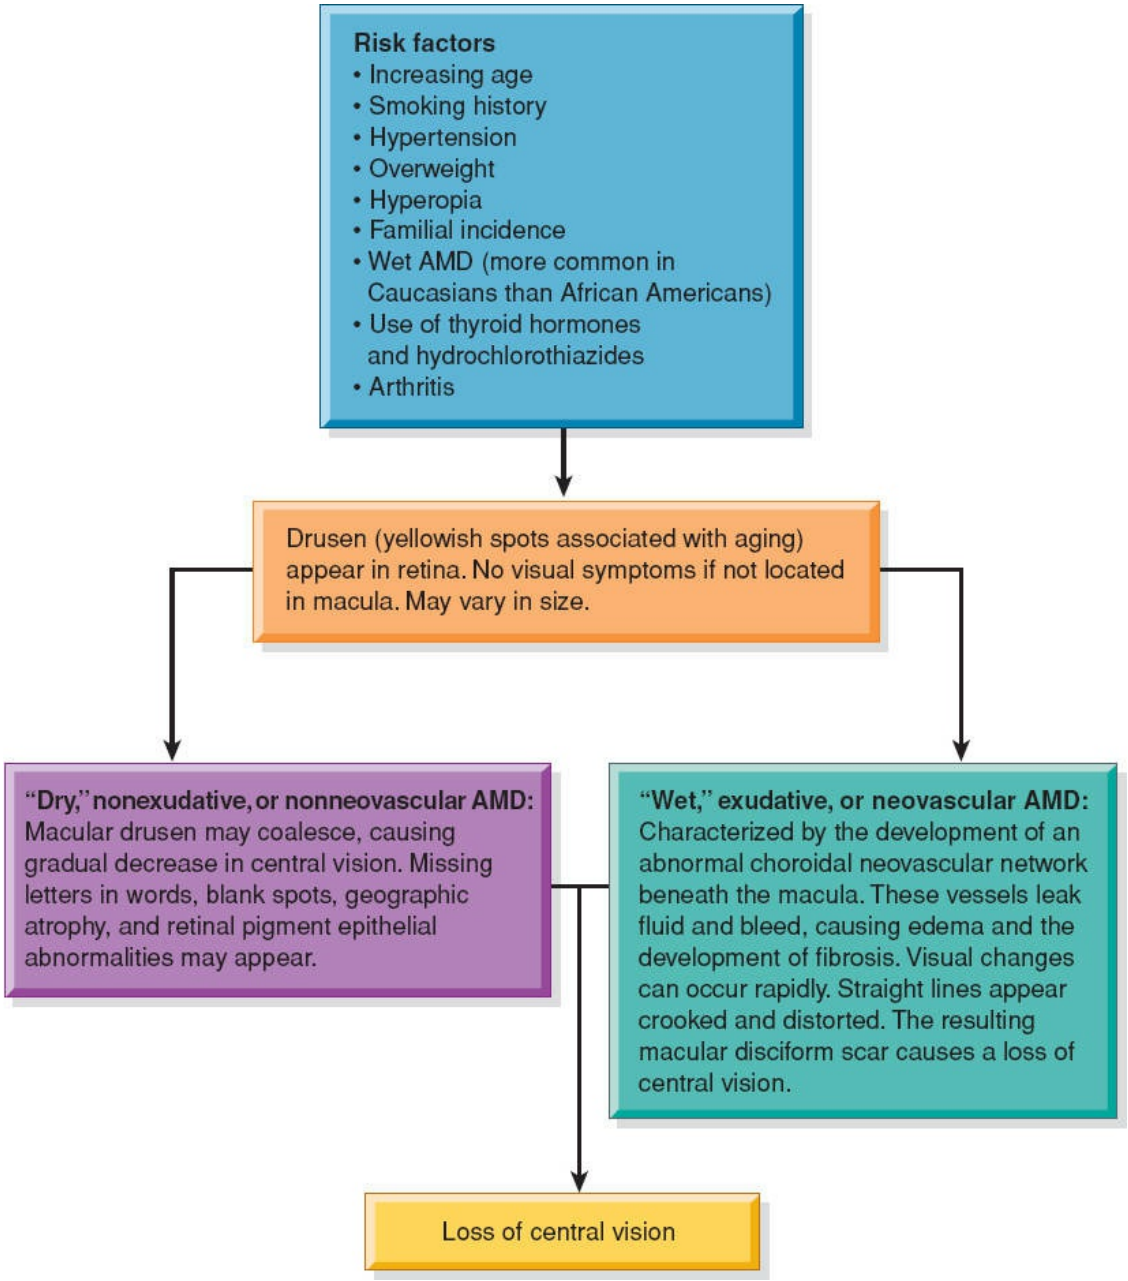

FIGURE 49-8 Progression of age-related macular degeneration (AMD): pathways to vision loss.

Verteporfin is a light-activated dye, so patient education is important preoperatively. The dye within the blood vessels near the surface of the skin could become activated with exposure to strong light. This would include bright sunlight, tanning booths, halogen lights, and the bright lights used in dental offices and operating rooms; ordinary indoor light is not a problem. The patient should be instructed to bring dark sunglasses, gloves, a wide-brimmed hat, long-sleeved shirt, and slacks to the setting where PDT will be performed. The patient must be cautioned to avoid exposure to direct sunlight or bright light for 5 days after treatment. Inadvertent sunlight exposure can lead to severe blistering of the skin and sunburn that may require plastic surgery.

Other treatment options are commonly used in the management of advanced wet AMD; they involve intravitreous injection of vascular endothelial growth factor (VEGF) and inhibitor-like medications. Bleeding risk in intravitreal injections is minimal such that

anticoagulation is continued.

Nursing Management

Nursing management is primarily educational. Most patients benefit from the use of bright lighting and magnification devices and from referral to a low-vision center. Some low-vision centers send representatives to the patient's home or place of employment to evaluate the living and working conditions and make recommendations to improve lighting, thereby improving vision and promoting safety.

Amsler grids are given to patients to use in their home to monitor for a sudden onset or distortion of vision. These may provide the earliest sign that macular degeneration is getting worse. Patients should be encouraged to use these grids and to look at them, one eye at a time, several times each week with glasses on. If there is a change in the grid (e.g., if the lines or squares appear distorted or faded), the patient should notify the ophthalmologist immediately and should arrange to be seen promptly.

ORBITAL AND OCULAR TRAUMA

Whether affecting the eye or the orbit, trauma to the eye and surrounding structures may have devastating consequences for vision. It is preferable to prevent injury rather than treat it. Box 49-8 details safety measures to prevent orbital and ocular trauma.

Types of Trauma

Orbital Trauma

Injury to the orbit is usually associated with a head injury; hence, the patient's general medical condition must first be stabilized before conducting an ocular examination. Only then is the globe assessed for soft tissue injury. During inspection, the face is meticulously assessed for underlying fractures, which should always be suspected in cases of blunt trauma. To establish the extent of ocular injury, visual acuity is assessed as soon as possible, even if it is only a rough estimate. Soft tissue orbital injuries often result in damage to the optic nerve. Major ocular injuries, indicated by a soft globe, prolapsing tissue, ruptured globe, and hemorrhage, require immediate surgical attention.

BOX 49-8 Health Promotion

Preventing Eye Injuries

In and Around the House
Advise patients to:

- Make sure that all spray nozzles are directed away from themselves before pressing down on the handle.
- Read instructions carefully before using cleaning fluids, detergents, ammonia, or harsh chemicals, and to wash hands thoroughly after use.
- Use grease shields on frying pans to decrease spattering.
- Wear special goggles to shield their eyes from fumes and splashes when using powerful chemicals.
- Use opaque goggles to avoid burns from sunlamps.

In the Workshop
Advise patients to:

- Protect their eyes from flying fragments, fumes, dust particles, sparks, and splashed chemicals by wearing safety glasses.
- Read instructions thoroughly before using tools and chemicals, and follow precautions for their use.

Around Children
Advise patients to:

- Pay attention to age and maturity level of a child when selecting toys and games, and to avoid projectile toys, such as darts and pellet guns.
- Supervise children when they are playing with toys or games that can be potentially dangerous.
- Teach children the correct way to handle potentially dangerous items, such as scissors and pencils.

In the Garden
Advise patients to:

- Avoid letting anyone stand at the side of or in front of a moving lawn mower.
- Pick up rocks and stones before going over them with the lawn mower (stones can be hurled out of the rotary blades and rebound off curbs or walls, causing severe injury to the eye).
- Make sure that pesticide spray can nozzles are directed away from the face.
- Avoid low-hanging branches.

Around the Car
Advise patients to:

- Put out all smoking materials and matches before opening the hood of the car.
- Use a flashlight, not a match or lighter, to look at the battery at night.
- Wear goggles when grinding metal or striking metal against metal while performing auto body repair.
- Take standard safety precautions when using jumper cables (wear goggles; make sure the cars are not touching one another; make sure the jumper cable clamps never touch each other; never lean over the battery when attaching cables; and never attach a cable to the negative terminal of a dead battery).

In Sports
Advise patients to:

- Wear protective safety glasses, especially for sports such as racquetball, squash, tennis, baseball, and basketball.
- Wear protective caps, helmets, or face protectors when appropriate, especially for sports such as ice hockey.

Around Fireworks
Advise patients to:

- Wear eye glasses or safety goggles.
- Avoid using explosive fireworks.
- Never allow children to ignite fireworks or stand near others when lighting fireworks.
- Douse firework duds in water instead of attempting to relight them.

Soft Tissue Injury and Hemorrhage

The signs and symptoms of soft tissue injury from blunt or penetrating trauma include tenderness, ecchymosis, lid swelling, proptosis (i.e., downward displacement of the eyeball), and hemorrhage. Closed injuries lead to contusions with subconjunctival hemorrhage, commonly known as a *black eye.* Blood accumulates in the tissues of the conjunctiva. Hemorrhage may be caused by a soft tissue injury to the eyelid or by an

underlying fracture.

Management of soft tissue hemorrhage that does not threaten vision is usually conservative and consists of thorough inspection, cleansing, and repair of wounds. Cold compresses are used in the early phase, followed by warm compresses. Hematomas that appear as swollen, fluctuating areas may be surgically drained or aspirated; if they are causing significant orbital pressure, they may be surgically evacuated.

Penetrating injuries or a severe blow to the head can result in severe optic nerve damage. Visual loss can be sudden or delayed and progressive. Immediate loss of vision after an ocular injury is usually irreversible. Delayed visual loss has a better prognosis. Corticosteroid therapy is indicated to reduce optic nerve swelling. Surgery, such as optic nerve decompression, may be performed.

Orbital Fractures

Orbital fractures are detected by facial x-rays. Depending on the orbital structures involved, orbital fractures can be classified as blowout, zygomatic or tripod, maxillary, midfacial, orbital apex, and orbital roof fractures. Blowout fractures result from compression of soft tissue and the sudden increase in orbital pressure when the force is transmitted to the orbital floor, the area of least resistance.

The inferior rectus and inferior oblique muscles, with their fat and fascial attachments, or the nerve that courses along the inferior oblique muscle may become entrapped, and the globe may be displaced inward (i.e., enophthalmos). Computed tomography (CT) can identify the muscle and its auxiliary structures that are entrapped. These fractures are usually caused by blunt small objects, such as a fist, knee, elbow, or tennis or golf ball.

Orbital roof fractures are dangerous because of potential complications to the brain. Surgical management of these fractures requires a neurosurgeon and an ophthalmologist. The most common indications for surgical intervention are displacement of bone fragments disfiguring the normal facial contours, interference with normal binocular vision caused by extraocular muscle entrapment, interference with mastication in zygomatic fracture, and obstruction of the nasolacrimal duct. Surgery is usually nonemergent, and a period of 10 to 14 days gives the ophthalmologist time to assess ocular function, especially the extraocular muscles and the nasolacrimal duct. Emergency surgical repair is usually not performed unless the globe is displaced to the maxillary sinus. Surgical repair is primarily directed at freeing the entrapped ocular structures and restoring the integrity of the orbital floor.

Foreign Bodies

Foreign bodies that enter the orbit are usually tolerated, except for copper, iron, and vegetable materials, such as those from plants or trees, which may cause purulent infection. X-rays and CT scans are used to identify the foreign body. A careful history is important, especially if the foreign body has been in the orbit for a period of time and the incident forgotten. It is important to identify metallic foreign bodies because they prohibit the use of magnetic resonance imaging (MRI) as a diagnostic tool.

After the extent of the orbital damage is assessed, the decision to use conservative treatment or surgical removal is made. In general, orbital foreign bodies are removed if they are superficial and anterior in location; have sharp edges that may affect adjacent orbital structures; or are composed of copper, iron, or vegetable material. Surgical intervention is

directed at preventing further ocular injury and maintaining the integrity of the affected areas. Cultures are usually obtained, and the patient is placed on prophylactic IV antibiotics that are later changed to oral antibiotics.

Ocular Trauma

Ocular trauma is the leading cause of blindness among children and young adults, especially male trauma victims. The most common circumstances of ocular trauma are occupational injuries (e.g., construction industry), sports (e.g., baseball, basketball, racquet sports, boxing), weapons (e.g., air guns, BB guns), assault, motor vehicle crashes (e.g., broken windshields), and explosions (e.g., blast fragments).

There are two types of ocular trauma in which the first response is critical: chemical burn and foreign object in the eye. With a chemical burn, the eye should be immediately irrigated with tap water or normal saline. With a foreign body, no attempt should be made to remove the foreign object. The object should be protected from jarring or movement to prevent further ocular damage. No pressure or patch should be applied to the affected eye. All traumatic eye injuries should be protected using a metal shield, if available, or a stiff paper cup until medical treatment can be obtained (Fig. 49-9).

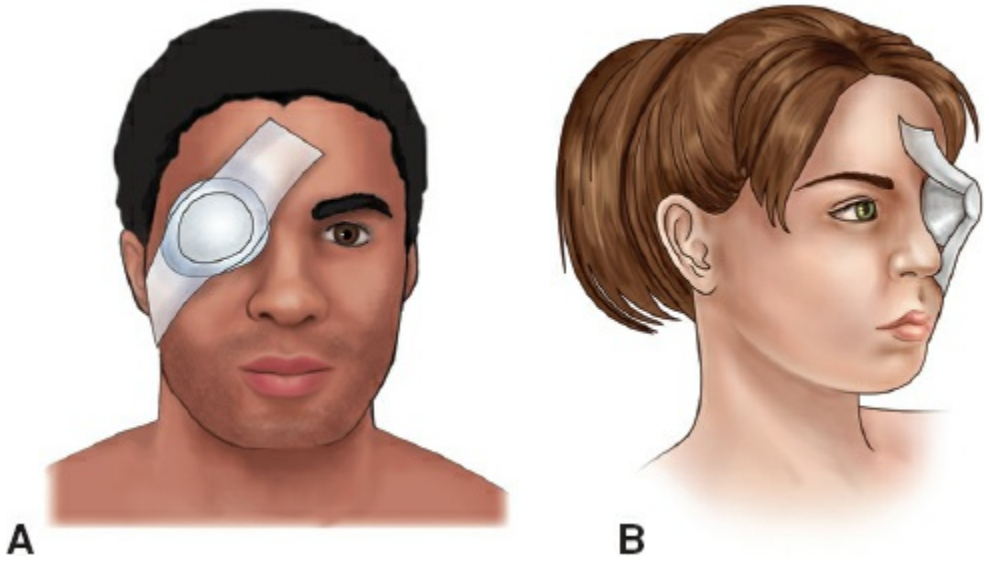

FIGURE 49-9 Two kinds of eye patches. A. Aluminum shield. B. Stiff paper cup shield (creative substitute when aluminum shield is unavailable).

Clinical Manifestations and Assessment

The nurse obtains a thorough history, particularly assessing the patient's ocular history, such as preinjury vision in the affected eye or past ocular surgery. Details related to the injury that help in the diagnosis and assessment of need for further tests include the nature of the ocular injury (i.e., blunt or penetrating trauma); the type of activity that caused the injury to determine the nature of the force striking the eye; and whether onset of vision loss was sudden, slow, or progressive. For chemical eye burns, the chemical agent must be identified and tested for pH if the agent is available. The nurse examines the corneal surface for foreign bodies, wounds, and abrasions and then the other external structures of the eye. Pupillary size, shape, and light reaction of the pupil of the affected eye are compared with the other eye. The nurse assesses ocular motility (ability of the eyes to move synchronously up, down, right, and left).

Medical Management

Splash Injuries

Splash injuries are irrigated with normal saline solution before further evaluation occurs. In cases of a ruptured globe, cycloplegic agents (agents that paralyze the ciliary muscle) or topical antibiotics must be deferred because of potential toxicity to exposed intraocular tissues. Further manipulation of the eye must be avoided until the patient is under general anesthesia. Parenteral, broad-spectrum antibiotics are initiated. Tetanus antitoxin is administered, if indicated, as well as analgesics. Tetanus prophylaxis is recommended for full-thickness ocular and skin wounds.

Foreign Bodies and Corneal Abrasions

After removal of a foreign body from the surface of the eye, an antibiotic ointment is applied and the eye is patched. The eye is examined daily for evidence of infection until the wound is completely healed.

Contact lens wear is a common cause of corneal abrasion. The patient experiences severe pain and photophobia (ocular pain on exposure to light). Corneal epithelial defects are treated with antibiotic ointment and a pressure patch to immobilize the eyelids. Topical anesthetic eye drops must not be given to the patient to take home for repeated use after corneal injury because their effects mask further damage, delay healing, and can lead to permanent corneal scarring. Corticosteroids are avoided while the epithelial defect exists.

Penetrating Injuries and Contusions of the Eyeball

Sharp penetrating injury or blunt contusion force can rupture the eyeball. When the eye wall, cornea, and sclera rupture, rapid decompression or herniation of the orbital contents into adjacent sinuses can occur. In general, blunt traumatic injuries (with an increased incidence of retinal detachment, intraocular tissue avulsion, and herniation) have a worse prognosis than penetrating injuries. Most penetrating injuries result in marked loss of vision with the following signs: hemorrhagic chemosis (edema of the conjunctiva), conjunctival laceration, shallow anterior chamber with or without an eccentrically placed pupil, hyphema (hemorrhage within the anterior chamber), or vitreous hemorrhage.

Hyphema is caused by contusion forces that tear the vessels of the iris and damage the anterior chamber angle. Preventing rebleeding and prolonged increased IOP are the goals of treatment for hyphema. In severe cases, the patient is hospitalized with moderate activity restriction. An eye shield is applied. Topical corticosteroids are prescribed to reduce inflammation. An antifibrinolytic agent, aminocaproic acid (Amicar), stabilizes clot formation at the site of hemorrhage. Aspirin is contraindicated.

A ruptured globe and severe injuries with intraocular hemorrhage require surgical intervention. Vitrectomy, surgical removal of vitreous fluid and stabilization of the retina, is performed for traumatic retinal detachments. Primary enucleation (complete removal of the eyeball and part of the optic nerve) is considered only if the globe is irreparable and has NLP. It is a general rule that enucleation is performed within 2 weeks of the initial injury (in an eye that has no useful vision after sustaining penetrating injury) to prevent the risk of

sympathetic ophthalmia (an inflammation created in the uninjured eye by the affected eye that can result in blindness of the uninjured eye).

Intraocular Foreign Bodies

A patient who complains of blurred vision and discomfort should be questioned carefully about recent injuries and exposures. Patients may be injured in a number of different situations and experience an intraocular foreign body (IOFB). Precipitating circumstances can include working in construction; striking metal against metal; being involved in a motor vehicle crash with facial injury; a gunshot wound; grinding-wheel work; and an explosion.

IOFB is diagnosed and localized by slit-lamp biomicroscopy and indirect ophthalmoscopy, as well as CT or ultrasonography. MRI is contraindicated because most foreign bodies are metallic and magnetic. It is important to determine the composition, size, and location of the IOFB and affected eye structures. Every effort should be made to identify the type of IOFB and whether it is magnetic. Iron, steel, copper, and vegetable matter cause intense inflammatory reactions. The incidence of endophthalmitis is also high. If the cornea is perforated, tetanus prophylaxis and IV antibiotics are administered.

Ocular Burns

Alkali, acid, and other chemically active organic substances, such as Mace and tear gas, cause chemical burns. Alkali burns (e.g., lye, ammonia) result in the most severe injury because they penetrate the ocular tissues rapidly and continue to cause damage long after the initial injury is sustained. They also cause an immediate rise in IOP. Acids (e.g., toilet bowl cleaners, bleach, car battery fluid, refrigerant) generally cause less damage because the precipitated necrotic tissue proteins form a barrier to further penetration and damage. Chemical burns may appear as superficial punctate keratopathy (i.e., spotty damage to the cornea), subconjunctival hemorrhage, or complete marbleizing of the cornea.

In treating chemical burns, every minute counts. Immediate tap-water irrigation should be started on site before transport of the patient to an emergency department. In the Emergency Department, only a brief history and examination are performed, then the corneal surfaces and conjunctival fornices are immediately and copiously irrigated with normal saline or any neutral solution. A local anesthetic is instilled, and a lid speculum is applied to overcome blepharospasm (i.e., spasms of the eyelid muscles that result in closure of the lids). Particulate matter must be removed from the fornices using moistened, cotton-tipped applicators and minimal pressure on the globe. Irrigation continues until the conjunctival pH normalizes (between 7.3 and 7.6). The pH of the corneal surface is checked by placing a pH paper strip in the fornix. Antibiotics are instilled, and the eye is patched.

The goal of intermediate treatment is to prevent tissue ulceration and promote re-epithelialization. Intense lubrication using nonpreserved (i.e., without preservatives to avoid allergic reactions) artificial tears is essential. Re-epithelialization is promoted with patching or therapeutic soft lenses. The patient is usually monitored daily for several days. Prognosis depends on the type of injury and adequacy of the irrigation immediately after exposure. Long-term treatment consists of two phases: restoration of the ocular surface through grafting procedures and surgical restoration of corneal integrity and optical clarity.

Thermal injury is caused by exposure to a hot object (e.g., curling iron, tobacco, ash), whereas photochemical injury results from ultraviolet irradiation or infrared exposure (e.g., exposure to the reflections from snow, sun gazing, viewing an eclipse of the sun without an adequate filter). These injuries can cause corneal epithelial defect, corneal opacity, conjunctival chemosis (edema) and injection (congestion of blood vessels), and burns of the eyelids and periocular region. Antibiotics and a pressure patch for 24 hours constitute the treatment of mild injuries. Scarring of the eyelids may require oculoplastic surgery, whereas corneal scarring may require corneal surgery.

INFECTIOUS AND INFLAMMATORY CONDITIONS

Inflammation and infections of eye structures are common. Eye infection is a leading cause of blindness worldwide. Table 49-3 summarizes selected common infections and their treatment. Conjunctivitis and orbital cellulitis are discussed below.

CONJUNCTIVITIS

Conjunctivitis (inflammation of the conjunctiva) is the most common ocular disease worldwide. Its appearance varies from a mildly pink appearance of the conjunctiva (hence the common term *pink eye*) because of subconjunctival blood vessel congestion to copious purulent drainage.

Clinical Manifestations and Assessment

Conjunctivitis may be unilateral or bilateral, but the infection usually starts in one eye and then spreads to the other eye by hand contact.

Clinical features important to evaluate are the type of discharge (watery, mucoid, purulent, or mucopurulent), presence or absence of lymphadenopathy (enlargement of the preauricular and submandibular lymph nodes where the eyelids drain), important symptoms such as a foreign-body sensation, irritation, a scratching or burning sensation, a sensation of fullness around the eyes, crusting of the eyelids, itching, visual blurring, and photophobia (Tu, 2015). Common organisms isolated are *Streptococcus pneumoniae, Haemophilus influenzae*, and *Staphylococcus aureus.* Two sexually transmitted agents associated with conjunctivitis are *Chlamydia trachomatis* and *Neisseria gonorrhoeae.* Diagnosis is based on the distinctive characteristics of ocular signs, acute or chronic presentation, and identification of any precipitating events. Positive results of swab smear preparations and cultures confirm the diagnosis.

Types of Conjunctivitis

Conjunctivitis is classified according to its cause. The major causes are microbial infection, allergy, and irritating toxic stimuli. A wide spectrum of organisms can cause conjunctivitis, including bacteria (e.g., *Chlamydia*), viruses, fungi and parasites. Conjunctivitis can also result from an existing ocular infection or can be a manifestation of a systemic disease.

Microbial Conjunctivitis

Bacterial Conjunctivitis

Bacterial conjunctivitis can be acute or chronic. The acute type can develop into a chronic condition. Signs and symptoms can vary from mild to severe. Chronic bacterial conjunctivitis is usually seen in patients with lacrimal duct obstruction, chronic dacryocystitis (infection of the nasolacrimal sac), and chronic blepharitis (eyelid inflammation). The most common causative microorganisms are *S. pneumoniae, H. influenzae,* and *S. aureus.*

Bacterial conjunctivitis manifests with an acute onset of redness, burning, and discharge. There is conjunctival irritation, and injection in the fornices. The exudates are variable but are usually present on waking in the morning. The eyes may be difficult to open because of adhesions caused by the exudate. Purulent discharge occurs in severe acute bacterial infections, whereas mucopurulent discharge appears in mild cases. In gonococcal conjunctivitis, the symptoms are more acute and may present with profuse and purulent exudate, lymphadenopathy, and pseudomembranes.

TABLE 49-3 Common Infections and Inflammatory Disorders of Eye Structures

Disorder	Description	Management
Hordeolum (stye)	Acute suppurative infection of the glands of the eyelids caused by *Staphylococcus aureus*. The lid is red and edematous, with a small collection of pus in the form of an abscess. There is considerable discomfort.	Warm compresses are applied directly to the affected lid area three to four times a day for 10–15 minutes. If the condition is not improved after 48 hours, incision and drainage may be indicated. Application of topical antibiotics may be prescribed thereafter.
Chalazion	Sterile inflammatory process involving chronic granulomatous inflammation of the meibomian glands; can appear as a single granuloma or multiple granulomas in the upper or lower eyelids.	Warm compresses applied three to four times a day for 10–15 minutes may resolve the inflammation in the early stages. Most often, however, surgical excision is indicated. Corticosteroid injection to the chalazion lesion may be used for smaller lesions.
Blepharitis	Chronic bilateral inflammation of the eyelid margins. There are two types: staphylococcal and seborrheic. Staphylococcal blepharitis is usually ulcerative and is more serious due to the involvement of the base of hair follicles. Permanent scarring can result.	The seborrheic type is chronic and is usually resistant to treatment, but the milder cases may respond to lid hygiene. Staphylococcal blepharitis requires topical antibiotic treatment. Instructions on lid hygiene (to keep the lid margins clean and free of exudates) are given to the patient.
Bacterial keratitis	Infection of the cornea by *S. aureus*, *Streptococcus pneumoniae*, and *Pseudomonas aeruginosa*	Fortified (high-concentration) antibiotic eyedrops are administered every 60 minutes around the clock for the first 24–48 hours. When a positive response to treatment is demonstrated, antibiotics may be tapered down to every 2–3 hours for 2 weeks. Systemic antibiotics may be administered to fortify topical antibiotics. Cycloplegics are administered to reduce pain caused by ciliary spasm. Corticosteroid therapy and subconjunctival injections of antibiotics are controversial.
Herpes simplex keratitis	Leading cause of corneal blindness in the United States. Symptoms are severe pain, tearing, and photophobia. The dendritic ulcer has a branching, linear pattern with feathery edges and terminal bulbs at its ends. Herpes simplex keratitis can lead to recurrent stromal keratitis and persist to 12 months, with residual corneal scarring.	Many lesions heal without treatment and residual effects. The treatment goal is to minimize the damaging effect of the inflammatory response and eliminate viral replication within the cornea. Penetrating keratoplasty is indicated for corneal scarring and must be performed when the herpetic disease has been inactive for many months.

Chlamydial conjunctivitis includes trachoma (a bilateral chronic follicular conjunctivitis of childhood that leads to blindness during adulthood if left untreated) and inclusion conjunctivitis. Trachoma is prevalent in areas with hot, dry, and dusty climates, and in areas with poor living conditions. It is spread by direct contact or fomites, and the vectors can be insects such as flies and gnats. Symptoms include red, inflamed eyes, tearing, photophobia, ocular pain, purulent exudates, preauricular lymphadenopathy (anterior to the auricle of the ear), and lid edema. At the middle stage of the disease, an acute inflammation occurs, after which trichiasis (turning inward of hair follicles) and entropion begin to develop, causing corneal erosion and ulceration. The late stage of the disease is characterized by scarred conjunctiva, subepithelial keratitis (inflammation of the cornea), abnormal vascularization of the cornea (pannus), and residual scars from the follicles. Severe corneal ulceration can lead to perforation and blindness.

Inclusion conjunctivitis affects sexually active people who have genital chlamydial infection. Transmission is by oral–genital sex or hand-to-eye transmission. Indirect transmission can occur in inadequately chlorinated swimming pools. The eye lesions usually appear a week after exposure and may be associated with a nonspecific urethritis or cervicitis.

Viral Conjunctivitis

Viral conjunctivitis can be acute and chronic. The discharge is watery, and follicles are

prominent. Severe cases include *pseudomembranes.* Pseudomembranes appear as tissue that covers the conjunctiva or sclera but are actually composed of mucus, fibrin, bacteria, or immune system cells. The common causative organisms are adenovirus and herpes simplex virus. Conjunctivitis caused by adenovirus is highly contagious. The condition is usually preceded by symptoms of upper respiratory infection. Corneal involvement causes extreme photophobia. Symptoms include extreme tearing, redness, and foreign-body sensation that can involve one or both eyes. There is lid edema, ptosis, and conjunctival hyperemia (dilation of the conjunctival blood vessels) (Fig. 49-10). These signs and symptoms vary from mild to severe and may last for 2 weeks. Viral conjunctivitis, although self-limited, tends to last longer than bacterial conjunctivitis.

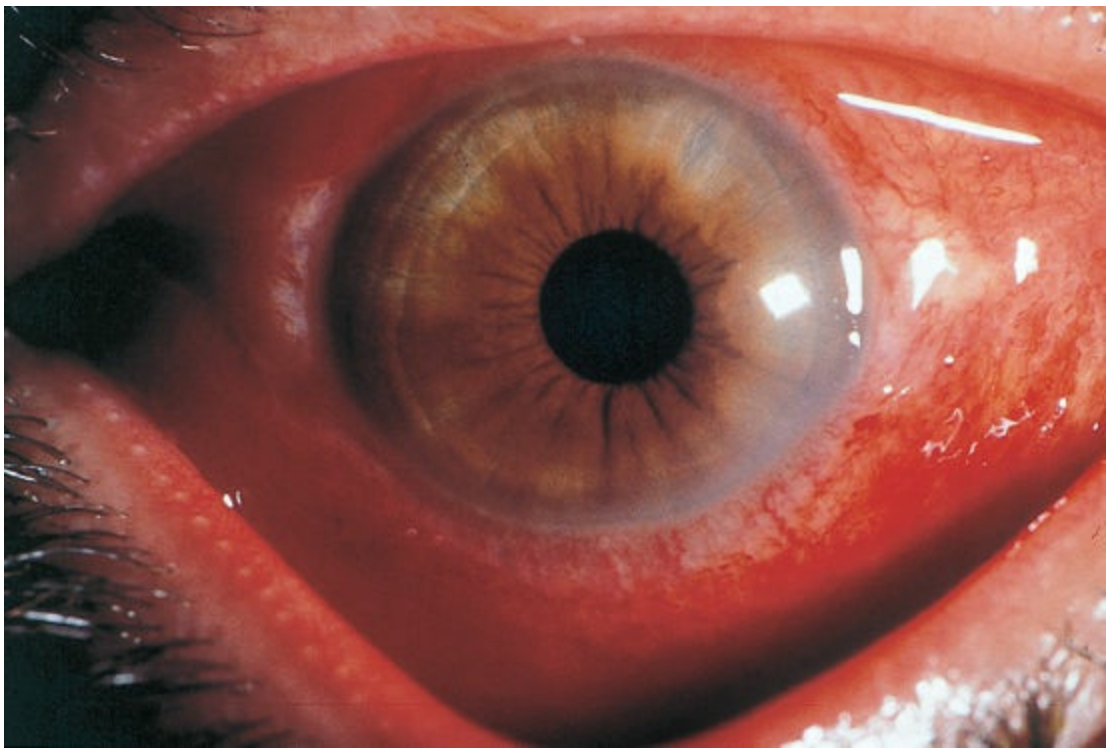

FIGURE 49-10 Conjunctival hyperemia in viral conjunctivitis.

Nursing Alert
The clinical term for hyperemia of the conjunctiva is known as "injected."

Epidemic keratoconjunctivitis (EKC) is a highly contagious viral conjunctivitis that is easily transmitted from one person to another among household members, school children, and health care workers. The outbreak of epidemics is seasonal, especially during the summer, when people use swimming pools. EKC is most often accompanied by preauricular lymphadenopathy and occasionally periorbital pain. EKC can lead to keratopathy (corneal disease).

Allergic Conjunctivitis

Immunologic or allergic conjunctivitis is a hypersensitivity reaction that occurs as part of allergic rhinitis (hay fever), or it can be an independent allergic reaction. Patients often present with a history of atopy, a genetic predisposition toward hypersensitivity reactions.

Atopic conditions include allergies (e.g., food and seasonal), asthma, and atopic dermatitis (e.g., eczema). Allergic conjunctivitis is characterized by extreme pruritus, epiphora (i.e., excessive secretion of tears), injection, and usually severe photophobia. A string-like mucoid discharge is usually associated with rubbing the eyes because of severe pruritus. Vernal conjunctivitis is also known as *seasonal conjunctivitis* because it appears mostly during warm weather.

Toxic Conjunctivitis

Chemical conjunctivitis can be the result of medications; chlorine from swimming pools; exposure to toxic fumes among industrial workers; or exposure to other irritants, such as smoke, hair sprays, acids, and alkalis.

Medical and Nursing Management

The management of conjunctivitis depends on the type (Table 49-4). Most types of mild and viral conjunctivitis are self-limiting, benign conditions that may not require treatment. Box 49-9 includes patient teaching information about viral conjunctivitis. For more severe cases, topical antibiotics, eye drops, or ointments are prescribed. Patients with gonococcal conjunctivitis require urgent antibiotic therapy. If left untreated, this ocular disease can lead to corneal perforation and blindness. The systemic complications can include meningitis and generalized septicemia.

ORBITAL CELLULITIS

Orbital cellulitis is inflammation of the tissues surrounding the eye.

Pathophysiology

Orbital cellulitis may result from bacterial, fungal, or viral inflammatory conditions of contiguous structures, such as the face, oropharynx, dental structures, or intracranial structures. It can also result from foreign bodies and from a pre-existing ocular infection or from generalized septicemia. Infection of the sinuses is the most frequent cause. Infection originating in the sinuses can spread easily to the orbit through the thin bony walls and foramina or by means of the interconnecting venous system of the orbit and sinuses. The most common causative organisms are staphylococci and streptococci in adults and *H. influenzae* in children.

Clinical Manifestations and Assessment

The symptoms include pain, lid swelling, conjunctival edema, proptosis, and decreased ocular motility. With such edema, optic nerve compression can occur and IOP may increase.

The severe intraorbital tension caused by abscess formation and the impairment of optic nerve function in orbital cellulitis can result in permanent visual loss. Because of the orbit's proximity to the brain, orbital cellulitis can lead to life-threatening complications, such as intracranial abscess and cavernous sinus thrombosis.

TABLE 49-4 Management of Conjunctivitis

Conjunctivitis	Management
Bacterial Conjunctivitis	Acute bacterial conjunctivitis is almost always self-limiting, lasting 2 weeks if left untreated. If treated with antibiotics, it may last a few days, except for gonococcal conjunctivitis. Gonococcal conjunctivitis ceases within hours of topical antibiotic therapy and may be discontinued 24 hours after treatment. For trachoma, usually broad-spectrum antibiotics are administered topically and systemically. Surgical management includes the correction of trichiasis (eyelashes growing inward toward the conjunctiva and cornea) to prevent conjunctival scarring. Adult inclusion conjunctivitis requires 1 week of antibiotics. Prevention of reinfection is important, and affected individuals and their sexual partners must seek treatment for sexually transmitted disease, if indicated.
Viral Conjunctivitis	Viral conjunctivitis is not responsive to any treatment. Cold compresses may alleviate some symptoms. It is extremely important to remember that viral conjunctivitis, especially epidemic keratoconjunctivitis, is highly contagious. Patient instructions should include an emphasis on hand hygiene and avoiding sharing of hand towels, face cloths, and eye drops. Tissues should be directly discarded into a covered trash can. All forms of tonometry must be avoided unless medically indicated. All multidose medications must be discarded at the end of each day or when contaminated. Infected employees and others must not be allowed to work or attend school until symptoms have resolved, which can take 3–7 days.
Allergic Conjunctivitis	Patients with allergic conjunctivitis, especially recurrent vernal or seasonal conjunctivitis, are usually given corticosteroids in ophthalmic preparations. Depending on the severity of the disease, they may be given oral preparations. Use of vasoconstrictors, such as topical epinephrine solution, cold compresses, ice packs, and cool ventilation usually provide comfort by decreasing swelling.
Toxic Conjunctivitis	For conjunctivitis caused by chemical irritants, the eye must be irrigated immediately and profusely with saline or sterile water.

Medical and Nursing Management

Immediate administration of high-dose, broad-spectrum, systemic antibiotics is indicated. Cultures and Gram-stained smears are obtained. Monitoring changes in visual acuity, degree of proptosis, central nervous system function (e.g., nausea, vomiting, fever, cognitive changes), displacement of the globe, extraocular movements, pupillary signs, and the fundus is extremely important. Consultation with an otolaryngologist is necessary, especially when sinusitis is suspected. In the event of abscess formation or progressive loss of vision, surgical drainage of the abscess or sinus is performed. Sinusotomy and antibiotic irrigation are also performed.

BOX 49-9 Patient Education

Instructions for Patients with Viral Conjunctivitis

Viral conjunctivitis is a highly contagious eye infection. It can easily spread from one person to another. The symptoms can be alarming, but they are not serious. The following information will help you understand this eye condition and how to take care of yourself and/or your family member at home.

- Your eyes will look red and will have watery discharge, and your lids will be swollen for about a week.
- You will experience eye pain, a sandy sensation in your eye, and sensitivity to light.
- Symptoms will resolve after about 1 week.
- You may use light, cold compresses over your eyes for about 10 minutes four to five times a day to soothe the pain.
- You may use artificial tears for the sandy sensation in your eye, and mild pain medications, such as acetaminophen (Tylenol).
- You need to stay at home. Children must not play outside. You may return to work or school after 7 days, when the redness and discharge have cleared. You may obtain a doctor's note to return to work or school.
- Do not share towels, linens, makeup, or toys.
- Wash your hands thoroughly and frequently, using soap and water, including before and after you apply artificial tears or cold compresses.
- Use a new tissue every time you wipe the discharge from each eye. You may dampen the tissue with clean water to clean the outside of the eye.
- You may wash your face and take a shower as you normally do.
- Discard all of your makeup articles. You must not apply makeup until the disease is over.
- You may wear dark glasses if bright lights bother you.
- If the discharge from your eye turns yellowish and pus-like, or you experience changes

in your vision, you need to return to the health care provider for an examination.

TREATMENT MODALITIES FOR EYE INJURIES AND DISORDERS

Common treatments discussed in this section include surgery and pharmacologic treatment.

SURGICAL PROCEDURES

Orbital Surgeries

Orbital surgeries may be performed to repair fractures, remove a foreign body, or remove benign or malignant growths. The eyeball is lined with muscle, connective, and adipose tissues and is housed in the bony orbit, which is about 4 cm high, wide, and deep. It is shaped roughly like a four-sided pyramid, surrounded on three sides by the sinuses: ethmoid (medially), frontal (superiorly), and maxillary (inferiorly). Surgical procedures involving the orbit and lids affect facial appearance (cosmesis). The goals are to recover and preserve visual function and to maintain the anatomic relationship of the ocular structures to achieve cosmesis. During the repair of orbital fractures, the orbital bones are realigned to follow the anatomic positions of facial structures.

Orbital surgical procedures involve working around delicate structures of the eye, such as the optic nerve, retinal blood vessels, and ocular muscles. Complications of orbital surgical procedures may include blindness as a result of damage to the optic nerve and its blood supply. Sudden pain and loss of vision may indicate intraorbital hemorrhage or compression of the optic nerve. Ptosis and diplopia may result from trauma to the extraocular muscles during the surgical procedure, but these conditions typically resolve after a few weeks.

Prophylaxis with IV antibiotics is the usual postoperative regimen after orbital surgery, especially with repair of orbital fractures and removal of an intraorbital foreign body. IV corticosteroids are used if there is a concern about optic nerve swelling. Topical ocular antibiotics are typically instilled, and antibiotic ointments are applied externally to the skin suture sites.

For the first 24 to 48 hours postoperatively, ice compresses are applied over the periocular area to decrease periorbital swelling, facial swelling, and hematoma. The head of the patient's bed should be elevated to a comfortable position (30 to 45 degrees).

Discharge teaching should include medication instructions for oral antibiotics, instillation of ophthalmic medications, and application of ocular compresses.

Enucleation

Enucleation is the removal of the entire eye and part of the optic nerve. It may be performed for the following conditions:

- Severe injury resulting in prolapse of uveal tissue (iris, ciliary body, and choroid), or loss of light projection (the ability to identify the direction of the light source) or perception
- An irritated, blind, painful, deformed, or disfigured eye, usually caused by glaucoma, retinal detachment, or chronic inflammation
- An eye without useful vision that is producing or has produced sympathetic ophthalmia (inflammation of the eye or conjunctiva) in the other eye
- Intraocular tumors that are untreatable by other means

The procedure for enucleation involves the separation and cutting of each of the ocular muscles, dissection of the Tenon capsule (fibrous membrane covering the sclera), and cutting of the optic nerve from the eyeball. The insertion of an orbital implant typically follows, and the conjunctiva is closed. A large pressure dressing is applied over the area. Box 49-10 discusses ocular prostheses.

Evisceration

Evisceration involves the surgical removal of the intraocular contents through an incision or opening in the cornea or sclera. Evisceration may be performed to treat severe ocular trauma with ruptured globe, severe ocular inflammation, or severe ocular infection. The optic nerve, sclera, extraocular muscles, and sometimes the cornea are left intact. The main advantage of evisceration over enucleation is that the final cosmetic result and motility after fitting the ocular prosthesis are enhanced. This procedure would be more acceptable to a patient whose body image is severely threatened. The main disadvantage is the high risk of sympathetic ophthalmia.

Exenteration

Exenteration is the removal of the eyelids, the eye, and various amounts of orbital contents. It is indicated in malignancies in the orbit that are life-threatening or when more conservative modalities of treatment have failed or are inappropriate. An example is squamous cell carcinoma of the paranasal sinuses, skin, and conjunctiva with deep orbital involvement. In its most extensive form, exenteration may include the removal of all orbital tissues and resection of the orbital bones.

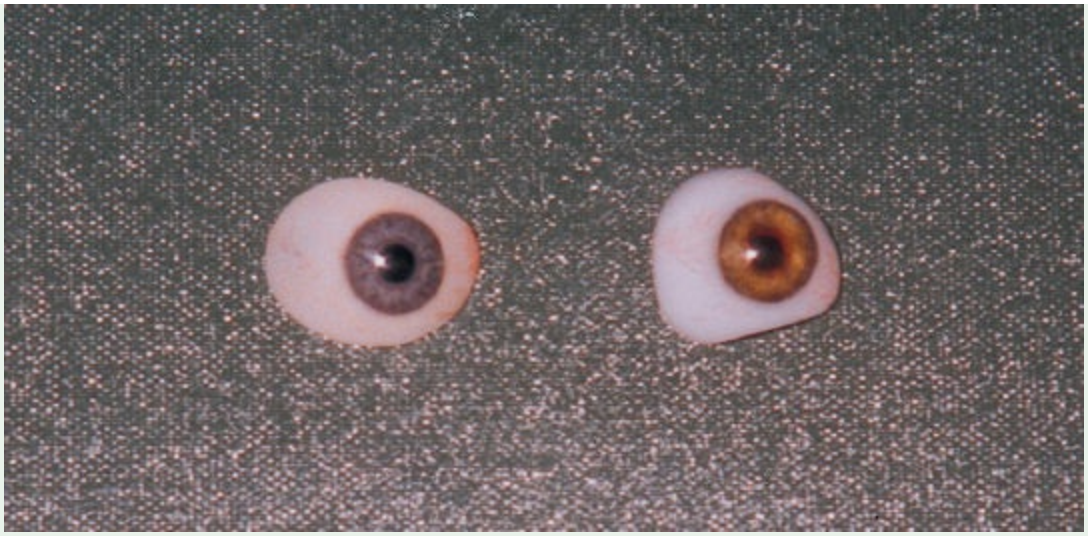
PHARMACOLOGIC TREATMENT

The main objective of ocular medication delivery is to maximize the amount of medication that reaches the ocular site of action in sufficient concentration to produce a beneficial therapeutic effect. This is determined by the dynamics of ocular pharmacokinetics: absorption, distribution, metabolism, and excretion.

BOX 49-10 Ocular Prostheses

Orbital implants and conformers (ocular prostheses usually made of silicone rubber) maintain the shape of the eye after enucleation or evisceration to prevent a contracted, sunken appearance. The temporary conformer is placed over the conjunctival closure after the implantation of an orbital implant. A conformer is placed after the enucleation or evisceration procedure to protect the suture line, maintain the fornices, prevent contracture of the socket in preparation for the ocular prosthesis, and promote the integrity of the eyelids.

All ocular prosthetics have limitations in their motility. There are two designs of eye prostheses (see figure below). The anophthalmic ocular prostheses are used in the absence of the globe. Scleral shells look just like the anophthalmic prosthesis but are thinner and fit over a globe with intact corneal sensation. An eye prosthesis usually lasts about 6 years, depending on the quality of fit, comfort, and cosmetic appearance. When the anophthalmic socket is completely healed, conformers are replaced with prosthetic eyes.



Eye prostheses. (*Left*) Anophthalmic ocular prosthesis. (*Right*) Scleral shell.

An ocularist is a specially trained and skilled professional who makes prosthetic eyes. After the ophthalmologist is satisfied that the anophthalmic socket is completely healed and is ready for prosthetic fitting, the patient is referred to an ocularist. The healing period is usually 6 to 8 weeks. It is advisable for the patient to have a consultation with the ocularist before the fitting. Obtaining accurate information and verbalizing concerns can lessen anxiety about wearing an ocular prosthesis.

Medical Management

Removal of an eye has physical, social, and psychological ramifications for any person. The significance of loss of the eye and vision must be addressed in the plan of care. The patient's preparation should include information about the surgical procedure and placement of orbital implants and conformers and the availability of ocular prosthetics to enhance cosmetic appearance. In some cases, patients may choose to see an ocularist before the surgery to discuss ocular prosthetics.

Nursing Management

Teaching About Postsurgical Care

Patients who undergo eye removal need to know that they will usually have a large ocular pressure dressing, which is typically removed after a week, and that an ophthalmic topical antibiotic ointment is applied in the socket three times daily. When surgical eye removal is immediate and unexpected, as in the case of ocular trauma, the nurse's role in providing emotional support is crucial.

After the removal of an eye, there is a loss of depth perception. Patients must be advised to take extra caution in their ambulation and movement to avoid miscalculations that may result in injury. It may take some time to adjust to monocular vision. Patients using conformers must be advised that the prosthetic may accidentally fall out of the socket. If this happens, the conformer must be washed, wiped dry, and placed back in the socket.

Teaching Patients Self-Care

Patients need to be taught how to insert, remove, and care for the prosthetic eye. Proper hand hygiene must be observed before inserting and removing an ocular prosthesis. A suction cup may be used if there are problems with manual dexterity. Precautions, such as draping a towel over the sink and closing the sink drain, must be taken to avoid loss of the prosthesis. When instructing patients or family members, a return demonstration is important to assess the level of understanding and ability to perform the procedure.

Before insertion, the inner punctal or outer lateral aspects and the superior and inferior aspects of the prosthesis must be identified by locating the identifying marks, such as a reddish color in the inner punctal area. For people with low vision, other forms of identifying markers, such as dots or notches, are used. The upper lid is raised high enough to create a space. The patient slides the prosthesis up, underneath, and behind the upper eyelid. Meanwhile, the patient pulls the lower eyelid down to help put the prosthesis in place and to have its inferior edge fall back gradually to the lower eyelid. The lower eyelid is checked for correct positioning.

To remove the prosthesis, the patient cups one hand on the cheek to catch the prosthesis, places the forefinger of the free hand against the midportion of the lower eyelid, and gazes upward. Gazing upward brings the inferior edge of the prosthesis nearer the inferior eyelid margin. With the finger pushing inward, downward, and laterally against the lower eyelid, the prosthesis slides out, and the patient's cupped hand acts as the receptacle.

Continuing Care

An eye prosthesis can be worn and left in place for several months. Hygiene and comfort are usually maintained with daily irrigation of the prosthesis in place with normal saline solution, hard contact lens solution, or artificial tears. In the case of dry eye symptoms, the use of ophthalmic ointment lubricants or oil-based drops, such as vitamin E and mineral oil, can be helpful. Removing crusting and mucous discharge that accumulate overnight is performed with the prosthesis in place. Malposition may occur when wiping or rubbing the prosthesis in the socket. The prosthesis can be repositioned with the use of clean fingers. Proper wiping of the prosthesis should be a gentle temporal-to-nasal motion to avoid malpositions.

Concepts in Ocular Medication Administration

Topical administration of ocular medications results in only a 1% to 7% absorption rate by the ocular tissues. Ocular absorption involves the entry of a medication into the aqueous humor through the different routes of ocular medication administration. The rate and extent of aqueous humor absorption are determined by the characteristics of the medication and the anatomy and physiology of the eye. Natural barriers of absorption that diminish the efficacy of ocular medications include the following:

- *Limited size of the conjunctival sac.* The conjunctival sac can hold only 50 μL, and any excess is wasted. The volume of one eye drop from commercial topical ocular solutions typically ranges from 20 to 35 μL.
- *Corneal membrane barriers.* The epithelial, stromal, and endothelial layers are barriers to absorption.
- *Blood–ocular barriers.* Blood–ocular barriers prevent high ocular tissue concentration of most ophthalmic medications because they separate the bloodstream from the ocular tissues and keep foreign substances from entering the eye, thereby limiting a medication's efficacy.
- *Tearing, blinking, and drainage.* Increased tear production and drainage due to ocular irritation or an ocular condition may dilute or wash out an instilled eye drop; blinking expels an instilled eye drop from the conjunctival sac.

Distribution of an ocular medication into the various ocular tissues varies by tissue type; the various tissues (e.g., conjunctiva, cornea, lens, iris, ciliary body, choroids) absorb medications to varying degrees. Medications penetrate the corneal epithelium by diffusion by passing through the cells (intracellular) or by passing between the cells (intercellular). Water-soluble (hydrophilic) medications diffuse through the intracellular route, and fat-soluble (lipophilic) medications diffuse through the intercellular route. Topical administration usually does not reach the retina in significant concentrations. Because the space between the ciliary process and the lens is small, medication diffusion in the vitreous is slow. When high concentrations of medication in the vitreous are required, intraocular injection is often chosen to bypass the natural ocular anatomic and physiologic barriers.

Aqueous solutions are most commonly used for the eye. They are the least expensive medications and interfere least with vision. However, corneal contact time is brief because tears dilute the medication. Ophthalmic ointments have extended retention time in the conjunctival sac and provide a higher concentration than eye drops. The major disadvantage of ointments is the blurred vision that results after application. In general, eyelids and eyelid margins are best treated with ointments. Contact lenses and collagen shields soaked in antibiotics are alternative delivery methods for treating corneal infections.

Of all these delivery methods, the topical route of administration—instilled eye drops and applied ointments—remains the most common. Topical instillation, which is the least invasive method, permits self-administration of medication and produces fewer side effects.

Preservatives are commonly used in ocular medications. Benzalkonium chloride, for example, prevents the growth of organisms and enhances the corneal permeability of most

medications; however, some patients are allergic to this preservative. This may be suspected even if the patient had never before experienced an allergic reaction to systemic use of the medication in question. Eye drops without preservatives can be prepared by pharmacists.

Commonly Used Ocular Medications

Common ocular medications include topical anesthetic, mydriatic, and cycloplegic agents that reduce IOP; anti-infective medications, corticosteroids, nonsteroidal anti-inflammatory drugs (NSAIDs), antiallergy medications, eye irrigants, and lubricants.

Topical Anesthetics

One or two drops of proparacaine hydrochloride (Ophthaine 0.5%) and tetracaine hydrochloride (Pontocaine 0.5%) are instilled before diagnostic procedures such as tonometry. Topical anesthetics are also used for severe eye pain, to allow the patient to open his or her eyes for examination or treatment. The nurse must instruct the patient not to rub his or her eyes while anesthetized because this may result in corneal damage.

Patients with corneal abrasions and erosions experience severe pain and are often tempted to overuse topical anesthetic eye drops. Overuse of these drops results in softening of the cornea. Prolonged use of anesthetic drops can delay wound healing and can lead to permanent corneal opacification and scarring, resulting in visual loss.

Mydriatics and Cycloplegics

Mydriasis, or pupil dilation, is the main objective of the administration of mydriatic and cycloplegic agents (Table 49-5). These two types of medications function differently and are used in combination to achieve the maximal dilation that is needed during surgery and fundus examinations to give the ophthalmologist a better view of the internal eye structures. Mydriatics potentiate alpha-adrenergic sympathetic effects that result in the relaxation of the ciliary muscle leading to dilatation of the pupil. The patient may have difficulty reading. The patient is advised to wear sunglasses (most eye clinics provide protective sunglasses). The ability to drive is dependent on the person's age, vision, and comfort level.

TABLE 49-5 Mydriatics and Miotics

Medication	Forms	Indication/Dosages	Action	Duration	Nursing Considerations
Phenylephrine (Dilate, Neofrin)	Solution (0.12%, 2.5%, 10%)	Instill 1 drop per dose and may repeat in 1 hour for: Mydriasis Posterior synechiae and minor eye irritation	Dilates pupil by contracting dilator muscle. Peaks within 10–60 minutes	3–7 hours	Monitor for systemic effects of hypertension if 10% solution is administered.
Atropine (Isopto Atropine)	Ointment (1%) Solution (0.5%–2%)	Instill 1–2 drops for acute iritis, uveitis, or cycloplegic refraction, three to four times daily	Dilates pupil by anticholinergic action. Peaks within 30 minutes–3 hours	7–10 days	Have antidote available, physostigmine salicylate (IM or IV). Watch patient for signs and symptoms of glaucoma.
Scopolamine hydrobromide (Isopto Hyoscine)	Solution (0.25%)	Instill 1–2 drops for acute iritis, uveitis, or cycloplegic refraction, once to four times daily	Same action as atropine Peaks within 15–45 minutes	3–7 days	Observe patient closely for disorientation or delirium. May be given to patients sensitive to atropine.
Pilocarpine hydrochloride (Isopto Carpine)	Gel (4%) Solution (0.25%–1%)	Apply one ribbon of gel into lower conjunctival sac once daily at bedtime. Instill 1–2 drops of solution for open-angle glaucoma, acute angle-closure glaucoma, or mydriasis caused by mydriatic or cycloplegic drugs	Cholinergic effect of pupil constriction (miosis) and deepening of anterior chamber. Peaks within 30–85 minutes	4–8 hours	Monitor vital signs. Monitor drug administration carefully. If taken by mouth, contact poison control center or take patient to ED immediately.

Nursing Alert

Mydriatic and cycloplegic agents affect the central nervous system. Their effects are most prominent in children and elderly patients; these patients must be assessed closely for symptoms, such as increased blood pressure, tachycardia, dizziness, ataxia, confusion, disorientation, incoherent speech, and hallucination. These medications are contraindicated in patients with narrow angles or shallow anterior chambers, and in patients taking monoamine oxidase inhibitors or tricyclic antidepressants.

Antiglaucoma Medications

Therapeutic medications for glaucoma are used to lower IOP by decreasing aqueous production or increasing aqueous outflow. Because glaucoma calls for lifetime therapy, the patient must be instructed regarding both the ocular and systemic side effects of the medications.

Most antiglaucoma medications affect the accommodation of the lens and limit light entry through a constricted pupil. Visual acuity and the ability to focus may be affected. Factors to consider in selecting glaucoma medications are efficacy, systemic and ocular side effects, convenience, and cost.

Anti-Infective Medications

Anti-infective medications include antibiotic, antifungal, and antiviral agents. Most are

available as drops, ointments, or subconjunctival or intravitreal injections. Antibiotics include penicillin, cephalosporins, aminoglycosides, and fluoroquinolones. The main antifungal agent is amphotericin B (Abelcet). Side effects of amphotericin are serious, and include severe pain, conjunctival necrosis, iritis, and retinal toxicity. Antiviral medications include acyclovir (Zovirax) and ganciclovir (Cytovene). Patients receiving ocular agents are subject to the same side effects and adverse reactions as those receiving anti-infective oral or parenteral medications.

Box 49-11 GUIDELINES FOR NURSING CARE

Instilling Eye Medications

Equipment

- Medication(s) as ordered
- Cotton balls or gauze
- Optional: Eye dressing

Implementation

ACTION	RATIONALE
1. Ensure adequate lighting.	1. Adequate lighting ensures the procedure will be carried out using appropriate technique.
2. Perform hand hygiene.	2. Hand hygiene and aseptic technique is important to decrease the risk of contamination of supplies and the spread of further infection.
3. Don clean gloves and, if necessary or required, gently clean any crusts or drainage from the eyelid margins, wiping from the inner to the outer canthus and using a fresh gauze pad or cotton ball moistened with warm water for each stroke.	3. Cleaning the eyes promotes patient comfort and promotes absorption of medications. Additionally, debris is removed from the nasolacrimal duct.
4. Prepare medication. Read the label of the eye medication to make sure it is the correct medication. Shake suspensions or "milky" solutions to obtain the desired medication level. Verify which eye is to be treated.	4. Proper checking of medication and which eye is to be treated is an essential right. Mixing of medication in suspension is required.
5. Assume proper position for instillation of eye medications.	5. Positioning of the patient's head in a supine position or, if sitting, hyperextended in a "sniffing position" allows for proper instillation of ophthalmic medication, particularly drops.
6. Do not touch the tip of the medication container to any part of the eye or face. Hold the lower lid down; do not press on the eyeball. Apply gentle pressure to the cheek bone to anchor the finger holding the lid.	6. Maintaining aseptic technique avoids contamination of materials, such as the medication container. Using the cheek bone as a fulcrum to steady the arm allows for improved medication delivery.
7. Apply medication. Instill eye drops before applying ointments. *For eye drops:* Eye drops should be instilled at a distance of approximately 1 in from the eye. Before instilling the eyedrops, instruct the patient to look up and away. The lower lid is gently pulled down to instill the drops in the conjunctival sac. Immediately after instilling eye drops, apply gentle pressure on the inner canthus (punctal occlusion) near the bridge of the nose for 3–5 minutes. Using a clean tissue, gently pat the skin to absorb excess eyedrops that run onto the patient's cheeks. *For eye ointment:* Apply a ½-in ribbon of ointment to the lower conjunctival sac. Immediately after ointment instillation, ask the patient to roll his or her eyes behind closed lids.	7. Medication is administered into the conjunctival sac, rather than on the eyeball, which can cause discomfort. Gentle pressure on the inner canthus (punctal occlusion) is done to decrease the risk of systemic absorption of the medication. Rolling the eye helps to distribute the medication over the surface of the eyeball.
8. Wait 5 minutes before instilling another eye medication.	8. Allow for absorption of one medication to occur prior to applying another one.
9. Perform hand hygiene.	9. Hand hygiene prevents further contamination post instillation.

Corticosteroids and Nonsteroidal Anti-Inflammatory Drugs

The topical preparations of corticosteroids are commonly used in inflammatory conditions of the eyelids, conjunctiva, cornea, anterior chamber, lens, and uvea. Because these topical eye drops are suspensions, the patient is instructed to shake the bottle several times to promote mixture of the medication and maximize its therapeutic effect. The most common ocular side effects of long-term topical corticosteroid administration are glaucoma, cataracts, susceptibility to infection, impaired wound healing, mydriasis, ptosis, and high IOP. To avoid the side effects of corticosteroids, NSAIDs are used as an alternative in controlling inflammatory eye conditions and postoperatively to reduce inflammation.

Antiallergy Medications

Ocular hypersensitivity reactions are extremely common and result primarily from responses to environmental allergens. Most allergens are airborne or carried to the eye by the hand or by other means, although allergic reactions may also be drug-induced. Corticosteroids are commonly used as anti-inflammatory and immunosuppressive agents to

control ocular hypersensitivity reactions.

Ocular Irrigants and Lubricants

Irrigating solutions are used to cleanse the external lids to maintain lid hygiene, to irrigate the external corneal surface to regain normal pH (e.g., in chemical burns), to irrigate the corneal surface to eliminate debris, or to inflate the globe intraoperatively. These solutions have various compositions (sodium, potassium, magnesium, calcium, bicarbonate, glucose, and glutathione) that are safe to use with an intact corneal surface; however, the corneal surface should not be irrigated in cases of threatened corneal perforation. Sterile irrigating solutions, such as Dacriose, for lid hygiene are available. For patients with severe corneal ulcer, specific orders must be obtained regarding whether it is safe to irrigate the corneal surface or just to cleanse the external lids. Although it is good practice to promote hygiene, prevention of complications must be the primary concern.

Lubricants, such as artificial tears, help alleviate corneal irritation, such as dry eye syndrome. Artificial tears are topical preparations of methyl or hydroxypropyl cellulose that are prepared as eye drop solutions, ointments, or ocular inserts (inserted at the lower conjunctival cul-de-sac once each day).

Nursing Management

The objectives in administering ocular medications are to ensure proper administration to maximize the therapeutic effects and to ensure the safety of the patient by monitoring for systemic and local side effects. Absorption of eye drops by the nasolacrimal duct is undesirable because of the potential systemic side effects of ocular medications. To diminish systemic absorption and minimize the side effects, it is important to occlude the puncta (Box 49-11).

Before the administration of ocular medications, the nurse warns the patient that blurred vision, stinging, and a burning sensation are symptoms that ordinarily occur after instillation and are temporary. Risk for interactions of the ocular medication with other ocular and systemic medications must be emphasized; therefore, a careful patient interview regarding the medications being taken must be obtained.

Emphasis must be placed on hand hygiene techniques before and after medication instillation. The tip of the eye drop bottle or the ointment tube must never touch any part of the patient's eye. The medication must be recapped immediately after each use. The patient or the caregiver at home should be asked to demonstrate actual eye drop or ointment instillation and punctal occlusion.

CHAPTER REVIEW

Critical Thinking Exercises

1. You are employed in an eye clinic in which the majority of patients are elderly, and the majority of medications that are prescribed for these patients are topical agents. Develop an evidence-based teaching plan for patients and caregivers that provides instructions in the proper administration of ocular drops and ointments. What evidence supports the medication administration techniques and associated safety precautions that you have included in the teaching plan? What evidence supports the principles of learning that you considered regarding the elderly population that the clinic serves? What is the strength of the evidence? What criteria would you use to determine the strength of the evidence?

2. In the emergency department, you are caring for a man who has been involved in a motor vehicle crash in which there was a broken windshield. He states that he has a headache and a stiff neck, that his vision is "blurry," and that he has a "scratching pain" in his right eye. He requests a cold compress for his eyes. How would you respond to this patient's request? What diagnostic tests do you anticipate would be used to determine the cause for the patient's symptoms of blurred vision and pain in the eye? What information would you communicate to the health care provider?

NCLEX-Style Review Questions

1. When the nurse is gathering a history from a patient newly diagnosed with glaucoma,

the patient reports the following statement to the nurse. Which statement would be consistent with the patient's diagnosis?

a. "I began seeing halos around lights and had dim vision."
b. "I had a difficult time matching my blue socks."
c. "My eyes began to tear and itch."
d. "I could see the street signs better than my hand."

2. Which statement by the patient diagnosed with viral conjunctivitis indicates that more teaching is necessary?

a. "I will wash my hands frequently."
b. "I will use a washcloth to clean both my eyes, starting with the infected eye and moving to the uninfected eye."
c. "I will avoid contact with other people until my symptoms are gone."
d. "I will discard any leftover eye medication when the infection is gone."

3. The nurse is caring for a baseball player who reports getting hit in the head with a baseball 1 hour prior to admission in the ED. What assessment requires immediate reporting?

a. Eye pain
b. Flashing lights in the visual field
c. Headache, pain intensity rated as 2/10
d. Superficial head abrasion

4. The patient with significant visual impairment requires assistance with ADLs. The nurse provides support when serving food by performing which action?

a. Leaving the tray on the patient's bedside table
b. Serving hot food as quickly as possible
c. Describing the food on the tray in terms of the face of a clock
d. Ensuring all food is soft

5. A patient, who is seen in the vision clinic, has been diagnosed with glaucoma. What initial topical medication would the nurse expect to be included in the treatment plan for this patient?

a. Mydriatic
b. Antifungal
c. Beta blocker
d. Miotic

CHAPTER 50

Nursing Management: Patients with Hearing and Balance Disorders

Carolynn Spera Bruno

Learning Objectives

After reading this chapter, you will be able to:

1. List the manifestations that may be exhibited by a person with a hearing disorder.
2. Identify ways to communicate effectively with a person with a hearing disorder.
3. Differentiate problems of the external ear from those of the middle ear and inner ear.
4. Compare the various types of surgical procedures used for managing middle ear disorders and appropriate nursing care.
5. Describe the different types of inner ear disorders, including the clinical manifestations, diagnosis, and management.

The delicate structure and function of the ear make early detection and accurate diagnosis of disorders necessary for preservation of normal hearing and balance. Medical surgical nurses will care for patients with hearing loss because of a wide variety of reasons. This chapter addresses the assessment and management of hearing and balance disorders common to the adult population.

HEARING LOSS

More than 36 million people in the United States report some form of hearing loss. *Healthy People 2010* initiated a goal to promote the hearing health of the nation through prevention, early detection, treatment, and rehabilitation.

Pathophysiology

Hearing loss may be the result of a conduction problem, a sensorineural loss, mixed, or of a psychogenic issue. Conductive hearing loss usually results from an external ear disorder, such as impacted cerumen, or a middle ear disorder, such as otitis media or otosclerosis. In such instances, the efficient transmission of sound by air to the inner ear is interrupted. A sensorineural loss involves damage to the cochlea or vestibulocochlear nerve. Patients with mixed hearing loss have conductive loss and sensorineural loss, resulting from dysfunction of air and bone conduction. A functional (or psychogenic) hearing loss is nonorganic and unrelated to detectable structural changes in the hearing mechanisms; it is usually a manifestation of an emotional disturbance.

Many environmental factors have an adverse effect on the auditory system and gradually result in permanent sensorineural hearing loss. The most common is noise (unwanted and unavoidable sound), which has been identified as one of today's environmental hazards. The volume of noise that surrounds us daily has increased into a potentially dangerous source of physical and psychological damage.

Risk Factors

About 5% of the world population suffers from disabling hearing loss with prevalence increasing with every age decade, and it is higher in men than in women across all age decades (Baloh & Jen, 2016). Box 50-1 summarizes risk factors.

The National Institutes of Deafness and Other Communication Disorders (NIDCD) estimates that approximately 15% (26 million) of Americans between 20 and 69 years of age have high-frequency hearing loss due to exposure to loud sounds or noise at work or in leisure activities. *Noise-induced hearing loss* (NIHL) refers to hearing loss that follows a long period of exposure to loud noise (e.g., heavy machinery, engines, artillery). Occupations such as carpentry, plumbing, and coal mining have the highest risk of noise-induced hearing loss. Recreational activities, such as listening to loud sounds through earbuds or headphones or exposure to loud concerts, as well as exposure to leaf blowers or lawnmowers can place people at risk for NIHL.

Box 50-1 Risk Factors for Hearing Loss

- Family history of sensorineural impairment
- Congenital malformations of the cranial structure (ear)
- Low birth weight (less than 1,500 g)
- Use of ototoxic medications (e.g., gentamicin, loop diuretics)
- Recurrent ear infections
- Bacterial meningitis
- Chronic exposure to loud noises
- Chronic exposure to loud volume using headphones or earbuds
- Perforation of the tympanic membrane

Acoustic trauma refers to hearing loss caused by a single exposure to an extremely intense noise, such as an explosion. Usually, noise-induced hearing loss occurs at a high frequency (about 4,000 Hz). However, with continued noise exposure, the hearing loss can become more severe and include adjacent frequencies. The minimum noise level known to cause NIHL, regardless of duration, is about 85 to 90 dB.

Noise exposure is inherent in many jobs (e.g., mechanics, printers, pilots, musicians) and in hobbies, such as woodworking and hunting. The Occupational Safety and Health Administration requires that workers wear ear protection to prevent noise-induced hearing loss when exposed to noise above the legal limits. Ear protection against noise is the most effective preventive measure available. There are no medications that protect against NIHL; hearing loss is permanent because the hair cells in the organ of Corti are destroyed.

Clinical Manifestations and Assessment

Early manifestations of hearing impairment and loss may include tinnitus, increasing inability to hear when in a group, and a need to turn up the volume of the television. Hearing impairment can also trigger changes in attitude, the ability to communicate, the awareness of surroundings, and even the ability to protect oneself, affecting a person's quality of life. In a classroom, a student with impaired hearing may be uninterested, inattentive, and have failing grades. A person at home may feel isolated because of an inability to hear the clock chime, the refrigerator hum, the birds sing, or the traffic pass. A pedestrian who is hearing-impaired may attempt to cross the street and fail to hear an approaching car. People with impaired hearing may miss parts of a conversation. Many people are unaware of their gradual hearing impairment. Often, it is not the person with the hearing loss but the people with whom he or she is communicating who recognize the impairment first (Box 50-2).

For various reasons, some people with hearing loss refuse to seek medical attention or wear a hearing aid. Others feel self-conscious wearing a hearing aid. Insightful people generally ask those with whom they are trying to communicate to let them know whether difficulties in communication exist. These attitudes and behaviors should be taken into account when counseling patients who need hearing assistance. The decision to wear a hearing aid is a personal one that is affected by these attitudes and behaviors.

BOX 50-2 Focused Assessment

Hearing Loss

Be on the alert for the following signs and symptoms:

- *Speech deterioration:* The person who slurs words or drops word endings, or produces flat-sounding speech, may not be hearing correctly. The ears guide the voice, both in loudness and in pronunciation.
- *Fatigue:* If a person tires easily when listening to conversation or to a speech, fatigue may be the result of straining to hear. Under these circumstances, the person may become irritable very easily.
- *Indifference:* It is easy for the person who cannot hear what others say to become depressed and disinterested in life in general.
- *Social withdrawal:* Not being able to hear what is going on causes a person who is hearing-impaired to withdraw from situations that might prove embarrassing.
- *Insecurity:* Lack of self-confidence and fear of mistakes create a feeling of insecurity in many people who are hearing-impaired. No one likes to say the wrong thing or do anything that might appear foolish.
- *Indecision and procrastination:* Loss of self-confidence makes it increasingly difficult for a person who is hearing-impaired to make decisions.
- *Suspiciousness:* The person who is hearing-impaired, who often hears only part of what is being said, may suspect that others are talking about him or her or that

portions of the conversation are deliberately spoken softly so that he or she will not hear them.

- *False pride:* The person who is hearing-impaired wants to conceal the hearing loss and thus often pretends to be hearing when he or she actually is not.
- *Loneliness and unhappiness:* Although everyone wishes for quiet now and then, *enforced* silence can be boring and even somewhat frightening. People with a hearing loss often feel isolated.
- *Tendency to dominate the conversation:* Many people who are hearing-impaired tend to dominate the conversation, knowing that as long as it is centered on them and they can control it, they are not so likely to be embarrassed by some mistake.

Gerontologic Considerations 

With aging, changes occur in the ear that may eventually lead to hearing deficits. Although few changes occur in the external ear, cerumen tends to become harder and drier, posing a greater chance of impaction. In the middle ear, the tympanic membrane may atrophy or become sclerotic. In the inner ear, cells at the base of the cochlea degenerate. A familial predisposition to sensorineural hearing loss is also seen, manifested by inability to hear high-frequency sounds, followed in time by the loss of middle and lower frequencies. The term presbycusis is used to describe this progressive hearing loss.

In addition to age-related changes, other factors can affect hearing in older adults, such as lifelong exposure to loud noises (e.g., jets, guns, heavy machinery, circular saws). Certain medications, such as aminoglycosides and aspirin, have ototoxic effects when kidney changes (e.g., in the older person) result in delayed medication excretion and increased levels of the medications in the blood. Although the use of quinine for treatment of leg cramps has been banned by the FDA, it was widely used and is found in lower quantities in tonic water. Quinine can cause ringing in the ears or hearing loss. Psychogenic factors and other disease processes (e.g., diabetes) also may be partially responsible for sensorineural hearing loss.

When hearing loss occurs, proper evaluation and treatment are warranted. *Healthy People 2010* identified eight objectives for decreasing the problems caused by hearing loss. One of these objectives for people diagnosed with hearing loss or deafness is to use rehabilitation services and supplemental devices to improve communication with other people. *Healthy People 2020 provide specific target measures for addressing hearing disorder objectives.* Resources are available in workplaces and in schools. The Individuals with Disabilities Education Act (IDEA) was developed to ensure that children and adults, including elderly adults, receive the same opportunities in the educational system as those without hearing impairment.

Care of elderly patients includes recognizing emotional reactions related to hearing loss, such as suspicion of others because of an inability to hear adequately; frustration and anger, with repeated statements such as, "I didn't hear what you said"; and feelings of insecurity because of the inability to hear the telephone or alarms. The Americans with Disabilities Act (ADA) of 1990 required that all emergency services are accessible to people who have text message telephones (TTYs). In addition, in 1998, the Department of Justice mandated that all 911 centers in the United States be accessible to people with Text Telephone (TTYs).

Medical Management

Implanted Hearing Devices

Three types of implanted hearing devices are commercially available: semi-implantable hearing device, fully implantable device, and the cochlear implant, the bone conduction device. Cochlear implants are for patients with little or no hearing and are discussed below. Bone conduction devices, which transmit sound through the skull to the inner ear, are used in patients with a conductive hearing loss if a hearing aid is contraindicated (e.g., those with chronic infection). The device is implanted postauricularly under the skin into the skull, and an external device—worn above the ear, not in the canal—transmits the sound through the skin. Currently there are two types of implantable hearing aid devices, semi-implantable and fully implantable. Semi-implantable devices consist of a magnetic component that is implanted in the auditory ossicle, a receiver and a sound processor. Whereas, fully implantable middle ear devices consist of a sensor, sound processor along with a driver that is connected to the auditory ossicle.

The bone-anchored hearing aid (BAHA) may be fully or partially implantable. It is surgically implanted behind the ear in the mastoid area. The middle ear implantation (MEI) is implanted in the middle ear cavity and designed to move the bones directly rather than only amplifying sound. The BAHA is used for conductive or mixed hearing loss or unilateral sensorineural hearing loss, while the MEI is used for moderate to severe sensorineural hearing loss.

Cochlear Implant

A cochlear implant is an auditory prosthesis used for people with profound bilateral sensorineural hearing loss who do not benefit from conventional hearing aids. The hearing loss may be congenital or acquired. An implant does not restore normal hearing; rather, it amplifies sound so the person detects medium to loud environmental sounds and conversation. The implant provides stimulation directly to the auditory nerve, bypassing the nonfunctioning hair cells of the inner ear. The microphone and signal processor, worn outside the body, transmit electrical stimuli to the implanted electrodes. The electrical signals stimulate the auditory nerve fibers and then the brain, where they are interpreted.

Candidates for a cochlear implant, who are usually at least 1 year of age, are selected after careful screening by otologic history, physical examination, audiologic testing, x-rays, and psychological testing. Children who receive cochlear implants prior to 18 months of age achieve the greatest hearing, appreciation of sound and music, and development of speech as compared to older children who receive the implants (NIDCD, 2014). Criteria for choosing adults who may benefit from a cochlear implant include the following:

- Profound sensorineural hearing loss in both ears
- Inability to hear and recognize speech well with hearing aids
- No medical contraindication to a cochlear implant or general anesthesia
- Indications that being able to hear would enhance the patient's life (some candidates who are deaf do not view themselves as having a disability that needs to be cured)

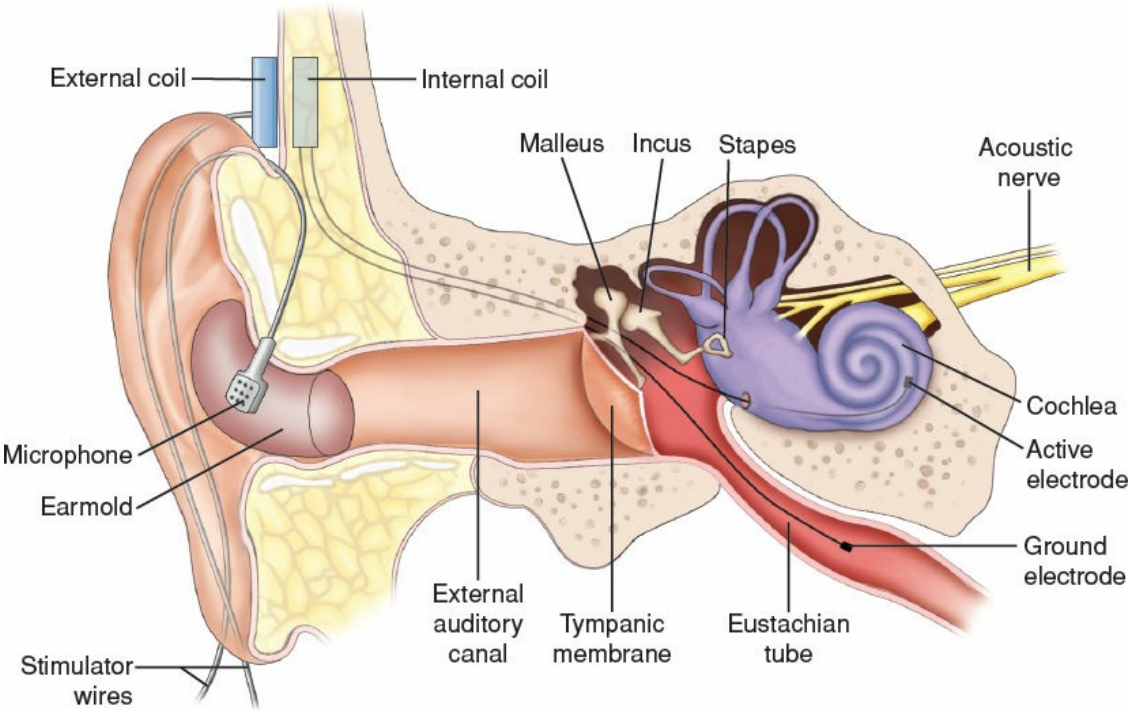

FIGURE 50-1 The cochlear implant. The internal coil has a stranded electrode lead. The electrode is inserted through the round window into the scala tympani of the cochlea. The external coil (the transmitter) is held in alignment with the internal coil (the receiver) by a magnet. The microphone receives the sound. The stimulator wire receives the signal after it has been filtered, adjusted, and modified so that the sound is at a comfortable level for the patient. Sound is passed by the external transmitter to the inner coil receiver by magnetic conduction and then is carried by the electrode to the cochlea.

Concept Mastery Alert

Conductive hearing loss is not an indication for cochlear implants. People with profound bilateral sensorineural hearing loss who do not benefit from conventional hearing aids do qualify as candidates for cochlear implants.

The surgery involves implanting a small receiver in the temporal bone through a postauricular incision and placing electrodes into the inner ear (Fig. 50-1). The microphone and transmitter are worn on an external unit. The patient undergoes extensive cochlear rehabilitation with the multidisciplinary team, which includes an audiologist and speech pathologist. Several months may be needed to learn to interpret the sounds heard. Children and adults who lost their hearing before they learned to speak take much longer to acquire speech. There are wide variations of success with cochlear implants, and there is also controversy about their use, especially among the Deaf community. Patients who have had a cochlear implant are cautioned that magnetic resonance imaging (MRI) will inactivate the implant; MRI is to be used only when there is no other diagnostic option.

Aural Rehabilitation

If hearing loss is permanent or cannot be treated by medical or surgical means, or if the patient elects not to undergo surgery, aural rehabilitation may be beneficial. The purpose of aural rehabilitation is to maximize the communication skills of the person with hearing

impairment. Aural rehabilitation includes auditory training, speech reading, speech training, and the use of hearing aids and hearing guide dogs.

Auditory training emphasizes listening skills so the person who is hearing-impaired concentrates on the speaker. Speech reading (formerly known as *lip reading*) can help fill the gaps left by missed or misheard words. The goals of speech training are to conserve, develop, and prevent deterioration of current communication skills.

It is important to identify the type of hearing impairment a person has so that rehabilitative efforts can be directed at his or her particular need. Surgical correction may be all that is necessary to treat and improve a conductive hearing loss by eliminating its cause. With advances in hearing aid technology, amplification for patients with sensorineural hearing loss is more helpful than ever.

Hearing Aids

A hearing aid is a device through which speech and environmental sounds are received by a microphone, converted to electrical signals, amplified, and reconverted to acoustic signals. Many aids available for sensorineural hearing loss depress the low frequencies, or tones, and enhance hearing for the high frequencies. The evolution in technology has led to the availability of many smaller and more effective hearing aids. It is estimated that 98% of all hearing aids sold today are behind-the-ear, in-the-ear, or in-the-canal types (Table 50-1).

A hearing aid should be fitted according to the patient's needs (e.g., type of hearing loss, manual dexterity, and preferences) by a certified audiologist licensed to dispense hearing aids. Many states have consumer protection laws that allow the hearing aid to be returned after a trial use if the patient is not completely satisfied.

A hearing aid makes sounds louder, but it does not improve a patient's ability to discriminate words or understand speech. People who have low discrimination scores (i.e., 20%) on audiograms may derive little benefit from a hearing aid. Hearing aids amplify all sounds, including background noise, which may be disturbing to the wearer. Box 50-3 identifies additional problems associated with hearing aid use. Computerized hearing aids are available to compensate for background noise or allow amplification at certain programmed frequencies rather than at all frequencies. Occasionally, depending on the type of hearing loss, binaural aids (i.e., one for each ear) may be indicated. Box 50-4 provides tips for hearing aid care.

TABLE 50-1 Hearing Aids

Site (and Range of Hearing Loss)	Advantages	Disadvantages
Body, usually on the trunk (mild–profound)	Separation of receiver and microphone prevents acoustic feedback, allowing high amplification. Generally used in a school setting.	Bulky; requires long wire, which may be cosmetically displeasing; some loss of high-frequency response.
Behind the ear (mild–profound)	Economical; powerful, with no long wires; easily used by children—adapts easily as the child grows, with only the ear mold needing replacement.	Large size, are visible.
In the ear (mild–moderately severe)	The in-the-ear (ITE) is custom molded fitting within the outer ear or partially filling the lower outer ear. One-piece custom fit to contour of ear; no tubes or cords; miniature microphone is located in the ear, which is a more natural placement; more cosmetically appealing due to easy concealment.	Smaller size limits output; patients who have arthritis or cannot perform tasks requiring good manual dexterity may have difficulty with the small size of the aid and/or its battery; can require more repair than the behind-the-ear aid.
In the canal (mild–moderately severe)	In-the-canal (ITC) are custom molded to fit partially in the ear canal and are less visible; completely-in-canal (CIC) or the mini CIC is molded to fit inside the ear canal and is the smallest and least visible type, so more cosmetically pleasing.	Smaller aids require good manual dexterity. CICs are prone to earwax building up and dampening the speaker. Small batteries have a short life and are difficult to handle. There is no volume control.

Hearing Guide Dogs

Specially trained service dogs are available to assist the person with a hearing loss. People who live alone are eligible to apply for a dog trained by, for example, International Hearing Dog, Inc. The dog reacts to the sound of a telephone, a doorbell, an alarm clock, a baby's cry, a knock at the door, a smoke alarm, or an intruder. The dog alerts its handler by physical contact; the dog then runs to the source of the noise. In public, the dog positions itself between the person with hearing impairment and any potential hazard that the person cannot hear, such as an oncoming vehicle or a loud, hostile person. In most states, a certified hearing guide dog is legally permitted access to public transportation, public eating places, and stores, including food markets.

BOX 50-3 Hearing Aid Problems

Improper Aid Selection

Consumers often find they cannot adjust to the hearing aid, but there are many hearing aids on the market to choose from. One consideration is sound amplification. The amplifier is a transformer that increases the amplitude of the electrical signal sent to the receiver. The receiver takes the sound and transmits it to the ear. A mismatch between receiver and amplifier increases sound distortion and may become intolerable to patients. The open mold provides a full shell or half shell instrument. Aids need to transmit sound well, fit comfortably, and be aesthetically pleasing.

Inadequate Amplification

- Dead batteries
- Cerumen in ear
- Cerumen or other material in mold

- Wires or tubing disconnected from aid
- Aid turned off or volume too low
- Improper mold
- Improper aid for degree of loss

Pain from Mold

- Improperly fitted mold
- Ear skin or cartilage infection
- Middle ear infection
- Ear tumor
- Unrelated conditions of the *temporomandibular* joint, throat, or larynx

Whistling Noise

- Loose ear mold
- Improperly made
- Improperly worn
- Worn out

BOX 50-4 Patient Education

Tips for Hearing Aid Care

Cleaning

- Behind the ear (BTE) hearing aids may be washed infrequently using soap and water. Ensure that the device is dried thoroughly after cleaning.
- It is recommended to use a soft, cotton cloth to clean and remove dried cerumen for most hearing aid devices, such as in-the-ear hearing aids (ITE).
- Many hearing aid manufacturers advertise online information including cleaning directions.
- Clean the cannula with a small pipe cleaner-like device.
- Prevent complications by proper care of the ear device and keeping the ear canal clean and dry.

Malfunctioning

Inadequate amplification, a whistling noise, or pain from the mold can occur when a hearing aid is not functioning properly.

- Check for malfunctions:
  - Is the switch on properly?
  - Are the batteries charged and positioned correctly?

- If the hearing aid is still not working properly, notify the hearing aid dealer.
- If the unit requires extended time for repair, the dealer may lend you a hearing aid until the repair can be accomplished.

Recognizing Complications

Common medical complications include external otitis media and pressure ulcers in the external auditory canal.

- Be alert for signs and symptoms of these infections, including painful ear, especially when the external ear is touched, canal swelling, redness, difficulty hearing, pain radiating to the jaw area, and fever.
- If any of these symptoms are present, notify your health care provider for evaluation. You may need medication to treat infection, pain, or both.

Nursing Management

Communicating Effectively

Nurses who understand the different types of hearing loss are more successful in adopting a communication style to fit the needs and preferences of every patient. Trying to speak in a loud voice to a person who cannot hear high-frequency sounds only makes understanding more difficult. However, strategies such as talking into the less-impaired ear and using gestures and facial expressions can help (Box 50-5).

A major issue for many people who are deaf or hearing-impaired is that they have other health problems that often do not receive attention, in large part because of communication barriers with their health care practitioners and the physical environment. The American Disabilities Act and Section 504 of the 1973 Rehabilitation Act mandates that people with disabilities have access to health care facilities and programs, thereby reducing disparity among individuals who are sensory and physically impaired. To meet the health care needs of patients who are hearing-impaired, practitioners are legally obligated to make accommodations for a patient's inability to hear. Providing interpreters for those who can communicate through sign language is essential in many situations so that the practitioner can effectively communicate with the patient.

During health care and screening procedures, the health care practitioner must be aware that patients who are deaf or hearing-impaired have certain limitations. They are unable to read lips, see a signer, or read written materials in the dark rooms required during some diagnostic tests. The same situation exists if the practitioner is wearing a mask or is not in the direct line of vision. Nurses and other health care practitioners must work with patients who are deaf or hearing-impaired and their families to identify practical and effective means of communication and to ensure accommodations are made. Refer to agency protocols for assistance when communicating with individuals who are hearing-impaired during a health care visit.

Maintaining a Quiet Environment

Loud, persistent noise has been found to cause constriction of peripheral blood vessels, increased blood pressure and heart rate (because of increased secretion of adrenalin), and increased gastrointestinal activity, as well as disturb patterns of sleep. Although research is needed to address the overall effects of noise on the human body, a quiet environment is more conducive to peace of mind (Box 50-6). A person who is ill feels more at ease when noise is kept to a minimum. The World Health Organization set noise guidelines for hospitals since noise negatively affect patient outcomes and staff performance (Berglund, Lindvall, & Schwela, 1999). Infrastructure designs, such as noiseless call bell systems and sound-masking floors and walls, represent attempts to decrease noise in hospitals.

CONDITIONS OF THE EXTERNAL EAR

CERUMEN IMPACTION

Cerumen normally accumulates in the external canal in various amounts and colors. Although wax does not usually need to be removed, impaction occasionally occurs.

BOX 50-5 Communicating with People Who are Hearing-Impaired

For the person who is hearing-impaired whose speech is difficult to understand:

- Consider how the person prefers to communicate with others. Do not assume that writing, gestures, or other means are the best or preferred technique.
- Consider if the person uses sign language. Interpreters are available in person or by video from the American Sign Language Inc., Interpreting Service (ASLI). These specialists provide the best means of communication, and provide accurate, professional services.
- Devote full attention to what the person is saying. Look and listen—do not try to attend to another task while listening.
- Engage the speaker in conversation when it is possible for you to anticipate the replies. This enables you to become accustomed to any peculiarities in speech patterns.
- Try to determine the essential context of what is being said; you can often fill in the details from context.
- Do not try to appear as if you understand if you do not.
- If you cannot understand at all or have serious doubt about your ability to understand what is being said, have the person write the message rather than risk misunderstanding. Having the person repeat the message in speech, after you know its content, also aids you in becoming accustomed to the person's pattern of speech.
- Written communication is an excellent resource. Written material should be written at a third-grade level so that the majority of people can understand it.

For the person who is hearing-impaired who speech reads:

- If you need to get the patient's attention, wave your hand in front of his or her visual field.
- When speaking, always face the person and smile.
- Make sure your face is as clearly visible as possible. Locate yourself so that your face is well lighted; avoid being silhouetted against strong light. Do not obscure the person's view of your mouth in any way; avoid talking with any object held in your mouth.
- Be sure that the patient knows the topic or subject before going ahead with what you

plan to say. This enables the person to use contextual clues in speech reading.

- Speak slowly and distinctly, pausing more frequently than you would normally.
- If you question whether some important direction or instruction has been understood, check to be certain that the patient has the full meaning of your message.
- If for any reason your mouth must be covered (as with a mask), and you must direct or instruct the patient, write the message.

Clinical Manifestations and Assessment

Impaction causes otalgia, a sensation of fullness or pain in the ear, with or without a hearing loss. Accumulation of cerumen as a cause of hearing loss is especially significant in the older population. Attempts to clear the external auditory canal with cotton-tipped applicators, matches, hairpins, and other implements are dangerous because trauma to the skin, infection, and damage to the tympanic membrane can occur.

Medical and Nursing Management

Cerumen can be removed by irrigation, suction, or instrumentation. Unless the patient has a perforated eardrum or an inflamed external ear (i.e., otitis externa), gentle irrigation with tap water usually helps remove impacted cerumen, particularly if it is not tightly packed into the external auditory canal. For successful removal, the water stream must flow behind the obstructing cerumen to move it first laterally and then out of the canal. To prevent injury, the lowest effective pressure should be used. However, if the eardrum behind the impaction is perforated, water can enter the middle ear, producing acute pain, vertigo and infection. If irrigation is unsuccessful, a trained health care provider can perform direct visual, mechanical removal on a cooperative patient.

BOX 50-6 Nursing Research

Bridging the Gap to Evidence-Based Practice

Darbyshire, J., & Young, J. (2013). An investigation of sound levels on intensive care units with reference to the WHO guidelines. *Darbyshire and Young Critical Care, 17*, R187. Retrieved from http://ccforum.com/content/17/5/R18

Purpose

Patients in intensive care units (ICUs) suffer from sleep deprivation arising from nursing interventions and ambient noise. This may exacerbate confusion and ICU-related delirium. The World Health Organization (WHO) suggests that average hospital sound levels should not exceed 35 dB with a maximum of 40 dB overnight. The authors monitored five ICUs to check compliance with these guidelines.

Design

Sound levels were recorded in five adult ICUs in the United Kingdom. Two sound level monitors recorded concurrently for 24 hours at the ICU central stations and adjacent to patients. Sample values to determine levels generated by equipment and external noise were also recorded in an empty ICU side room.

Findings

Average sound levels always exceeded 45 dBA and, for 50% of the time, exceeded between 52 and 59 dBA in individual ICUs. There was diurnal variation with values decreasing after evening handovers to an overnight average minimum of 51 dBA at 4 am. Peaks above 85 dBA occurred at all sites, up to 16 times per hour overnight and more frequently during the day. WHO guidelines on sound levels could be achieved only in a side room by switching off all equipment.

Nursing Implications

All ICUs had sound levels greater than WHO recommendations, but the WHO recommended levels are so low, they are not achievable in an ICU. Levels adjacent to patients are higher than those recorded at central stations. Unit-wide noise reduction

programs or mechanical means of isolating patients from ambient noise, such as earplugs, should be considered.

Instilling a few drops of warmed glycerin, mineral oil, or half-strength hydrogen peroxide into the ear canal for 30 minutes can soften cerumen before its removal. Ceruminolytic agents, such as peroxide in glyceryl (Debrox), are available; however, these compounds may cause an allergic dermatitis reaction. Using any softening solution two or three times a day for several days is generally sufficient. If the cerumen cannot be dislodged by these methods, instruments, such as an ear curette, aural suction, and a binocular microscope for magnification, can be used by a provider with specialized training.

FOREIGN BODIES

Objects may be inserted into the ear canal by children. Occasionally, beads or parts to toys are found in the external ear canal. Some objects are inserted intentionally into the ear by adults who may have been trying to clean the external canal or relieve itching. Insects may also enter the ear canal. In either case, the effects may range from no symptoms to profound pain and decreased hearing.

Removing a foreign body from the external auditory canal can be quite challenging, and in unskilled hands may be dangerous. The object may be pushed completely into the bony portion of the canal, lacerating the skin and perforating the tympanic membrane. The three standard methods for skilled practitioners to remove foreign bodies are the same as those for removing cerumen: irrigation, suction, and instrumentation. The contraindications for irrigation are also the same. Foreign vegetable bodies and insects tend to swell; thus, irrigation is contraindicated. Usually, an insect can be dislodged by instilling mineral oil, which will suffocate the insect and allow it to be removed using alligator forceps or a loop-wired instrument. A referral to a specialist in Ears, Eyes, Nose Throat may be indicated. In some circumstances, the foreign body may have to be extracted in the operating room with the patient under general anesthesia.

CONDITIONS OF THE MIDDLE EAR

TYMPANIC MEMBRANE PERFORATION

Perforation of the tympanic membrane is usually caused by infection or trauma. Sources of trauma include skull fracture, explosive injury, or a severe blow to the ear. Less frequently, perforation is caused by foreign objects (e.g., cotton-tipped applicators, bobby pins, keys) that have been pushed too far into the external auditory canal. In addition to tympanic membrane perforation, injury to the ossicles and even the inner ear may result; thus, attempts by patients to clear the external auditory canal should be discouraged. During infection, the tympanic membrane can rupture if the pressure in the middle ear exceeds the atmospheric pressure in the external auditory canal.

Clinical Manifestations and Assessment

Symptoms of tympanic membrane perforation include whistling sounds upon sneezing and blowing nose, reduced hearing, purulent drainage from ear(s), and/or otalgia.

Medical and Nursing Management

Although most tympanic membrane perforations heal spontaneously within weeks after rupture, some may take several months to heal. Some perforations persist because scar tissue grows over the edges of the perforation, preventing extension of the epithelial cells across the margins and healing. In the case of a head injury or temporal bone fracture, a patient is observed for evidence of cerebrospinal fluid: otorrhea or rhinorrhea, a clear, watery drainage from the ear or nose, respectively. If present, the nurse is aware that this represents an abnormal communication between the subarachnoid space and the tympanomastoid space, with a risk of a central nervous system (CNS) infection. While healing, the ear must be protected from water.

Perforations that do not heal on their own may require surgery. The decision to perform a tympanoplasty (surgical repair of the tympanic membrane) is usually based on the need to prevent potential infection from water entering the ear or the desire to improve the patient's hearing. Performed on an outpatient basis, tympanoplasty may involve a variety of surgical techniques. In all techniques, tissue (commonly from the temporalis fascia) is placed across the perforation to allow healing. Surgery is usually successful in closing the perforation permanently and improving hearing. Postoperative instructions after middle ear surgery are found in Box 50-7.

OTOSCLEROSIS

Otosclerosis involves the stapes and is thought to result from the formation of new, abnormal spongy bone, especially around the oval window, with resulting fixation of the stapes. The efficient transmission of sound is prevented because the stapes cannot vibrate and carry the sound as conducted from the malleus and incus to the inner ear. Otosclerosis is more common in women and frequently hereditary, and pregnancy may worsen it.

Clinical Manifestations and Assessment

Otosclerosis may involve one or both ears and manifests as a progressive conductive or mixed hearing loss. The patient may or may not complain of tinnitus (ringing in the ear). Otoscopic examination usually reveals a normal tympanic membrane. Bone conduction is better than air conduction on Rinne testing. The audiogram confirms conductive hearing loss or mixed loss, especially in the low frequencies.

BOX 50-7 Patient Education

Self-Care After Middle Ear or Mastoid Surgery

Postoperative instructions for patients who have had middle ear and mastoid surgery may vary among otolaryngologists. General teaching guidelines for the patient may include:

- Take antibiotics and other medications as prescribed.
- Blow the nose gently, one side at a time, for 1 week after surgery.
- Sneeze and cough with the mouth open for a few weeks after surgery.
- Avoid heavy lifting (over 10 lb), straining, and bending over for a few weeks after surgery.
- Popping and crackling sensations in the operative ear are normal for approximately 3–5 weeks after surgery.
- Temporary hearing loss is normal in the operative ear due to fluid, blood, or packing in the ear.
- Report excessive or purulent ear drainage to the surgeon. Some slightly bloody or serosanguineous drainage from the ear is normal after surgery.
- Change the cotton ball in the ear as needed.
- Avoid getting water in the operative ear for 2 weeks after surgery. You may shampoo the hair 2–3 days postoperatively if the ear is protected from water by saturating a cotton ball with petroleum jelly (or some other water-insoluble substance) and loosely placing it in the ear. If the postauricular suture line becomes wet, pat (do not rub) the area and cover it with a thin layer of antibiotic ointment.

Medical and Nursing Management

There is no known nonsurgical treatment for otosclerosis. However, some physicians believe the use of sodium fluoride can mature the abnormal spongy bone growth and prevent the breakdown of the bone tissue. Amplification with a hearing aid also may help.

One of two surgical procedures may be performed, the stapedectomy or the stapedotomy. A stapedectomy involves removing the stapes superstructure and part of the footplate and inserting a tissue graft and a suitable prosthesis (Fig. 50-2). The surgeon drills a small hole into the footplate to hold a prosthesis. The prosthesis bridges the gap between the incus and the inner ear, providing better sound conduction. Stapes surgery is very successful; approximately 95% of patients experience resolution of conductive hearing loss. Balance disturbance or true vertigo, which rarely occurs in other middle ear surgical procedures, may occur during the postoperative period for several days.

MIDDLE EAR MASSES

Other than cholesteatoma (middle ear or mastoid tumor), masses in the middle ear are rare. A glomus jugulare tumor is a tumor that arises from the jugular vein and appears as a red blemish on or behind the tympanic membrane upon examination with an otoscope. Glomus jugulare tumors are rarely malignant; however, due to their location, treatment may be necessary to relieve symptoms. The treatment for glomus tumors is surgical excision, except in poor surgical candidates, in whom radiation therapy is used.

A facial nerve neuroma is a tumor on cranial nerve VII, the facial nerve. These types of tumors are usually not visible on otoscopic examination but are suspected when a patient presents with a facial nerve paresis. X-ray evaluation is used to identify the site of the tumor along the facial nerve. The treatment is surgical removal.

CONDITIONS OF THE INNER EAR

Almost 8 million American adults are affected by a chronic problem with balance, and an additional 2.4 million are affected by dizziness alone. Balance or vestibular problems are reported in approximately 9% of the older adult population over 65 years of age. In the United States, there are 1.6 million older adults who are treated for falls in emergency departments each year (NIH, 2015). Disorders of balance are a major cause of falls in the older population. Body balance is maintained by the cooperation of the muscles and joints of the body (proprioceptive system), the eyes (visual system), and the labyrinth (vestibular system). These areas send their information about equilibrium, or balance, to the brain (cerebellar system) for coordination and perception in the cerebral cortex. Since the brain obtains its blood supply from the cardiovascular system, arteriosclerosis can also cause a disturbance in balance. Likewise, impaired vision can have an impact on equilibrium. The vestibular apparatus of the inner ear provides feedback regarding the movements and the position of the head and body in space.

Patients and health care providers frequently use the term *dizziness* to describe any altered sensation of orientation in space. Vertigo is defined as the misperception or illusion of motion of the person or the surroundings. Most people with vertigo describe a spinning sensation or say they feel as though objects are moving around them. *Ataxia* is a failure of muscular coordination and may be present in patients with vestibular disease. Syncope, fainting, and loss of consciousness are not forms of vertigo and usually indicate disease in the cardiovascular system.

Nystagmus is an involuntary rhythmic movement of the eyes, and slight oscillation may be a normal variant. However, when nystagmus is pathologic, it is an ocular disorder associated with vestibular dysfunction. Nystagmus can be horizontal, vertical, or rotary and can be caused by a disorder in the central or peripheral nervous system.

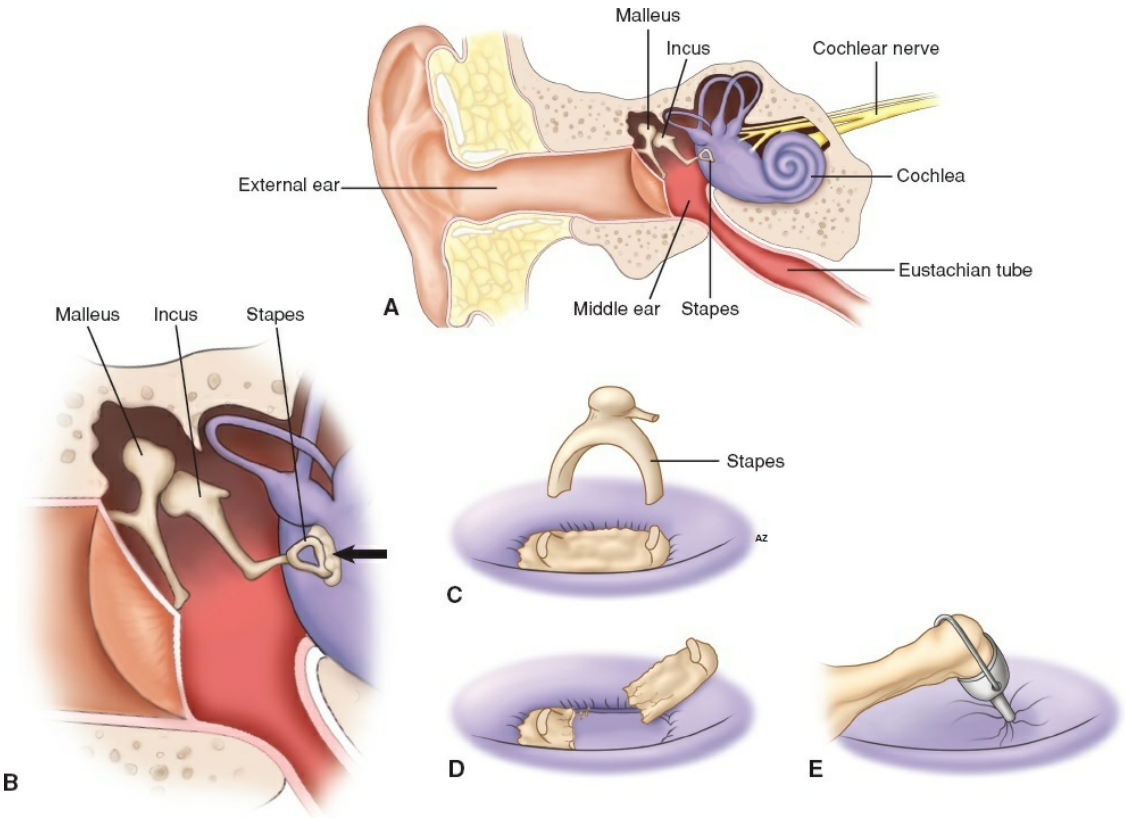

FIGURE 50-2 Stapedectomy for otosclerosis. A. Normal anatomy. B. Arrow points to sclerotic process at the foot of the stapes. C. Stapes broken away surgically from its diseased base. The hole in the footplate provides an area where an instrument can grasp the plate. D. The footplate is removed from its base. Some otosclerotic tissue may remain, and tissue is placed over it. E. Robinson stainless-steel prosthesis in position.

MOTION SICKNESS

Motion sickness is a disturbance of equilibrium caused by constant motion. For example, it can occur aboard a ship, while riding on a merry-go-round or swing, or in the back seat of a car.

Clinical Manifestations and Assessment

Motion sickness manifests itself with diaphoresis, pallor, nausea, and vomiting caused by vestibular overstimulation. These manifestations may persist for several hours after the stimulation stops.

Medical and Nursing Management

Over-the-counter antihistamines, such as dimenhydrinate (Dramamine) or meclizine hydrochloride (Antivert), may provide some relief of nausea and vomiting by blocking the conduction of the vestibular pathway of the inner ear. Anticholinergic medications, such as scopolamine patches, may also be effective because they antagonize the histamine response. These must be replaced every few days. Common side effects, such as dry mouth and drowsiness, may occur. Potentially hazardous activities, such as driving a car or operating heavy machinery, should be avoided.

MÉNIÈRE DISEASE

Ménière disease is a disorder of the inner ear that causes vertigo, tinnitus, a feeling of fullness or pressure in the ear, and fluctuating hearing loss.

Pathophysiology

Ménière disease is believed to be the result of fluctuating pressure within the inner ear or the mixing of inner ear fluids. The membranous labyrinth of the inner ear contains a fluid called *endolymph.* The membranes can become dilated because of malabsorption of the fluid in the endolymphatic sac or a blockage in the drainage of fluid in the endolymphatic duct within the labyrinth. This dilation is termed endolymphatic hydrops or a ballooning of the membranous labyrinth, which results in increased pressure in the system or rupture of the inner ear membrane producing symptoms of Ménière disease.

Risk Factors

According to the National Institute on Deafness and Other Communication Disorders (NIDCD), Ménière disease affects approximately 615,000 people in the United States, and 45,500 new cases are diagnosed each year (NIH, 2015). More common in adults, it has an average age of onset in the 40s, with symptoms usually beginning between 20 and 60 years of age. Ménière disease appears to be equally common in both genders and occurs bilaterally in about 20% of patients. About 50% of the patients who have Ménière disease have a positive family history of the disease. Patients who present at greater risk also include those with a recent viral illness or upper respiratory infection, allergy sufferers, smokers, patients with stress or fatigue, alcohol users, and in those who take aspirin.

Clinical Manifestations and Assessment

Symptoms of Ménière disease include fluctuating, progressive sensorineural hearing loss; tinnitus or a roaring sound; a feeling of pressure or fullness in the ear; and episodic, incapacitating vertigo, often accompanied by nausea and vomiting. These symptoms range in severity from a minor nuisance to extreme disability, especially if the attacks of vertigo are severe. At the onset of the disease, perhaps only one or two of the symptoms are manifested.

Some clinicians believe that there are two subsets of the disease, known as atypical Ménière disease: cochlear and vestibular. Cochlear Ménière disease is recognized as a fluctuating, progressive sensorineural hearing loss associated with tinnitus and aural pressure in the absence of vestibular symptoms or findings. Vestibular Ménière disease is characterized as the occurrence of episodic vertigo associated with aural pressure but no cochlear symptoms. Patients may experience either cochlear or vestibular disease symptoms; however, eventually all of these symptoms develop.

Vertigo is usually the most troublesome complaint related to Ménière disease. A careful history is taken to determine the frequency, duration, severity, and character of the patient's vertigo attacks. Vertigo may last minutes to hours, possibly accompanied by nausea or vomiting. Diaphoresis and a persistent feeling of imbalance or disequilibrium may awaken patients at night. Some patients report that these feelings last for days. However, they usually feel well between attacks. Hearing loss may fluctuate, with tinnitus and aural pressure waxing and waning with changes in hearing. These feelings may occur during or before attacks, or they may be constant. Long periods of remission may occur.

Physical examination findings are usually normal, with the exception of those of cranial nerve VIII. Sounds from a tuning fork (Weber test) may lateralize to the unaffected ear. Using a Rinne test, the normal finding of air conduction remaining greater than bone conduction usually is found. An audiogram typically reveals a sensorineural hearing loss in the affected ear. This can be in the form of a "Pike's Peak" pattern, which looks like a hill or mountain. A sensorineural loss in the low frequencies occurs as the disease progresses. The electronystagmogram may be normal or may show reduced vestibular response. Imaging using magnetic resonance may also prove useful in diagnosis of CNS lesions.

Medical Management

Most patients with Ménière disease can be successfully treated with diet and medication. Many patients can control their symptoms by adhering to a low-sodium (2,000 mg/day) diet, with no caffeine and alcohol. Box 50-8 describes dietary guidelines that may be useful in Ménière disease. The amount of sodium is one of many factors that regulate the balance of fluid within the body. Sodium and fluid retention disrupts the delicate balance between endolymph and perilymph in the inner ear. Medications to control allergies or improve blood circulation of the inner ear prove helpful. Eliminating tobacco use and stress reduction can also decrease the severity of symptoms. Psychological evaluation may be indicated as comorbidity of vertigo and anxiety is well established in the literature. A plan of nursing care for a patient with vertigo is available online at http://thepoint.lww.com/Honan2e.

Pharmacologic Therapy

Pharmacologic therapy for Ménière disease consists of antihistamines, such as meclizine (Antivert), which suppress the vestibular system. Benzodiazepines, such as diazepam (Valium), may be used in acute instances to help control vertigo. Antiemetics, such as promethazine (Phenergan) suppositories, help control the nausea, vomiting, and vertigo because of their antihistamine effect. Betahistine hydrochloride and diuretic therapy may reduce the severity of symptoms by lowering the pressure in the endolymphatic system. Intake of foods containing potassium (e.g., bananas, cantaloupe, oranges) is necessary if the patient takes a diuretic that causes potassium loss. There is no scientific basis for the use of vasodilators, such as nicotinic acid, papaverine hydrochloride (Pavabid), and methantheline bromide (Banthine), to alleviate the symptoms, but they are often used in conjunction with other therapies. Corticosteroids are useful in reducing edema of the labyrinth and inflammation, in order to improve healing of the inner ear structures.

BOX 50-8

Nutrition Alert 

Dietary Guidelines for Patients with Ménière Disease

Advise patients to:

- Limit foods high in salt or sugar. Be aware of foods with hidden salts and sugars.
- Eat meals and snacks at regular intervals to stay hydrated. Missing meals or snacks may alter the fluid level in the inner ear.
- Eat fresh fruits, vegetables, and whole grains. Limit the amount of canned, frozen, or processed foods with high sodium content.
- Drink plenty of fluids daily. Water, milk, and low-sugar fruit juices are recommended. Limit intake of coffee, tea, and soft drinks. Avoid caffeine because of

its diuretic effect.

- Limit alcohol intake. Alcohol may change the volume and concentration of the inner ear fluid and may worsen symptoms.
- Avoid monosodium glutamate (MSG), which may increase symptoms.
- Avoid aspirin and aspirin-containing medications. Aspirin may increase tinnitus and dizziness.

Surgical Management

Although most patients respond well to conservative therapy, some continue to have disabling attacks of vertigo. If these attacks reduce their quality of life, patients may elect to undergo chemical treatment or surgery for relief. Vestibular rehabilitation can assist to restore function in patients with permanent disorder. Surgical procedures, such as labyrinthectomy, vestibular neurectomy, or endolymphatic sac decompression, may be considered.

Endolymphatic Sac Decompression

Endolymphatic sac decompression, or shunting, theoretically equalizes the pressure in the endolymphatic space. A shunt or drain is inserted in the endolymphatic sac through a postauricular incision. Many otolaryngologists favor this procedure as a first-line surgical approach to treat the vertigo of Ménière disease because it is relatively simple and safe and can be performed on an outpatient basis.

Middle and Inner Ear Perfusion

Ototoxic medications, such as streptomycin or gentamicin, can be administered to patients by infusion into the middle and inner ear. These medications are used to destroy vestibular function and decrease vertigo. The success rate for eliminating vertigo is about 85%, but the risk of significant hearing loss is high. After the procedure, many patients have a period of imbalance that lasts several weeks.

Intraotologic Catheters

In an attempt to deliver medication directly to the inner ear, catheters are being developed to provide a conduit from the outer ear to the inner ear. The route of the catheter is from the external ear canal through or around the tympanic membrane and to the round window niche or membrane. Medicinal fluids can be placed against the round window for a direct route to the inner ear fluids.

Potential uses of these catheters include treatment for sudden hearing loss and various disorders causing intractable vertigo. Future applications may include tinnitus and slowly progressing sensorineural hearing loss. Intratympanic injections of ototoxic medications for round window membrane diffusion can be used to decrease vestibular function. Established surgical techniques can be used for the patient with vertigo who has not responded to medical or physical therapeutic modalities.

Vestibular Nerve Sectioning

Vestibular nerve sectioning provides the greatest success rate (98%) in eliminating the attacks of vertigo. It can be performed by a translabyrinthine approach (i.e., through the hearing mechanism) or in a manner that can conserve hearing (i.e., suboccipital or middle cranial fossa), depending on the degree of hearing loss. Most patients with incapacitating Ménière disease have little or no effective hearing. Cutting the nerve prevents the brain from receiving input from the semicircular canals. This procedure requires a brief hospital stay.

TINNITUS

Tinnitus is a symptom of an underlying disorder of the ear that is associated with hearing loss. This condition affects approximately 10% of the U.S. population between 40 and 70 years of age. The severity of tinnitus may range from mild to severe. Patients describe tinnitus as a roaring, buzzing, or hissing sound in one or both ears. Numerous factors may contribute to the development of tinnitus, including several ototoxic substances (Box 50-9). Underlying disorders that contribute to tinnitus may include thyroid disease, hyperlipidemia, vitamin B_{12} deficiency, psychological disorders (e.g., depression, anxiety), fibromyalgia, otologic disorders (Ménière disease, acoustic neuroma), and neurologic disorders (head injury, multiple sclerosis).

A physical examination should be performed to determine the cause of tinnitus. Diagnostic testing determines if hearing loss is present. An audiograph speech discrimination test or a tympanogram may be used to help determine the cause. Some forms of tinnitus are irreversible; therefore, patients may need teaching and counseling about ways of adjusting to their treatment and dealing with tinnitus in the future.

BOX 50-9 Selected Ototoxic Substances

- *Diuretics:* Ethacrynic acid, furosemide, acetazolamide
- *Chemotherapeutic agents:* Cisplatin, nitrogen mustard
- *Antimalarial agents:* Quinine, mefloquine, chloroquine
- *Anti-inflammatory agents:* Salicylates (aspirin), indomethacin
- *Chemicals:* Alcohol, arsenic
- *Aminoglycoside antibiotics:* Amikacin, gentamicin, kanamycin, netilmicin, neomycin, streptomycin, tobramycin
- *Other antibiotics:* Erythromycin, minocycline, polymyxin B, vancomycin
- *ACE inhibitors:* Enalapril, moexipril, ramipril
- *Acetic acids:* Diclofenac, indomethacin, ketorolac
- *Alpha blockers:* Doxazosin
- *Anti-arrhythmics:* Flecainide, propafenone, quinidine, tocainide
- *Calcium-channel blockers:* diltiazem, nifedipine, nisoldipine

- *H_1-blockers:* Cetirizine, fexofenadine
- *Metals:* Gold, mercury, lead

BENIGN PAROXYSMAL POSITIONAL VERTIGO

Benign paroxysmal positional vertigo (BPPV) is a brief period of incapacitating vertigo that occurs when the position of the patient's head is changed with respect to gravity, typically by placing the head back with the affected ear turned down. The onset is sudden and followed by a predisposition for positional vertigo, usually for hours to weeks but occasionally for months or years. Other symptoms may include lightheadedness, blurred vision, and nausea and vomiting.

Pathophysiology

BPPV is thought to be due to the disruption of debris in the labyrinth, termed otoconia (small crystal particles of calcium carbonate that detach and float in the endolymph and cause symptomatology). This is frequently stimulated by head trauma, infection (particularly of the respiratory tract), or other events. Precipitating factors include sneezing or coughing, or the vertigo may be induced by any change in head positioning. Bed rest is recommended for patients with acute symptoms.

Clinical Manifestations and Assessment

Diagnosis of BBPV is performed after an ear examination, audiogram, and test of nerve responses and use of the Dix–Hallpike test, also called the Nylen–Barany test. The test involves making the patient undergo a rapid change from an erect seated position to a supine position with the head hanging over the edge of the examination table to the left, right, or center. Dizziness and peripheral vertigo will be elicited with the affected ear pointing downward. The eyes are examined for a brief period for nystagmus present while the head is maintained in a provoking position, which also commonly accompanies vertigo. Nystagmus and vertigo may be present for less than 30 seconds during maneuvers.

Medical and Nursing Management

Repositioning techniques can be used to treat vertigo, such as the Epley maneuver. The maneuver is designed to reposition the canalith and involves quick movements of the head. The noninvasive procedure is performed by placing the patient in a sitting position and turning the head to a 45-degree angle on the affected side and 30 to 45 degrees backward. Then the patient is quickly moved to the supine position. The procedure is repeated, tilting the head to the opposite side. The patient must not lie flat for 48 to 72 hours after repositioning to prevent the particles from reentering the posterior canal. The procedure is safe, inexpensive, and easy to perform.

Patients with acute vertigo are treated with medications that target vertigo and its related symptoms of nausea, vomiting, and anxiety. Vestibular suppressants that are commonly used originate from classes of anticholinergics (scopolamine), antihistamines (meclizine, dimenhydrinate), and benzodiazepines. Meclizine is often the drug of choice, with patients treated for a 1- to 2- week course of therapy. Antiemetic medications, such as phenothiazines, are used to treat nausea. Meclizine has both vestibular suppressant and antiemetic effects.

Vestibular rehabilitation can be used in the management of vestibular disorders. This strategy promotes active use of the vestibular system through an interdisciplinary team approach, including medical and nursing care, stress management, biofeedback, vocational rehabilitation, and physical therapy. A physical therapist prescribes balance exercises that help the brain compensate for the impairment to the balance system.

OTOTOXICITY

A variety of medications may have adverse effects on the cochlea, vestibular apparatus, or cranial nerve VIII. All but a few, such as aspirin and quinine, cause irreversible hearing loss. At high doses, aspirin toxicity can produce bilateral tinnitus. IV medications, especially the aminoglycosides, are the most common cause of ototoxicity, and they destroy the hair cells in the organ of Corti (see Box 50-9).

To prevent loss of hearing or balance, patients receiving potentially ototoxic medications should be counseled about the side effects of these medications. These medications should be used with caution in patients who are at high risk for complications, such as children, the elderly, pregnant patients, patients with kidney or liver problems, and patients with current hearing disorders. Blood levels of the medications should be monitored, and patients receiving long-term IV antibiotics should be monitored with an audiogram twice each week during therapy.

Nursing Alert

Many intravenous medications require careful monitoring of the highest (peak) and lowest (trough) concentration of the drug in the patient's blood to ensure that the dosage is within the therapeutic range and to prevent toxicity. The trough is drawn just before a drug is scheduled to be given whereas the peak is drawn after the drug is administered (typically 30 minutes).

ACOUSTIC NEUROMA

Acoustic neuromas develop in 1 of every 10,000 people per year. These neuromas account for 5% to 10% of all intracranial tumors and seem to occur with equal frequency in men and women of any age, although most occur during middle age.

Pathophysiology

Acoustic neuromas are slow-growing, benign tumors of cranial nerve VIII, usually arising from the Schwann cells of the vestibular portion of the nerve. Most acoustic tumors arise within the internal auditory canal and extend into the cerebellopontine angle to press on the brainstem, possibly destroying the vestibular nerve.

Clinical Manifestations and Assessment

The most common assessment findings of patients with *acoustic neuromas are unilateral tinnitus and hearing loss with or without vertigo or balance disturbance*. If the tumor is large, the trigeminal nerve may be involved resulting in facial paresthesia, hypesthesia (sensitivity to touch), and discomfort. Facial paresis and disturbance in taste result from facial nerve involvement, which occurs less commonly. It is important to identify asymmetry in audiovestibular test results so that further workup can be performed to rule out an acoustic neuroma. MRI with a paramagnetic contrast agent (i.e., gadolinium or Magnevist) is the imaging study of choice. If the patient is claustrophobic or cannot undergo an MRI for other reasons, or if the scan is unavailable, a computed tomography (CT) scan with contrast dye is performed; however, MRI is more sensitive than CT in delineating a small tumor.

Medical and Nursing Management

Surgical removal of acoustic tumors is the treatment of choice because these tumors do not respond well to radiation or chemotherapy. Because treatment of acoustic tumors crosses several specialties, the interdisciplinary treatment approach involves a neurologist and a neurosurgeon. The objective of the surgery is to remove the tumor while preserving facial nerve function. Most acoustic tumors have damaged the cochlear portion of cranial nerve VIII, and hearing is impaired. In these patients, the surgery is performed using a translabyrinthine approach, and the hearing mechanism is destroyed. If hearing is still good before surgery, a suboccipital or middle cranial fossa approach to removing the tumor may be used. This procedure exposes the lateral third of the internal auditory canal and preserves hearing.

Complications of surgery include facial nerve paralysis, cerebrospinal fluid leakage, meningitis, and cerebral edema. Death from acoustic neuroma surgery is rare.

CHAPTER REVIEW

Critical Thinking Exercises

1. You are visiting an older man for a postoperative home visit following a cholecystectomy. He tells you that he has had severe leg cramps at nighttime and has started drinking tonic daily. He has noticed a significant improvement in the leg cramps. During your assessment, you also learn that he has a significant hearing loss, and his wife tells you that she thinks that his hearing has worsened over the past several months; however, she attributes his hearing loss to advanced age and to anxiety regarding his recent surgery. Devise a teaching plan for this patient and his wife. Provide a rationale for each part of the plan.

2. A 20-year-old man, a member of a college swim team, has recurrent external otitis—his third episode in the past 6 weeks. He is being treated at an ear-nose-throat clinic. Devise an evidence-based teaching plan for this patient including holistic, pharmacologic, and nonpharmacologic measures.

NCLEX-Style Review Questions

1. A 56-year-old patient who is hearing-impaired is scheduled for a colonoscopy. Which nursing action is most appropriate in performing patient education prior to the procedure?
   a. Face the patient directly, smile, and speak slowly.
   b. Continue to administer medications while educating the patient.
   c. Nod to make up for awkward silence, even if you don't know what is being said.
   d. Use only gestures to communicate the highlights of content to be covered.

2. The nurse caring for the patient with Ménière disease restricts the following foods in the

dietary plan. Select all that apply.

a. Coffee
b. Wine
c. Baked potato
d. Cheese
e. Milk

3. During preoperative teaching, the 25-year-old patient receiving cochlear implants states, "I will be able to fully regain my hearing with the implants." What is the nurse's best response to the patient?
   a. "The implants will assist you to detect medium to loud environmental sound and conversation rather than restoring normal hearing."
   b. "The implant will assist you to restore normal hearing fully."
   c. "The implants will be immediately effective."
   d. "The implant will require minimal rehabilitation in order for you to recognize sounds."

4. How might a patient with tinnitus describe hearing sound to the nurse?
   a. Sputtering
   b. Muffled
   c. Loud
   d. Buzzing

5. A patient taking aspirin for stroke prevention reports the development of hearing disturbances. The appropriate intervention is to decrease the dose in order to prevent which condition?
   a. Ototoxicity
   b. Vertigo
   c. Nystagmus
   d. Otitis externa

Problems Related to Integumentary Function

A 48-year-old electrician has come to the emergency department via ambulance after falling and sustaining a high-voltage electrical burn. He has a full-thickness (third-degree) burn on his abdomen that will need autografting.

- Describe the nursing management of this patient in the emergent phase of burn

injury.

- Discuss graft site care and donor site care following an autograft.
- What are the long-term complications for this patient?

CHAPTER 51

Nursing Assessment: Integumentary Function

Commander Patina S. Walton-Battle

Learning Objectives

After reading this chapter, you will be able to:

1. Identify the structures and functions of the skin.
2. Differentiate the composition and function of each skin layer: epidermis, dermis, and subcutaneous tissue.
3. Describe the normal aging process of the skin and skin changes common in elderly patients.
4. List appropriate questions that help elicit information during an assessment of the skin.
5. Describe the components of physical assessment that are most useful when examining the skin, hair, and nails.
6. Identify and describe primary and secondary skin lesions and their pattern and distribution.
7. Discuss common skin tests and procedures used in diagnosing skin and related disorders.

The skin is the largest organ in the body and makes up approximately 12% of body weight. It is responsible for regulation of body temperature, maintenance of normal fluid and electrolyte balance, sensation, and protection from infection and the environment. Nurses care for patients with burns, skin infections, surgical wounds, and secondary skin abnormalities associated with systemic disease; this chapter provides the knowledge necessary to assess, diagnose, and manage skin abnormalities and describes when to seek referrals to the primary care provider or specialist.

ANATOMIC AND PHYSIOLOGIC OVERVIEW

The integumentary system comprises multiple subunits that work simultaneously. The system includes skin and its appendages, such as hair, nails, and sweat or sebaceous glands, which are lined with epidermal cells (Van De Graaff, 2014).

Anatomy of the Skin

The skin is composed of three layers: epidermis (outermost layer), dermis (inner layer), and hypodermis (innermost layer) (Fig. 51-1). Five distinct layers compose the epidermis; from innermost to outermost they are the stratum basale, stratum spinosum, stratum granulosum, stratum lucidum, and stratum corneum (Anderson, 2012). Each layer becomes more differentiated (i.e., mature and with more specific functions) as it rises from the basal stratum germinativum layer to the outermost stratum corneum layer. The stratum lucidum is found only on the skin of the palms and soles (James, Berger, & Elston, 2016a). The epidermis and the dermis are separated by a structure called the basement membrane zone. This zone contains proteins that can target various autoantibodies that can be found in patients with autoimmune blistering diseases (Anderson, 2012). The dermis, which is the thickest layer of skin, is composed principally of collagen, a fibrous protein synthesized primarily by fibroblast cells, which are important in remodeling and repairing skin. This layer is split up into two regions, the papillary dermis and reticular dermis. This connective tissue layer contains nerve endings, sensory receptors, capillaries, and elastic fibers.

Epidermis

The epidermis consists of continuously dividing cells covered on the surface by dead cells that were originally deeper in the dermis but were pushed upward by the newly developing, more differentiated cells underneath. This external layer is almost completely replaced every 3 to 4 weeks. The dead cells contain large amounts of keratin, an insoluble, fibrous protein that forms the outer barrier of the skin and has the capacity to repel pathogens and prevent excessive fluid loss from the body. Keratin is the principal hardening ingredient of the hair and nails.

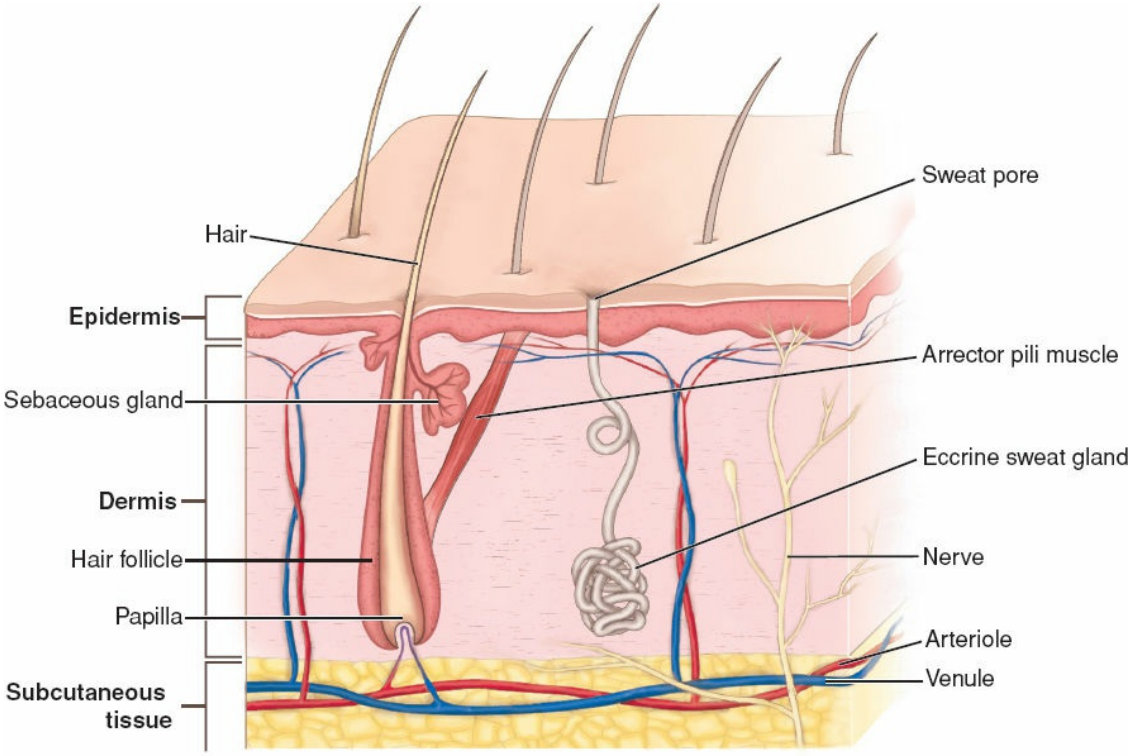

FIGURE 51-1 Anatomic structures of the skin.

Melanocytes are the special cells of the epidermis that are primarily involved in producing the pigment melanin, which colors the skin and hair. Most of the skin of dark-skinned people and the darker areas of the skin on light-skinned people (e.g., the areola) contain larger amounts of this pigment. Albinism is associated with a lack of melanin and is discussed later in the chapter. Production of melanin is controlled by a hormone secreted from the hypothalamus of the brain called *melanocyte-stimulating hormone.* Melanin provides a natural protection against the harmful effects of ultraviolet light; however, it does not provide complete protection from the sun's damaging rays.

Two other types of cells are common to the epidermis: Merkel and Langerhans cells. Merkel cells are receptors that transmit stimuli to the axon through a chemical synapse and therefore are associated with the sense of touch. Langerhans cells are accessory cells of the afferent immune system that play a role in cutaneous (skin) immune system reactions. These cells process invading antigens and transport the antigens to the lymph system to activate the T lymphocytes.

The junction of the epidermis (basement membrane zone, BMZ) and dermis is an area of many undulations and furrows called rete ridges. This junction anchors the epidermis to the dermis and permits the free exchange of essential nutrients between the two layers. If the BMZ is interrupted, it must re-form to successfully achieve healing of the tissue (Wysocki, 2016).

Dermis

The dermis makes up the largest portion of the skin, providing strength and structure. It is composed of two layers: papillary and reticular. The papillary dermis lies directly beneath the epidermis and is composed primarily of fibroblast cells capable of producing one form

of collagen, a component of connective tissue. The reticular layer lies beneath the papillary layer and also produces collagen and elastic bundles. The dermis is also made up of blood and lymph vessels, nerves, sweat and sebaceous glands, and hair roots. The dermis is often referred to as the "true skin." It is especially thick on the palms and soles, while thin over the eyelids and scrotum; thus, it is not surprising that in conditions of fluid volume excess, patients develop edema in thin skinned areas, resulting in periorbital and scrotal edema. An infection of the dermis that spreads rapidly within the skin and subcutaneous structures is termed *cellulitis.* It is usually caused by staphylococci or streptococci and presents with redness, warmth, swelling, and tenderness, usually of the limbs.

Hypodermis

The subcutaneous tissue, or hypodermis, is the innermost layer of the skin. It is primarily adipose tissue, which provides a cushion between the skin layers, muscles, and bones. It promotes skin mobility, molds body contours, and insulates the body. Fat is deposited and distributed according to the person's gender and in part accounts for the difference in body shape between men and women. Overeating results in increased deposition of fat beneath the skin. The subcutaneous tissues and the amount of fat deposited are important factors in body temperature regulation.

Nursing Alert

An area of skin indurated (hardened) from collagen deposits in the cutaneous and subcutaneous tissue as a result of chronic inflammation is termed sclerosis. Examples include keloid formation, stasis dermatitis, and scleroderma.

Anatomy of Hair, Nails, and Glands of the Skin

Hair

An outgrowth of the skin, hair is present over the entire body except for the palms and soles. The hair consists of a root formed in the dermis and a hair shaft that projects beyond the skin. It grows in a cavity called a *hair follicle* (see Fig. 51-1). Proliferation of cells in the bulb of the hair causes the hair to form.

Hair follicles undergo cycles of growth and rest. The rate of growth varies; beard growth is the most rapid, followed by hair on the scalp, axillae, thighs, and eyebrows. The growth or anagen phase may last up to 6 years for scalp hair, whereas the telogen or resting phase lasts approximately 4 months. During telogen, hair is shed from the body. The hair follicle recycles into the growing phase spontaneously, or it can be induced by plucking out hairs. Growing and resting hairs can be found side by side on all parts of the body. About 90% of the 100,000 hair follicles on a normal scalp are in the growing phase at any one time, and 50 to 100 scalp hairs are shed each day. In conditions in which inflammation causes damage to the root of the hair, regrowth is possible. However, if inflammation causes damage to the hair follicle, stem cells are destroyed and the hair does not grow.

Hair in different parts of the body serves different functions. The hairs of the eyes (i.e., eyebrows and lashes), nose, and ears filter out dust, microbes, and airborne debris. Hair color is supplied by various amounts of melanin within the hair shaft. Gray or white hair reflects the loss of pigment. Hair quantity and distribution can be affected by endocrine conditions. For example, Cushing syndrome causes hirsutism, especially in women; hypothyroidism (i.e., underactive thyroid) causes coarse hair; while hyperthyroidism (i.e., overactive thyroid) is associated with fine hair. In many cases, chemotherapy and radiation therapy cause hair thinning or weakening of the hair shaft, resulting in partial or complete alopecia from the scalp and other parts of the body.

Nails

On the dorsal surface of the fingers and toes, a hard, transparent plate of keratin, called the *nail*, overlies the skin. The nail grows from its root, which lies under a thin fold of skin called the *cuticle*. The nail protects the fingers and toes by preserving their highly developed sensory functions, such as for picking up small objects.

Nail growth is continuous throughout life, with an average growth of 0.1 mm daily. Growth is faster in fingernails than toenails and tends to slow with aging. Complete renewal of a fingernail takes about 170 days, whereas toenail renewal takes 12 to 18 months.

Glands of the Skin

There are two types of skin glands: sebaceous glands and sweat glands (see Fig. 51-1). The sebaceous glands are associated with hair follicles. The ducts of the sebaceous glands empty sebum onto the space between the hair follicle and the hair shaft. For each hair, there is a sebaceous gland, the secretions of which lubricates the hair and renders the skin soft and pliable.

Sweat glands are found in the skin over most of the body surface, but they are heavily concentrated in the palms of the hands and soles of the feet. Only the glans penis, the margins of the lips, the external ear, and the nail bed are devoid of sweat glands. Sweat glands are subclassified into two categories: eccrine and apocrine.

The eccrine sweat glands are found in all areas of the skin. Their ducts open directly onto the skin surface. The thin, watery secretion called *sweat* is produced in the basal, coiled portion of the eccrine gland and is released into its narrow duct.

The apocrine sweat glands are larger than eccrine sweat glands and are located in the axillae, anal region, scrotum, and labia majora. Their ducts generally open onto hair follicles. The apocrine glands become active at puberty. In women, they enlarge and recede with each menstrual cycle. Apocrine glands produce a milky sweat that is sometimes broken down by bacteria to produce the characteristic underarm odor.

Functions of the Skin

Protection

The skin covering most of the body is no more than 1 mm thick, but it provides very effective protection against invasion by aqueous, chemical, and mechanical assault; and bacterial and viral pathogens as well as ultraviolet rays (Wysocki, 2016). The thickened skin of the palms and soles protects against the effects of the constant trauma that occurs in these areas.

The stratum corneum, the outer layer of the epidermis, provides the most effective barrier to epidermal water loss to maintain a homeostatic environment and penetration of environmental factors, such as chemicals, microbes, and insect bites. Various lipids are synthesized in the stratum corneum and are the basis for the barrier function of this layer. These are long-chain lipids that are better suited than phospholipids for water resistance. The presence of these lipids in the stratum corneum creates a relatively impermeable barrier for water egress and for the entry of toxins, microbes, and other substances that come in contact with the surface of the skin.

Some substances do penetrate the skin but meet resistance in trying to move through the channels between the cell layers of the stratum corneum. Microbes and fungi, which are part of the body's normal flora, cannot penetrate unless there is a break in the skin barrier.

Sensation

The receptor endings of nerves in the skin allow the body to constantly monitor the conditions of the immediate environment. The primary functions of the receptors in the skin are to sense temperature, pain, light touch, and pressure (or heavy touch). Different nerve endings respond to each of the different stimuli. Although the nerve endings are distributed over the entire body, they are more concentrated in some areas than in others. For example, the fingertips are more densely innervated than the skin on the back.

Fluid Balance

The stratum corneum, the outermost layer of the epidermis, has the capacity to absorb water, thereby preventing an excessive loss of water and electrolytes from the internal body and retaining moisture in the subcutaneous tissues. When skin is damaged, as occurs with a severe burn, large quantities of fluids and electrolytes may be lost rapidly, possibly leading to circulatory collapse, shock, and death.

The skin is not completely impermeable to water. Small amounts of water continuously evaporate from the skin's surface. This evaporation, called *insensible perspiration*, amounts to approximately 600 mL daily in a normal adult. Insensible water loss varies with the body and ambient temperature. In a person with a fever, the fluid loss increases. If the fever is between 38.3°C (101°F) and 39.4°C (103°F), a loss of 500 mL per 24 hours is anticipated; whereas if the temperature if over 39.4°C (over 103°F), a loss of 1,000 mL at a minimum is expected (Porat & Dinarello, 2015).

Thermoregulation

The body continuously produces heat as a result of the metabolism of food, which produces energy. This heat is dissipated primarily through the skin.

Evaporation from the skin aids heat loss by conduction. Heat is conducted through the skin into water molecules on its surface, causing the water to evaporate. The water on the skin surface may be from insensible perspiration, sweat, or the environment.

Under normal conditions, metabolic heat production is balanced by heat loss, and the internal temperature of the body is maintained constant at approximately 37°C (98.6°F). The rate of heat loss depends primarily on the surface temperature of the skin, which is a function of the blood flow to the skin. Increased blood flow to the skin results in more heat delivered to the skin and a greater rate of heat loss from the body. In contrast, decreased skin blood flow decreases the skin temperature and helps conserve heat for the body. When the temperature of the body begins to fall, as occurs on a cold day, the blood vessels of the skin constrict, thereby reducing heat loss from the body.

Sweating is another process by which the body can regulate the rate of heat loss. Sweating does not occur until the core body temperature exceeds 37°C (98.6°F), regardless of skin temperature. In extremely hot environments, the rate of sweat production may be as high as 1 L per hour. Under some circumstances (e.g., emotional stress), sweating may occur as a reflex and may be unrelated to the need to lose heat from the body.

Vitamin Synthesis

Skin exposed to ultraviolet light can convert substances necessary for synthesizing vitamin D (cholecalciferol). Vitamin D is essential for preventing osteoporosis and rickets, a condition that causes bone deformities and results from a deficiency of vitamin D, calcium, and phosphorus (Box 51-1).

Immune Response Function

Recent research has confirmed a definite action of Langerhans cells (specialized cells in the skin) in facilitating the uptake of IgE-associated allergens. This action plays a pivotal role in the pathogenesis of atopic dermatitis and other allergic diseases, such as asthma and allergic rhinitis (Amin, 2012; James, Berger, & Elston, 2016b). These findings support the concept of a systemic regulatory mechanism as a trigger for allergic diseases and suggest that this trigger can be aggravated by local inflammation (Amin, 2012; James et al., 2016b).

Nursing Alert

Localized opening of the normally tight endothelial junctions leads to interstitial edema in the deep layers of the skin and subcutaneous tissue of the face, tongue, hands, face, and genitalia. Occasionally, the tongue or pharynx can be involved. It may be related to allergy or idiopathic in nature. Histamine that is contained in mast cells is released with a variety or immunologic, nonimmunologic, physical, and/or chemical stimuli. The released histamine causes hyperpermeability of the microvessels, which allows fluid to leak out into affected areas and causes the characteristic appearance. Nurses observe for the tense swelling of the lips that develops rapidly. Angioedema is frequently associated with an allergic reaction and may present with hives. If shortness of breath is also noted, the medical provider must be contacted immediately as severe swelling of the airway and tongue can be life-threatening.

BOX 51-1 Nursing Research

Bridging the Gap to Evidence-Based Practice

Colantonio, S., Bracken, M. B, & Beecker, J. (2014). The association of indoor tanning and melanoma in adults: Systematic review and meta-analysis. *Journal of the American Academy of Dermatology, 70*(5), 847–857.

Purpose

The authors sought to update the evidence of the association of melanoma and indoor tanning, focusing on frequency of use and exposure to newer tanning beds. Databases searched included: Scopus, MEDLINE, and Cumulative Index to Nursing and Allied Health Literature in 2013. All observational studies that included patients with melanoma who had tanned indoors were included. Odds ratios (OR) with 95% confidence intervals (CI) were extracted and combined using generic inverse variance methods assuming a random effects model. In all, 31 studies were included with data available on 14,956 melanoma cases and 233,106 controls.

Findings

Compared with never using, the OR for melanoma associated with ever using indoor tanning beds was 1.16 (95% CI 1.05–1.28). Similar findings were identified in recent studies with enrollment occurring in the year 2000 onward (OR 1.22, 95% CI 1.03–1.45) and in subjects attending more than 10 tanning sessions (OR 1.34, 95% CI 1.05–1.71). Using tanning beds is associated with a subsequent melanoma diagnosis. Exposure from more than 10 tanning sessions is most strongly associated, and there was no statistically significant difference in this association before and after 2000, suggesting that newer tanning technology is not safer than older models.

Nursing Implications

This study supports the relationship between indoor tanning and melanoma risk and suggests that public education is needed to correct the misunderstanding of the negative effects of indoor tanning. Nurses can play a pivotal role in educational efforts.

Gerontologic Considerations 

The skin undergoes many physiologic changes associated with normal aging. A lifetime of excessive sun exposure, systemic diseases, and poor nutrition can increase the range of skin problems and the rapidity with which they appear. In addition, certain medications (e.g., antihistamines, antibiotics, diuretics) are photosensitizing and increase the damage that results from sun exposure. The outcome is an increasing vulnerability to injury and to certain diseases. Skin problems are common among older people. Refer to Table 51-1 for skin changes in the elderly.

Many skin changes and lesions are part of normal aging. Recognizing these lesions enables the examiner to assist the patient to feel less anxious about changes in skin. Box 51-2 summarizes some changes that are expected to appear as the skin ages. These are normal and require no special attention unless the skin becomes infected or irritated.

ASSESSMENT

Some conditions may subject the patient to a protracted illness, leading to feelings of depression, frustration, self-consciousness, poor self-image, and rejection. Itching and skin irritations, which are features of many skin diseases, may be a constant annoyance. These discomforts may result in loss of sleep, anxiety, and depression, all of which reinforce the general distress and fatigue that frequently accompany skin disorders.

For patients suffering such physical and psychological discomforts, the nurse needs to provide understanding, explanations of the problem, appropriate instructions related to treatment, nursing support, and encouragement. It is imperative to overcome any aversion that may be felt when caring for patients with unattractive skin disorders. The nurse should show no sign of hesitancy when approaching patients with skin disorders. Such hesitancy only reinforces the psychological trauma of the disorder.

Because patients with skin conditions may be viewed negatively by others, these patients may become distraught and avoid interaction with people. Skin conditions can lead to disfigurement, isolation, job loss, and economic hardship.

Health History

During the health history interview, the nurse asks about any family and personal history of skin allergies; allergic reactions to food, medications, and chemicals; previous skin problems; and skin cancer. The names of cosmetics, soaps, shampoos, and other personal hygiene products are obtained if there have been any recent skin problems noticed with the use of these products. The health history contains specific information about the onset, signs and symptoms, location, and duration of any pain, itching, rash, or other discomfort experienced by the patient. The nurse inquires about tattoos because they involve the injection of ink into the dermis of the skin and are associated with an increased risk for blood-borne disease, skin infections, and allergic reactions. Box 51-3 lists selected questions useful in obtaining appropriate information.

TABLE 51-1 GERONTOLOGIC CONSIDERATIONS / Age-Related Changes of the Skin

Structural Changes	Associated Physical Findings
Thinning at the junction of the dermis and epidermis result in fewer anchoring sites between the two skin layers, which means that even minor injury or stress to the epidermis can cause it to shear away from the dermis.	Increased vulnerability of aged skin to trauma
The epidermis and dermis thin and flatten.	Wrinkles, sags, and overlapping skin folds
Loss of the subcutaneous tissue substances of elastin, collagen, and fat	Decreased protection and cushioning of underlying tissues and organs, decreased muscle tone, and loss of the insulating properties of fat.
Cellular replacement slows as a result of aging, and there is thinning of the dermal layers.	Skin becomes fragile and transparent.
The blood supply to the skin also changes with age. Vessels, especially the capillary loops, decrease in number and size.	Vascular changes are associated with delayed wound healing.
Sweat and sebaceous glands decrease in number and functional capacity.	Dry and scaly skin
Reduced hormonal levels of androgens	Associated with declining sebaceous gland function
Hair growth gradually diminishes, especially over the lower legs and dorsum of the feet. Thinning is common in the scalp, axilla, and pubic areas.	Decreased hair growth, hair loss
Photoaging (damage from excessive sun exposure)	Profound wrinkling; increased loss of elasticity; mottled, pigmented areas; cutaneous atrophy; and benign or malignant lesions

BOX 51-2 Benign Changes in Elderly Skin

- Cherry angiomas (bright red "moles")
- Diminished hair, especially on scalp and pubic area
- Dyschromias (color variations):
  - Solar lentigo (liver spots)

- Melasma (dark discoloration of the skin)
- Lentigines (freckles)

- Neurodermatitis (itchy spots)
- Seborrheic keratoses (crusty brown "stuck-on" patches)
- Spider angiomas (network of dilated capillaries radiating from a central arteriole)
- Telangiectasias (red marks on skin caused by stretching of the superficial blood vessels)
- Wrinkles (a small fold, ridge, or crease in the skin)
- Xerosis (dryness)
- Xanthelasma (yellowish waxy deposits on upper and lower eyelids)
- Ichthyosis (fish scale appearance of the skin)

Unfolding Patient Stories: Vincent Brody • Part 2

Recall from Chapter 2 Vincent Brody, with chronic obstructive pulmonary disease (COPD), who spends most of the day in a recliner chair smoking and has a poor nutritional intake due to shortness of breath. He is admitted to the hospital with COPD exacerbation. What are the factors related to his diagnosis? What background information can influence skin breakdown? Describe the skin assessment performed by the nurse.

Care for Vincent and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

Physical Assessment

Assessment of the skin involves the entire skin area, including the mucous membranes, scalp, hair, and nails. The skin is a reflection of a person's overall health, and alterations commonly correspond to disease in other organ systems. Inspection and palpation are techniques commonly used in examining the skin. The room must be well lighted and warm. A penlight may be used to highlight lesions. The patient completely disrobes and is adequately draped. Gloves are worn during skin examination if a rash or lesions are to be palpated.

BOX 51-3 Health History Related to Skin Disorders

Patient history relevant to skin disorders may be obtained by asking the following questions:

- When did you first notice this skin problem? (Also investigate duration and intensity)
- Has it occurred previously?
- Are there any other symptoms?
- What site was first affected?
- What did the rash or lesion look like when it first appeared?
- Where and how fast did it spread?
- Do you have any itching, burning, tingling, or crawling sensations?
- Is there any loss of sensation?
- Is the problem worse at a particular time or season?
- How do you think it started?
- Do you have a history of hay fever, asthma, hives, eczema, or allergies?
- Who in your family has skin problems or rashes?
- Did the eruptions appear after certain foods were eaten? Which foods?
- When the problem occurred, had you recently consumed alcohol?
- What relation do you think there may be between a specific event and the outbreak of the rash or lesion?
- What medications are you taking?
- What topical medication (ointment, cream, salve) have you put on the lesion (including over-the-counter medications)?
- What skin products or cosmetics do you use?
- What is your occupation?
- What in your immediate environment (plants, animals, chemicals, infections) might be precipitating this disorder? Is there anything new, or are there any changes in the environment?

- Does anything touching your skin cause a rash?
- How has this affected you (or your life)?
- Is there anything else you wish to talk about in regard to this disorder?

The general appearance of the skin is assessed by observing color, temperature, moisture or dryness, skin texture (rough or smooth), lesions, vascularity, mobility, and the condition of the hair and nails. Skin turgor, possible edema, and elasticity are assessed by palpation.

Assessing Color

Skin color varies from person to person and ranges from ivory to deep brown to almost pure black. The skin of exposed portions of the body, especially in sunny, warm climates, tends to be more pigmented than the rest of the body.

Almost every process that occurs on the skin causes some color change. For example, hypopigmentation may be caused by a fungal infection, eczema, or vitiligo; hyperpigmentation can occur after sun injury, as a result of aging, or with disease processes such as Addison because of stimulation of melanocyte-stimulating hormone. The vasodilation that occurs with fever, sunburn, and inflammation produces a pink or reddish hue to the skin. Pallor is an absence of or a decrease in normal skin color and vascularity and is best observed in the conjunctivae or around the mouth. Assessing for pallor in the palms and soles of patients with dark skin may be helpful (Bickley & Szilagyi, 2013).

In people with dark skin, melanin is produced at a faster rate and in larger quantities than in people with light skin. Healthy dark skin has a reddish base or undertone. The buccal mucosa, tongue, lips, and nails normally are pink. Dark pigment responds with discoloration after injury or inflammation, and patients with dark skin more often experience postinflammatory hyperpigmentation than do those with lighter skin. The hyperpigmentation eventually fades but may require months to a year to do so. Table 51-2 provides an overview of color changes in people who are light-skinned and dark-skinned.

Concept Mastery Alert

Pallor can best be determined by examining conjunctivae or around the mouth. Nail beds are not necessarily a reliable area when assessing for pallor.

In general, people with dark skin suffer the same skin conditions as those with light skin. They are less likely to have skin cancer but more likely to have keloid or scar formation and disorders resulting from occlusion or blockage of hair follicles.

Erythema

Erythema is redness of the skin caused by the congestion of capillaries. To determine possible inflammation, the skin is palpated for increased warmth and for smoothness (i.e., edema) or hardness (i.e., intracellular infiltration).

Cyanosis

Cyanosis is the bluish discoloration that results from a lack of oxygen in the blood. It appears with shock or with respiratory or circulatory compromise. In people with light skin, cyanosis manifests as a bluish hue to the lips, fingertips, and nail beds (Fig. 51-2). In people who are dark-skinned, the skin may appear blue and dull or assume a gray hue. The term *central cyanosis* refers to desaturation of oxygen in the blood and this is reflected in the mucous membranes and skin, whereas *peripheral cyanosis* implies increased oxygen extraction from the blood because of sluggish blood flow, or vasoconstriction related to exposure to cold environments, which is reflected in the extremities. The nurse assesses the patient for additional indications of decreased tissue perfusion, including cold, clammy skin; a rapid, thready pulse; and rapid, shallow respirations. The conjunctivae of the eyelids are examined for pallor and petechiae.

TABLE 51-2 Color Changes in Light and Dark Skin

Etiology	Light Skin	Dark Skin
Pallor		
Anemia: Decreased hematocrit Shock: Decreased perfusion, vasoconstriction	Generalized pallor	Brown skin appears yellow-brown, dull; black skin appears ashen gray, dull. (Observe areas with least pigmentation: conjunctivae, mucous membranes)
Local arterial insufficiency	Marked localized pallor (lower extremities, especially when elevated)	Ashen gray, dull; cool to palpation
Albinism: Total absence of pigment melanin	Whitish pink	Tan, cream, white
Vitiligo: A condition characterized by destruction of the melanocytes in circumscribed areas of the skin (may be localized or widespread)	Patchy, milky white spots, often symmetric bilaterally	Same
Cyanosis		
Increased amount of unoxygenated hemoglobin:	Dusky blue	Dark but dull, lifeless; only severe cyanosis is apparent in skin. (Observe conjunctivae, oral mucosa, nail beds)
Central: Chronic heart and lung diseases cause arterial desaturation	Bluish discoloration of skin, mucous membranes and nail beds	
Peripheral: Exposure to cold, anxiety	Nail beds dusky	

Erythema		
Hyperemia: Increased blood flow through engorged arterial vessels, as in inflammation, fever, alcohol intake, blushing	Red, bright pink	Purplish tinge, but difficult to see because epidermal melanin may alter disease presentation by masking erythema (Palpate for increased warmth with inflammation, taut skin, and hardening of deep tissues)
Polycythemia: Increased red blood cells, capillary stasis	Ruddy blue in face, oral mucosa, conjunctivae, hands and feet	Well concealed by pigment. (Observe for redness in lips)
Carbon monoxide poisoning	Bright, cherry red in face and upper torso	Cherry red nail beds, lips, and oral mucosa
Stasis dermatitis (venous stasis) is poor venous return in the lower extremities causing hemosiderin staining and cracking of the skin (skin breakdown) that causes stasis ulcers or venous ulcers.	Brown or rusty discoloration of the skin resulting from a buildup of hemosiderin (iron-containing pigment derived from the breakdown of hemoglobin) in the interstitial fluid	More difficult to detect signs of venous insufficiency such as hemosiderin staining (reddish, brown color) (James et al., 2016a; Reddy, Lenzy, Brown, & Gilchrest, 2013)
Venous disease	Edema, hyperpigmentation surrounding the skin (reddish or brown due to hemosiderin), warmth at feet with palpable pulses (exception if no coexisting arterial disease)	Edema, hyperpigmentation surrounding the skin (reddish or brown due to hemosiderin), warmth at feet with palpable pulses (exception if no coexisting arterial disease)
Jaundice		
Increased serum bilirubin concentration (>2.5–3 mg/dL) due to liver dysfunction or hemolysis, as after severe burns or some infections	Yellow first in sclerae, hard palate, and mucous membranes; then over skin	Check sclerae for yellow near limbus; do not mistake normal yellowish fatty deposits in the periphery under eyelids for jaundice. (Jaundice is best noted at junction of hard and soft palate, on palms)
Carotenemia: Increased level of serum carotene from ingestion of large amounts of carotene-rich foods	Yellow-orange tinge in forehead, palms and soles, and nasolabial folds, but no yellowing in sclerae or mucous membranes	Yellow-orange tinge in palms and soles
Uremia: Kidney failure causes retained urochrome pigments in the blood	Orange-green or gray overlying pallor of anemia; may also have ecchymoses and purpura	Easily masked. (Rely on laboratory and clinical findings)
Brown-Tan		
Addison disease: Cortisol deficiency stimulates increased melanin production	Bronzed appearance, an "external tan"; most apparent around nipples, perineum, genitalia, and pressure points (inner thighs, buttocks, elbows, axillae)	Easily masked. (Rely on laboratory and clinical findings)
Café-au-lait spots: Caused by increased melanin pigment in basal cell layer	Tan to light brown, irregularly shaped, oval patch with well-defined borders	Often not visible in a person with very dark skin

Nursing Alert

Cyanosis is a late sign and symptom of hypoxemia, as 5 g of hemoglobin (normal level is 15 g/dL) are desaturated before cyanosis is evident. In cases of carbon monoxide poisoning, the level of carboxyhemoglobin does not affect color; therefore, the patient may be profoundly hypoxemic without evidence of cyanosis.

Jaundice

Jaundice, a yellowing of the skin, is directly related to elevations in serum bilirubin and is often first observed in the sclerae and mucous membranes (see Fig. 51-2). The term *icterus* is used to describe yellowing of the sclerae (white of the eyes).

Striae

The nurse assesses for striae (stretch marks), which occurs when the elastic fibers in the reticular dermis rupture. Striae are seen in conditions of weight gain, such as pregnancy and obesity, in muscle building, with prolonged use of oral or topical corticosteroids, or in Cushing syndrome (increased adrenal cortical activity) (see Chapter 31).

Assessing Rash

In instances of pruritus (i.e., itching), the patient is asked to indicate which areas of the body are involved. The skin is then stretched gently to decrease the reddish tone and make the rash more visible. Pointing a penlight laterally across the skin may highlight the rash, making it easier to observe. The differences in skin texture are then assessed by running the tips of the fingers lightly over the skin. The borders of the rash may be palpable. The patient's mouth and ears are included in the examination (sometimes rubeola, or measles, causes a red cast to appear on the ears). The patient's temperature is assessed, and the lymph nodes are palpated.

FIGURE 51-2 Examples of skin color changes: the bluish tint of cyanosis (*left*) and the yellow hue of jaundice (*right*).

Assessing Skin Lesions

Skin lesions are the most prominent characteristics of dermatologic conditions. They vary in size, shape, and cause and are classified according to their appearance and origin. Skin lesions can be described as primary or secondary. Primary lesions are the initial lesions and are characteristic of the disease itself. Secondary lesions result from external causes, such as scratching, trauma, infections, or changes caused by wound healing. Depending on the stage of development, skin lesions are further categorized according to type and appearance (Table 51-3). The degree of pigmentation of the patient's skin may affect the appearance of a lesion. In patients with darker skin, lesions may be black, maroon, purple, or gray instead of the tan or red seen in patients with light skin.

TABLE 51-3 Primary and Secondary Skin Lesions

Lesion	Description	Examples
Primary Lesions		
Macule, patch 	Flat, nonpalpable skin color change (color may be brown, white, tan, purple, red) • *Macule:* less than 1 cm, circumscribed border • *Patch:* greater than 1 cm, may have irregular border	Freckles, flat moles, petechia, rubella, vitiligo, port wine stains, ecchymosis
Papule, plaque 	Elevated, palpable, solid mass with a circumscribed border Plaque may be coalesced papules with flat top • *Papule:* less than 0.5 cm • *Plaque:* greater than 0.5 cm	*Papules:* Elevated nevi, warts, lichen planus *Plaques:* Psoriasis, actinic keratosis
Nodule, tumor 	Elevated, palpable, solid mass that extends deeper into the dermis than a papule • *Nodule:* 0.5–2 cm; circumscribed • *Tumor:* greater than 1–2 cm; tumors do not always have sharp borders	*Nodules:* Lipoma, squamous cell carcinoma, poorly absorbed injection, dermatofibroma *Tumors:* Larger lipoma, carcinoma
Vesicle, bulla 	Circumscribed, elevated, palpable mass containing serous fluid • *Vesicle:* less than 0.5 cm • *Bulla:* greater than 0.5 cm	*Vesicles:* Herpes simplex/zoster, chickenpox, poison ivy, second-degree burn (blister) *Bulla:* Pemphigus, contact dermatitis, large burn blisters, poison ivy, bullous impetigo
Wheal 	Elevated mass with transient borders; often irregular; size and color vary Caused by movement of serous fluid into the dermis; does not contain free fluid in a cavity (as, for example, a vesicle does)	Urticaria (hives), insect bites

Pustule  Pustule	Pus-filled vesicle or bulla	Acne, impetigo, furuncles, carbuncles
Cyst  Cyst	Encapsulated fluid-filled or semisolid mass in the subcutaneous tissue or dermis	Sebaceous cyst, epidermoid cysts
Secondary Lesions		
Erosion  Erosion	Loss of superficial epidermis that does not extend to dermis; depressed, moist area	Ruptured vesicles, scratch marks
Ulcer  Ulcer	Skin loss or damage at or extending past the epidermis. May include necrotic tissue development, bleeding or scarring	Stasis ulcer of venous insufficiency, pressure ulcer
Fissure  Fissure	Linear crack in the skin that may extend to dermis	Chapped lips or hands, athlete foot
Scales  Scales	Flakes secondary to desquamated, dead epithelium that may adhere to skin surface; color varies (silvery, white); texture varies (thick, fine)	Dandruff, psoriasis, dry skin, pityriasis rosea

Crust  Crust	Dried residue of serum, blood, or pus on skin surface Large, adherent crust is a scab	Residue left after vesicle rupture: impetigo, herpes, eczema
Scar (cicatrix)  Scar	Skin mark left after healing of a wound or lesion; represents replacement by connective tissue of the injured tissue • *Young scars:* red or purple • *Mature scars:* white or glistening	Healed wound or surgical incision
Keloid  Keloid	Hypertrophied scar tissue secondary to excessive collagen formation during healing; elevated, irregular, red Greater incidence among African Americans	Keloid of ear piercing or surgical incision
Atrophy  Atrophy	Thin, dry, transparent appearance of epidermis; loss of surface markings; secondary to loss of collagen and elastin; underlying vessels may be visible	Aged skin, arterial insufficiency
Lichenification  Lichenification	Thickening and roughening of the skin or accentuated skin markings that may be secondary to repeated rubbing, irritation, scratching	Contact dermatitis

A preliminary assessment of the eruption or lesion helps identify the type of dermatosis and indicates whether the lesion is primary or secondary. At the same time, the anatomic distribution of the eruption should be observed because certain diseases affect certain sites of the body and are distributed in characteristic patterns and shapes (Figs. 51-3 and 51-4). To determine the extent of the regional distribution, the left and right sides of the body should be compared while the color and shape of the lesions are assessed. After observation, the lesions are palpated to determine their texture, shape, and border and to see if they are soft and filled with fluid or hard and fixed to the surrounding tissue.

A disposable metric ruler is used to measure the size of the lesions so that any further extension can be compared with this baseline measurement. Skin lesions are described clearly and in detail on the patient's health record, using precise terminology.

Characteristics of Lesions

After the characteristic distribution of the lesions has been determined, the following information should be obtained and described clearly and in detail:

- Color of the lesion
- Any redness, heat, pain, or swelling

- Size and location of the involved area
- Pattern of eruption (e.g., macular, papular, scaling, oozing, discrete, confluent)
- Distribution of the lesion (e.g., bilateral, symmetric, linear, circular)

FIGURE 51-3 Anatomic distribution of common skin disorders. A. Contact dermatitis (shoes). B. Contact dermatitis (cosmetics, perfumes, earrings). C. Seborrheic dermatitis. D. Acne. E. Scabies. F. Herpes zoster (shingles).

If acute open wounds or lesions are found on inspection of the skin, a comprehensive assessment should be made and documented. This assessment should address the following issues:

- *Wound bed:* Inspect for necrotic, slough, granulation or epithelial tissue, exudate, color, and odor.
- *Wound edges and margins:* Observe for undermining (i.e., extension of the wound under the surface skin) or epibole (rolled edges), and evaluate for condition.
- *Wound size:* Measure in centimeters (cm), as appropriate, to determine diameter and depth of the wound and surrounding erythema.
- *Surrounding skin:* Assess for color, suppleness and moisture, irritation, induration (abnormal firmness of tissue), and scaling.

Assessing Vascularity

After the color of the skin has been evaluated and lesions have been inspected, an assessment of vascular changes in the skin is performed. A description of vascular changes includes location, distribution, color, size, and the presence of pulsations. Common vascular changes include petechiae, ecchymoses, Telangiectasia (spider veins), angiomas, and venous stars. Petechiae are small (less than 2 mm in diameter) lesions that are red or purple in color. They are associated with broken capillaries or indicative of platelet abnormalities, specifically thrombocytopenia (low platelet counts).

Assessing Hydration

Skin moisture, temperature, and texture are assessed primarily by palpation. The turgor (i.e., elasticity) of the skin, which decreases in normal aging, may be a factor in assessing the hydration status of a patient. The forearm, sternum, or forehead is recommended for assessing turgor in the elderly, rather than the hand, owing to the loss of elasticity with aging. The nurse pinches the skin of the sternum with the thumb and index finger, creating a tent of skin. Upon releasing it, normal turgid skin promptly resumes its shape, whereas a persistent fold or tent is associated with fluid volume deficit.

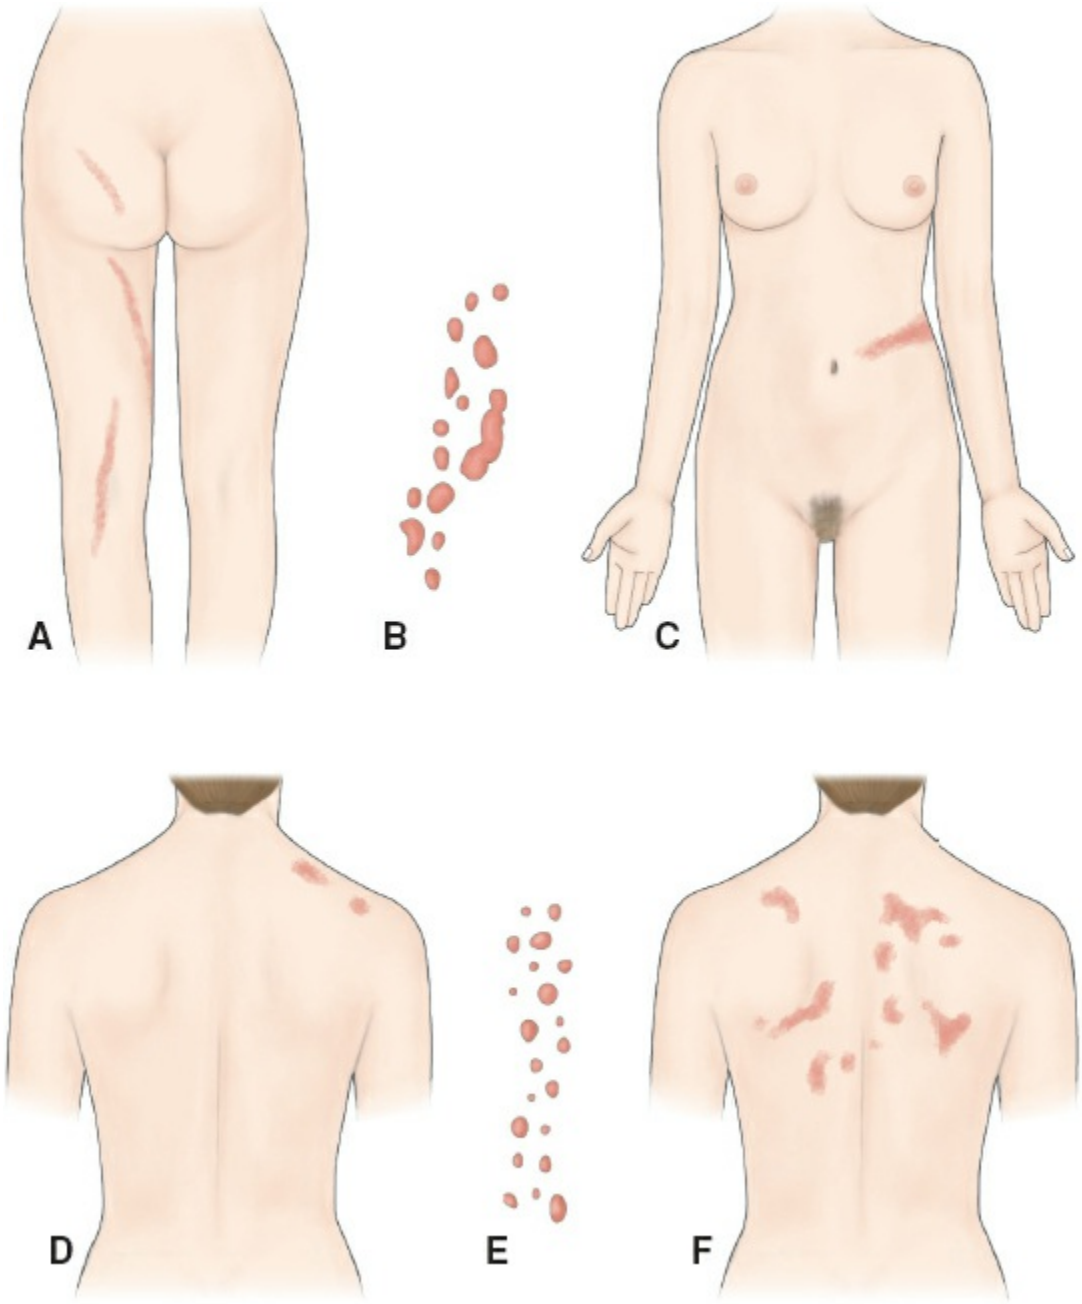

FIGURE 51-4 Skin lesion configurations. A. Linear (in a line). B. Annular and arciform (circular or arcing). C. Zosteriform (linear along a nerve route). D. Grouped (clustered). E. Discrete (separate and distinct). F. Confluent (merged).

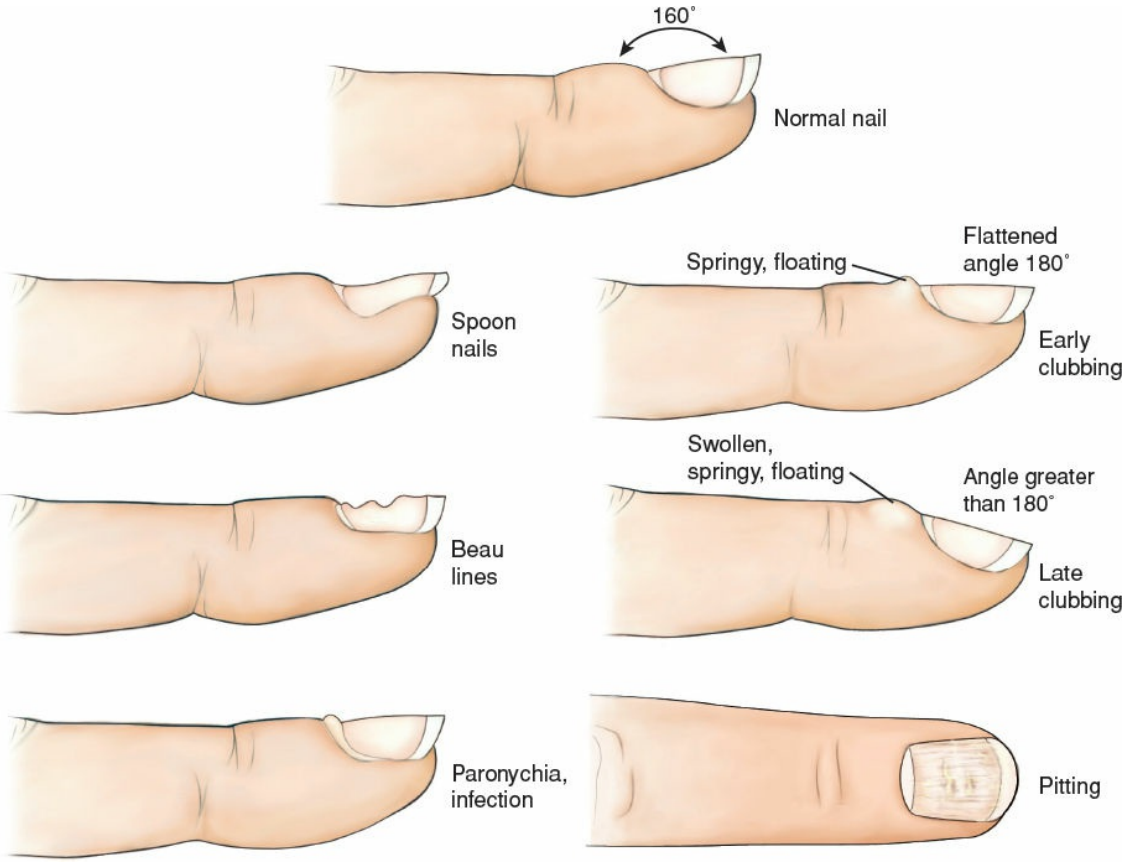

FIGURE 51-5 Common nail disorders.

Assessing the Nails

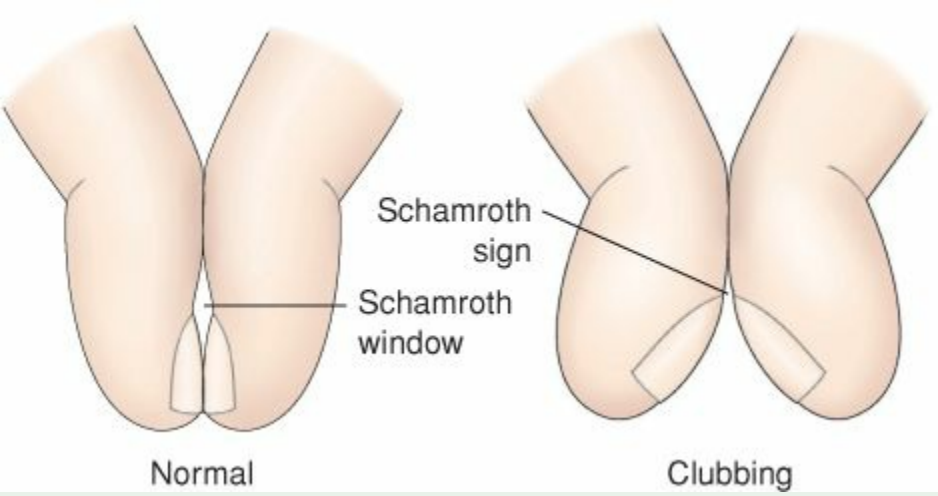
A brief inspection of the nails includes observation of configuration, color, and consistency. Many alterations in the nail or nail bed reflect local or systemic abnormalities in progress or resulting from past events (Fig. 51-5). Transverse depressions known as *Beau lines* in the nails may reflect retarded growth of the nail matrix because of severe illness or, more commonly, local trauma. Ridging, hypertrophy, and other changes may also be visible with local trauma. Paronychia, an inflammation of the skin around the nail, is usually accompanied by tenderness and erythema. The angle between the normal nail and its base is 160 degrees. When palpated, the nail base is usually firm. Clubbing is manifested by a straightening of the normal angle (at least 180 degrees) and softening of the nail base (Box 51-4). The softened area feels sponge-like when palpated.

Assessing the Hair

Hair assessment involves inspection and palpation. Gloves are worn by the examiner, and the examination room should be well lighted. Separating the hair so that the condition of the skin underneath can be easily seen, the nurse assesses color, texture, and distribution. The wooden end of a cotton swab can be used to make small parts in the hair, so that the scalp can be inspected. Any abnormal lesions, evidence of itching, inflammation, scaling, or signs of infestation (i.e., lice or mites) are documented.

BOX 51-4 Assessing for Clubbing

Although the mechanism is unknown for the characteristic changes to the nails, clubbing is frequently associated with hypoxemia. The nail changes are painless and usually found bilaterally. If the underlying cause is removed, clubbing is reversible. To assess for clubbing, have the patient place both forefinger nails together and look between them. If a small diamond space is visible at the nail base then the nails are *not* clubbed (Schamroth sign).



Color and Texture

Natural hair color ranges from white to black. Hair begins to turn gray with age, initially during the third decade of life, when the loss of melanin begins to become apparent. However, it is not unusual for the hair of younger people to turn gray as a result of hereditary traits. The person with albinism (i.e., partial or complete absence of pigmentation) has a genetic predisposition to white hair from birth. The natural state of the hair can be altered by using hair dyes, bleaches, and curling or relaxing products. The types of products used are identified in the assessment.

The texture of scalp hair ranges from fine to coarse, silky to brittle, oily to dry, and shiny to dull, and hair can be straight, curly, or kinky. Dry, brittle hair may result from overuse of hair dyes, hair dryers, and curling irons, or from endocrine disorders, such as thyroid dysfunction. Oily hair is usually caused by increased secretion from the sebaceous glands close to the scalp. If the patient reports a recent change in hair texture, the underlying reason is pursued; the alteration may arise simply from the overuse of commercial hair products or from changing to a new shampoo.

Distribution

Body hair distribution varies with location. Hair over most of the body is fine, except in the axillae and pubic areas, where it is coarse. Pubic hair, which develops at puberty, forms a diamond shape extending up to the umbilicus in boys and men. Female pubic hair resembles an inverted triangle. If the pattern found is more characteristic of the opposite gender, it may indicate an endocrine problem and further investigation is in order. Racial

differences in hair are expected, such as straight hair in Asians and curly, coarser hair in people of African descent.

Men tend to have more body and facial hair than do women. Loss of hair, or alopecia, can occur over the entire body or be confined to a specific area. Scalp hair loss may be localized to patchy areas or may range from generalized thinning to total baldness. When assessing scalp hair loss, it is important to investigate the underlying cause with the patient. Patchy hair loss may be from habitual hair pulling or twisting; excessive traction on the hair (e.g., braiding too tightly); excessive use of dyes, straighteners, and oils; chemotherapeutic agents (e.g., doxorubicin, cyclophosphamide); fungal infection; or moles or lesions on the scalp. Regrowth may be erratic, and distribution may never attain the previous thickness.

Hair Loss. The most common cause of hair loss is male pattern baldness, which affects more than one half of the male population and is believed to be related to heredity, aging, and androgen (male hormone) levels. Androgen is necessary for male pattern baldness to develop. The pattern of hair loss begins with receding of the hairline in the frontal-temporal area and progresses to gradual thinning and complete loss of hair over the top of the scalp and crown.

Other Changes. Male pattern hair distribution may be seen in some women at the time of menopause, when the hormone estrogen is no longer produced by the ovaries. In women with hirsutism, excessive hair may grow on the face, chest, shoulders, and pubic area. When menopause is ruled out as the underlying cause, hormonal abnormalities related to pituitary or adrenal dysfunction must be investigated.

Diagnostic Evaluation

Skin Biopsy

Performed to obtain tissue for microscopic examination, a skin biopsy may be obtained by scalpel excision or by a skin punch instrument that removes a small core of tissue. Biopsies are performed on skin nodules, plaques, blisters, ulcers, and other lesions to rule out malignancy and to establish an exact diagnosis.

Patch Testing

Performed to identify substances to which the patient has developed an allergy, patch testing involves applying the suspected allergens to normal skin under occlusive patches. The development of redness, fine elevations, or itching is considered a weak positive reaction; fine blisters, papules, and severe itching indicate a moderately positive reaction; and blisters, pain, and ulceration indicate a strong positive reaction.

Skin Scrapings

Tissue samples are scraped from suspected fungal lesions with a scalpel blade moistened with oil, so that the scraped skin adheres to the blade. The scraped material is transferred to a glass slide, covered with a coverslip, and examined microscopically. The spores and hyphae of dermatophyte infections, as well as infestations such as scabies, can be visualized.

Clinical Photographs

Photographs are taken to document the nature and extent of the skin condition and are used to determine progress or improvement resulting from treatment. They are sometimes used to track the status of moles to document if the characteristics of the mole are changing.

CHAPTER REVIEW

Critical Thinking Exercises

1. You are caring for an elderly African American woman who is hospitalized with a stroke. She has hemiparesis of her right arm and leg and is receiving physical therapy. Because of the patient's age and her limited mobility, what would the patient be at high risk for and what would your assessment include in examining her skin?

2. You are volunteering at the skin cancer screening booth at a community health fair. A middle-aged man approaches you about a skin lesion. He states that he is a landscaper and works long hours all year long. Discuss the possible types of lesions that can be found and how you would describe the lesion after assessing it.

3. An 88-year-old male patient is admitted to the hospital after a visit to his provider's

office. Initial nursing assessment reveals that he has a poor skin turgor. What effects will this have on skin integrity?

NCLEX-Style Review Questions

1. A 90-year-old patient with multiple medical problems is admitted to the hospital's geriatric care unit. The nursing assessment reveals weight loss, poor capillary perfusion, and delayed skin turgor. These findings should alert the gerontologic nurse to which condition?
   a. Aspiration
   b. Fluid volume deficit
   c. Pressure ulcers
   d. Contractures

2. During assessment, what does the nurse recognize as a normal function of the skin?
   a. Thermal regulation
   b. Vitamin E production
   c. Vitamin C production
   d. Releasing of carbon dioxide

3. A patient has returned to the room postoperatively. The nurse examines the patient's nail beds to assess for what condition?
   a. Cyanosis
   b. Respiratory rate
   c. Edema
   d. Cellulitis

4. What does the nurse look for when assessing the characteristics of a lesion? Select all that apply.
   a. Heat
   b. Claudication
   c. Size
   d. Erythema
   e. Pattern

5. What changes in the older adult best describe why aging process increases risk for impairment in skin integrity?
   a. Epidermal cells thicken
   b. Dermal thickness increases
   c. Decreased elastin, collagen, and fat
   d. Maceration

CHAPTER 52

Nursing Management: Patients with Dermatologic Problems

Commander Patina S. Walton-Battle

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the general management of the patient with an abnormal skin condition.
2. Describe general principles of wound care
3. Identify stages of pressure ulcers
4. Discuss the general management of a patient with pruritus
5. Describe the health education needs of the patient with infections of the skin and parasitic skin diseases.
6. Discuss care of patients with noninfectious, inflammatory dermatoses, including psoriasis.
7. Describe nursing management of the patient with skin cancer.
8. Describe characteristics of the various types of Kaposi sarcoma.

Regardless of the environment where they work, nurses manage skin care. Additionally, nurses predict patients who will be at risk for skin problems, assess skin changes, and intervene to prevent injury and maintain skin viability. As nurses, it is also important to utilize preventative practices to reduce transmission of infection or further injury, and maintain skin viability.

GENERAL MANAGEMENT OF SKIN DISORDERS

Nursing management of skin disorders includes protecting the skin, preventing infection, reversing inflammation, administering therapeutic baths, and administering medications.

PROVIDING SKIN CARE

Protecting the Skin

Some skin problems are aggravated by bathing. The essence of skin care in bathing a patient with skin problems is as follows:

- A mild, lipid-free soap or soap substitute is used.
- The area is rinsed completely and blotted dry with a soft cloth.
- Deodorant soaps are avoided.

Special care is necessary when changing dressings. Pledgets (small compress of material, usually cotton or gauze) saturated with oil, sterile saline or water, wound cleansers, or another prescribed solution help to loosen crusts, remove exudates, or free an adherent dry dressing.

Preventing Infection

Potentially infectious skin lesions should be regarded strictly as such, and proper precautions should be observed until the diagnosis is established. Most lesions with purulent drainage contain infectious material. The health care provider must adhere to standard contact precautions carried out according to Occupational Safety and Health Administration (OSHA) regulations.

Nursing Alert

The nurse is aware that, for patients with contact precautions, a gown and gloves should be worn for all interactions that may involve contact with the patient or potentially contaminated areas in the patient's environment. The personal protective equipment (PPE) is donned before room entry and discarded before exiting (Denton, Topping, & Humphreys, 2016).

Reversing Inflammation

The type of skin lesion (e.g., oozing, infected, or dry) usually determines the type of local medication or treatment that is prescribed. As a rule, if the skin is acutely inflamed (i.e., hot), erythematous (red), and edematous (swollen) and draining, it is best to apply wet or specialty dressings and/or soothing lotions. For chronic conditions in which the skin surface is dry and scaly, water-soluble emulsions, creams, ointments, and pastes are used. The therapy is modified as the responses of the skin indicate. The patient and the nurse should note whether the medication or dressings seem to irritate the skin. The success or failure of therapy usually depends on adequate instruction and motivation of the patient and family, and the support of health care personnel promotes adherence to instructions.

Administering Therapeutic Baths (Balneotherapy)

Baths or soaks, known as balneotherapy, are useful when large areas of skin are affected. The baths remove crusts, scales, and old medications and relieve the inflammation and pruritus (itching) that accompany acute dermatoses. Additional information about therapeutic baths is given in Box 52-1.

Administering Pharmacologic Therapy

Topical Preparations

Table 52-1 lists some commonly used topical preparations.

BOX 52-1 Therapeutic Baths

Types of Therapeutic Baths

Bath Solution	Effects and Uses
Water	Same effect as wet dressings
Saline	Used for widely disseminated lesions
Colloidal (Aveeno, oatmeal)	Antipruritic, soothing
Sodium bicarbonate (baking soda)	Cooling
Starch	Soothing
Medicated tars	Psoriasis and chronic eczema
Bath oils	Antipruritic and emollient action; acute and subacute generalized eczematous eruptions

Nursing Interventions

- Fill the tub half full.
- Keep the water at a comfortable temperature.
- Do not allow the water to cool excessively.
- Use a bath mat because *medications added to the bath can cause the tub to be slippery.*
- Apply an emollient cream to damp skin after the bath if lubrication is desired.
- Because tars are volatile, the bath area should be well ventilated.
- Maintain a constant room temperature without drafts.
- Encourage the patient to wear light, loose clothing after the bath.

TABLE 52-1 Common Topical Preparations and Medications

Preparation	Product Name
Bath preparations	
With tar	Balnetar, Doak Oil, Lavatar
With colloidal oatmeal	Aveeno Oilated Bath Powder
With oatmeal and mineral oil	Aveeno Bath Oil, Nutra Soothe
With mineral oil	Nutraderm Bath Oil, Lubath, Alpha-Keri Bath Oil
Moisturizer creams	Acid Mantle Cream, Curel Cream, Dermasil, Eucerin, Lubriderm, Noxzema Skin Cream
Moisturizer ointments	Aquaphor Ointment, Eutra Swiss Skin Cream, Vaseline Ointment
Topical anesthetics	Anesthetic drugs such as lidocaine, tetracaine, benzocaine, and prilocaine in a cream, ointment, or gel. EMLA cream (lidocaine 2.5% and prilocaine 2.5%) is an example of one most commonly used.
Topical antibiotics	Bacitracin, Polysporin (bacitracin and polymyxin B), Bactroban ointment or cream (mupirocin 2%), erythromycin 2% (Emgel, Eryderm Solution), clindamycin phosphate 1% (Cleocin cream, gel, solution), gentamicin sulfate 1% (Garamycin cream or ointment), 1% silver sulfadiazine cream (Silvadene)

Lotions

Lotions are used frequently to replenish lost skin oils or to relieve pruritus. They are usually applied directly to the skin, but a dressing soaked in the lotion can be placed on the affected area. Lotions must be applied every 3 or 4 hours for sustained therapeutic effect because if left in place for a long period, they may crust and cake on the skin.

There are two types of lotions: suspensions and liniments. Suspensions are medicines that are mixed with a liquid, usually water, in which it cannot dissolve and, therefore, remains intact in the form of small particles. The important thing to remember about suspensions is to shake the medication before giving each dose so that the medicine particles are evenly distributed throughout the liquid. An example is calamine lotion, which provides a rapid cooling and drying effect as it evaporates, leaving a thin, medicinal layer of powder on the affected skin. Liniments are lotions with oil added to prevent crusting. An example of a liniment is Ben-Gay for muscle aches.

Powders

Powders usually have a talc, zinc oxide, bentonite, or cornstarch base and are dusted on the skin with a shaker or applied with cotton sponges. Although their therapeutic action is brief, powders act as hygroscopic agents that absorb and retain moisture from the air and reduce friction between skin surfaces and clothing or bedding.

Creams and Emulsions

Creams may be suspensions of oil in water or emulsions of water in oil, with additional ingredients to prevent bacterial and fungal growth. Both may cause an allergic reaction, such as contact dermatitis (discussed on page 1473). Oil-in-water creams are easily applied and usually are the most cosmetically acceptable to the patient. Although they can be used on the face, they tend to have a drying effect. Water-in-oil emulsions are greasier and are preferred for drying and flaking dermatoses.

Gels

Gels are semisolid emulsions that become liquid when applied to the skin or scalp. The water-based gels appear to penetrate the skin more effectively, are greaseless and odorless, and cause less stinging on application. They are especially useful for acute dermatitis in which there is weeping exudate (e.g., poison ivy).

Pastes

Pastes are mixtures of powders and ointments and are used in inflammatory blistering conditions. They adhere to the skin and may be difficult to remove without using oil (e.g., olive oil or mineral oil). Pastes are applied with a wooden tongue depressor or gloved hand.

Ointments

Ointments retard water loss and lubricate and protect the skin. Ointments are better moisturizers or hydrators of the skin due to better adherence to the skin and pharmacologic formulations (Kanfer, Tettley-Amialo, Au, & Hughes-Formella, 2016). They are the preferred vehicle for delivering medication to patients with chronic or localized dry skin conditions, such as eczema or psoriasis (e.g., triamcinolone). Other ointments are used to aid in healing and treatment of pressure ulcers, varicose ulcers, and dehiscent wounds (e.g., Xenaderm). Ointments are applied with a wooden tongue depressor or gloved hand and applied up to twice a day.

Sprays and Aerosols

Spray and aerosol preparations may be used on any widespread dermatologic condition (e.g., 3M Cavilon Skin Protectant; Convatec Aloe Vesta Skin Protectant). They evaporate on contact and are used infrequently.

Corticosteroids

Corticosteroids are widely used in treating dermatologic conditions to provide anti-inflammatory, antipruritic, and vasoconstrictive effects. The patient is taught to apply the product sparingly and rub it into the prescribed area thoroughly. Absorption of topical corticosteroid is enhanced when the skin is hydrated or when the affected area is covered by an occlusive or moisture-retentive dressing. Inappropriate use of topical corticosteroids can result in local and systemic side effects, especially when the medication is absorbed through inflamed and excoriated skin or is used for long periods on sensitive areas. Local side effects may include skin atrophy and thinning, striae (bandlike streaks), and telangiectasia (small dilated blood vessels on the surface of the skin). Thinning of the skin results from the ability of corticosteroids to inhibit the synthesis of skin collagen. The thinning process can be reversed by discontinuing the medication, but striae and telangiectasia are permanent. Systemic side effects may include hyperglycemia and symptoms of Cushing syndrome (refer to Chapter 31). Caution is required when applying corticosteroids around the eyes for two reasons: (1) long-term use may cause glaucoma or cataracts, and (2) the anti-inflammatory effect of corticosteroids may mask existing viral or fungal infections.

Concentrated (fluorinated) corticosteroids are never applied on the face or intertriginous areas (i.e., axilla and groin) because these areas have a thinner stratum corneum and absorb the medication much more quickly than do other areas of the body, such as the forearm or legs.

Nursing Alert

It is important for the nurse to consider that penetration of a topical steroid depends on the skin site, which varies based upon the denseness of the stratum corneum, blood supply, and tissue integrity of the involved area. According to Nicol (2016), penetration of topical steroids applied to the eyelids or scrotum is 4 times greater than for the forehead and 36 times greater than the palms and soles. Thus, thinner and less intact skin has a higher absorption and thus poses a higher risk for side effects.

Intralesional Therapy

Intralesional therapy consists of injecting a sterile suspension of medication (usually a corticosteroid) into or just below a lesion. Although this treatment may have an anti-inflammatory effect, local atrophy may result if the medication is injected into subcutaneous fat. Skin lesions treated with intralesional therapy include psoriasis, keloids, and cystic acne.

Systemic Medications

Systemic medications are also prescribed for skin conditions. These include corticosteroids for short-term therapy for contact dermatitis or for long-term treatment of a chronic dermatosis, such as pemphigus vulgaris. Other frequently used systemic medications

include antibiotics, antifungals, antihistamines, sedatives, tranquilizers, analgesics, and cytotoxic (destructive of cells) agents.

Caring for Wounds

Wound Dressings

There are three types of wound dressings: primary, secondary, and active. Primary dressings have only a protective function and maintain a moist environment for natural healing. They include those that just cover the area (e.g., DuoDERM, Tegaderm) and may remain in place for several days. Secondary dressings are capable of absorbing wound exudate while (1) maintaining a moist environment in the area of the wound and (2) allowing the surrounding skin to remain dry. They include hydrocolloids, alginates, and hydrogels. Secondary dressings are able to modify the physiology of the wound environment by modulating and stimulating cellular activity and by releasing growth factor (Bryant & Nix, 2016). Active dressings improve the healing process and decrease healing time. They include skin grafts and biologic skin substitutes. Both interactive and active dressings create a moist environment at the interface of the wound with the dressing.

Nursing Alert

Primary dressings are usually considered passive and provide protection to the wound, whereas interactive dressings create a moist wound environment and interact with the wound bed components to further enhance wound healing. Interactive dressings may reduce colonization count, reduce the level of exudate, improve wound bed moisture retention, improve wound collagen matrix, remove cellular products, or provide protection for the epithelializing bed (Bryant & Nix, 2016).

Because so many wound care products are available, it is often difficult to select the most appropriate product for a specific wound. Selection of products should be made carefully because of their expense. Both clinical efficacy and health-related outcomes (e.g., decreased pain, increased mobility) should be used to measure the success of a product for a wound. Even with the availability of a large variety of dressings, an appropriate selection can be made if certain principles are maintained. Table 52-2 is a guide to wound dressing functions and categories.

Occlusive Dressings

Occlusive dressings cover a topical medication that is applied to a skin lesion. The area is kept airtight by using plastic film (e.g., plastic wrap). Plastic film is thin and readily adapts to all sizes, body shapes, and skin surfaces. In general, plastic wrap should be used no more than 12 hours each day.

Transparent Films

Transparent films are thin, transparent, polyurethane, impermeable adhesive films that are used for partial thickness, minimally draining, or closed wounds. They permit visualization of the wound, promote autolysis, reduce friction, and are sometimes used as a secondary

dressing. Examples are Op-Site and Tegaderm.

Specialty Absorptive Dressings

These are used for heavily exudating wounds. The dressings absorb copious amounts of drainage. Examples of these are Exudry and ABD pads.

Moisture-Retentive Dressings

Commercially produced moisture-retentive dressing can perform the same functions as wet dressings but are more efficient at removing exudate because of their higher moisture-vapor transmission rate; some have reservoirs that can hold excessive exudate. A number of moisture-retentive dressings are already impregnated with saline solution, petrolatum, zinc-saline solution, hydrogel, or antimicrobial agents, thereby eliminating the need to coat the skin to avoid maceration. Depending on the product used and the type of dermatologic problem encountered, most moisture-retentive dressings may remain in place from 12 to 24 hours; some can remain in place as long as a week.

Hydrogels

Hydrogels are polymers with a water content of 90% to 95%. They are available in impregnated sheets or as gel in a tube. Their high moisture content makes them ideal for autolytic débridement of wounds. They are semitransparent, allowing for wound inspection without dressing removal. They are comfortable and soothing for the painful wound. They require a secondary dressing to keep them in place. Hydrogels are appropriate for superficial wounds with high serous output, such as abrasions, skin graft sites, and draining venous ulcers.

Hydrocolloids

Hydrocolloids are composed of a water-impermeable, polyurethane outer covering separated from the wound by a hydrocolloid material. They are adherent and nonpermeable to water vapor and oxygen. As water evaporates over the wound, it is absorbed into the dressing, which softens and discolors with the increased water content. The dressing can be removed without damage to the wound. As the dressing absorbs water, it produces a foul-smelling, yellowish covering over the wound. This is a normal chemical interaction between the dressing and wound exudate and should not be confused with purulent drainage from the wound. Most can be left in place for as long as 7 days.

Foam Dressings

Foam dressings are nonadherent and require a secondary dressing to keep them in place. Moisture is absorbed into the foam layer, decreasing maceration of surrounding tissue. A moist environment is maintained, and removal of the dressing does not damage the wound. Foams are a good choice for exudative wounds. They are especially helpful over bony prominences because they provide contoured cushioning.

TABLE 52-2 Quick Guide to Wound Dressing Function and Categories

Function	Action	Example
Absorption	Absorbs exudate	Alginates, composite dressings, foams, gauze, hydrocolloids, hydrogels
Cleansing	Removes purulent drainage, foreign debris, and devitalized tissue	Wound cleansers
Débridement	*Autolytic*; covers a wound and allows enzymes to self-digest sloughed skin *Chemical or enzymatic*; applied topically to break down devitalized tissue *Mechanical*; removes devitalized tissue with mechanical force	Absorption beads, pastes, powders; alginates; composite dressings; foams; hydrate gauze; hydrogels; hydrocolloids; transparent films; wound care systems Enzymatic débridement agents Wound cleansers, gauze (wet to dry), whirlpool
Diathermy	Produces electrical current to promote warmth and new tissue growth	Ultrasound and microwave (diathermy)
Hydration	Adds moisture to a wound	Gauze (saturated with saline solution), hydrogels, wound care systems
Maintain moist environment	Manages moisture levels in a wound and maintains a moist environment	Composites, contact layers, foams, gauze (impregnated or saturated), hydrogels, hydrocolloids, transparent films, wound care systems
Manage high-output wounds	Manages excessive quantities of exudate	Pouching systems
Pack or fill dead space	Prevents premature wound closure or fills shallow areas and provides absorption	Absorbent beads, powders, pastes; alginates, composites, foams, gauze (impregnated and nonimpregnated)
Protect and cover wound	Provides protection from the external environment	Composites, compression bandages/wraps, foams, gauze dressings, hydrogels, hydrocolloids, transparent film dressings
Protect periwound skin	Prevents moisture and mechanical trauma from damaging delicate tissue around the wound	Composites, foams, hydrocolloids, pouching systems, skin sealants, transparent film dressings
Provide therapeutic compression	Provides appropriate levels of support to the lower extremities in venous stasis disease	Compression bandages, wraps, support stockings

Alginates

Calcium alginates (e.g., AlgiSite M, Kaltostat, Sorbsan, Algicell) are derived from brown seaweed and consist of very absorbent calcium alginate fibers that can absorb 20 times their weight (Bryant & Nix, 2016). They are useful in areas where the tissue is highly irritated or macerated. The alginate dressing forms a moist pocket over the wound while the surrounding skin stays dry. The dressing also reacts with wound fluid and forms a foul-smelling coating. Alginates work well when packed into a deep cavity, wound, or sinus tract with heavy drainage. They are nonadherent and require a secondary dressing.

Antimicrobial Dressings

Antimicrobial dressings are used for partial and full-thickness wounds. They help to control or decrease the bioburden and odor for minimal and heavy exudating wounds. They are a topical antifungal and antibiotic agent that come in ointments, gels, impregnated gauze, hydrofiber, and pads. Examples are Acticoat 7 and Aquacel Ag (hydrofiber).

Collagen Dressings

These dressings stimulate the wound and accelerate wound healing. Some forms can be left on for up to 7 days. They are used for minimal to moderate exudating wounds that are partial to full thickness. Examples are Promogran and ColActive.

Tissue Engineered Skin

Apligraf and Dermagraft are dressings made up of a bioabsorbable matrix of collagen or suture material that contains living cytokines and fibroblasts. When applied to wounds, these agents stimulate platelet activity and potentially decrease wound-healing time (Bryant & Nix, 2016). Bioengineered skin works by maintaining wound moisture, providing a structure for regeneration of cells, and supplying beneficial cytokines.

Débridement

Débridement is the removal of nonviable tissue from pressure and vascular ulcers, burns, surgical or traumatic wounds, and other types of wounds.

Autolytic Débridement

Autolytic débridement is a process that uses the body's own digestive enzymes to break down necrotic tissue. The wound is kept moist with occlusive dressings. Eschar and necrotic debris are softened, liquefied, and separated from the bed of the wound.

Enzymatic Débridement

Several commercially available products contain the same enzymes that the body produces naturally. These are called enzymatic débriding agents; an example is a collagenase (Santyl). Application of these products speeds the rate at which necrotic tissue is removed. This method is slower and no more effective than surgical débridement.

Mechanical Débridement

Wet-to-dry dressings are still used, but not very much. It is considered a nonselective method of débridement, which removes necrotic tissue and absorbs small to large amounts of exudates. This method exposes healthy tissue in the wound and can damage it as well.

Wet dressings (wet compresses applied to the skin) were traditionally used for acute, weeping, inflammatory lesions. They have become almost obsolete because of the many newer products available for wound care (Ramundo, 2016).

Negative Pressure Wound Therapy

In this therapy, an open-cell, reticulated foam, gauze, or specially designed dressing is placed into the wound, sealed with semi-occlusive drape, and exposed to subatmospheric pressure via an evacuation tube connected to a computerized pump. It is used for acute and chronic open wounds. It also can be used on partial to full-thickness wounds, as well as partial-thickness burns.

Hyperbaric Oxygen Therapy

Hyperbaric oxygenation (HBO) is an adjunctive therapy that requires the patient to breathe 100% oxygen while under increased atmospheric pressure in a pressure chamber. It is recommended that hyperbaric therapy be utilized for limb-threatening diabetic wounds of the lower extremities and pressure ulcers. Also, it is used for hypoxic vascular wounds of the lower extremity (Bryant & Nix, 2016). Those who received HBO as part of their wound care regimen healed faster than those who received standard treatment (Ramundo, 2016).

Pharmacologic Therapy

Pain management can be challenging. In managing any patient with acute or chronic wounds, it is important to identify and measure the degree, site, and type of pain. This aids in utilizing the appropriate treatment for pain (Hopt, Shapshak, Junkins, & O'Neil, 2016).

SKIN CONDITIONS

Pruritus

While not a disorder but a manifestation, pruritus (itching) is one of the most common symptoms of patients with dermatologic disorders.

GENERAL PRURITUS

Pathophysiology

Itch receptors are unmyelinated, penicillate (brush-like) nerve endings that are found exclusively in the skin, mucous membranes, and cornea. Although pruritus is usually caused by a primary skin disease with resultant rash or lesions, it may occur without a rash or lesion. This is referred to as *essential pruritus*, which generally has a rapid onset, may be severe, and interferes with normal daily activities.

Pruritus may be the first indication of a systemic internal disease, such as diabetes mellitus, blood disorders, or cancer (occult malignancy of the breast or colon; Hodgkin disease, other lymphomas). It may also accompany kidney, liver, and thyroid diseases (Box 52-2). Some common oral medications, such as aspirin, antibiotics, hormones (i.e., estrogens, testosterone, or oral contraceptives), and opioids (i.e., morphine or cocaine) may cause pruritus directly or by increasing sensitivity to ultraviolet light. Certain soaps and chemicals, radiation therapy, prickly heat (miliaria), and contact with woolen garments are also associated with pruritus. Pruritus may also be caused by psychological factors, such as excessive stress in family or work situations.

BOX 52-2 Systemic Disorders Associated with Generalized Pruritus

- Chronic kidney disease
- Obstructive biliary disease (primary biliary cirrhosis, extrahepatic biliary obstruction, drug-induced cholestasis)
- Endocrine disease (thyrotoxicosis, hypothyroidism, diabetes mellitus)
- Psychiatric disorders (emotional stress, anxiety, neurosis, phobias)
- Malignancies (polycythemia vera, Hodgkin disease, lymphoma, leukemia, multiple myeloma, mycosis fungoides, and cancers of the lung, breast, central nervous system, and GI tract)
- Neurologic disorders (multiple sclerosis, brain abscess, brain tumor)
- Infestations (scabies, lice, other insects)
- Pruritus of pregnancy (pruritic urticarial papules of pregnancy [PUPP], cholestasis of pregnancy, pemphigoid of pregnancy)
- Folliculitis (bacterial, candidiasis, dermatophyte)
- Skin conditions (seborrheic dermatitis, folliculitis, iron deficiency anemia, atopic dermatitis)

Scratching the pruritic area causes the inflamed cells and nerve endings to release histamine, which produces more pruritus, generating a vicious itch–scratch cycle. If the patient responds to an itch by scratching, the integrity of the skin may be altered, and excoriation, erythema, raised areas (i.e., wheals), infection, or changes in pigmentation may result. Pruritus usually is more severe at night and is less frequently reported during waking hours, most likely because the person is distracted by daily activities. At night, when there are few distractions, even the slightest pruritus cannot be ignored easily. Severe itching can be debilitating.

Gerontologic Considerations 

Pruritus occurs frequently in elderly people as a result of dry skin. Elderly people are also more likely to have a systemic illness that triggers pruritus, are at higher risk for occult malignancy, and are more likely to be taking multiple medications than younger people. All of these factors increase the incidence of pruritus in elderly people.

Medical and Nursing Management

A thorough history and physical examination usually provide clues to the underlying cause of the pruritus, such as hay fever, allergy, recent administration of a new medication, or a change of cosmetics or soaps. After the causative agent has been identified and removed (if possible), treatment of the condition should relieve the pruritus. Signs of infection and environmental clues, such as warm, dry air or irritating bed linens, should be identified. In general, washing with soap and hot water is avoided. Bath oils containing a surfactant that makes the oil mix with bath water (e.g., Alpha-Keri) may be sufficient for cleaning. A warm bath with a mild soap followed by application of a bland emollient to moist skin can control xerosis (dry skin). Applying a cold compress, or cool agents that contain menthol and camphor (which constrict blood vessels) may also help relieve pruritus. If baths have been prescribed, the nurse reminds the patient to use tepid (not hot) water and to shake off the excess water and blot between intertriginous areas (body folds) with a towel. Rubbing vigorously with the towel is avoided because this overstimulates the skin and causes more itching. It also removes water from the stratum corneum (horny layer or outermost layer of the epidermis). Immediately after bathing, the patient should lubricate the skin with an emollient to trap moisture. The nurse instructs patient to avoid situations that cause vasodilation, such as exposure to an overly warm environment and ingestion of alcohol or hot foods and liquids. Activities that result in perspiration should be limited because perspiration may irritate and promote pruritus. If the patient is troubled at night with itching that interferes with sleep, the nurse can advise wearing cotton clothing next to the skin rather than synthetic materials. The room should be kept cool and humidified. Vigorous scratching should be avoided and nails kept trimmed to prevent skin damage and infection. When the underlying cause of pruritus is unknown and further testing is required, the nurse explains each test and the expected outcome.

Topical corticosteroids may be beneficial as anti-inflammatory agents to decrease itching. Oral antihistamines are even more effective because they can overcome the effects of histamine released from damaged mast cells. An antihistamine, such as diphenhydramine (Benadryl) or hydroxyzine (Atarax), prescribed in a sedative dose at bedtime, may be beneficial in producing a restful and comfortable sleep. Nonsedating antihistamine medications, such as fexofenadine (Allegra), are more appropriate to relieve daytime pruritus. Tricyclic antidepressants may be prescribed for pruritus of neuropsychogenic origin. If pruritus continues, further investigation of a systemic problem is advised.

PERINEAL AND PERIANAL PRURITUS

Pathophysiology

Pruritus of the genital and anal regions may be caused by small particles of fecal material lodged in the perianal crevices or attached to anal hairs. Alternatively, it may result from perianal skin damage caused by scratching, moisture, and decreased skin resistance as a result of corticosteroid or antibiotic therapy. Other possible causes of perianal itching include local irritants such as scabies and lice, local lesions such as hemorrhoids, fungal or yeast infections, and pinworm infestation. Foods associated with anal pruritus include

coffee, tea, cola, beer, chocolate, and tomatoes. Occasionally, no cause for genital and anal pruritus can be identified.

Medical and Nursing Management

The nurse instructs the patient to follow proper hygiene measures and to discontinue home and over-the-counter remedies. The perineal or anal area should be rinsed with lukewarm water and blotted dry with cotton balls. Premoistened tissues may be used after defecation. Cornstarch can be applied in the skinfold areas to absorb perspiration.

As part of health teaching, the nurse instructs the patient to avoid bathing in water that is too hot and to avoid using bubble baths, sodium bicarbonate, and detergent soaps, all of which aggravate dryness. To keep the perineal or perianal skin as dry as possible, patients should avoid wearing underwear made of synthetic fabrics. Local anesthetic agents should not be used because of possible allergic effects. The patient should also avoid vasodilating agents or stimulants (e.g., alcohol, caffeine) and mechanical irritants, such as rough or woolen clothing. A diet that includes adequate fiber may help maintain soft stools and prevent minor trauma to the anal mucosa.

ULCERATION

Superficial loss of surface tissue as a result of death of cells is called an ulceration. A simple ulcer, such as the kind found in a small, superficial, partial-thickness burn, tends to heal by granulation if kept clean and protected from injury. If exposed to the air, the serum that escapes will dry and form a scab, under which the epithelial cells grow and cover the surface completely. The four most common ulcers noted are arterial, venous, neuropathic/diabetic, and pressure ulcers (Table 52-3).

TABLE 52-3 Characteristics of Ulcers

Ulcer Type	Location	Description of Wound Bed	Exudate	Description of Wound Edges
Arterial 	Tips of toes, pressure points, areas of trauma	Pale or necrotic	Minimal amount	Well defined
Venous 	Commonly located in the lower leg just above the ankle (gaiter region)	Dark red, "ruddy"	Moderate to large amounts	Poorly defined; irregular
Neuropathic 	Plantar surface over metatarsal heads	Typically red (unless coexisting ischemia)	Moderate to large amounts	Well defined
Pressure 	Any boney prominence	Erythremic or purplish in discoloration due to pressure	Minimal to large amounts	Poorly to well defined

ARTERIAL ULCERS

Ulcers related to problems with arterial circulation are seen in patients with hypertension, diabetes, cigarette smoking, hypercholesterolemia, obesity, and sedentary lifestyle. Arterial ulcers are caused by lower extremity arterial disease (LEAD), which is inadequate blood flow to the tissue, resulting in severe tissue ischemia, and which can create ulcers that are extremely painful (Doughty & Sparks-Defriese, 2016). This condition is also referred to as peripheral arterial disease (PAD), peripheral vascular disease (PVD), or peripheral arterial occlusive disease (PAOD). In patients with LEAD and ulcers, treatment of the ulcers is concurrent with treatment of the arterial disease. Management includes the use of the dressings and/or tissue perfusion improvement. Perfusion and tissue oxygenation can improve outcomes via surgical options (bypass graft, angioplasty), medications (antiplatelets, vasodilators, hemorheologics [decrease the viscosity of the blood], antilipemics [decrease lipid levels], analgesics), lifestyle changes, and adjunctive therapies (hyperbaric oxygen therapy) (Doughty & Sparks-Defriese, 2016). If these interventions are

instituted early in the progression of an ulcer, the condition can often be effectively improved. Surgical amputation of an affected limb is a last resort.

VENOUS ULCERS

Venous ulcers are more common than arterial ulcers. They occur due to impaired return of venous blood from the tissue to the heart, also known as chronic venous insufficiency (CVI) or lower extremity venous disease (LEVD). Risk factors are valvular dysfunction caused by obesity, multiple pregnancies, thrombophlebitis, leg trauma (deep vein thrombosis or fractures), and thrombophilic conditions (increased coagulability of the blood). Other risks factors include arthritis or calf muscle dysfunction, IV drug use involving the affected extremity, sedentary lifestyle, or prolonged standing. Healing can be affected by diabetes, smoking, nutrition, and medications (Carmel & Bryant, 2016). Management includes reduction of edema, prevention of complications, and appropriate topical therapy or specialty dressings (Carmel & Bryant, 2016).

NEUROPATHIC ULCERS

Diabetic foot ulcers are also known as neuropathic ulcers or lower extremity neuropathic disease (LEND). These ulcers occur due to reduced blood supply to the nerves, also known as microvascular damage, which can lead to neuropathy. Neuropathy is classified as loss of sensation. Risk factors include history of amputations or ulcers, long duration of diabetes and/or poor glucose control, limited joint mobility, long history of smoking, obesity, poor vision, poor footwear, vascular insufficiency, structural deformities and callus formation, absence of protective sensation, and autonomic neuropathy, causing decreased sweating and dry feet (Driver, Brentton, Allen, & Park, 2016).

Early prevention can be achieved through comprehensive annual foot examinations, glycemic control, limiting other health complications, and offloading (pressure relief). Wound management may include débridement, treatment of infection if needed, and topical, specialty wound care dressing and/or adjunctive therapies (Driver et al., 2016). For further information related to diabetic neuropathy, refer to Chapter 30.

PRESSURE ULCERS

Pathophysiology

Pressure ulcers involve the breakdown of the skin due to prolonged pressure, friction, and shear forces, and insufficient blood supply, usually at bony prominences. Pressure ulcers are localized areas of infarcted soft tissue that occur when pressure applied to the skin over time is greater than normal capillary closure pressure, which is about 32 mm Hg. Weight-bearing bony prominences are most susceptible to pressure ulcer development because they are covered only by skin and small amounts of subcutaneous tissue. Susceptible areas include the sacrum and coccygeal areas, ischial tuberosities (especially in people who sit for prolonged periods), greater trochanter, heel, knee, malleolus, medial condyle of the tibia, fibular head, scapula, and elbow (Fig. 52-1).

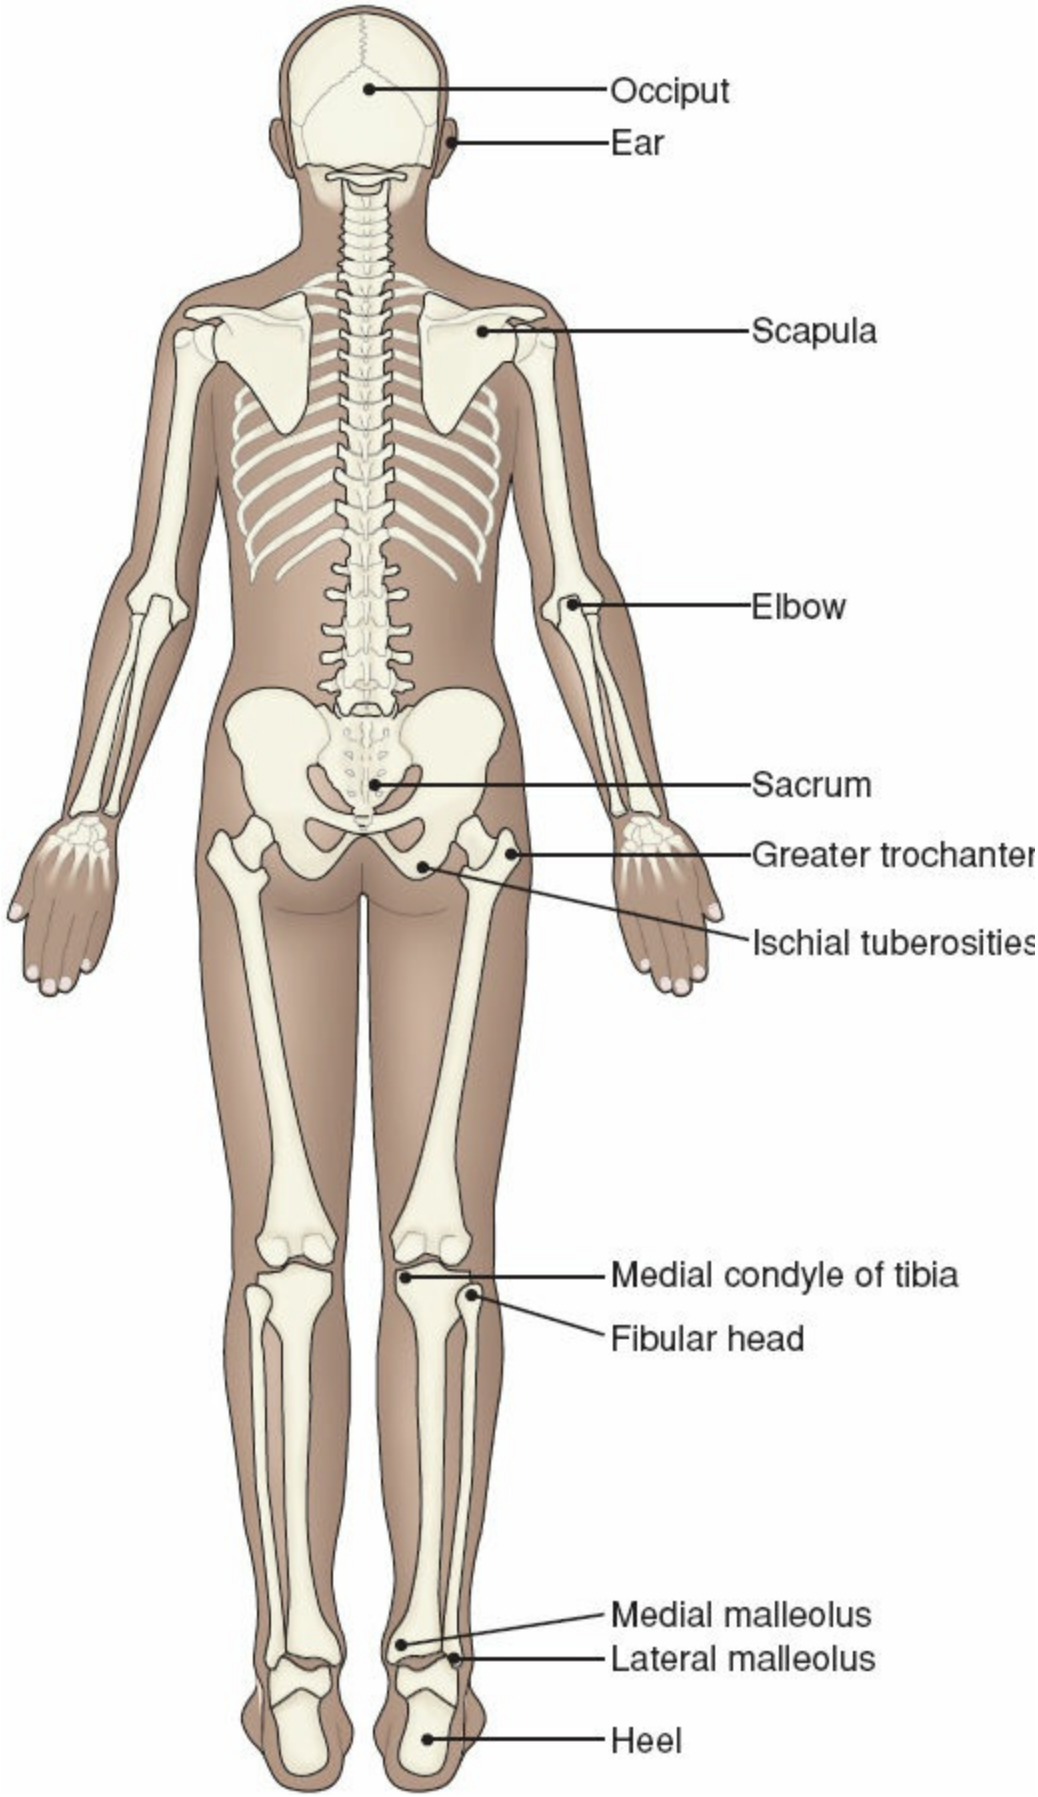

FIGURE 52-1 Areas susceptible to pressure ulcers.

Risk Factors

Box 52-3 summarizes risk factors for pressure ulcers.

Clinical Manifestations and Assessment

The initial sign of pressure is erythema (redness of the skin) caused by reactive hyperemia, which normally resolves in less than 1 hour. Unrelieved pressure results in tissue ischemia or anoxia. The cutaneous tissues become broken or destroyed, leading to progressive destruction and necrosis of underlying soft tissue, and the resulting pressure ulcer is painful and slow to heal. The nurse assesses the patient's mobility, sensory perception, cognitive abilities, tissue perfusion, nutritional status, friction and shear forces, sources of moisture on the skin, age, and skin condition. Scales such as the Braden or Norton scale may be used to facilitate systematic assessment and quantification of a patient's risk for pressure ulcers although the nurse should recognize that the reliability of these scales is not well established for all patient populations. If a pressure area is observed, the nurse notes its size and location and uses a grading system to describe its severity (refer to Box 52-4 for current standards in assessing and staging pressure ulcers). A recent study of interrater reliability in identifying classification of pressure ulcers revealed low reliability; therefore, it is imperative that nurses use a consistent scale (Pieper, 2016).

BOX 52-3 Risk Factors for Pressure Ulcers

- Immobility, compromised mobility
- Prolonged pressure on tissue
- Altered skin moisture: excessively dry, excessively moist (perspiration, urine, feces, or drainage produces maceration [softening] of the skin)
- Equipment: Casts, traction, restraints
- Impaired sensory perception or cognition
- Decreased tissue perfusion (seen with diabetes, obesity, and edema). Patients who are critically ill have a lower capillary closure pressure and, thus, higher risk.
- Decreased nutritional status (anemia, hypoalbuminemia, vitamin deficiency)
- Friction and shear forces

BOX 52-4 Stages of Pressure Ulcers

Stage I

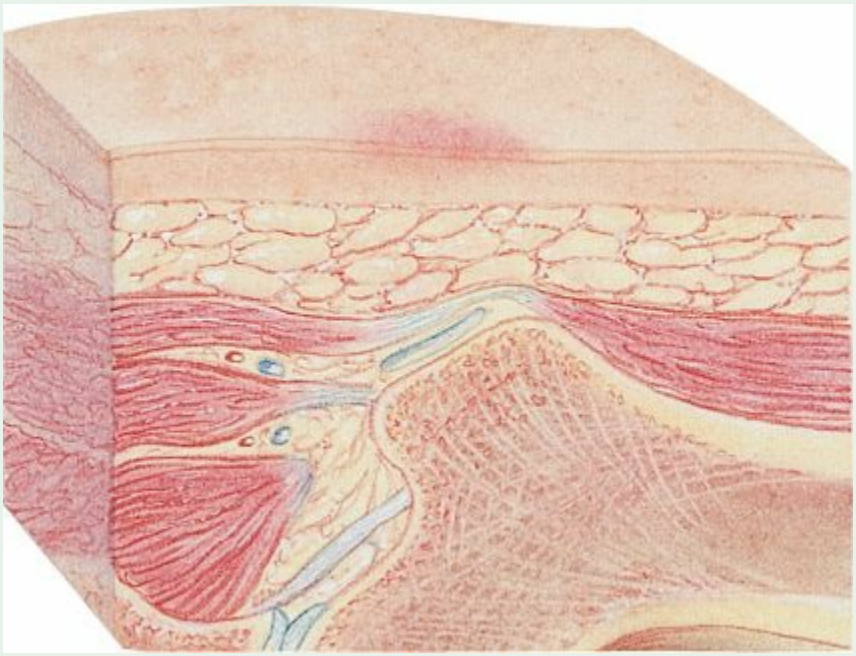
Description

Ulcer appears as intact skin with nonblanchable erythema of a localized area, usually over a bony prominence. Darkly pigmented skin may not have visible blanching; its color may differ from the surrounding area.

The area may be painful, firm, soft, and warmer or cooler in temperature as compared to adjacent tissue. Stage I may indicate patients who are "at risk" (a heralding sign of risk).

Treatment

To permit healing of Stage I pressure ulcers, the pressure is removed to allow increased tissue perfusion; nutritional status and fluid and electrolyte balance are maintained; friction and shear are reduced; and moisture to the skin is avoided.



Stage II

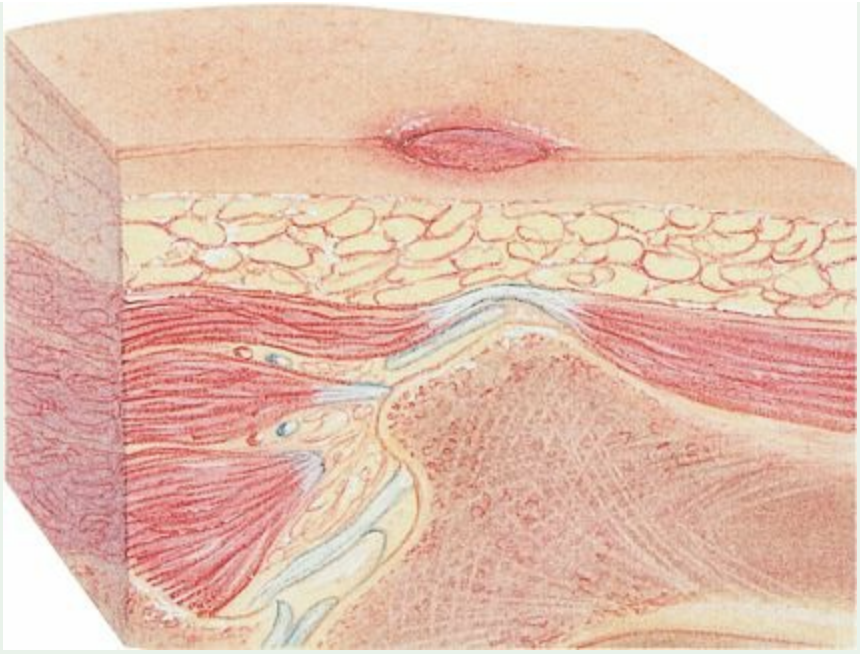
Description

Ulcer appears as partial-thickness loss of dermis, presenting as a shallow open ulcer with a red or pink wound bed, without slough. It may also present as an intact or open/ruptured serum-filled blister.

It may be a shiny or dry shallow ulcer without slough or bruising (bruising indicates suspected deep tissue injury). This stage should not be used to describe skin tears, tape burns, perineal dermatitis, maceration, or excoriation.

Treatment

In addition to measures listed for Stage I pressure ulcers, a moist environment, in which migration of epidermal cells over the ulcer surface occurs more rapidly, should be provided to aid wound healing. The ulcer is gently cleansed with sterile saline solution. Use of a heat lamp to dry the open wound is avoided as is the use of antiseptic solutions that damage healthy tissues and delay wound healing. Semipermeable occlusive dressings, hydrocolloid wafers, or wet saline dressings are helpful in providing a moist environment for healing and in minimizing the loss of fluids and proteins from the body.



Stage III

Description

There is full-thickness tissue loss. Subcutaneous fat may be visible, but bone, tendon, or muscle is not exposed. Slough may be present but does not obscure the depth of tissue loss. The ulcer may include undermining and tunneling.

The depth of a Stage III pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput and malleolus do not have subcutaneous tissue, and Stage III ulcers here can be shallow. In contrast, areas of significant adiposity can develop Stage III pressure ulcers that are extremely deep. Bone/tendon is not visible or directly palpable.

Treatment

Stage III and IV pressure ulcers are characterized by extensive tissue damage. In addition to the measures listed for Stage I, these advanced, draining, necrotic pressure ulcers must be cleaned (débrided) to create an area that will heal. Necrotic, devitalized tissue favors bacterial growth, delays granulation, and inhibits healing. Wound cleaning and dressing are uncomfortable; therefore, the nurse must prepare the patient for the procedure by explaining what will occur and administering prescribed analgesia.

Débridement may be accomplished by wet-to-damp dressing changes, mechanical flushing of necrotic and infective exudate, application of prescribed enzyme preparations that dissolve necrotic tissue, or surgical dissection. If an eschar covers the ulcer, it is removed surgically to ensure a clean, vitalized wound. Exudate may be absorbed by dressings or special hydrophilic powders, beads, or gels. Cultures of infected pressure ulcers are obtained to guide the selection of antibiotic therapy.

After the pressure ulcer is clean, a topical treatment is prescribed to promote granulation. New granulation tissue must be protected from reinfection, drying, and

damage, and care should be taken to prevent pressure and further trauma to the area. Dressings, solutions, and ointments applied to the ulcer should not disrupt the healing process. Multiple agents and protocols are used to treat pressure ulcers, but consistency is an important key to success. Objective evaluation of the pressure ulcer (e.g., measurement of the size and depth of the pressure ulcer, inspection for granulation tissue) for response to the treatment protocol must be made every 4–6 days. Taking photographs at weekly intervals is a reliable strategy for monitoring the healing process, which may take weeks to months.

Stage IV

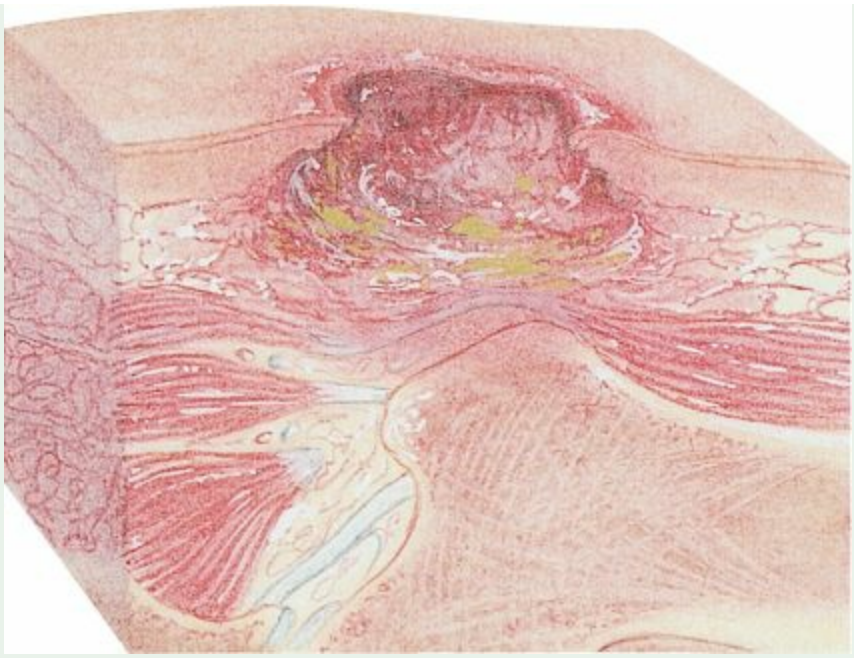
Description

There is full-thickness tissue loss with exposed bone, tendon, or muscle. Slough or eschar may be present on some parts of the wound bed. These ulcers often include undermining and tunneling.

The depth of a Stage IV pressure ulcer varies by anatomical location. The bridge of the nose, ear, occiput, and malleolus do not have subcutaneous tissue, and these ulcers can be shallow. Stage IV ulcers can extend into muscle and/or supporting structures (e.g., fascia, tendon, or joint capsule), making osteomyelitis possible. Exposed bone/tendon is visible or directly palpable.

Treatment

See Stage III treatment. In addition, surgical intervention may be necessary when the ulcer is extensive, when complications (e.g., fistula) exist, and when the ulcer does not respond to treatment. Surgical procedures include débridement, incision and drainage, bone resection, and skin grafting. Osteomyelitis is a common complication of wounds of Stage IV depth. See Chapter 41 for more information on osteomyelitis.



Unstageable

An unstageable lesion shows full-thickness tissue loss in which the base of the ulcer is covered by slough (yellow, tan, gray, green, or brown) and/or eschar (tan, brown or black) in the wound bed.

Until enough slough and/or eschar is removed to expose the base of the wound, the true depth and, therefore, stage cannot be determined. Stable (dry, adherent, intact without erythema or fluctuance) eschar on the heels serves as the body's natural (biologic) cover and should not be removed.

Suspected Deep Tissue Injury (DTI)

Suspected deep tissue injury (DTI) appears as a purple or maroon localized area of discolored intact skin or blood-filled blister due to damage of underlying soft tissue from pressure and/or shear. The area may be preceded by tissue that is painful, firm, mushy, boggy, warmer, or cooler as compared to adjacent tissue.

DTI may be difficult to detect in individuals with dark skin tones. Evolution may include a thin blister over a dark wound bed. The wound may further evolve and become covered by thin eschar. Evolution may be rapid, exposing additional layers of tissue even with optimal treatment.

Nursing Alert

Beginning in 2008, Medicare regulations do not reimburse for treatment of pressure ulcers acquired in the hospital, even if the ulcer was present on admission but undocumented. Therefore, it is imperative that accurate recognition and staging of pressure ulcers occurs in all patients.

Medical and Nursing Management

Treatment depends on stage (see Box 52-4). Nursing interventions for prevention and management of pressure ulcers include turning and repositioning the patient every 1 to 2 hours when in bed, and shifting of weight every 15 minutes while in a chair to allow the blood to flow into the ischemic areas to help tissues recover from the effects of pressure. The recumbent position is preferred to the semi-Fowler position because of increased supporting body surface area in this position, with careful attention paid to the repositioning of the patient's ankles, elbows, and shoulders. The nurse inspects the patient's skin at each position change and assesses for temperature elevation. If redness or heat is noted, or if the patient complains of discomfort, pressure on the area must be relieved.

A pillow or commercial heel protector may be used to support the heels off the bed when the patient is supine. Supporting the patient in a 30-degree side-lying position avoids pressure on the trochanter. At times, special equipment and beds may be needed to help relieve the pressure on the skin, such as wheelchair cushions and static support devices (such as high-density foam, air, or liquid mattress overlays). Shear occurs when patients are pulled, allowed to slump, or move by digging heels or elbows into the mattress. Raising the head of the bed by even a few centimeters increases the shearing force over the sacral area; therefore, the semi-reclining position is avoided in patients at risk. The patient is encouraged to remain active and is ambulated whenever possible. Exercise and repositioning improve tissue perfusion. Massage of erythematous areas is avoided because damage to the capillaries and deep tissue may occur.

Strategies to improve cognition and sensory perception may include stimulating the patient to increase awareness of self in the environment, encouraging the patient to participate in self-care, or supporting the patient's efforts toward active compensation for loss of sensation (e.g., a patient with paraplegia lifting up from the sitting position every 15 minutes).

Continuous moisture on the skin must be prevented by meticulous hygiene measures. Perspiration, urine, stool, and drainage must be removed from the skin promptly. The skin may be lubricated with a bland lotion to keep it soft and pliable. Drying agents and powders are avoided. Topical barrier ointments (e.g., petroleum jelly) may be helpful in protecting the skin of patients who are incontinent. Absorbent pads that wick moisture away from the body should be used to absorb drainage.

The patient's nutritional status must be adequate, and a positive nitrogen balance must be maintained because pressure ulcers develop more quickly and are more resistant to treatment in patients with nutritional disorders. A high-protein diet with protein supplements may be helpful. Iron preparations may be necessary to raise the hemoglobin concentration so that tissue oxygen levels can be maintained within acceptable limits. Ascorbic acid (vitamin C) is necessary for tissue healing. Other nutrients associated with healthy skin include vitamin A, B vitamins, zinc, and sulfur. See Box 52-5 for a systematic overview of research on preventing pressure ulcers.

Gerontologic Considerations 

In older adults, the skin has diminished epidermal thickness, dermal collagen, and tissue elasticity. The skin is drier as a result of diminished activity of the sebaceous and sweat glands. Cardiovascular changes result in decreased tissue perfusion. Muscles atrophy, and bone structures become prominent. Diminished sensory perception and reduced ability to reposition oneself contribute to prolonged pressure on the skin. Therefore, older adults are more susceptible to pressure ulcers, which cause pain and suffering and reduce quality of life.

SEBORRHEIC DERMATITIS

Seborrhea is excessive production of sebum (secretion of sebaceous glands) in areas where sebaceous glands are normally found in large numbers, such as on the face, scalp, eyebrows, eyelids, sides of the nose and upper lip, malar regions (cheeks), ears, axillae, under the breasts, in the groin, and in the gluteal crease of the buttocks. Seborrheic dermatitis is a chronic inflammatory disease of the skin with a predilection for areas that are well supplied with sebaceous glands or lie between skin folds, where the bacteria count is high.

Clinical Manifestations and Assessment

Two forms of seborrheic dermatitis can occur, an oily form and a dry form. Either form may start in childhood and continue throughout life. The oily form appears moist or "greasy." There may be patches of yellowish-red or gray-white, greasy skin, with white dry scaling macules and/or papules, with slight erythema, predominantly on the forehead, nasolabial fold, beard area, scalp, and between adjacent skin surfaces in the regions of the axillae, groin, and breasts (Clark, Pope, & Jaboori, 2015). Small pustules or papulopustules resembling acne may appear on the trunk. The dry form, consisting of flaky desquamation of the scalp with a profuse amount of fine, powdery scales, is commonly called dandruff. The mild forms of the disease are asymptomatic. When scaling occurs, it is often accompanied by pruritus, which may lead to scratching and secondary infections and excoriation.

BOX 52 Nursing Research

Bridging the Gap to Evidence-Based Practice

Tayyib, N., & Coyer, F. (2016). Effectiveness of pressure ulcer prevention strategies for adult patients in intensive care units: A systematic review. *Worldviews on Evidence-Based Nursing, 13*(6), 432–444.

Purpose

Pressure ulcers are associated with substantial health burden, but could be preventable. Hospital-acquired pressure ulcers (HAPUs) prevention has become a priority for all healthcare settings, as it is considered a sign of quality of care providing. Intensive care unit (ICU) patients are at higher risk for HAPUs development. Despite the availability of published prevention strategies, there is a little evidence about which strategies can be safely integrated into routine standard care and have an impact on HAPUs prevention. The aim was to synthesize the best available evidence regarding the effectiveness of single strategies designed to reduce the incidence and prevalence of HAPUs development in ICUs.

Design

The search strategy was designed to retrieve studies published in English across CINAHL, Medline, Cochrane Central Register of Controlled Trials, Embase, Scopus, and Mednar between 2000 and 2015. All adult ICU participants were aged 18 years or over. This review included randomized controlled trials, quasi-experimental and comparative studies. The studies that were selected for retrieval were assessed by two independent reviewers for methodologic validity prior to inclusion in the review using standardized critical-appraisal instruments.

Findings

The review included 25 studies, and the meta-analysis revealed a statistically significant effect of a silicon foam dressing strategy in reducing HAPUs incidence (effect size =

4.62; 95% CI: 0.05–0.29; p <0.00001, effect size = 4.50; 95% CI: 0.05–0.31; p = 0.00001, respectively) in critically ill patients. Evidence of the effectiveness of nutrition, skin-care regimen, positioning and repositioning schedule, support surfaces, and the role of education in prevention of HAPUs development in the ICU was limited, which precludes strong conclusions.

Nursing Implications

The review provides an evidence-based guide to future priorities for clinical practice. In particular, a silicone foam dressing has positive impact in reducing sacrum and heel HAPUs incidence in the ICU.

Seborrheic dermatitis has a genetic predisposition. Hormones, nutritional status, infection, and emotional stress influence its course. The remissions and exacerbations of this condition should be explained to the patient. If a person has not previously been diagnosed with this condition and suddenly appears with a severe outbreak, a complete history and physical examination should be considered.

Medical and Nursing Management

Because there is no known cure for seborrhea, the objective of therapy is to control the disorder and allow the skin to repair itself. Seborrheic dermatitis of the body and face may respond to a topically applied glucocorticoid cream or low-potency topical steroids (e.g., desonide), which allays the secondary inflammatory response (Clark et al., 2015). However, glucocorticoids should be used with caution near the eyelids, because they can induce glaucoma and cataracts in predisposed patients. Patients with seborrheic dermatitis may develop a secondary candidal (yeast) infection in body creases or folds and may have to use a topical antifungal (e.g., ciclopirox or ketoconazole) (Clark et al., 2015). To avoid this, patients should be advised to ensure maximum aeration of the skin and to clean areas where there are creases or folds in the skin carefully. Patients with persistent candidiasis should be evaluated for diabetes. Ultraviolet radiation therapy can be beneficial as a form of treatment as well.

The mainstay of dandruff treatment is proper, frequent shampooing (at least three times weekly) with medicated shampoos. Two or three different types of shampoo should be used in rotation to prevent the seborrhea from becoming resistant to a particular shampoo. The shampoo is left on at least 5 to 10 minutes. As the condition of the scalp improves, the treatment can be less frequent. Antiseborrheic shampoos include those containing selenium sulfide suspension, zinc pyrithione, salicylic acid or sulfur compounds, and tar shampoo that contains sulfur or salicylic acid. Instructions for using medicated shampoos are reinforced for people with dandruff who require treatment. Frequent shampooing is contrary to some cultural practices; the nurse should be sensitive to these differences when teaching the patient about home care.

A person with seborrheic dermatitis is advised to avoid external irritants, excessive heat, and perspiration; rubbing and scratching prolong the disorder. To avoid secondary infection, the patient should air the skin and keep skin folds clean and dry.

The patient is cautioned that seborrheic dermatitis is a chronic problem that tends to reappear. The goal is to keep it under control. Patients need to be encouraged to adhere to the treatment program. Those who become discouraged and disheartened by the effect on body image should be treated with sensitivity and encouraged to express their feelings.

VIRAL SKIN INFECTIONS

HERPES ZOSTER

Herpes zoster, also called *shingles*, is an infection caused by the varicella-zoster virus, a member of a group of DNA viruses. The viruses causing chickenpox and herpes zoster are indistinguishable, hence the name varicella-zoster virus. The disease is characterized by a painful vesicular eruption along the area of distribution of the sensory nerves from one or more posterior ganglia.

Pathophysiology

After a case of chickenpox runs its course, the varicella-zoster viruses responsible for the outbreak lie dormant inside nerve cells near the brain and spinal cord. Later, when these latent viruses are reactivated because of declining cellular immunity, they travel by way of the peripheral nerves to the skin, where the viruses multiply and create a red rash of small, fluid-filled vesicles. About 10% of adults get shingles during their lifetimes, usually after 50 years of age. There is an increased frequency of herpes zoster infections among patients with weakened immune systems and cancers (especially leukemias and lymphomas), those on chemotherapy, and in individuals who are HIV infected.

Clinical Manifestations and Assessment

The eruption is usually accompanied or preceded by pain, which may radiate over the entire region supplied by the affected nerves. The pain may be burning, lancinating (tearing or sharply cutting), stabbing, or aching. Some patients have no pain, but itching and tenderness may occur over the area. Sometimes, malaise and gastrointestinal (GI) disturbances precede the eruption. The patches of grouped vesicles appear on the red and swollen skin. The early vesicles, which contain serum, later may become purulent, rupture, and form crusts. The inflammation is usually unilateral, involving the thoracic, cervical, or cranial nerves in a band-like configuration. Usually the blisters are confined to a narrow region of the face or trunk (Fig. 52-2). The clinical course varies from 1 to 3 weeks. If an ophthalmic nerve is involved, the patient may have eye pain. Inflammation and a rash on the trunk may cause pain with the slightest touch. The healing time varies from 7 to 26 days.

Herpes zoster in healthy adults is usually localized and benign. However, in patients who are immunosuppressed, the disease may be severe and disabling.

Medical and Nursing Management

There is evidence that infection is arrested if oral antiviral agents, such as acyclovir (Zovirax), valacyclovir (Valtrex), or famciclovir (Famvir), are administered within 24 hours of the initial eruption. IV acyclovir, if started early, is effective in significantly reducing the pain and halting the progression of the disease. In older patients, the pain from herpes zoster may persist as postherpetic neuralgia (persistent pain of the affected nerve after healing) for months after the skin lesions disappear.

FIGURE 52-2 Herpes zoster (shingles).

The goals of herpes zoster management are to relieve the pain and to reduce or avoid complications, which include infection, scarring, and postherpetic neuralgia and eye complications. Pain is controlled with analgesics because adequate pain control during the acute phase helps prevent persistent pain patterns. Systemic corticosteroids may be prescribed for patients older than 50 years of age to reduce the incidence and duration of postherpetic neuralgia. Healing usually occurs more quickly in those who have been treated with corticosteroids. Triamcinolone (Aristocort, Kenacort, Kenalog) injected subcutaneously under painful areas is effective as an anti-inflammatory agent.

Ophthalmic herpes zoster occurs when an eye is involved. This is considered an

ophthalmic emergency, and the patient should be referred to an ophthalmologist immediately to prevent the possible sequelae of keratitis, uveitis, ulceration, and blindness.

People who have been exposed to varicella by primary infection or by vaccination are not at risk for infection after exposure to patients with herpes zoster.

HERPES SIMPLEX

Herpes simplex is a common skin infection. There are two types of the causative virus, which are identified by viral typing. In general, herpes simplex type 1 occurs on the mouth and type 2 occurs in the genital area, but both viral types can be found in both locations. About 85% of adults worldwide are seropositive for herpes type 1. The prevalence of type 2 is lower; type 2 usually appears at the onset of sexual activity. Herpes simplex type 2 is discussed in detail in Chapter 35. Serologic testing shows that many more people are infected than have a history of clinical disease.

Herpes simplex infection is classified as a true primary infection, a nonprimary initial episode, or a recurrent episode. True primary infection is the initial exposure to the virus. A nonprimary initial episode is the initial episode of either type 1 or type 2 in a person previously infected with the other type. Recurrent episodes are subsequent episodes of the same viral type.

TINEA

Fungi—tiny members of a subdivision of the plant kingdom that feed on organic matter—are responsible for various common skin infections. In some cases, they affect only the skin and its appendages (hair and nails). In other cases, internal organs are involved, and the diseases may be life-threatening. However, superficial infections rarely cause even temporary disability and usually respond readily to treatment. Secondary infection with bacteria, *Candida*, or both organisms may occur.

The most common fungal skin infection is tinea (Fig. 52-3), which is also called *ringworm* because of its characteristic appearance of a ring or rounded tunnel under the skin. Tinea infections affect the head, body, groin, feet, and nails. Table 52-4 summarizes the tinea infections.

To obtain a specimen for diagnosis, the lesion is cleaned and a scalpel or glass slide is used to remove scales from the margin of the lesion. The scales are dropped onto a slide to which potassium hydroxide has been added. The diagnosis is made by examination of the infected scales microscopically for spores and hyphae or by isolating the organism in culture. Under Wood's light, a specimen of infected hair appears fluorescent; this may be helpful in diagnosing some cases of tinea capitis.

FIGURE 52-3 Tinea corporis. Tinea is one of several conditions (granuloma annulare, nummular eczema) that produces circular lesions. In tinea, the margin of the lesion contains microvesicles, which are best visualized by peering through the lens of a lighted otoscope, and is raised. The flat central area often shows fine scaling. (Reprinted with permission from Fleisher, G. R., Ludwig, S., & Baskin, M. N.

(2004). *Atlas of pediatric emergency medicine*. Philadelphia, PA: Lippincott Williams & Wilkins.)

SCABIES

Scabies is an infestation of the skin by the itch mite *Sarcoptes scabiei.* The disease may be found in people living in substandard hygienic conditions, but it can occur in anyone. Infestations may or may not be associated with sexual activity. The mites frequently involve the fingers, and hand contact may produce infection. In children, overnight stays with friends or the exchange of clothes may be a source of infection.

TABLE 52-4 Tinea (Ringworm) Infections

Type and Location	Clinical Manifestations	Treatment
Tinea corporis (body)	• Begins with red macule, which spreads to a ring of papules or vesicles with central clearing. • Lesions are found in clusters. • Many spread to the hair, scalp, or nails. • Very pruritic. • An infected pet may be the source.	• Mild conditions: topical antifungal creams • Severe conditions: griseofulvin or terbinafine
Tinea cruris (groin area; "jock itch")	• Begins with small, red scaling patches, which spread to form circular elevated plaques. • Very pruritic. • Clusters of pustules may be seen around borders.	• Mild conditions: topical antifungal creams • Severe conditions: griseofulvin or terbinafine
Tinea pedis (foot; "athlete's foot")	• Soles of one or both feet have scaling and mild redness with maceration in the toe webs. • More acute infections may have clusters of clear vesicles on dusky base.	• Soak feet in vinegar and water solution. • Resistant infections: griseofulvin or terbinafine • Terbinafine (Lamisil) daily for 3 months
Tinea unguium (toenails; affects about 50% of adults)	• Nails thicken, crumble easily, and lack luster. • Whole nail may be destroyed.	• Itraconazole (Sporanox) in pulses of 1 week a month for 3 months in cases of terbinafine failure

Clinical Manifestations and Assessment

It takes approximately 4 weeks from the time of contact for the patient's symptoms to appear. The patient complains of severe itching caused by a delayed type of immunologic reaction to the mite or its fecal pellets. During examination, the nurse asks the patient where the pruritus is most severe. A magnifying glass and a penlight are held at an oblique angle to the skin while a search is made for the small, raised burrows created by the mites. The burrows may be multiple, straight or wavy, brown or black, thread-like lesions, most commonly observed between the fingers and on the wrists. Other sites are the extensor surfaces of the elbows, the knees, the edges of the feet, the points of the elbows, around the nipples, in the axillary folds, under pendulous breasts, and in or near the groin or gluteal fold, penis, or scrotum. Red, pruritic eruptions usually appear between adjacent skin areas. However, the burrow is not always visible. Any patient with a rash may have scabies.

One classic sign of scabies is the increased itching that occurs during the overnight hours, perhaps because the increased warmth of the skin has a stimulating effect on the parasite. Hypersensitivity to the organism and its products of excretion also may contribute to the pruritus. If the infection has spread, other members of the family and close friends also complain of pruritus about a month later.

Secondary lesions are quite common and include vesicles, papules, excoriations, and crusts. Bacterial superinfection may result from constant excoriation of the burrows and papules.

The diagnosis is confirmed by recovering *S. scabiei* or the mites' by-products from the skin. A sample of superficial epidermis is scraped from the top of the burrows or papules with a small scalpel blade. The scrapings are placed on a microscope slide and examined through a microscope at low power to demonstrate evidence of the mite (Monsel & Chosidow, 2015).

Gerontologic Considerations 

Elderly patients living in long-term care facilities are susceptible to outbreaks of scabies because of close living quarters, poor hygiene due to limited physical ability, and the potential for incidental spread of the organisms by staff members. Although pruritus may be severe in the older patient, the vivid inflammatory reaction seen in younger people seldom occurs. Scabies may not be recognized in the elderly person; the pruritus may be attributed erroneously to the dry skin of old age or to anxiety.

Health care personnel in extended-care facilities should wear gloves when providing hands-on care for a patient suspected of having scabies until the diagnosis is confirmed and treatment completed. It is advisable to treat all residents, staff, and families of patients at the same time to prevent reinfection. Because geriatric patients may be more sensitive to side effects of the scabicides, they should be observed closely for reactions.

Medical and Nursing Management

The patient is instructed to take a warm, soapy bath or shower to remove the scaling debris from the crusts and then to dry thoroughly and allow the skin to cool. A prescription scabicide, such as lindane (Kwell), crotamiton (Eurax), or 5% permethrin (Elimite), is applied thinly to the entire skin from the neck down, sparing only the face and scalp (which are not affected in scabies). The medication is left on for 12 to 24 hours, after which the patient is instructed to wash thoroughly. One application may be curative, but it is advisable to repeat the treatment in 1 week.

CONTACT DERMATITIS

Contact dermatitis is an inflammatory reaction of the skin to physical, chemical, or biologic agents.

Pathophysiology

The epidermis is damaged by repeated physical and chemical irritations. Contact dermatitis may be of the primary irritant type, in which a nonallergic reaction results from exposure to an irritating substance, or it may be an allergic reaction resulting from exposure of sensitized people to contact allergens. Common causes of irritant dermatitis are soaps, detergents, scouring compounds, and industrial chemicals. Predisposing factors include extremes of heat and cold, frequent contact with soap and water, and a pre-existing skin disease (Box 52-6).

Clinical Manifestations and Assessment

The eruptions begin when the causative agent contacts the skin. The first reactions include pruritus, burning, and erythema, followed closely by edema, papules, vesicles, and oozing or weeping. In the subacute phase, these vesicular changes are less marked, and they alternate with crusting, drying, fissuring, and peeling. If repeated reactions occur or if the patient continually scratches the skin, lichenification (thickening of the horny layer of the skin) and pigmentation occur. Secondary bacterial invasion may follow.

Medical and Nursing Management

The objectives of management are to rest the involved skin and protect it from further damage. The distribution pattern of the reaction is identified to differentiate between allergic and irritant contact dermatitis. A detailed history is obtained. If possible, the offending irritant is removed. Local irritation should be avoided, and generally soap is not used until healing occurs.

BOX 52-6 Patient Education

Strategies for Avoiding Contact Dermatitis

The following precautions may help prevent repeated cases of contact dermatitis. Follow these instructions for at least 4 months after your skin appears to be completely healed:

- Study the pattern and location of your dermatitis and think about which things have touched your skin and which things may have caused the problem. Try to avoid contact with these materials.
- Avoid heat, soap, and rubbing, all of which are external irritants.
- Choose bath soaps, laundry detergents, and cosmetics that do not contain fragrance.
- Avoid using a fabric softener dryer sheet (Bounce, Cling Free). Fabric softeners that are added to the washer may be used.
- Avoid topical medications, lotions, or ointments, except those specifically prescribed for your condition.
- Wash your skin thoroughly immediately after exposure to possible irritants.
- When wearing gloves (e.g., for washing dishes or general cleaning), be sure they are cotton-lined. Do not wear them more than 15 or 20 minutes at a time.

Many preparations are advocated for relieving dermatitis. In general, a bland, unmedicated lotion is used for small patches of erythema. Cool, wet dressings also are applied over small areas of vesicular dermatitis. Finely cracked ice added to the water often enhances its antipruritic effect.

Wet dressings usually help clear the oozing eczematous lesions. Then a thin layer of cream or ointment containing a corticosteroid may be used. Medicated baths at room temperature are prescribed for larger areas of dermatitis. For severe, widespread conditions, a short course of systemic corticosteroids may be prescribed.

NONINFECTIOUS INFLAMMATORY DERMATOSES

PSORIASIS

Considered one of the most common skin diseases, psoriasis affects approximately 2% of the population, appearing more often in people of European ancestry. It is thought that this chronic, noninfectious, inflammatory disease stems from a hereditary defect that causes overproduction of keratin. Onset may occur at any age, but psoriasis is most common in people between 15 and 35 years of age. Psoriasis has a tendency to improve and then recur periodically throughout life (Augustin & Radtke, 2016).

Pathophysiology

Although the primary cause of psoriasis is unknown, a combination of specific genetic makeup and environmental stimuli may trigger the onset of disease. Current evidence supports an immunologic basis for the disease (Mrowietz & Reich, 2009). Periods of emotional stress and anxiety aggravate the condition, and trauma, infections, and seasonal and hormonal changes also are trigger factors.

Epidermal cells are produced at a rate that is about six to nine times faster than normal. The cells in the basal layer of the skin divide too quickly, and the newly formed cells move so rapidly to the skin surface that they become evident as profuse scales or plaques of epidermal tissue. The psoriatic epidermal cell may travel from the basal cell layer of the epidermis to the stratum corneum and be cast off in 3 to 4 days, which is in sharp contrast to the normal 26 to 28 days. As a result of the increased number of basal cells and rapid cell passage, the normal events of cell maturation and growth cannot take place. This abnormal process does not allow the normal protective layers of the skin to form.

Clinical Manifestations and Assessment

Lesions appear as red, raised patches of skin covered with silvery scales. The scaly patches are formed by the buildup of living and dead skin resulting from the vast increase in the rate of skin cell growth and turnover (Fig. 52-4). If the scales are scraped away, the dark-red base of the lesion is exposed, producing multiple bleeding points. These patches are not moist and may be pruritic. One variation of this condition is called *guttate* (in the shape of a drop) psoriasis because the lesions remain about 1 cm wide and are scattered like raindrops over the body. This variation is believed to be associated with a recent streptococcal throat infection. Psoriasis may range in severity from a cosmetic source of annoyance to a physically disabling and disfiguring disorder.

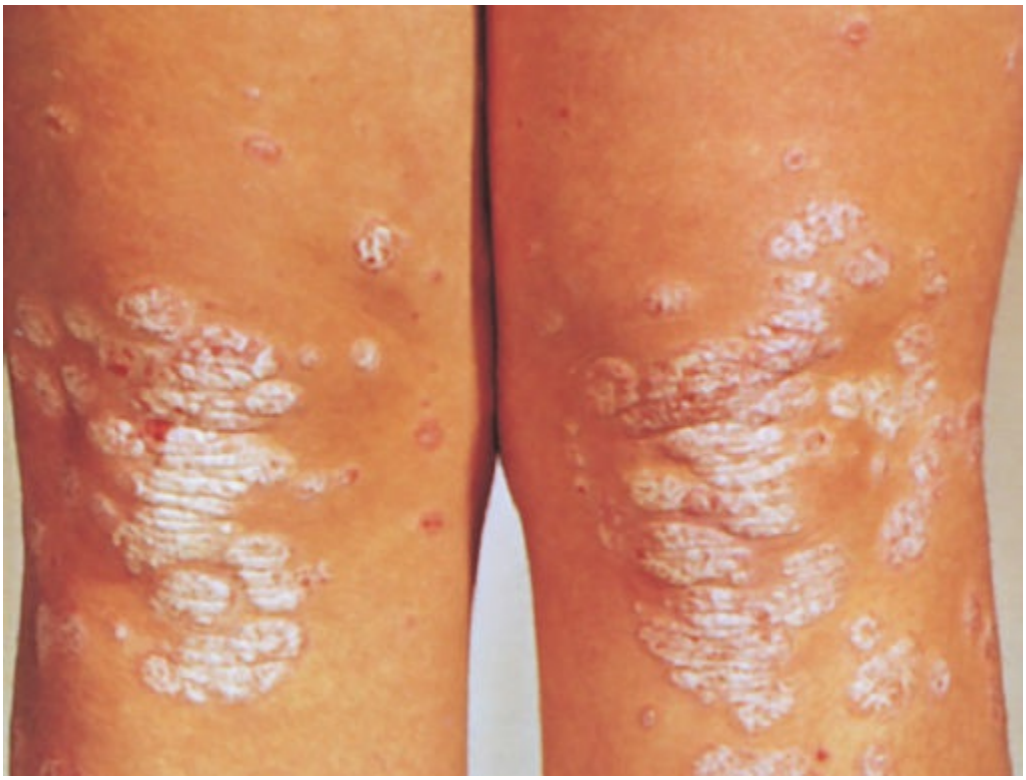


FIGURE 52-4 Psoriasis. Reprinted with permission from Bickley, L. S. (2013). *Bate's guide to physical examination and history taking*. Philadelphia, PA: Lippincott Williams & Wilkins.

Particular sites of the body tend to be affected most by this condition; they include the scalp, the extensor surface of the elbows and knees, the lower part of the back, and the genitalia. Bilateral symmetry is a feature of psoriasis. In approximately one fourth to one half of patients, the nails are involved, with pitting, discoloration, crumbling beneath the free edges, and separation of the nail plate. When psoriasis occurs on the palms and soles, it can cause pustular lesions called *palmar pustular psoriasis.*

The presence of the classic plaque-type lesions generally confirms the diagnosis of psoriasis. Because the lesions tend to change histologically as they progress from early to chronic plaques, biopsy of the skin is of little diagnostic value. There are no specific blood tests for diagnosing the condition. When in doubt, the health care provider should assess

for signs of nail and scalp involvement and for a positive family history.

Complications

Asymmetric rheumatoid factor–negative arthritis of multiple joints occurs in about 5% of people with psoriasis. The arthritic development can occur before or after the skin lesions appear. The relationship between arthritis and psoriasis is not understood, although recent studies suggest there is interplay among genetics, environmental factors, and the immune system (Augustin & Radtke, 2016). Erythrodermic psoriasis, an exfoliative psoriatic state, involves disease progression that affects the total body surface. The patient is acutely ill, with impaired temperature regulation and fluid and protein loss. Erythrodermic psoriasis often appears in people with chronic psoriasis after infections, after exposure to certain medications, or following withdrawal of systemic corticosteroids.

Medical and Nursing Management

The goals of management are to slow the rapid turnover of epidermis, to promote resolution of the psoriatic lesions, and to control the natural cycles of the disease. There is no known cure.

The therapeutic approach should be one that the patient understands; it should be cosmetically acceptable and minimally disruptive to the patient's lifestyle. Treatment involves the commitment of time and effort by the patient and possibly the family. First, any precipitating or aggravating factors are addressed. An assessment is made of lifestyle because psoriasis is significantly affected by stress. The patient is informed that treatment of severe psoriasis can be time-consuming, expensive, and aesthetically unappealing at times.

Removal of Scales

The most important principle of psoriasis treatment is gentle removal of scales. This can be accomplished with baths. Oils (e.g., olive oil, mineral oil, Aveeno Oilated Oatmeal Bath) or coal tar preparations (e.g., Balnetar) can be added to the bath water and a soft brush used to scrub the psoriatic plaques gently. After bathing, the application of emollient creams containing alpha-hydroxy acids (e.g., Lac-Hydrin, Penederm) or salicylic acid continues to soften thick scales. The patient and family should be encouraged to establish a regular skin care routine that can be maintained even when the psoriasis is not in an acute stage.

Pharmacologic Therapy

With the recent addition of biologic medications, four types of therapy are now commonly used: topical, intralesional, oral, and injectable (Table 52-5).

Topical Agents

Topically applied agents are used to slow the overactive epidermis without affecting other tissues. These agents include lotions, ointments, pastes, creams, and shampoos. Topical corticosteroids may be applied for their anti-inflammatory effect. Choosing the correct strength of corticosteroid for the involved site and choosing the most effective vehicle base are important aspects of topical treatment. In general, high-potency topical corticosteroids should not be used on the face and intertriginous areas, and their use on other areas should be limited to a 4-week course of twice-daily applications. A 2-week break should be taken before repeating treatment with the high-potency corticosteroids. For long-term therapy, moderate-potency corticosteroids are used. On the face and intertriginous areas, only low-potency corticosteroids are appropriate for long-term use (see Table 52-6).

Occlusive dressings may be applied to increase the effectiveness of the corticosteroid. Large rolls of tubular plastic can be used to cover the arms and legs. Another option is a vinyl jogging suit. The medication is applied, and the suit is put on over it. The hands can be wrapped in gloves, the feet in plastic bags, and the head in a shower cap. Occlusive dressings should not remain in place longer than 8 hours. The skin should be inspected carefully for the appearance of atrophy, hypopigmentation, striae, and telangiectasias, all side effects of corticosteroids.

When psoriasis involves large areas of the body, topical corticosteroid treatment can be expensive and involve some systemic risk. The more potent corticosteroids, when applied to large areas of the body, have the potential to cause adrenal suppression through percutaneous absorption of the medication. In this event, other treatment modalities (e.g., nonsteroidal topical medications, ultraviolet light) may be used instead or in combination to decrease the need for corticosteroids.

Two topical nonsteroidal treatments introduced within the past few years are calcipotriene (Dovonex) and tazarotene (Tazorac). Treatment with these agents tends to suppress epidermopoiesis (i.e., development of epidermal cells) and cause sloughing of the rapidly growing epidermal cells. Calcipotriene 0.05% is a derivative of vitamin D_2. It works by decreasing the mitotic turnover of the psoriatic plaques. Its most common side effect is local irritation. The intertriginous areas and face should be avoided when using this medication. The patient should be monitored for symptoms of hypercalcemia. Calcipotriene is available as a cream for use on the body and a solution for the scalp. It is not recommended for use by elderly patients because of their more fragile skin or by pregnant or lactating women.

TABLE 52-5 Current Pharmacologic Treatment for Psoriasis

Topical Agents	Use	Selected Agents
Biologicals	Moderate to severe lesions	Cyclosporine (Neoral), alefacept (Amevive), etanercept (Enbrel), infliximab (Remicade)
Topical corticosteroids	Mild to moderate lesions Moderate to severe lesions Severe lesions Lesions on face and groin	Aristocort, Kenalog, Valisone Lidex, Psorcon, Cutivate Temovate, Diprolene, Ultravate Aclovate, DesOwen, Hytone 2.5%
Topical nonsteroidals	Mild to severe lesions	Retinoids, such as tazarotene (Tazorac) Vitamin D_3 derivative calcipotriene (Dovonex)
Coal tar products	Mild to moderate lesions	Coal tar and salicylic acid ointment (Aquatar, Estar gel, Fototar, Zetar); anthralin (AnthraDerm, Dritho-Cream); Neutrogena T-Derm, Psori Gel
Medicated shampoos	Scalp lesions	Neutrogena T-Gel, T-Sal, Zetar, Head & Shoulders, Desenex, Selsun Blue, Bakers P&S (emulsifying agent with phenol, saline solution, and mineral oil)
Intralesional therapy	Thick plaques and nails	Kenalog, Cordran-impregnated tape, Fluoroplex
Systemic therapy	Extensive lesions and nails Psoriatic arthritis	Methotrexate (Folex, Mexate); hydrouria (Hydrea); retinoic acid (Tegison) (not to be used in women of childbearing age) Oral gold (auranofin), etretinate, methotrexate
Photochemotherapy	Moderate to severe lesions	UVA or UVB light with or without topical medications PUVA (combines UVA light with oral psoralens, or topical Trisoralen)

TABLE 52-6 Potency: Topical Corticosteroids

Potency	Topical Corticosteroid
Over-the-counter	0.5–1.0% hydrocortisone
Lowest	Dexamethasone 0.1% (Decaderm) Alclometasone 0.05% (Aclovate) Hydrocortisone 2.5% (Hytone)
Low–Medium	Desonide 0.05% (DesOwen, Tridesilon) Fluocinolone acetonide 0.025% (Synalar) Hydrocortisone valerate 0.2% (Westcort) Betamethasone valerate 0.1% (Valisone) Fluticasone propionate 0.05% (Cutivate)
Medium–High	Triamcinolone acetonide 0.1–0.5% (Aristocort) Fluocinonide 0.05% (Lidex) Desoximetasone 0.05–0.25% (Topicort) Fluocinolone 0.2% (Synalar) Diflorasone diacetate 0.05% (Psorcon)
Very high	Clobetasol propionate 0.05% (Temovate) Betamethasone dipropionate 0.05% (Diprolene) Halobetasol propionate 0.05% (Ultravate)

Tazarotene, a retinoid, causes sloughing of the scales covering psoriatic plaques. As with other retinoids, it causes increased sensitivity to sunlight by loss of the outermost layer of skin so the patient should be cautioned to use an effective sunscreen and avoid other photosensitizers (e.g., tetracycline, antihistamines). Tazarotene is listed as a Category X drug in pregnancy; reports indicate evidence of fetal risk, and the risk of use in pregnant women clearly outweighs any possible benefits. A negative result on a pregnancy test should be obtained before initiating this medication in women of childbearing age, and an effective contraceptive should be continued during treatment. Side effects include burning, erythema, or irritation at the site of application and worsening of psoriasis.

Intralesional Agents

Intralesional injections of the corticosteroid triamcinolone acetonide (Aristocort, Kenalog-10, Trymex) can be administered directly into highly visible or isolated patches of psoriasis that are resistant to other forms of therapy. Care must be taken to ensure that the medication is not injected into unaffected skin.

Systemic Agents

Although systemic corticosteroids may cause rapid improvement of psoriasis, their usual risks and the possibility of triggering a severe flare-up on withdrawal limit their use. Systemic cytotoxic preparations, such as methotrexate, have been used in treating extensive psoriasis that fails to respond to other forms of therapy.

Methotrexate appears to inhibit DNA synthesis in epidermal cells, thereby reducing the turnover time of the psoriatic epidermis. However, the medication can be toxic, especially to the liver, kidneys, and bone marrow. Laboratory studies must be monitored to ensure that the hepatic, hematopoietic, and renal systems are functioning adequately. The patient should avoid drinking alcohol while taking methotrexate because alcohol ingestion increases the possibility of liver damage. The medication is teratogenic (produces physical defects in the fetus) and thus should not be administered to pregnant women.

Hydroxyurea (Hydrea) also inhibits cell replication by affecting DNA synthesis. The patient is monitored for signs and symptoms of bone marrow depression.

Cyclosporine A, a cyclic peptide used to prevent rejection of transplanted organs, has shown some success in treating severe, therapy-resistant cases of psoriasis. However, its use is limited by side effects such as hypertension and nephrotoxicity.

Oral retinoids (i.e., synthetic derivatives of vitamin A and its metabolite, vitamin A acid) modulate the growth and differentiation of epithelial tissue. Etretinate is especially useful for severe pustular or erythrodermic psoriasis. Etretinate is a teratogen with a very long half-life; it cannot be used in women with childbearing potential.

Photochemotherapy

One treatment for severely debilitating psoriasis is a psoralen (phototoxic) medication (e.g., methoxsalen) combined with ultraviolet-A (PUVA) light therapy. Ultraviolet light is the portion of the electromagnetic spectrum containing wavelengths ranging from 180 to 400 nm. In this treatment, the patient takes a photosensitizing medication (usually 8-methoxypsoralen) in a standard dose and is subsequently exposed to long-wave ultraviolet light as the medication plasma levels peak. Although the mechanism of action is not completely understood, it is thought that when psoralen-treated skin is exposed to ultraviolet-A light, the psoralen binds with DNA and decreases cellular proliferation. PUVA is not without its hazards; it has been associated with long-term risks of skin cancer, cataracts, and premature aging of the skin (Augustin & Radtke, 2016). The PUVA unit consists of a chamber that contains high-output black-light lamps and an external reflectance system. The exposure time is calibrated according to the specific unit in use and the anticipated tolerance of the patient's skin. The patient is usually treated two or three times each week until the psoriasis clears. An interim period of 48 hours between treatments is necessary; it takes this long for any burns resulting from PUVA therapy to become evident.

After the psoriasis clears, the patient begins a maintenance program. Once little or no disease is active, less potent therapies are used to keep minor flare-ups under control.

Ultraviolet-B (UVB) light therapy is also used to treat generalized plaques. UVB light ranges from 270 to 350 nm, although research has shown that a narrow range, 310 to 312 nm, is the action spectrum. It is used alone or combined with topical coal tar. Side effects are similar to those of PUVA therapy. If access to a light treatment unit is not feasible, the

patient can expose himself or herself to sunlight. The risks of all light treatments are similar and include acute sunburn reaction; exacerbation of photosensitive disorders, such as lupus, rosacea, and polymorphic light eruption (a rash related to photosensitivity that can take on many forms); as well as other skin changes, such as increased wrinkles, thickening, and an increased risk for skin cancer.

EXFOLIATIVE DERMATITIS

Exfoliative dermatitis is a serious condition characterized by progressive inflammation in which generalized erythema and shedding of the skin occur. It may be associated with chills, fever, prostration, severe toxicity, and a pruritic scaling of the skin.

Pathophysiology

There is a profound loss of stratum corneum (i.e., outermost layer of the skin), which causes capillary leakage, hypoproteinemia, and negative nitrogen balance. Because of widespread dilation of cutaneous vessels, large amounts of body heat are lost, and exfoliative dermatitis has a marked effect on the entire body.

Exfoliative dermatitis has a variety of causes. It is considered to be a secondary or reactive process to an underlying skin or systemic disease. It may appear as a part of the lymphoma group of diseases and may precede the clinical manifestations of lymphoma.

Clinical Manifestations and Assessment

This condition starts acutely as a patchy or a generalized erythematous eruption accompanied by fever, malaise, and, occasionally, GI symptoms. The skin color changes from pink to dark red. Redness and other color changes are usually not noticed in patients with darker tones. It is recommended that the skin should be compared with the adjacent or opposite area of the body to note skin color changes. The skin should also be assessed for firmness and bogginess when palpated as well as the presence of pain, edema, warmth or cooler temperatures.

After a week, the characteristic exfoliation (i.e., scaling) begins, usually in the form of thin flakes that leave the underlying skin smooth and red, with new scales forming as the older ones come off. Hair loss may accompany this disorder. Relapses are common. The systemic effects include high-output heart failure, intestinal disturbances, breast enlargement, elevated levels of uric acid in the blood (i.e., hyperuricemia), and temperature disturbances.

Medical and Nursing Management

The objectives of management are to maintain fluid and electrolyte balance and to prevent infection. The treatment is individualized and supportive and should be initiated as soon as the condition is diagnosed.

The patient may be hospitalized and placed on bed rest. All medications that may be implicated are discontinued. A comfortable room temperature should be maintained because the patient does not have normal thermoregulatory control as a result of temperature fluctuations caused by vasodilation and evaporative water loss. Fluid and electrolyte balance must be maintained because there is considerable water and protein loss from the skin surface. Administration of plasma volume expanders may be indicated.

BLISTERING DISORDERS

PEMPHIGUS

Pemphigus is a group of serious diseases of the skin characterized by the appearance of bullae (blisters) of various sizes on apparently normal skin (Fig. 52-5) and mucous membranes.

Pathophysiology

Pemphigus is an autoimmune disease involving immunoglobulin G. It is thought that the pemphigus antibody is directed against a specific cell-surface antigen in epidermal cells. A blister forms from the antigen–antibody reaction. The level of serum antibody is predictive of disease severity.

FIGURE 52-5 Vesicles on the chin (in pemphigus). (From Hall, J. C. (2006). *Sauer's manual of skin diseases*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Risk Factors

Genetic factors may also have a role in its development, with the highest incidence among those of Jewish or Mediterranean descent. This disorder usually occurs in men and women in middle and late adulthood. The condition may be associated with the use of penicillins and captopril and with the disorder myasthenia gravis.

Clinical Manifestations and Assessment

Most patients present with oral lesions appearing as irregularly shaped erosions that are painful, bleed easily, and heal slowly. The skin bullae enlarge, rupture, and leave large, painful, eroded areas that are accompanied by crusting and oozing. A characteristic offensive odor emanates from the bullae and the exuding serum. There is blistering or sloughing of uninvolved skin when minimal pressure is applied (Nikolsky sign). The eroded skin heals slowly, and large areas of the body eventually are involved. Bacterial superinfection is common.

Complications

The most common complications arise when the disease process is widespread. Before the advent of corticosteroid and immunosuppressive therapy, patients were very susceptible to secondary bacterial infection. Skin bacteria have relatively easy access to the bullae as they ooze, rupture, and leave denuded (loss of epidermis) areas exposed to the environment. Fluid and electrolyte imbalance results from fluid and protein loss as the bullae rupture. Hypoalbuminemia is common when the disease process includes extensive areas of the body's skin surface and mucous membranes.

Medical and Nursing Management

The goals of therapy are to bring the disease under control as rapidly as possible, to prevent loss of serum and the development of secondary infection, and to promote re-epithelization (i.e., renewal of epithelial tissue).

Corticosteroids are administered in high doses to control the disease and keep the skin free of blisters. The high dosage level is maintained until remission is apparent. In some cases, corticosteroid therapy must be maintained for life. High-dose corticosteroid therapy has serious toxic effects.

Immunosuppressive agents (e.g., azathioprine, cyclophosphamide, gold) may be prescribed to help control the disease and reduce the corticosteroid dose. Plasmapheresis temporarily decreases the serum antibody level and has been used with variable success, although it is generally reserved for life-threatening cases.

BULLOUS PEMPHIGOID

Bullous pemphigoid is an acquired disease of flaccid blisters appearing on normal or erythematous skin.

Clinical Manifestations and Assessment

Bullous pemphigoid appears more often on the flexor surfaces of the arms, legs, axilla, and groin. Oral lesions, if present, are usually transient and minimal. When the blisters break, the skin has shallow erosions that heal fairly quickly. Pruritus can be intense, even before the appearance of the blisters. Bullous pemphigoid is common in the elderly, with a peak incidence at about 60 years of age. There is no gender or racial predilection, and the disease can be found in patients throughout the world.

Medical and Nursing Management

Medical treatment includes topical corticosteroids for localized eruptions and systemic corticosteroids for widespread involvement. Systemic corticosteroids (e.g., prednisone) may be continued for months, in alternate-day doses. The patient needs to understand the implications of long-term corticosteroid therapy.

Complications

Infection and Sepsis

The patient is susceptible to infection because the barrier function of the skin is compromised. Bullae are also susceptible to infection, and sepsis may follow. The skin is cleaned to remove debris and dead skin and to prevent infection.

Secondary infection may be accompanied by an unpleasant odor from skin or oral lesions. *Candida albicans* of the mouth (i.e., thrush) commonly affects patients receiving high-dose corticosteroid therapy. The oral cavity is inspected daily, and any changes are reported. Oral lesions are slow to heal.

Infection is the leading cause of death in patients with blistering diseases. Particular attention is given to assessment for signs and symptoms of local and systemic infection. Seemingly trivial complaints or minimal changes are investigated because corticosteroids can mask or alter typical signs and symptoms of infection. The patient's vital signs are monitored, and temperature fluctuations are documented. The patient is observed for chills, and all secretions and excretions are monitored for changes suggesting infection. Results of culture and sensitivity tests are monitored. Antimicrobial agents are administered as prescribed, and response to treatment is assessed. Health care personnel must perform effective hand hygiene and wear gloves.

In hospitalized patients, environmental contamination is reduced as much as possible. Protective isolation measures and standard precautions are warranted.

Fluid and Electrolyte Imbalance

Extensive denudation of the skin leads to fluid and electrolyte imbalance because of significant loss of fluids and sodium chloride from the skin. This sodium chloride loss is responsible for many of the systemic symptoms associated with the disease and is treated by IV administration of saline solution.

A large amount of protein and blood is also lost from the denuded skin areas. Blood component therapy may be prescribed to maintain the blood volume, hemoglobin level, and plasma protein concentration. Serum albumin, protein, hemoglobin, and hematocrit values are monitored.

The patient is encouraged to maintain adequate oral fluid intake. Cool, nonirritating fluids are encouraged to maintain hydration. Small, frequent meals or snacks of high-protein, high-calorie foods (e.g., oral nutritional supplements, eggnog, milkshakes) help maintain nutritional status. Parenteral nutrition is considered if the patient cannot eat an adequate diet.

TOXIC EPIDERMAL NECROLYSIS AND STEVENS–JOHNSON SYNDROME

Toxic epidermal necrolysis (TEN) and Stevens–Johnson syndrome (SJS) are potentially fatal skin disorders and the most severe forms of erythema multiforme.

These diseases are mucocutaneous reactions that constitute a spectrum of reactions, with TEN being the most severe. The mortality rate from TEN is 30% to 35%. TEN and SJS are triggered by a reaction to medications. Antibiotics, especially sulfonamides, antiseizure agents, nonsteroidal anti-inflammatory drugs (NSAIDs), are the medications implicated most frequently (Bryant, 2016).

Risk Factors

These conditions occur in patients of all ages and both genders. The incidence is increased in older people because of their use of many medications. People who are immunosuppressed, including those with HIV infection and AIDS, have a high risk of SJS and TEN. Although the incidence of TEN and SJS in the general population is about 2 to 3 cases per 1 million people in the United States, the risk associated with sulfonamides in HIV-positive individuals may approach 1 case per 1,000 (Bryant, 2016). Most patients with TEN have an abnormal metabolism of the medication; the mechanism leading to TEN seems to be a cell-mediated cytotoxic reaction.

Clinical Manifestations and Assessment

TEN and SJS are characterized initially by conjunctival burning or itching, cutaneous tenderness, fever, cough, sore throat, headache, extreme malaise, and myalgias (i.e., aches and pains). These signs are followed by a rapid onset of erythema involving much of the skin surface and mucous membranes, including the oral mucosa, conjunctiva, and genitalia. In severe cases of mucosal involvement, there may be danger of damage to the larynx, bronchi, and esophagus from ulcerations. Large, flaccid bullae develop in some areas; in other areas, large sheets of epidermis are shed, exposing the underlying dermis. Fingernails, toenails, eyebrows, and eyelashes may be shed along with the surrounding epidermis. The skin is excruciatingly tender, and the loss of skin leaves a weeping surface similar to that of a total-body, partial-thickness burn; hence the condition is also referred to as "scalded skin syndrome."

Histologic studies of frozen skin cells from a fresh lesion and cytodiagnosis of collections of cellular material from a freshly denuded area are conducted. A history of use of medications known to precipitate TEN or SJS may confirm medication reaction as the underlying cause.

Immunofluorescent studies may be performed to detect atypical epidermal autoantibodies. A genetic predisposition to erythema multiforme has been suggested but has not been confirmed in all cases.

Medical and Nursing Management

The goals of treatment include control of fluid and electrolyte balance, prevention of sepsis, and prevention of ophthalmic complications. Supportive care is the mainstay of treatment.

All nonessential medications are discontinued immediately. If possible, the patient is treated in a regional burn center because aggressive treatment similar to that for severe burns is required. Skin loss may approach 100% of the total body surface area. Surgical débridement or hydrotherapy in a Hubbard tank (large steel tub) may be performed to remove involved skin.

Tissue samples from the nasopharynx, eyes, ears, blood, urine, skin, and unruptured blisters are obtained for culture to identify pathogenic organisms. IV fluids are prescribed to maintain fluid and electrolyte balance, especially in the patient who has severe mucosal involvement and who cannot easily take oral nourishment. Because an indwelling IV catheter may be a site of infection, fluid replacement is carried out by nasogastric tube and then orally as soon as possible.

Initial treatment with systemic corticosteroids is controversial. Some experts argue for early high-dose corticosteroid treatment. However, in most cases, the risk of infection, the complication of fluid and electrolyte imbalance, the delay in the healing process, and the difficulty in initiating oral corticosteroids early in the course of the disease outweigh the perceived benefits. In patients with TEN thought to result from a medication reaction, corticosteroids may be administered; however, the patient should be monitored closely for adverse effects.

Protecting the skin with topical agents is crucial. Various topical antibacterial and anesthetic agents are used to prevent wound sepsis and to assist with pain management. Systemic antibiotic therapy is used with extreme caution. Temporary biologic dressings (e.g., pigskin, amniotic membrane) or plastic semi-permeable dressings (e.g., Vigilon) may be used to reduce pain, decrease evaporation, and prevent secondary infection until the epithelium regenerates. Meticulous oropharyngeal and eye care is essential when there is severe involvement of the mucous membranes and the eyes.

As the patient completes the acute inpatient stage of illness, the focus is directed toward rehabilitation and outpatient care or care in a rehabilitation center. Throughout this care, the patient and family members are involved in the care and are instructed in the procedures, such as wound care and dressing changes that will need to be continued at home. The patient and family members are assisted in acquiring dressing supplies that will be needed at home.

The patient and family members are also provided with instructions about pain management, nutrition, measures to increase mobility, and prevention of complications, including prevention of infection. They are taught the signs and symptoms of complications and instructed when to notify the health care provider. When appropriate, instructions are provided in writing to the patient and family so they can refer to these instructions when necessary at later times.

Interdisciplinary follow-up care is imperative to ensure that the patient's progress continues. Some patients will require care in a rehabilitation center before returning home. Others will require outpatient physical and occupational therapy for an extended period. When the patient returns home, the home care nurse coordinates the care provided by the

various members of the health care team (e.g., primary care provider, physical therapist, occupational therapist, and dietician). The nurse also monitors the patient's progress, provides ongoing assessment to identify complications, and monitors the patient's adherence to the plan of care. The patient's adaptation to the home care environment and the patient's and family's needs for support and assistance are also assessed. Referrals to community agencies are made as appropriate.

Complications

Sepsis

The major cause of death from TEN is infection, and the most common sites of infection are the skin and mucosal surfaces, lungs, and blood. The organisms involved most often are *Staphylococcus aureus, Pseudomonas, Klebsiella, Escherichia coli, Serratia*, and *Candida*. Monitoring vital signs closely and noticing changes in respiratory, renal, and GI function may quickly detect the beginning of an infection. Strict asepsis is always maintained during routine skin care measures. Hand hygiene and wearing sterile gloves when carrying out procedures are essential. When the condition involves a large portion of the body, the patient should be in a private room to prevent possible cross-infection from other patients. Visitors should wear protective garments and wash their hands before and after coming into contact with the patient. People with any infections or infectious disease should not visit the patient until they are no longer a danger to the patient. Refer to Chapter 54 for more details on sepsis.

Conjunctival Retraction, Scars, and Corneal Lesions

The nurse inspects the eyes daily for signs of pruritus, burning, and dryness, which may indicate progression to keratoconjunctivitis, the principal eye complication. Applying a cool, damp cloth over the eyes may relieve burning sensations. The eyes are kept clean and observed for signs of discharge or discomfort, and the progression of symptoms is documented and reported. Administering an eye lubricant, when prescribed, may alleviate dryness and prevent corneal abrasion. Using eye patches or reminding the patient to blink periodically may also counteract dryness. The patient is instructed to avoid rubbing the eyes or putting any medication into the eyes that has not been prescribed or approved by the provider.

BENIGN SKIN TUMORS

Table 52-7 provides descriptions of and treatments for common benign skin lesions.

MALIGNANT SKIN TUMORS

Skin cancer is the most common cancer in the United States. If the incidence continues at the present rate, an estimated one of eight fair-skinned Americans will eventually develop skin cancer, especially basal cell carcinoma. Because the skin is easily inspected, skin cancer is readily seen and detected and is the type of cancer that is treated most successfully.

Exposure to the sun is the leading cause of skin cancer; incidence is related to the total amount of exposure to the sun. Sun damage is cumulative, and harmful effects may be severe by 20 years of age. The increase in skin cancer probably reflects changing lifestyles and the emphasis on sunbathing and related activities in light of changes in the environment, such as holes in the Earth's ozone layer. Changes in the ozone layer from the effects of worldwide industrial air pollutants, such as chlorofluorocarbons, have prompted concern that the incidence of skin cancers, especially malignant melanoma, will increase. The ozone layer, a stratospheric blanket of bluish, explosive gas formed by the sun's ultraviolet radiation, varies in depth with the seasons and is thickest at the North and South Poles and thinnest at the equator. Scientists believe that it helps protect the earth from the effects of solar ultraviolet radiation. Proponents of this theory predict an increase in skin cancers as a consequence of changes in the ozone layer. Other skin cancer risk factors are summarized in Box 52-7. Protective measures should be used throughout life, and nurses should inform patients about risk factors associated with skin cancer.

BASAL CELL AND SQUAMOUS CELL CARCINOMA

The most common types of skin cancer are basal cell carcinoma (BCC) and squamous cell (epidermoid) carcinoma (SCC). The third most common type, malignant melanoma, is discussed separately. Skin cancer is diagnosed by biopsy and histologic evaluation.

BOX 52-7 Risk Factors for Skin Cancer

- Fair-skinned, fair-haired, blue-eyed people, particularly those of Celtic origin, with insufficient skin pigmentation to protect underlying tissues
- People who sustain sunburn and who do not tan
- Chronic sun exposure (certain occupations, such as farming, construction work)
- Exposure to chemical pollutants (industrial workers in arsenic, nitrates, coal, tar and pitch, oils and paraffins)
- Sun-damaged skin (elderly people)
- History of x-ray therapy for acne or benign lesions
- Scars from severe burns
- Chronic skin irritations
- Immunosuppression
- Genetic factors

Clinical Manifestations and Assessment

BCC is the most common type of skin cancer. It generally appears on sun-exposed areas of the body and is more prevalent in regions where the population is subjected to intense and extensive exposure to the sun. The incidence is proportional to the age of the patient (average, 60 years of age) and the total amount of sun exposure, and it is inversely proportional to the amount of melanin in the skin.

BCC usually begins as a small, waxy nodule with rolled, translucent, pearly borders; telangiectatic vessels may be present. As it grows, it undergoes central ulceration and, sometimes, crusting (Fig. 52-6). The tumors appear most frequently on the face. BCC is characterized by invasion and erosion of contiguous (adjoining) tissues. It rarely metastasizes, but recurrence is common. However, a neglected lesion can result in the loss of a nose, an ear, or a lip. Other variants of BCC may appear as shiny, flat, gray or yellowish plaques.

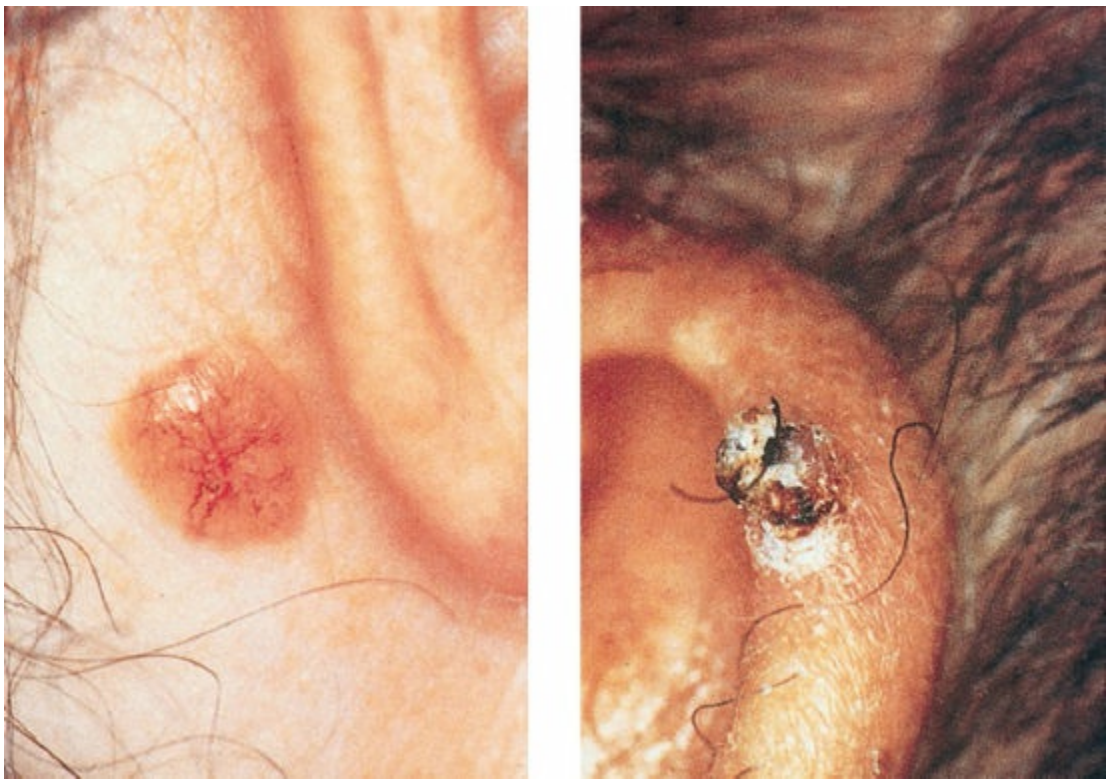

FIGURE 52-6 Basal cell carcinoma (*left*) and squamous cell carcinoma (*right*). (Reprinted by permission from *New England Journal of Medicine*, *326*, 169–170; 1992.)

TABLE 52-7 Benign Skin Lesions

Lesion	Description	Treatment
Cysts	Cysts of the skin are epithelium-lined cavities that contain fluid or solid material.	
	Epidermal cysts (epidermoid cysts) occur frequently and are slow-growing, firm, elevated tumors frequently noted on the face, neck, upper chest, and back.	Removal of the cysts provides a cure.
	Pilar cysts (trichilemmal cysts), formerly called sebaceous cysts, frequently are found on the scalp. They originate from the middle portion of the hair follicle and from the cells of the outer hair root sheath.	Treatment is surgical removal.
Seborrheic and actinic keratoses	**Seborrheic keratoses** are benign, wartlike lesions of various sizes and colors, ranging from light tan to black, that are usually located on the face, shoulders, chest, and back.	Treatment is removal of the tumor tissue by excision, electrodesiccation, and curettage, or application of carbon dioxide or liquid nitrogen.
	Actinic keratoses are premalignant skin lesions that develop in chronically sun-exposed areas of the body. They appear as rough, scaly patches with underlying erythema. A small percentage of these lesions gradually transforms into cutaneous squamous cell carcinoma.	They are usually removed by cryotherapy or shave excision.
Verrucae: Warts	**Warts** are common, benign skin tumors caused by infection with the human papillomavirus, which belongs to the DNA virus group. People of all ages may be affected, but the warts occur most frequently in patients between 12 and 16 years of age.	They may be treated with locally applied laser therapy, liquid nitrogen, salicylic acid plasters, or electrodesiccation.
	Genitalia and perianal warts are known as *condylomata acuminata*. They may be transmitted sexually. Condylomata that affect the uterine cervix predispose the patient to cervical cancer.	They are treated with liquid nitrogen, cryosurgery, electrosurgery, topically applied trichloroacetic acid, and curettage.
Angiomas	**Angiomas** are benign vascular tumors that involve the skin and the subcutaneous tissues. They are present at birth and may occur as flat, violet-red patches (port-wine angiomas) or as raised, bright-red, nodular lesions (strawberry angiomas). The latter tend to involute spontaneously within the first few years of life, but port-wine angiomas usually persist indefinitely.	Most patients use masking cosmetics (i.e., Covermark or Dermablend) to camouflage the lesions. The argon laser is being used on various angiomas with some success. Treatment of strawberry angiomas is more successful if undertaken as soon after birth as possible.
Pigmented nevi: Moles	**Moles** are common skin tumors of various sizes and shades, ranging from yellowish brown to black. They may be flat, macular lesions or elevated papules or nodules that occasionally contain hair. Most pigmented nevi are harmless lesions. However, in rare cases, malignant changes occur, and a melanoma develops at the site of the nevus. Nevi that show a change in color or size, become symptomatic (e.g., itch), or develop irregular borders should be removed to determine if malignant changes have occurred. Moles that occur in unusual places (palms of the hands and soles of the feet) should be examined carefully for any irregularity and for notching of the border and variation in color. Nevi larger than 1 cm should be examined carefully. Excised nevi should be examined histologically.	
Keloids	**Keloids** are benign overgrowths of fibrous tissue at the site of a scar or trauma. They appear to be more common among dark-skinned people. Keloids are asymptomatic but may cause disfigurement and cosmetic concern.	The treatment, which is not always satisfactory, consists of surgical excision, intralesional corticosteroid therapy, and radiation.

SCC is a malignant proliferation arising from the epidermis. Although it usually appears on sun-damaged skin, it may arise from normal skin or from pre-existing skin lesions. It is of greater concern than BCC because it is a truly invasive carcinoma, metastasizing by the blood or lymphatic system.

Metastases account for 75% of deaths from SCC. The lesions may be primary, arising on the skin and mucous membranes, or they may develop from a precancerous condition, such as actinic keratosis (lesions occurring in sun-exposed areas), leukoplakia (premalignant lesion of the mucous membrane), or scarred or ulcerated lesions. SCC appears as a rough, thickened, scaly tumor that may be asymptomatic or may involve bleeding (see Fig. 52-6).

The border of an SCC lesion may be wider, more infiltrated, and more inflammatory than that of a BCC lesion. Secondary infection can occur. Exposed areas, especially of the upper extremities and of the face, lower lip, ears, nose, and forehead, are common sites.

The incidence of BCC and SCC is increased in all people who are immunocompromised, including those infected with HIV. Clinically, the tumors have the same appearance as in people who are not HIV-infected; however, in patients with HIV, the tumors may grow more rapidly and recur more frequently. These tumors are managed the same as those for the general population. Frequent follow-up (every 4 to 6 months) is recommended to monitor for recurrence.

Medical Management

The goal of treatment is to eradicate the tumor. The treatment method depends on the tumor location; the cell type, location, and depth; the cosmetic desires of the patient; the history of previous treatment; whether the tumor is invasive; and whether metastatic nodes are present. The management of BCC and SCC includes surgical excision, Mohs' micrographic surgery, electrosurgery, cryosurgery, and radiation therapy.

Surgical Management

The primary goal is to remove the tumor entirely. The best way to maintain cosmetic appearance is to place the incision properly along natural skin tension lines and natural anatomic body lines. In this way, scars are less noticeable. The size of the incision depends on the tumor size and location but usually involves a length-to-width ratio of 3:1.

The adequacy of the surgical excision is verified by microscopic evaluation of sections of the specimen. When the tumor is large, reconstructive surgery with use of a skin flap or skin grafting may be required. The incision is closed in layers to enhance cosmetic effect. A pressure dressing applied over the wound provides support. Infection after a simple excision is uncommon if proper surgical asepsis is maintained.

Mohs' Micrographic Surgery

Mohs' micrographic surgery is the technique that is most accurate and that best conserves normal tissue. The procedure removes the tumor layer by layer. The first layer excised includes all evident tumor and a small margin of normal-appearing tissue. The specimen is frozen and analyzed by section to determine if the entire tumor has been removed. If not, additional layers of tissue are shaved and examined until all tissue margins are tumor-free. In this manner, only the tumor and a safe, normal-tissue margin are removed. Mohs' surgery is the recommended tissue-sparing procedure, with extremely high cure rates for both BCC and SCC. It is the treatment of choice and the most effective for tumors around the eyes, nose, upper lip, and auricular and periauricular areas.

Electrosurgery

Electrosurgery is the destruction or removal of tissue by electrical energy. The current is converted to heat, which then passes to the tissue from a cold electrode. Electrosurgery may be preceded by curettage (excising the skin tumor by scraping its surface with a curette). Then electrodesiccation is implemented to achieve hemostasis and to destroy any viable malignant cells at the base of the wound or along its edges. Electrodesiccation is useful for lesions smaller than 1 to 2 cm (0.4 to 0.8 in) in diameter.

This method takes advantage of the fact that the tumor is softer than surrounding skin and, therefore, can be outlined by a curette, which "feels" the extent of the tumor. The tumor is removed and the base cauterized. The process is repeated twice. Usually, healing occurs within a month.

Cryosurgery

Cryosurgery destroys the tumor by deep-freezing the tissue. A thermocouple needle

apparatus is inserted into the skin, and liquid nitrogen is directed to the center of the tumor until the tumor base is –40°C to –60°C. Liquid nitrogen has the lowest boiling point of all cryogens, is inexpensive, and is easy to obtain. The tumor tissue is frozen, allowed to thaw, and then refrozen. The site thaws naturally and then becomes gelatinous and heals spontaneously. Swelling and edema follow the freezing. The appearance of the lesion varies. Normal healing, which may take 4 to 6 weeks, occurs faster in areas with a good blood supply.

Radiation Therapy

Frequently radiation therapy is performed for cancer of the eyelid, the tip of the nose, and areas in or near vital structures (e.g., facial nerve). It is reserved for older patients because x-ray changes may be seen after 5 to 10 years, and malignant changes in scars may be induced by irradiation 15 to 30 years later.

The patient should be informed that the skin may become red and blistered. A bland skin ointment prescribed by the provider may be applied to relieve discomfort. Also the patient should be cautioned to avoid exposure to the sun.

Nursing Management

Because many skin cancers are removed by excision, usually patients are treated in outpatient surgical units. The role of the nurse is to teach the patient about prevention of skin cancer and about self-care after treatment.

Teaching Self-Care

Usually the wound is covered with a dressing to protect the site from physical trauma, external irritants, and contaminants. The nurse instructs the patient about when to report for a dressing change or provides written and verbal information on how to change dressings, including the type of dressing to purchase, how to remove dressings and apply fresh ones, and the importance of hand hygiene before and after the procedure.

The patient watches for excessive bleeding and tight dressings that compromise circulation. If the lesion is in the perioral area, the patient is instructed to drink liquids through a straw and limit talking and facial movement. Dental work should be avoided until the area is completely healed.

After the sutures are removed, an emollient cream may be used to help reduce dryness. Applying a sunscreen over the wound is advised to prevent postoperative hyperpigmentation if the patient spends time outdoors.

Follow-up examinations should be at regular intervals, usually every 3 months for a year, and should include palpation of the adjacent lymph nodes. The nurse instructs the patient to seek treatment for any moles that are subject to repeated friction and irritation, and to watch for indications of potential malignancy in moles as described previously. The importance of life-long follow-up evaluations is emphasized.

Teaching Skin Cancer Prevention

Studies show that regular daily use of a sunscreen with a solar protection factor (SPF) of at least 15 can reduce the recurrence of skin cancer by as much as 40% (Box 52-8). The sunscreen should be applied to head, neck, arms, and hands every morning at least 30 minutes before leaving the house and reapplied every 4 hours if the skin perspires. Intermittent application of sunscreen only when exposure is anticipated has been shown to be less effective than daily use. The longer exposure is believed to contribute to the increasing incidence of melanoma. Although the evidence is insufficient, nurses should discuss the issues with patients who are at high risk of skin cancer.

BOX 52-8 Health Promotion

Preventing Skin Cancer

- Teach patients that sunscreens are rated in strength from 4 (weakest) to 50 (strongest). The solar protection factor, or SPF, indicates how much longer a person can stay in the sun before the skin begins to redden. For example, if the person normally can stay in the sun for 10 minutes before reddening begins, an SPF of 4 will protect the person from reddening for about 40 minutes. A sunscreen with an

SPF of 15 or greater is recommended under most conditions and indicates 93% protection; an SPF of 34 indicates 97% protection.

- Remind patients that up to 50% of ultraviolet rays can penetrate loosely woven clothing.
- Remind patients that ultraviolet light can penetrate cloud cover, and sunburn still can occur.
- Teach children to avoid all but modest sun exposure and to use a sunscreen regularly for life-long protection.
- Advise patients to:
  - Avoid tanning if their skin burns easily, never tans, or tans poorly.
  - Avoid unnecessary exposure to the sun, especially during the time of day when ultraviolet radiation (sunlight) is most intense (10 am to 3 pm).
  - Avoid sunburns.
  - Apply a sunscreen daily to block harmful sun rays.
  - Use a sunscreen with an SPF of 15 or higher that protects against both ultraviolet-A (UVA) and ultraviolet-B (UVB) light.
  - Reapply water-resistant sunscreens after swimming, if heavily sweating, and every 2–3 hours during prolonged periods of sun exposure.
  - Avoid applying oils before or during sun exposure (oils do not protect against sunlight or sun damage).
  - Use a lip balm that contains a sunscreen with an SPF of 15 or higher.
  - Wear protective clothing, such as a broad-brimmed hat and long sleeves.
  - Avoid using sun lamps for indoor tanning, and avoid commercial tanning booths.

Nurses should also encourage skin self-examination (Box 52-9).

MALIGNANT MELANOMA

A malignant melanoma is a cancerous neoplasm in which atypical melanocytes are present in the epidermis and the dermis (and sometimes the subcutaneous cells). It is the most lethal of all the skin cancers and is responsible for about 3% of all cancer deaths (Castiglione et al., 2016). Malignant melanoma can occur in one of several forms: superficial spreading melanoma, lentigo-maligna melanoma, nodular melanoma, and acral-lentiginous melanoma. These types have specific clinical and histologic features as well as different biologic behaviors. Most melanomas arise from cutaneous epidermal melanocytes, but some appear in preexisting nevi (i.e., moles) in the skin or develop in the uveal tract of the eye. Melanomas occasionally appear simultaneously with cancer of other organs.

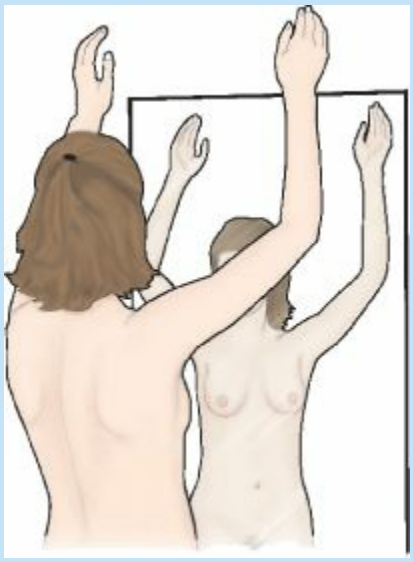
BOX 52-9 Patient Education

Periodic Self-Examination

Prevention of melanoma/skin cancer is the best weapon against these diseases, but if a

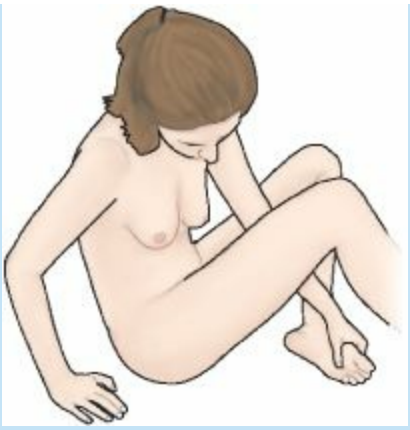
melanoma should develop, it is almost always curable if caught in the early stages. Practice periodic self-examination to aid in early recognition of any new or developing lesion. The following is one way of self-examination that will ensure that no area of the body is neglected. To perform your self-examination, you will need a full-length mirror, a hand mirror, and a brightly lit room.

1. Examine the body front and back in the mirror, then the right and left sides, with the arms raised.

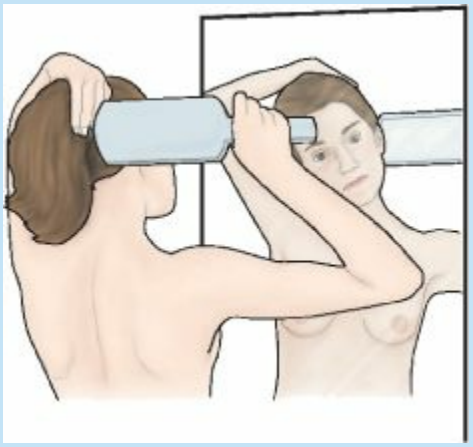


2. Bend the elbows, looking carefully at the forearms, back of the upper arms, and palms

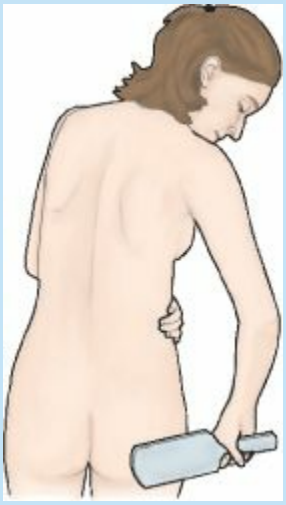
3. Next, look at the back of the legs and feet, the spaces between the toes, and the soles of the feet.



4. Examine the back of the neck and the scalp with a hand-held mirror. Part the hair to lift.



5. Finally, check the back and buttocks with a hand mirror.



The worldwide incidence of melanoma doubles every 10 years, an increase that is

probably related to increased recreational sun exposure, changes in the ozone layer, and improved methods of early detection. Median age at diagnosis is 50 years of age, although melanoma affects all age groups. The incidence of melanoma is increasing faster than that of almost any other cancer, and the mortality rate is increasing faster than that of any other cancer except lung cancer. In the Unites States, approximately 76,690 new cases of malignant melanoma are diagnosed annually, and 9,480 patients will succumb to this disease, accounting for 1% to 2% of all cancer deaths in the United States (Schuchter, 2016). It is estimated that one of 37 men and one of 56 women will be diagnosed with malignant melanoma (Schuchter, 2016, p. 1373).

Risk Factors

The cause of malignant melanoma is unknown, but ultraviolet rays are strongly suspected based on indirect evidence, such as the increased incidence of melanoma in countries near the equator and in people younger than 30 years of age who have used a tanning bed more than 10 times per year. Ethnicity is a risk factor; in general, 1 in 100 Caucasians acquires melanoma each year. As many as 10% of patients with melanoma are members of a family that is more melanoma-prone. They have multiple changing moles (dysplastic nevi), which are susceptible to malignant transformation. Patients with dysplastic nevus syndrome have been found to have unusual moles, larger and more numerous moles, lesions with irregular outlines, and pigmentation located all over the skin. Microscopic examination of dysplastic moles shows disordered, faulty growth. Box 52-10 lists risk factors for malignant melanoma.

Types

Superficial Spreading Melanoma

Superficial spreading melanoma occurs anywhere on the body and is the most common form of melanoma. It usually affects middle-aged people and occurs most frequently on the trunk and lower extremities. The lesion tends to be circular, with irregular outer portions. The margins of the lesion may be flat or elevated and palpable (Fig. 52-7). This type of melanoma may appear in a combination of colors, with hues of tan, brown, and black mixed with gray, blue-black, or white. Sometimes a dull pink rose color can be seen in a small area within the lesion.

BOX 52-10 Risk Factors for Malignant Melanoma

- Fair-skinned or freckled, blue-eyed, light-haired people of Celtic or Scandinavian origin
- People who burn and do not tan or who have a significant history of severe sunburn
- Environmental exposure to intense sunlight (older Americans retiring to the southwestern United States appear to have a higher incidence)
- History of melanoma (personal or family)
- Skin with giant congenital nevi

FIGURE 52-7 Two forms of malignant melanoma: superficial spreading (*left*) and nodular (*right*). (From Bickley, L. S. (2013). *Bates' guide to physical examination and history taking* (10th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Lentigo-Maligna Melanoma

Lentigo-maligna melanoma is a slowly evolving, pigmented lesion that occurs on exposed skin areas, especially the dorsum of the hand, the head, and the neck in elderly people. Often, the lesion is present for many years before it is examined by a provider. It first appears as a tan, flat lesion, but in time it undergoes changes in size and color.

Nodular Melanoma

Nodular melanoma is a spherical, blueberry-like nodule with a relatively smooth surface and a relatively uniform, blue-black color (see Fig. 52-7). It may be dome-shaped with a smooth surface. It may have other shadings of red, gray, or purple. Sometimes, nodular melanomas appear as irregularly shaped plaques. The patient may describe this as a blood blister that fails to resolve. A nodular melanoma invades directly into the adjacent dermis (i.e., vertical growth) and, therefore, has a poorer prognosis.

Acral-Lentiginous Melanoma

Acral-lentiginous melanoma occurs in areas not excessively exposed to sunlight and where hair follicles are absent. It is found on the palms of the hands, on the soles, in the nail beds, and in the mucous membranes of people who are dark-skinned. These melanomas appear as irregular, pigmented macules that develop nodules. They may become invasive early.

Clinical Manifestations and Assessment

Biopsy results confirm the diagnosis of melanoma. An excisional biopsy specimen provides information on the type, level of invasion, and thickness of the lesion. An excisional biopsy specimen that includes a 1-cm margin of normal tissue and a portion of underlying subcutaneous fatty tissue is sufficient for staging a melanoma in situ or an early, noninvasive melanoma. Incisional biopsy should be performed when the suspicious lesion is too large to be removed safely without extensive scarring. Biopsy specimens obtained by shaving, curettage, or needle aspiration are not considered reliable histologic proof of disease.

A thorough history and physical examination should include a meticulous skin examination and palpation of regional lymph nodes that drain the lesional area. Box 52-11 discusses assessing moles. Because melanoma occurs in families, a positive family history of melanoma is investigated so that first-degree relatives, who may be at high risk for melanoma, can be evaluated for atypical lesions. After the diagnosis of melanoma has been confirmed, a chest x-ray, complete blood cell count, liver function tests, and radionuclide or computed tomography scans are usually performed to stage the extent of disease.

BOX 52-11 Assessing the ABCDEs of Moles

A for Asymmetry

- The lesion does not appear balanced on both sides. If an imaginary line were drawn down the middle, the two halves would not look alike.
- The lesion has an irregular surface with uneven elevations (irregular topography) either palpable or visible. A change in the surface may be noted from smooth to scaly.
- Some nodular melanomas have a smooth surface.

B for Irregular Border

- Angular indentations or multiple notches appear in the border.
- The border is fuzzy or indistinct, as if rubbed with an eraser.

C for Variegated Color

- Normal moles are usually a uniform light to medium brown. Darker coloration indicates that the melanocytes have penetrated to a deeper layer of the dermis.
- Colors that may indicate malignancy if found together within a single lesion are shades of red, white, and blue; shades of blue are ominous.
- White areas within a pigmented lesion are suspicious.
- Some malignant melanomas, however, are not variegated but are uniformly colored (bluish-black, bluish-gray, bluish-red).

D for Diameter

- A diameter exceeding 6 mm (about the size of a pencil eraser) is considered more suspicious, although this finding without other signs is not significant. Many benign skin growths are larger than 6 mm, whereas some early melanomas may be smaller.

E for Elevation, Enlargement, and/or Evolution

- The lesion is raised above the surface, enlarged, and/or has an uneven surface. *Evolution* refers to a lesion that has changed significantly (size, shape, symptoms [e.g., itching, tenderness, crusting, bleeding]) over time.

Medical and Nursing Management

Treatment depends on the level of invasion and the depth of the lesion. Surgical excision is the treatment of choice for small, superficial lesions. Deeper lesions require wide local excision, after which skin grafting may be necessary. Sentinel node biopsy accurately identifies whether microscopic melanoma cells involve regional lymph nodes. The sentinel lymph node is the first node by which cancer is likely to spread from the primary tumor before spreading to other lymph nodes. This technique is used to sample the nodes nearest the tumor and to spare the patient the long-term sequelae of extensive removal of lymph nodes if the sample nodes are negative. If the sentinel node is positive, then lymph node dissection is performed.

Some investigational therapies include biologic response modifiers (e.g., interferon-alpha, interleukin-2), adaptive immunotherapy (i.e., lymphokine-activated killer cells), and monoclonal antibodies directed at melanoma antigens. Immunotherapy modifies immune function and other biologic responses to cancer. New Immunotherapy approaches for treatment of melanoma and molecularly targeted therapy based upon somatic mutation profile have led to recent FDA approvals that have redefined the standard of care for malignant melanoma. Ipilimumab, which blocks cytotoxic T-lymphocyte antigen (CTLA-4), has shown promise in patients with cases of advanced melanoma (Stage IV), with 3-year survival rate of 21% versus 12% (Schuchter, 2016). Monoclonal antibodies, such as nivolumab, have shown recent success in patients with advanced melanoma. Identification of somatic mutations in the gene encoding the serine-threonine protein kinase B-RAF (*BRAF*) is found in approximately 50% of melanomas (Ferri, 2016). Recently combination targeted therapy with the use of molecularly targeted therapies has shown a response rate of 70% (Schuchter, 2016). Several other studies are attempting to develop and test autologous immunization against specific tumor cells. These studies are in the experimental stage but show promise for future development of a vaccine against melanoma.

Further surgical intervention may be performed to debulk the tumor or to remove part of the organ involved (e.g., lung, liver, or colon). However, the rationale for more extensive surgery is for relief of symptoms, not for cure.

METASTATIC SKIN TUMORS

The skin is an important, although not a common, site of metastatic cancer. All types of cancer may metastasize to the skin, but carcinoma of the breast is the primary source of cutaneous metastases in women. Other sources include cancer of the large intestine, ovaries, and lungs. In men, the most common primary sites are the lungs, large intestine, oral cavity, kidneys, or stomach. Skin metastases from melanomas are found in both genders. The clinical appearance of metastatic skin lesions is not distinctive, except perhaps in some cases of breast cancer in which diffuse, brawny hardening of the skin of the involved breast is seen. In most instances, metastatic lesions occur as multiple cutaneous or subcutaneous nodules of various sizes that may be skin-colored or different shades of red.

KAPOSI SARCOMA

Kaposi sarcoma (KS) is a malignancy of endothelial cells that line the small blood vessels. KS is manifested clinically by lesions of the skin, oral cavity, GI tract, and lungs. The skin lesions consist of reddish-purple to dark-blue macules, plaques, or nodules. KS is subdivided into three categories:

- Classic KS occurs predominantly in men of Mediterranean or Jewish ancestry between 40 and 70 years of age. Most patients have nodules or plaques on the lower extremities that rarely metastasize beyond this area. Classic KS is chronic, relatively benign, and rarely fatal.
- Endemic (African) KS affects people predominantly in the eastern half of Africa near the equator. Men are affected more often than women, and children can be affected as well. The disease may resemble classic KS, or it may infiltrate and progress to lymphadenopathic forms.
- Immunosuppression-associated KS occurs in transplant recipients and people with AIDS. This form of KS is characterized by local skin lesions and disseminated visceral and mucocutaneous diseases. The greater the degree of immunosuppression, the higher the incidence of KS. Immunosuppression-related KS that results from AIDS is an aggressive tumor that involves multiple body organs. Its presentation resembles that of KS associated with immunosuppressive therapy. Most patients are between 20 and 40 years of age. Refer to Chapter 37 for more information about KS and AIDS.

CHAPTER REVIEW

Critical Thinking Exercises

1. You are caring for an elderly woman in her home. She has a long history of peripheral vascular disease and now has developed a venous stasis ulcer on her lower leg just above the ankle. Her health care provider has prescribed a moisture-retentive dressing that is impregnated with hydrogel. The dressing is to be changed every 3 days, and the patient asks you why the dressing is not changed every day. How would you explain to the patient the purpose of the dressing? Identify the evidence that supports the use of moisture-retentive dressings for venous ulcers. Discuss the strength of the evidence regarding their effectiveness in the promotion of wound healing.

2. You are caring for a middle-aged woman who has recently been diagnosed with diabetes mellitus. On preparing for discharge, she tells you that she has had itchy, dry, flaky skin during the winter months for several years and that she bathes every morning and night to try to get rid of the itching and dryness. She also states that it is difficult for her to avoid scratching her itchy skin. What teaching would you provide to this patient? What are this patient's risks of developing more serious skin conditions if the dryness and itching of her skin continue?

3. You are assigned to the emergency department and are caring for a young adult who is being treated for heatstroke following a golf game on a very hot day. As he is awaiting

discharge, he tells you that he is concerned about developing skin cancer because he spends so much time in the sun. After providing the patient with information about risk factors for, and prevention of, heatstroke, what other patient education would you provide? What are the risk factors for skin cancer? What health promotion strategies would be encouraged for this patient?

NCLEX-Style Review Questions

1. A patient is seen in the wound clinic for a pressure ulcer on his left leg. There is full-thickness tissue loss with the bone exposed. The nurse would correctly document this wound as being in which stage?
   a. I
   b. II
   c. III
   d. IV

2. The health care provider has ordered Collagenase for a patient with a left leg necrotic ulcer. What does the nurse understands about the use of collagenase?
   a. Removes necrotic tissue and absorbs small to large amounts of exudates
   b. Uses the body's own digestive enzymes to break down necrotic tissue
   c. Speeds the rate at which necrotic tissue is removed
   d. Uses a high moisture-vapor transmission rate to remove exudate

3. A 20-year-old patient is being seen in the dermatology clinic for a basal cell carcinoma on her eye. The nurse would expect the physician to complete which intervention?
   a. Electrosurgery
   b. Mohs' micrographic surgery
   c. Cryosurgery
   d. Radiation

4. Topical corticosteroid therapy has been ordered for a patient with pruritus. What information should be incorporated into the plan of care for this patient?
   a. Apply liberally in the prescribed area.
   b. Absorption is enhanced when skin is dry.
   c. Local side effects may include skin atrophy and thinning.
   d. Absorption is decreased when covered with an occlusive dressing.

5. A 55-year-old patient with leukemia is being seen in the clinic for complaints of burning pain in the back. The patient has been diagnosed with shingles. The nurse would expect which medication classification to be ordered to reduce pain and halt the progression of the disease?
   a. Anti-inflammatory
   b. Antiviral

c. Antibiotic
d. Antifungal

CHAPTER 53

Nursing Management: Patients with Burn Injury

Jacqueline Laird

Learning Objectives

After reading this chapter, you will be able to:

1. Discuss the classification system used for burn injuries.
2. Describe the local and systemic effects of a major burn injury.
3. Discuss the potential fluid and electrolyte alterations of the emergent/resuscitative and acute phases of burn management.
4. Describe nursing management of the patient with burn injuries.

In comparison to the larger health care picture, burn patients are few. However, severe burn injuries are catastrophic injuries that often have "long-term consequences regarding physical, psychological, social, vocational, and aesthetic aspects of recovery" (Renneberg et al., 2014). Although overall survival for fire, burn, and smoke inhalation exceeds 96%, approximately 3,400 deaths result annually in the United States (American Burn Association [ABA, 2015], National Burn Repository [ABA, nd]). At the time of injury, at least 50% of the burn fatalities occur because of massive hemorrhaging (Sheridan, 2016).

Burns are categorized as thermal (including electrical burns), radiation, electrical, or chemical. The skin and the mucosa of the upper airways are the sites of tissue destruction. Disruption of the skin can lead to increased fluid loss, infection, hypothermia, compromised immunity, and changes in function, appearance, and body image. The nurse caring for the burn patient requires astute assessment skills and a high level of knowledge about physiologic changes after a major burn injury to detect subtle changes in the patient's condition.

OVERVIEW OF BURN INJURY

Incidence of Burn Injury

The two most common burn etiologies are flame and scald. The home remains the most common place of occurrence, accounting for 65% of burn injuries cared for in burn centers. Scald injuries are the most preventable burn injury in children under 5 years of age (ABA, 2015). A burn can affect any person at any time, in any place. Burns involve people of all ages and socioeconomic groups. Each year, approximately 500,000 people with burn injuries receive medical treatment, and just over 3,000 deaths occur annually from fire and smoke inhalation. Residential fires account for 2,800 of these deaths, with the remaining 300 from motor vehicle accidents (National Hospital Ambulatory Medical Care Survey [NHAMCS], 2011). Approximately 70% of all burn victims are men. Children under 5 years of age represent 19%, and people over 60 years of age represent 13% of burn cases (ABA, 2015). Although prognosis can be influenced by several factors, the most important variables include: severity of the burn, the presence of inhalation injury, associated injuries, the patient's age, and comorbid conditions (DeKoning, 2016).

People who are prone to burn injuries are the elderly, smokers, and people with disabilities, neurologic illness, substance abuse issues, and psychiatric illness.

Gerontologic Considerations

Persons over 60 years of age are likely to live alone and have reduced mobility, changes in vision, and decreased sensation in the feet and hands. These changes place them at risk for suffering a burn. Morbidity and mortality rates associated with burns are greater in the elderly (ABA, 2015) than in the remainder of the population. Thinning and loss of elasticity of the skin predispose them to deep injury from a thermal insult that might cause a less severe burn in a younger person. Furthermore, chronic illnesses decrease the older person's ability to withstand the multisystem stresses imposed by major burn injury. Mortality is nearly 90% in patients who are older than 60 years of age, have a burn that is greater than 40% of the total body surface area (TBSA), and have an inhalation injury (Sheridan, 2016). Successful prevention campaigns have been linked to smoke detectors, carbon monoxide detectors, fire extinguishers, escape plans, sprinkler systems, enforcement of fire codes, and fire safe cigarettes (Pertschuk, Hobart, Paloma, Larkin, & Balbach, 2013).

Classification of Burns

Burn injuries are classified by the depth of the injury and the extent of the TBSA that is burned.

Depth

Burns are classified according to the depth of tissue destruction. Cell damage occurs at temperatures of at least 45°C (113°F). The depth depends on how much of the skin's dermis is affected. Burn depth determines whether spontaneous healing will occur and helps to determine the plan of care.

The following factors are considered in determining the depth of a burn:

- How the injury occurred
- Causative agent, such as flame, scald, chemical, or hot tar
- Temperature of the burning agent
- Duration of contact with the agent
- Thickness of the skin in the burned area

Burns are described as superficial, superficial partial-thickness, deep partial-thickness, or full-thickness injuries (Fig. 53-1; Table 53-1). Formerly referred to as a first-degree burn, a superficial burn damages only the epidermis (outer layer of the skin). The area is red and dry, with slight swelling but no blister, and painful, like a sunburn. These burns heal in about 7 days with usually no scarring. In a superficial partial-thickness burn (one of two types of second-degree burns), the epidermis is destroyed and a small portion of the underlying dermis (deep, vascular inner portion of skin) is injured. The skin is blistered, the exposed dermis is red and moist, and hair follicles are intact. These burns will heal in 14 to 21 days usually without scarring.

A deep partial-thickness burn (the second of the two types of second-degree burns), extends into the reticular layer of the dermis (dense connective tissue that gives the skin strength and elasticity and houses sweat glands, lymph vessels, and hair follicles) and is hard to distinguish from a full-thickness burn. It is red or white, mottled, and can be moist or fairly dry. The patient is in severe pain. Deep partial burns usually take longer than 3 weeks to heal (3 to 8 weeks) and can heal with permanent scarring (some of these burns tend to have a better appearance when grafted).

A full-thickness burn (formerly called a third- or fourth-degree burn) involves total destruction of the dermis and extends into the subcutaneous fat. It can also involve muscle and bone. It heals by contraction or epithelial migration. Wound color ranges widely from mottled white to red, brown, or black. Skin can appear charred and leathery, and hair follicles and sweat glands are destroyed. These burns are so severe that the patient no longer experiences a pain sensation. Healing does not happen spontaneously; this injury will require surgery, and significant scarring is expected (DeKoning, 2016).

Nursing Alert

It is important for the nurse to acknowledge that even when skin is no longer in contact with the

burn source, skin damage can continue. In the case of scald burns, 1 second of contact with hot tap water at 68°C (155°F) may result in a burn that destroys both the epidermis and the dermis, causing a full-thickness injury (ABA, 2014a). A deep partial-thickness burn can convert to full-thickness burns within 24 hours of injury, thus immediate assessment and management, which includes the application of cool tap water for a minimum of 5 minutes, is important to decrease the risk of thermal injury (ABA, 2014b). It is imperative that the nurse remove all jewelry, rings, watches, or belts, which are typically made of metal, since they can retain heat, cause thermal injury, and act as a tourniquet with tissue swelling. Burning clothing must be removed immediately, and the wound should be covered with a sterile dressing or clean cloth that is loosely wrapped. If clothing has adhered to the wound, it should not be removed. The use of ice water on large burns can result in hypothermia and increased mortality, whereas tap water is associated with a reduction in pain and may reduce the progression of tissue necrosis and need for skin grafting (Varley, Sarginson, & Young, 2015).

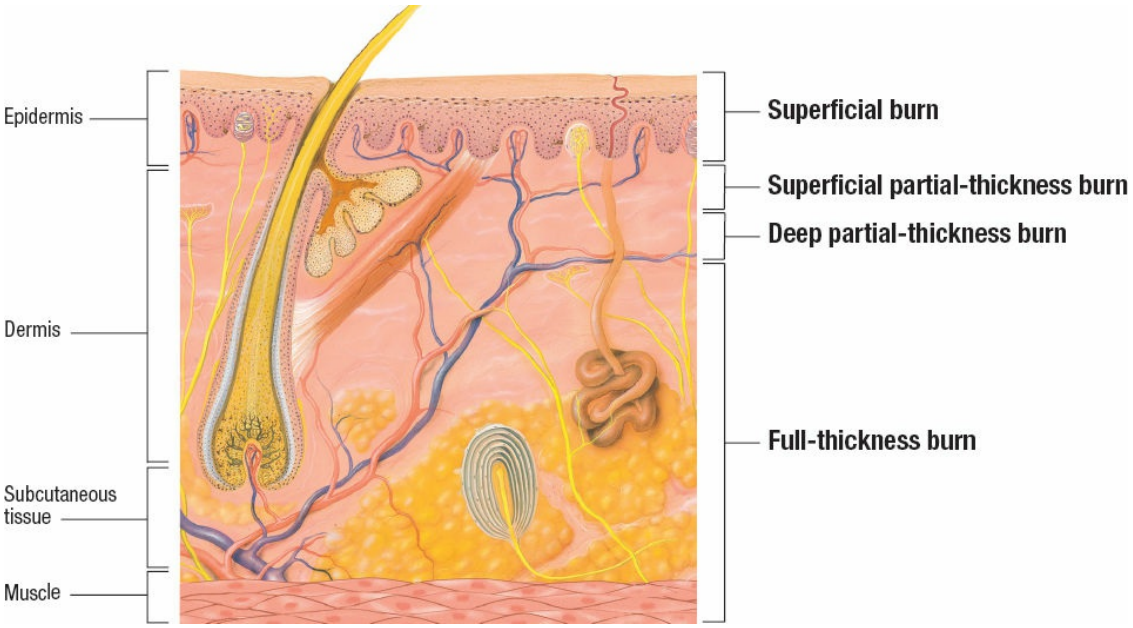

FIGURE 53-1 Depth of burn injury.

TABLE 53-1 Characteristics of Burns According to Depth

Depth of Burn	Causes	Skin Involvement	Symptoms	Wound Appearance	Recuperative Course
Superficial	Thermal injury (heat/cold), electromagnetic energy, solar radiation or topical caustic chemicals	Involves only the epidermis	Erythema and edema of skin	Redness, swelling, does not blister, pain	Three days or less
Superficial partial-thickness (similar to first-degree)	Sunburn Low-intensity flash	Epidermis; possibly a portion of dermis	Tingling Hyperesthesia (supersensitivity) Pain that is soothed by cooling	Reddened; blanches with pressure; dry Minimal or no edema Possible blisters	Complete recovery within 5–10 days; usually no scarring Peeling
Deep partial-thickness (similar to second-degree)	Scalds Flash flame Contact	Epidermis, upper dermis, portion of deeper dermis	Pain Hyperesthesia Sensitive to cold air	Blistered, mottled red base; broken epidermis; weeping surface Edema	Recovery in 3–8 weeks Some scarring and depigmentation contractures Infection may convert it to full thickness
Full-thickness (similar to third-degree)	Flame Prolonged exposure to hot liquids Electric current Chemical Contact	Epidermis, entire dermis, and sometimes subcutaneous tissue; may involve connective tissue, muscle, and bone	Pain free Shock Hematuria (blood in the urine) and possibly hemolysis (blood cell destruction) Possible entrance and exit wounds (electrical burn)	Dry; pale white, leathery, or charred Broken skin with fat exposed Edema	Eschar sloughs Grafting necessary Scarring and loss of contour and function; contractures Loss of digits or extremity possible

Extent of Body Surface Area Injured

Various methods are used to estimate the TBSA affected by burns; among them are the rule of nines and the Lund and Browder method.

Rule of Nines

The rule of nines (Fig. 53-2) is a simple and common way to estimate the extent of burns. The system assigns percentages in multiples of nine to major body surfaces with the perineum forming the remaining 1%. This method must be modified in the pediatric population because of the proportionally larger heads and smaller limbs in children.

Lund and Browder Method

A more precise, age-specific method of estimating the extent of a burn is the Lund and Browder method, which recognizes the percentage of surface area of various anatomic parts, especially the head and legs, in relation to growth. Because of changes in body proportion with growth, the calculated TBSA changes with age as well (Bittner, 2015). By dividing the body into very small areas and providing an estimate of the proportion of TBSA accounted for by each body part, one can obtain a reliable estimate of TBSA burned.

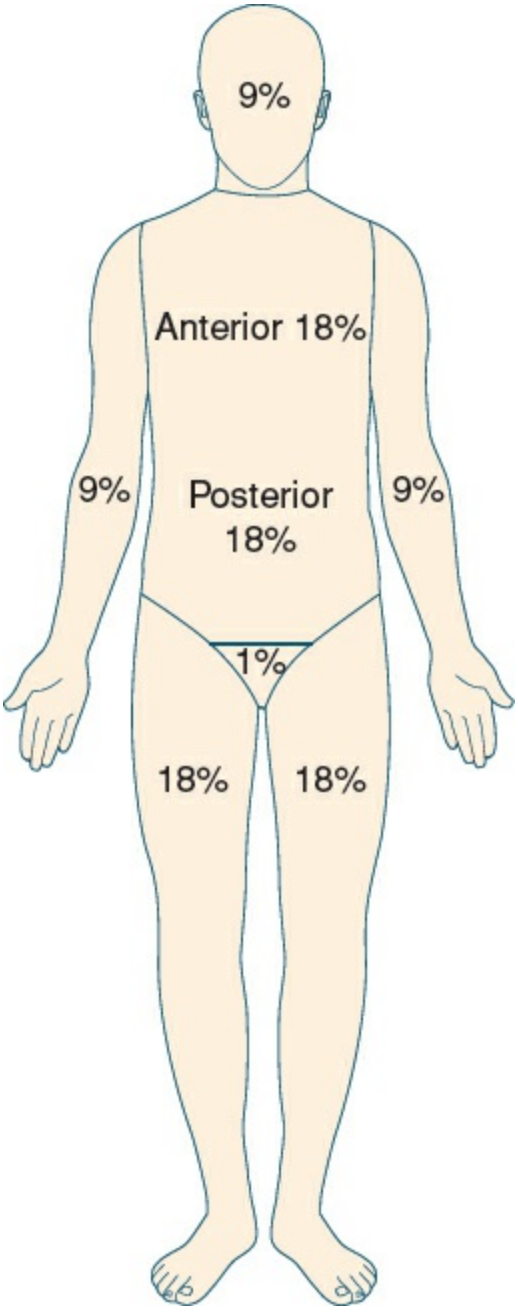

FIGURE 53-2 The rule of nines: Estimated percentage of total body surface area (TBSA) in the adult is arrived at by sectioning the body surface into areas with a numerical value related to nine. (Note: The anterior and posterior head total 9% of TBSA.)

Severity Grading System

The Severity Grading System (Box 53-1) adopted by the ABA includes: minor, moderate, and major burns.

PATHOPHYSIOLOGY

Burns are a dynamic injury set that result in a cascade of local tissue and systemic inflammatory effects depending on the percentage of TBSA involved. Local effects of burns include the denaturation of protein (which results in the disruption and potential destruction of cells), liberation of vasoactive substances, and the formation of edema. As a result of the cellular injury, the osmotic and hydrostatic pressure gradients are disrupted and intravascular fluid leaks into interstitial spaces. This damage is distributed throughout the injury as some cells die instantly, some are irreversibly damaged, and some—if appropriate interventions occur—will survive. There are three distinct zones that appear in a bull's eye pattern. The zone of coagulation (in the center) is where the tissue is completely destroyed; the zone of stasis surrounds the nonviable tissue and is potentially viable; the zone of hyperemia has increased blood flow secondary to the natural inflammatory response (Fig. 53-3).

BOX 53-1 Classification of Extent of Burn Injury

Minor Burn Injury

- Second-degree burn of less than 15% total body surface area (TBSA) in adults or less than 10% TBSA in children
- Third-degree burn of less than 2% TBSA not involving special care areas (eyes, ears, face, hands, feet, perineum, joints)
- Excludes all patients with electrical injury, inhalation injury, or concurrent trauma and all at-risk patients (i.e., extremes of age, intercurrent disease)

Moderate, Uncomplicated Burn Injury

- Second-degree burns of 15–25% TBSA in adults or 10–20% in children
- Third-degree burns of less than 10% TBSA not involving special care areas
- Excludes all patients with electrical injury, inhalation injury, or concurrent trauma; all at-risk patients (i.e., extremes of age, intercurrent disease)

Major Burn Injury

- Second-degree burns of at least 25% TBSA in adults or at least 20% in children
- All third-degree burns 10% or more TBSA
- All burns involving eyes, ears, face, hands, feet, perineum, joints
- All patients with inhalation injury, electrical injury, or concurrent trauma; all at-risk patients

From Morton, P. G., & Fontaine, D. (2008). Critical care nursing: A holistic approach (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Burns that exceed 20% TBSA may produce a local and a systemic response and are considered major burn injuries. The incidence and significance of pathophysiologic changes are proportional to the extent of burn injury, with a maximal response seen in burns covering 60% or more TBSA (Sheridan, 2016). Additionally, burns of 60% TBSA cause depressed myocardial contractility; this, in combination with the loss of circulating plasma volume, hemoconcentration, and massive edema formation (Latenser, 2015), results in both distributive and hypovolemic shock (see Chapter 54). Fluid volume loss is greatest in the first 6 to 8 hours; capillary integrity returns toward normal by 36 to 48 hours after the burn (Demling, 2015). These patients are best served when transferred to a verified burn center as they are candidates for the occurrence of burn shock.

Burn Shock: Cardiovascular Alterations

Shock occurs when oxygen supply does not meet tissue demand. Burn shock develops from several abnormalities of the circulation. The initial systemic event is hemodynamic instability, which results from loss of capillary integrity and a subsequent shift of fluid, sodium, and protein from the intravascular space into the interstitial spaces. This leaky capillary syndrome increases cell permeability at the burn site, as well as throughout the body. In the major burn, this syndrome far exceeds the useful effect of the inflammatory response. Progressive edema develops in unburned tissue and organs, causing hypoperfusion and hypovolemic shock. As fluid loss continues and vascular volume decreases, the cardiac output (CO) and blood pressure (BP) fall. This is the onset of burn shock. The systemic response is caused by the release of cytokines and other mediators into the systemic circulation. The result is overwhelming; there is an increase in peripheral vascular resistance secondary to the edema formation, a decrease in blood volume, and a decrease in CO (Latenser, 2015). Thus, burn shock is characterized by capillary leak, "third spacing" of fluid, severe hypovolemia, and decreased CO. If the burn patient is not resuscitated adequately, circulatory collapse ensues.

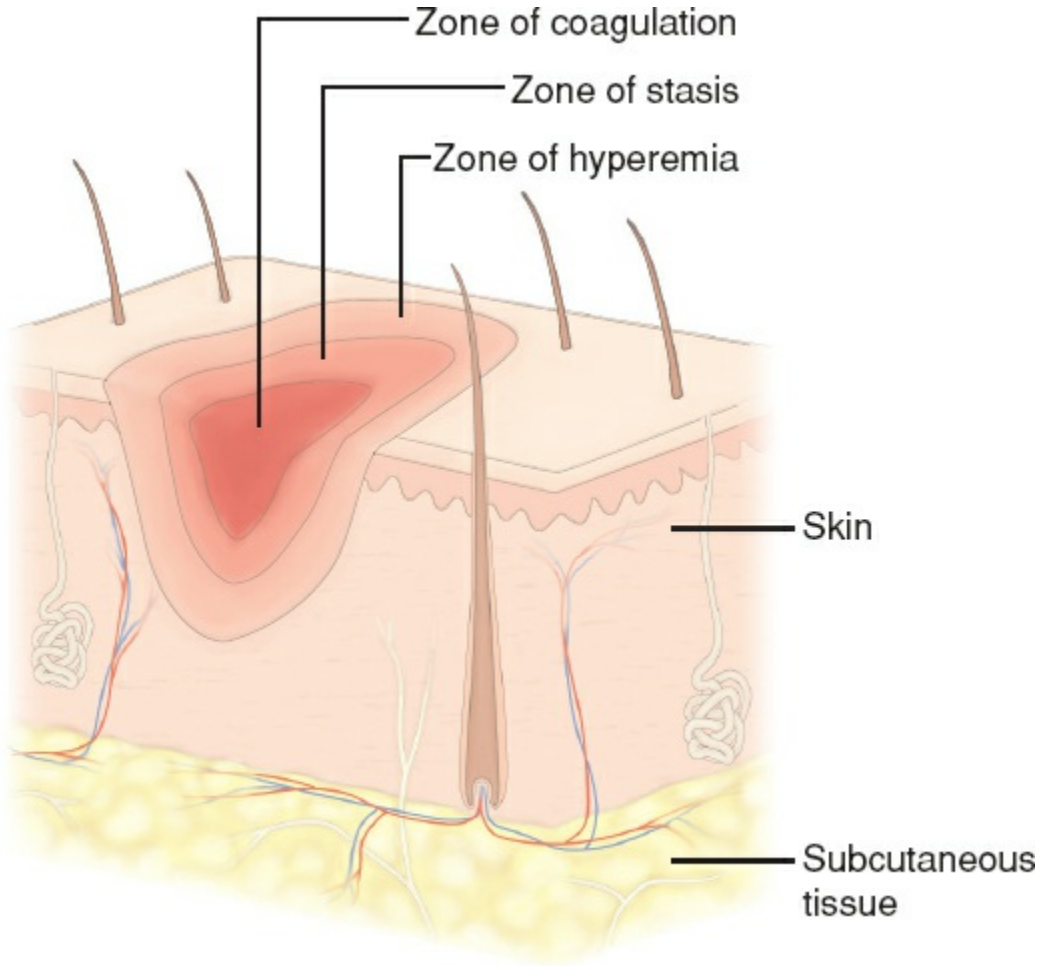

FIGURE 53-3 Zones of burn injury. Each burned area has three zones of injury. The inner zone (known as the area of coagulation, in which cellular death occurs) sustains the most damage. The middle area, or zone of stasis, has a compromised blood supply, inflammation, and tissue injury. The

outer zone—the zone of hyperemia—sustains the least damage.

Fluid and Electrolyte Alterations

Prompt fluid resuscitation maintains the BP in the low-normal range and improves CO. In general, the greatest volume of fluid leak occurs in the first 24 to 36 hours after the burn. As the capillaries begin to regain their integrity, burn shock resolves and fluid returns to the vascular compartment. As fluid is reabsorbed from the interstitial tissue into the vascular compartment, blood volume increases. If kidney and cardiac function is adequate, urinary output increases. Lactated Ringer's (LR) solution is the preferred IV fluid for burn resuscitation because the sodium (130 mEq/L) and potassium (K^+; 4 mEq/L) concentrations are similar to normal intravascular levels (sodium of 135 to 145 mEq/L and K^+ of 3.5 to 5 mEq/L). LR also contains lactate (28 mEq/L), which can be converted by the liver to bicarbonate (the blood buffer) to aid in correcting the metabolic acidosis frequently seen in burn shock.

Patients with large burn wounds are at risk for abdominal compartment syndrome, especially if fluid resuscitation is delayed. Fluid shifts into the abdominal cavity, causing increased abdominal distention that interferes with pulmonary ventilation. The volume loss into the peritoneal space results in a decreasing CO, hypotension, and a decreasing urine output. The increased intra-abdominal pressure compresses the inferior vena cava and restricts blood flow and perfusion to abdominal organs, further compromising renal, hepatic, and visceral organ function. The adult patient who is critically ill will have an intra-abdominal pressure that varies with respiration of approximately 5 to 7 mm Hg but may be higher in patients with obesity (Kirkpatrick et al., 2013). Bladder pressures of greater than 25 mm Hg are an indicator of increasing abdominal pressure, resulting in inadequate organ perfusion, and indicate the need for abdominal decompression. Clinical presentation may include a tense, distended abdomen, progressive oliguria (urine output below 400 mL), and increased ventilatory requirements (Sheridan, 2016).

Nursing Alert
The nurse recognizes that the clinical goal is to administer adequate but not excessive fluid while safeguarding that soft tissues are not rendered ischemic by increasing pressure beneath inelastic eschar or tense muscle compartments (Sheridan, 2016).

Nursing Alert
Nurses measure intra-bladder pressure (IBP) using a bladder catheter (Foley), a pressure monitor or a manometer, room temperature saline solution, and a 60-mL syringe. A pressure monitor is set up and connected to the catheter drainage bag at the aspiration port via a Luer-lock or needle. Once the bladder is empty, 25 to 50 mL (depending on institutional policy) of saline solution is instilled through the bladder catheter using a 60-mL syringe, and it is clamped. The clamp must be on the drainage tubing below the aspiration port to allow measurement of bladder pressure. Patients must be in a supine position since head of bed elevation can have a significant impact on the reading (Kirkpatrick et al., 2013). The symphysis pubis (at the midaxillary line) is used as the zero reference point for the pressure bag at the midaxillary line. The pressure is recorded, the clamp released, and urine is allowed to flow into the drainage bag. The nurse remembers to subtract the amount of fluid

instilled from the patient's urinary output to maintain an accurate Intake and Output (I&O) record (Fig. 53-4).

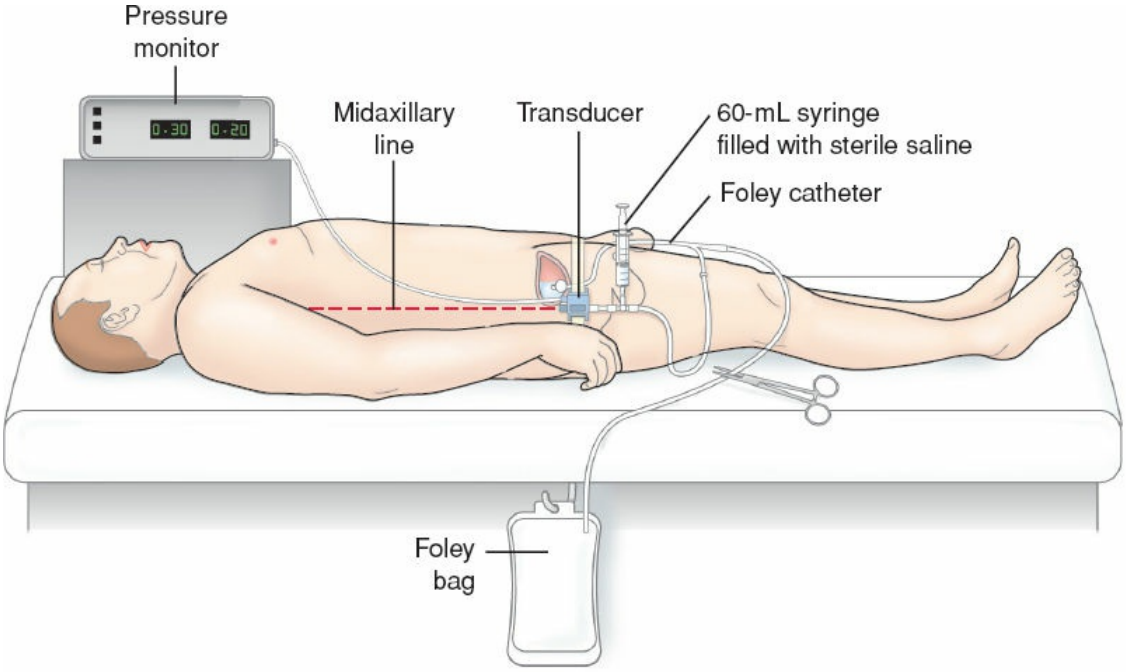

FIGURE 53-4 Measuring intra-bladder pressure. To assess for the development of abdominal compartment syndrome, the intra-bladder pressure may be monitored.

Patients with a major burn develop massive systemic edema. As fluid resuscitation proceeds, the edema worsens. As the taut, burned tissue becomes unyielding to the edema underneath its surface, it begins to act like a tourniquet, especially if the burn is circumferential. This complication is similar to a compartment syndrome. The provider may need to perform an escharotomy, a surgical incision into the eschar (also referred to as "black wound" because of the wounds appearance of thick, dry, black necrotic tissue) to relieve the constricting effect of the burned tissue. Refer to Chapter 42 for details on compartment syndrome.

Burn shock is a physiologic insult combining hypovolemic and distributive shock. Circulating blood volume decreases dramatically during burn shock due to severe capillary leak with variation of serum sodium levels in response to fluid resuscitation. Usually, hyponatremia (sodium depletion) is present. Immediately after burn injury, hyperkalemia (excessive potassium) results from massive cell destruction. The outcome is a dramatic outpouring of fluids, electrolytes, and proteins into the interstitium with rapid equilibrium of intravascular and interstitial compartments. These changes are reflected in loss of circulating plasma volume, hemoconcentration, massive edema formation, decreased urine output, and depressed cardiovascular function (Latenser, 2015). Lactic acidosis is frequently seen in burn shock due to hypovolemia and hypoperfusion; thus, while the lactate in LR IV solution can be converted to base bicarbonate to correct the acidemia, the goal of treatment is aimed at reversing the hypoperfusion. Hypokalemia (potassium depletion) may occur later, with fluid shifts and inadequate potassium replacement. However, plasma lactate levels are significant markers of shock and resuscitation, and appear to be correlated to predict morbidity and outcome. A normal serum lactic acid level in venous blood is 0.5 to

2.2 mEq/L. See discussion of fluid and electrolyte changes in the Emergent/Resuscitative Phase later in the chapter.

Nursing Alert
The nurse is aware that severe lactic acidosis (pH less than 7.2) is associated with a high early mortality. Approximately 17% of patients with a pH below 7.2 are ultimately discharged from the hospital (Seifter, 2016).

Nursing Alert
Ringer's lactate IV solution contains 28 mEq of lactate (28 mmol/L), which is metabolized into bicarbonate by the liver, aiding in correction of metabolic acidosis. However, the nurse is aware that liver function must be assessed to ensure adequate metabolism of this IV solution.

Pulmonary Alterations

Inhalation injury necessitates prolonged hospitalization and remains a major cause of morbidity and mortality. An inhalation injury can occur when a person is trapped inside a burning structure or involved in an explosion that leads to the inhalation of superheated air, steam, and noxious gas. Inhalation injury has a significant impact on a patient's ability to survive (DeKoning, 2016).

Clinical consequences can include upper airway edema, bronchospasm, small airway occlusion, loss of ciliary clearance, increased dead space, intrapulmonary shunting, decreased lung compliance, chest wall compliance, tracheobronchitis, and pneumonia (Sheridan, 2016).

Pulmonary injuries fall into two categories: upper airway injury, and inhalation injury below the glottis, including carbon monoxide poisoning. Upper airway injury results from direct heat and edema. It is manifested by mechanical obstruction of the upper airway as small particles may reach the terminal bronchioles, causing bronchospasms and edema. Direct injury to the upper airway causes airway swelling that typically leads to maximal edema in the first 24 to 48 hours after injury and often requires a short course of endotracheal intubation for airway protection (Friedstat, Endorf, & Gibran, 2014).

Inhalation injury below the glottis results from inhaling noxious gases or steam. The injury results directly from chemical irritation of the pulmonary tissues at the alveolar level. These injuries cause loss of ciliary action, hypersecretion, severe mucosal edema, and possibly bronchospasm. The pulmonary surfactant is reduced, resulting in atelectasis (collapse of alveoli). Expectoration of carbon particles in the sputum is the cardinal sign of this injury.

Carbon monoxide is probably the most common cause of inhalation injury because it is a by-product of the combustion of organic materials and, therefore, is present in smoke. The pathophysiologic effects are caused by tissue hypoxia, a result of carbon monoxide combining with hemoglobin to form carboxyhemoglobin (COHb or HbCO), which competes with oxygen for available hemoglobin-binding sites. The affinity of hemoglobin for carbon monoxide is 250 times greater than that for oxygen. Refer to Table 53-2 for symptoms of CO poisoning. Standard care usually consists of 100% oxygen for 6 hours until the HbCO level is below 10% and the patient is asymptomatic (Ferri, 2016; Sheridan, 2016).

Administering 100% oxygen is essential to accelerate the removal of carbon monoxide from the hemoglobin molecule. Monitor oxygen saturation by pulse oximetry, but be aware that pulse oximetry readings will be falsely elevated in patients with elevated carboxyhemoglobin levels. Simply subtract the measured COHb level from the pulse oximetry value to determine the true oxygen saturation (Drigalla & Gemmill, 2011).

TABLE 53-2 Symptoms of Carbon Monoxide Toxicity

Blood Carboxyhemoglobin Level (%)	Symptoms
Less than 15–20	Headache, dizziness, occasional confusion
20–40	Disorientation, visual impairment
40–60	Agitation, combativeness, hallucinations, coma, and shock
60	Death

Reprinted with permission from Barash, P., Cullen, B., & Stoelting, R. (2013). *Handbook of clinical anesthesia* (7th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Nursing Alert

The pulse oximeter contains a light source (light-emitting diode [LED]) and a light detector, the sensor. The light source beams red and infrared light through the skin and blood, and the amount of light received by the detector is measured. The difference of the transmitted light during and between heart beats is calculated and converted to the percent of hemoglobin that is saturated with oxygen, the SpO_2. While the clinical usefulness of pulse oximeter cannot be disputed, there are at least two important limitations that the nurse needs to be aware of:

1. *Unfortunately, pulse oximeters cannot distinguish oxygenated Hb (HbO_2) from carbon monoxide-poisoned hemoglobin, aka carboxyhemoglobin (HbCO). Thus falsely high SpO_2 saturations are seen in CO poisoning despite inadequate oxygenation of Hb. Moreover, the deficit in oxygen delivery to peripheral tissue is exacerbated by the ability of carbon monoxide to impair the release of oxygen that is bound to hemoglobin, often referred to as a decrease in the p50 (oxygen tension at which hemoglobin is 50% saturated).*
2. *While the SpO_2 accurately reflects the percentage of Hb saturation with O_2 under most conditions, it does not measure total O_2 carrying content of the blood. This can be particularly misleading in the anemic patient where the percent of Hb saturation may be normal but total oxygen delivery to tissues is markedly reduced as a consequence of the fall in red blood cell numbers.*

Pulmonary abnormalities are not always immediately apparent. More than half of all patients with burn injuries with pulmonary involvement do not initially demonstrate pulmonary signs and symptoms. Any patient with possible inhalation injury must be

observed for at least 24 hours for respiratory complications. Indicators of possible pulmonary damage include the following:

- History indicating that the burn occurred in an enclosed area
- Burns of the face or neck
- Singed nasal hair
- Hoarseness, voice change, dry cough, stridor
- Sooty or bloody sputum
- Labored breathing or tachypnea (rapid breathing) and other signs of reduced oxygen levels (hypoxemia)
- Erythema and blistering of the oral or pharyngeal mucosa

Diagnosis of inhalation injury is an important priority, and nurses should consider assessing if the patient was confined in a closed area, if there are facial burns, were nasal hairs burned, or if there is carbonaceous debris in the mouth or sputum (Sheridan, 2016). Carboxyhemoglobin levels and fiberoptic bronchoscopy are used to assess for inhalation injuries as well. Pulmonary complications secondary to inhalation injuries include acute respiratory failure and acute respiratory distress syndrome (ARDS). ARDS is common in these patients and can increase mortality to 66%. A 100% mortality was noted where the TBSA was greater than 60% in combination with inhalation injury and ARDS (Friedstat et al., 2014). Refer to Chapter 10 for more information on ARDS.

Renal Alterations

Kidney function may be altered as a result of decreased blood volume. If muscle damage occurs, myoglobin and hemoglobin are released from the muscle cells and excreted by the kidney; this is common in high-voltage injuries or deep thermal burns. The urine will have a pigmented appearance. Adequate fluid volume replacement restores renal blood flow, increasing the glomerular filtration rate and urine volume. Fluids should be titrated to achieve a urine output of 2 mL/kg/hr (Sheridan, 2016). If there is inadequate blood flow through the kidneys, the hemoglobin and myoglobin occlude the renal tubules, resulting in acute tubular necrosis and kidney failure. Blood urea nitrogen (BUN), serum creatinine levels, and urinary output are monitored to evaluate kidney function. Diuretics have no role in this phase of patient management unless fluid overload has occurred (Nemer & Clark, 2016).

Immunologic Alterations

The immunologic defenses of the body are greatly altered by a serious burn injury as it diminishes resistance to infection. The loss of skin integrity is compounded by the release of abnormal inflammatory factors. There is a significant impairment of the production and release of granulocytes and macrophages from bone marrow; the resulting immunosuppression places the patient with burn injury at high risk for sepsis (see Chapter 54 for details on septicemia).

Thermoregulatory Alterations

Loss of skin also results in an inability to regulate body temperature. Therefore patients with burn injuries may exhibit low body temperatures in the early hours after injury. Then, as hypermetabolism resets core temperatures, the patient becomes hyperthermic for much of the post-burn period, even in the absence of infection.

Gastrointestinal Alterations

Two potential gastrointestinal (GI) complications may occur: paralytic ileus (absence of intestinal peristalsis) and Curling ulcer. Decreased peristalsis and bowel sounds are manifestations of paralytic ileus resulting from burn trauma. Gastric distention and nausea may lead to vomiting unless gastric decompression is initiated. Gastric bleeding secondary to massive physiologic stress may be signaled by occult blood in the stool, regurgitation of "coffee ground" material from the stomach, or bloody vomitus. These signs suggest gastric or duodenal erosion (Curling ulcer).

MANAGEMENT OF BURN INJURY

Burn care must be based on burn depth and local response, the extent of the injury, and the presence of a systemic response. Burn care is divided into three phases: emergent/resuscitative phase, acute/intermediate phase, and rehabilitation phase. Although priorities exist for each of the phases, they overlap, and assessment and management of specific problems and complications are not limited to these phases but take place throughout burn care. The three phases and the priorities for care are summarized in Table 53-3. Box 53-2 summarizes emergency care at the burn scene.

Emergent/Resuscitative Phase

Immediate Care

It is important to remember the CABD (circulation, airway, breathing, disability) steps (formerly called ABCs [Airway, Breathing, and Circulation]) of all trauma care during the early post-burn period. Refer to Chapter 56 for further details.

TABLE 53-3 Phases of Burn Care

Phase	Duration	Priorities
Emergent/resuscitative	From onset of injury to completion of fluid resuscitation	• First aid • Prevention of shock • Prevention of respiratory distress • Detection and treatment of concomitant injuries • Wound assessment and initial care
Acute/intermediate	From beginning of diuresis to near completion of wound closure	• Wound care and closure • Prevention or treatment of complications, including infection • Nutritional support
Rehabilitation	From major wound closure to return to patient's optimal level of physical and psychosocial adjustment	• Prevention of scars and contractures • Physical, occupational, and vocational rehabilitation • Functional and cosmetic reconstruction • Psychosocial counseling

BOX 53-2 Emergency Procedures at the Burn Scene

- *Extinguish the flames:* When clothes catch fire, the flames can be extinguished if the person falls to the floor or ground and rolls ("stop, drop, and roll"); anything available to smother the flames, such as a blanket, rug, or coat, may be used. Standing still forces the person to breathe flames and smoke, and running fans the flames. If the burn source is electrical, the electrical source must be disconnected.
- *Cool the burn:* After the flames are extinguished, the burned area and adherent clothing are soaked with *cool* water, briefly, to cool the wound and halt the burning process. Once a burn has been sustained, the application of cool water is the best first-aid measure. Soaking the burn area intermittently in cool water or applying cool towels gives immediate and striking relief from pain and limits local tissue edema and damage. However, *never* apply ice directly to the burn, *never* wrap the person in ice, and *never* use cold soaks or dressings for longer than several minutes; such procedures may worsen the tissue damage and lead to hypothermia in people with large burns.
- *Remove restrictive objects:* If possible, remove clothing immediately. Adherent clothing may be left in place once cooled. Other clothing and all jewelry (especially rings), including all piercings, should be removed to allow for assessment and to prevent constriction secondary to rapidly developing edema.
- *Cover the wound:* The burn should be covered as quickly as possible to minimize

bacterial contamination and decrease pain by preventing air from coming into contact with the injured surface. Sterile dressings are best, but any clean, dry cloth can be used as an emergency dressing. Ointments and salves should *not* be used. Other than the dressing, no medication or material should be applied to the burn wound.

- *Irrigate chemical burns:* Chemical burns resulting from contact with a corrosive material are irrigated immediately. Most chemical laboratories have a high-pressure shower for such emergencies. If such an injury occurs at home, brush off the chemical agent, remove clothes immediately, and rinse all areas of the body that have come in contact with the chemical. Rinsing can occur in the shower or any other source of continuous running water. If a chemical gets in or near the eyes, the eyes should be flushed with cool, clean water immediately. Outcomes for the patient with chemical burns are significantly improved by rapid, sustained flushing of the injury at the scene.

Circulation must be assessed quickly. Apical pulse and BP are monitored frequently. Tachycardia (abnormally rapid heart rate, over 100 bpm) and slight hypotension are expected soon after the burn. A urinary catheter is inserted, and strict intake and output is recorded. Monitoring of hourly urine output and daily weights provides clues about fluid volume status. Any evidence of decreasing urine output or hemodynamic instability requires immediate notification of the provider. A large-bore (16- or 18-gauge) IV catheter should be inserted in a nonburned area for fluid replacement.

It is important to support the *airway* and protect the cervical spine. If edema of the airway develops, endotracheal intubation may be necessary.

The nurse assesses and promotes *breathing.* For mild pulmonary injury, 100% humidified oxygen is administered. Intubation and ventilation may be necessary. The nurse monitors the respiratory rate, lung sounds, and oxygen saturation and notifies the provider if dyspnea, stridor, or changes in respiratory patterns or saturation levels reflect declining ventilation and oxygenation.

Nursing Alert

Breathing must be assessed and a patent airway established immediately during the initial minutes of emergency care. Immediate therapy is directed toward establishing an airway and administering humidified 100% oxygen. If qualified personnel and equipment are available and the victim has severe respiratory distress or airway edema, the rescuers can insert an endotracheal tube and initiate manual ventilation.

Nursing Alert

In the event of a high-voltage electrical injury, spinal cord injury can result from the direct effect of electrical current or can occur secondary to trauma associated with blunt injury. Thus, the cervical spine should be immobilized. Additionally, electrical injury interferes with cardiac conduction and can cause direct trauma to cardiac muscle fibers, resulting in a number of arrhythmias, including asystole, ventricular fibrillation, sinus

tachycardia, and premature ventricular contractions (PVCs). Because the arrhythmias can present hours after the incident, cardiac monitoring for patients with all electrical injuries for at least 24 hours after cessation of arrhythmia is suggested.

Additionally, related to *disability*, the neurologic status is assessed quickly in the patient with extensive burns. The nurse is aware that restlessness, confusion, difficulty attending to questions, or decreasing level of consciousness may indicate cerebral hypoxia. Often, the patient is awake and alert initially, and vital information can be obtained at that time. A secondary head-to-toe survey of the patient is carried out to identify other potentially life-threatening injuries.

Assessment

Initial priorities in the emergency department remain *CABD.* After adequate circulatory and respiratory functions have been established, and the patient's condition is stable, attention is directed to the burn wound itself.

Information needs to include the time of the burn injury, the source of the burn, how the burn was treated at the scene, and any history of falling with the injury. A history of pre-existing diseases, allergies, medications, and the use of drugs, alcohol, and tobacco is obtained at this point to aid in planning the patient's care. Because poor tissue perfusion accompanies burn injuries, only IV analgesia (usually morphine) is administered, and it should be titrated according to patient need.

If the burn exceeds 20% TBSA, a nasogastric tube should be inserted and connected to low suction. All patients who are intubated should have a nasogastric tube inserted to decompress the abdomen and prevent vomiting.

Assessment of both the TBSA burned and the depth of the burn are completed. Careful attention is paid to keeping the patient warm during wound assessment. Baseline values for height, weight, arterial blood gases, carboxyhemoglobin, hematocrit, electrolyte values, blood alcohol level, drug panel, urinalysis, and baseline electrocardiogram (ECG) are obtained. Because burns are contaminated wounds, tetanus prophylaxis is administered if the patient's immunization status is not current (less than 5 years since last tetanus) or unknown (Advanced Burn Life Support [ABLS], 2012; Ferri, 2016).

Transfer to a Burn Center

The depth and extent of the burn are considered in determining whether the patient should be transferred to a burn center. However, if the patient's prognosis does not support transport to a burn center, nurses may contact burn center nurses via telephone and ask for support in patient management. Examples of criteria for referral to a burn unit can be found at http://ameriburn.org/BurnCenterReferralCriteria.pdf.

Management of Fluid Loss and Shock

Next to managing respiratory difficulties, the most urgent need is preventing irreversible shock by replacing lost fluids and electrolytes (Table 53-4). The total volume and rate of IV fluid replacement are gauged by the patient's response and guided by the resuscitation formula. Numerous fluid resuscitation formulas exist; the nurse needs to be familiar with

current institutional protocols. The adequacy of fluid resuscitation is determined primarily by monitoring vital signs and urine output totals, an index of renal perfusion. Urine output totals of 0.5 to 1 mL/kg/hr in adults and 1 mL/kg/hr in children have been used as resuscitation goals (ABLS, 2012). Within the first 24 hours after injury, if the urinary output exceeds 50 mL/hr, the rate of IV fluid administration may be decreased because excessive fluid resuscitation may be deleterious for burn patients. Use of advanced technology, such as monitoring with pulmonary artery catheters and esophageal echo-Doppler, to evaluate hemodynamic response in burn-shock resuscitation have utility but carry risks, such as infection and aspiration. Thus, traditional variables of hourly assessment of urinary output and vital signs are used to evaluate the adequacy of fluid replacement therapy. For patients with pre-existing cardiopulmonary disease or kidney disorders, or with patients of extreme age (very young or old), additional hemodynamic parameters may be required to evaluate fluid status (Sheridan, 2016). Factors that are associated with the increased fluid requirements include delayed resuscitation, scald burn injuries, inhalation injuries, high-voltage electrical injuries, hyperglycemia, alcohol intoxication, and chronic diuretic therapy.

TABLE 53-4 Fluid and Electrolyte Changes in the Emergent/Resuscitative Phase

Fluid accumulation phase (shock phase)
Plasma → interstitial fluid (edema at burn site)

Observation	Explanation
Generalized dehydration	Plasma leaks through damaged capillaries.
Reduction of blood volume	Secondary to plasma loss, fall of blood pressure, and diminished cardiac output
Decreased urinary output	Secondary to: Fluid loss Decreased renal blood flow Sodium and water retention caused by increased adrenocortical activity Hemolysis of red blood cells, causing hemoglobinuria and myonecrosis or myoglobinuria
Potassium (K^+) excess	Massive cellular trauma causes release of K^+ into extracellular fluid (ordinarily, most K^+ is intracellular).
Sodium (Na^+) deficit	Large amount of Na^+ is lost in trapped edema fluid and exudate and by shift into cells as K^+ is released from cells (ordinarily, most Na^+ is extracellular).
Metabolic acidosis (base–bicarbonate deficit)	Loss of bicarbonate ions accompanies sodium loss.
Hemoconcentration (elevated hematocrit)	Liquid blood component is lost into extravascular space.

The projected fluid requirements for the first 24 hours are calculated by the clinician

based on the extent of the burn injury. Formulas have been developed for estimating fluid loss based on the estimated percentage of burned TBSA and the weight of the patient. The length of time since the burn injury occurred is very important in calculating estimated fluid needs. Formulas must be adjusted so that initiation of fluid replacement reflects the time of injury. Resuscitation formulas are approximations only and are individualized to meet the requirements of each patient.

Nursing Alert
Intravenous resuscitation formulas are to be used only as guides. The patient's response, evidenced by heart rate, blood pressure, and urine output, is the primary determinant of actual fluid therapy and must be assessed at least hourly.

The ABA consensus formula provides for the volume of an isotonic solution (e.g., LR) to be administered during the first 24 hours in a range of 2 to 4 mL/kg/% TBSA.

Adults and older children (over 14 years of age, weighing more than 40 kg) receive:

2 mL of LR × kg × the % burn

Infants and children (under 14 years of age, weighing less than 40 kg) receive:

3 mL of LR × kg × the % burn

Patients with electrical injuries have LR administered:

4 mL × kg × the % burn (ABLS, 2012).

For children weighing less than 10 kg, D5LR is typically the solution administered. Half of the calculated total should be given over the first 8 post-burn hours, and the other half should be given over the next 16 hours. The rate and volume of the infusion must be regulated according to the patient's response by changing the hourly infusion rates. Another formula widely used is the Parkland formula, which is 4 mL/kg/% TBSA over 24 hours, using LR. It also administers half of the volume over the first 8 hours post-burn and the remaining half is administered over the next 16 hours. The use of formulas and TBSA methods can improve the accuracy and ease of calculating fluid resuscitation requirements. Again, practitioners should take note that the resuscitation formula serves only as a guideline, and the patient's response to fluid therapy is the best parameter to use.

The following example illustrates use of the consensus formula in a 70-kg (154-lb) patient with a 50% TBSA burn:

1. Consensus formula: 2 to 4 mL/kg/% TBSA
2. 2 × 70 × 50 = 7,000 mL/24 hr
3. Plan to administer: first 8 hours = 3,500 mL, or 437 mL/hr; next 16 hours = 3,500 mL, or 219 mL/hr

Nursing Implications

Nursing assessment in the emergent phase of burn injury focuses on the major priorities for

any trauma patient. Vital signs and respiratory status are monitored closely. Circulation, sensation, and mobility (CSM) of burn area is assessed hourly. Refer to Chapter 40 for details on musculoskeletal assessment. Hourly, the nurse will assess warmth, capillary refill, pulses, sensation, and movement of the affected extremity using the unaffected extremity for comparison. A Doppler (ultrasound device) is useful to assess perfusion of the affected extremity. Elevation of burned extremities is crucial to decrease edema. Loss of pulse or sensation must be reported to the provider immediately.

Nursing Alert
If a blood pressure cuff is wrapped around a patient's arm, the cuff must be removed from the extremity between readings since it may act as a tourniquet as the extremity swells.

Nursing Alert
Dressings impede circulation if they are wrapped too tightly. The peripheral pulses must be checked frequently and burned extremities elevated on pillows.

Assessment includes monitoring of fluid intake and output. Urine output is measured hourly. Burgundy-colored/pigmented urine suggests muscle damage. Administering and monitoring IV therapy is a major nursing responsibility.

Body temperature, body weight, current illnesses, and use of medications are assessed. A head-to-toe assessment is performed, focusing on signs and symptoms of concomitant illness, injury, or developing complications. Assessing the extent of the burn wound continues and is facilitated with anatomic diagrams (described previously).

Comorbid conditions coupled with the burn injury contribute to the high mortality rates of patients 60 years of age and older. Decreased function of the cardiovascular, renal, and pulmonary systems increases the need for close observation of elderly patients with even relatively minor burns during the emergent and acute phases. Acute kidney failure is much more common in elderly patients than in those younger than 40 years of age. The margin of difference between hypovolemia and fluid overload is very small. Suppressed immunologic response, a high incidence of malnutrition, and an inability to withstand metabolic stressors further compromise the elderly person's ability to heal. As a result of these issues, close monitoring and prompt treatment of complications are mandatory. A plan of nursing care for a patient during the emergent/resuscitative phase of burn injury is available online at http://thepoint.lww.com/Honan2e.

Acute/Intermediate Phase

The acute or intermediate phase of burn care follows the emergent/resuscitative phase and begins 48 to 72 hours after the burn injury. During this phase, attention is directed toward continued assessment and maintenance of respiratory and circulatory status, fluid and electrolyte balance (Table 53-5), and GI function. Infection prevention, burn wound care, pain management, and nutritional support are priorities at this stage.

TABLE 53-5 Fluid and Electrolyte Changes in the Acute Phase

Fluid remobilization phase (state of diuresis)
Interstitial fluid → plasma

Observation	Explanation
Hemodilution (decreased hematocrit)	Blood cell concentration is diluted as fluid enters the intravascular compartment; loss of red blood cells destroyed at burn site occurs.
Increased urinary output	Fluid shift into intravascular compartment increases renal blood flow and causes increased urine formation.
Sodium (Na^+) deficit	With diuresis, sodium is lost with water; existing serum sodium is diluted by water influx.
Potassium (K^+) deficit (occurs occasionally in this phase)	Beginning on the fourth or fifth post-burn day, K^+ shifts from extracellular fluid into cells.
Metabolic acidosis	Loss of sodium depletes fixed base; relative carbon dioxide content increases.

Maintenance of Circulatory and Respiratory Status

Changes may occur as the effects of resuscitative fluid and the chemical reactions of smoke ingredients with lung tissues become apparent. Pulmonary complications are not unusual.

Pneumonia is the most frequent clinically related complication and occurred in 30% of

patients with fire/flame injuries (Sheridan, 2016). The frequency of pneumonia and respiratory failure is much greater in patients with 4 days or more of mechanical ventilation than those with less than 4 days. The incidence of clinically related complications for patients with 0 days of mechanical ventilation increases with age and tops out at nearly 20% for those 80 years of age and over (ABA, 2015). Ideally, the best practice is to remove the endotracheal tube as soon as possible to decrease the risk of infection transmission. The arterial blood gas values and other parameters determine the need for intubation and mechanical ventilation. Humidified oxygen is provided as necessary to maintain adequate oxygen saturation and provide moisture to injured tissues. The nurse assesses breath sounds, and respiratory rate, rhythm, depth, and chest symmetry, and notifies providers with concerns over pulmonary deterioration, such as increasing dyspnea or stridor and changes in respiratory patterns. As capillaries regain integrity, diuresis begins. If cardiac or renal function is inadequate, fluid overload occurs and symptoms of congestive heart failure may result. Early detection allows for early intervention and carefully calculated fluid intake. Cautious administration of fluids and electrolytes continues during this phase of burn care. Blood components are administered as needed to treat blood loss and anemia.

Infection Prevention

Until recently, a common cause of death in patients with burn wounds was wound sepsis; while early excisions and grafting have made an impact in decreasing its frequency, infection is still a major issue (Sheridan, 2016).

The immunosuppression, absent epithelial barriers, and multiple invasive devices that accompany extensive burn injury place the patient at high risk of sepsis. Despite aseptic precautions and the use of topical antimicrobial agents, the burn wound is an excellent medium for bacterial growth and proliferation. While the wound is healing, it must be protected from infection. A primary source of bacterial infection is the patient's intestinal tract, the source of most microbes. A major secondary source of pathogenic microbes is the environment. Infection control is a major role of the burn team in providing wound care. Gown, mask, and gloves are worn while caring for the patient with open burn wounds. Clean technique is used when caring directly for burn wounds.

Antibiotics are seldom prescribed prophylactically because of the risk of promoting resistant strains of bacteria, and they do not seem to reduce the incidence of septic complications. Systemic antibiotics are administered when there is documentation of positive cultures in, for example, urine, sputum, or blood. Careful attention is paid to antibiotic use because inappropriate use of antibiotics significantly affects the microbial flora present and increases the risk of drug resistance. Fast excisions and grafting are the most effective ways to prevent infection in this population (Sheridan, 2016).

Wound Care

Wound care is the single most time-consuming element of burn care after the emergent phase. The nurse needs to make astute assessments of wound status, use creative approaches to wound dressing, and support the patient and family during the emotionally distressing and very painful experience of wound care.

Various measures are used to clean the burn wound. After the wounds are cleansed, the prescribed method of wound care is performed. Provider preferences, the availability of

skilled nursing staff, and resources in terms of number of personnel, supplies, and time must be considered in choosing the best method. The goal is to protect the wound until either spontaneous healing or skin grafting can be achieved. Patient comfort and ability to participate in the prescribed treatment are also important considerations.

Topical Antibacterial Therapy

There is general agreement that some form of antimicrobial therapy applied to the burn wound is the best method of local care. Topical antibacterial therapy does not sterilize the wound; it simply reduces the number of bacteria. For more than 50 years, it has been recognized that silver has bacteriostatic and bacteriocidal properties that make it an excellent treatment agent (Table 53-6).

Criteria for choice of topical agents include the following:

- They are effective against gram-negative organisms and even fungi.
- They are clinically effective.
- They penetrate the eschar but are not systemically toxic.
- They do not lose their effectiveness, allowing another infection to develop.
- They are cost-effective, available, and acceptable to the patient.
- They are easy to apply and remove, minimizing nursing care time.

Wound Débridement

As debris accumulates on the wound surface, it can delay the healing process. Débridement has two goals:

- To remove tissue contaminated by bacteria and foreign bodies
- To remove devitalized tissue or burn eschar in preparation for grafting and wound healing

Early surgical excision to remove devitalized tissue along with early burn wound closure is recognized as the most important factor contributing to survival of a patient with a major burn injury.

TABLE 53-6 Overview of Selected Topical Antibacterial Agents Used for Burn Wounds

Agent	Indication	Application	Nursing Implications
Silver sulfadiazine 1% (Silvadene) water-soluble cream	• Most bactericidal agent • Minimal penetration of eschar	Apply 1/16-in layer of cream with a sterile glove 1–3 times daily.	• Watch for leukopenia 2–3 days after initiation of therapy. (Leukopenia usually resolves within 2–3 days.) • Anticipate formation of pseudoeschar (proteinaceous gel), which is removed easily after 72 hours.
Mafenide acetate 5–10% (Sulfamylon) hydrophilic-based cream	• Effective against gram-negative and gram-positive organisms • Diffuses rapidly through eschar • In 10% strength, it is the agent of choice for electrical burns because of its ability to penetrate thick eschar.	Apply thin layer with sterile glove twice a day. Change the dressing every 12 hours as prescribed.	• Monitor arterial blood gas levels and discontinue as prescribed if acidosis occurs. Mafenide acetate is a strong carbonic anhydrase inhibitor that may reduce renal buffering and cause metabolic acidosis. • Premedicate the patient with an analgesic before applying mafenide acetate because this agent causes severe burning pain for up to 20 minutes after application.
Silver nitrate 0.5% aqueous solution	• Bacteriostatic and fungicidal • Does *not* penetrate eschar	Apply solution to gauze dressing and place over wound. Keep the dressing wet but covered with dry gauze and dry blankets to decrease vaporization. Remoisten every 2 hours, and re-dress wound daily as prescribed.	• Monitor serum sodium (Na^+) and potassium (K^+) levels and replace as prescribed. Silver nitrate solution is hypotonic and acts as a wick for sodium and potassium. • Protect bed linen and clothing from contact with silver nitrate, which stains everything it touches black.
Acticoat	• Effective against gram-negative and gram-positive organisms and some yeasts and molds • Delivers a uniform, antimicrobial concentration of silver to the burn wound	Moisten with sterile water only (*never* use normal saline as it will deactivate the silver in the dressing). Apply directly to wound. Cover with absorbent secondary dressing. Remoisten every 3–4 hours with sterile water.	• Do not use oil-based products or topical antimicrobials with Acticoat burn dressing. Keep Acticoat moist, not saturated. May produce a "pseudoeschar" from silver after application. • Can be left in place for 3–5 days. Also available in Acticoat 7, which can be left in place for up to 7 days without the need to change the dressing.

Wound Coverage

If wounds are full-thickness or extensive, spontaneous healing is not possible, and treatment of the wound is necessary until coverage with a graft of the patient's own skin (autograft) is possible. Autografts are the ideal covering for burn wounds because the grafts are the patient's own skin and, therefore, are not rejected by the patient's immune system.

The purposes of wound coverage are to decrease the risk of infection; prevent further loss of protein, fluid, and electrolytes through the wound; and minimize heat loss through evaporation. Once the wound is surgically excised, a wound covering is applied to keep the area moist and promote the granulation process.

Homograft is donor skin from a cadaver. It is a biologic dressing that has several uses. In extensive burns, it save lives by providing temporary wound coverage and protecting the granulation tissue until autografting is possible. Biologic dressings also provide temporary immediate coverage for clean, superficial burns and decrease the wound's evaporative water and protein loss. They decrease pain by protecting nerve endings and are an effective barrier against water loss and entry of bacteria. Biosynthetic and synthetic skin substitutes continue to be used as temporary wound coverings.

In an attempt to develop the ideal burn wound covering product, dermal substitutes have been created. It is believed that skin substitutes enhance the healing process of an open wound when autologous skin is unavailable.

Care of the Graft Site. Occlusive dressings are commonly used initially after grafting to immobilize the graft. Synthetic dressings may be used to protect grafts. The patient is positioned and turned carefully to avoid disturbing the graft or putting pressure on the graft site. If an extremity has been grafted, it is elevated to minimize edema.

Care of the Donor Site. A moist gauze dressing is applied at the time of surgery to maintain pressure and to stop any oozing. With all types of covering, donor sites must remain clean, dry, and free from pressure. Because a donor site is usually a partial-thickness wound, it will heal spontaneously within 7 to 14 days with proper care. Donor sites are painful, and additional pain management must be a part of the patient's care.

Pain Management

Pain is inevitable during recovery from any burn injury. Burn pain has been described as one of the most intense and prolonged types of pain. The pain starts immediately after injury and can last long into the recovery phase. Also the tissue surrounding a thermal burn is usually painful. Hyperalgesia (enhanced intensity of pain sensation) has been known to occur in burn patients; the pain threshold is lowered and pain can last minutes or hours for no apparent reason (Hall, 2012). Pain is related to tissue destruction, as well as to the inflammatory response, which causes the release of histamine, bradykinin, and prostaglandin that are irritating to exposed peripheral nerve endings (Brookman, 2016).

Pain in patients with burn wounds can be divided into four types: (1) Rest pain, constant background, and dull pain; (2) Breakthrough pain, intermittent, short duration, rapid onset (can be excruciating); (3) Procedural, short durations, greatest intensity (wound cleansing, therapy); and (4) Psychogenic pain, anticipatory pain without stimulation (Brookman, 2016). The nurse should be aware that rest pain (background) is best handled by administering regularly scheduled long-acting opioids for continuous coverage; procedural pain requires premedication with analgesic medications before painful procedures (Hall, 2012). Breakthrough pain occurs when blood levels of analgesic agents decrease below the level required to control background pain. Psychogenic pain, which is pain that may be caused by an emotional issue, often fear, depression, stress, or anxiety, may be managed with early psychological evaluation and patient-specific treatment.

Pain changes in time as the wound is covered with new skin, healing takes place, and scars form. Management of the often-severe pain is one of the most difficult challenges facing the burn team. Many factors contribute to the pain experience. These factors include the severity of the pain, the adequacy of the health care provider's assessment of the pain, appropriateness of pharmacologic treatment of pain, multiple procedures involved in burn care, and evaluation of the effectiveness of pain relief measures. Literature suggests that, despite advances in pain management, many burn patients are undertreated for pain. The outstanding features of burn pain are its intensity and long duration; thus, all medical providers should understand that opioid tolerance is not addiction, and pain should be managed when there is a clinical need. Furthermore, necessary wound care carries with it the anticipation of pain and anxiety. Refer to Chapter 7 for discussion of tolerance versus addiction.

In partial-thickness burns, the nerve endings are exposed, resulting in excruciating pain with exposure to air currents. Although nerve endings are destroyed in full-thickness burns, the margins of the burn wound are hypersensitive to pain, and there is pain in adjacent

structures. Healing of full-thickness burns creates significant discomfort as regenerating nerve endings become entrapped in scar formation. Most severe burns are a combination of partial-thickness and full-thickness burns.

The patient's pain level must be assessed throughout the day because each type of pain is different, and various management strategies may be needed to address the different types of pain. The nurse uses a pain intensity scale to assess pain level (e.g., 1 to 10), and documents response to the treatment plan consistently. Opioid administration via the IV route, particularly in the emergent and acute phases of burn management, remains the mainstay for pharmacologic management. Titration of analgesic agents to obtain relief while minimizing side effects is crucial. The patient's requirements for analgesia are often high, but fear of addiction on the part of the patient and the health care provider hampers adequate opioid administration. Morphine sulfate remains the analgesic of choice. It is titrated to obtain pain relief based on the patient's self-report of pain. There is increasing evidence that ketamine is a good analgesic in burn pain (Nemer & Clark, 2016).

Fentanyl is another useful opioid, particularly for procedural pain, because it has a rapid onset, high potency, and short duration, all of which make it effective for use with procedures.

Patient-controlled analgesia (PCA) maintains a steady level of opioid for pain relief and enables the patient to administer intermittent doses of medication.

Sustained-release opioids, such as MS Contin or oxycodone (OxyContin), have also been used successfully in the treatment of burn pain. These medications can effectively treat the resting pain that is associated with burn injury. Additional medications must be prescribed with these to cover breakthrough pain.

Also, nursing interventions, such as teaching the patient relaxation techniques, giving the patient some control over wound care and analgesia, and providing frequent reassurance, are helpful and should not be overlooked. Other pain-relieving approaches include distraction through video programs or video games, hypnosis, biofeedback, and behavioral modification.

Anxiety and pain go hand in hand. The entire burn experience can produce severe anxiety, which can, in turn, exacerbate pain. Therefore, the ideal pain management regimen must incorporate the treatment of pain and anxiety and must be individualized for each patient.

It is important for the nurse to differentiate restlessness due to pain from restlessness due to hypoxia; a thorough respiratory assessment can help discriminate the etiology, noting oxygen saturation, lung sounds, chest expansion, and respiratory rate. The nurse also assesses the patient's sleep patterns since lack of sleep and rest interferes with healing, comfort, and restoration of energy. If necessary, sedatives are prescribed.

Nutritional Support

Burn injuries produce profound metabolic abnormalities fueled by the exaggerated stress response to the injury. It is essential to control this response by increasing the anabolic process through adequate nutrition, decreasing heat loss from wounds, and maintaining a warm environment. Controlling secondary stress, such as pain and anxiety, also helps control the stress response.

The most important of these interventions is to provide adequate nutrition and calories.

Healing of the burn wound consumes large quantities of energy. Several formulas exist for estimating the daily metabolic expenditure and caloric requirements. The enteral route of feeding is far superior to the parenteral route. Feedings are started as soon as possible. Vitamin and mineral supplements may be prescribed, and the nurse collaborates with the dietitian to plan a protein- and calorie-rich diet that is acceptable to the patient. Other treatment modalities include early excision and skin grafting of the burn wound, aggressive prevention or treatment of infections, and adequate exercise with physical therapy to lessen muscle wasting and increase strength.

Promoting Mobility

An early priority is to prevent complications of immobility. Deep breathing, turning, and proper positioning are essential nursing practices that prevent atelectasis and pneumonia, control edema, and prevent pressure ulcers and contractures. These interventions are modified to meet the patient's needs. Low–air-loss and rotation beds may be useful, and early sitting and ambulation are encouraged. If the lower extremities are burned, elastic pressure bandages should be applied before the patient is placed in an upright position.

Psychological and Emotional Support

Family functioning is disrupted with burn injury. One of the nurse's responsibilities is to support the patient and family. Family members need to be instructed about ways that they can support the patient as adaptation to burn trauma occurs. The burn injury has tremendous psychological, economic, and practical impact on the patient and family. Referrals for social services or psychological counseling should be made as appropriate.

Rehabilitation Phase

Rehabilitation begins immediately after the burn has occurred and often extends for years after injury. In the aftermath of the acute stages of burn injury, the patient increasingly focuses on the alterations in self-image and lifestyle that may occur. Wound healing, psychosocial support, and restoration of maximal functional activity remain priorities so that the patient can have the best quality of life both personally and socially. The body goes through many changes as it heals. As the burn wound becomes a burn scar, the burn survivor may be faced with new complications. Often reconstructive surgery to improve body appearance and function is needed.

Hypertrophic Scarring

The wound is in a dynamic state for 1.5 to 2 years after the burn occurs. If appropriate measures are instituted during this active period, the scar tissue can lose its redness and soften. Healed areas that are prone to hypertrophic scarring require the patient to wear a pressure garment. Pressure needs to be continuous. Gentle superficial massage aids in softening the connective tissue. Patients must be instructed about the need for lubrication and protection of the healing skin and the need to use pressure garments for at least 1 year after the injury. Treatment during rehabilitation is expected to include elastic pressure garments, splints, and exercise under the supervision of an experienced physical and occupational therapy team.

Continuing Care

Follow-up care by an interdisciplinary burn care team is necessary. Patients who receive care in a burn center usually return to the burn clinic for evaluation by the burn team, modification of home care instructions, and planning for reconstructive surgery. Many patients require outpatient physical or occupational therapy. It is often the nurse who is responsible for coordinating all aspects of care and ensuring that the patient's needs are met.

Patients who return home after a severe burn injury need referral for home care. Social services and community nursing services must be contacted to provide optimal care and supervision after hospital discharge. The home care nurse assesses the patient's physical and psychological status, as well as the adequacy of the home setting for safe and adequate care. The nurse monitors the plan of care and notes any problems that interfere with the patient's ability to carry out the care.

Patients who have survived burn injuries frequently suffer profound losses. These include not only a loss of body image due to disfigurement but also losses of personal property, homes, loved ones, and ability to work. The American Burn Association (ABA) has consistently advocated to help uninsured patients with disabling burn injuries receive care through Medicare, and supported the Affordable Healthcare Act (ACA) offering all Americans' the opportunity to secure health care insurance coverage (ABA, n.d.).

The health care team must actively promote a healthy body image and self-concept so that these patients can accept or challenge others' perceptions of those who are disfigured or disabled. Several burn patient support groups and other organizations throughout the

United States offer services for burn survivors. They provide caring people (often people who have themselves recovered from burn injuries) who can visit the patient in the hospital or home or telephone the patient and family periodically to provide support and counseling about skin care, cosmetics, and problems related to psychosocial adjustment (www.phoenix-society.org). These organizations, and many regional burn centers, sponsor group meetings and social functions at which outpatients are welcome. Some also provide school-reentry programs and are active in burn prevention activities. If more information is needed regarding burn prevention, the ABA can help locate the nearest burn center and offer current burn prevention tips (www.ameriburn.org).

CHAPTER REVIEW

Critical Thinking Exercises

1. A 75-year-old woman was scalded in the bathtub, where she sustained 25% full-thickness wounds to both lower legs before being found by her niece. It is not known how long the woman was in the tub. She has been independent and living alone for the past 15 years; however, her niece has offered to have her aunt come and live with her family. On admission to the emergency department, the woman's temperature is 94°F (35.5°C) and her weight is 111 lb (50 kg). She has diabetes as well as a history of heart failure and hypertension. What are the priorities in her medical and nursing care during the emergent phase of burn care? What assessment parameters would you monitor closely? Is she a likely candidate for skin grafting?

2. An 18-year-old woman sustained second-degree burns from a tanning bed. Her burns cover her entire chest, abdomen, back, and legs. She has large blisters on her chest and the backs of her knees. Using the rule of nines, estimate the percent of TBSA burned. Estimate her fluid resuscitation needs. Describe nursing care, including patient teaching that is important for this patient. She is rating her pain level 10 out of 10. What comfort measures can you use to manage her pain?

3. A 50-year-old man who weighs 111 lb (50 kg) was transferred to the emergency department after his truck caught fire. He has circumferential burns on both of his legs, his anterior chest, and his entire right upper extremity. He was unable to extricate himself from the truck and suffered inhalation burns as well. Using the rule of nines chart, estimate the percent of TBSA burned. What are the emergency priorities for this patient? What are the fluid resuscitation requirements for this patient based on his percent of burn and his weight? What assessment parameters would you monitor closely? What pain management strategies would be indicated for this patient?

NCLEX-Style Review Questions

1. The nurse is caring for a 32-year-old with circumferential full-thickness burns to the right arm and trunk. Which nursing intervention has the highest priority in the plan of

care?

a. Assess radial pulses several times a day.
b. Enforce airborne infection control procedures.
c. Perform range-of-motion exercises several times per day.
d. Remove blisters from the burn area.

2. A patient with severe burn injuries to the abdomen and legs becomes combative when it is time to change the dressings. What nursing intervention will be most helpful to this patient?

a. Allow the patient to determine the time of dressing change.
b. Premedicate the patient with pain and anxiety medications before dressing change.
c. Tell the patient it is OK to cry during the dressing change.
d. Explain the importance of dressing changes.

3. A nurse would suspect an inhalation injury with which of the following findings? Select all that apply.

a. History of burn occurring in an enclosed space
b. Carbonaceous sputum
c. Egophony
d. Stridor
e. Singing of nasal hair

4. What is a reasonable option for pain management for a 50-year-old man who has just sustained 20% partial-thickness burns to his right leg and abdomen?

a. Fentanyl 50 μg intravenously
b. Morphine sulfate 10 mg IM into the left deltoid
c. Calm, reassuring words to help relax him
d. Oxycodone 10 mg PO

5. A patient who was burned at 10:00 AM reports a pre-burn weight of 154 lb (70 kg). The estimated total body surface area (TBSA) burned is 60%. Using the Parkland/Baxter formula, the nurse verifies that the total amount of intravenous lactated Ringer solution to be infused by 6:00 PM on the day of the burn is which of the following?

a. 5,200 mL
b. 7,470 mL
c. 8,400 mL
d. 16,800 mL

Other Acute Problems

An 80-year-old patient is in acute kidney failure and has been diagnosed with multiple organ dysfunction syndrome (MODS). She underwent a right hip replacement 2 days ago and currently has a temperature of 102.6°F.

- What are treatment measures to reverse MODS?

- What patient populations are at increased risk for developing MODS?
- Discuss nursing care of patients with MODS.

CHAPTER 54

Nursing Management: Shock and Multisystem Failure

Linda Honan • Philip R. Martinez, Jr. • Kelly S. Grimshaw

Learning Objectives

After reading this chapter, you will be able to:

1. Describe shock and its underlying pathophysiology.
2. Compare clinical findings of the preshock, shock, and end-organ damage stages of shock.
3. Describe similarities and differences in hypovolemic, cardiogenic, distributive, and obstructive shock states.
4. Identify medical and nursing management priorities in treating patients in shock.
5. Identify vasoactive medications used in treating shock, and describe nursing implications associated with their use.

Shock is a life-threatening condition with a variety of underlying causes. The progression of shock is neither linear nor predictable. Nurses caring for patients with shock and for those at risk for shock must understand the underlying mechanisms of shock and recognize its subtle as well as more obvious signs. Rapid assessment and response are essential to the patient's recovery.

OVERVIEW

Shock can best be defined as a condition in which tissue perfusion is inadequate to deliver oxygen and nutrients to support vital organs and cellular function. This definition differs from more traditional views of shock because it does not depend on absolute criteria for parameters, such as blood pressure (BP).

Nursing Alert
By the time BP drops, damage has already been occurring at the cellular and tissue levels. Therefore, the patient at risk for shock must be assessed and monitored closely before the BP falls.

Adequate blood flow to the tissues and cells requires the following components:

adequate cardiac pump, effective vasculature and circulatory system, and sufficient blood volume. If one component is impaired, perfusion to the tissues is threatened or compromised. Without treatment, inadequate blood flow to the tissues results in poor delivery of oxygen and nutrients to the cells, cellular starvation, cell death, organ dysfunction progressing to organ failure, and eventual death.

Shock affects all body systems. It may develop rapidly or slowly, depending on the underlying cause. During shock, the body struggles to survive, utilizing a variety of homeostatic, compensatory mechanisms to restore blood flow. Any insult to the body can create a cascade of events resulting in poor tissue perfusion, which means that nurses should be vigilant about watching for signs of shock in all patients, regardless of their primary problem or diagnosis.

PATHOPHYSIOLOGY

Tissue perfusion is determined by cardiac output (CO) and systemic vascular resistance (SVR). CO is the amount of blood pumped by the heart in liters per minute (usual CO is about 4 to 6 L/min but varies greatly depending on the metabolic needs of the body). CO depends on stroke volume, determined by ventricular preload (volume), and heart rate, which is controlled in large part by the autonomic nervous system. Afterload is related closely to, and often equated with, the aortic pressure. It depends on the contractility of the right or left side of the heart and SVR (the resistance to the flow of blood out from the ventricles and a key determinant of aortic pressure). It is helpful to think of SVR as a vise grip on the aorta. If the vise is tightened, the SVR and aortic pressure rise, and now it requires more work for the ventricle to pump blood out. In contrast, if the vise grip is released from the aorta, there is little resistance to the outflow of blood and the work required of the heart muscle is diminished. Conventionally, the primary underlying pathophysiologic process is used to classify the shock state (Box 54-1 provides classifications). When considering possible causes of shock and potential interventions, nurses should remember that the interplay of these two factors (CO and SVR) is what determines the extent of the course of shock and the prognosis of the patient.

BOX 54-1 Classifications of Shock

- Hypovolemic shock occurs when there is a decrease in the intravascular volume. Hypovolemia can be the result of an imbalance of intake and output, such as in patients with dehydration or hemorrhage.
- Cardiogenic shock occurs when the heart has an impaired pumping ability; it may be of coronary or noncoronary event origin.
- Obstructive shock occurs when there is decreased oxygen delivery due to an obstructive cause, such as pericardial tamponade, tension pneumothorax, PE, or abdominal compartment syndrome.
- Distributive shock is caused by alterations in vascular smooth muscle tone, caused by nervous system injury, inflammatory release causing vasodilation, or complications associated with medications such as epidural anesthesia. Septic shock is technically considered a "distributive" type of shock. Sepsis is a complex condition, caused by an infection with profound vasodilation.

In all types of shock, the cells lack an adequate blood supply and are inadequately oxygenated; therefore, they must produce energy through anaerobic metabolism. This results in an acidotic intracellular environment, along with a host of electrolyte derangements. In stress states such as shock, catecholamines, cortisol, glucagon, and inflammatory cytokines and mediators are released, causing hyperglycemia and insulin resistance in an effort to mobilize glucose for cellular metabolism.

Nursing Alert

Tight glycemic control (blood glucose, 80 to 110 mg/dL) was considered to reduce morbidity and mortality of patients who were acutely ill. While a higher blood glucose concentration has been associated with adverse outcomes in a variety of clinical settings, recent research studies reveal inconsistent results, suggesting that, in patients who are critically ill, a less aggressive glycemic target is appropriate (e.g., a blood sugar of less than or equal to 120 mg/dL was an independent risk factor associated with an increased mortality in patients who were nondiabetic) (Chan et al., 2016). The optimal strategy for the management of hyperglycemia (also called stress hyperglycemia) in patients who are critically ill with and without diabetes is unknown; however, maintaining the glucose of 140 to 180 mg/dL avoids marked hyperglycemia while minimizing the risk of iatrogenic hypoglycemia (Stapleton & Heyland, 2016).

As the hypoxemia progresses, cellular metabolism becomes anaerobic, which causes the lactic acid level to rise. Excess levels of lactic acid limit the amount of adenosine triphosphate (ATP) produced, and normal cell function cannot be maintained. Recall ATP which is in every cell is responsible for storing and supplying needed energy to the cell. The impaired Na^+/K^+ and ATP membrane pump function results in intracellular accumulation of sodium and loss of K^+. Cellular edema results from the increased intracellular sodium and increased capillary permeability, further decreasing the CO. As the cell membrane becomes more permeable, allowing electrolytes and fluids to seep out of and into the cell, cell structures, primarily the mitochondria, are damaged; and cell death results.

Pathophysiology Alert

Shock often affects the mitochondria within the cell, which normally function at the lowest oxygen tensions in the body (mitochondrial pO_2 is about 5 mm Hg). However, they consume almost all the oxygen used by the body. More than 95% of aerobic chemical energy comes from mitochondrial work (aka oxidative phosphorylation), and the oxygen-dependent combustion of fuel substrates (primarily fats, amino acids, carbohydrates, ketones) into carbon dioxide (CO_2), water, and ATP. Because of this oxygen dependence, the mitochondria of patients in shock can be referred to as "canaries in the coal mine" since often they are affected first during inadequate tissue perfusion. Historically miners would carry canaries into the mine tunnels since the buildup of gases such as carbon monoxide would kill the canary before killing the miners, thus it was a warning to get out! Similarly, without sufficient oxygen, ATP is generated by potential mitochondrial fuels that are anaerobic. Thus lactic acid accumulates in the blood (Jones & Kline, 2014).

STAGES OF SHOCK

Shock is believed to progress along a continuum. One way to understand the physiologic responses and subsequent clinical signs and symptoms is to divide the continuum into separate stages:

- A *nonprogressive stage* (also called the *compensated stage or preshock*)
- A *progressive stage* (also called the *uncompensated stage or shock*)
- An *irreversible stage* (also called *End-organ dysfunction* which results in irreversible organ damage)

TABLE 54-1 Clinical Findings in Stages of Shock

	Stage		
Finding	*Nonprogressive stage; Compensated stage* or Preshock	*Progressive stage; Uncompensated Stage* or Shock	*Irreversible stage or* End-Organ Dysfunction
Blood pressure	Near normal	Systolic below 80–90 mm Hg; Mean arterial pressure (MAP) less than 65 mm Hg	Requires mechanical or pharmacologic support
Heart rate	Over 100 bpm	100–150 bpm	Erratic or asystole
Respiratory status	Fewer than 20 breaths/min	Rapid, shallow respirations; crackles	May require assisted ventilation
Skin	Cold, clammy	Mottled, petechiae	Jaundice
Urinary output	Mildly decreased	Severely decreased	Anuric, requires dialysis
Mentation	Confusion	Lethargy	Unresponsive
Acid–base balance	Respiratory alkalosis	Metabolic acidosis	Profound acidosis

The earlier on this continuum that shock is recognized and interventions are initiated, the greater the patient's chance of survival. Table 54-1 compares clinical findings in the different stages of shock.

NONPROGRESSIVE STAGE (COMPENSATED STAGE OR PRESHOCK)

Pathophysiology

In preshock, or the compensatory stage of shock, the BP often remains within normal limits. Compensatory responses, such as vasoconstriction, increased heart rate, and increased contractility of the heart, contribute to maintaining adequate CO and SVR. This results from stimulation of the sympathetic nervous system and subsequent release of catecholamines (epinephrine and norepinephrine). Patients display the often-described "fight-or-flight" response. Thus, tachycardia or a modest change in systemic blood pressure (increase or decrease) may be the only clinical sign of early shock. Adult patients can often compensate for up to a 10% total volume loss through normal homeostatic mechanisms. Conversely, patients who have other medical problems or who take certain medications (such as beta blockers or calcium channel blockers) may have a diminished ability to

compensate.

Clinical Manifestations and Assessment

Despite a near-normal BP, the patient may show other clinical signs indicating inadequate organ perfusion. Tachycardia, peripheral vasoconstriction, and anxiety are common. Anxiety, along with feelings of doom, are common signs of shock during this early phase and often are not recognized in patients or attributed to something other than developing shock.

Medical and Nursing Management

At this nonprogressive stage, treatment is directed toward identifying the cause of shock, correcting the underlying disorder, and initiating aggressive measures aimed at supporting the body's compensatory mechanisms. Because compensation cannot be maintained indefinitely, measures such as fluid replacement and medication therapy must be initiated early to maintain an adequate BP and reestablish and maintain adequate tissue perfusion. *Early intervention along the continuum of shock is the key to improving the patient's prognosis.* Therefore, the nurse must assess the patient at risk for shock systematically to recognize the subtle clinical signs of the compensatory stage before the patient progresses to uncompensated shock. Box 54-2 highlights considerations for recognizing shock in older patients.

The role of the nurse at this stage is to monitor the patient's hemodynamic status and promptly report deviations to the provider, to assist in identifying and treating the underlying disorder by continuous in-depth assessment of the patient, to administer prescribed fluids and medications, and to promote patient safety. In assessing tissue perfusion, the nurse specifically observes for changes in level of consciousness, vital signs, urinary output, skin, and laboratory values. Constant reassessment is warranted at this stage. Nurses should try to maintain a calm environment for both the patient's and family's sake and also ensure that assessments and interventions are rapid and ongoing. Providing brief explanations about the diagnostic and treatment procedures, supporting the patient during these procedures, and providing information about their outcomes reduces stress and anxiety and thus promotes the patient's physical and mental well-being. Speaking in a calm, reassuring voice and using gentle touch also help ease the patient's concerns.

BOX 54-2 Gerontologic Considerations

Recognizing Shock in Older Patients

The physiologic changes associated with aging, coupled with pathologic and chronic disease states, place older people at increased risk for developing a state of shock and possibly multiple organ dysfunction syndrome (MODS). Elderly people can recover from shock if it is detected and treated early with aggressive and supportive therapies. Nurses play an essential role in assessing and interpreting subtle changes in older patients' responses to illness.

- During hypovolemic states, medications such as beta-blocking agents (metoprolol [Lopressor]) used to treat hypertension may mask tachycardia, a primary compensatory mechanism to increase CO.
- The aging immune system may not mount a truly febrile response (temperature over 40°C or 104°F), but an increasing trend in body temperature should be addressed.
- The heart does not function well in hypoxemic states, and the aging heart may

respond to decreased myocardial oxygenation with arrhythmias that may be misinterpreted as a normal part of the aging process.

- Changes in mentation may be inappropriately misinterpreted as dementia. Older people with a sudden change in mentation should be aggressively treated for the presence of infection and organ hypoperfusion.

Nursing Alert

For patients experiencing shock, if perfusion does not improve despite aggressive interventions, the nurse recognizes that the body will shunt blood from organs such as the skin, kidneys, and gastrointestinal (GI) tract to the brain and heart to ensure adequate blood supply to these vital organs. As a result, the skin is cool and clammy, bowel sounds are hypoactive, and urine output decreases.

PROGRESSIVE STAGE (UNCOMPENSATED STAGE OR SHOCK)

In the progressive stage, the patient loses the ability to compensate for the insult, infection, or injury. It is during this stage that clinical signs become more obvious.

Pathophysiology

The heart and kidneys are among the first organs to show signs of dysfunction. Up until now on the continuum, the myocardium has kept pace by increasing CO, but this can only go on for a limited time. The body's inability to meet increased oxygen requirements produces ischemia, and biochemical mediators cause myocardial depression. This leads to failure of the cardiac pump, even if the underlying cause of the shock is not of cardiac origin.

The systemic impact of hypotension, and thus hypoperfusion, on the kidneys results in decreased urine output. In addition, the inflammatory response to injury is activated, and proinflammatory and anti-inflammatory cytokines and mediators are released, which, in turn, activate the coagulation system in an effort to reestablish homeostasis. At the same time, acidosis impairs all enzymatic functions, including coagulation. A cascade of progressive organ failure resulting from poor tissue perfusion is illustrated in Figure 54-1. Thus it is common for a systemic inflammatory response, coined SIRS, to occur in patients with shock (see section on Septic Shock, page 1521).

Even if the underlying cause of the shock is reversed, the sequence of compensatory responses to the decrease in tissue perfusion perpetuates the shock state, and a vicious cycle ensues. It is believed that the body's appropriate or inappropriate response in this stage of shock may be the primary factor determining the patient's survival.

Clinical Manifestations and Assessment

Clinical manifestations that may be seen include symptomatic tachycardia, dyspnea, restlessness, diaphoresis, metabolic acidosis, hypotension, prolonged capillary refill (more than 2 seconds), decreasing pulse pressure, and oliguria. The most frequent neurologic finding in patients with shock is alteration in the level of consciousness, ranging from confusion to coma (Rivers, 2016, p. 673). Skin changes will depend on the type of shock and may include cool, clammy skin (related to vasoconstriction) or warm, pink skin (related to peripheral vasodilation of distributive shock).

Nursing Alert

Although BP readings alone are unreliable indicators of circulatory status, a single episode of systolic BP of less than 80 mm Hg is associated with an 18% increase in hospital mortality (Rivers, 2016).

Nursing Alert

Pulse pressure is the difference between the systolic and diastolic pressure; for example, for a BP of 120/80, the pulse pressure is 40 mm Hg. Pulse pressure rises when the stroke volume increases and narrows when resistance to outflow decreases (Porth, 2015). The pulse pressure may decrease before the systolic pressure decreases, and in patients with shock pulse pressure is less than 25 mm Hg. Nurses are key to identifying narrowing pulse pressures in patients early in the course of shock and should immediately report a pulse pressure of less than 25 mm Hg to the provider, even if other signs of shock have not yet manifested.

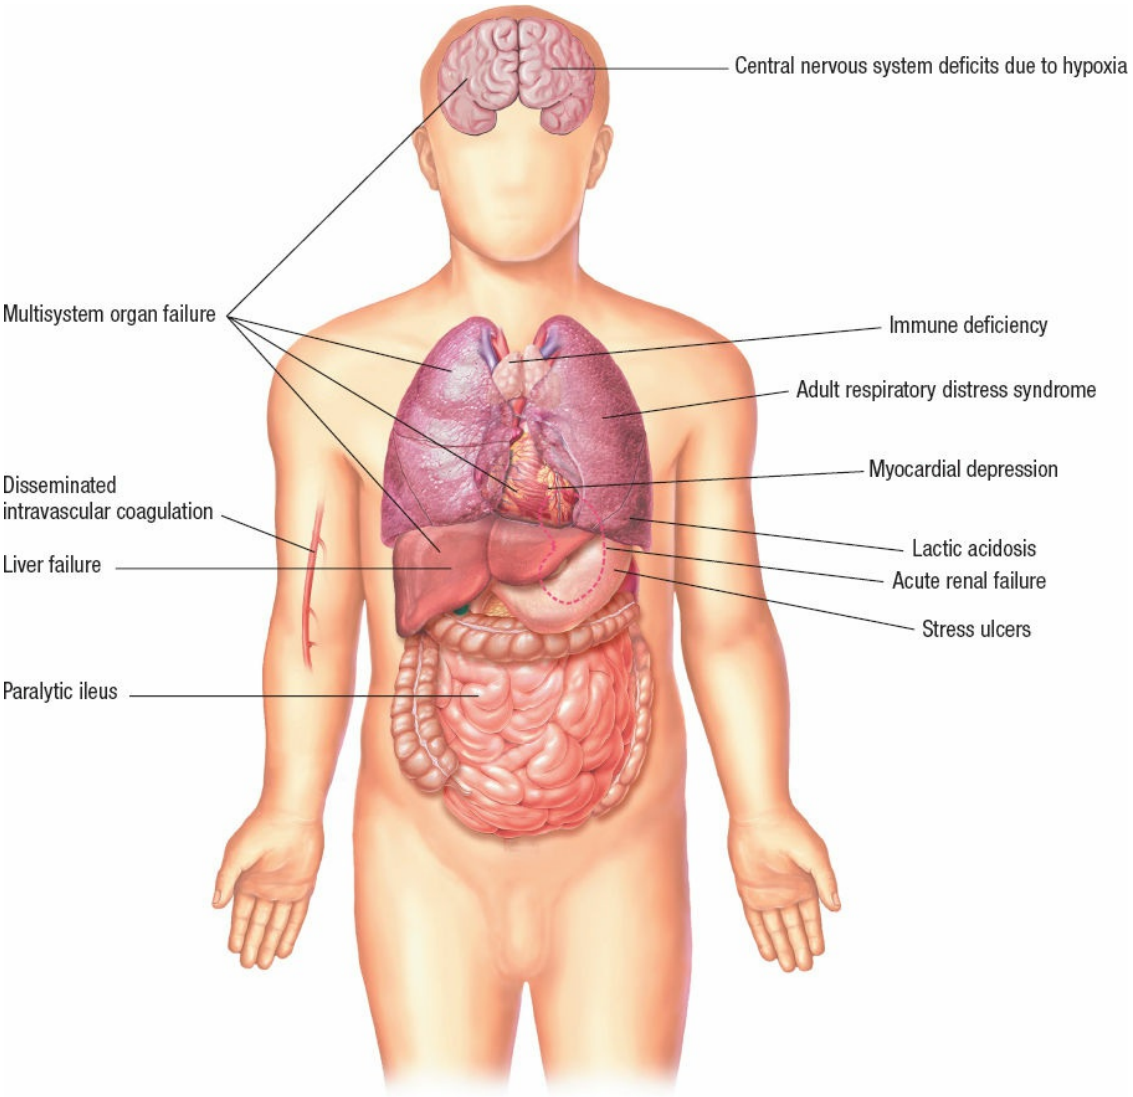

FIGURE 54-1 Multiorgan system effects of shock.

Medical and Nursing Management

Early and aggressive interventions are essential to the survival of patients in shock; therefore, identifying patients who may be in shock and reporting subtle changes in assessment are imperative. Initially, two large-bore peripheral IVs (at least 16 gauge) are inserted to prepare for fluid administration (Rivers, 2016). Two IV lines allow simultaneous administration of fluid, medications, and blood component therapy if required. Patients in shock are often cared for in the intensive care (ICU) setting in order to

- facilitate close monitoring (hemodynamic monitoring, arterial line insertion, electrocardiographic [ECG] monitoring, arterial blood gases [ABGs], oxygen saturation, serum electrolyte levels, physical and mental status changes);
- allow for rapid and frequent administration of various prescribed medications and fluids;
- provide access for strict measurement of intake and output (Foley catheter may be inserted, and urine output should be measured vigilantly: A urine output of less than 30 mL/hr or 0.5 mL/kg/hr is indicative of renal hypoperfusion and/or hypovolemia); and possibly
- provide interventions with supportive technologies, such as mechanical ventilation, dialysis, extracorporeal membrane oxygenation (ECMO), and intra-aortic balloon pump.

Nursing care of patients in shock requires expertise in assessing and understanding shock and the significance of changes in assessment data.

Specific management of shock depends on the type of shock and its underlying cause, but, in general, care is aimed at achieving the following goals using the acronym ASSESS:

A: Assess frequently the body's response to shock
S: Support the pumping action of the heart
S: Support the respiratory system
E: Encourage patient and family involvement in care, particularly in end-of-life discussions
S: Strengthen the competence of the vascular system
S: Significantly optimize intravascular volume

IRREVERSIBLE STAGE (END-ORGAN DYSFUNCTION)

Pathophysiology

If adequate tissue perfusion is not restored in a timely fashion, irreversible end-organ damage ensues. This represents the point along the shock continuum where end-organ damage is so severe that the patient does not respond to treatment and cannot survive. As the damage increases, acidosis may become so severe that even aggressive therapies such as vasopressor support may not work. For example, kidney and liver failure, compounded by the release of necrotic tissue toxins, will create an overwhelming metabolic acidosis. If the integrity of the gut barrier is compromised, bacteria and their toxins can be translocated into the bloodstream. With severe hypoperfusion of the liver, massive elevations in the

enzyme aminotransferase and extensive hepatocellular damage occurs. Anaerobic metabolism contributes to a worsening lactic acidosis. Respiratory system failure prevents adequate oxygenation and ventilation despite mechanical ventilatory support, and the cardiovascular system is ineffective in maintaining an adequate mean arterial pressure (MAP; MAP = [(2 × diastolic pressure + systolic pressure)/3]) for tissue perfusion. Multiple organ dysfunction progressing to complete organ failure has occurred, and death is imminent. Multiple organ dysfunction can occur as a progression along the shock continuum or as a syndrome unto itself and is described in more detail on page 1528.

Nursing Alert

To optimize end-organ perfusion, the nurse monitors the MAP. Although a specific MAP goal has not been established for all shock states, an MAP of at least 60 to 65 mm Hg is a reasonable goal (Rivers, 2016).

Medical and Nursing Management

Specific therapies in this stage are usually the same as for shock. Although the patient may have progressed from shock to irreversible end-organ damage, the judgment that the shock is irreversible can be made only retrospectively, on the basis of the patient's failure to respond to treatment. As in shock, the nurse focuses on carrying out prescribed treatments, monitoring the patient, preventing complications, protecting the patient from injury, and providing comfort.

Offering brief explanations to the patient about what is happening is essential even if there is no certainty that the patient hears or understands what is being said. Simple comfort measures, including reassuring touches, should continue to be provided despite the patient's nonresponsiveness to verbal stimuli. As it becomes obvious that the patient is unlikely to survive, the family must be informed about the prognosis and likely outcome. Clear, honest communication is imperative as families may not understand what is happening with the patient. Opportunities should be provided, throughout the patient's care, for the family to see, touch, and talk to the patient. Close family friends or spiritual advisors may be of comfort to the family members in dealing with the inevitable death of their loved one. Whenever possible, the patient's family should be approached regarding any living wills, advance directives, or other written or verbal wishes the patient may have shared in the event that he or she became unable to participate in end-of-life decisions. In some cases, ethics committees may assist families and health care teams in making difficult decisions.

GENERAL MANAGEMENT STRATEGIES IN SHOCK

As described previously, and in the discussion of types of shock to follow, management in all types and all phases of shock includes the following:

- Optimization of systemic oxygen delivery to improve tissue oxygenation
- Fluid replacement to restore intravascular volume
- Vasoactive medications to restore vasomotor tone and improve cardiac function
- Nutritional support to address the metabolic requirements that are often dramatically increased in shock

Therapies described in this section require collaboration among all members of the health care team to ensure that the manifestations of shock are quickly identified and that adequate and timely treatment is instituted to achieve the best outcome possible (see Fig. 54-2).

Optimize Oxygen Delivery

The first step is to assess oxygenation and provide supplemental oxygen as needed. Oxygen is administered to increase the amount of oxygen carried by available hemoglobin in the blood. A patient who is confused may feel apprehensive with an oxygen mask or cannula in place, and frequent explanations about the need for the mask may reduce some of the patient's fear and anxiety. Frequent assessment of the respiratory status is warranted since many patients with severe shock will require intubation and ventilatory support. Continuous oxygen saturation monitoring is expected. It is important to consider that intubation and mechanical ventilation not only provides for delivery of oxygen and removal of carbon dioxide but also reduces the work of breathing, which, in the patient with hypoperfusion, further exacerbates lactic acidemia (Rivers, 2016). Nurses understand that when patients are "working to breathe," this strenuous use of accessory respiratory muscles can increase oxygen consumption by 50% to 100% and decrease cerebral blood flow by 50% (Jones & Kline, 2014).

Fluid Replacement

The fluids administered vary but may include crystalloids (electrolyte solutions that move freely between intravascular and interstitial spaces), colloids (large-molecule IV solutions), and blood components (Table 54-2). The best fluid to treat shock remains controversial. In emergencies, the "best" fluid is often the fluid that is readily available and is dependent on the type of shock and patient presentation. Fluid resuscitation should be initiated early and aggressively in patients with shock to maximize intravascular volume. For example, in patients with septic shock, an intravenous fluid challenge (20 to 30 mL/kg) may be given rapidly of crystalloid IV fluid to improve intravascular volume (Dellinger et al., 2013; Ferri, 2016). A bolus of 500 mL titrated to MAP or measurement of preload is recommended according to Rivers (2016), and repeated based on the absence of pulmonary edema and evidence of improving tissue perfusion. Both crystalloids (e.g., saline and lactated Ringer's [LR] solution) and colloids (e.g., albumin) may be administered to restore intravascular volume. However, IV fluid choice remains dependent on the type of shock and on the specific patient presentation. For example, in patients with septic shock, crystalloid fluid remains the IV fluid of choice (Dellinger et al., 2013). Conversely, Hespan, a type of colloid fluid, has been shown to cause increased organ damage and mortality in patients who are critically ill, including those with shock (Rivers, 2016). Blood should be given for hypovolemic shock due to trauma and/or hemorrhage, although initially crystalloids may be given to patients to restore intravascular volume while waiting for blood products to transfuse.

Common crystalloid fluids used for resuscitation in hypovolemic shock include 0.9% sodium chloride solution (normal saline) and LR solution. LR is an electrolyte solution containing the lactate ion, which should not be confused with lactic acid. The exogenous lactate is converted to bicarbonate by the liver, thus assisting in treatment of the acidosis. It is important to assess for liver disease when using this solution as the acidosis may worsen when LR is administered to patients with severe liver dysfunction. Additionally, because each liter contains 4 mEq of potassium per liter, it should not be given to patients with severe hyperkalemia. Care also must be taken when administering normal saline rapidly as large volumes result in hyperchloremic metabolic acidosis and coagulopathy (Rivers, 2016). If colloids are administered, the nurse understands that they expand intravascular volume by exerting oncotic pressure, thereby pulling fluid into the intravascular space. Colloidal solutions have the same effect as hypertonic solutions in increasing intravascular volume, but less volume of fluid is required than with crystalloids. Albumin is a colloid that is commonly ordered to treat hypovolemic shock. The disadvantage of colloids is their high cost, and outcomes of patients with hypovolemic shock are equivalent regardless if they are given crystalloids or albumin (Rivers, 2016). Regardless of the solution administered it is important to avoid "over resuscitation" and thus causing fluid volume excess.

TABLE 54-2 Fluid Replacement in Shock

Fluids	Advantages	Disadvantages
Crystalloids		
0.9% sodium chloride (normal saline solution)	Widely available, inexpensive	Requires large volume of infusion; can cause hyperchloremic metabolic acidosis, pulmonary edema
Lactated Ringer's (LR)	Lactate ion helps buffer metabolic acidosis	Requires large volume of infusion; can cause pulmonary edema; should not be used in patients with severe hyperkalemia or patients with severe liver dysfunction
Hypertonic saline (3%, 5%, 7.5%)	Small volume needed to restore intravascular volume	Danger of hypernatremia, central pontine myelinolysis, and increased serum osmolality
Colloids		
Albumin (5%, 25%)	Rapidly expands plasma volume	Expensive; requires human donors; limited supply; can cause heart failure
Dextran (40, 70)	Synthetic plasma expander	Interferes with platelet aggregation; not recommended for patients with hemorrhagic shock
Hetastarch	Synthetic; less expensive than albumin; effect lasts up to 36 hours	Prolongs bleeding and clotting times

The patient receiving fluid replacement in the context of shock must be monitored frequently for adequate urinary output, changes in mental status, skin perfusion, and changes in vital signs. Lung sounds are auscultated frequently to detect signs of fluid accumulation.

Often, a central venous line is inserted in order to measure central venous pressure (CVP). In addition to physical assessment, the CVP helps in monitoring the patient's response to fluid resuscitation. A normal CVP is 2 to 8 mm Hg. Several readings are obtained to determine a range, and fluid replacement is continued to achieve a CVP of 8 to 12 mm Hg; higher-than-"normal" CVPs readings are desired since ventricles tend to stiffen during shock (Jones & Kline, 2014).

Nursing Alert

The nurse understands that the CVP represents the volume in the right atrium and, therefore, is reflective of the amount of preload to the right ventricle. But in patients with shock, because of the stiffening of the ventricles, the CVP cannot predict what is actually pumped out by the left ventricle; thus the nurse considers parameters such as urinary output (increasing), MAP, and lactate concentrations (decreasing) as measures of improved hemodynamic response to treatment.

With newer technologies, catheters can be placed that allow the monitoring of intravascular pressures and venous oxygen levels. Assessment of mixed venous oxygen saturation (SvO_2) or $ScvO_2$ (central venous oxygen saturation) is done with a CVP line or from a special pulmonary artery catheter that has fiber optics capable of calculating the oxygen saturation of hemoglobin. SvO_2 reflects the balance between oxygen delivery and oxygen consumption. Knowing the SvO_2 in conjunction with pulse oximetry is helpful in evaluating the adequacy of oxygenation; newer technology allows for continuous $SvO_2/ScvO_2$ measurements similar to the pulse oximetry. A normal $SvO_2/ScvO_2$ is 70% to 80% (i.e., when the blood is returning to the right side of the heart, it has lost only 20% to

30% of its oxygen). An $SvO_2/ScvO_2$ of 50% to 70% reveals that more oxygen is being extracted from the RBCs; when the $SvO_2/ScvO_2$ is at 30% to 50% the oxygen extraction is becoming exhausted and lactic acidosis begins, and at 25% to 30%, severe lactic acidosis exists. $SvO_2/ScvO_2$ below 25% is associated with cellular death (Reyer, 2013). When the SvO_2 drops, it reflects the increased consumption of oxygen and the need for intervention.

Knowing the CVP assists in evaluating the intravascular volume. Also the BP, urine output, and base deficit all are suggestive of intravascular volume status. Hemodynamic monitoring with arterial and pulmonary artery lines may be implemented to allow close monitoring of the patient's perfusion and cardiac status, as well as response to therapy. For additional information about hemodynamic monitoring, see Chapter 55.

Vasoactive Medication Therapy

Vasoactive medications can be used in patients with all forms of shock to improve the patient's hemodynamic stability when fluid therapy alone cannot maintain adequate MAP. Different medications work on different aspects of CO, and specific medications are selected depending on the underlying cause (see Chapter 55, Table 55-9). Although most of the medications have several effects, these medications are used to (1) increase the strength of myocardial contractility, (2) regulate the heart rate, (3) reduce myocardial resistance, and (4) initiate vasoconstriction.

Receptors in the sympathetic nervous system are known as alpha-adrenergic and beta-adrenergic receptors. Beta-adrenergic receptors are further classified as beta-1 and beta-2 adrenergic receptors. When alpha-adrenergic receptors are stimulated, blood vessels constrict in the cardiorespiratory and GI systems, skin, and kidneys. When beta-1 adrenergic receptors are stimulated, heart rate and myocardial contraction increase. When beta-2 adrenergic receptors are stimulated, vasodilation occurs in the heart and skeletal muscles, and the bronchioles relax. The medications used in treating shock consist of various combinations of vasoactive medications to maximize tissue perfusion by stimulating or blocking the alpha- and beta-adrenergic receptors.

When vasoactive medications are administered, the nurse must monitor vital signs frequently (at least every 15 minutes until stable, or more often if indicated). Vasoactive medications should be administered through a central venous line because infiltration and extravasation of some vasoactive medications can cause tissue necrosis and sloughing. An IV pump must be used to ensure that the medications are delivered safely and accurately. Often, invasive monitoring using an arterial line is used to titrate medications accurately. Individual medication dosages are usually titrated by the nurse, who adjusts drip rates based on the prescribed dose and the patient's response. Dosages are changed to maintain the MAP at a physiologic level that ensures adequate tissue perfusion (usually above 65 mm Hg). Vasoactive medications should be tapered when possible, and the patient should be weaned from medication with frequent monitoring of BP (at least every 15 minutes).

Nutritional Support

Nutritional support is an important aspect of care for patients with shock. Increased metabolic rates during shock increase energy requirements and, therefore, caloric requirements. The release of catecholamines early in the shock continuum causes depletion of glycogen stores in about 8 to 10 hours. Nutritional energy requirements are then met by breaking down lean body mass. In this catabolic process, skeletal muscle mass is broken down even when the patient has large stores of fat or adipose tissue. Loss of skeletal muscle greatly prolongs the patient's recovery time. Parenteral or enteral nutritional support should be initiated as soon as possible, with some form of enteral nutrition always administered. The integrity of the GI system depends on direct exposure to nutrients. Stress ulcers occur frequently in patients who are acutely ill because of the compromised blood supply to the GI tract. Therefore, antacids (e.g., Carafate), H_2 blockers (e.g., famotidine [Pepcid], ranitidine [Zantac]), and/or proton pump inhibitors (e.g., lansoprazole [Prevacid]) are prescribed to prevent ulcer formation by inhibiting gastric acid secretion or increasing gastric pH.

TYPES OF SHOCK

Hypovolemic Shock

Hypovolemic shock, the most common type of shock, is characterized by a decreased intravascular volume. Intracellular fluid accounts for about two thirds of the total body water. The remaining one third of fluid is in the extracellular space that is divided into two compartments: intravascular space (IVS, inside blood vessels) or interstitial space (ISS, surrounding tissues). Approximately three quarters of the extracellular fluid is in the ISS, and the remaining one quarter is in the IVS. Thus, the normal intravascular volume is 4 to 6 L. Hypovolemic shock occurs when there is a reduction in intravascular volume by 15% to 25%, which represents a loss of 750 to 1,500 mL of blood in a 70-kg (154-lb) person.

Pathophysiology

Hypovolemic shock can be caused by sudden fluid losses, such as hemorrhage, or by a gradual deficit in I&O, such as dehydration. See Chapter 56, Table 56-1 for further information on hemorrhagic shock. Figure 54-3 depicts the sequence of events in hypovolemic shock. Box 54-3 discusses risk factors for hypovolemic shock.

Medical Management

Major goals in the treatment of hypovolemic shock are (1) to restore intravascular volume, (2) to reverse the sequence of events leading to inadequate tissue perfusion, and (3) to correct the underlying cause of the fluid loss as quickly as possible. Depending on the severity of shock and the patient's condition, it is likely that efforts will be made to address all three goals simultaneously.

If the patient is hemorrhaging, efforts are made to stop the bleeding. This may involve applying pressure to the bleeding site or a surgery or procedure to stop internal bleeding. If the cause of the hypovolemia is diarrhea or vomiting, medications to treat diarrhea and vomiting are administered while efforts are made to identify and treat the cause. In elderly patients, dehydration is a common cause of hypovolemia.

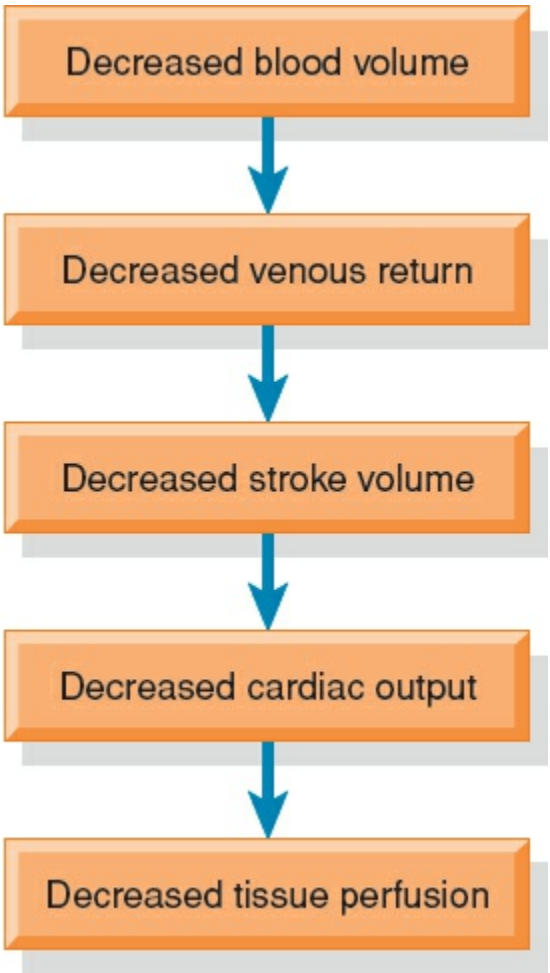

FIGURE 54-3 Pathophysiologic sequence of events in hypovolemic shock.

If the underlying cause of the hypovolemia is dehydration, medications are also administered to reverse the cause of the dehydration. For example, insulin is administered if dehydration is secondary to hyperglycemia, and desmopressin (DDAVP) is administered for patients with diabetes insipidus.

Beyond reversing the primary cause of the decreased intravascular volume, fluid

replacement (also referred to as fluid resuscitation) is of primary concern. At least two large-gauge IV lines are inserted to establish access for fluid administration. Because the goal of the fluid replacement is to restore intravascular volume, it is necessary to administer fluids that will remain in the intravascular compartment, to avoid fluid shifts from the intravascular compartment into the intracellular or interstitial compartment. Blood products may need to be administered, particularly if the cause of the hypovolemic shock is hemorrhage. Packed red blood cells are administered to replenish the patient's oxygen-carrying capacity, in conjunction with other fluids that will expand volume. Plasma and platelet transfusions can help with fluid resuscitation and also treat other underlying problems. The need for transfusions is based on the patient's individual perfusion needs, which are determined by vital signs, blood gas values, and clinical appearance rather than an arbitrary laboratory value. An area of active research is the development of synthetic forms of blood (i.e., compounds capable of carrying oxygen in the same way that blood does) as potential alternatives to blood component therapy. Risks inherent to administering blood include the possibility of a transfusion reaction.

BOX 54-3 Risk Factors for Hypovolemic Shock

External: Fluid losses:

- Trauma
- Surgery
- Vomiting
- Diarrhea
- Diuresis
- Diabetes insipidus
- NPO status

Internal: Fluid shifts:

- Hemorrhage
- Burns
- Ascites
- Peritonitis
- Dehydration

Commonly, positioning the patient with his or her head down, known as the *Trendelenburg position*, has been thought to increase blood flow to vital organs by increasing preload. This practice has not been found to be supported by evidence and, in fact, may worsen pulmonary gas exchange and risk of aspiration (Rivers, 2016). An alternative is to elevate the patient's legs slightly to improve cerebral circulation and promote venous return to the heart, but this position is contraindicated for patients with head injuries.

Nursing Management

Primary prevention of shock is an essential focus of nursing care. Hypovolemic shock can be prevented in some instances by closely monitoring patients who are at risk for fluid deficits and assisting with fluid replacement before intravascular volume is depleted. In other circumstances, nursing care focuses on assisting with treatment targeted at the cause of the shock and restoring intravascular volume.

General nursing measures include ensuring safe administration of prescribed fluids and medications and documenting their administration and effects. Another important nursing role is monitoring for signs of complications and side effects of treatment and reporting these signs early in treatment.

Administering blood transfusions safely is a vital nursing role. In emergency situations, it is important to acquire blood specimens quickly, to obtain a baseline complete blood count, and to type and cross-match the blood in anticipation of blood transfusions. A patient who receives a transfusion of blood products must be monitored closely for adverse effects (see Chapter 20).

Fluid replacement complications can occur, often when large volumes are administered rapidly. Therefore, the nurse monitors the patient closely for cardiovascular overload and edema. The risk of these complications is increased in the elderly and in patients with pre-existing cardiac disease. Hemodynamic pressure, vital signs, ABGs, serum lactate levels, hemoglobin and hematocrit levels, and fluid I&O are among the parameters monitored. Temperature should also be monitored closely to ensure that rapid fluid resuscitation does not precipitate hypothermia. IV fluids may need to be warmed during the administration of large volumes. Physical assessment focuses on observing the jugular veins for distention and monitoring CVP. CVP is typically low in hypovolemic shock; it increases with effective treatment, and is significantly increased with fluid overload and heart failure. The nurse must monitor cardiac and respiratory status closely and report to the provider any changes in BP, pulse pressure, heart rate and rhythm, and lung sounds.

CARDIOGENIC SHOCK

Cardiogenic shock occurs when the heart's ability to contract and to pump blood is impaired and the supply of oxygen is inadequate for the heart and tissues. Cardiogenic shock is seen most often in patients with myocardial infarction (MI). Other causes of cardiogenic shock are related to conditions that stress the myocardium (e.g., severe hypoxemia, acidosis, hypoglycemia, and hypocalcemia), as well as in conditions that result in ineffective myocardial function (e.g., cardiomyopathies, valvular damage, and arrhythmias).

Pathophysiology

In cardiogenic shock, CO, which is a function of stroke volume and heart rate, is compromised. When stroke volume and heart rate decrease or become erratic, BP falls (systolic blood pressure is less than 90 mm Hg or there is a decrease from baseline of more than 30 mm Hg for more than 30 minutes), and systemic tissue perfusion is compromised (urine output decreases, skin becomes cool and mottled, mental status changes [sensorium becomes clouded], anxiety is obvious, capillary refill is delayed). Blood supply for the heart muscle itself is inadequate, resulting in further decreases in CO (cardiac index is less than 2.2 L/min/m^2). Additionally, diastolic dysfunction increases left atrial pressure, which leads to pulmonary congestion and hypoxemia that can further exacerbate myocardial ischemia and impair ventricular performance (pulmonary capillary wedge pressure is greater than 18 mm Hg). This can occur rapidly or over a period of days. Patients in cardiogenic shock may experience the pain of angina and develop arrhythmias and hemodynamic instability. Figure 54-4 depicts the pathophysiology of cardiogenic shock.

Nursing Alert

In the case of heart failure resulting in cardiogenic shock, the nurse assesses for jugular vein distention (JVD), rales, shortness of breath, and S_3 gallop.

Medical Management

The goals of management in cardiogenic shock are (1) to limit further myocardial damage and preserve the healthy myocardium and (2) to improve the cardiac function by increasing cardiac contractility, decreasing ventricular afterload, or both. In general, these goals are achieved by increasing oxygen supply to the heart muscle while reducing oxygen demands.

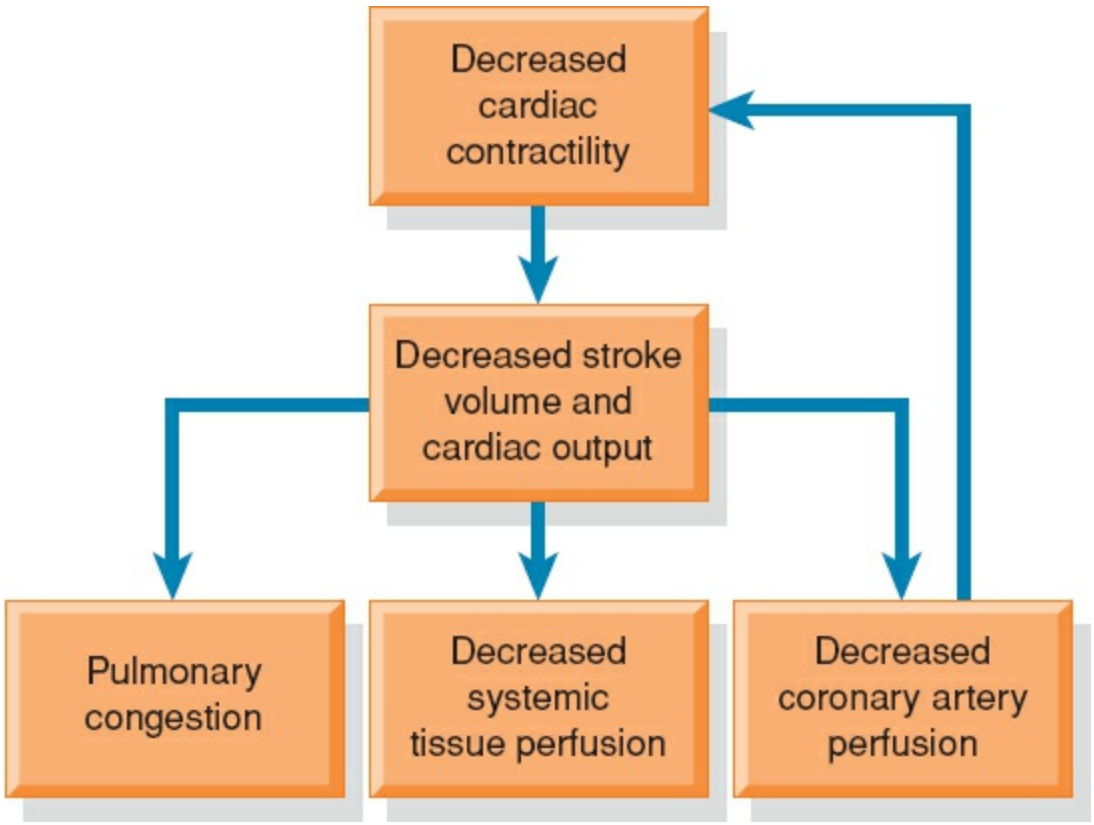

FIGURE 54-4 Pathophysiologic sequence of events in cardiogenic shock.

As with all forms of shock, the underlying cause of cardiogenic shock must be corrected. It is necessary first to treat the oxygenation needs of the heart muscle to ensure its continued ability to pump blood to other organs. In the case of cardiogenic shock due to ischemia or infarction, the patient may require thrombolytic therapy, angioplasty, coronary artery bypass graft surgery, intra-aortic balloon pump therapy, ventricular assist device (VAD), or some combination of these treatments. General interventions for cardiogenic shock include supplemental oxygen, controlling chest pain, providing selected fluid support, administering vasoactive medications, controlling heart rate with medication or pacemaker, and using a mechanical assist device if needed. Serial laboratory markers for ventricular dysfunction (e.g., BNP) and cardiac enzyme levels (i.e., troponin-I) are measured, serial 12-lead ECGs are obtained, and frequently an echocardiogram is ordered to assess the degree of myocardial damage or dysfunction.

Pharmacologic Therapy

Oxygen

In the early stages of shock, supplemental oxygen is administered at a rate sufficient to achieve an oxygen saturation exceeding 90%. Monitoring of ABG values and pulse oximetry values helps determine whether the patient requires a more aggressive method of oxygen delivery.

Analgesia

If a patient experiences chest pain, an IV analgesic (commonly morphine sulfate) is administered for pain relief. In addition to relieving pain, morphine dilates the blood vessels. This reduces the workload of the heart by both decreasing the cardiac filling pressure (preload) and reducing the pressure against which the heart muscle has to eject blood (afterload).

Antiplatelet Agents and Beta Blockers

Antiplatelet agents, such as aspirin, should be given in the case of a patient with acute MI. In addition, a beta blocker is used to decrease workload of the heart and preserve cardiac muscle. The use of these medications in the case of a patient with cardiogenic shock can be complicated since beta blockers will decrease BP. See Chapter 14 for acute treatment of chest pain and MI.

Nursing Alert
During an acute MI, aspirin may be ordered to prevent worsening thrombosis in the coronary arteries. When administering aspirin in this acute situation, the nurse should ask the patient to chew aspirin (162 to 325 mg) rather than swallow a whole enteric-coated aspirin. Chewing aspirin allows for a more rapid absorption rate than does swallowing it whole (Anderson, 2016; Feldman & Cryer, 1999).

Vasoactive Medications

Vasoactive medication therapy consists of multiple pharmacologic strategies to restore and maintain adequate CO. In cardiogenic shock, the aims of vasoactive medication therapy are to improve cardiac contractility, optimize preload and afterload, reduce myocardial oxygen demand, and stabilize heart rate and rhythm. Medications commonly used to treat cardiogenic shock include dobutamine, dopamine, and nitroglycerin. See Table 55-9 for a review of common vasoactive medications.

Nursing Alert
The nurse is vigilant in observing the patient's response to vasoactive agents because of the potential of worsening myocardial ischemia by increasing cardiac work.

Dopamine is a sympathomimetic agent. It acts as an inotrope and a vasopressor (at higher doses). It may be used with dobutamine and nitroglycerin to improve tissue perfusion. Sympathomimetic agents must be used with caution in patients with cardiogenic shock since they increase myocardial oxygen demand and can worsen failure. Also, in patients with severe metabolic acidosis, which occurs in the later stages of shock, the effectiveness of dopamine is diminished. Norepinephrine also may be considered as a first-line agent for hypotension in patients with cardiogenic shock; it is a vasoactive agent that

acts primarily as a vasoconstrictor, has a mild inotropic effect, and increases coronary flow while having less of an effect on heart rate in patients with tachycardia (Hollenberg, 2016).

If tissue perfusion remains inadequate, inotropic therapy may be considered with dobutamine, which predominantly affects beta-1 adrenergic receptors (increases the strength of myocardial activity and improves CO). Dobutamine enhances the strength of cardiac contraction, improving stroke volume ejection and overall CO. Because it also has some beta-2 properties, vasodilation occurs (decreased afterload), and the bronchioles relax. The nurse is aware that dobutamine may exacerbate hypotension is some patients (related to vasodilatory effects) and can precipitate tachyarrhythmias (Hollenberg, 2016).

IV nitroglycerin in low doses acts as a venous vasodilator and, therefore, reduces preload. At higher doses, nitroglycerin causes arterial vasodilation and reduces afterload as well. These actions, in combination with dobutamine, increase CO while minimizing cardiac workload. In addition, vasodilation enhances blood flow to the myocardium, improving oxygen delivery to the weakened heart muscle. A combination of medications may be prescribed, depending on the patient's response to treatment. All vasoactive medications have adverse effects, making specific medications more useful than others at different stages of shock.

Nursing Alert

Vasoactive medications should never be stopped abruptly because this could cause severe hemodynamic instability, perpetuating the shock state.

Diuretics

Diuretics such as furosemide (Lasix) may be administered to reduce the workload of the heart by reducing fluid accumulation. Diuretics must be used cautiously since they can lead to hypovolemia. In addition, aggressive diuresis can lead to metabolic alkalosis, often referred to as a *contraction alkalosis.* The use of diuretics can also lead to electrolyte abnormalities, the most common of which is hypokalemia.

Antiarrhythmic Medications

Multiple factors, such as hypoxemia, electrolyte imbalances, and acid–base imbalances, contribute to serious cardiac arrhythmias in all patients with shock. In addition, as a compensatory response to decreased CO and BP, the heart rate increases beyond normal limits. This impedes CO further by shortening diastole and thereby decreasing the time for ventricular filling. Consequently, antiarrhythmic medications are required to stabilize the heart rate. For a full discussion of cardiac arrhythmias, as well as commonly prescribed medications, see Chapter 17.

Fluid Status

Appropriate fluid administration is also necessary in the treatment of cardiogenic shock. Administration of fluids must be monitored closely to detect signs of fluid overload. Incremental IV fluid boluses are cautiously administered to determine optimal filling pressures for improving CO. Nurses should use caution when administering fluids rapidly because rapid fluid administration in patients with cardiac failure may result in acute pulmonary edema. Fluid overload and pulmonary edema are risks because of ineffective

cardiac function and accumulation of fluid in the pulmonary tissues.

Mechanical Assistive Devices

If CO does not improve despite supplemental oxygen, vasoactive medications, and fluid boluses, mechanical assistive devices can sometimes be used temporarily to improve the heart's ability to pump. Intra-aortic balloon counterpulsation or left and right ventricular assist devices and total temporary artificial hearts are means of providing temporary circulatory assistance and are reviewed in Chapters 16 and 55.

Nursing Management

Preventing Cardiogenic Shock

In many circumstances, identifying at-risk patients early, promoting adequate perfusion of the heart muscle, and decreasing cardiac workload can prevent cardiogenic shock. Risk factors include advanced age, anterior MI or previous MI, diabetes, hypertension, multivessel CAD, and peripheral vascular and cerebrovascular diseases (Hollenberg, 2016). Patients who have decreased ejection fractions, larger infarctions, and echo results that demonstrate a lack of hyperkinesis in the myocardial remote from the infarction should be considered at risk for cardiogenic shock (Hollenberg, 2016). Minimizing patient risk can be accomplished by conserving the patient's energy, promptly relieving angina, and administering supplemental oxygen, aspirin, and beta blockers. When cardiogenic shock is present, nursing management includes working with other members of the health care team to prevent shock from progressing and to restore adequate cardiac function and tissue perfusion.

Monitoring Hemodynamic Status

A major role of the nurse is monitoring the patient's hemodynamic and cardiac status. Arterial lines and ECG monitoring equipment must be well maintained and functioning properly. The nurse anticipates the medications, IV fluids, and equipment that might be used and is ready to assist in implementing these measures. Changes in hemodynamic, cardiac, pulmonary, and renal status and laboratory values are documented and reported promptly. In addition, adventitious breath sounds, changes in cardiac rhythm, and other abnormal physical assessment findings are reported immediately.

Administering Medications

The nurse documents and records medications and treatments that are administered, as well as the patient's response to treatment.

The nurse must be knowledgeable about the desired effects, as well as the side effects, of medications. For example, it is important to monitor the patient for decreased BP after administering morphine or nitroglycerin. Patients receiving thrombolytic therapy must be monitored for bleeding. Arterial and venous puncture sites must be observed for bleeding, and pressure must be applied at the sites if bleeding occurs. Neurologic assessment is essential after the administration of thrombolytic therapy to assess for the potential complication of cerebral hemorrhage associated with the therapy. IV infusions must be observed closely because tissue necrosis and sloughing may occur if vasopressor medications infiltrate the tissues. Urine output, blood urea nitrogen (BUN), and serum creatinine levels are monitored to detect decreased kidney function secondary to the effects of cardiogenic shock or its treatment.

Enhancing Safety and Comfort

Throughout care, the nurse must take an active role in safeguarding the patient, enhancing comfort, and reducing anxiety. This includes administering medication to relieve chest

pain, preventing infection at the multiple arterial and venous line insertion sites, protecting the skin, and monitoring respiratory and kidney function. Proper positioning of the patient promotes effective breathing without decreasing BP and may also increase patient comfort while reducing anxiety.

Brief explanations about procedures that are being performed and the use of comforting touch often provide reassurance to the patient and family. The family is usually anxious and benefits from opportunities to see and talk to the patient. Explanations of treatments and the patient's responses are often comforting to family members.

DISTRIBUTIVE SHOCK

Distributive shock, also sometimes called circulatory shock, occurs when the body's ability to adjust vascular tone is impaired, and thus blood volume is abnormally displaced in the vasculature (e.g., when blood volume pools in peripheral blood vessels). The displacement of blood volume causes a relative hypovolemia because not enough blood returns to the heart, which leads to subsequent inadequate tissue perfusion. The vascular tone is determined both by central regulatory mechanisms, as in BP regulation, and by local regulatory mechanisms, as in tissue demands for oxygen and nutrients. Therefore, distributive shock can be caused either by a loss of sympathetic tone or by release of biochemical mediators from cells.

The varied mechanisms leading to the initial vasodilation in distributive shock further subdivide this classification of shock into three types: (1) septic shock, (2) neurogenic shock, and (3) anaphylactic shock. Other causes of distributive shock are rare but include toxic shock syndrome, drug overdose, neurogenic insults, addisonian crisis, and myxedema coma (Rivers, 2016). In all types of distributive shock, massive arterial and venous dilation allows blood to pool peripherally. The different types of shock cause variations in the pathophysiologic chain of events. Risk factors for distributive shock are summarized in Box 54-4.

BOX 54-4 Risk Factors for Distributive Shock

Septic shock:

- Immunosuppression
- Extremes of age (under 1 year of age and over 65 years of age)
- Malnourishment
- Chronic illness
- Invasive procedures

Neurogenic shock:

- Spinal cord injury
- Spinal anesthesia
- Depressant action of medications
- Glucose deficiency

Anaphylactic shock:

- Penicillin sensitivity
- Transfusion reaction
- Bee sting allergy
- Latex sensitivity
- Severe allergy to some foods or medications

SEPTIC SHOCK

Septic shock, the most common type of distributive shock, is caused by widespread, overwhelming infection in combination with a dysregulated host immune response. Because of the increased sophistication of antibiotic therapy and improved recognition of sepsis and initiation of intensive care management, the incidence of septic shock has declined. Approximately 750,000 cases of severe sepsis or septic shock occur annually in the United States, with mortality rates of about 25 to 35%, which is down from rates of 70% in 2010 (Russell, 2016). Finding and aggressively treating the source of infection, as well as providing aggressive cardiopulmonary support, are important determinants of the clinical outcome.

Risk Factors

Nosocomial infections (infections occurring in the hospital) in patients who are critically ill that may progress to septic shock commonly originate in the lungs (pneumonia) and urinary (pyelonephritis) and GI tract (peritonitis, intra-abdominal abscess, cholangitis), although they can originate anywhere in the body (refer to Table 54-3 for common sites related to sepsis). Organisms include gram-positive or negative bacteria, fungi, and, rarely, protozoa or rickettsiae are associated with septic shock; commonly gram-positive bacteria, especially methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococci (VRE), penicillin-resistant *Streptococcus pneumoniae*, and resistant gram-negative bacilli are seen (Russell, 2016). Additional risk factors are age, immunocompromise due to malnutrition, alcoholism, malignancy, diabetes mellitus, and AIDS; invasive procedures and indwelling medical devices; and the increased number of resistant microorganisms. Elderly patients continue to be at particular risk for sepsis because of decreased physiologic reserves and an aging immune system. The incidence of septic shock can be reduced by carrying out infection control practices, including the use of meticulous aseptic technique, properly cleaning and maintaining equipment, and using thorough hand hygiene techniques.

Pathophysiology

When microorganisms invade body tissues, patients exhibit an immune response. This immune response provokes the activation of biochemical cytokines and mediators associated with an inflammatory response and produces a complex cascade of physiologic events that leads to poor tissue perfusion. Widespread endothelial injury leads to increased capillary permeability, which triggers seepage of protein-rich fluid from the capillaries, and vasodilation, which occurs when injured endothelial cells release nitric acid (a potent vasodilator). These two effects interrupt the ability of the body to provide adequate perfusion, oxygen, and nutrients to the tissues and cells. In addition, proinflammatory and anti-inflammatory cytokines released during the inflammatory response activate the coagulation system, which begins to form clots in areas where a clot may or may not be needed, further compromising tissue perfusion. The imbalance of the inflammatory response and the clotting and fibrinolysis cascades are considered critical elements of the devastating physiologic progression that is present in patients with severe sepsis. To illustrate, the increased permeability within the lung is a key component of acute lung injury (ALI), whereas increased permeability in the intestine can lead to translocation of intestinal bacteria.

Clinical Manifestations and Assessment

Sepsis is defined by presence of at least two of the four signs of the systemic inflammatory response syndrome: (1) fever (above 38°C) or hypothermia (below 36°C); (2) tachycardia (more than 90 beats/min); (3) tachypnea (more than 20 breaths/min), hypocapnia (partial pressure of carbon dioxide less than 32 mm Hg), or the need for mechanical ventilatory assistance; and (4) leukocytosis (more than 12,000 cells/μL), leukopenia (fewer than 4,000 cells/μL), or a left shift (more than 0% immature band cells) in the circulating white blood cell differential and suspected or proven infection plus a documented or suspected infection (Russell, 2016, p. 685).

Systemic inflammatory response syndrome (SIRS) presents clinically like sepsis. The only difference between SIRS and sepsis is that an identifiable causative infectious agent is established in the latter. SIRS/sepsis results in an inflammatory and immunologic response that is overwhelming, thought to be caused in large part by an array of inflammatory cytokines, including but not confined to tumor necrosis factor (TNF). The inflammatory response also leads to increased coagulation, and coagulation triggers inflammation; a positive feedback loop is at play that has the potential to disrupt essential kidney, cardiovascular, and respiratory function (Russell, 2016). Any overwhelming insult can stimulate SIRS and may progress to sepsis; noninfectious disorders include pancreatitis and drug intoxication. Therefore, despite an absence of infection, antibiotic agents still may be administered because of the possibility of unrecognized infection. Additional therapies directed to support patients with SIRS are similar to those for sepsis. If the inflammatory process progresses, septic shock may develop.

TABLE 54-3 Common Sites and Diseases Associated with Sepsis/Systemic Inflammatory Response Syndrome (SIRS)

Organ System	Location	Disease
Respiratory	Upper respiratory tract	Sinusitis Mastoiditis
	Lower respiratory tract	Pneumonia Lung abscess Empyema
Gastrointestinal	Mediastinum Hepatobiliary Intra-abdominal	Esophageal rupture/perforation Hepatic abscess Cholangitis Cholecystitis Intestinal infarction/perforation Pancreatitis Intra-abdominal/diverticular abscess
Cardiovascular	Mediastinum Native or prosthetic cardiac valve	Postoperative mediastinitis Endocarditis
Genitourinary	Kidney, ureter, and bladder	Perinephric abscess Pyelonephritis Cystitis
Neurologic	Brain and meninges	Meningitis Intracranial abscess
Dermatologic	Traumatic wound, surgical wound, or burn site	Soft tissue abscess Necrotizing fasciitis Infected decubitus ulcer Full and partial thickness burn
Prosthetic	Central/peripheral venous catheter Arterial catheter Ventriculoperitoneal shunt Dialysis catheter Articular prosthetic device Dialysis graft/shunt	Catheter infection Infected prosthesis
Other	Vascular system	Septic thrombophlebitis

Reprinted with permission from Stenbit, A., & Serio, A. (2010). Sepsis. In R. Irwin & J. Rippe (Eds.), *Manual of intensive care management (Chapter 123)*. Philadelphia, PA: Lippincott Williams & Wilkins.

Sepsis is an evolving process, without a predictable linear progression. In the past, septic shock has been described as having two phases, a hyperdynamic (warm) and a hypodynamic (cold) phase. Although the division into phases may promote understanding of sepsis, its actual progression into severe sepsis and septic shock is not always easy to recognize clinically. Initially, a hyperdynamic response occurs; it is characterized by a high CO with systemic vasodilation. The BP may remain within normal limits, or the patient may be hypotensive but responsive to fluids. The heart rate increases, progressing to tachycardia. Fever, with warm, flushed skin and bounding pulses, is evident. The respiratory rate is elevated. Urinary output may remain at normal levels or decrease. GI status may be compromised, as evidenced by nausea, vomiting, diarrhea, or decreased bowel sounds. Signs of hypermetabolism include increased serum glucose and insulin resistance. Subtle changes in mental status, such as confusion or agitation, may be present.

As the sepsis progresses, tissues become more underperfused and acidotic, compensation begins to fail, and the patient becomes more hypodynamic. The cardiovascular system also begins to fail, the BP does not respond to vasoactive agents and fluid resuscitation, and signs of end-organ damage are visible (e.g., kidney failure, pulmonary failure, hepatic failure). As sepsis progresses to septic shock, the BP drops, and the skin becomes cool and pale. Temperature may be normal or below normal. Heart and respiratory rates remain rapid. Urine output decreases, and multiple organ dysfunction syndrome (MODS) develops (discussed on page 1528).

BOX 54-5 Definitions in Sepsis

Bacteremia: The presence of bacteria in the blood

Infection: The presence of microorganisms that trigger an inflammatory response

Systemic inflammatory response syndrome (SIRS): A syndrome resulting from a *severe clinical insult* that initiates an overwhelming inflammatory response by the body; defined as two or more of the following conditions:

- Temperature greater than 38.5°C or less than 35.0°C
- Heart rate of more than 90 bpm
- Respiratory rate of more than 20 breaths/min or $PaCO_2$ of less than 32 mm Hg
- White blood cell count of more than 12,000 cells/mL, less than 4,000 cells/mL, or greater than 10% immature (band) forms

Sepsis: A systemic response to *infection;* may occur after a burn, surgery, or serious illness and is defined as the presence of SIRS, plus the presence of an infectious source (either by documented culture or by visualizing focal infection)

Severe sepsis: Defined as sepsis, plus at least one of the following signs of organ hypoperfusion:

- Areas of mottled skin
- Capillary refill of more than 3 seconds
- Decreased urinary output (less than 0.5 mg/kg for 1 hour) (oliguria)
- Lactate greater than 2 mmol/L (lactic acidosis)
- Abrupt change in mental status (decreased Glasgow Coma Scale)
- Platelet count of less than 100,000 or disseminated intravascular coagulation (DIC) (thrombocytopenia)
- Acute lung injury or acute respiratory distress syndrome (ARDS) (hypoxemia)
- Cardiac dysfunction

Septic shock: Shock associated with sepsis; defined as severe sepsis, plus one of the following:

- Mean arterial pressure (MAP) of less than 60 after fluid resuscitation; systolic blood pressure less than 90 mm Hg or a decrease from baseline that is greater than 40 mm Hg, despite adequate fluid resuscitation.
- Need for vasoactive medication in order to maintain MAP of greater than 60.

Adapted from Annane, D., & Cavaillon, J. M. (2005). Septic shock. Lancet, *365*(9453), 63–78; Sommers, M. S. (2003). The cellular basis of septic shock. Critical Care Nursing Clinics of North America, *15*(1), 13–26.

In an effort to promote recognition and earlier treatment of patients with sepsis, the Society of Critical Care Medicine defined a common set of terms and cues for clinicians (Box 54-5).

Medical Management

Current treatment of septic shock involves *identification and elimination of the cause of infection and aggressive cardiopulmonary support* to prevent or limit end-organ damage and death. Specimens of blood, sputum, urine, and wound drainage are collected for culture using aseptic technique. Any potential routes of infection must be eliminated. IV lines may need to be removed and reinserted at other body sites; the patient will require scrupulous sterile techniques for the insertion of catheters, with consideration of the use of antibiotic-impregnated catheters (Russell, 2016). If possible, urinary catheters are removed or replaced. Any abscesses are drained, and necrotic areas are surgically débrided.

Fluid replacement must be instituted to correct the hypovolemia that results from the incompetent vasculature and the inflammatory response. Crystalloids, colloids, and blood products may be administered to increase intravascular volume. IV fluids boluses (in the range of 20 to 40 mL/kg) may be ordered to improve intravascular volume (Rivers, 2016).The CVP, MAP, urinary output, and SvO_2 are used to guide therapy.

Oxygen is administered and guided by the pulse oximeter, SvO_2, and clinical presentation. Many patients will require mechanical ventilation, with a lower tidal volume (typically greater than 6 mL/kg of ideal body weight [IBW]), which has been associated with decreased mortality from ALI and acute respiratory distress syndrome (ARDS). ARDS and ALI are discussed in Chapter 10.

Preventing the progress from sepsis to septic shock necessitates early diagnosis and aggressive resuscitation. The patient's responses to treatment are closely monitored, and resuscitation is continued until CVP is greater than 8, MAP is greater than 65 mm Hg, urine output is 0.5 mL/kg/hr or more, and SvO_2 is greater than 70%. This approach is associated with a decreased mortality and should be considered standard of care in the management of septic shock.

Pharmacologic Therapy

Antibiotics

Before antibiotic therapy is initiated, it is important that all cultures be obtained. However, if obtaining cultures is delayed, the nurse is aware that antimicrobials should be administered within 1 hour of identification of septic shock. The nurse anticipates the need for blood, sputum, urine, and wound cultures, and, depending on the site of the expected infection, additional cultures may be obtained from the cerebrospinal fluid (in the case of suspected meningitis) or pleural space (if empyema is suspected). If the infecting organism is unknown, empiric broad-spectrum antibiotics are started. When culture and sensitivity reports become available, the antibiotic agents can be changed to those that are more specific to the infecting organism and less toxic to the patient.

Nursing Alert

It is important for the nurse to consider all possible sources of the infection. Symptoms such as cough, sputum production, adventitious lung sounds and increased work of breathing suggests pneumonia; pleuritic chest pain, decreased fremitus, and a dull,

flat sound on percussion suggests empyema; dysuria and costovertebral angle tenderness suggests pyelonephritis; erythema and drainage and warmth from IV lines suggests line sepsis; whereas headache and stiff neck suggest meningitis.

Vasopressors

Therapy with vasopressors (e.g., norepinephrine, epinephrine) is expected if a mean arterial blood pressure of greater than 65 mm Hg is not achieved by IV hydration alone. The nurse monitors the MAP, the CVP, O_2 saturation, and SvO_2, as well as the hourly urine output (aim is greater than 0.5 mL/kg/hr) to assess evidence of improving perfusion (improved mental status, peripheral perfusion).

Glucocorticoids

Glucocorticoids have been used in the treatment of septic shock with varying effect for decades. The general concept is that, since septic shock represents a significant physiologic stress, dysfunction of the hypothalamic–pituitary–adrenal axis may be one factor that leads to increased mortality. Several studies have attempted to investigate the effect of administering steroids to septic patients. Drawbacks to steroid administration include increased infection rate and increased risk of superinfections, worsening glycemic control, and impaired wound healing. High-dose corticosteroids do not improve outcomes in the full spectrum of patients with sepsis or ARDS, and the evidence supporting the use of low-dose corticosteroids in septic shock remains controversial (Russell, 2016, p. 690). If the patient has not responded to vasopressor support, corticosteroids may be considered.

Nutritional Therapy and Glycemic Control

Aggressive nutritional supplementation is critical in the management of patients with septic shock because malnutrition further impairs the patient's compensatory mechanisms. Nutritional supplementation should be initiated as soon as possible. Enteral feeding, rather than parental nutrition, is associated with improved outcomes, although reasons for this remain unclear. Evidence is particularly strong for enteral nutrition in surgical patients who are critically ill. Regarding glycemic control, intense insulin therapy increases the risk of higher rates of hypoglycemia and perhaps increased mortality and, therefore, is not recommended (Russell, 2016). However, the nurse assesses and alerts the team when the patient's blood glucose level is outside the range of 140 to 180 mg/dL.

Nursing Management

Nurses caring for patients in any setting must keep in mind the risks of sepsis and the high mortality rate associated with sepsis, severe sepsis, and septic shock. All invasive procedures must be carried out with aseptic technique after careful hand hygiene. In addition, IV lines, arterial and venous puncture sites, surgical incisions, traumatic wounds, urinary catheters, and pressure ulcers must be monitored for signs of infection in all patients. Nurses should identify patients who are at particular risk for sepsis and septic shock (i.e., elderly and immunosuppressed patients and those with extensive trauma, burns, or diabetes), keeping in mind that these high-risk patients may not develop typical or classic signs of infection and sepsis. For example, confusion may be the first sign of infection and sepsis in elderly patients.

Monitoring and constant reassessment are primary nursing tasks when caring for a patient with septic shock. Vital signs, hemodynamics (CVP, SvO_2, SVR, CO), urinary output, mental status, and physical assessment findings must be reported accurately and in a timely fashion so that interventions can be instituted. When caring for a patient with septic shock, the nurse collaborates with other members of the health care team to identify the site and source of sepsis and the specific organisms involved. Appropriate specimens for culture and sensitivity are often obtained by the nurse.

Elevated body temperature (hyperthermia) is common in patients with sepsis and raises the patient's metabolic rate and oxygen consumption. Fever is one of the body's natural mechanisms for fighting infections. Therefore, elevated temperatures may not be treated unless they reach dangerous levels (greater than 40°C [104°F]) or unless the patient is uncomfortable. Efforts may be made to reduce the temperature by administering acetaminophen or applying a hypothermia blanket. During these therapies, the nurse monitors the patient closely for shivering, which increases oxygen consumption. Efforts to increase comfort are important if the patient experiences fever, chills, or shivering.

The nurse administers prescribed IV fluids and medications, including antibiotic agents and vasoactive medications, to restore vascular volume. Because of decreased perfusion to the kidneys and liver, serum concentrations of antibiotic agents that are normally cleared by these organs may increase and produce toxic effects. Therefore, the nurse monitors blood levels (antibiotic agent, peak and trough levels of antibiotics (if available), BUN, creatinine, white blood cell count, hemoglobin, hematocrit, platelet levels, coagulation studies) and reports changes to the provider. Daily weights and close monitoring of serum prealbumin levels help determine the patient's protein requirements. Additionally, the nurse expects that deep vein thrombosis (DVT) and stress ulcer prophylaxis will be instituted.

NEUROGENIC SHOCK

Pathophysiology

In neurogenic shock, vasodilation occurs as a result of a loss of balance between parasympathetic and sympathetic stimulation. Sympathetic stimulation causes vascular smooth muscle to constrict, and parasympathetic stimulation causes the vascular smooth muscle to relax or dilate. The patient experiences a predominant parasympathetic

stimulation that causes vasodilation lasting for an extended period because of acute interruption of sympathetic function. It is important to understand that the blood volume is adequate, but because the vasculature is dilated, the blood volume is displaced, producing a hypotensive (low BP) state (see Box 54-1, p. 1509). Thus, this is a situation where blood volume is stable, but the drastic dilatation of the vasculature causes a relative hypovolemia. The overriding parasympathetic stimulation that occurs with neurogenic shock causes a severe decrease in the patient's SVR and sometimes bradycardia. Inadequate BP results in the insufficient perfusion of tissues and cells that is common to all shock states.

Nursing Alert

The nurse understands that the preganglionic axons of the SNS have origins in the thoracolumbar region of the spinal cord. Thus, patients with spinal cord injuries in the cervical or upper thoracic spinal cord are at risk for neurogenic shock. Without the tonic sympathetic input to the systemic vasculature, the vagal response of bradycardia and decreased SVR are unopposed and culminate in hypotension. Prompt recognition and treatment is essential to avoid potential organ damage.

Neurogenic shock can be caused by spinal cord injury (commonly above the level of T6), spinal anesthesia, or nervous system damage. It may also result from the depressant action of medications or from lack of glucose (e.g., insulin reaction or shock). Neurogenic shock may have a prolonged course (spinal cord injury) or a short one (syncope or fainting). Normally, during states of stress, the sympathetic stimulation causes the BP and heart rate to increase. In neurogenic shock, the sympathetic system is not able to respond to body stressors.

Clinical Manifestations and Assessment

The clinical characteristics of neurogenic shock are signs of parasympathetic stimulation. It is characterized by dry, warm skin rather than the cool, moist skin seen in hypovolemic shock. Another characteristic is hypotension with bradycardia, rather than the tachycardia that characterizes other forms of shock.

Medical Management

Treatment of neurogenic shock involves IV fluid or plasma expanders, vasopressors, and restoring sympathetic tone, either through the stabilization of a spinal cord injury or, in the instance of spinal anesthesia, by positioning the patient properly. Specific treatment depends on cause of the shock. Further discussion of management of patients with a spinal cord injury is presented in Chapter 45. If hypoglycemia (insulin shock) is the cause, glucose is rapidly administered. Hypoglycemia and the insulin reaction are described further in Chapter 30. Current guidelines recommend maintaining an MAP of 85 to 90 mm Hg for 1 week post injury to promote spinal cord perfusion (Hickey, 2014, p. 400).

Nursing Management

In suspected spinal cord injury, neurogenic shock may be prevented by carefully immobilizing the patient to prevent further damage to the spinal cord. The nurse is aware that orthostatic hypotension caused by loss of vasomotor tone below the level of the spinal cord lesion can occur with position changes. Even slightly raising the head of the bed for a new tetraplegic patient can result in a drastic hypotension (Hickey, 2014).

Nursing interventions are directed toward supporting cardiovascular and neurologic function until the usually transient episode of neurogenic shock resolves. Apply sequential compression devices since pooled blood increases the risk for thrombus formation. The nurse must check the patient daily for any lower extremity pain, redness, tenderness, unilateral edema, and warmth of the calves. If the patient complains of pain, and objective assessment of the calf is suspicious, the patient should be evaluated for DVT. Administration of heparin or low–molecular-weight heparin (Lovenox) may prevent thrombus formation. Passive range of motion of the immobile extremities also helps promote circulation.

A patient who has experienced a spinal cord injury may not report pain caused by internal injuries. Therefore, in the immediate postinjury period, the nurse must monitor the patient closely for signs of internal bleeding that could lead to hypovolemic shock. In hemorrhagic shock, the nurse is aware that tachycardia will be present versus bradycardia with neurogenic shock.

ANAPHYLACTIC SHOCK

Anaphylactic shock occurs rapidly and is life-threatening. Annual mortality rates of 1,500 to 2,000 deaths in the United States per year are attributed to systemic anaphylaxis (Schwartz, 2016). Medications (e.g., antibiotics, NSAIDs, contrast media, and blood products) are triggers in 55% of cases, while food (26%) and insect bites (19%) are other frequent causes; combined they are the most common causes of anaphylaxis (Brown & Turner, 2017; Ferri, 2016). Approximately 6% of children and 3% to 4% of adults have food allergy (Brown & Turner, 2017).

Because anaphylactic shock occurs in patients already exposed to an antigen and who have developed antibodies to it, it can sometimes be prevented. Patients with known allergies should understand the consequences of subsequent exposure to the antigen and should wear medical identification that lists their sensitivities. This could prevent inadvertent administration of a medication that would lead to anaphylactic shock. In addition, patients and families need instruction about emergency use of medications for treatment of anaphylaxis.

Nursing Alert

Latex allergies are a risk for health care workers and patients who have multiple mucosal exposures to latex. Nurses should use nonlatex gloves when possible, and patients at risk (patients with spina bifida, spinal cord injuries, and congenital abnormalities of the genitourinary tract) should be catheterized when needed with nonlatex

equipment.

Pathophysiology

Anaphylactic shock is caused by a severe allergic reaction when patients who have already produced antibodies to a foreign substance (antigen) develop a systemic antigen–antibody reaction. This reaction provokes mast cells and basophils to release potent vasoactive substances, such as histamine or bradykinin, causing widespread vasodilation, capillary permeability, and potentially catastrophic vascular collapse. Mast cells in any organ system may be involved, depending on the distribution of the instigating stimulus; in general the principal targets include the cardiovascular, cutaneous, respiratory, and GI systems (where mast cells are most abundant) (Schwartz, 2016, p. 1698). An equally important feature of anaphylactic shock is the onset of severe bronchospasm, which causes airway compromise (stridor, wheezing, shortness of breath) and urticaria. A delayed recurrence of the reaction, without re-exposure to the allergen, can sometimes occur. This has been termed a *biphasic reaction* and most commonly occurs 8 to 10 hours after the first symptoms; therefore, patients with severe reactions are generally observed for at least 10 hours.

Clinical Manifestations and Assessment

The clinical manifestations are related to the potent vasoactive and smooth muscle contractile actions due to mast cell release of vasoactive substances. For example, the vasodilatation results in erythema, decreased venous return to the heart, and subsequent hypotension; activation of multiple inflammatory pathways causes fluid extravasation, seen as angioedema, tissue edema, and hypovolemia; whereas the smooth muscle contraction is associated with bronchospasm and abdominal and pelvic cramps. Thus the nurse observes for generalized hives, pruritus or flushing, angioedema, swelling of the tongue and/or uvula, dyspnea, wheezing, stridor, hypoxemia, and reduced blood pressure. GI symptoms, including nausea, vomiting, abdominal cramps, and diarrhea, may precede the more generalized clinical manifestations described previously after ingestion of an antigen (Haupt & Grandhi, 2017, p. 437). Serum mast cell tryptase (MCT) is the only widely available assay used to confirm the diagnosis of anaphylaxis (Brown & Turner, 2017, p. 354).

Medical Management

Treatment of anaphylactic shock requires removing the causative antigen (e.g., discontinuing an antibiotic agent) and administering medications that restore vascular tone. In addition, the health care team will need to provide emergency airway support, position the patient in supine (see Alert below), administer oxygen, provide ventilation support (endotracheal intubation or tracheotomy may be necessary to establish an airway), perform external chest compressions if cardiac arrest occurs, and prepare for early administration of epinephrine. Epinephrine is usually given intramuscularly in the thigh in a dose of 0.01 mg/kg with a usual dose of 0.2 to 0.5 mg for adults (maximum dose of 0.6 mg), which can be repeated every 5 to 30 minutes if the response is inadequate. Epinephrine is given for its vasoconstrictive action as well its effect of reducing bronchospasm (Brown & Turner, 2017). When epinephrine is given early (before the onset of shock), systemic absorption of IM epinephrine is rapid, with a response seen in minutes. IV epinephrine carries more risks, and incorrect dosing has been associated with serious adverse events (Brown & Turner, 2017). However, in patients with severe anaphylaxis, the nurse considers that decreased perfusion to the muscle may result in slow absorption of epinephrine into the circulation; therefore, IV epinephrine may be necessary. Diphenhydramine (Benadryl), given intramuscularly or intravenously, may be administered to reverse the urticaria and pruritus but is not likely to reduce the hypotension of tissue edema (Schwartz, 2016). Nebulized medications, such as albuterol (Proventil), may also be given to reverse histamine-induced bronchospasm. Glucocorticoids may be considered to prevent a rebound, biphasic reaction, although it is unlikely to be beneficial acutely because of the slow onset of action (Ferri, 2016; Schwartz, 2016). IV lines are inserted to provide access for administering fluids and medications. Aggressive IV fluid resuscitation is expected with hypotension. The patient's cardiac status is monitored, and the electrocardiogram is assessed because anaphylaxis and treatments can be associated with arrhythmias and cardiac ischemia. Pulse oximetry is also expected to monitor oxygenation status and response to treatment. Anaphylaxis and specific chemical mediators are discussed further in Chapter 38.

Nursing Alert

It is important to note that Fowler's (upright) or semi-Fowler's (semi recumbent) position has been associated with fatal anaphylaxis. Changing the patient's position to one that is upright reduces venous return to the heart and is proposed to exacerbate the pathophysiologic processes occurring in anaphylaxis; therefore, keeping a patient flat is suggested to improve venous return to the heart, a key aspect of the initial response to anaphylaxis (Brown & Turner, 2017).

Nursing Alert

Nurses understand that epinephrine is typically supplied as 1 mg/mL (1:1,000 dilution). Most authorities recommend that 0.3 to 0.5 mg of the 1:1,000 solution (0.3 to 0.5 mL) be given intramuscularly in the anterolateral aspect of the thigh.

Nursing Management

The nurse plays an important role in preventing anaphylactic shock. The nurse must assess all patients for allergies or previous reactions to antigens (e.g., medications, blood products, foods, contrast agents, latex) and communicate the existence of these allergies or reactions to others. In addition, the nurse assesses the patient's understanding of previous reactions and the steps taken by the patient and family to prevent further exposure to antigens. When new allergies are identified, the nurse advises the patient to wear or carry identification that names the specific allergen or antigen.

When administering any new medication, the nurse observes all patients for allergic reactions. This is especially important with IV medications. Allergy to penicillin is one of the most common causes of anaphylactic shock. Patients who have a penicillin allergy may also develop an allergy to similar medications. For example, they may react to cefazolin sodium (Ancef) because it has a similar antimicrobial action of attaching to the penicillin-binding proteins found on the walls of infectious organisms. Previous adverse drug reactions increase the risk that the patient will develop an undesirable reaction to a new medication. If the patient reports an allergy to a medication, the nurse must be aware of the risks involved in the administration of similar medications.

In the hospital and outpatient diagnostic testing sites, the nurse must identify patients who are at risk for anaphylactic reactions to the contrast agents (radiopaque, dye-like substances that may contain iodine) that are used for diagnostic tests. These include patients with a known allergy to iodine or fish and those who have had previous allergic reactions to contrast agents. This information must be conveyed to the staff at the diagnostic testing site, including radiology staff. The nurse anticipates that "pre-medication" regimens are likely to be administered in patients with known contrast allergies.

Nursing Alert

Pre-medication with steroids and Benadryl may be recommended for patients who have had a previous reaction to contrast agent (gadolinium-based contrast or iodinated contrast) and a similar contrast will be administered (ACR, 2016).

The nurse must be knowledgeable about the clinical signs of anaphylaxis, must take immediate action if signs and symptoms occur, and must be prepared to begin cardiopulmonary resuscitation if cardiopulmonary arrest occurs. In addition to monitoring the patient's response to treatment, the nurse assists with intubation if needed, monitors the hemodynamic status, ensures IV access for administration of medications, administers prescribed medications and fluids, and documents treatments and their effects.

Nursing Alert

If IV epinephrine is required, the nurse carefully titrates the medication to prevent a hypertensive surge. Symptoms of tachycardia, pallor, diaphoresis, and arrhythmias in a patient with normal or raised blood pressure are indicative of epinephrine toxicity. The provider should be notified and the infusion rate reduced (Brown & Turner, 2017).

Additionally, the nurse observes carefully the effect of epinephrine in patients with cerebrovascular or coronary artery disease, hypertension, diabetes, hyperthyroidism, cardiomyopathy, or narrow-angle glaucoma, in whom adverse events, such as MI, stroke, or pulmonary edema, can be precipitated (Schwartz, 2016, p. 1702).

Community health and home care nurses who administer medications, including antibiotic agents, in the patient's home or other settings, must be prepared to administer epinephrine subcutaneously or intramuscularly in the event of an anaphylactic reaction. Prescriptions for prefilled epinephrine syringe (EpiPen or EpiPen Jr.) should be given, and the patient and significant others are instructed on how to administer the EpiPen and that the patient needs to carry it on his or her person at all times. After recovery from anaphylaxis, the patient and family require an explanation of the event. Furthermore, the nurse provides instruction and counseling about avoiding future exposure to antigens and administering emergency medications to treat anaphylaxis.

OBSTRUCTIVE SHOCK

Obstructive shock is caused by a physical obstruction to blood flow, either in the heart or major blood vessels. This causes a decrease in CO and thus a decrease in tissue perfusion. Common causes of obstructive shock include cardiac tamponade, tension pneumothorax, and pulmonary embolism (PE). Obstructive shock is common in the setting of trauma.

Pathophysiology

In the case of tension pneumothorax or hemothorax, air or blood has entered the pleural space and caused a restriction in lung expansion. If enough air is trapped, then eventually pressure builds up and compresses the vessels and myocardium. This compression reduces preload (volume of blood) and increases afterload, in addition to restricting the expansion of the myocardium during filling. Clinical presentation may include JVD, crepitus (with pneumothorax), dyspnea, chest pain, tachycardia and tachypnea, tracheal shifting away from the tension pneumothorax, and decreased breath sounds on the affected side. Tension pneumothorax is common in trauma but can also develop spontaneously or as a complication from a procedure such as central line placement. Patients who are mechanically ventilated are at higher risk of developing a clinically significant pneumothorax due to increased ventilatory pressures.

Cardiac tamponade results from excessive blood or fluid inside the pericardium, the sac that surrounds the heart. This can result from a traumatic or infectious cause with a resultant restriction on the pumping ability of the heart. Signs and symptoms of cardiac tamponade include narrowing pulse pressure (difference between the systolic and diastolic pressure; normally 40 mm Hg), chest pain, distant or muffled heart sounds, JVD, hypotension, and tachycardia.

A PE is a clot that gets lodged in the pulmonary vasculature and causes ischemia to the capillary beds. If large enough, the embolism interferes significantly with pulmonary blood flow, which causes blood to back up into the right side of the heart. As the clot increases the pressure in the pulmonary artery, the right heart must beat faster and harder to overcome the pressure. Overall, CO is decreased as the patient goes into right-sided heart failure. Clots that have traveled from the lower extremities cause most PEs. Signs and symptoms of PE include pleuritic chest pain, shortness of breath, tachycardia, and hypoxia (refer to Chapter 10 for more details).

Medical Management

In the case of cardiac tamponade and tension pneumothorax, a procedure done by a qualified clinician should be performed immediately to relieve the obstruction. If the patient is experiencing obstructive shock, then these procedures are done emergently at the bedside. A chest radiograph is often used to diagnose a pneumothorax, although computed tomography (CT) scans and even ultrasound are more sensitive. A chest tube or needle decompression is the primary procedure to relieve tension pneumothorax. Cardiac tamponade is diagnosed similarly, with echocardiography being the most effective. Pericardiocentesis is the treatment for cardiac tamponade and involves inserting a needle into the pericardium to draw off fluid or blood.

The treatment of PE is usually aimed toward preventing clot expansion, although if the patient is experiencing obstructive shock, then other treatment, such as thrombolytic drugs or surgical embolectomy, may be considered. Depending on the severity of the PE, mechanical ventilation and hemodynamic support may be needed to stabilize the patient. PE is usually diagnosed using a CT angiogram, but other imaging and laboratory tests can be used as well.

Nursing Management

Because patients with tension pneumothorax and cardiac tamponade who are experiencing obstructive shock will need an emergent procedure, nurses should focus on facilitating that process. This includes collecting and setting up equipment, communicating effectively with staff, and helping gain consent from the patient and/or family. Careful monitoring of the patient prior to, during, and after the procedure is essential. If a chest tube is placed, then a chest drainage system (e.g., Pleuravac) will need to be set up and connected to suction as ordered. The chest tube setup needs to be monitored to ensure that it is functioning correctly and also to record output. A postprocedure chest radiograph will be ordered, and the results should be followed closely.

Nursing care of a patient with a PE that is causing obstructive shock involves monitoring and initiating ventilatory and hemodynamic support similar to what is done for patients with other types of shock. A primary function of the nurse in this situation is to facilitate diagnostic testing and imaging and then institute treatment in a timely manner. Patients with a PE large enough to cause obstructive shock have a very high mortality and often die within an hour of presentation.

Patients who experience obstructive shock are often quite suddenly acutely ill. This affects the entire health care team as decisions need to be made quickly, and the nurse should work hard to maintain a calm environment. Since obstructive shock usually has a sudden onset, families are quite often surprised when given news about massive PE or other causes of obstructive shock. Having other support personnel in place, such as a social worker or a chaplain, to provide support is advised.

MULTIPLE ORGAN DYSFUNCTION SYNDROME

MODS is altered organ function in patients who are acutely ill that requires medical intervention to support continued organ function. It is another phase in the progression of shock states. The actual incidence of MODS is difficult to determine because it develops with acute illnesses that compromise tissue perfusion. It is defined as severe organ dysfunction of two or more organ systems lasting at least 24 to 48 hours in the setting of sepsis, trauma, burns, or severe inflammatory conditions (Tiesi et al., 2016). It is important to note that the definition includes the number of dysfunctional organs and duration. Mortality rates when two organ systems are involved are 40%; and persistent dysfunction (more than 72 hours) present in three organ systems can result in a mortality risk of 80%.

Nursing Alert

Clinicians may use the SOFA scale to rapidly identify adult patients with organ dysfunction and risk for poor outcomes. The acronym stands for Sequential (Sepsis-related) Organ Failure Assessment (SOFA) and includes parameters such as the PaO_2/FiO_2 ratio (respiratory system), the platelet count (coagulation), bilirubin level (hepatic system), MAP (cardiovascular system), Glasgow Coma Scale (CNS system), and creatinine and urine output (renal system). A higher SOFA score is associated with an increased probability of

mortality (Singer et al., 2016).

Pathophysiology

The inflammation, tissue injury, and other sequelae associated with MODS are thought to be caused by an unregulated host response. MODS may result from any form of shock because of inadequate tissue perfusion. As previously described, in patients with shock, all organ systems suffer damage from a lack of adequate perfusion, which can result in organ failure.

Diagnosis	Systemic Blood Pressure	Heart Rate	Central Venous Pressure (CVP)	Pulmonary Artery Pressure	Cardiac Output (CO)	Systemic Vascular Resistance (SVR)
Cardiogenic: Myocardial Infarction (MI), Cardiac Tamponade, Pulmonary Emboli	↓	↑	↑	↑	↓	↑
Hypovolemic: Hemorrhage, Diarrhea, Burns, Dehydration	↓	↑	↓	↓	↓	↑
Septic: Severe Infection	↓	↑	↓	↓	↑↓	↓
Anaphylactic: Type 1 Hypersensitivity Reaction	↓	↑	↓	↓	↓	↓
Neurogenic: Brain Damage, Spinal Cord Injury	↓	↓	↓	↓	↓	↓

FIGURE 54-5 Types of shock. Shock results from (1) an inability of the heart to pump adequately (cardiogenic shock); (2) decreased effective blood volume as a consequence of severely reduced blood or plasma volume (hypovolemic shock); or (3) widespread vasodilation (septic; anaphylactic or neurogenic shock). Increased vascular permeability may complicate vasodilation by contributing to reduced effective blood volume. (Adapted from Lawrence, P., Bell, R., Dayton, M., & Hebert, J. (2012). *Essentials of general surgery* (5th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Clinical Manifestations and Assessment

Various causes of MODS have been identified, including dead or injured tissue, infection, and perfusion deficits. However, it is not possible as yet to predict which patients will develop MODS, partly because much of the organ damage occurs at the cellular level and, therefore, cannot be directly observed or measured. The most common types of organ dysfunction seen with MODS are acute kidney failure and ARDS. However, organ failure can affect the other body systems:

- Hepatic: jaundice, elevated liver function tests (LFTs), decreased albumin and elevated PT
- Hematologic: decreased platelets, elevated PT/APTT, increased D-dimer
- Central nervous system (CNS): altered level of consciousness (LOC), confusion, psychosis
- Respiratory: tachypnea, hypoxemia, PaO_2/FiO_2 greater than 300 (see Chapter 10)
- Cardiovascular: tachycardia, hypotension, altered CVP and pulmonary artery pressure (PAP) readings

Advanced age, malnutrition, and coexisting diseases appear to increase the risk of MODS in patients who are acutely ill.

Medical Management

Prevention remains the top priority in managing MODS. Elderly patients are at increased risk for MODS because of the lack of physiologic reserve associated with aging and the natural degenerative process, especially immune compromise. Early detection and documentation of initial signs of infection are essential in managing MODS in elderly patients. Subtle changes in mentation and a gradual rise in temperature are early warning signs. Other patients at risk for MODS are those with chronic illness, malnutrition, immunosuppression, or surgical or traumatic wounds.

If preventive measures fail, treatment measures to reverse MODS are aimed at (1) controlling the initiating event, (2) promoting adequate organ perfusion, and (3) providing nutritional support.

Nursing Management

The general plan of nursing care for patients with MODS is the same as that for patients in septic shock. Primary nursing interventions are aimed at early and aggressive hemodynamic support until primary organ insults are halted. Providing information and support to family members is a critical role of the nurse. It is important that the health care team address end-of-life decisions to ensure that supportive therapies are congruent with the patient's wishes (see Chapter 3).

Refer to Figure 54-5 for a review of the various forms of shock.

CHAPTER REVIEW

Critical Thinking Exercises

1. You administer an antibiotic to a patient before he goes to surgery. The patient's chart states that he has no known drug allergies. After 15 minutes, the patient complains of anxiety, shortness of breath, and chest discomfort. He is flushed and visibly uncomfortable. What are your nursing priorities in providing care to this patient? What clinical signs and symptoms would you look for to determine if he is experiencing anaphylactic shock? What nursing interventions and medical treatments would you anticipate?

2. An elderly woman is admitted to the medical floor for a urinary tract infection. You notice that she has become steadily more tachycardic and her urine output has dropped to 15 cc for the last hour. How would you assess this patient for the possibility of sepsis?

3. While working in the emergency department, you see a victim of a motor vehicle accident brought in by ambulance. His pelvis appears deformed, he is pale, diaphoretic, and his heart rate is 124. What type of shock is this patient most likely in? What led you to that conclusion? Name some interventions that would help this patient.

4. You are taking care of a patient in the ICU with a spinal cord injury. His BP has not been responsive to repeated fluid boluses. What type of shock is he mostly likely experiencing? Name some appropriate interventions.

NCLEX-Style Review Questions

1. During a conversation about a patient, a new nurse states to the charge nurse, "His BP is 92/50, so he can't be in shock." Which response by the charge nurse indicates that the new nurse does not completely understand the symptoms of shock?
   a. Patients can have a near-normal BP, yet still have inadequate tissue perfusion.
   b. The cutoff for shock is a systolic pressure of 100 mm Hg.
   c. Shock is determined by mean arterial pressure.
   d. Shock is determined by a heart rate of over 100.

2. A patient with a GI bleed arrives at the emergency department with the following vital signs: Temperature 37.4°C, HR 112, RR 26, BP 88/44. The nurse recognizes that this patient is most likely experiencing or at risk for which type of shock?
   a. Anaphylactic
   b. Neurogenic
   c. Hypovolemic
   d. Septic

3. A patient comes in to the urgent care center complaining of shortness of breath and dizziness after being stung by a bee. The patient loses consciousness in the waiting room. The receptionist has called 911. The nurse anticipates that which medication will be considered first?
   a. Diphenhydramine (Benadryl)
   b. Phenytoin (Dilantin)
   c. Epinephrine IV
   d. Epinephrine IM

4. In early goal-directed therapy for shock, the nurse knows that which parameter is the highest priority when evaluating effectiveness of therapy?
   a. Heart rate and BP
   b. SvO_2 and O_2 saturation
   c. Base deficit and hematocrit
   d. SvO_2 and CVP

5. A patient develops low BP and tachycardia and is very agitated. The nurse remembers that a central line was placed 3 hours ago. The patient's lung sounds are decreased on one side, and tracheal deviation is present. The nurse realizes that this patient is most likely experiencing which type of shock?
   a. Hypovolemic
   b. Obstructive
   c. Anaphylactic
   d. Neurogenic

CHAPTER 55

Nursing Management: Critical Care

Kelly S. Grimshaw

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the role of the critical care nurse in health care.
2. Describe nursing management of common problems in the critical care environment.
3. Understand common interventions and equipment used in the critical care environment.

The nurse's priority in caring for patients who are critically ill is to prevent harm and provide physical care, education, and emotional support to patients and families in an effort to return them to the highest possible state of health or to help them toward a peaceful death. Nurses are in the unique position of standing with the patient and family at the center of multisectoral activity. They are at the bedside to act as a care provider and liaison to other health care workers in an effort to coordinate said care. This chapter covers the role of the nurse in critical care and critical care responsibilities and modalities.

THE CRITICAL CARE ENVIRONMENT

Historical tradition dictates the critical care environment to be a separate place or unit within a hospital building. After the Institute of Medicine (IOM) challenge to hospitals to prevent avoidable deaths, over 65% of hospitals in the United States (National Academies of Sciences, Engineering, and Medicine, 2015) have implemented rapid response teams (RRTs). These RRTs usually consist of a doctor, an advanced practice registered nurse (APRN) or physician assistant (PA), a respiratory therapist, and a critical care nurse. These teams were established in hospitals to address the concerns of those patients outside of the intensive care unit (ICU) who were seen as requiring a higher level of care. The RRTs currently in place are able to provide the required higher level of care even when the patient is physically outside of the ICU and awaiting a bed inside the unit, thus making critical care a process and not a place.

NEUROLOGIC ISSUES

A neurologically healthy person is one who is awake, alert, and oriented, with the ability to respond appropriately to his or her environment without sensory or physical limitations. Whether or not a person is admitted with a specific neurologic or neurosurgical diagnosis, other medical problems or interventions may impact his or her neurologic status.

Altered Level of Consciousness

The causes of altered mental states are numerous and varied but can be remembered using the mnemonic in Table 55-1. Most ICU patients are at risk for mental status changes due to a myriad of potential factors: previously existing mental illness, increased age, severity of illness and comorbidities, sleep deprivation, and/or medications. Assessing changes in level of consciousness (LOC) alerts the nurse to neurologic impairment. A thorough review of possible causes and early intervention can impact a patient's long-term recovery. Refer to Chapter 43 for performing mental status assessment.

Delirium

Delirium is a confused state that has a sudden onset and can last hours to days or weeks; it is characterized by hyperactivity and has the potential to be reversible. For example, the patient who quickly becomes confused and agitated while attempting to pull out IV lines and get out of bed is experiencing delirium. These patients require extensive nursing time and often need someone to be present in the room with them at all times to prevent injury. The consequences of delirium cannot be underestimated. Though probably underdiagnosed, it has been found that delirium leads to a myriad of sequelae including: increased medicinal and restraint interventions, increased length of stay, persistent cognitive impairment with admission to chronic care facilities, and increased mortality (Sangeeta et al., 2015).

Pain and Anxiety

Pain and anxiety are interrelated and should be assessed together. For example, chest pain often produces great anxiety.

TABLE 55-1 Causes of Altered Mental Status

	Cause	Example	Possible Nursing Interventions
A	Alcohol	Intoxication Withdrawal	Institute fall precautions Institute seizure precautions Institute ICU sedation protocol; Clinical Institute Withdrawal Assessment-Alcohol (CIWA-A) scale
E	Epilepsy Endocrine Electrolytes	New onset or low medication level Hypothyroidism Hyper or hyponatremia	Check medication level Check thyroid level IV fluids and serial sodium levels as ordered
I	Insulin	Hypoglycemia	Check glucose level Administer dextrose as ordered
O	Opiates and other drugs	Narcotic overdose	Administer reversal agent as ordered Airway protection with elevated head of bed
U	Uremia	Acute or chronic kidney failure	Follow trends of blood urea nitrogen and creatinine levels Ensure patency of dialysis access shunts and IV lines
T	Trauma Temperature	Hypothermia	Serial temperature measurements Blanket warmer Administer warm IV fluids as ordered
I	Infection	Sepsis	Obtain blood and body fluids for culture as ordered Administer antibiotics as ordered Ensure IV lines and Foley catheters have been changed according to hospital policy
P	Poison	Confusion, seizures, coma	Supportive care until poison is neutralized or removed
S	Shock Stroke Space occupying lesion Subarachnoid hemorrhage	Hypovolemia Thrombolic or hemorrhagic Tumor Trauma or unmonitored anticoagulation use	IV fluids and cardiac pressors to support cerebral blood flow Call for stroke alert if found with acute symptoms Monitor for signs of increased intracranial pressure (ICP) Ensure functioning of ICP monitor or ventricular shunts

Emergency Medicine/Altered Mental Status. (2014). Retrieved on May 13, 2015 from http://en.wikibooks.org/

Pain

Critical care patients can experience pain as a result of their injury or disease as well as its treatment. It is well known that pain elicits a stress response, leading to a catabolic state with increased cardiac workload and an impaired immune response. Care must be taken to ensure that all ICU patients are assessed for any pain, whether or not they are able to communicate their pain level. Prevention and treatment of pain should include both pharmacologic and nonpharmacologic methods in collaboration with the patient (if able) and the medical team. Refer to Chapter 7 for details on pain assessment and management.

Anxiety

Anxiety has been defined as a universal experience with physical side effects and a subjective sense of danger or dread (Silver, Shapiro, & Milrod, 2013). Each hospital also provides

scales for objectifying signs and symptoms of anxiety, such as the Richmond Agitation and Sedation Scale (RASS), in order to standardize treatment and minimize its effects (see Fig. 55-1).

Table 55-2 summarizes assessment of anxiety. An ICU stay has inherent stressors of pain, lack of control over one's environment, impaired communication, and possible fears of imminent death, issues that are all causes for severe anxiety. It is estimated that up to 22% of patients admitted to an ICU suffer from posttraumatic stress disorder (PTSD) as a result of their admission, and its prevention is of paramount importance when considering recovery and post discharge quality of life (Rock, 2014).

Dependency and Withdrawal

Use and abuse of illegal and legal drugs is pervasive in the United States, with an estimated incidence of 9.2% of the general population (SAMHSA, 2014) reporting use and abuse. It is important to realize that people of all ages and from all walks of life may have a chemical dependence issue and that admission to the ICU will not "cure" this problem. It will more likely be that these patients require more pain and sedation medication to achieve desired effects, such as prevention of withdrawal and its sequelae.

+4	Combative, violent, of immediate danger to himself and staff
+3	Very agitated, aggressive, pulls or removes tubes or catheters
+2	Agitated frequent nonpurposeful movement, dyssynchronous with the ventilator
+1	Restless, anxious but not aggressive
0	Alert and calm
–1	Drowsy, not fully alert, but has sustained eye-opening/eye contact to *voice* **(>10 s)**
–2	Light sedation-briefly awakens with eye contact to *voice* **(<10 s)**
–3	Moderate sedation—moves or opens eyes to *voice* **(but no eye contact)**
–4	Deep sedation. No response to voice. Movement or eye opening to *physical* stimulation
–5	Unarousable. No response to *voice or physical* stimulation

FIGURE 55-1 The Richmond Agitation and Sedation Scale (RASS). (Reprinted with permission from Bigatello, L. M., Alam, H., Allain, R. M., Bittner, E. A., Hess, D., Pino, R. M., & Schmidt, U. (Eds.), *Critical care handbook of the Massachusetts General Hospital*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Depression

Medical literature is filled with articles and studies demonstrating depression or depressed mood as a component of chronic and critical illness. It is also well known that many of the medications prescribed in the ICU, such as beta blockers, can cause depression. Patients admitted on antidepressive agents should continue them with the shortest interruption possible. Patients exhibiting signs of prolonged or exaggerated mood should be evaluated by a psychiatry provider for adequate diagnosis and treatment in order to facilitate the healing process.

Suicidal ideation, and actions taken with the intent to kill oneself, is another issue requiring assessment in the hospital setting. Suicide ranks as the 10th most common cause of death in the United States and a frequently reported sentinel event in health care institutions (CDC, 2014). The Joint Commission (2015) requires facilities to assess patients for suicidal ideation on admission and throughout their stay as it poses such a great risk in these institutions. Admission to the ICU during a hospital stay does not diminish the need to assess patients for any suicidal thoughts or actions.

Sensory and Motor Function

Impairment of sensory and motor function (ability to feel and physically react to one's environment) can arise from various sources, including spinal cord injury, peripheral vascular disease, and/or medical restraint devices. Alterations in sensation and motion can be viewed on a negative to positive continuum, ranging from insensate to numbness, normal, tingling, and then pain.

Communication

Communication allows patients and families to interact with health care system professionals in order to satisfy physical, emotional, and spiritual needs. The ICU environment and neurologic status deficits can make communication difficult. It is imperative that critical care nurses work to improve communication in order to satisfy the previously mentioned needs of their patients and families. Suggested methods may include:

- Asking yes or no questions to which the patient may nod his or her head
- Using an electronic tablet for texting
- Using a board with preprinted phrases to which he or she can point
- Using language and sign language interpreters (from within the hospital or interpreter services)
- Making a paper and pencil available

TABLE 55-2 Anxiety Assessment

Assessment	Possible Nursing Interventions
Does my patient have anxiety? If so, at what level?	Presume that all ICU patients are at risk for anxiety! Use appropriate scale to assess level of anxiety, such as the Richmond Agitation and Sedation Scale.
Why is the patient experiencing anxiety?	Provide any information for which the lack of information is the cause of anxiety.
What is the most appropriate medication?	Administer antianxiety medications if ordered.
What is the most appropriate method of delivery?	Assess the patient's ability to tolerate oral medication.
What nonpharmacologic methods of reducing anxiety are available?	Allow for visitation and distraction. Allow pet therapy if available and acceptable to patient.
Is our plan for anxiety relief working?	Reevaluate the patient regularly.
Does my patient have anxiety, and is unable to communicate this?	Observe nonverbal behavior including facial expressions, body language, gaze aversion; advocate for patients.

CARDIOVASCULAR ISSUES

Cardiovascular problems can be broadly categorized as those arising from the heart and vascular system and those affecting the heart and arterial and venous systems (Table 55-3). Patients may be admitted to critical care units for a number of concerns related to the cardiovascular system, including:

- a history of cardiovascular disease requiring careful observation, although not admitted specifically for cardiovascular disease, an active cardiac problem requiring advanced intervention, or
- another active medical problem affecting their cardiovascular status, such as hemorrhage or sepsis.

Monitoring the Patient

Depending upon the individual patient's condition, different levels of monitoring and intervention will be required. Table 55-4 provides a summary of the different levels of monitoring.

TABLE 55-3 Sources of Cardiac Disease

Sources of Disease	Example
Cardiac	
Myocardial	Left ventricular hypertrophy, congestive heart failure
Ischemic	Coronary artery disease, myocardial infarction
Conductive	Atrial fibrillation, heart blocks
Valvular	Mitral regurgitation, aortic stenosis
Other	
Infection	Pericarditis, sepsis, viral cardiomyopathy
Neurologic system	Spinal shock
Peripheral vascular system	Hypertension, deep vein thrombosis, pulmonary embolism
Respiratory system	Pulmonary hypertension
Renal system	Kidney failure leading to fluid overload
Trauma	Cardiac contusion, cardiac tamponade
Hemorrhage	Circulatory collapse

TABLE 55-4 Monitoring the Cardiac Patient

Conditions and Circumstances	Related Monitoring and Interventions
• Patients who are expected to do well, but need additional monitoring in case unexpected complications, such as bleeding, or arrhythmias arise	Vital sign assessment Oxygen saturation Cardiac monitor Peripheral IV access in case of emergency
• Patients about to leave the critical care environment and who are awake, hemodynamically stable, and able to eat and drink	All of the above
• Patients admitted with singular issues, such as an elective surgery or uncomplicated medical diagnoses, who are expected to recover, but have a cardiac history (such patients may need IV fluids and medications for a limited time period).	All of the above + IV fluids, IV medications, or minimal blood products
• Patients who have a medical or surgical issue, in which recovery depends on the medical team's provision of more precise monitoring (such as heart failure)	All of the above + Central venous access and/or arterial line access
• Patients who are at risk for complications, or for whom basic monitoring and fluids have failed; patients requiring cardiac pressor support (these patients are often compromised due to sepsis).	All of the above + Vasoactive medications and/or further blood products
• Patients who have an unclear cardiac status, have not responded well to lesser interventions, or have undergone cardiac surgery	All of the above + Pulmonary artery catheterization
• Cardiac failure due to any cause	All of the above + Counterpulsation via intra-aortic balloon pump
• Complete cardiac failure	All of the above + Ventricular assist device

It is important to remember that monitors, invasive lines, and other devices are to assist in confirming or disproving physical examination results and clinical judgments, not replace them.

TABLE 55-5 Effects of Preload and Afterload on the Heart

Factor	Possible Cause	Effects on Heart
Increased preload	Increased fluid volume Vasoconstriction	Increases stroke volume Increases ventricular work Increases myocardial oxygen requirements
Decreased preload	Hypovolemia Vasodilation	Decreases stroke volume Decreases ventricular work Decreases myocardial oxygen requirements
Increased afterload	Hypovolemia Vasoconstriction	Decreases stroke volume Increases ventricular work Increases myocardial oxygen requirements
Decreased afterload	Vasodilation	Increases stroke volume Decreases ventricular work Decreases myocardial oxygen requirements

Intravenous Access in the Cardiac Patient

Peripheral Intravenous Access

At a minimum, peripheral intravenous (IV) access should be obtained on all patients in the critical care environment. Peripheral IVs give the health care team access the vascular system in case of emergency; a potential site for blood sampling; and the ability to provide fluids, medications, and nutrition. Contraindications to specific placements (right vs. left side) will include history of mastectomy, arterial-venous shunt placement, peripherally inserted central catheter (PICC) line placement, thrombus, trauma, and other device placements, such as splints and casts. IV lines in the feet are reserved only for emergencies; they are to be removed as soon as possible and never inserted in the feet of patients with diabetes. Potential complications include bruising, infection, extravasation of fluids and medications, and air embolus.

An arterial line is a peripheral IV in the arterial system used for frequent blood pressure monitoring when a patient requires vasoactive medications (such as nitroprusside) and frequent blood sampling. It is not for administration of fluids or medications. Potential complications include ischemia, thrombosis, infiltration, and exsanguination.

Central Intravenous Lines

Central IV lines (Fig. 55-2) are used for a number of reasons, including:

- Failure to obtain or maintain peripheral access
- Complication of peripheral access
- The patient requires numerous access sites, parenteral nutrition, or hypertonic fluid administration
- Treatment failure with IV fluids necessitates the first level of hemodynamic monitoring for readings of central venous pressure (CVP)
- The patient requires vasoactive medications that place his or her limb at risk if an infiltrate occurs

The triple-lumen catheter is a central line that measures the CVP or the amount of fluid returning to the heart at the level of the right atrium (termed *preload*, see Table 55-5). See Chapter 12 for more information on CVP monitoring.

Pulmonary Artery Catheter

Pulmonary artery catheter (PACs) are used when previous interventions have not yielded the expected outcome (increased urine output with increased IV fluid administration), or when the patient has a complicating factor, such as kidney or heart failure or pulmonary hypertension, that makes clinical judgments difficult without additional information. After decades of its use in practice, there is still no consensus as to whether PACs improve patient outcomes. Without that evidence and because they increase the risk of complications, such as pneumothorax, cardiac arrhythmias, and pulmonary artery rupture, the use of PACs is decreasing. However, they still can be a helpful tool in assisting in the overall evaluation of

a patient.

PACs allow the medical and nursing team to monitor, intervene upon, and evaluate:

- Blood volume status
- Blood flow
- Tissue oxygenation

Figure 55-3 illustrates components of the PAC system.

Blood Volume Status

Blood volume status is the amount of blood circulating in the enclosure of the arterial and venous systems. This fluid exerts or creates a pressure that can be monitored to determine preload: The greater the blood volume, the greater the pressure (assuming no confounding variables, such as severe hypertension). Using Starling's Law the volume can be increased to give the heart a greater stretch or potential energy with which to pump blood to the body without causing overstretch and failure. It can be compared to a sling shot pulled back ever farther to throw a stone farther without stretching the sling to the point of breaking.

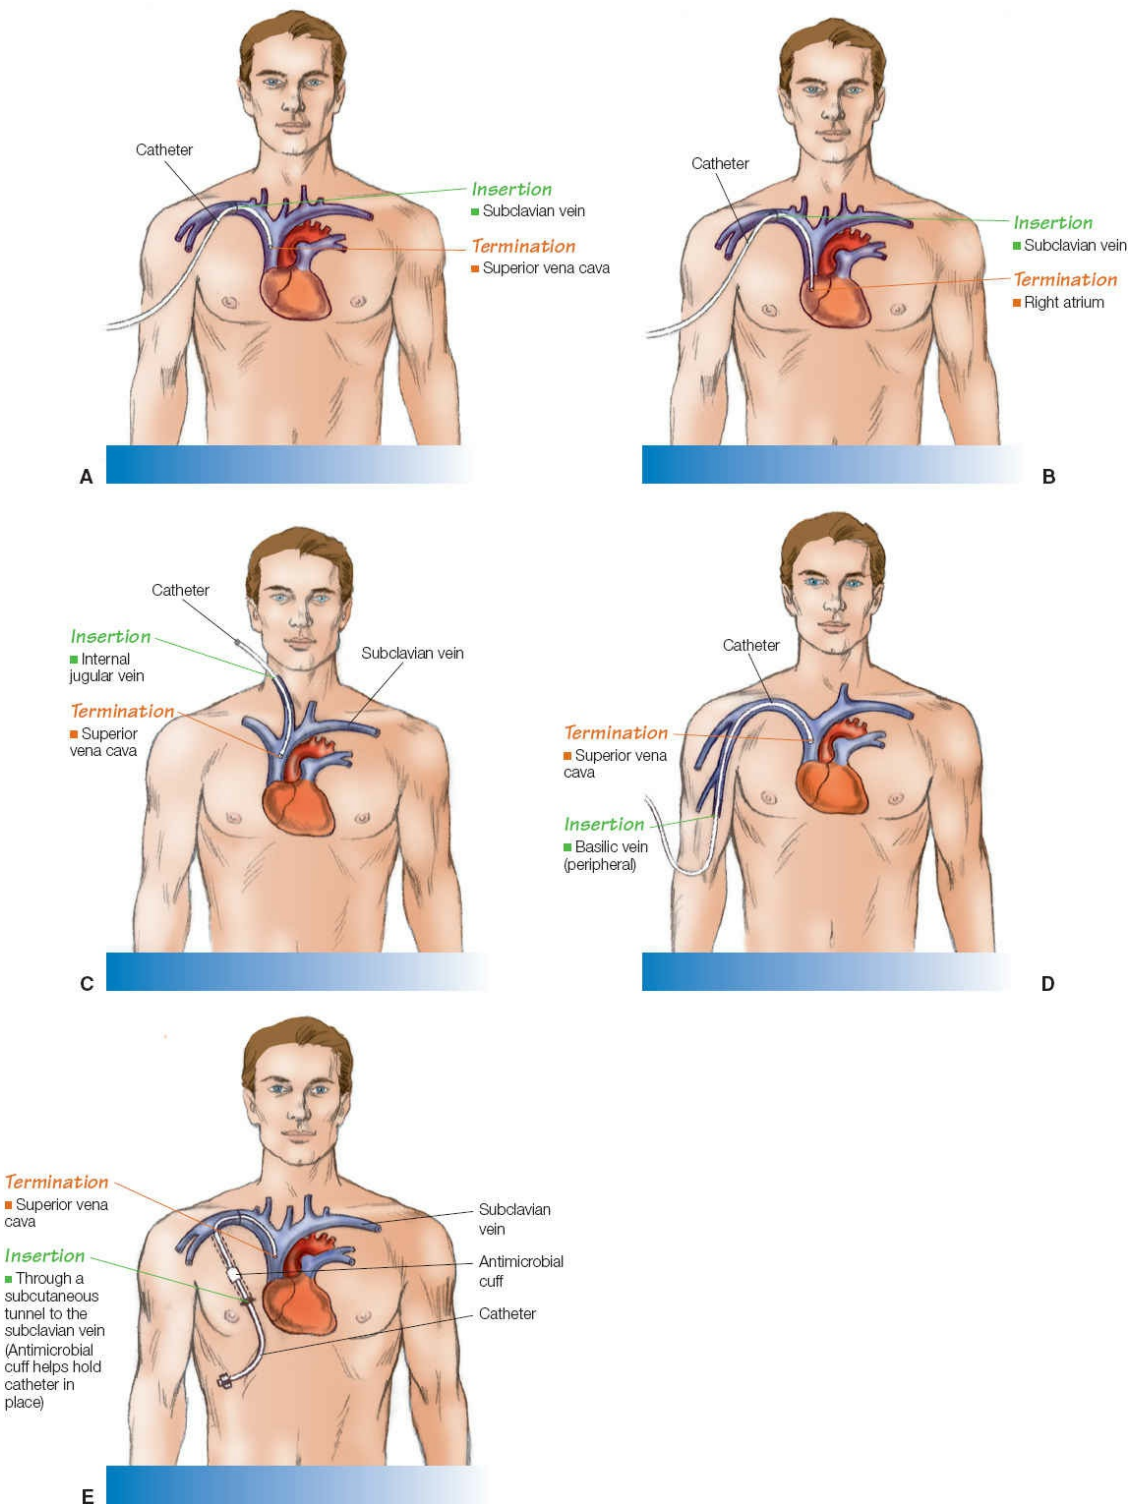

FIGURE 55-2 Central vein catheter pathways showing various insertion and termination sites. Typically, a central vein catheter is inserted in the subclavian or internal jugular vein. (A) Subclavian insertion ending in Superior Vena Cava (SVC); (B) Subclavian insertion ending in the right atrium; (C) Jugular insertion ending in the SVC; (D) Peripherally inserted central catheter (PICC) ending in the SVE; (E) Hickman Catheter ending in the SVC. (From Lippincott Williams & Wilkins. (2010). *Hemodynamic monitoring made incredibly visual* (2nd ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

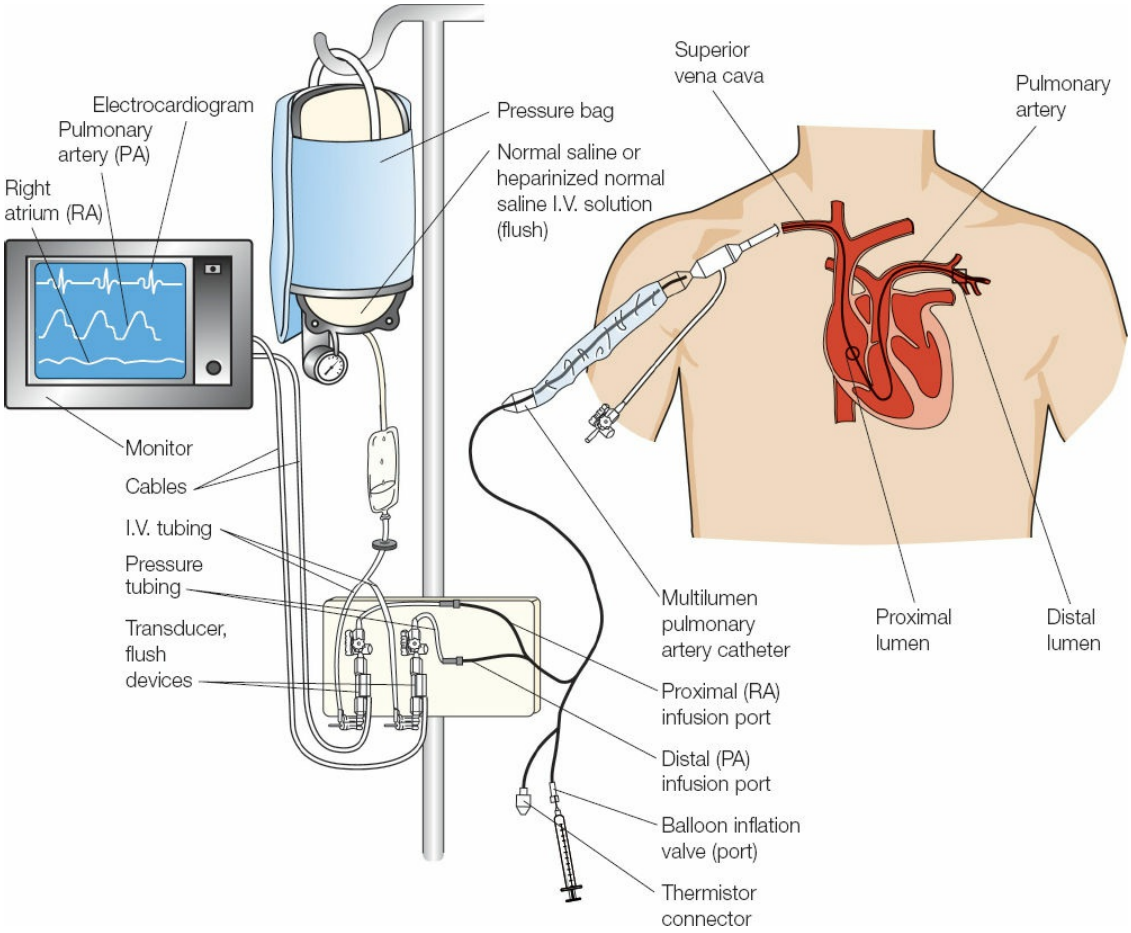

FIGURE 55-3 Components of the pulmonary artery catheter (PAC) monitoring system. (From Lippincott Williams & Wilkins. (2010). *Hemodynamic monitoring made incredibly visual* (2nd ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

A PAC measures and calculates the pressures described in Table 55-6.

It is important to remember that the blood volume measurements describe the total amount of pressure exerted in the vasculature by a particular volume of fluid. They do not describe the components of the blood, such as percentage of red blood cells (RBCs; hematocrit) or plasma. Specific laboratory values, such as the complete blood count (CBC), determine these percentages. The goals of treatment involve restoring and maintaining an adequate blood volume with the right proportions of blood components that best support organ perfusion.

Blood Flow

The right side of the heart pumps blood to the pulmonary system, and the left side pumps blood to itself via the coronary arteries and the rest of the body via the aorta. The PAC measures how the heart is pumping and how the vasculature is receiving or resisting the flow. Table 55-7 describes PAC blood flow measurements.

It is important to remember that the numbers in the table are general values and that the 98-lb elderly patient will have different requirements than the 200-lb professional defensive lineman. In order to account for differences in body size, index measurements are used (Table 55-8).

Tissue Oxygenation

The ability of tissues to receive and use oxygen depends upon many variables, from physiologic disorders and medical procedures to prescribed medications and their interactions. The health care team is responsible for manipulating these variables to maximize delivery and usage. In general, the following indicate how the patient is doing:

- Arterial pH and partial pressure
- Venous pH and partial pressure
- End organ function, such as urine production
- Lactic acid level
- Mixed venous oxygen saturation (MvO_2)

TABLE 55-6 Pulmonary Artery Catheter Pressure Measurements

Measurement	Definition	Formula (If Applicable)	Normal Value (mm Hg)
Mean arterial pressure (MAP)	Average arterial pressure throughout the cardiac cycle	Systolic BP + 2(diastolic BP)/3	70–105
Right atrial pressure (RAP)	Pressure at the level of the right atrium		2–8
Pulmonary artery systolic pressure (PAS)	Pressure in pulmonary artery during systole		20–30
Pulmonary artery diastolic pressure (PAD)	Pressure in the pulmonary artery during diastole		8–15
Mean pulmonary artery pressure (MPAP)	Average pressure in the pulmonary artery throughout the cardiac cycle	PAS + 2(PAD)/3	10–15
Pulmonary artery wedge pressure	The indirect measurement of pressure in the left ventricle at the end of diastole		6–12

TABLE 55-7 Pulmonary Artery Catheter Blood Flow Measurements

Measurement	Definition	Formula (If Applicable)	Normal Value
Heart rate (HR)	The number of beats per minute		60–100 bpm
Stroke volume (SV)	The amount of blood ejected from the left ventricle with each beat	End-diastolic volume – end systolic volume	Patient dependent
Cardiac output	The amount of blood pumped to the body each minute	HR × SV	4–8 L/min
Pulmonary vascular resistance (PVR)		PAM – PAWP/CO × 80	50–150 dynes/sec/cm^{-5}
Systemic vascular resistance (SVR)		MAP – RAP/CO × 80	900–1,200 dynes/sec/cm^{-5}

TABLE 55-8 Pulmonary Artery Catheter Indices

Measurement	Definition	Formula	Normal Value
Stroke volume index	As above accounting for body surface area (BSA)		30–60 mL/beat/m^2
Cardiac index	As above accounting for BSA	CI/BSA	2.4–5 L/min/m^2
Pulmonary vascular resistance index (PVRI)	As above accounting for BSA	PAM – PAWP/CI × 80	200–350 dynes/sec/cm^{-5}
Systemic vascular resistance index (SVRI)	As above accounting for BSA	MAP – RAP/CI × 80	1,800–2,800 dynes/sec/cm^{-5}

Nursing Alert

The lactic acid level represents the end product of anaerobic metabolism used by the body during times of insufficient oxygen supply. Lactic acidosis is generally considered to be present if the plasma lactate concentration is greater than 4 to 5 mEq/L. However, the nurse may see a rise in the lactic acid level as oxygen supplied via blood flow is initially restored. Consider a patient with a vascular blockage to his or her leg during which the leg is not receiving enough oxygen and the extremity is cold and pale without pulses. Lactic acid is building up in the leg, but this lactic acid is not measured because blood flow is blocked. Once vascular flow is restored, marked with a return of warmth and peripheral pulses, there will be an initial rise in lactic acid as the body releases it into the now flowing bloodstream. Thus, the nurse must consider the serum lactic level in conjunction with the patient's clinical situation.

Nursing Alert

As bodies neither make nor store oxygen, humans have evolved and adapted with a safety mechanism to ensure oxygen delivery occurs in times of decreased supply and/or increased demand. The body only uses a portion of the oxygen delivered to the bloodstream during one circuit from the heart and lungs to the rest of the body and back. Consider a person experiencing cardiopulmonary arrest, when 4 to 6 minutes may pass without a heartbeat before brain damage occurs. This is because there is still oxygen in the blood from his last inspiration. The normal value for MvO_2 is 75%. Thus, the body used only 25% of delivered oxygen during the last lap through the body. A decrease in MvO_2 below 75% means the body is not receiving enough oxygen and/or has an increased demand for oxygen.

The various IV and intra-arterial lines discussed in the previous section are used to monitor cardiac function; they do not change it. To improve a patient's cardiac status, practitioners remove the root cause of the problem and provide support via the use of IV fluids, blood products, vasoactive medications, and medical devices.

Intravenous Fluids and Blood Products

IV fluids are given to obtain and help maintain a euvolemic and isotonic state within the body. The type and amount of fluid will be dependent upon each individual's medical situation. These crystalloid solutions in various concentrations and combinations contain electrolytes and sometimes sugars:

- Saline
- Lactated Ringer's
- 5% dextrose in water

IV solutions with larger molecules designed to expand IV volume with increased oncotic pressures include:

- Albumin
- Hespan™ or Hetastarch™

Blood products can help with hydration and volume expansion, as well as provide additional or replacement oxygen-carrying capacity, clotting factors, and platelets:

- Packed red blood cells (pRBC)
- Fresh-frozen plasma (FFP)
- Pooled platelets
- Cryoprecipitate

McEvoy and Shander (2013) report that up to one third of people admitted to the ICU receive at least one blood product transfusion. Unfortunately, no evidence-based guideline exists to help practitioners determine when the benefits of transfusion outweigh the risks of human error, impaired immune function, and infection that often accompany transfusion.

Vasoactive Medications

Many medications are used to help support cardiovascular function. Vasoactive medications given in the ICU are designed to alter preload, afterload, contractility, and cardiac rhythm, as required by the patient's underlying disease and physiologic condition. These are potent drugs with a myriad of potential adverse effects necessitating close titration and monitoring in an ICU setting. Table 55-9 summarizes those IV medications most commonly used in the ICU.

Medical Devices

Patients in the ICU may require medical devices to assist with cardiac function.

Pacemakers

Pacemakers are medical devices generally used to treat cardiac disease caused by conduction problems. They can be placed temporarily or permanently in order to improve cardiac function with or without adjunct medications. Permanent pacemakers are discussed in Chapter 17.

Temporary pacemakers are used during cardiac surgery and medical emergencies. They can be placed in a variety of ways:

- *External pacemakers:* Involves placement of electrodes on the front and side or back of the chest to deliver repeated shocks
- *Transvenous pacemakers:* Involves placement of a wire into the right ventricle via a central IV catheter
- *Epicardial pacemaker:* Involves surgical placement of wires into the epicardium to prevent and treat postsurgical conduction defects
- *Transthoracic cardiac pacemakers:* Involves introduction of a wire into the right ventricle, which is attached to a generator

TABLE 55-9 Vasoactive Medications

Medication	Action or Effect	Indications	Dosing Range
Amiodarone	Decreased heart rate	Ventricular Tachycardia Atrial fibrillation	Arrhythmia dependent
Diltiazem	Decreased heart rate and blood pressure	Atrial fibrillation Paroxysmal Supraventricular Tachycardia Hypertension	5–15 mg/hr
Dobutamine	Increased heart contractility Increased blood pressure	Congestive heart failure Low cardiac output	2.5–20 µg/kg/min
Dopamine	Increased heart rate and blood pressure	Bradycardia Hypotension	2–20 µg/kg/min
Epinephrine	Increased heart rate and blood pressure	Anaphylaxis Shock	1–10 µg/min
Esmolol	Decreased heart rate	Tachycardia Hypertension	500 µg/kg load 50–200 µg/kg/min
Nitroglycerin	Decreased blood pressure Arterial vasodilatation	Myocardial ischemia Congestive heart failure Hypertension	10–20 µg/min
Nitroprusside	Decreased blood pressure	Congestive heart failure Hypertensive crisis	3 µg/kg/min—effect
Norepinephrine	Increased blood pressure	Cardiac arrest Hypotension	1–20 µg/min
Phenylephrine	Increased blood pressure	Hypotension	40–200 µg/min
Vasopressin	Increased blood pressure	Diabetes insipidus Gastrointestinal bleed Septic shock	0.02–0.04 units/min

Whether temporary or permanent, pacemakers necessitate that care for a patient with a pacemaker includes monitoring of the pacemaker's function and the patient's physical response to the pacing. This will include pain management and sedation for those with external pacers, infection control for newly inserted pacers, and physical assessment of cardiac, pulmonary, renal, and peripheral vascular function. See Chapter 17 for more detailed discussion.

Intra-Aortic Balloon Pump

Patients with temporary or permanent heart muscle damage are unable to adequately perfuse their own heart and other organs. First attempts to improve cardiac muscle function include fluids and medications, but, at times, patients will require additional support in the form of an intra-aortic balloon pump (IABP). A balloon in placed in the descending aorta via a femoral artery. The balloon can be alternately inflated and deflated (Fig. 55-4). It is programmed to inflate during diastole, which pushes blood back toward the cardiac muscle itself, as well as toward the brain. It deflates just before the ejection phase of systole and acts as a vacuum that pulls blood into the aorta with less effort from the left ventricle. An IABP essentially decreases the workload of the heart, allowing the heart muscle to rest and recover while improving organ perfusion. The machine itself can be programmed to assist with every heartbeat or every second, third, or fourth alternate beat, depending upon patient requirements. Care for patients on an IABP includes monitoring cardiac function with the use of a PAC and assessing peripheral circulation to the extremity below its insertion site.

Ventricular Assist Device

A ventricular assist device (VAD) is an implantable device in which cannulas are inserted into the atria or ventricles to support the right side of the heart, left side of the heart, or both sides by taking over the work of delivering blood to the pulmonary artery and/or aorta (see Fig. 55-5). There are three types of VADs. A right VAD (right ventricular assist device [RVAD]) provides pulmonary support by diverting blood from the right atrium or failing right ventricle to the VAD, which pumps the blood into the pulmonary circulation via the VAD connection to the left pulmonary artery.

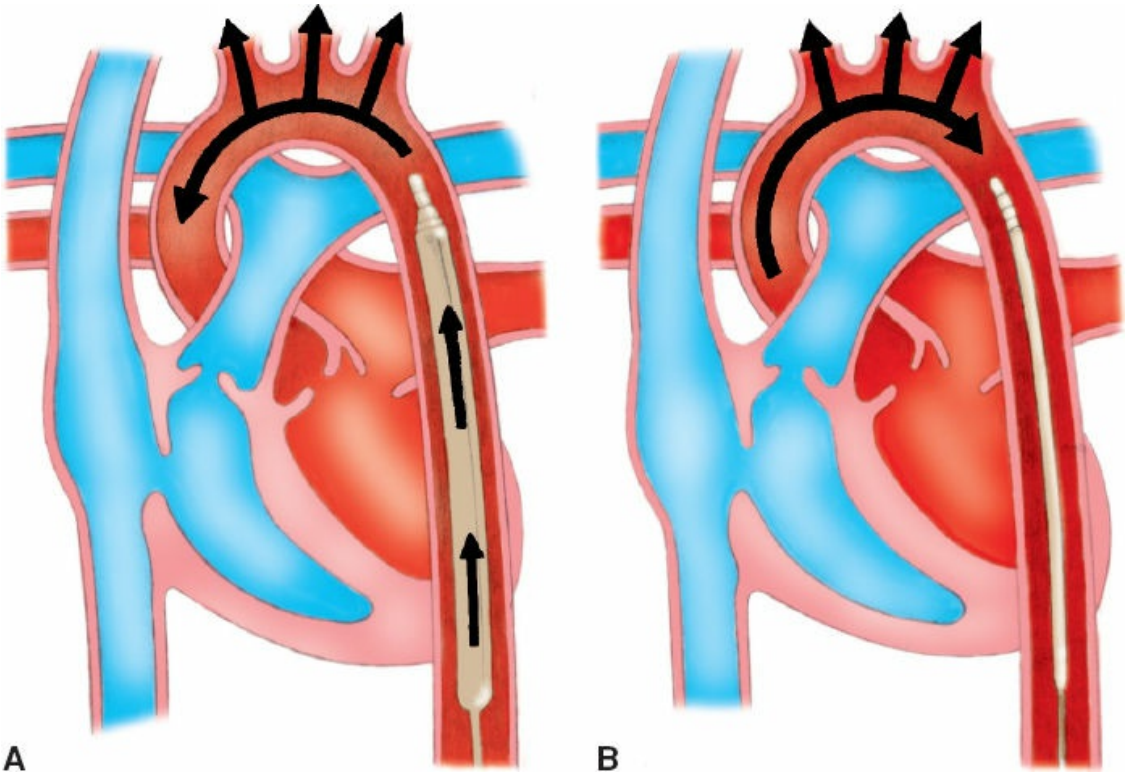

FIGURE 55-4 Direction of blood flow when the pump inflates and deflates the balloon. A. Balloon inflation: The balloon inflates as the aortic valve closes and diastole begins. Diastole increases perfusion to the coronary arteries. B. Balloon deflation: The balloon deflates before ventricular ejection, when the aortic valve opens. This deflation permits ejection of blood from the left ventricle against a lowered resistance. As a result, aortic end-diastolic pressure and afterload decrease and cardiac output rises. (From Lippincott Williams & Wilkins. (2010). *Hemodynamic monitoring made incredibly visual* (2nd ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

With a left VAD (left ventricular assist device [LVAD]), blood flows from the left atrium or ventricle to the VAD, which then pumps blood back to the body via the VAD connection to the aorta. A RVAD and LVAD combination is referred to as *biventricular* (BiVAD) *support.*

VADs are reserved for patients who cannot be weaned from maximum volume/inotropic support or the IABP, are awaiting cardiac transplantation, or have class IV heart failure but are not candidates for transplantation. This intervention is the last-line treatment for cardiac failure and requires high-intensity nursing care to monitor cardiac function and the myriad of potential adverse effects, which range from infection, bleeding, and neurologic deficits to kidney and device failure. While usually deemed to be a temporary measure, VADs are gaining prominence due patients with refractory heart failure who cannot be transplanted who are creating a cohort of patients requiring long-term assistance without definitive cure. Thus VAD support is the destination therapy. These patients are living in communities and should be known to emergency services in case of power outages (refer to Chapter 16 for further details).

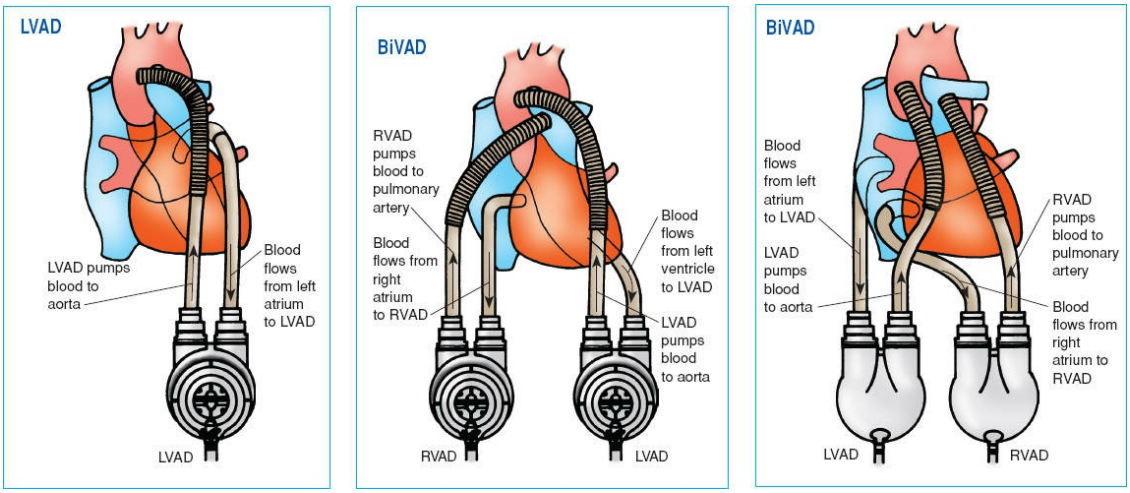

FIGURE 55-5 Cannulation options. Ventricular assist devices (VADs) divert blood from failing ventricles to a pump that can effectively eject it. This diversion can occur by cannulation of either the atria or the ventricles. LVAD, left VAD; RVAD, right VAD; BiVAD, biventricular support. (From Lippincott Williams & Wilkins. (2010). *Hemodynamic monitoring made incredibly visual* (2nd ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

RESPIRATORY ISSUES

Respiratory Failure

Respiratory failure and the advent of mechanical ventilation led to the creation of critical care as a specialty service. As times change, so does technology. The use of noninvasive ventilator support (NIV) for respiratory complications is now a first line of treatment for an ever increasing number of patient populations and care settings (Mas & Masip, 2014). The number of patients needing ventilatory support is expected to grow over the next decades. Respiratory failure can generally be divided into two main categories (see Box 55-1).

Oxygen Delivery

In the critical care environment, oxygen is treated as a drug, requiring a providers' order and nursing assessment of the patient's response to this prescription. The need for oxygen therapy and its specific method of delivery varies according to patient condition. Some patients will receive O_2 therapy as a preventative measure. Supplemental oxygen will assist some patients with extra oxygen delivery during acute episodes, such as in cases of myocardial infarction (MI). For the more critically ill, it will serve as an intervention to ensure oxygen delivery when they are unable to maintain their own ventilatory or respiratory function. Oxygen is the most commonly prescribed gas in the critical care environment. See Chapter 10 for detailed information on oxygen delivery systems and nursing responsibilities.

BOX 55-1 Causes of Respiratory Failure

Hypoxemic respiratory failure (too little oxygen reaches the tissues):

- Anemia
- Hemorrhage
- Intracardiac shunts
- Acute respiratory distress syndrome (ARDS)

Ventilatory respiratory failure (too little oxygen is exchanged for carbon dioxide):

- Airway obstruction (chronic bronchitis, emphysema, cystic fibrosis)
- Weakness of breathing (acute intoxication, obesity with sleep apnea)
- Muscular weakness (spinal cord injury, muscular dystrophy)
- Lung disease (pneumonia, pulmonary edema)
- Chest wall abnormalities (scoliosis, severe kyphosis)

Nursing Alert

The nurse considers oxygen a drug, which has benefits and risks. The risks associated with oxygen increase as the FiO_2 increases. Healthy lungs may be able to tolerate FiO_2 levels of less than 60%; however, when lungs are damaged, FiO_2 that exceeds 50% may result in a toxic alveolar O_2 concentration (Tokarczyk, Greenberg, & Vender, 2013). Excessive O_2 concentrations have been associated with acute respiratory distress syndrome (ARDS), injury to the lung parenchyma, retinopathy (premature neonates), and resorptive atelectasis (see Chapter 10) (Reardon, Mason, & Clinton, 2014). Although the benefits of oxygen therapy typically outweigh the risks, the nurse is mindful that every intervention employed has to be evaluated for the risk/benefit balance.

Positive Airway Pressure

As explained by Hess (2013) positive airway pressure machines, whether intermittent or continuous (CPAP), have been used for many years as a method of oxygen delivery in patients requiring assistance with keeping the upper airway open or improving intrathoracic pressure and lung volumes without invasive intubation of the trachea. When initiated for the first time, positive airway pressure is usually started in a highly monitored setting in order to assess for claustrophobia and nausea and vomiting (risk for gastric distention increases with positive pressures above 25 cm H_2O). This therapy requires patient cooperation and spontaneous ventilation, and the patient must also be able to tolerate some periods off the mask in order to eat and drink or perform mouth care and skin assessments. CPAP is most effective when there is a resilient seal around the airway to minimize air leak, but that poses a risk for skin irritation. The nurse assesses pressure areas and provides skin care as needed.

Noninvasive Ventilation

Noninvasive ventilation (NIV) appears similar to the methods of oxygen delivery discussed previously, but it is, in fact, not the same. NIV provides a greater pressure on the inspiratory phase than on expiration, unloading the work of the respiratory muscles and providing complete respiratory support (Hess, 2013).

Intubation and Mechanical Ventilation

Many patients in the ICU will require intubation and mechanical ventilation during their admission. It is hoped that this will be required for only a short time period to assist in supporting the patient's recovery from illness or injury. However, this advanced technology has moved from the acute care arena into chronic care facilities and even homes. Intubation and ventilation allow for:

- Airway protection in the event of neurologic deterioration or acute intoxication
- Airway protection during sedation for testing and procedures
- Airway clearance for those unable to manage their own secretions
- Management of respiratory function during surgery
- Rest for the patient with muscular fatigue
- Increased FIO_2 for the arterially hypoxic patient
- Increased flow and pressure to ensure adequate ventilation.

Caring for a patient on mechanical ventilation has become an integral part of nursing care in critical care and progressive care units. Positive patient outcomes depend on an understanding of the indications for and principles of mechanical ventilation, as well as the goals of therapy.

Nursing Alert

It is important to remember that the right main bronchus is wider, shorter, and more vertical than the left. This physiologic difference may lead to inadvertent intubation of the right lung only. It is essential to listen to both sides of the chest for bilateral breath sounds, mark the correct endotracheal tube (ETT) placement at lip or nares, and monitor for high- and low-pressure alarms.

Types of Ventilators

Today's most commonly used ventilators are programmed to deliver oxygen through positive pressure. The ventilator pushes air into the lungs instead of creating a vacuum or negative pressure to pull air into the lungs when breathing spontaneously. Expiration occurs passively and endotracheal intubation or tracheotomy is necessary. There are three types of positive-pressure ventilators:

- *Time-cycled ventilators:* These terminate inspiration after a preset time. The volume of air the patient receives is regulated by the length of inspiration and the flow rate of the air. These are rarely used in the adult population.
- *Volume-cycled ventilators:* These are the ventilators used most commonly. The volume of air delivered with each inspiration is preset. Once this volume is delivered to the patient, the ventilator cycles off and exhalation occurs passively. The volume of air delivered by the ventilator is relatively constant, ensuring consistent, adequate breaths despite varying airway pressures.

- *Pressure-cycled ventilators:* These deliver a flow of air (inspiration) until it reaches a preset pressure and then cycle off to allow expiration to occur passively. The major limitation is that the volume of air or oxygen can vary as the patient's airway resistance or compliance changes. The tidal volume delivered may be inconsistent (the amount of air inhaled and exhaled with a normal breath).

Ventilator Modes

Volume-Cycled Ventilators

Controlled Mandatory Ventilation. Controlled mandatory ventilation (CMV) delivers a set tidal volume at a set rate. It is used for the patient who is chemically paralyzed and sedated or whose neurologic status has deteriorated to the point that no drive to breathe exists.

Assist Control. Assist control (AC) also delivers a set tidal volume but allows patients to set their own respiratory rate. When they take a breath, they receive the entire preset tidal volume, thus decreasing their work of breathing. If the rate is set high enough, it is essentially the same as CMV.

Synchronized Intermittent Mandatory Ventilation. Synchronized intermittent mandatory ventilation (SIMV) delivers a number of breaths at a preset tidal volume to ensure a minimum number of breaths with an adequate tidal volume. Patients may breathe spontaneously but will receive only the tidal volume they are able to inspire on their own.

High-Frequency Ventilation. High-frequency ventilation (HFV), or oscillating ventilators, deliver very small tidal volumes from 3 to 6 mL/kg or 50 to 80 mL in a range from 60 to over 200 times a minute. This works on the principle of oxygen diffusion gently pulsating throughout the lungs. Patients on this form of ventilation also require sedation.

Pressure-Cycled Ventilators

Pressure Support Ventilation. Pressure support ventilation (PSV) is a mode of ventilation in which the patient breathes spontaneously but uses additional pressure during inspiration to increase airflow through the ventilator tubing and artificial airway. This decreases the work of breathing caused by a narrowed airway. Patients using pressure support are often in the process of being weaned from the ventilator.

Continuous Positive Airway Pressure. Positive air flow is used via the ETT while the patient is on the ventilator (rather than using a mask, as discussed previously). It is also used as a method of decreasing the work of breathing while weaning the patient from the ventilator.

Airway Pressure Release Ventilation. Airway pressure release ventilation (APRV) is a newer mode of assistance that improves alveolar recruitment using pressure. It is essentially BiPAP on the ventilator using inverse ratio ventilation. It allows patients to breathe with the presence of end expiratory pressure in the alveoli, but this pressure is momentarily released to allow for gas release and ventilation.

Inverse Ratio Ventilation. Inverse ratio ventilation (IRV) changes the normal inspiration to expiration ratios of 1 part inspiration to 2 parts expiration (1:2) to a ratio of 1:1 or more than 1:1 up to 1:4. Prolonging the inspiratory time allows alveolar recruitment (more alveoli used during respiration) at lower pressure levels, thus maintains or improves gas exchange at lower levels of PEEP. This is an uncomfortable way of breathing, and patients may need to be sedated.

Ventilator Settings

The primary provider will order individualized ventilator settings for the patient that will include the following:

Rate

The rate is the number of breaths the machine will give each minute.

Fraction of Inspired Air

Each breath will be given with a specified setting for inspired oxygen level, FIO_2. The goal for the FIO_2 is the lowest possible setting to provide adequate partial pressure of oxygen (PaO_2) in the bloodstream without the side effects of high oxygen percentages, such as nitrogen washout and alveolar collapse.

Tidal Volume

The tidal volume (Tv) is the amount of air given in each breath. This is usually between 5 and 7 mL of air per kilogram of body weight. This allows for air flow without overextending and damaging the alveoli. The Tv multiplied by the rate equals the minute volume (Mv). Patients with ARDS are generally managed with a low tidal volume (6 mL/Kg of ideal body weight).

Positive End Expiratory Pressure

The theory behind positive end expiratory pressure (PEEP) is that it mimics the pressure left in the lungs by closure of the glottis, which is now interrupted by placement of an ETT. PEEP is used to keep alveoli open during exhalation, to allow more time for gas exchange, and to increase *functional residual capacity,* or the amount of air in the lungs at the end of expiration. Levels of PEEP above 5 cm H_2O put the patient at risk for alveolar rupture, pneumothorax, and decreased cardiac output via referred pressure counteracting forward blood flow from the heart. The ventilator-induced damage is termed *barotrauma.*

Nursing Management

Nursing care of the patient who is mechanically ventilated requires expert technical skills.

Care is taken to simultaneously assess, intervene upon, and evaluate both the patient and the technology.

Assessing the Patient

The patient's physiologic response to illness or injury and particular indications for

mechanical ventilation will determine the specific ventilator orders. The nurse should continually assess the patient's condition and resulting increase or decrease in ventilatory support required by said condition. For example, a patient with a recent decrease in neurologic function is no longer able to draw spontaneous breaths and will need an increase in the number of breaths provided by the ventilator.

Patients must be able to "allow" the ventilator to perform its function without interference caused by anxiety, biting the ETT, or problems with coughing or increased secretions. If the patient is able to let this happen and coordinate his own breaths with the machine, he is said to have *synchrony* with the ventilator. The nurse must assess the underlying cause of intolerance to mechanical ventilation and remove it in order to promote recovery of respiratory function. Common interventions include sedation, pain control, and adequate suctioning.

Assessing the Equipment

The ventilator needs to be assessed to make sure that it is functioning properly and that the settings are appropriate. While not primarily responsible for the functioning of the ventilator, the nurse is responsible for the patient and, therefore, needs to evaluate how ventilator function affects the patient's overall status.

Ventilator alarms are designed to indicate that the ventilator is unable to deliver what it has been programmed to give the patient or that the patient is unable to tolerate the current settings.

Common problems with the ventilator include:

- Disconnection or kinking of tubing
- Disconnection of tubing from ETT or tracheostomy tube
- Water in the tubing
- Change in air temperature beyond set limits

Common problems with the settings include:

- Limits set too high or too low, especially when exercising or weaning patients

Common problems with the patient include:

- Desynchronized breathing pattern between patient and ventilator
- Biting of the ETT
- Improper placement or inadvertent movement of ETT
- Coughing and/or sputum production interfering with air flow
- Lung or chest cavity fluid and pressure problems, as from congestive heart failure, pulmonary edema, and pneumothorax

Nursing Alert

Pressure limits is one of the ventilator settings with an alarm. Again, either patient condition or the equipment may be the cause of an alarm. Pressure alarms on the ventilator may indicate a dangerous situation. Low-pressure alarms may indicate disconnection from the machine or displacement of the airway.

A high-pressure alarm usually indicates resistance to or obstruction of airflow from biting on the ETT, a kink in the tubing, or something as severe as bronchospasm or pneumothorax.

Preventing and Managing Adverse Effects of Mechanical Ventilation

As with many medical interventions, mechanical ventilation has the potential to cause complications or undesired secondary effects, and the nurse's priority is patient safety via a focus on preventing problems associated with any treatment modalities.

Ventilator-Associated Pneumonia. Currently, in the critical care world, ventilator-associated pneumonia (VAP) is receiving a lot of attention from patient advocacy groups, health care professionals, and regulatory bodies. It is caused by a patient being placed on a ventilator for a period of at least 48 hours whose oral and nasal secretions pooling above the ETT balloon fall into the lungs upon movement of the pliable balloon. Unfortunately, the mechanical ventilator is both a cause and an assistant in the treatment for pneumonia. The bacterium found in patients with VAP is usually *Pseudomonas*, but any infection not present when a person is placed on a ventilator constitutes VAP.

This infection forces the hospital to develop, implement, and monitor a policy for its prevention. The most important intervention for infection control in the ICU remains handwashing and hand rubbing with alcohol-based solutions. Additional measures include avoiding nasal insertion of endotracheal and gastric tubes, monitoring ETT cuff pressure (above 20 cm H_2O is associated with prevention of bacteria leakage around the cuff into the lower respiratory tract), providing mouth care at a minimum of every 4 hours with an antiseptic such as chlorhexidine to maintain mucosal integrity and prevent pooling of secretions, and keeping the head of the patient's bed elevated to at least 30 degrees (Chastre & Luyt, 2016). Refer to Chapter 10 for more details on VAP.

Increased Intracranial Pressure. Upon receiving air, the positive pressure in the chest decreases venous return and may leave a higher volume of blood in the cranium. This can lead to altered LOC.

Altered Mental Status. Anxiety and discomfort from being placed on a ventilator, the frequent care in the form of suctioning, and persistent ventilator alarms can easily lead to sleep deprivation. Sleep deprivation, in turn, can affect changes in mental status and delay healing, as will be discussed further in this chapter.

Decreased Cardiac Output. The higher pressure in the pulmonary tree makes it difficult for blood to return to the heart from other areas of the body. If there is less blood returning, there is less blood to pump back to the body, causing hypotension and lower cardiac output.

Hypervolemia. The decreased pressure sensed by baroreceptors in the aorta may trick the body into believing hypovolemia exists; it reacts by stimulating production of antidiuretic hormone (ADH). Release of too much hormone may cause an overaccumulation of fluid in the vasculature, necessitating diuretics.

Venous Thromboembolism. Ventilated patients are prone to spending more time in bed

due to instability or the practical difficulties of walking around when attached to the ventilator. Pooling of blood in the large veins of the legs (and upper extremities as well) while in bed can lead to clot formation and increase the possibility of pulmonary embolus (PE). With an incidence varying from 10% to 20% among hospitalized patients (Camden & Ludwig, 2014), deep venous thrombosis is an adverse effect with significant morbidity and potential mortality. Prophylaxis in the form of antiembolic stockings, compression boots, range-of-motion (ROM) activity, early mobility, and administration of antiplatelet medications (such as heparin) is advised for all patients who are intubated.

Barotrauma. As the name implies, barotrauma is damage to organs and vessels due to elevated pressures in the thoracic cavity. It is important to remember that this same trauma is possible in the abdominal cavity as well (further details on Abdominal Compartment Syndrome [ACS] are in Chapter 53; Fig. 53-4 details measuring intra-bladder pressure).

Pneumothorax. Pneumothorax is a specific form of barotrauma resulting in the collapse of a lung (it is helpful to compare it to popping an overfilled balloon). Corrective action in the form of a chest tube is often required (Chapter 10 details this complication).

Gastrointestinal Bleeding. It has been found (MacLaren & Campbell, 2014) that most intubated patients develop gastrointestinal damage with up to 5% of these ulcerations causing hemodynamically significant bleeding. Although the reasons remain unclear, it is thought that gut ischemia and reperfusion injury leads to mucosal and/or deep tissue damage in the stomach and duodenum, which leads to ulcers and bleeding. The incidence of GI bleeding has decreased over the last few decades and is largely due to standard administration of proton pump inhibitors (PPIs, such as pantoprazole) or H_2-histamine antagonists (such as ranitidine) in patients with previous or current GI bleeds. Although seen less frequently, the adverse effects of significant bleeding due to stress ulcers cannot be underestimated, and prophylaxis with the medications noted here remains the standard of care. However, recent research reveals that potential harm may be associated with stress ulcer prophylaxis, including increased risk of infectious complications (nosocomial pneumonia and *Clostridium difficile*-associated diarrhea). In addition, for patients with cirrhosis, an increased mortality rate is observed with the use of PPIs (Buendgens, Koch, & Tacke, 2016). Guidelines for intervention are continuously evolving. It is up to the practitioner to keep up with the research findings and to apply the evidence to clinical practice.

Promoting Effective Airway Clearance

The presence of an ETT and continuous positive-pressure ventilation increases the production of secretions, regardless of the patient's underlying condition. Nursing interventions focus on maintaining a clear airway via turning and positioning, meticulous mouth care, and endotracheal/tracheal suctioning as needed.

Promoting Optimal Level of Mobility

The use of a mechanical ventilator limits the patient's mobility. The nurse helps the patient whose condition has become stable to get out of bed and move to a chair as soon as possible. Early mobility and muscle activity are beneficial because they stimulate

respirations and improve patient psychological status. If the patient is unable to get out of bed, the nurse encourages performance of active ROM exercises every 6 to 8 hours. If the patient cannot perform these exercises, the nurse performs passive ROM exercises every 8 hours to prevent contractures and venous stasis.

Promoting Optimal Communication

It is important to develop alternative methods of communication for the patient who is receiving mechanical ventilation. The nurse assesses the patient's communication abilities. Once the patient's limitations are known, the nurse offers several appropriate communication approaches: lip reading (use single key words), pad-and-pencil or erasable slate, communication board, electronic tablet, gesturing, sign language, or electric larynx. Use of a "talking" or fenestrated tracheostomy tube may be suggested to the provider; this allows the patient to talk while on the ventilator. The nurse makes sure that the patient's eyeglasses, hearing aid, sign interpreter, and language translator are available if needed to enhance the patient's ability to communicate.

Promoting Coping Ability

Encouraging the family to verbalize their feelings about the ventilator, the patient's condition, and the environment in general is beneficial. Explaining procedures helps reduce anxiety and familiarizes the patient with ventilator procedures. To restore a sense of control, the nurse encourages the patient to participate in decisions about care as appropriate. The patient may become withdrawn or depressed while receiving mechanical ventilation. It is important to provide diversions. Stress reduction techniques (e.g., a back rub, relaxation measures) help relieve tension and help the patient deal with anxieties and fears about the dependence on the ventilator.

Concept Mastery Alert

While tidal volume and vital capacity both describe the amount of air inhaled and exhaled, tidal volume is used for a normal breath, and vital capacity is used for the maximum amount of air that can be expelled after a maximum inhalation.

Weaning the Patient from the Ventilator

Mechanical ventilation is not a natural condition, and prolonged intubation carries a number of potentially serious side effects; therefore, every effort is made to make the need for this intervention as short as possible, with weaning from the ventilator initiated at the earliest possible time consistent with patient safety. The goal is to get the patient in the most optimal condition to succeed in weaning from the ventilator. While there are many indicators leading a practitioner to believe a patient is ready to wean, the following have proven the most predictive:

- Vital capacity (the maximum amount of air that can be expelled after a maximum inhalation) should be at least 10 mL per kg of body weight.
- Negative inspiratory force (NIF, the ability to take a deep breath and to generate a

cough strong enough to clear secretions; NIF should be at least –20 cm H_2O)

- Tidal volume (amount of air inhaled and exhaled in a normal breath; should be at least 5 mL/kg)
- Minute ventilation (total amount of air inhaled and exhaled in a minute; should be less than 10 L/min)
- Rapid shallow breathing index (RSBI, a ratio determined by the frequency of respirations [breaths per minute] divided by the tidal volume [measured in liters]); an RSBI less than 105 is considered criteria for weaning to extubation, while greater than 120 is considered as predictive of the necessity for ventilator support.

Other criteria to consider include:

- Cardiovascular stability
- Adequate and stable arterial blood gas analysis
- Nutritional support with increasing or normal levels of phosphate, magnesium, and albumin
- Ability to swallow and manage saliva and secretions

ENDOCRINE ISSUES

The endocrine system participates along with the neurologic system to regulate bodily functions, such as growth and development, tissue function, metabolism, and even mood. Disorders of the endocrine system result from the secretion of too much or too little hormone, as well as from too much or too little sensitivity to a particular hormone.

This section covers hormones of particular importance in the critical care environment.

Problems Related to Antidiuretic Hormone

ADH is secreted from the posterior pituitary gland and helps to conserve water in the body. Head trauma and kidney disorders can decrease secretion, while trauma, various cancers, hemorrhage, and infection may lead to excessive secretion of ADH. Decreased secretion leads to diabetes insipidus (DI), while excessive secretion causes syndrome of inappropriate diuretic hormone (SIADH). Recall that DI or SIADH are commonly seen in TBI (see Chapter 45 for further discussion).

Patients at risk for altered ADH secretion should be monitored for neurologic changes as well as volume status via intake and output calculations, serum sodium levels, and serum and urine osmolality. Treatment for increased secretion involves water restriction, saline infusion, and use of demeclocycline, which blocks renal response to ADH. Treatment for decreased secretion is replacement of the hormone via one of the various forms of ADH, more commonly known as *arginine vasopressin.*

Problems Related to Thyroid Hormone

The thyroid gland uses iodine to make thyroxine (T_4) and triiodothyronine (T_3). These hormones are involved in body metabolism, alertness, mood, body temperature, and general energy and oxygen use. Disorders of secretion are viewed in relation to normal function; the trajectory ranges from:

Myxedema coma ↔ Hypothyroidism ↔ Normal function ↔ Hyperthyroidism ↔ Graves disease ↔ Thyroid storm

Critical illnesses, such as cancers and infections, can alter the secretion of these hormones. Metabolism is either adversely increased or decreased at a time when metabolic control is required. Too much hormone results in nervousness, anxiety, hyperthermia, and eventual cardiac failure. Other patients with a history of thyroid disorders or surgery, or those not responding to a range of medical treatments, should have their thyroid hormone levels checked and supplemented, if necessary, to ensure assistance with increased metabolic demands.

Problems Related to Cortisol

Cortisol, secreted by the adrenal glands, is better known as the stress or fight-or-flight hormone. Levels are highest in the morning upon arising, in response to increased activity levels.

Problems related to too little or too much cortisol can be viewed on a continuum from:

Addison disease ↔ Normal function ↔ Cushing disease

At times, the level of this hormone is increased due to factors such as increased and prolonged stress; this leads to impaired cognition, hypertension, decreased thyroid and immune system function, hyperglycemia, and decreased bone density and muscle mass.

More commonly in the ICU, cortisol levels are low due to low perfusion states, infection, or adverse effects of medications. People with low levels of cortisol are unable to mount a physical response to bodily stressors and are likely to have fatigue, lower body temperature, and hypotension. Patients who meet clinical criteria for low cortisol levels are frequently given a cortisol stimulation test to determine if replacement is required to increase the body's metabolic response to illness.

Problems Related to Insulin

The beta cells of the pancreas secrete insulin to help move glucose into the cells to be used as an energy substrate. The majority of people with insulin disorders have type I or type II diabetes mellitus and are at particular risk for acute episodes of hyper- or hypoglycemia with the added stress of a critical illness. Patients with particularly brittle disease may be affected by sugar levels on this continuum:

Hypoglycemia ↔ Normal glucose level ↔ Diabetic ketoacidosis (DKA) or Hyperosmolar hyperglycemic nonketotic syndrome (HHNS), also called hyperglycemic hyperosmolar syndrome (HHS)

Patients with diabetes are frequently admitted to the ICU with complications of their illness, but it is also a disease frequently diagnosed for the first time while hospitalized. All patients admitted to the ICU should have their blood glucose monitored three to four times a day to ensure they are able to maintain their glucose levels below each hospital's prescribed upper limit. For those who are unable to maintain a lower level of glucose, insulin therapy should be initiated according to hospital policy, with frequent monitoring of glucose levels to ensure lower levels without hypoglycemia. The most recent recommendations for insulin therapy target a glucose range of 140 to 180 mg/dL in most patients who are critically ill (Schiffner, 2014).

GASTROINTESTINAL ISSUES

As with oxygen, food and drink becomes a medical prescription in the ICU. It is also regulated by practicalities such as kitchen schedules and nursing time to deliver food to or feed patients.

Nutritional Support

In the critical care unit, nutritional support is required to prevent catabolism of protein stores and provide the necessary elements for healing. The question in the ICU is not whether or not patients should be fed but, rather, when and how. Current trends in feeding lean include early initiation of enteral feedings whenever possible with increases to target energy needs within the first 48 hours of admission (Singer et al., 2014).

Food

Because nature knows best, the optimal method of feeding patients is through oral intake of food and fluids. Specific diets will be altered depending on a patient's diagnoses. These may include altered content (low fat or low salt), altered consistency (soft or pureed), or with altered fluid (fluid restriction). The nurse ensures an environment and physical condition that makes the patient amenable to eating. Prevention of nausea and vomiting, pain relief, and proper positioning in a chair or upright in bed can all increase a person's appetite. At times, smaller more frequent meals consisting of something the patient likes to eat may help increase intake, maintain weight, and provide a diversion from the ICU environment.

Tube Feedings

A percentage of patients have a working GI tract but will not be able to take food orally due to their physiologic condition (dementia with dysphagia) or medical intervention (endotracheal intubation). These patients receive tube feedings. A particular liquid formula is recommended with collaboration of the dietician and medical practitioner. Again, the actual formula will depend upon the patient's diagnosis and current condition. Box 55-2 describes nursing responsibilities for patients receiving tube feedings. Tube feeding pumps deliver the nutrition via a variety of tubes that may include:

BOX 55-2 Caring for Patients Receiving Tube Feedings

With tube feeding patients, the nurse is responsible for:

- Noting that placement has been verified by the medical team via radiography, which is the gold standard for checking tube placement
- Assess patient's tolerance to medication and feeding administration (noting abdominal distention and complaints of abdominal pain, observing for passage of flatus and stool)
- Double-check placement by measurement of tube length, follow institutional procedures which may include assessing the pH measurement of aspirate (remains an area where further research is warranted); listening for air insufflation over the stomach; this method is common, but its accuracy is controversial
- Preventing accidental dislodgement by patient or staff
- Maintaining patency of the tubes

- Monitoring for intolerance to feeding
- Monitoring for constipation and diarrhea

- *Nasogastric tube (NGT):* A tube inserted into the nares and ending in the stomach; used for gastric drainage or feeding (may be inserted orally if recommended)
- *Flexible feeding tube:* A synthetic tube of large or small bore (size) inserted into the nares to the stomach; softer, more flexible than the NGT, without the ability to convert to a drainage tube if needed
- *Postpyloric tube:* A longer variety of the flexible feeding tube that reaches past the stomach into the duodenum, in order to use the small bowel when the stomach has the potential to not tolerate feeding or the risk of aspiration is high
- *Percutaneous endoscopic gastrostomy (PEG) tube:* A tube inserted by the physician directly through the abdominal wall into the stomach; removes the discomfort, potential for accidental dislodgement, and potential for sinus infections caused by nasally inserted tubes
- *Gastrojejunostomy (G-J) tube:* A tube that allows for simultaneous feeding of the small bowel and drainage of the stomach

Nursing Alert
Intolerance to feeding is a complicated issue with consequences for deteriorating nutritional status and aspiration pneumonia. Aspiration of GI contents into the lungs leads to increased morbidity and prolonged hospitalization. Risk factors for aspiration may include decreased mental status, placement of the head of the bed at less than 30 degrees, sedatives, vomiting, and high gastric residual volumes.

Parenteral Nutrition

Unfortunately, there are times when a patient is unable to tolerate enteral feeding and nutritional support must be given intravenously. Total parenteral nutrition (TPN) or central parenteral nutrition (CPN) provides amino acids, dextrose, and fat. Because of its high osmolality, it must be given by a central catheter, such as a triple-lumen or Hickman™ catheter, or by a peripheral IV that terminates in a central vein, such as a PICC line. This type of support is used as a method to supplement or completely replace enteral feeding. However, it has numerous potential consequences, including pneumothorax during catheter insertion, catheter infection (due to high concentration of sugar in the solution), and liver failure. The goal is to use this support for as short a time as possible before returning to enteral feeds and eventually to having the patient provide his or her own oral intake. Partial parenteral nutrition (PPN) may be administered via a peripheral IV because of the solution's lower osmolality. A number of metabolic complications are associated with parenteral nutrition, including hyperglycemia, electrolyte abnormalities, and irritation at the IV site.

TABLE 55-10 Immunonutrition

Element	Effects	Comment
Arginine (conditionally nonessential amino acid)	• Stimulation of growth hormone • Precursor in nitric oxide production • Improves immune function • Reduces healing time of injuries (particularly bone) • Increases muscle mass • Improved insulin sensitivity	Its use in septic patients remains controversial as the effects of sepsis on arginine metabolism or of arginine metabolism on sepsis are unclear.
Glutamine (conditionally nonessential amino acid)	• A substrate for DNA synthesis • Major role in protein synthesis • Primary source of fuel for enterocytes • Precursor for rapidly dividing immune cells, thus aiding in immune function • Regulation of acid–base balance in the kidney by producing ammonium • Alternative fuel source for the brain • Blocks cortisol-induced protein catabolism	It remains unclear whether outcomes are improved via enteral or IV administration.
Omega-3 fatty acids	• Reduced Inflammation • Reduced lipid circulation in the bloodstream • Decreased platelet aggregation • Reduced cytokine production • Improved insulin sensitivity	
Copper	• Increased erythrocyte production • Increased absorption of iron • Maintenance of cytochrome p450 cycle • Vitamin C metabolism	
Selenium	• Maintenance of the cytochrome p450 system • DNA repair	
Zinc	• Increased growth hormone • Increased uptake of insulin • Increased cell division and promotion of wound healing • Treatment of diarrhea	

Immunonutrition

A deficit of nutrients can increase infection rates, length of hospital stay, and mortality. These nutrients are additional supplements to the various methods of feeding. Depending on patient diagnosis and condition, the nutrients in Table 55-10 should be considered.

Slow Motility

For a patient to tolerate feedings, the stomach must empty its contents into the small intestine, where nutrients are actually digested. This emptying is partially regulated by cholecystokinin (CCK) and polypeptide YY (PYY) levels that serve to slow gastric emptying. Unfortunately, it has been found that levels of these substances are elevated during critical illness, causing delayed emptying. Diabetes, gastroparesis (delayed gastric emptying), and slowed gut peristalsis due to pain medications are common causes of slow motility. This slow motility of gastric and intestinal contents can lead to nausea, vomiting, aspiration, and decreased nutritional status, which must be prevented or corrected as soon as possible. Current trends favor the use of promotility drugs, such as metoclopramide and/or erythromycin. It is not yet clear if these medications contribute to improved outcomes, and recommendations may change after future study. Adequate hydration and physical movement also assist in maintaining proper GI function.

If motility cannot be improved, the general consensus dictates movement to small bowel feedings before adding or replacing enteral feeds with parenteral nutrition.

Diarrhea

Diarrhea is frequently seen in the ICU and has been found to be related to enteral therapy, hypoalbuminemia, antibiotic therapy, and sepsis. This makes the issue of diarrhea very difficult as enteral therapy is a treatment for low protein states and antibiotic therapy is required for treatment of overwhelming infections. Once diagnosed, the underlying cause, symptomatology, and potential adverse effects of diarrhea must be addressed and mitigated.

Causes

Enteral Therapy

The use of tube feedings is often required to prevent and treat malnutrition in the ICU. The clinical team needs to evaluate the composition of the prescribed feeding for possible changes required in the fiber or water content or osmolality. Current trends find that continuous feeding via a pump instead of intermittent feeding will decrease the amount of diarrhea. Patient care and testing often require changes of position, transfer, or NPO status, which interrupt feedings because it is considered unsafe to feed a patient while he or she is lying flat during turns and transfers. NPO status for individual medications (Dilantin therapy) or tests also decreases nutritional intake. If possible, nursing needs to plan care in order to limit feeding interruptions. Fewer interruptions in feeding will maintain optimal caloric intake and reduce glucose fluctuations and the risk for diarrhea.

Hypoalbuminemia

Albumin is a protein responsible for maintaining oncotic pressure in the vascular system and, thus, distribution of fluids in the body. Low albumin levels cause water to leave the vasculature and accumulate in other parts of the body, such as the GI tract and tissues.

Antibiotics

The use of antibiotics changes normal gut flora depending upon the sensitivity of bacteria to the prescribed medications. The use of cephalosporins and quinolones is known to place patients at higher risk for overgrowth of *Clostridium difficile*, which forms a covering membrane inside the GI tract. The membrane acts to prevent absorption of fluid and nutrients and causes diarrhea. This particular infection requires yet another antibiotic treatment with metronidazole and vancomycin.

Sepsis

Generalized infections not necessarily specific to the GI tract nonetheless have consequences for this system. Inflammation, cytokine release, and alterations in blood flow and the permeability of GI mucosa have also been found to cause diarrhea.

Symptoms and Adverse Effects

Diarrhea can be uncomfortable, painful, and embarrassing for the patient. It also requires extensive nursing time to keep patients clean and free of complications. The adverse effects of diarrhea are numerous and can impact outcomes. Hemodynamic instability due to fluid

and electrolyte losses needs to be corrected with replacement of IV fluids, electrolytes, and minerals. This prevents cardiac arrhythmias and low perfusion states. Malnutrition due to poor absorption because of diarrhea, at a time when metabolic requirements are elevated, needs intervention with a possible change in feeding formula or supplementation with parenteral nutrition. Fecal contents and even skin cleansers change the normal pH of the skin and can lead to breakdown and the formation of pressure ulcers.

Prevention and Treatment of Diarrhea

The first goal is to prevent diarrhea. The second goal is to stop it as soon as possible if preventative efforts fail. Some of these efforts will be ordered by the provider, with patient response monitored by nursing. Interventions include:

- Change in feeding formula, with higher fiber content or lower osmolality
- Prescription of probiotics, such as *Lactobacillus*, to alter gut flora
- Use of antidiarrheal medications, such as loperamide
- Frequent turning of patient to relieve pressure and enhance evaluation of skin
- Use of skin barrier lotions to prevent contact between skin and fecal contents

Constipation

Patients in the ICU are also at risk for constipation. Incidence varies widely, as do definitions, with levels from 5% to 83% being reported in various studies (Rodrigo & Flávia, 2013). Constipation can be defined as difficulty in or failure to defecate for at least 3 days. Potential causes include decreased fluid intake or hypovolemia, immobility, and side effects of medications such as narcotics. Complications range from mild discomfort and bloating to intolerance to feedings and obstruction and perforation.

Constipation has also been shown to increase bacterial overgrowth and sepsis and is even associated with an increase in the number of days mechanical ventilation is required (Rodrigo & Flávia, 2013). The goal is to prevent constipation via provision of hydration, fiber intake, and the use of pharmacologic agents if prescribed. Various bowel regimens akin to those used in patients with slow motility are employed, including digital extraction of rectal contents, enemas, and suppositories. Once the lower GI tract is cleared, it is possible to provide medication via the upper intestinal tract to clear out fecal contents from areas unreachable by other means.

RENAL ISSUES

Many patients in a critical care unit are either at risk for or have pre-existing renal problems, particularly if they have a history of diabetes or hypertension. Damage to the renal system can be acute, chronic, or acute on chronic. Sources of kidney damage are classified as prerenal, intrarenal, and postrenal (refer to Chapter 27 for further details).

Promotion of Kidney Function

Despite the statistics given previously, many patients admitted to the ICU will have normal kidney function. However, admission to the ICU places patients at risk for kidney dysfunction; therefore, nurses need to monitor urine output and laboratory values such as serum creatinine, blood urea nitrogen, creatinine clearance, and glomerular filtration rates (GFR) in order to ensure continued function or intervene as soon as possible in the event of declining function.

Spontaneous Voiding

The most comfortable method of urinating is to be able to go to the bathroom independently. The ability to do this necessitates functioning kidneys, the mental ability to recognize the need to void, and the physical strength and balance required for mobility. If patients are able to void spontaneously, the nurse should provide them every opportunity to do so. This eliminates the possibility of urinary catheter–related infections. It is important to note, however, that having to go to the bathroom is a very frequent reason for confused patients trying to get out of bed. The practice of toileting patients every few hours prevents the consequences of falls, incontinence, and skin breakdown.

Condom Catheters

Condom catheters are placed on males when they are able to void spontaneously and strict hourly monitoring of urinary output is not required. Additionally, if patients are confused, unable to realize the need to urinate, or lack the ability to use a bathroom or urinal, this provides an alternative to incontinence. Unfortunately, an alternative to condom catheters has not been developed for women.

Urinary Catheters

Urinary catheters are inserted into the bladder by way of the urethra and are used to provide samples of urine for testing, a method of monitoring urine output when concerned with hemodynamic compromise, and as a means for controlling incontinence and skin breakdown. While convenient for staff, urinary catheters are associated with more than 30% of all nosocomial infections in hospitalized patients (Saint, 2014). Standard practice should include aseptic insertion, daily preventative cleaning of the catheter with soap and water, wiping away from the urethra, episodic cleaning after bowel movements as noted previously, maintaining a closed system, ensuring the drainage bag is below the level of the bladder, and proper anchoring of the catheter on the leg to prevent undue strain on it.

According the Centers for Disease Control and Prevention, the most important risk factor for developing a catheter-associated urinary tract infection (CAUTI) is prolonged use of the urinary catheter (2015). Thus the removal of the catheter at the earliest possible time is recommended.

Renal Insufficiency

People with a GFR less than 60 mL/min are said to have renal insufficiency; their ability to filter and excrete metabolic waste products is impaired. Prevention of further deterioration of kidney function is critical. This will include hemodynamic support to maintain blood flow, as the kidneys require up to 20% of the cardiac output. Additionally, the medical team and pharmacists have to evaluate drug dosages because the clearance of medications is impacted by renal excretion. Patients requiring IV contrast for radiographic studies are often prescribed "renal protection" in the form of normal saline and medications, such as acetylcysteine, before their studies. Despite all efforts, some patients will progress from renal insufficiency to kidney failure, so the nurse must remain vigilant to deteriorating function.

Kidney Failure

In patients who are critically ill, the development of acute kidney injury (AKI) is associated with a mortality rate of 50% or greater (Kudlow et al., 2014). Therefore, efforts to mimic normal renal mechanisms are accomplished via renal replacement or dialysis until kidney function resumes. Patients with end-stage renal disease (ESRD), also termed end-stage kidney failure, have the option of complete renal replacement for extended periods of time.

Nursing Alert

Acute tubular necrosis (ATN), commonly related to hypoperfusion and/or nephrotoxic agents, is associated with AKI in patients who are critically ill. Therefore the nurse monitors urinary output hourly in patients who are critically ill, assesses the serum peak and trough levels of nephrotoxic medications, and alerts the provider when urinary output is less than 30 mL/hr (or 0.5 to 1 mL/kg/hr) and/or abnormal peak and trough levels are seen.

Renal Replacement

Renal replacement is accomplished via hemodialysis, peritoneal dialysis, or kidney transplant through either cadaver or living donation. Dialysis can be provided for a short period of time, to allow the kidneys time to recover from an acute injury such as ATN; as a bridge to renal transplantation; or on a permanent basis. Other indications for starting renal replacement therapy include:

- Uremic encephalopathy: Confusion, asterixis, and seizures
- Pericarditis
- Bleeding
- Fluid overload unresponsive to diuretics
- Pleuritis
- Metabolic derangements: Metabolic acidosis, hyperkalemia, hyperphosphatemia, hyper- or hypocalcemia
- Protracted nausea and vomiting
- Weight loss or signs of malnutrition
- Overdose of medications/poisons that are dialyzable

Renal replacement therapies are discussed in detail in Chapter 27.

MUSCULOSKELETAL ISSUES

People admitted to critical care units are usually confined to bed for extended periods of time. Neurologic, cardiovascular, and respiratory instability are reasons why patients are restricted to bed rest in the ICU. Sometimes interventions (ICP monitors, balloon pumps) or the desire to prevent the increased oxygen demands of movement (heart failure, respiratory insufficiency) necessitate bed rest. Other reasons for prolonged bed rest include conflicting priorities in the nursing staff ("Do I spend my time with my patient who is actively hemorrhaging, or with the one who needs to get out of bed?"), or lack of knowledge regarding the importance of physical activity. Being in the recumbent position is not a natural state, and prolonged bed rest has a plethora of adverse effects that are outlined in Table 55-11. Deconditioning is seen in patients after as few as 3 days of bed rest. This leads to a decline in overall ability to function and increases the need for admittance into rehabilitation centers after hospitalization. It is important for nurses to be aware of these potential complications and to create the opportunity for movement and limitation of bed rest activity whenever possible.

TABLE 55-11 Effects of Bed Rest

System	Potential Effects
Neurologic	Anxiety Hallucinations
Cardiovascular	Hypovolemia Decreased carotid baroreceptor response Orthostatic hypotension Deep venous thrombosis
Respiratory	Atelectasis Pneumonia Pulmonary Embolus
Gastrointestinal	Ileus Constipation
Genitourinary	Urinary stasis Renal calculi
Endocrine	Insulin resistance Hyperglycemia
Musculoskeletal	Muscular atrophy Bone demineralization Contractures
Skin	Decubitus ulcers
Psychosocial	Depression
Other	Increased catabolism of immunoglobulin G Increased colonization with *Staphylococcus aureus*

From Timmerman, R. A. (2007). A mobility protocol for critically ill adults. *Dimensions of Critical Care Nursing*, *26*(5), 175–179; Rubin, M. (1988). The physiology of bed rest. *The American Journal of Nursing*, *88*(1), 50–58.

ICU-Acquired Weakness

ICU-acquired weakness is an increasingly recognized disorder characterized by the inability of a patient to move against resistance. Witteveena (2015) describes this as a complication associated with increased short- and long-term morbidity and mortality. It encompasses both myopathy and neuropathy with multifactorial causes beyond the scope of this chapter. Patients at risk for this disorder include those with systemic inflammatory response syndrome (SIRS) and sepsis, hyperglycemia, as well as those receiving corticosteroids or neuromuscular blocking agents. Weakness can be difficult to diagnose in the ICU due to confounding issues, such as altered neurologic status, but is often first noticed when patients are unable to be removed from a ventilator. Preventative and rehabilitative measures generally include early identification and treatment of potential causes of multiple organ failure (in particular severe sepsis and septic shock), avoiding unnecessary deep sedation and hyperglycemia, promotion of early mobilization, and thoughtful decisions regarding the risks versus benefits of corticosteroids.

Contractures

Contractures are limitations in ROM of a joint with resultant inability to perform activities of daily living. Dammeyer et al. (2013) note shortening of muscle sarcomeres and the start of contractures begin with just 1 day of bed rest.

Foot drop (Fig. 55-6) is a specific type of contracture defined by the inability to lift the dorsum (anterior surface) of the foot and toes upward (dorsiflexion). It can be caused by neurologic or muscular diseases as well as by inactivity during bed rest. The inability to lift the feet impairs the person's ability to mobilize and improve overall functioning. The use of footboards to maintain dorsiflexion, allowing for some weight bearing by tipping beds forward, and early mobilization in the ICU are recommended nursing interventions.

Nitrogen Wasting

To maintain a healthy state, the body requires equilibrium between the amounts of protein supplied and muscle mass breakdown/turnover. Refer to Box 22-2, Establishing Positive Nitrogen Balance, for further details on attaining and maintaining a positive nitrogen balance. Critical illness often leads to increased requirements at a time when protein is either used for healing or lost at a higher rate due to immobility and/or disease processes.

FIGURE 55-6 Foot drop is a consequence of weakened muscles for dorsiflexion, resulting in permanent plantarflexion. (From Lambert, H. W., & Wineski, L. E. (2010). *Lippincott's illustrated Q&A review of anatomy and embryology* (2nd ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Bone Demineralization

Weight-bearing contributes to calcium uptake by the bones, promoting continued strength and bone formation. When on bed rest, calcium is excreted from the bones at higher levels, while at the same time the patient may be at risk for decreased intake due to anorexia or intolerance to feedings.

Nursing Alert

The variety of ill effects from bed rest demonstrated throughout the literature and in this book should alert every nurse to the need for their patients to move. If out of bed activity is restricted, active/passive ROM should be employed, at a minimum of every shift. It is important to note that while sitting in a chair is helpful, the need to walk is paramount in terms of improving cardiovascular, respiratory, GI, and musculoskeletal status. In short, if allowed, the nurse should encourage and help the patient to get out of bed.

INTEGUMENTARY ISSUES

Admission to the ICU places the patient's skin at risk. Because of decreased mental status or decreased ability to change position, hypoperfusion, fever, immobility, and restraint, a patient may not be able to move in response to discomfort. The state of a patient's skin should be documented on arrival to the unit, in order to follow changes. This documentation also has financial implications as Medicare is no longer reimbursing hospitals for hospital-acquired alterations in skin integrity, such as pressure ulcers.

Planned Medical Breaks in Skin Integrity

Intravenous Lines

The skin is normally one contiguous unit. The simple act of placing a peripheral IV in a patient disrupts skin continuity and serves as a planned medical break in the skin and a potential source of infection. All IV lines should be monitored for signs of infection (erythema [redness], warmth, and discharge at the IV site or an elevated temperature), and lines should be changed according to hospital policy.

Procedures

Minor procedures, such as pacemaker or PEG placement, are other examples of planned medical interventions that require breaks in the skin. Again, infection control is of paramount importance.

Surgery

Surgical procedures interrupt skin and tissue integrity. Postsurgical infections can arise from deep tissue and organs, but surgical incisions require specific care and attention to prevent infection and poor wound healing.

Unplanned Breaks in Skin Integrity

Skin Tears

A majority of patients in the ICU are elderly and are affected by natural changes in the skin. More specifically, there is a flattening of the dermis and increased movement between the dermis and epidermis. When the two are separated, a skin tear occurs. ICU patients are prone to skin tears due to their age, medication history (chronic steroid use), immobility, and altered mental status. ICU patients are also prone to skin tears due to nursing interventions, such as tape removal, as well as due to friction and shear forces when pulling patients up in bed. Protection of the limbs from skin tears requires vigilance and patience on the part of the nurse. This means asking for enough help to turn or move a large patient.

Pressure Ulcers

A pressure ulcer is a localized injury to the skin and/or underlying tissue, usually over a bony prominence, as a result of pressure alone or pressure in combination with shear and/or friction. These breaks in the skin can progress from the skin to subcutaneous tissue and bone. Because muscle and subcutaneous tissue are more susceptible to pressure-induced injury than skin, pressure ulcers are often worse than their initial appearance. Pressure ulcers are staged to guide clinical description of the depth of observable tissue destruction (see Chapter 52). Beinlich and Meehan (2014) state that these wounds cost the Medicare system up to 3.6 billion dollars each year. Box 55-3 provides risk factors for pressure ulcer development.

BOX 55-3 Risk Factors for Pressure Ulcer Development

- Malnutrition
- Hemodynamic instability
- Predisposing diseases, such as diabetes
- Advanced age
- Infection
- Motor/sensory deficits
- Decreased mental status
- Incontinence
- Mobility/activity deficit

Medications, such as sedatives, vasoactive agents, neuromuscular blocking agents

- Contractures
- Spasms

Unfortunately, many patients in critical care have one or more of these risk factors.

Nursing Alert
Nurses hold the vast majority of responsibility for patient skin assessment, frequent turning, and skin care for pressure ulcer prevention. Early identification of and aggressive treatment for such ulcers is required.

See Chapter 52 for pressure ulcer staging and management.

PSYCHOSOCIAL ISSUES

Entry into an ICU is stressful for patients and for their friends and families. Psychosocial issues can also play a part in the reason for ICU admission. Addiction to legal or illegal drugs, violence, and reckless behavior can all lead to serious accidents and illnesses. Nurses must always consider the possible psychosocial issues and disruptions that patients and families are confronting.

Fear

Every patient and family should be assessed to determine the presence of psychosocial issues. Fear or apprehension, awe, or anxiety due to perceived danger is a frequent entity in critical care. Patients and families can be afraid of death, permanent disability, and the critical care environment itself, where care of oneself or a loved one is entrusted to strangers. Lack of information regarding the plan of care and prognosis, as well as lack of understanding of the information provided, is also a common cause of fear. Patients who frequently use the call bell or call out for help and family members who are confrontational or demand constant nursing presence in the patient's room provide examples of not coping with the stress of ICU admission. Methods of decreasing fear for patients and families are not complex, yet they require time and patience on the part of nursing staff. Suggestions for allaying fear include:

- Introduction of staff and their roles in caring for the patient
- Explanation of what you are going to do to or with a patient and why
- Allowing family and friends to be present in the room
- Educating patients and families according to needs and desires
- Informing patients and families of progress or failure to progress

Grieving

Grieving is the process of coming to terms with loss: one's impending death, death of a loved one, loss of function and freedom, loss of self-image, and loss of future opportunities. The stages of grief are well defined throughout the literature, and all nurses should be aware of them. People will differ in their coping behaviors, and nurses should help people develop their best coping practices possible. This is a difficult and often time-consuming process. If nurses are unable to spend much time with grieving patients and families, it is imperative to find the patient alternate help: a colleague with more experience with grieving patients, a pastor, a social worker, hospital volunteers, family, or friends.

Violence

Violence in the home and workplace should never be tolerated, but it is a fact that critical care nurses must confront. Patients may have been a victim of past or recent injury. The sad fact is that many nurses can also report being a victim of violence at the hands of their patients. A study by Speroni et al. (2014) found that 76% of nurses experienced violence at the hands of patients and/or visitors. This included intimidation, verbal abuse, threats of physical violence, or actual violence. The nurse's goals are to identify patients at risk for being abused by others in their life, identify patients or families with a potential for violence against hospital staff, and establish a zero-tolerance workplace violence policy across the nation.

Patient Safety

Many people live with violence in their home, either through neglect or outright physical abuse. The elderly requiring significant time and resources from family members may be at increased risk for abuse as others become frustrated with their increasing disabilities. Assessing for a history of past injuries or evidence of current injury with appropriate referrals is warranted.

Patients with suicidal ideation also need to be protected in the acute care setting. This may include:

- A provider's order for one-to-one observation at all times
- A provider's order for chemical or mechanical restraint
- Removal of dangerous objects in the room
- Limit-setting and negotiation with the patient
- Family and/or friend intervention as appropriate

Staff Safety

Patients at risk for harming staff members require specific interventions:

- Notification of security and administration of the potential for violence
- Keeping the patient in view at all times
- Approaching the patient with a calm but firm demeanor only with support from colleagues (and security as required)

END-OF-LIFE ISSUES

The critical care nurse will encounter many patients of various ages who are facing the ends of their lives.

Some of these deaths are unexpected, while others are anticipated. Each critical care nurse needs to be aware of his or her patient's medical prognosis and the patient's and family's response to a poor prognosis. Coping mechanisms will vary widely and range from sitting vigil by the patient to avoidance. An important component of care is providing patients with realistic information about their prognosis and end-of-life care while providing emotional support as they adjust to the idea of death.

Unexpected Death

Society expects that young people will not die. Sadly, accidents, suicides, and illness do claim young lives. This requires nurses to be cognizant of these issues and support patients and families through anger, denial, and the other stages of grief. A number of studies have demonstrated that being with the patient at the end of life is important for many, and those who request it should have someone present whenever they wish—including during resuscitation efforts.

If there is to be any solace in the death of a young or relatively young person, it can be found in the arena of organ and tissue donation. Patients who meet the criteria for past health and current diagnosis of brain death are eligible to donate organs to those on the various transplant lists. This places nurses in a difficult position at times due to their simultaneous obligations to care for a particular patient and their family while informing organ donation services of a potential donor. When the diagnosis of brain death is made, it is usually up to the senior medical staff and organ procurement services to approach the family about the possibility of organ donation.

Expected Death

Patients with a severe chronic illness or those of an advanced age have most likely had a number of experiences with the health care system and may be somewhat more mentally and emotionally prepared for death. ICU nurses need to be aware of their patients' advanced directives and living wills in order to advocate for their wishes during hospital care. These patients may have placed limits on what treatments they will allow in the event they can no longer speak for themselves, and nurses need to support these wishes or changes in those wishes. At this stage of their patient's life, nurses can provide the means to make the patient as comfortable as possible while allowing family and friends to come to terms with the impending loss of a loved one.

OTHER ISSUES

Sleep

Sleep is an essential bodily function, with significant impact on recovery from illness. Critical care patients are known to become sleep deprived due to their illness, ICU admission, pain, medical procedures, and nursing care. No matter the cause, sleep deprivation has been associated with adverse effects in the ICU. A study by Weinhouse (2014) indicated lack of sleep to be a major and memorable stressor for those discharged from an ICU.

Nursing care interferes with patients' ability to move through the stages of sleep toward rapid eye movement (REM), the deepest form of sleep. It requires an average of 90 minutes to reach REM sleep. How often is a patient left comfortable and undisturbed for at least 90 minutes in an ICU? The answer is not often enough.

A number of interventions may assist in promoting sleep:

- Clustering care
- Adequate pain relief
- Ensuring synchrony with the ventilator
- Noise and light reduction
- Day and night routines
- Sleep-promoting medications, such as melatonin
- Relaxation therapy, massage, and white noise
- Alarm limits (set limits appropriate to the individual patient, to minimize nuisance alarms)

Falls

It has been estimated that up to 84% of hospital adverse events are related to patient falls (Aranda-Gallardo et al., 2013). It is also noted that 30% of patient falls lead to injury of which up to 6% lead to serious injury or death (Aranda-Gallardo et al., 2013). Despite the implementation of fall prevention programs, research reveals little impact on decreasing fall rates while a patient is hospitalized. Ideally, the only way to prevent falls is to have a mentally and physically strong enough person be with each patient at all times; something not financially feasible for most hospitals. Realistically, what can be done is to identify risk factors for falling and arrange the care environment as well as possible to reduce the possibility of falls occurring (Table 55-12).

TABLE 55-12 Minimizing Falls

Risk Factors	Nursing Interventions to Decrease Risk for the Individual
History of falls	• Identify the patient as being at risk for falls. • Implement fall protocol.
Fear of falling	• Encourage patient to verbalize feelings. • Institute physical therapy consult to help patient demonstrate their ability to move safely.
Bowel and bladder incontinence	• Implement toileting routine. • Monitor bowel function to prevent diarrhea and constipation.
Cognitive impairment	• Evaluate patient for reversible causes of cognitive impairment/delirium and eliminate causes as possible. • Institute close observation by placing patient in view of nursing staff. • Start one-to-one observation. • Use monitoring devices, such as bed and chair exit alarms.
Mood	• Encourage verbalization of feelings. • Evaluate patient's ability to concentrate and learn new information. • Encourage engagement in daily activities. • Provide diversional activity. • Refer to geriatric psychiatry as appropriate.
Dizziness	• Monitor lying, sitting, and standing blood pressures, and continually evaluate for factors contributing to dizziness. • Set up environment to avoid movements that result in dizziness/vertigo. • If diabetic, monitor blood sugars and facilitate interventions to maintain appropriate blood sugars.
Functional impairment	• Encourage participation in personal care activities at highest level (i.e., if possible, encourage ambulation to bathroom rather than use of bedpan). • Refer to physical and occupational therapy as appropriate.
Medications	• Review medications with medical practitioner and determine need for each medication. • Ascertain that medications are being used at lowest possible dosages to obtain desired results.
Medical problems	• Assure patient that medical problems are not a reason to remain in bed and prevent participation in functional activities.
Environment	• Remove furniture if patient can't sit on it and have his or her feet reach the floor. • Remove clutter. • Make sure furniture and any assistive devices used are in good condition. • Make sure lighting is adequate. • *Avoid* the use of four side rails and other forms of restraint.

From Gray-Micelli, D. (2007). Preventing falls in acute care. In E. Capezuti, D. Zwicker, M. Mezey, & T. Fulmer (Eds.), *Evidence-based geriatric nursing protocols for best practice* (3rd ed.). New York: Springer Publishing Company.

Transport of the ICU Patient

Patients who are critically ill are often safest inside the ICU, where staff and equipment are available for monitoring as needed. New technology has led to the availability of an ever-increasing number of tests and interventions that are able to be done at the bedside. This includes portable x-rays, endoscopies, and ultrasounds and even minor surgical procedures, such as tracheostomy and PEG tube placement. However, there are a number of times when a patient will require transportation from the ICU to the operating room or, more frequently, to the radiology department. The radiology department may be required for tests such as computed tomography (CT) scan or intervention such as cardiac stent placement. Intra-hospital movement of patients has long been known to be the cause of adverse effects: pain, increased intracranial pressure, hypotension, arrhythmia, hypoxia, VAP, decreased nutritional intake, hypo- and hyperglycemia, inadvertent disconnection from equipment, and falls.

SBAR (Situation, Background, Assessment, Recommendation)*

NOTE: Pronounced S-BAR and first used by the military to improve the effectiveness of communication between care givers, the SBAR approach is recommended by patient safety experts. SBAR forms vary depending on purpose and setting. Some places use SBAR for giving hand-off situations (when one nurse transfers patient care to another). Some places use SBAR forms like the one below for calling physicians about a problem.

→ **Have the chart in hand before you make the phone call, and be sure you can readily communicate all of the following information.**

S **SITUATION:** Have the chart in hand before you make the phone call, and be sure you can readily communicate all the following: Briefly state the issue or problem: what it is, when it happened (or how it started) and how severe it is. Give the signs and symptoms that cause you concern.

B **BACKGROUND:** Give the date of admission and current medical diagnoses. Determine the pertinent medical history and give a brief synopsis of the treatment to date (eg, medications; oxygen use; nasogastric tube; IVs, code status).

A **ASSESSMENT:** Give most recent vital signs and any changes in the following:

- ❑ Mental status – neuro signs
- ❑ Respirations
- ❑ Pulse – skin color
- ❑ Comfort – Pain
- ❑ GI status (nausea-vomiting-diarrhea, distention)
- ❑ Urine Output
- ❑ Bleeding-Drainage
- ❑ Other: _____

R **RECOMMENDATION:** State what you think should be done. For example:

- ❑ Come see the patient now
- ❑ Get a consultation
- ❑ Get additional studies (eg, CXR, ABG, EKG, CBC, other)
- ❑ Transfer the patient to ICU
- ❑ If the patient doesn't improve
- ❑ How frequent do you want vital signs.
- ❑ If there's no improvement, by when do you want us to call you?

*Data from: Haig, K, Sutton, S. and Whittington, J. (2006). SBAR: A Shared Mental Model for Improving Communication Between Clinicians. *Journal of Quality and Patient Safety*, *32*(3), 167–175. Available: http://www.jcipatientsafety.org/fpfd/psp/SBAR.pdf

Source: R. Alfaro-LeFevre Handouts © 2007–2013 www.AlfaroTeachSmart.com

FIGURE 55-7 SBAR Tool promotes consistent communication. (From Alfaro-LeFevre, R. (2013). *Applying nursing process*. Philadelphia, PA: Lippincott Williams & Wilkins.)

Patients are placed at risk from transport due to decreased number of staff available to the patient, disruptions in continuity of care, decreased ability to monitor patients in places like the magnetic resonance imaging (MRI) suite, and possible adverse effects of the test itself. With these known risks to patient safety, a number of tools and guidelines have been developed to minimize adverse events associated with transport.

One communication tool, often called a "ticket to ride" using the Situation-Background-Assessment-Recommendation (SBAR; see Fig. 55-7), can be used to exchange information about a patient being transferred to the care of another health care professional. This tool ensures that all pertinent information required is up to date and available on one piece of paper as a reference for the person taking charge of the patient's care (AHRQ, 2015).

Transfer from the ICU

Eventually, all patients with some form of recovery will be discharged from the ICU. This usually occurs after morning provider rounds, when it is decided the patient is well enough to leave the unit for a lower level of care, such as a progressive care/step-down unit or other appropriate nursing unit. However, the need for ICU beds in the United States remains high, and many times, the least ill patient in the ICU is transferred later in the day to make room for someone more critically ill. This frequently happens late in the day or at night, when floor nursing staff levels are lower. It has been found that transfer from the ICU later than 6 PM is associated with readmission to the ICU and increased mortality (Dashiell, 2014). While the decision to transfer a patient is a medical and administrative one, nurses must either advocate for their patients to stay in the ICU or put their patients in the best position to do well outside of the ICU. Doing well outside of the ICU is the goal for all patients.

CHAPTER REVIEW

Critical Thinking Exercises

1. You have received a shift report that your patient, who sustained a femur fracture in a motor vehicle accident, is alert and oriented. Upon your initial assessment, you find the patient agitated and confused. What are some possible causes of this change in mental status?

2. Your patient with congestive heart failure is intubated with a pulmonary artery catheter in place. Your catheter measurements are very different from the measurements taken during the last shift. What are some possible reasons for these differences?

3. Your patient, admitted 14 days ago with respiratory failure, is unable to wean from the ventilator. What are possible causes of his inability to wean from this respiratory support?

NCLEX-Style Review Questions

1. A patient who is an IV drug user has had surgery to fix a broken femur after a motor vehicle accident (MVA). She requests morphine sulfate for pain control every hour, although it is ordered for every 3 hours. What is the nurse's most appropriate response?
   a. Tell her she can only have morphine every 3 hours.
   b. Tell her she is making her addiction stronger.
   c. Give her an extra dose of morphine anyway.
   d. Notify the provider of the patient's request for more frequent pain medication.

2. The nurse is caring for a 72-year-old patient admitted with pneumonia and using a nasal cannula. During the first assessment, the nurse finds the O_2 saturation is 87%. What

action will the nurse take first?

a. Continue the physical assessment.
b. Increase oxygen by providing an oxygen mask.
c. Call the provider.
d. Check to see if the oxygen is actually flowing and the tubing is not kinked.

3. A patient, who underwent a total gastrectomy due to cancer, has just arrived from the operating room. The patient has a Salem sump tube (SST; double-lumen NG tube) in place. Care of this patient and the SST tube include which of the following actions? Select all that apply.

a. Placing the SST to low continuous wall suction
b. Frequent and vigorous flushing of the NG tube to ensure patency
c. Placing a sign at the head of the bed reminding staff not to alter the tube's position
d. Ensuring the NG tube is securely taped to the patient's nose and noting measurement in the plan of care
e. Head of bed should be flat to facilitate drainage

4. The nurse knows that the inability to wean from a ventilator is associated with which of the following laboratory or diagnostic studies?

a. Albumin level of 4.0 g/dL
b. Tidal volume of 7 mL/kg
c. Normal sinus rhythm
d. Negative inspiratory force (NIF) of –15 cm H_2O

5. The nurse knows that complications associated with bed rest include which of the following? Select all that apply.

a. Hypertension
b. Constipation
c. Decubitus ulcer
d. Kidney stones
e. Venous stasis

CHAPTER 56

Nursing Management: Emergencies and Disasters

Deborah S. Adelman

Learning Objectives

After reading this chapter, you will be able to:

1. Discuss priority emergency measures instituted for any patient with an urgent condition.
2. Describe primary and secondary survey content and assessment of the emergency patient.
3. Discuss the priorities and assessment of the trauma patient.
4. Describe the fundamental elements of a hospital disaster plan.
5. Discuss how triage in a disaster differs from triage in an emergency.
6. Evaluate the different levels of personal protection and decontamination procedures that may be necessary during an event involving mass casualties or weapons of mass destruction.
7. Identify the effects of chemical and nerve agents, and the decontamination and treatment procedures that are necessary.

The emergency nurse has had specialized education, training, experience, and expertise in assessing and identifying patients' health care problems in crisis situations. The emergency nurse establishes priorities, monitors and continuously assesses patients of all ages who are acutely ill and injured, supports and attends to families, supervises allied health personnel, and teaches patients and families within a time-limited, high-pressured care environment. An additional component of emergency nursing is providing care during disasters, when local resources are overwhelmed.

EMERGENCY NURSING

The nursing process provides a logical framework for problem solving in the emergency department (ED). Patients in the ED have a wide variety of actual or potential problems, and their condition may change constantly. Therefore, nursing assessment must be continuous, and nursing diagnoses must adjust with the patient's condition.

Emergency nursing requires an understanding of triage and assessment and management of common acute disorders and injuries.

FOUNDATIONS OF EMERGENCY NURSING

Triage

Triage is used to sort patients into groups based on the severity of their health problems and the immediacy with which these problems must be treated. All EDs share this characteristic of a hierarchy based on the potential for loss of life. A basic and widely used triage system that was in use for many years consisted of three categories: emergent, urgent, and nonurgent (The ESI Triage Research Team, LLC, 2012; Box 56-1). In this acuity system that was used previously, patients who may have needed many resources yet had a lower acuity need might have been assigned a lower triage level, which did not reflect the care they needed. Additionally, the three-category system did not address issues such as managing patient flow in EDs or issues of overcrowding and wait time, and did not demonstrate consistent reliability and validity.

BOX 56-1 Traditional Triage Acuity System

Three categories:

- *Emergent:* Patients with the highest priority or life-threatening conditions
- *Urgent:* Patients with serious health problems that are not considered immediately life-threatening
- *Nonurgent:* Patients who do not have life-threatening illnesses

A fourth class was incorporated, termed "fast-track," and includes patients that require simple first aid or basic primary care and may be treated in the emergency department or safely referred to a clinic or health provider's office.

A more refined comprehensive triage system has been implemented to incorporate the changes in the use of the ED for both emergency and routine health care. The most effective triage systems are simple and require no complex scoring methodology. A four-level system is commonly used in the United States:

1. Immediate (I—red): Patients have life-threatening injuries that probably are survivable with immediate treatment. Examples are tension pneumothorax, respiratory distress, major external hemorrhage, and airway injuries. Ideally, with limited resources, the only patients categorized as red will be those who would benefit from immediate short-duration treatment and then could be retriaged as yellow.
2. Delayed (II—yellow): Patients require definitive treatment, but no immediate threat to life exists. Patients can wait for treatment without jeopardy. Examples include minor extremity fractures, laceration with hemorrhage controlled, and burns over less than 25% of body surface area.
3. Minimal (III—green): Patients have minimal injuries, are ambulatory, and can self-treat or seek alternative medical attention independently. Examples include minor

lacerations, contusions, and abrasions.

4. Expectant (0—black): Patients have lethal injuries and usually will die despite treatment. Examples include devastating head injuries, major third-degree burns over most of the body, and destruction of vital organs. Retriage of this group may be done as resources become available (Starr, Allen, & Stewart, 2011).

The increased number of triage levels assists the triage nurse to more precisely determine the needs of the patient and the urgency for treatment. There are alternative triage systems that are used in the United States, therefore the nurse should follow institutional policies. For example, the Emergency Severity Index (ESI) has been endorsed by the American College of Emergency Physicians and the Emergency Nurses Association; it is a five-level triage algorithm that considers the patient's clinical presentation, vital signs, and the amount and type of resources (examples include laboratory, IV hydration, radiologic studies, simple or complex procedures, medications, consultation, etc.) needed to treat the patient (The ESI Triage Research Team, LLC, 2012). Nurses in the triage area collect baseline data: full vital signs including pain assessment, history of the current event and medical history, current medications, brief behavioral/mental status assessment, height, weight, allergies, and system review with a focus on the presenting complaint and clinical presentation. These data are recorded for reference by all health care team members treating the patient. Common assessment data are outlined in Box 56-2.

Primary and Secondary Surveys

A systematic approach to effectively establishing and treating health priorities is the primary survey/secondary survey approach. The primary survey focuses on stabilizing life-threatening conditions. The ED staff work collaboratively and follow the CABD (circulation, airway, breathing, disability) method:

- Evaluate and restore cardiac output by controlling hemorrhage, preventing and treating shock, and maintaining or restoring effective circulation, including the prevention and management of hypothermia.
- Establish a patent airway.
- Provide adequate ventilation, employing resuscitation measures when necessary. Protection of cervical spine in trauma patients is mandatory when ventilating and resuscitation measures are needed.
- Determine neurologic disability by assessing neurologic function using the Glasgow Coma Scale (see Box 45-6 in Chapter 45). Evaluate for spinal cord injury if indicated.

BOX 56-2 Data Collected by the Triage Nurse

- Patient's presenting complaint of illness or injury
- Level of pain
- Level of consciousness
- Circumstances, precipitating events, location, and time of the injury or illness
- Treatment of injury or illness prior to arrival in the emergency department (ED)
- Method of arrival to ED
- Physician or health practitioner seen for nonemergent care
- Health status prior to injury or illness
- History of medical illness and previous surgeries
- Previous hospitalizations
- Allergies including medications, eggs, latex, nuts, etc.
- Current medications
- Use of recreational drugs
- Smoking history
- Evaluation of immunizations for currency (tetanus)
- Brief assessment of body systems, including behavioral health screening for depression or suicidal ideation
- Last menstrual period (females of childbearing age)
- Time of last meal or oral intake
- Focused assessment on system involved with presenting complaint

- Special circumstances or requests of patient, especially those related to limitations regarding treatments (i.e., resuscitation status or refusal of blood products)

After these priorities have been addressed, the ED team proceeds with the secondary survey. This includes the following:

- A complete health history and head-to-toe assessment
- Diagnostic and laboratory testing
- Insertion or application of monitoring devices, such as electrocardiogram (ECG) electrodes, arterial lines, or urinary catheters
- Splinting of suspected fractures
- Cleansing, closure, and dressing of wounds
- Performance of other necessary interventions based on the patient's condition

Unfolding Patient Stories: Carl Shapiro • Part 2

Recall from Chapter 14 Carl Shapiro, who was diagnosed with hypertension and hyperlipidemia during a routine visit to his primary care provider. He arrives in the ED with a blood pressure of 210/110. The nurse discovers that he stopped his antihypertensive medication due to erectile dysfunction. How does the nurse maintain patient privacy in the ED during discussion of personal issues? What topics should be included in an individualized discharge plan to address his concerns, educational needs, and continuity of care when the nurse receives orders for an ACE inhibitor, captopril (Capoten), and discharge home?

Care for Carl and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

CARING FOR LIFE-THREATENING CONDITIONS

Emergency nurses often confront airway obstruction and hemorrhage. These conditions are life-threatening and require immediate intervention to prevent death.

AIRWAY OBSTRUCTION

Acute upper airway obstruction is a life-threatening medical emergency. The airway may be partially or completely occluded. Partial obstruction of the airway can lead to progressive hypoxia, hypercarbia (increased carbon dioxide levels in the blood), and respiratory and cardiac arrest. If the airway is completely obstructed, permanent brain injury or death will occur within 3 to 5 minutes, secondary to hypoxia. Air movement is absent in the presence of complete airway obstruction. Oxygen saturation of the blood decreases rapidly because the obstructed airway prevents entry of air into the lungs. Oxygen deficit occurs in the brain, resulting in unconsciousness, with death following rapidly.

Causes

Upper airway obstruction has a number of causes, including aspiration of foreign bodies, anaphylaxis, viral or bacterial infection, trauma, and inhalation or chemical burns. For elderly patients, especially those in extended-care facilities, sedatives and hypnotic medications, diseases affecting motor coordination (e.g., Parkinson disease), and mental dysfunction (e.g., dementia, mental retardation) are risk factors for asphyxiation by food. In adults, aspiration of a bolus of meat is the most common cause of airway obstruction. In children, small toys, buttons, coins, and other objects are commonly aspirated in addition to food. Peritonsillar abscesses, epiglottitis, and other acute infectious processes of the posterior pharynx can also result in airway obstruction.

Nursing Alert
The nurse listens for severe stridor (loud, harsh, vibratory sound of variable pitch); if present and the patient has a persistent pulse, suspicion of aspiration of a foreign body or food should be considered. If this is suspected, a Heimlich maneuver (see Box 56-3) may dislodge the obstructing body.

Clinical Manifestations and Assessment

Typically, a person with a foreign-body airway obstruction cannot speak, breathe, or cough. The patient may clutch the neck between the thumb and fingers (this is known as the *universal distress signal*). Other common signs and symptoms include choking, apprehensive appearance, inspiratory and expiratory stridor, labored breathing, use of accessory muscles (suprasternal and intercostal retraction), flaring nostrils, increasing anxiety, restlessness, and confusion. Cyanosis and loss of consciousness develop as hypoxia worsens.

Assessment of the patient who has a foreign object occluding the airway may involve simply asking the person whether he or she is choking and requires help. If the person is unconscious, inspection of the oropharynx may reveal the offending object. X-rays, laryngoscopy, or bronchoscopy also may be required.

If the patient can breathe and cough spontaneously, a partial obstruction should be suspected.

Medical and Nursing Management

For partial obstruction, the patient is encouraged to cough forcefully and to persist with spontaneous coughing and breathing efforts as long as adequate air exchange exists. Oxygen saturation should be monitored to evaluate oxygenation. Supplemental oxygen should be administered. There may be some wheezing between coughs. If the patient demonstrates a weak, ineffective cough, a high-pitched noise while inhaling, increased respiratory difficulty, or cyanosis, he should be managed as if there were complete airway obstruction.

BOX 56-3 Managing a Foreign-Body Airway Obstruction

Heimlich Maneuver (Subdiaphragmatic Abdominal Thrusts)

For conscious patient (sitting or standing):

1. Stand behind the patient and wrap your arms around the patient's waist. If the victim is shorter than the rescuer, the rescuer may kneel behind the victim.
2. Make a fist with one hand.
3. Place the thumb side of the fist against the victim's abdomen, in the midline slightly above the navel and well below the breastbone.
4. Grasp your fist with the other hand and press your fist into the victim's abdomen with a quick upward thrust.
5. Repeat thrusts until the object is expelled from the airway or the victim becomes unresponsive.
6. Give each new thrust with a separate and distinct movement to relieve the obstruction.

   Abdominal thrusts may be performed if the choking victim is responsive and lying down.

Chest Thrusts

For the patient who is conscious and sitting or standing and in advanced stages of pregnancy or markedly obese:

1. Stand behind the patient with your arms under the patient's axillae to encircle the patient's chest.
2. Place the thumb side of your fist on the middle of the patient's sternum, taking care to avoid the xiphoid process and the margins of the rib cage.
3. Grasp your fist with the other hand and perform backward thrusts until the foreign body is expelled or the patient becomes unconscious. Each thrust should be administered with the intent of relieving the obstruction.

Unresponsive Choking, Adult Choking Victim Lying Down

If the choking victim becomes unresponsive, begin the sequence of cardiopulmonary resuscitation (CPR) by calling for support (or activating the emergency response system

in a nonhospital setting). When opening the airway to deliver rescue breaths, open the victim's mouth wide, look for any foreign bodies, and remove any objects that can be seen. Be careful not to push any objects deeper into the airway. A blind finger sweep to search for foreign objects is not recommended. If the airway remains obstructed, reposition head and attempt to deliver rescue breaths a second time. Begin compressions and continue with advanced life support measures.

Adapted from American Heart Association (AHA). (2016). *Part 5: Adult basic life support*. Retrieved July 11, 2015 from http://circ.ahajournals.org/content/122/18_suppl_3/S685.full

After the obstruction is removed, rescue breathing is initiated if the patient has absent or inadequate respiratory effort. If the patient has no pulse, cardiac compressions are instituted. These measures provide oxygen to the brain, heart, and other vital organs until definitive medical treatment can restore and support normal heart and ventilatory activity.

Establishing an Airway

Establishing an airway may be as simple as repositioning the patient's head to prevent the tongue from obstructing the pharynx. Alternatively, other maneuvers, such as abdominal thrusts (also called subdiaphragmatic abdominal thrusts), the head-tilt–chin-lift maneuver, the jaw-thrust maneuver, or insertion of specialized equipment, may be needed to open the airway, remove a foreign body, or maintain the airway. Box 56-3 provides guidelines for performing the Heimlich maneuver and abdominal and chest thrusts. In all maneuvers, the cervical spine must be protected from injury. After these maneuvers are performed, the patient is assessed for breathing by watching for chest movement and listening and feeling for air movement.

The head-tilt–chin-lift maneuver is used only if there is no suspected injury to the cervical spine. It is performed as follows:

- The patient is placed supine on a firm, flat surface.
- If the patient is lying face down, the body is turned as a unit so that the head, shoulders, and torso move simultaneously with no twisting. This requires a minimum of two, preferably three staff members.
- Next, the airway is opened using either the head-tilt–chin-lift maneuver or the jaw-thrust maneuver:
  - In the head-tilt–chin-lift maneuver, one hand is placed on the victim's forehead, and firm backward pressure is applied with the palm to tilt the head back. This will move the tongue forward (away from the back of the throat). The fingers of the other hand are placed under the bony part of the lower jaw (mandible) near the chin, and gently lifted up (Fig. 56-1). The chin and the teeth are lifted so that the teeth are almost brought together.
  - In the jaw-thrust maneuver, after one hand is placed on each side of the patient's jaw, the angles of the patient's lower jaw are grasped and lifted, displacing the mandible forward. This is a safe approach to opening the airway of a patient with suspected neck injury because it can be accomplished without extending the neck.

Oropharyngeal Airway

An oropharyngeal airway is a semicircular tube or tube-like plastic device that is inserted over the back of the tongue into the lower posterior pharynx in a patient who is breathing spontaneously but who is unconscious. This type of airway prevents the tongue from falling back against the posterior pharynx and obstructing the airway. It also allows health care providers to suction secretions. It should be reserved for unconscious patients without gag reflex. A nasopharyngeal airway is tolerated better by patients who are not deeply unconscious, but it should be avoided in patients with craniofacial trauma (Carlson & Wang, 2016). (See Box 56-4.)

FIGURE 56-1 The head-tilt–chin-lift maneuver. (LifeART image (© 2010). Lippincott Williams & Wilkins. All rights reserved.)

Intubation

Endotracheal intubation is used to establish and maintain the airway in patients with respiratory insufficiency or hypoxia. Endotracheal intubation is indicated for the following reasons: (1) to establish an airway for a patient who cannot be adequately ventilated with an

oropharyngeal airway, (2) to bypass an upper airway obstruction, (3) to prevent aspiration, (4) to permit connection of the patient to a resuscitation bag or mechanical ventilator, and (5) to facilitate the removal of tracheobronchial secretions. Because the procedure requires skill, endotracheal intubation is performed only by those who have had extensive training. However, the emergency nurse is commonly called on to assist with intubation (Fig. 56-2).

If the patient is not hospitalized and cannot be intubated in the field, emergency medical personnel may insert an esophagotracheal airway (The ESI Triage Research Team, LLC, 2012). The tube rapidly provides pharyngeal ventilation and is used in conjunction with a bag-valve mask for ventilation. When the tube is inserted into the trachea, it functions like an endotracheal tube (Fig. 56-3).

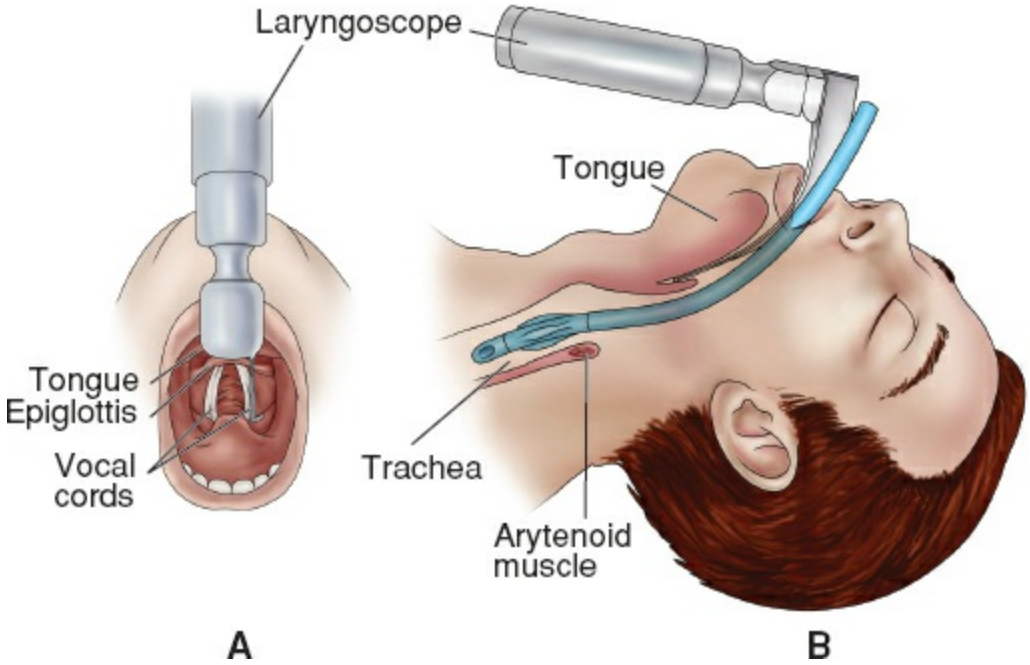

FIGURE 56-2 Endotracheal intubation in a patient without a cervical spine injury. A. The primary glottis landmarks for tracheal intubation as visualized with proper placement of the laryngoscope. B. Positioning the endotracheal tube.

Box 56-4 GUIDELINES FOR NURSING CARE

Inserting an Oropharyngeal Airway

Equipment

- Oropharyngeal airway
- Nonsterile gloves
- Protective eyewear if secretions are profuse or patient is coughing
- Equipment for suctioning

Implementation

ACTION	RATIONALE
1. Insert only in an unconscious patient who does not have a gag reflex with a risk of airway occlusion and no cervical spine injury, oral trauma, or recent oral surgery.	1. An oropharyngeal airway can prevent the tongue from occluding the airway against the posterior pharynx in an unconscious patient. Patients with known or suspected cervical spine injury may require emergent intubation for airway protection and ventilatory support. It is only used in an unconscious patient since vomiting and laryngospasm may be stimulated by the airway in a conscious or semi-conscious patient. Oral trauma, recent oral surgery may be a contraindication to inserting an oropharyngeal airway.
2. Remove dentures if present before insertion.	2. Remove dentures to prevent them from causing an airway obstruction.
3. Measure the oral airway alongside the head. Correct size of the airway should extend from the corner of the mouth to the tip of the earlobe (Reardon, Mason, & Clinton, 2014).	3. Accurate measurement is needed to ensure the airway is appropriately sized to prevent the tongue from occluding the airway.
4. Extend the patient's head by placing one hand under the bony chin. With the other hand, tilt the head backward by applying pressure to the forehead while simultaneously lifting the chin forward. Open the patient's mouth.	4. When positioning the head for insertion, the head may be tilted back *only* if the patient has had the cervical spine cleared. In the patient with a potential cervical spine injury, use only the jaw-thrust maneuver to aid in positioning the head for airway insertion. Position facilitates insertion.
5. (**A**) Insert the oropharyngeal airway with the tip facing up toward the roof of the mouth until it passes the uvula. (**B**) Rotate the tip 180 degrees so that the tip is pointed down toward the pharynx. 	5. This displaces the tongue anteriorly, and the patient then breathes through and around the airway. 6. Ensure the distal end of the oropharyngeal airway is in the hypopharynx and the flange is approximately at the patient's lips. Make sure that the tongue has not been pushed into the airway.	6. An incorrectly placed airway can itself cause airway obstruction by pushing the tongue posteriorly into the hypopharynx.

The two balloons that surround the tube are inflated after the tube is inserted. One balloon is large (100 mL) and occludes the oropharynx. This permits ventilation by forcing air through the larynx. The smaller balloon is inflated with 15 mL of air and can occlude the trachea if it is inadvertently placed there (Sethi, Desai, Tyagi, & Kumar, 2014). Breath sounds are auscultated after balloon inflation to make sure that the oropharyngeal balloon (or cuff) does not obstruct the glottis. The patient can be ventilated through either one of the two ports (e.g., tracheal or esophageal) of the tube, depending on whether the tube is placed in the trachea or esophagus.

Cricothyroidotomy

Cricothyroidotomy is the opening of the cricothyroid membrane to establish an airway. This procedure is used in emergency situations in which endotracheal intubation is either not possible or contraindicated, as in patients with airway obstruction from extensive maxillofacial trauma, cervical spine injuries, laryngospasm, laryngeal edema (after an allergic reaction or extubation), hemorrhage into neck tissue, or obstruction of the larynx.

Maintaining the Airway

After the airway is determined to be unobstructed, the nurse must ensure that adequate ventilation is maintained. Satisfactory management of ventilations may prevent hypoxia and hypercapnia. The nurse must quickly assess for absent or diminished breath sounds as well as difficulty delivering artificial breaths for the patient. The nurse should monitor pulse oximetry, capnography (monitoring of the amount of exhaled carbon dioxide), and arterial blood gases (ABGs) if the patient requires airway or ventilatory assistance.

The nurse is aware that a tension pneumothorax can mimic hypovolemia, so ventilatory assessment precedes assessment for hemorrhage. A pneumothorax or sucking (open) chest wound is managed with a chest tube; immediate relief of the increasing positive intrapleural pressure (normally, the intrapleural pressure is negative) and maintenance of adequate ventilation should occur (refer to Chapter 10 for information on pneumothorax and chest tube insertion and management).

Nursing Alert

Trauma patients are kept on a stretcher to immobilize the spine. A backboard may be used for transporting the patient to the x-ray department, to the operating room, or to the intensive care unit. Cervical spine immobilization is maintained until cervical x-rays have been obtained and cervical spine injury has been ruled out. Ongoing neurologic examinations to assess for spinal cord impairment and change in level of consciousness (LOC) are essential.

HEMORRHAGE

Stopping bleeding is essential to the care and survival of patients in an emergency or disaster situation. Hemorrhage that results in the reduction of circulating blood volume is a primary cause of shock (see Chapter 54). Minor bleeding, which is usually venous, generally stops spontaneously unless the patient has a bleeding disorder or has been taking anticoagulants.

Clinical Manifestations and Assessment

The patient is assessed for signs and symptoms of shock: cool, moist skin (resulting from poor peripheral perfusion), decreasing blood pressure, decreasing pulse pressure, increasing heart rate, delayed capillary refill, and decreasing urine volume. These criteria are associated with an estimated blood loss of approximately 1,500 to 2,000 mL or 30% to 40% of blood volume; the nurse should assess for the earliest symptom of blood loss: increasing anxiety. Refer to Table 56-1 for estimated fluid and blood losses.

Nursing Alert

If the patient is hemorrhaging, the nurse understands that the Trendelenburg position does not improve cardiopulmonary status, and it may predispose the patient to aspiration and worsening pulmonary gas exchange, as well as increasing intracranial pressures. The supine position with passive leg-raising above the level of the heart may be effective. If passive leg-raising results in an increase in blood pressure or cardiac output (CO), then fluid resuscitation is indicated (Nickes & Gaillard, 2016).

Medical and Nursing Management

The goals of emergency management for patients with blood loss are to control bleeding, maintain adequate circulating blood volume for tissue oxygenation, and prevent shock. Patients who hemorrhage are at risk for cardiac arrest caused by hypovolemia with secondary anoxia; therefore, continuous ECG monitoring is expected. Nursing interventions are carried out collaboratively with other members of the emergency health care team.

Fluid Replacement

Whenever a patient is experiencing hemorrhage—whether external or internal—a loss of circulating blood results in a fluid volume deficit and decreased CO. Therefore, fluid replacement is imperative to maintain circulation. Typically, two large-gauge IV catheters are inserted to provide a means for fluid and blood replacement, and blood samples are obtained for analysis, typing, and cross-matching. Replacement fluids are administered as prescribed, depending on clinical estimates of the type and volume of fluid lost. Replacement fluids may include isotonic electrolyte solutions (lactated Ringer's, normal saline), colloids, and blood component therapy.

TABLE 56-1 Classes of Hemorrhagic Shock

Class I Hemorrhage: Loss of up to 15% of Blood Volume (up to 750 mL in 70-kg Adult)	Class II Hemorrhage: Loss of 15–30% of Blood Volume (750–1,500 mL)	Class III Hemorrhage: Loss of 30–40% of Blood Volume (1,500–2,000 mL)	Class IV Hemorrhage: Loss of over 40% of Blood Volume (more than 2,000 mL)
Heart rate (HR) less than 100	HR greater than 100	HR greater than 120	HR greater than 140
Systolic blood pressure (BP) normal	Systolic BP normal	Systolic BP decreased	Systolic BP markedly decreased
Respiratory rate (RR) 14–20	RR 20–30	RR 30–40	RR greater than 35
Increased or normal pulse pressure	Decreased pulse pressure	Decreased pulse pressure	Very narrow pulse pressure
Slight anxiety	Mildly anxious	Significant change in mental status: anxiety or confusion	Depressed mental status: confusion, lethargy, loss of consciousness
30 mL/hr	Small decrease in urine output (20–30 mL/hr)	Marked decrease in urine output (5–15 mL/hr)	Negligible urine output

Adapted from Chan, T. (2014). Hemorrhagic shock. In J. J. Schaider, A. Z. Barkin, R. M. Barkin, R. E. Wolfe, P. Shayne, & S. R. Hayden (Eds.), *Rosen & Barkin's 5-minute emergency medicine consult* (5th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Packed red blood cells (PRBCs) are infused when there is massive blood loss. In emergencies, if typed and cross-matched blood is not available, then reserve type O-negative blood for females younger than 50 years of age; all others should receive type O-positive. In a situation with a patient requiring resuscitation with massive blood loss, there is no time to type and cross-match or type and screen blood. Type O-negative blood provides safe administration of blood immediately without sensitizing an Rh-negative woman to Rh-positive blood (sensitization can result in neonatal complications during a later pregnancy). Promoting homeostasis and restoring tissue oxygenation is necessary as fast as possible. However, PRBCs will not aid greatly in these processes if plasma and

platelets are not also infused.

Once the hemorrhage is controlled, transfusion should cease when the hemoglobin concentration is greater than 10 g/dL (greater than 100 g/L). "Consensus recommendations for transfusion are a hemoglobin concentration between 6 and 7 g/dL (60 to 70 g/L) for those without cardiopulmonary, cerebral, or peripheral vascular disease. [When the hemoglobin is] between 6 and 10 g/dL (60 to 100 g/L), use clinical judgement for transfusion" (Somand & Ward, 2016, para 1). Additional platelets and clotting factors are given when large amounts of blood are needed because transfused PRBCs are deficient in clotting factors. These additional products are given based on the results of coagulation studies that suggest a platelet or clotting deficiency.

Controlling Blood Loss

If a patient is hemorrhaging externally (e.g., from a wound), a rapid physical assessment is performed as the patient's clothing is cut away in an attempt to identify the area of hemorrhage. Direct, firm pressure is applied over the bleeding area or the involved artery at a site that is proximal to (above) the wound (Fig. 56-4). Most bleeding can be stopped or at least controlled by application of direct pressure. Otherwise, unchecked arterial bleeding results in death. A firm pressure dressing is applied, and the injured part is elevated to stop venous and capillary bleeding if possible. If the injured area is an extremity, the extremity is immobilized to control blood loss.

Nursing Alert

In the event of amputated fingers or extremities, the nurse is aware that the body part should be wrapped with a moist, sterile, protective dressing, placed in a waterproof bag, and then placed in a container of ice water for preservation in the event that future reattachment is possible (Singer & Hollander, 2016). It is important to note that the amputated limb should never be placed in ice or water directly as serious cellular damage may occur.

A tourniquet is applied to an extremity only as a *last resort* when the external hemorrhage cannot be controlled in any other way and immediate surgery is not feasible. Care must be taken when applying a tourniquet because of the risk for loss of the extremity. The tourniquet is applied just proximal to the wound and tied tightly enough to control arterial blood flow. Documentation of the application of the tourniquet is critical so that all providers are aware of the time and placement; suggestions include flow sheet documentation, use of a skin-marking pencil or adhesive tape on the forehead with a "T," labeling the location of the tourniquet and application time. If there is no arterial bleeding, the tourniquet is removed and a pressure dressing is applied. In general, tourniquets should not be used for more than 30 minutes (Singer & Hollander, 2016). If the patient has suffered a traumatic amputation with uncontrollable hemorrhage, the tourniquet remains in place until the patient is in the operating room.

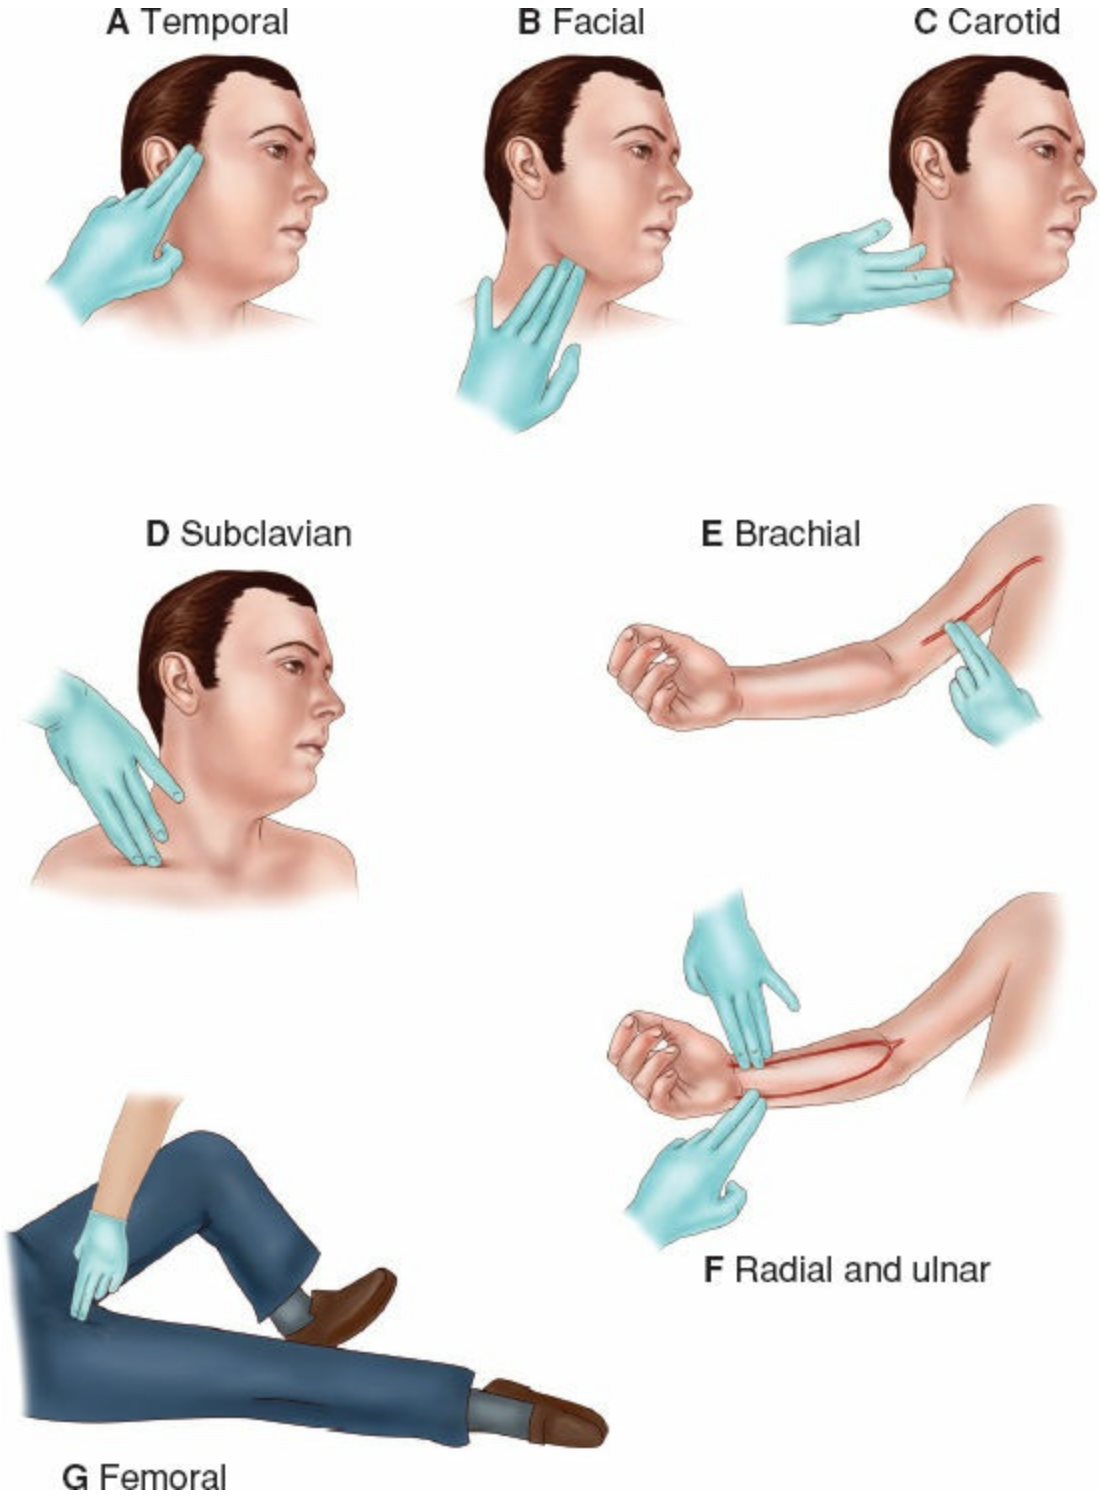

FIGURE 56-4 Pressure points for control of hemorrhage.

If the patient shows no external signs of bleeding but exhibits tachycardia, falling blood pressure, thirst, apprehension, cool and moist skin, or delayed capillary refill, internal hemorrhage is suspected. Typically, PRBCs are administered at a rapid rate, and the patient is prepared for more definitive treatment (e.g., surgery, endoscopy, pharmacologic therapy). In addition, laboratory specimens, including complete blood count (CBC), electrolytes, coagulation studies, type and cross-match, and ABG specimens, are obtained to evaluate pulmonary function and tissue perfusion and to establish baseline hemodynamic

parameters, which are then used as an index for determining the amount of fluid replacement the patient can tolerate and the response to therapy. The patient is maintained in the supine position and monitored closely until hemodynamic or circulatory parameters improve or until he or she is transported for definitive therapy or continued treatment.

Failure to provide adequate fluid resuscitation and definitely control the source of hemorrhage may lead to hypovolemic (hemorrhagic) shock. It is the most common cause of postinjury death and should be suspected in any patient with hypotensive trauma until proven otherwise (Cowell & Moore, 2014). Hypovolemic shock should be anticipated in any emergency situation in which profound blood or fluid (vomiting or diarrhea) loss has occurred. The goals of treatment are to restore and maintain tissue perfusion and to correct physiologic abnormalities. Chapter 54 provides detailed information on the management of hypovolemic shock.

Ongoing nursing surveillance of the *total patient* is maintained. Blood pressure, heart and respiratory rates, skin temperature, color, pulse oximetry, neurologic status, central venous pressure (CVP), ABGs, ECG recordings, hematocrit, hemoglobin, coagulation profile, electrolytes, and urinary output are monitored serially to assess patient response to treatment. Commonly, a flow sheet is used to document these parameters, providing an analysis of trends rather than single values to reveal improvement or deterioration of the patient's condition.

In addition, the body's defense mechanisms are supported. The patient should be reassured and comforted. Sedation may be used judiciously to relieve apprehension. Analgesics are used cautiously to relieve pain. Body temperature is maintained within normal limits to prevent increasing metabolic demands that the body may be unable to meet. Administration of large volumes of IV crystalloids, blood products, or both can result in hypothermia. Hypothermia may be prevented by warming the fluids before they are administered.

CARING FOR TRAUMA

Trauma (an unintentional or intentional wound or injury inflicted on the body from a mechanism against which the body cannot protect itself) is the fourth leading cause of death in the United States (Centers for Disease Control and Prevention [CDC], 2015a). Alcohol and drug abuse are often implicated as factors in both blunt and penetrating trauma.

In assessing and managing any patient with an emergency condition, but especially the patient experiencing trauma, documentation, including descriptions of all wounds, mechanism of injury, and time of events, as well as collection of evidence are essential. In trauma care, the nurse must be exceedingly careful with all potential evidence, handling and documenting it properly.

The basics of care management for patients with traumatic injury include an understanding that trauma in any patient (living or dead) has potential legal or forensic implications if criminal activity is suspected. Hence, proper management from both a medical and forensic perspective is essential. Box 56-5 describes collection of evidence.

BOX 56-5 Collection of Forensic Evidence

When clothing is removed from the patient who has experienced trauma, the nurse must be careful not to cut through or disrupt any tears, holes, blood stains, or dirt present on the clothing if criminal activity is suspected. Each piece of clothing should be placed in an individual paper bag. If the clothing is wet, it should be hung to dry. Clothing should not be given to families. Valuables should be placed in the hospital safe or clearly documented as to which family member they were given. If a police officer is present to collect clothing or any other items from the patient, each item is labeled. The transfer of custody to the officer, the officer's name, the date, and the time are documented.

If suicide or homicide is suspected in a trauma patient who is deceased, the medical examiner examines the body on site or has the body moved to the coroner's office for autopsy. All tubes and lines must remain in place. The patient's hands must be covered with paper bags to protect evidence on the hands or under the fingernails. In the patient who survives, tissue specimens may be swabbed from the hands and nails as potential evidence. Photographs of wounds or clothing are essential and should include a reference ruler in one photo and one photo without the ruler.

Documentation should also include any statements made by the patient in the patient's own words and surrounded by quotation marks. A chain of evidence is essential. If the patient's case is adjudicated in the future, clear documentation assists the judicial process and helps to identify the activities that occurred in the emergency department.

Multiple trauma is caused by a single catastrophic event that causes life-threatening

injuries to at least two distinct organs or organ systems. Mortality in patients with multiple trauma is related to the severity of the injuries and the number of systems and organs involved. Immediately after injury, the body is hypermetabolic, hypercoagulable, and severely stressed.

Care of the patient with multiple injuries requires a team approach, with one person responsible for coordinating the treatment. The nursing staff assumes responsibility for assessing and monitoring the patient, ensuring airway and IV access, administering prescribed medications, collecting laboratory specimens, and documenting activities and the patient's response.

Gross evidence of trauma may be slight or absent. Patients with multiple traumatic injuries should be assumed to have a spinal cord injury until it is proven otherwise. The injury regarded as the least significant in appearance may be the most lethal. For example, the pelvis fracture not identified until an x-ray is obtained may be the injury from which the patient is exsanguinating into the pelvic cavity. Another example is a tension pneumothorax that is insidiously increasing in size, eventually compressing both the heart and lungs, while the ED team is focused on repair of external lacerations. An obvious amputation of the arm may have already stopped bleeding from the body's normal response of vasoconstriction, despite being an obvious and devastating injury; meanwhile, the patient may be dying from an internal, less visible, injury.

The goals of treatment are to determine the extent of injuries and to establish priorities of treatment. Any injury interfering with a vital physiologic function (e.g., airway, breathing, circulation) is an immediate threat to life and has the highest priority for immediate treatment. Essential life-saving procedures are performed simultaneously by the emergency team. As soon as the patient is resuscitated, clothes are usually cut off, and a rapid physical assessment is performed. Transfer from field management to the ED must be orderly and controlled, with attention given to the verbal report from emergency medical services (EMS). Treatment in a level I trauma center is appropriate for patients experiencing major trauma.

WOUNDS

Wounds involving injury to soft tissues can vary from minor tears to severe crushing injuries. The primary goal of treatment is to restore the physical integrity and function of the injured tissue while minimizing scarring and preventing infection. Proper documentation of the characteristics of the wound, using precise descriptions and correct terminology, is essential. Such information may be needed in the future for forensic evidence. Photographs are helpful because they provide an accurate, visible depiction of the wound. Photographs also become important for exigent wounds (wounds that will heal and later be unidentifiable). Patients involved in domestic violence or trauma may need the photographs later to visually describe the extent of injury.

Determining *when* and *how* the wound occurred is important because a treatment delay increases infection risk. Using aseptic technique, the clinician inspects the wound to determine the extent of damage to underlying structures. Visible contamination of the wound increases the risk of wound infection. Additionally, the nurse is aware that bite wounds carry significant risk for infection owing to the high bacterial colonization in the mouth. Sensory, motor, and vascular function is evaluated for changes that might indicate

complications.

Hair around the wound may be clipped if it is anticipated that the hairs will interfere with wound closure. Shaving should be avoided; it may result in an increased incidence of wound infection since many bacteria reside in hair follicles (Tichter, Carter, & Stone, 2016). Complete removal of eyebrow hairs is avoided as regrowth may not occur; clipping eyebrow hair to 1 to 2 mm above the wound is recommended if hair is interfering with wound care.

If indicated, the area is infiltrated with a local intradermal anesthetic through the wound margins or by regional block. Patients with soft tissue injuries usually have localized pain at the site of injury. The nurse then assists the physician, nurse practitioner, or physician's assistant in cleaning and débriding the wound.

Wound cleaning requires the selection of methods that minimize chemical and mechanical trauma to the wound tissue while removing surface debris and contaminants (Slotts, 2015). Typically, the area around the wound is cleansed with normal saline solution or a polymer agent (e.g., Shur-Clens). Antibacterial agents, such as povidone–iodine (Betadine) or chlorhexidine, can be used to paint the intact skin surrounding the wound but should not be allowed to get into the wound since the solutions are associated with decreasing defense mechanisms and thus increase the risk of wound infection. With the emergence of antibiotic resistance, some researchers call for a reappraisal of the use of antiseptic solutions especially in the management of contaminated and infected wounds (Queirós et al., 2013). At present, a standardized regimen for wound cleaning has yet to be established. Nurses should refer to their facility's protocol.

To decrease the incidence of wound infection, the nurse anticipates both the use of wound irrigation and débridement of dead wound tissue. The wound will be irrigated gently and copiously with sterile isotonic saline solution to remove surface dirt. Approximately 50 to 100 mL of saline irrigation per 1 cm of laceration is considered as a general guideline (Nicks, Ayello, Woo, Nitzki-George, & Sibbald, 2010). The nurse ensures that the personal protective equipment (PPE) of face shields is utilized. Devitalized tissue and foreign matter are removed by the physician because they impede healing and may encourage infection. Any small bleeding vessels are clamped or tied. Alternatively, hemostasis of small bleeding vessels is achieved by clamping, tying, or cauterization. After wound treatment, a nonadherent dressing is commonly applied to protect the wound. The dressing may serve as a splint and also as a reminder to the patient that the area is injured.

Nursing Alert

The nurse is aware that irrigation may be high pressure or low pressure. High-pressure irrigation is used to clear debris and support reduction of infection. It is defined as approximately 7 psi (50 kPa) or greater and is achieved using any combination of a 30- to 65-mL syringe and a 19-gauge catheter or needle hub, or commercially available splashguard, with forceful depression of the syringe piston. Conversely low-pressure irrigation is defined as approximately 0.5 psi (3.5 kPa) or lower and is achieved with a slow, gentle wash. Low-pressure irrigation may be useful in simple, nonbite, uncontaminated wounds in highly vascular areas, such as the scalp and face (Tichter et al., 2016).

The decision to suture a wound depends on the nature of the wound, the time since the injury was sustained, the degree of contamination, and the vascularity of tissues. If primary closure is indicated, the wound is sutured or stapled, with the patient receiving either local anesthesia or moderate sedation. Sutures are placed near the wound edge, with the skin edges leveled carefully to promote optimal healing. Instead of sutures, sterile strips of reinforced microporous tape or a bonding agent (skin glue) may be used to close clean, superficial wounds.

Delayed primary closure may be indicated if tissue has been lost or there is a high potential for infection. A thin layer of gauze (to ensure drainage and prevent pooling of exudate), covered by an occlusive dressing, may be used. Other options include split-thickness cadaver allografts or porcine xenografts to simulate the function of epithelium. The wound is splinted in a functional position to prevent motion and decrease the possibility of contracture. Use of antibiotics to prevent infection depends on factors such as how the injury occurred, the age of the wound, the risk of contamination, and the presence of risk factors in the patient's medical history that decrease wound healing (diabetes, steroid use, chemotherapeutic agents, chronic kidney failure, peripheral vascular disease, advanced age, anemia, malnourishment). The site is immobilized and elevated to limit accumulation of fluid in the interstitial spaces of the wound.

Tetanus prophylaxis is administered as prescribed, based on the condition of the wound and the patient's immunization status. If the patient's last tetanus booster was given more than 5 years ago, or if the patient's immunization status is unknown, a tetanus booster must be given. The patient is instructed about signs and symptoms of infection and is instructed to contact the health care provider or clinic if there is sudden or persistent pain, fever or chills, bleeding, rapid swelling, foul odor, drainage, or redness surrounding the wound.

INTRA-ABDOMINAL INJURIES

Intra-abdominal injuries are categorized as penetrating or blunt trauma. Penetrating abdominal trauma (e.g., gunshot wounds, stab wounds) results in a high incidence of injury to hollow organs, particularly the small bowel; thus, they are serious and usually require surgery. The liver is the solid organ that is injured most frequently. In gunshot wounds, the most important factor is the velocity at which the missile (bullet) enters the body. The higher the velocity, the more extensive tissue damage is expected. All abdominal gunshot wounds that cross the peritoneum or are associated with peritoneal signs require surgical exploration. On the other hand, stab wounds may be managed nonoperatively. The nurse accurately documents the location and number of wounds. If abdominal viscera protrude, the area is immediately covered with sterile, moist saline dressings to keep the viscera from drying, and the patient is expected to go directly to the operating room for closure.

Nursing Alert

The nurse is alert for the following signs of peritonitis: guarding or protecting of an exquisitely tender abdominal region and board-like abdominal rigidity. Cough pain is also a marker for peritoneal inflammation: The patient is asked to cough, and if the pain intensifies, it is considered positive for peritoneal involvement (Bickley, 2013).

Blunt trauma to the abdomen may result from motor vehicle crashes, falls, blows, or explosions. Blunt trauma is commonly associated with extra-abdominal injuries to the chest, head, or extremities. Patients with blunt trauma are a challenge because injuries may be difficult to detect. The incidence of delayed and trauma-related complications is greater than that for penetrating injuries. This is especially true of blunt injuries involving the liver, kidneys, spleen, or blood vessels, which can lead to massive blood loss into the peritoneal cavity.

Clinical Manifestations and Assessment

As the history of the traumatic event is obtained, the abdomen is inspected for obvious signs of injury, including penetrating injuries, bruises, and abrasions. Abdominal assessment continues with auscultation of bowel sounds to provide baseline data from which changes can be noted. Absence of bowel sounds may be an early sign of intraperitoneal involvement. Further abdominal assessment may reveal progressive abdominal distention, involuntary guarding, tenderness, pain, muscular rigidity, or rebound tenderness, along with changes in bowel sounds, all of which are signs of peritoneal irritation (refer to Chapter 21 for further details of gastrointestinal [GI] assessment). Hypotension and signs and symptoms of shock may also be noted. Additionally, the chest and other body systems are assessed for injuries that frequently accompany intra-abdominal injuries.

Studies that aid in assessment include the following:

- Urinalysis to detect hematuria (indicative of a urinary tract injury)
- Ultrasound of abdomen to evaluate fluid collection (Focused Assessment with Sonography in Trauma or *FAST*)
- Peritoneal lavage to evaluate abdominal fluid collection
- Radiology and/or computed tomography (CT) scan to evaluate abdominal organ injury, fluid, foreign particles
- Serial hemoglobin and hematocrit levels to evaluate trends reflecting the presence or absence of bleeding; coagulation studies (prothrombin time [PT]; partial thromboplastin time [PTT]; international normalized ratio [INR]); blood typing
- White blood cell (WBC) count to detect elevation (generally associated with trauma)
- Serum amylase analysis to detect increasing levels, which suggest pancreatic injury or perforation of the GI tract

Hemorrhage frequently accompanies abdominal injury, especially if the liver or spleen has been traumatized. Therefore, the patient is assessed continuously for signs and symptoms of external and internal bleeding. The front of the body, flanks, and back are inspected for bluish discoloration, asymmetry, abrasion, and contusion (see Chapter 21 for descriptions of Cullen and Grey–Turner signs). Abdominal CT scans permit detailed evaluation of abdominal contents and retroperitoneal examination. Abdominal ultrasound studies can rapidly assess hemodynamically unstable patients to detect intraperitoneal bleeding. This is referred to as the Focused Assessment for Sonographic Examination in Trauma (FAST) examination.

The nurse suspects hemoperitoneum and splenic injuries if the patient complains of left shoulder pain. This symptom is termed *Kehr sign* and is referred pain due to diaphragmatic irritation associated with the splenic injury or intra-abdominal hemorrhaging. Pain in the right shoulder can result from laceration of the liver. Referred pain is a significant finding because it suggests intraperitoneal injury. The abdomen is assessed for tenderness, rebound tenderness, guarding, rigidity, spasm, increasing distention, and pain. To determine whether there is intraperitoneal injury and bleeding, the patient is usually prepared for

diagnostic procedures, such as abdominal ultrasonography, or abdominal CT scanning. FAST has rapidly replaced diagnostic peritoneal lavage (DPL), owing to its sensitivity (90%), specificity (95%), and accuracy (99%) in determining the presence of intra-abdominal fluid (Jang, 2013; Manthey & Nicks, 2008). Additionally, CT scans, because of their speed and detailed results, have largely replaced DPL in the stable patient. However, peritoneal lavage is useful in assessing hollow organ injury or when serial CT scans cannot be performed, as in patients with severe closed head injury or high spinal cord injury. It involves the instillation of 1 L of warmed lactated Ringer's or normal saline solution into the abdominal cavity. After a minimum of 400 mL has been returned, a fluid specimen is sent to the laboratory for analysis. Positive laboratory findings include a red blood cell count greater than 100,000/mm^3; a WBC count greater than 500/mm^3; or the presence of bile, feces, or food.

In patients with stab wounds, the nurse anticipates that a surgeon will assess whether the peritoneal space has been punctured. Fluid resuscitation may be required, and if perforation is confirmed, exploration in the operating room is expected. The need for tetanus booster will be evaluated, and antibiotics administration is anticipated.

Medical and Nursing Management

As indicated by the patient's condition, resuscitation procedures (restoration of circulation, airway, and breathing) are initiated. Circulating blood volume is maintained with IV fluid replacement, including blood component therapy, and the nurse monitors the patient's vital signs, oxygen saturation, urinary output, and mentation to detect stabilization or evidence of deterioration. A patent airway is maintained, and attempts to stabilize the respiratory, circulatory, and nervous systems are made. Bleeding is controlled by application of direct pressure to any external, bleeding wounds and by occlusion of any chest wounds.

Typically, when the patient presents with intra-abdominal injuries, oral fluids are withheld in anticipation of surgery, and a nasogastric tube may be inserted to decompress the stomach and reduce the risk of aspiration. Tetanus prophylaxis and broad-spectrum antibiotics are administered as prescribed.

Throughout the stay in the ED, the patient's condition is continuously monitored for changes. If there is continuing evidence of shock, blood loss, free air under the diaphragm, evisceration, hematuria, severe head injury, or suspected or known abdominal injury, the patient is rapidly transported to surgery. In most cases, blunt injuries to the liver and spleen are managed nonsurgically.

CRUSH INJURIES

Crush injuries occur when a person is caught between opposing forces (e.g., run over by a moving vehicle, compressed by machinery, crushed between two cars, crushed under a collapsed building).

Clinical Manifestations and Assessment

The patient is observed for the following:

- Hypovolemic shock resulting from extravasation of blood and plasma into injured tissues after compression has been released
- Paralysis of a body part
- Erythema and blistering of skin
- Damaged body part (usually an extremity) appearing swollen, tense, and hard
- Kidney dysfunction (prolonged hypotension causes kidney damage and acute renal insufficiency; myoglobinuria secondary to muscle damage can cause acute tubular necrosis and acute kidney failure). See Chapter 42, Box 42-7 for pathophysiology of rhabdomyolysis.

Medical and Nursing Management

In conjunction with maintaining the patient's circulation, airway, and breathing, the patient is observed for acute renal insufficiency. Injury to the back can cause severe kidney damage. Severe muscular damage may cause rhabdomyolysis, a significant release of myoglobin from ischemic skeletal muscle, which can result in acute tubular necrosis. In addition, major soft tissue injuries are splinted early to control bleeding and pain. Fluid resuscitation, as discussed previously, is expected and—in addition to stabilization of vital signs, urine output, and hemodynamic parameters—the serum lactic acid level may be monitored as a parameter of successful resuscitation. Lactic acid levels are discussed in Chapter 55.

If an extremity is injured, it is elevated to relieve swelling and pressure. To restore neurovascular function, the physician may perform a fasciotomy (surgical incision to the level of the fascia). Refer to Chapter 42 for details on compartment syndrome. Medications for pain and anxiety are then administered as prescribed, and the patient is quickly transported to the operating suite for wound débridement and fracture repair. A hyperbaric chamber (if available) may be used for hyperoxygenation of the crushed tissue, if indicated.

GENITOURINARY INJURY

A rectal or vaginal examination is performed by the primary care provider to determine injury to the pelvis, bladder, or intestinal wall. To decompress the bladder and monitor urine output, an indwelling catheter is inserted after a visual examination of the genitourinary area and rectal examination has been completed (not before). In the male patient, a high-riding prostate gland (abnormal position) discovered during a rectal examination indicates a potential urethral injury. Refer to Chapter 28 for details on genitourinary trauma.

ANAPHYLACTIC REACTION

An anaphylactic reaction is an acute systemic hypersensitivity reaction that occurs within seconds or minutes after exposure to certain foreign substances, such as medications, and other agents, such as latex, insect stings, or foods. Repeated administration of parenteral or oral therapeutic agents (e.g., repeated exposures to penicillin) may also precipitate an anaphylactic reaction when initially only a mild allergic response occurred. See Chapter 38 for the pathophysiology and clinical manifestations of anaphylaxis.

With an anaphylactic reaction, establishing a patent airway and ventilation is essential. This is performed while another person administers epinephrine. Early endotracheal intubation is essential to preserve airway patency, and oropharyngeal suction may be necessary to remove excessive secretions. Resuscitative measures are used, especially for patients with stridor and progressive pulmonary edema. If glottal edema occurs, emergent cricothyroidotomy may be necessary to provide an airway.

Simultaneously with airway management, aqueous epinephrine is administered as prescribed to provide rapid relief of the hypersensitivity reaction. Epinephrine may be

administered again if necessary and as prescribed. Judgment is used in choosing one of the following routes of administration:

- Subcutaneous injection for mild, generalized symptoms
- IM injection when the reaction is more severe and progressive, and with the knowledge that vascular collapse will delay absorption of the medication
- IV route (aqueous epinephrine diluted in saline solution and administered *slowly*), used in rare instances in which there is complete loss of consciousness and severe cardiovascular collapse. This method may precipitate cardiac arrhythmias, so ECG monitoring with a readily available defibrillator is necessary. This method is controversial and is not usually recommended because it can lead to more distress than initially present. An IV infusion of saline solution is initiated to provide for emergency access to a vein and to treat hypotension.

Additional treatments may include the following:

- Antihistamines (e.g., diphenhydramine [Benadryl]) to block further histamine binding at target cells
- Aminophylline titrated by IV drip for severe bronchospasm and wheezing refractory to other treatment
- Albuterol (Proventil, Ventolin) inhalers or humidified treatments to decrease bronchoconstriction; crystalloids, colloids, or vasopressors to treat prolonged hypotension
- Isoproterenol (Isuprel) or dopamine (Intropin) for reduced cardiac output; oxygen to enhance tissue perfusion
- IV benzodiazepines (e.g., diazepam [Valium]) for control of seizures, and corticosteroids (e.g., hydrocortisone [Solu-Cortef]) for prolonged reaction with persistent hypotension or bronchospasm

Depending on the severity of the acute symptoms, the patient may be admitted to the hospital for observation. The patient should be informed about ways to prevent anaphylactic reactions in the future.

Drug Alert!
Epinephrine results in α- and β-adrenergic effects, resulting in vasoconstriction and bronchial smooth-muscle relaxation. Epinephrine works rapidly to reduce throat swelling, open up the airways, and maintain blood pressure in patients. Age is not a barrier to epinephrine IM injections in patients with anaphylaxis (Boyce & Austen, 2015; Rowe & Gaeta, 2016).

CARING FOR POISONING

A poison is any substance that, when ingested, inhaled, absorbed, applied to the skin, or produced within the body in relatively small amounts, injures the body by its chemical action. Poisoning from inhalation and ingestion of toxic materials, both intentional and unintentional, constitutes a major health hazard and an emergency situation. Emergency treatment is initiated with the following goals:

- To remove or inactivate the poison before it is absorbed
- To provide supportive care in maintaining vital organ systems
- To administer a specific antidote to neutralize a specific poison
- To implement treatment that hastens the elimination of the absorbed poison

INGESTED (SWALLOWED) POISONS

Swallowed poisons may be corrosive. Corrosive poisons include alkaline and acid agents that can cause tissue destruction after coming into contact with mucous membranes. Alkaline products include lye, drain cleaners, toilet bowl cleaners, bleach, nonphosphate detergents, oven cleaners, and button batteries (batteries used to power watches, calculators, or cameras). Acid products include toilet bowl cleaners, pool cleaners, metal cleaners, rust removers, and battery acid.

Medical and Nursing Management

Control of the airway, ventilation, and oxygenation are essential. In the absence of cerebral or renal damage, the patient's prognosis depends largely on successful management of respiration and circulation. Measures are instituted to stabilize cardiovascular and other body functions. ECG, vital signs, and neurologic status are monitored closely for changes. Shock may result from the cardiodepressant action of the substance ingested, from venous pooling in the lower extremities, or from reduced circulating blood volume resulting from increased capillary permeability. An indwelling urinary catheter is inserted to monitor kidney function. Blood specimens are obtained to determine the concentration of drug or poison.

Efforts are made to determine what substance was ingested; the amount of the substance; the time since ingestion; signs and symptoms, such as pain or burning sensations, any evidence of redness or burn in the mouth or throat, pain on swallowing or an inability to swallow, vomiting, or drooling; age and weight of the patient; and pertinent health history.

Measures are instituted to remove the toxin or decrease its absorption. Consultation with a Poison Control Center is strongly recommended for definitive antidote and continued monitoring. The patient who has ingested a corrosive poison is given water or milk to drink for dilution. However, dilution is not attempted if the patient has acute airway edema or obstruction or if there is clinical evidence of esophageal, gastric, or intestinal burn or perforation. The following gastric emptying procedures may be used as prescribed:

- Syrup of ipecac to induce vomiting in the alert patient (*never* use with corrosive poisons)
- Gastric lavage for the obtunded patient. Gastric aspirate is saved and sent to the laboratory for toxicology screens.
- Activated charcoal administration if the poison is one that is absorbed by charcoal
- Cathartic, when appropriate

The specific chemical or physiologic antagonist (antidote) is administered as early as possible to reverse or diminish the effects of the toxin. If this measure is ineffective, procedures may be initiated to remove the ingested substance. These procedures include administration of multiple doses of charcoal, diuresis (for substances excreted by the kidneys), dialysis, or hemoperfusion once admitted to an appropriate inpatient setting. Hemoperfusion involves detoxification of the blood by processing it through an extracorporeal circuit and an adsorbent cartridge containing charcoal or resin, after which the cleansed blood is returned to the patient.

Throughout detoxification, the patient's vital signs, CVP, and fluid and electrolyte balance are monitored closely. Hypotension and cardiac arrhythmias are possible. Seizures are also possible because of central nervous system (CNS) excitement from the poison or from oxygen deprivation. If the patient complains of pain, analgesics are administered cautiously. Severe pain causes vasomotor collapse and reflex inhibition of normal physiologic functions.

Patients presenting with ingested poisoning need to be evaluated for accidental ingestion

versus intentional ingestion due to suicide attempt or other psychiatric disturbance. After the patient's condition has stabilized, written material should be given to the patient indicating the signs and symptoms of potential problems related to the poison ingested and signs or symptoms requiring evaluation by the primary care provider.

CARBON MONOXIDE POISONING

Carbon monoxide poisoning may occur as a result of industrial or household incidents or attempted suicide. It is a colorless, odorless gas that is implicated in more deaths than any other toxin except alcohol.

When unintentional carbon monoxide poisoning occurs, the health department should be contacted so that the dwelling or building in question can be inspected. Carbon monoxide exerts its toxic effect by binding to circulating hemoglobin and thereby reducing the oxygen-carrying capacity of the blood.

Clinical Manifestations and Assessment

Because the CNS has a critical need for oxygen, CNS symptoms predominate with carbon monoxide toxicity. A person with carbon monoxide poisoning may appear intoxicated (from cerebral hypoxia). Other signs and symptoms include headache, muscular weakness, palpitation, dizziness, and confusion, which can progress rapidly to coma. Skin color, which can range from pink or cherry-red to cyanotic and pale, is not a reliable sign. Pulse oximetry is also not valid because the hemoglobin is well saturated. It is not saturated with oxygen, but the pulse oximeter only reads whether or not the hemoglobin is saturated; in this case, it is saturated with carbon monoxide rather than oxygen.

Medical and Nursing Management

Exposure to carbon monoxide requires immediate treatment. Goals of management are to reverse cerebral and myocardial hypoxia and to hasten elimination of carbon monoxide. Whenever a patient inhales a poison, the following general measures apply:

- Carry the patient to fresh air immediately; open all doors and windows.
- Loosen all tight clothing.
- Initiate cardiopulmonary resuscitation if required; administer 100% oxygen.
- Prevent chilling; wrap the patient in blankets.
- Keep the patient as quiet as possible.
- Do not give alcohol in any form or permit the patient to smoke.

In addition, for the patient with carbon monoxide poisoning, carboxyhemoglobin levels are analyzed on arrival at the ED and before treatment with oxygen if possible. Oxygen at 100% is administered at atmospheric or preferably hyperbaric pressures to reverse hypoxia and accelerate the elimination of carbon monoxide. Oxygen is administered until the carboxyhemoglobin level is less than 5%. The patient is monitored continuously. Psychoses, spastic paralysis, ataxia, visual disturbances, and deterioration of mental status and behavior may persist after resuscitation and may be symptoms of permanent brain damage.

DISASTER NURSING

The World Health Organization (2015) defines disaster as any man-made or natural event that overwhelms the local community resources. Resources may be required from local, state, and federal agencies. International agency support may be required in cases where extensive intervention is required. Acts of terrorism, warfare, air or rail accidents, pandemic illness, weather-related events, toxic spills, or geologic events such as landslides and earthquakes are examples of some common disaster events that can result in casualties and tax the resources of health care facilities and their communities.

FEDERAL, STATE, AND LOCAL RESPONSES TO EMERGENCIES

When a mass casualty incident (MCI) occurs, the initial review and response occurs at the local level. Local emergency response agencies (including volunteer agencies) are typically the first responders. As the magnitude of the MCI is evaluated and scope of services needed is assessed, the progression to enlist aid from state and then federal resources may be made through official channels. Local and state Offices of Emergency Management coordinate interagency efforts. These organizations maintain a corps of emergency management personnel, including responders, planners, and administrative and support staff. A request for federal resources generally is made when local resources have become or are expected to become depleted due to the magnitude of the event. Federal resources are available through several departments, although the intent is to support local and state efforts rather than assume responsibility for any disaster response. Table 56-2 lists federal resources.

TABLE 56-2 Federal Disaster Resources

Federal Disaster Resources	Type of Support Available
Department of Health and Human Services (DHHS)	
Centers for Disease Control and Prevention (CDC)	Collaborates to create the expertise, information, and tools needed to protect the health of the nation and the world
National Disaster Medical System (NDMS)	Has many medical support teams, such as Disaster Medical Assistance Teams (DMATs), Disaster Mortuary Response Teams (DMORTs), Veterinary Medical Assistance Teams (VMATs), and National Medical Response Teams for Weapons of Mass Destruction (NMRTs)
Department of Justice (DOJ)	
Federal Emergency Management Agency (FEMA)	Provides scene control and collection of forensic evidence
Department of Homeland Security	
Federal Bureau of Investigation (FBI)	Can activate teams such as the Urban Search and Rescue Teams (USRTs)

The Incident Command System (ICS) is the local organization that coordinates personnel, facilities, equipment, and communication in any emergency situation. The ICS has a federal mandate and is an integral part of the National Incident Management System (NIMS). According to the Federal Emergency Management Administration (FEMA, 2015), the ICS can be used at all levels of disaster management to provide a standard management response that organizes and integrates the coordination of response for personnel, facilities, and equipment. It establishes common responses for planning and managing resources at all response levels.

HOSPITAL EMERGENCY PREPAREDNESS PLANS

Health care facilities are required by the Joint Commission to create a plan for emergency preparedness that addresses both internal and external disasters. This plan should be developed with attention to the most likely internal and external disaster potentials. Disaster exercises are required to simulate mass casualty events with participation from multiple agencies.

Components

The Joint Commission has created accreditation standards that cover eight essential areas for disaster operation plans. These emergency management standards include: expectations for plans for managing the consequences of emergencies; development and maintenance of an Emergency Operations Plan; establishing emergency communication strategies; planning for managing resources and assets during emergencies; managing safety and security during emergencies; defining staff roles and responsibilities; establishing strategies for managing utilities during emergencies; and developing strategies for managing patient clinical and support activities during an emergency (Joint Commission, 2012, 2013; McLaughlin, 2014).

Initiating the Disaster Plan

Notification of a disaster situation to a health care facility varies with each situation. In general, the notification to the facility comes from outside sources unless the initial incident occurred at the facility. The disaster activation plan should clearly state how the Emergency Operation Plan (EOP) is to be initiated. If communication is functioning, field incident command will give notice of the approximate number of arriving patients, although the number of self-referring patients will not be known and may impact resource management.

Identifying Patients

Patient tracking is a critical component of casualty management. Disaster tags, which are numbered and include triage priority, name, address, age, location and description of injuries, and treatments or medications given, are used to communicate patient information. The tag should be securely placed on the patient and remain with the patient at all times. The tag number and the patient's name are recorded in a disaster log. The log is used by the command center to track patients, assign beds, and provide families with information.

Triage During Mass Casualty Incidents

In nondisaster situations, health care workers assign a high priority and allocate the most resources to those who are the most critically ill. However, in a disaster, when health care providers are faced with a large number of casualties, the fundamental principle guiding resource allocation is to do the greatest good for the greatest number of people. Decisions are based on the likelihood of survival and consumption of available resources. Therefore, patients with conditions associated with a high mortality rate would be assigned a low triage priority in a disaster situation, even if the person is conscious. Although this may sound uncaring, from an ethical standpoint, the expenditure of limited resources on people with a low chance of survival, and denial of those resources to others with serious but treatable conditions, cannot be justified.

The triage officer rapidly assesses those injured at the disaster scene. Patients are immediately tagged and transported or given life-saving interventions. One person performs the initial triage while other EMS personnel perform life-saving measures (e.g., intubation) and transport patients. Although EMS personnel carry out initial field triage, secondary and continuous triage at all subsequent levels of care is essential.

Staff should control all entrances to the acute care facility so that incoming patients are directed to the triage area first. The triage area may be outside the entry or just at the door of the ED. This allows all patients, including those arriving by medical transport and those who walk in, to be triaged. Some patients already seen in the field may be reclassified in the triage area based on their current presentation.

Triage categories separate patients according to severity of injury. A special color-coded tagging system is used during an MCI so that the triage category is immediately obvious. There are several triage systems in use across the country, and every nurse should be aware of the system used by his or her facility and community. The North Atlantic Treaty Organization (NATO) triage system is one that is widely used and is presented here. It

consists of four colors—red, yellow, green, and black (Table 56-3). Each color signifies a different level of priority, with red representing the most significant but potentially survivable injuries through green representing minor injuries. Black designates "expected" death due to nonsurvivable injuries or patients in whom death appears to be imminent.

Communication with Media and Family

Communication is a key component of disaster management. Communication within the vast team of disaster responders is paramount; however, effective, informative communication with the media and worried family members is also crucial and must be addressed in the organization's disaster plan and communicated to staff.

Although the media have an obligation to report the news and can play a significant positive role in communication, the number of reporters and newscasters and their support teams can be overwhelming, possibly compromising operations and patient confidentiality. A clearly defined process for managing media requests that includes a designated spokesperson, a site for the dissemination of information (away from patient care areas), and a regular schedule for providing updates should be part of the disaster plan.

TABLE 56-3 NATO Triage Categories During a Mass Casualty Incident (MCI)

Triage Category	Priority	Color	Typical Conditions
Immediate: Injuries are life-threatening but survivable with minimal intervention. Individuals in this group can progress rapidly to expectant category if treatment is delayed.	1	Red	Sucking chest wound, airway obstruction secondary to mechanical cause, shock, hemothorax, tension pneumothorax, asphyxia, unstable chest and abdominal wounds, incomplete amputations, open fractures of long bones, and second-/third-degree burns of 15–40% total body surface area
Delayed: Injuries are significant and require medical care but can wait hours without threat to life or limb. Individuals in this group receive treatment only after immediate casualties are treated.	2	Yellow	Stable abdominal wounds without evidence of significant hemorrhage; soft tissue injuries; maxillofacial wounds without airway compromise; vascular injuries with adequate collateral circulation; genitourinary tract disruption; fractures requiring open reduction, débridement, and external fixation; most eye and central nervous system injuries
Minimal: Injuries are minor and treatment can be delayed hours to days. Individuals in this group should be moved away from the main triage area.	3	Green	Upper extremity fractures, minor burns, sprains, small lacerations without significant bleeding, behavioral disorders or psychological disturbances
Expectant: Injuries are extensive, and chances of survival are unlikely even with definitive care. Persons in this group should be separated from other casualties but not abandoned. Comfort measures should be provided when possible.	4	Black	Unresponsive patients with penetrating head wounds, high spinal cord injuries, wounds involving multiple anatomical sites and organs, second-/third-degree burns in excess of 60% of body surface area, seizures or vomiting within 24 hours after radiation exposure, profound shock with multiple injuries, agonal respirations; no pulse, no blood pressure, pupils fixed and dilated

The disaster plan helps prevent the release of contradictory or inaccurate information. Initial statements should focus on current efforts and what is being done to better understand the scope and impact of the situation. Information about casualties should not be released. Security staff should not allow media personnel access to patient care areas.

Friends and family members converging on the scene must be cared for by the facility. They may be feeling intense anxiety, shock, or grief and should be provided with information and updates about their loved ones as soon as possible and regularly thereafter. They should not be in the triage or treatment areas but in a designated area staffed by

available social service workers, counselors, therapists, and/or clergy. Access to this area should be controlled to prevent families from being disturbed.

Emotional and behavioral effects vary among affected people. Factors that influence a person's response to disaster include the degree and nature of the exposure to the disaster, loss of friends and loved ones, existing coping strategies, available resources and support, and the personal meaning attached to the event. Other factors, such as loss of home and valued possessions, extended exposure to danger, and exposure to toxic contamination, also influence response and increase the risk for adjustment problems. Those exposed to the dead and injured, those endangered by the event, the elderly, children, emergency first responders, and health care personnel caring for victims are considered to be at higher risk of emotional sequelae.

Nurses can assist victims of disasters and their families through active listening and providing emotional support, giving information, and referring patients to therapists or social workers. Health care workers must refer people to mental health care services because experience has shown that few disaster victims seek these services and early intervention minimizes psychological consequences. Nurses can also discourage victims from subjecting themselves to repeated exposure to the event through media replays and news articles, and encourage them to return to normal activities and social roles when appropriate.

The Nurse's Role in Disaster Response Plans

The role of the nurse during a disaster varies. The nurse may be asked to perform duties outside his or her area of expertise and may take on responsibilities normally held by physicians or advanced practice nurses. Although the exact role of a nurse in disaster management depends on the specific needs of the facility at the time, it should be clear which nurse or physician is in charge of a given patient care area and which procedures each individual nurse may or may not perform. Assistance can be obtained through the incident command center, and nonmedical personnel can provide services where possible.

New settings and atypical roles for nurses arise during a disaster; for example, the nurse may provide shelter care in a temporary housing area or bereavement support and assistance with identification of deceased loved ones. People may require crisis intervention, or the nurse may participate in counseling other staff members and in critical incident stress management (CISM) (discussed later in this chapter). Special care may be warranted for at-risk populations during a disaster including people who are disabled, elderly, young, pregnant, and members of other vulnerable populations.

Disasters can present a disparity between the resources of the health care agency and the needs of the victims. This generates ethical dilemmas for nurses and other health care providers. Issues include conflicts related to the following:

- Rationing care
- Futile therapy
- Consent
- Duty
- Confidentiality
- Resuscitation

Nurses may find it difficult to not provide medical care to the dying or to withhold information to avoid spreading fear and panic. Clinical scenarios that are unimaginable in normal circumstances confront the nurse in extreme instances. Other ethical dilemmas may arise out of health care providers' instinct for self-protection and protection of their families.

Nurses can plan for the ethical dilemmas they will face during disasters by establishing a framework for evaluating ethical questions before they arise and by identifying and exploring possible responses to difficult clinical situations. They can consider how the fundamental ethical principles of utilitarianism, beneficence, and justice will influence their decisions and care in disaster response. Education and practice of the disaster response plan can assist the nurse in achieving an understanding of the role changes and dilemmas that might impact job performance.

Critical Incident Stress Management

CISM is an approach to preventing and treating the emotional trauma that can affect emergency responders as a consequence of their jobs and that can also occur to anyone involved in a disaster or MCI. CISM is handled by teams trained in the techniques.

Components of CISM plans include defusings, debriefings, demobilization, and follow-up care after the incident. *Defusing* is a process by which the person receives education about recognition of stress reactions and management strategies for handling stress. *Debriefing* is a more complicated intervention; it involves a 2- to 3-hour process during which participants are asked about their emotional reactions to the incident, what symptoms they may be experiencing (e.g., flashbacks, difficulty sleeping, intrusive thoughts), and other psychological ramifications. As an intervention, *demobilization* is usually reserved for large-scale events with large numbers of participants from different disciplines. If separate defusing interventions were attempted for each group, CISM resources might be overwhelmed. Similar to the defusing intervention, responders are presented with information regarding expected stress reactions that they might experience and how to manage them. The responders are also provided an opportunity to rest and eat before returning to their normal, pre-incident routines. In the event of large-scale disasters, it might be appropriate to participate in the demobilization process after each shift of work. In *follow-up*, members of the CISM team contact the participants of a debriefing and schedule a follow-up meeting if necessary. People with ongoing stress reactions are referred to mental health specialists.

PREPAREDNESS AND RESPONSE

As a health care provider, a nurse must be prepared for terrorism and other disasters, which includes awareness of the potential for covert use of weapons of mass destruction (WMD), self-protection, and early detection, containment, or decontamination of substances and agents that may affect others by secondary exposure. The strength of many toxins, today's mobile society, and long incubation periods for some organisms and diseases can result in an epidemic that can quickly and silently spread across the entire country. For example, there must be awareness that a formerly healthy person with a rapid onset of flu-like symptoms can have an ominous illness, such as anthrax or severe acute respiratory syndrome (SARS), both of which are discussed in more detail later in the chapter.

Detection

Health care personnel should have a heightened awareness for trends that may suggest deliberate dispersal of toxic or infectious agents. Some general principles should be considered, such as the following:

- Awareness of an unusual increase in the number of people seeking care for fever, respiratory, or GI symptoms.
- Any clusters of patients presenting with the same unusual illness from a single location. Clusters can be from a specific geographic location, such as a city, or from a single sporting or entertainment event.
- Large number of rapidly fatal cases, especially when death occurs within 72 hours after hospital admission.
- Increase in disease incidence in a normally healthy population. These cases should be reported to the state health department and to the CDC, including information about recent travel and contact with others who have been ill or have recently died of a fatal illness.

Suspicions or findings are reported to the appropriate unit in the facility and to proper authorities in the community. Resources for information can include the infection control department, material safety data sheets (MSDS), the state health department, the CDC, the local poison control center, and many Internet sites. Reporting furnishes data elements to those agencies responsible for epidemiology and response. Reporting also allows for sharing of information among facilities and jurisdictions and can help determine the source of infections or exposure and prevent further exposures and even deaths.

Personal Protection

Preparedness and response involves the protection of the health care provider by additional PPE prior to contact with a patient who is contaminated or infected. The purpose of PPE is to shield health care workers from the chemical, physical, biologic, and radiologic hazards that may exist when caring for contaminated patients. The U.S. Environmental Protection Agency (EPA) has divided protective clothing and respiratory protection into four categories, level A through level D (Box 56-6) (U.S. Environmental Protection Agency [EPA], 2015).

BOX 56-6 Environmental Protection Agency Categories of Protective Clothing and Respiratory Protection

- Level A protection is worn when the highest level of protection for the respiratory system, skin, eye, and mucous membrane is required. This includes a self-contained breathing apparatus (SCBA) and a fully encapsulating, vapor-tight, chemical-resistant suit with chemical-resistant gloves and boots.
- Level B protection requires the highest level of respiratory protection but a lesser level of skin and eye protection than with level A situations. This level of protection includes positive-pressure, full face-piece SCBA or positive-pressure supplied air respirator with escape SCBA, inner and outer chemical-resistant gloves, face shield, hooded chemical-resistant clothing, coveralls, and outer chemical-resistant boots.
- Level C protection requires the air-purified respirator, which uses filters or sorbent materials to remove harmful substances from the air. A chemical-resistant coverall with splash hood, chemical-resistant gloves, and boots are included in level C protection.
- Level D protection is the typical work uniform. Level D protective equipment may include gloves, safety glasses, or a face shield.

Decontamination

Decontamination, the process of removing accumulated contaminants, is critical to the health and safety of health care providers by preventing secondary contamination. The decontamination plan should establish procedures and educate employees about decontamination procedures, identify the equipment needed and methods to be used, and establish methods for disposal of contaminated materials.

Effective decontamination must include a minimum of two steps. The first step is removal of the patient's clothing and jewelry and then rinsing the patient with water. Depending on the type of exposure, this step alone can remove a large amount of the contamination and decrease secondary contamination. Ideally, facilities should identify areas where patients can be decontaminated prior to entering the facility, to prevent accidental contamination of the emergency services area, staff, and other hospital areas and personnel. The second step consists of a thorough soap-and-water wash and rinse. When patients arrive at the facility after being assessed and treated by a prehospital provider, it should not be assumed that they have been thoroughly decontaminated.

NATURAL DISASTERS

Natural disasters may result in mass casualties. Natural disasters can occur anywhere at any time and include events such as tornadoes, hurricanes, floods, avalanches, tidal waves (e.g., tsunamis), earthquakes, and volcanic eruptions. In many cases, preparation prior to the natural disaster is the best-laid plan. In the event of a natural disaster, loss of communications, potable water, and electricity are usually the greatest obstacles to a well-coordinated emergency response. Even wireless technology (e.g., mobile or cellular phones, computers, other communication devices) may not be functional.

The majority of the immediate casualties are trauma-related. These mass casualties tax the trauma system to its limits to provide triage, transport of patients (in poor weather and road conditions), and management within the trauma centers. Electrocution is also a common injury and can result in death.

Excessive exposure to the natural elements and the need for food and water (by both patients and emergency responders) are critical issues. Without cover (e.g., buildings may be unsafe or destroyed) or safe water (e.g., water may be either contaminated or unavailable), injuries from exposure to heat, cold, or contaminated food or water can occur. Safety equipment that protects rescue workers from injury, exposure, and potentially dangerous animals must be readily available. Hypothermia can occur rapidly in workers who are exposed to water at temperatures of 75°F or less. As in all disasters, mental health workers and shelters are needed throughout the community. Veterinary assistance is also essential because frequently pets are abandoned and injured. After floods or water disasters, waterborne transmission of agents such as *Escherichia coli*, salmonella, shigella, typhoid, leptospirosis, malaria, and tularemia are common and cause widespread disease.

In some instances, early warning systems have assisted in decreasing the number of deaths from tornadoes and hurricanes. When buildings collapse, rapid response to identify and remove trapped victims is the only means of improving survivability. There is a direct relationship between time trapped and survival as well as the type of building construction and number of stories of the collapsed structure. Larger-scale issues that can cause significant later morbidity and mortality include the absence of water purification, waste removal, removal of human and animal remains, and vector control. Removal or disposal of biologic, chemical, and nuclear agents must also be considered.

BIOLOGIC AGENTS

Biologic weapons are weapons that spread disease among the general population or the military as part of biologic warfare. Biologic agents are delivered in either a liquid or dry state, applied to foods or water, or vaporized for inhalation or direct contact. Vaporization may be accomplished through spray or explosives loaded with the agent. Because of increases in business and pleasure travel by people in industrialized nations, an agent could be released in one city and affect people in other cities thousands of miles away. The vector can be an insect, animal, or person, or there may be direct contact with the agent itself.

Anthrax and smallpox are the two of the agents most likely to be used or weaponized. Table 56-4 describes other easily weaponized biologic agents.

Concept Mastery Alert

Ventilation support of breathing is not recommended for patients exposed to anthrax. Supportive care for clients having direct contact with botulism includes mechanical ventilation.

ANTHRAX

Inhaled anthrax is recognized as the most likely weaponized biologic agent available.

Bacillus anthracis is a naturally occurring gram-positive, encapsulated rod that lives in the soil in the spore state throughout the world. The bacterium is liberated when exposed to air and is infective only in the spore form. Contact with infected animal products (raw meat) or inhalation of the spores results in infection.

Pathophysiology

Animal studies have suggested that small amounts of inhaled anthrax spores (as low as 50 to 98 spores) may be sufficient to cause death in 10% of the exposed human population (Center for Infectious Disease Research and Policy [CIDRAP], 2013). As an aerosol, anthrax is odorless and invisible and can travel a great distance before disseminating; hence, the site of release and the site of infection can be miles apart. Incubation of the inhaled spores can be as long as 7 days.

TABLE 56-4 Examples of Biologic Agents that Can Be Used as Weapons

Agent/ Organism	Contagion	Decontamination and Protective Equipment	Signs and Symptoms	Treatment (Mortality Rate)
Tularemia (*Francisella tularensis*): gram-negative coccobacillus, one of the most infectious bacteria known	Direct contact with infected animals or aerosolized as a bioterror weapon; bites Not contagious through human-to-human contact	Standard barrier precautions Clothing and linens should be laundered under the usual hospital protocol.	*Initial:* Abrupt onset of fever, fatigue, chills, headache, lower backache, malaise, rigor, coryza (acute inflammation of the mucous membrane of the nasal cavities), dry cough, and sore throat without adenopathy. Nausea and vomiting or diarrhea possible. *As disease progresses:* Sweating, fever, progressive weakness, anorexia, and weight loss demonstrate continued illness. *Mortality secondary to:* Pneumonitis (if inhalation is the source) with copious watery or purulent sputum, hemoptysis, respiratory insufficiency, sepsis, and shock.	Streptomycin or gentamicin/ aminoglycoside for 10–14 days. Inhalation tularemia must be treated within 48 hours of onset. In mass casualty situations, doxycycline or ciprofloxacin is recommended. For persons exposed to tularemia, tetracycline or doxycycline is recommended for 14 days. (Mortality rate = 2%)
Botulism (*Clostridium botulinum*): Botulinum blocks acetylcholine-containing vesicles from fusing with the terminal membranes of the motor-neuron end-plate, resulting in a flaccid paralysis.	Direct contact Not contagious through human-to-human contact	Any skin exposure to the botulism toxin can be treated with soap and water or a 0.1% hypochlorite solution. Standard precautions are used when treating patients with botulism.	*Gastrointestinal botulism:* Abdominal cramps, nausea, vomiting, and diarrhea. *Inhalation botulism:* Fever; symmetric descending flaccid paralysis with multiple cranial nerve palsies. Classic signs and symptoms include diplopia, dysphagia, dry mouth, lack of fever, and alert mental status. Other possible symptoms include ptosis of the eyelids, blurred vision, enlarged sluggish pupils, dysarthria, and dysphonia. *Mortality secondary to:* Airway obstruction and inadequate tidal volume.	Supportive ventilatory therapy is necessary if respiratory infection occurs. Aminoglycosides and clindamycin are contraindicated because they exacerbate neuromuscular blockage. Equine antitoxin is used to minimize subsequent nerve damage. There is a 2% rate of anaphylaxis to the antitoxin; therefore, diphenhydramine (Benadryl) and epinephrine must be immediately available for use. Supportive care: Mechanical ventilation, nutrition, fluids, prevention of complications (Mortality rate = 5%)
Plague (*Yersinia pestis*): Nonsporulating gram-negative coccobacillus. The bacterium causes destruction and necrosis of the lymph nodes.	Contagious *Bubonic plague:* transmitted through flea bites with no person-to-person transmission *Pneumonic plague:* transmitted through respiratory droplet contact	Isolation barrier precautions with full face respirators. The patient should wear a mask. Rooms should receive a terminal cleaning. Clothing and linens with body fluids on them should be cleaned with the usual disinfectant. Routine precautions should be used in the case of death.	*Bubonic plague:* Sudden fever and chills, weakness, a swollen and tender lymph node (bubo) in the groin, axilla, or cervical area. The resultant bacteremia progresses to septicemia from the endotoxin and, finally, shock and death. *Primary septicemic plague:* Disseminated intravascular coagulation (DIC), necrosis of small vessels, purpura, and gangrene of the digits and nose (black death). *Pneumonic plague:* Severe bronchospasm, chest pain, dyspnea, cough, and hemoptysis. There is a 100% mortality associated with pneumonic plague if not treated within the first 24 hours.	Streptomycin or gentamicin for 10–14 days. Tetracycline or doxycycline is an acceptable alternative if an aminoglycoside cannot be given. People with close contact exposure (less than 2 m) require prophylaxis with doxycycline for 7 days. (Mortality rate = 50%)

Clinical Manifestations

Initial symptoms may resemble a common cold. Anthrax does not present as pneumonia. After several days, the symptoms may progress to severe breathing problems and shock.

Medical and Nursing Management

Inhalation anthrax is frequently fatal even with aggressive antibiotic and supportive therapy. Due to the presence of spores, antibiotic treatment is continued for 60 days. Anthrax cannot be spread from person to person, and standard level D universal precautions are sufficient.

SMALLPOX

Pathophysiology

Smallpox (variola) is classified as a DNA virus. It has an incubation period of 10 to 12 days. It is extremely contagious and is spread by direct contact, by contact with clothing or linens, or by inhaled droplets of saliva during contact with an infected person. During the incubation period there are no symptoms. When the virus has multiplied sufficiently to cause the fever and characteristic rash, the affected person not only feels ill but is also at the most infectious period (National Institute of Allergy and Infectious Diseases [NIAID], 2014). Aerosolization of the virus would result in widespread dissemination.

Clinical Manifestations and Assessment

Signs and symptoms of smallpox infection are similar to influenza and include high fever, malaise, headache, backache, and fatigue. After 2 to 3 days, a flat, red, lesioned rash appears, evolving at the same rate, beginning on the face, mouth, pharynx, and forearms. After several days, these lesions become filled with pus (Fig. 56-5) and form crusts in week 2. By week 3, these crusts have become scabs and begin to fall off (NIAID, 2014). There is a large amount of the virus in the saliva and pustules. Smallpox is contagious only after the appearance of the rash. There are two forms of smallpox, variola major and variola minor. Variola major is more common and results in a higher fever and more extensive rash. Variola major has a 30% case-fatality rate. Hemorrhagic smallpox, a subtype of variola major, includes all of the above signs and symptoms plus a dusky erythema and petechiae to frank hemorrhage of the skin and mucous membranes, resulting in death by day 5 or 6.

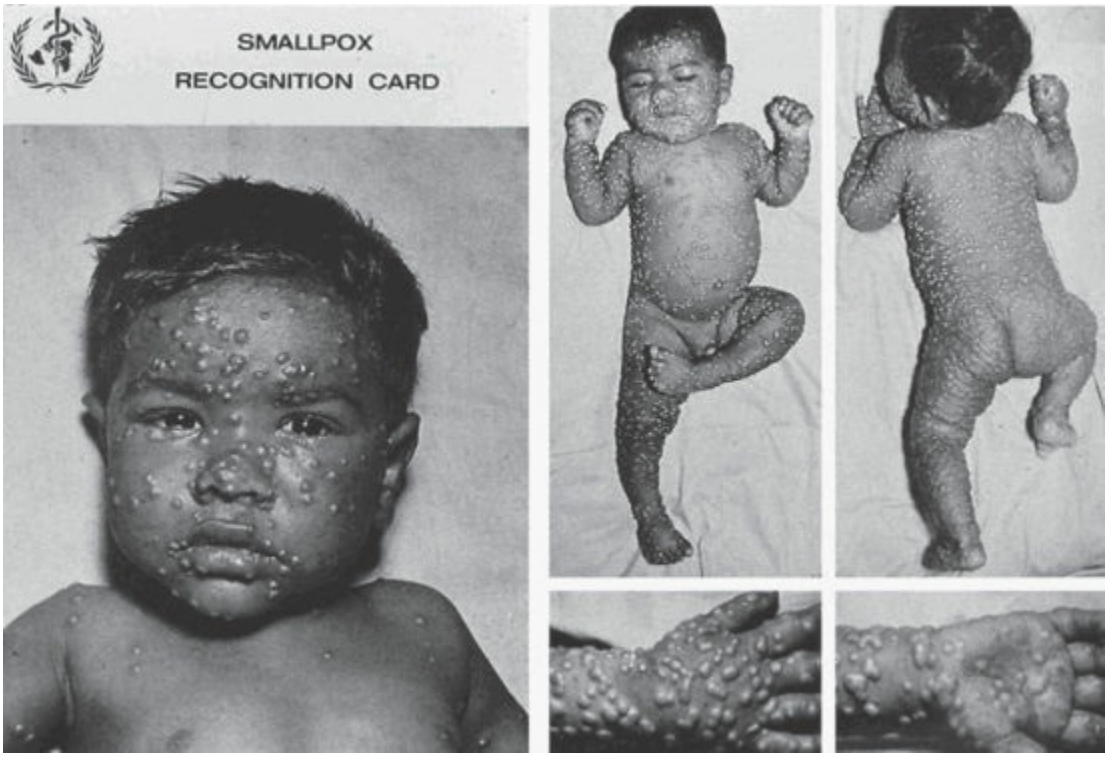

FIGURE 56-5 Patient with smallpox. (From Knipe, D. M., & Howley, P. M. (Eds.). (2001). *Field's virology* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Medical and Nursing Management

There is no specific treatment for smallpox, and vaccination is preventative. Treatment includes supportive care with antibiotics for any additional infection. The patient must be isolated with the use of transmission precautions. Laundry and biologic wastes should be autoclaved before being washed with hot water and bleach. Standard decontamination of the room is effective. All people who have household or face-to-face contact with the patient after the fever begins should be vaccinated within 4 days to prevent the infection or lessen the severity (NIAID, 2014).

SEVERE ACUTE RESPIRATORY SYNDROME

Not all mass casualty biologic events are terrorist-based. The SARS outbreak in 2003 is a prime example of a non–terrorist-based mass casualty biologic event. The disease started as "atypical" pneumonia in China, in February, and had spread to 29 countries throughout the world by July. Air travel and worldwide trade have increased the possibility that any contagious disease process may spread rapidly. The incubation period for SARS is 2 to 10 days.

Clinical Manifestations and Assessment

SARS should be considered in the event of an outbreak of atypical pneumonia with travel to an area with a known SARS outbreak, a health care worker with direct patient contact, or lab worker in a laboratory that contains live SARS-CoV. Early systemic signs are dry cough and shortness of breath with or without other respiratory symptoms. X-ray confirmed pneumonia or acute respiratory distress syndrome (ARDS) is evident at 7 to 10 days, along with fever and respiratory symptoms.

Medical and Nursing Management

Droplet precaution isolation and control of visits to the exposed patient are essential. Treatment is supportive. The overall case fatality rate is 10%, which increases to more than 50% in patients older than 60 years of age, putting frail, elderly people at risk.

Nursing Alert

The goal of Droplet Precautions is to prevent the transmission of pathogens spread through close respiratory or mucous membrane contact with respiratory secretions. Because the pathogens do not remain infectious over long distances, special air handling and ventilation are not required to prevent transmission. A single patient room is preferred for patients who require Droplet Precautions; however, if it is not available, consultation with infection control personnel is recommended regarding cohorting of patients. A mask is required for close contact (within 3 ft) with patients who are infectious, which is generally donned upon room entry. If the patient must be transported outside of the room, a mask should be applied (if tolerated), and the patient should be instructed in cough etiquette (cover the mouth/nose when coughing or sneezing, use and dispose of tissues). In addition, hand hygiene should be performed after hands have been in contact with respiratory secretions (CDC, 2015b; Siegel, Rhinehart, Jackson, & Chiarello, 2007).

CHEMICAL AGENTS

Agents that may be used in chemical warfare or terrorism are *overt*, in that the effects are more apparent and occur more quickly than those caused by biologic weapons. Agents are available and well-known, result in major mortality and morbidity, and cause panic and social disruption. There are many agents, including those that affect nerves (sarin, soman), those that affect blood (cyanide), vesicants (lewisite, nitrogen and sulfur mustard, phosgene), heavy metals (arsenic, lead), volatile toxins (benzene, chloroform), pulmonary agents (chlorine), and corrosive acids (nitric acid, sulfuric acid) (refer to Table 56-5).

Chemical agents vary in their absorption and effects. The *volatility* of chemical agents refers to the ability of the agent to become a vapor. Most chemicals are heavier than air, except for hydrogen cyanide, and heavier exposure occurs lower to the ground. *Persistence* of chemical agents means the chemical is less likely to vaporize and disperse. More volatile chemicals do not evaporate quickly and are more commonly used by military and terrorist agents than are industrial chemicals. *Toxicity* of the chemical agent is the ability to cause injury to the body. Toxicity is affected by concentration and length of exposure. *Latency* is the time from absorption to the appearance of symptoms. Sulfur mustards and pulmonary agents have the longest latency, whereas vesicants, nerve agents, and cyanide produce symptoms within seconds.

TABLE 56-5 Common Chemical Agents

Agent	Action	Signs and Symptoms	Decontamination and Treatment
Nerve Agents			
Sarin Soman organophosphates	Inhibition of cholinesterase	Increased secretions, gastrointestinal motility, diarrhea, bronchospasm	Soap and water Supportive care Benzodiazepine Pralidoxime Atropine
Blood Agent			
Cyanide	Inhibition of aerobic metabolism	Inhalation—tachypnea, tachycardia, coma, seizures. Can progress to respiratory arrest, respiratory failure, cardiac arrest, death.	Sodium nitrite Sodium thiocyanate Amyl nitrate Hydroxocobalamin
Vesicant Agents			
Lewisite Sulfur mustard Nitrogen mustard Phosgene	Blistering agents	Superficial to partial-thickness burn with vesicles that coalesce	Soap and water Blot; do not rub dry
Pulmonary Agents			
Phosgene Chlorine	Separation of alveoli from capillary bed	Pulmonary edema, bronchospasm	Airway management Ventilatory support Bronchoscopy

NERVE AGENTS

The most toxic agents in existence are the nerve agents, such as sarin, soman, tabun, VX, and organophosphates (pesticides). They are inexpensive, effective in small quantities, and

easily dispersed. In the liquid form, nerve agents evaporate into a colorless, odorless vapor. Organophosphates are similar in nature to the nerve agents used in warfare and are readily available. Nerve agents can be inhaled or absorbed percutaneously or subcutaneously. These agents bond with acetylcholinesterase, so that acetylcholine is not inactivated; the adverse result is continuous stimulation (hyperstimulation) of the nerve endings.

A very small drop of a nerve agent is enough to result in sweating and twitching at the site of exposure. A larger amount results in more systemic symptoms. Effects can begin anywhere from 30 minutes up to 18 hours after exposure. The more common organophosphates and carbamates (e.g., Sevin and malathion) that are used in agriculture result in less severe symptoms than do those used in warfare or in terrorist attacks. In an ordinary situation (e.g., nonwarfare, nonterrorist attack situation), a patient could arrive at the ED having been exposed to organophosphates unintentionally or intentionally, in a suicidal gesture.

Clinical Manifestations and Assessment

Signs and symptoms of nerve gas exposure are those of cholinergic crisis and include bilateral miosis (constriction of the pupil), visual disturbances, increased GI motility, nausea and vomiting, diarrhea, substernal spasm, indigestion, bradycardia and atrioventricular block, bronchoconstriction, laryngeal spasm, weakness, fasciculations (small, localized "twitching"), and incontinence. The patient must be examined in a dark area to truly identify miosis. Neurologic responses include insomnia, forgetfulness, impaired judgment, depression, and irritability. A lethal dose results in loss of consciousness, seizures, copious secretions, fasciculations, flaccid muscles, and apnea.

Medical and Nursing Management

Decontamination with copious amounts of soap and water or saline solution for 8 to 20 minutes is essential. The water is blotted, not wiped, off the skin. A 0.5% hypochlorite solution (bleach) can also be used (Agency for Toxic Substances and Disease Registry [ATSDR], 2014). The airway is maintained, and suctioning is frequently required. Plastic airway equipment will absorb sarin gas, which may result in continued exposure to the agent.

Atropine 2 to 4 mg is administered IV, followed by 2 mg every 3 to 8 minutes for up to 24 hours of treatment. Alternatively, IV atropine 1 to 2 mg/hr may be administered until clear signs of anticholinergic activity have returned (decreased secretions, tachycardia, and decreased GI motility). Another medication that may serve as an antidote is pralidoxime, which allows cholinesterase to become active against acetylcholine. Pralidoxime 1 to 2 g in 100 to 150 mL of normal saline solution is administered over 15 to 30 minutes. Pralidoxime has no effect on secretions and may have any of the following side effects: hypertension, tachycardia, weakness, dizziness, blurred vision, and diplopia.

Diazepam (Valium) or other benzodiazepines should be administered to control seizures, to decrease fasciculations, and to alleviate apprehension and agitation. Military personnel believed to be at risk for chemical attack are provided with Mark I automatic injectors, which contain 2-mg atropine and 600-mg pralidoxime chloride. Diazepam is administered by a partner.

BLOOD AGENTS

Blood agents, such as hydrogen cyanide and cyanogen chloride, have a direct effect on cellular metabolism, resulting in asphyxiation through alterations in hemoglobin. Cyanide is an agent that has profound systemic effects. It is commonly used in the mining of gold and silver and in the plastics and dye industries.

A cyanide release is often associated with the odor of bitter almonds. In house fires, cyanide is released during the combustion of plastics, rugs, silk, furniture, and other construction materials. There is a significant correlation between blood cyanide and carbon monoxide levels in patients who survive fires, and, in many cases, the cause of death is cyanide poisoning.

Clinical Manifestations and Assessment

Cyanide can be ingested, inhaled, or absorbed through the skin and mucous membranes. Cyanide is protein-bound and inhibits aerobic metabolism, leading to respiratory muscle failure, respiratory arrest, cardiac arrest, and death. Inhalation of cyanide results in flushing, tachypnea, tachycardia, nonspecific neurologic symptoms, stupor, coma, and seizure preceding respiratory arrest.

Medical and Nursing Management

Treatment of patients for cyanide poisoning includes rapid administration of amyl nitrate, sodium nitrite, and sodium thiosulfate, which is essential to the successful management of cyanide exposure. First, the patient is intubated and placed on a ventilator. Next, amyl nitrate pearls are crushed and placed in the ventilator reservoir to induce methemoglobinemia. Cyanide has a 20% to 25% higher affinity for methemoglobin than it does for hemoglobin; it binds with methemoglobin to form either cyanomethemoglobin or sulfmethemoglobin. The cyanomethemoglobin is then detoxified in the liver by the enzyme rhodanese. Next, IV sodium nitrite is administered to induce the rapid formation of methemoglobin. Sodium thiosulfate is then administered by IV; it has a higher affinity for cyanide than methemoglobin does and stimulates the conversion of cyanide to sodium thiocyanate, which can be excreted by the kidneys. Although they may be life-saving, these emergency medications do have side effects: sodium nitrite can result in severe hypotension, and thiocyanate can cause vomiting, psychosis, arthralgia, and myalgia.

The production of methemoglobin is contraindicated in patients suffering from smoke inhalation because they already have decreased oxygen-carrying capacity secondary to the carboxyhemoglobin produced by smoke inhalation. In facilities where a hyperbaric chamber is available, it may be used to provide oxygenation while the previously discussed therapies are initiated. An alternative suggested treatment for cyanide poisoning is hydroxocobalamin (vitamin B_{12a}). Hydroxocobalamin binds cyanide to form cyanocobalamin (vitamin B_{12}). It must be administered IV in large doses. Administration of vitamin B_{12} can result in a transient pink discoloration of mucous membranes, skin, and urine. In high doses, tachycardia and hypertension can occur, but they usually resolve within 48 hours.

CHAPTER REVIEW

Critical Thinking Exercises

1. A young woman arrives at the ED by ambulance after a car crash. She is immobilized on a backboard, with a cervical collar and an oxygen mask in place. There is a bruise across her abdomen where the seatbelt was applied. She complains of nausea and abdominal pain. You note no movement of the left chest wall and an angulated right arm. She has no pulses in her lower extremities and cannot move or feel her legs. How would you prioritize the patient's needs? Develop an assessment strategy, identify diagnostic studies that will benefit the patient, and describe the patient's treatment needs.

2. The following five patients present to the triage desk within minutes of each other. How would you prioritize and categorize each of these patients? Which ones need immediate attention? What initial care would you provide at triage?
   a. A child with medication-controlled asthma presents with rapid, shallow respirations and cyanosis around the lips and is very anxious. He has been this way for about 20

minutes.

b. A woman who has had a cold for 3 days says she has no primary care physician and must be seen right now because she cannot breathe. Her respirations are normal, pulse oxygenation saturations are 100%, and she has complaints of sinus drainage.
c. A woman was hit by an automobile while she was riding her bike. Instead of calling 911, a friend drove her to the ED. She is complaining of neck pain and tingling in her upper extremities since the injury. She is beginning to have difficulty taking a deep breath.
d. A young boy who was riding his skateboard arrives at the ED with an angulated wrist. Pulses are normal, but the wrist is painful.
e. An elderly woman presents with complaints of 24 hours of vomiting. Her vital signs are normal, but she is diaphoretic and appears weak.

3. You are the triage nurse at the receiving facility for casualties during a hurricane. Five patients arrive at the same time. Together with the surgeon on duty, you must identify the patients' needs. What are the patient needs of the following five patients? How would you classify/tag these patients?
   a. An elderly man with a respiratory rate of 8 breaths/min, color ashen, status unresponsive, with only palpable carotid pulses
   b. A 7-year-old child with a bleeding scalp laceration who needs intubation
   c. The 30-year-old mother of the 7-year-old child, who is crying hysterically and appears to have no pain or visible injuries
   d. A 15-year-old boy who complains of pain in his left leg, with obvious deformity at the calf but good pulses in the foot
   e. A 65-year-old woman who arrives in a police car holding her right wrist, which is cool, ecchymotic, and painful with good pulses

4. Multiple patients begin arriving at the ED complaining of burning eyes and difficulty breathing. All of these people work at the railroad yard, where tanker trucks frequently transport chemical agents. What should you do first? Where do you find information about chemical agents and their treatment?

NCLEX-Style Review Questions

1. When assessing a trauma patient presenting in the ED, what is the most important priority for the nurse?
   a. Controlling hemorrhage
   b. Inserting two large-gauge IV catheters for fluid resuscitation
   c. Obtaining name and phone number of nearest relative to inform them that the patient is in the hospital
   d. Establishing a patent airway

2. A 25-year-old patient is transported by paramedics to the ED following a fall from a

second-story balcony during a party. During the primary survey, respirations are noted to be snoring with a heavy alcohol odor to the breath. The patient is receiving 100% O_2 via face mask, and oxygen saturation is 91%. The patient withdraws from painful stimuli but is not speaking or responding appropriately to commands. What are the immediate priorities for care?

a. Open airway with head tilt-chin lift maneuver and obtain chest x-ray to assess for pneumothorax.
b. Draw labs for toxicology screen and administer 0.5-mg Ativan to prevent withdrawal seizures.
c. Perform jaw-thrust maneuver and reassess ventilation effort.
d. Rapidly transport patient to CT for brain CT to evaluate for neurologic injury.

3. There has been a natural gas explosion in a multistory office building in the city. Initial reports indicate that the ED will be receiving a large number of victims that will overwhelm current resources. What need will the nurse working in the ED anticipate?

a. Initiate the hospital emergency operation plan.
b. Call off-duty staff to come in and assist.
c. Request burn packs from central supply.
d. Take a meal break quickly before patients arrive.

4. A city has been hit by a tornado, and reports indicate significant numbers of casualties and injuries. The hospital has not been affected, and all systems are operational at this time. As patients arrive, they have been tagged by field responders using the NATO color coding for severity. What does the nurse working in the ED know about this system?

a. Patients tagged with a green tag require immediate and extensive use of resources for survival.
b. Patients with a red tag have minor injuries and can wait for care.
c. Children always receive a red tag.
d. Patients with a black tag are not a priority for treatment under MCI standards.

5. A 50-year-old patient presents to the ED with complaints of a fever and chills for the past 72 hours, body aches, and appears to be acutely ill. The nurse notes lesions on the patient's arms and face that have appear to be spreading quickly. What are immediate priorities for care?

a. An assessment of recent travel
b. Administer an antipyretic to reduce fever and body aches
c. Isolate from other patients and ensure all staff follow isolation precautions
d. Assist patient into a hospital gown for an immediate examination and give clothing to family members

Appendix A

Major Fluid and Electrolyte Imbalances

Imbalance	Contributing Factors	Signs/Symptoms and Laboratory Findings
Fluid volume deficit (FVD) (hypovolemia)	Loss of water and electrolytes, as in vomiting, diarrhea, fistulas, fever, excess sweating, burns, blood loss, gastrointestinal suction, and third-space fluid shifts; and decreased intake, as in anorexia, nausea, and inability to gain access to fluid Diabetes insipidus and uncontrolled diabetes mellitus also contribute to a depletion of extracellular fluid volume.	Acute weight loss; decreased skin turgor; oliguria; concentrated urine; weak, rapid pulse; prolonged capillary filling time; low CVP; ↓ blood pressure; orthostatic hypotension; flattened neck veins; dizziness; weakness; thirst and confusion; ↑ pulse; muscle cramps; sunken eyes *Labs indicate:* ↑ Hemoglobin and hematocrit, ↑ serum and urine osmolality and specific gravity, ↑ BUN out of proportion to serum creatinine
Fluid volume excess (FVE) (hypervolemia)	Compromised regulatory mechanisms, such as kidney failure, heart failure, and cirrhosis; overzealous administration of sodium-containing fluids; and fluid shifts (i.e., treatment of burns). Prolonged corticosteroid therapy, severe stress, and hyperaldosteronism augment fluid volume excess.	Acute weight gain, peripheral edema and ascites, distended jugular veins, crackles, and elevated CVP, shortness of breath, ↑ blood pressure, bounding pulse and cough, ↑ respiratory rate *Labs indicate:* ↓ Hemoglobin and hematocrit, ↓ serum and urine osmolality, ↓ urine specific gravity, decreased BUN (due to plasma dilution).
Sodium deficit (hyponatremia) Serum sodium <135 mEq/L	Loss of sodium, as in use of diuretics, loss of GI fluids, kidney disease, and adrenal insufficiency. Gain of water, as in excessive administration of D_5W and water supplements for patients receiving hypotonic tube feedings; disease states associated with SIADH, such as head trauma and oat-cell lung tumor; medications associated with water retention (oxytocin and certain tranquilizers); and psychogenic polydipsia. Patients with congestive heart failure or liver disease may present with hyponatremia despite an excess of total body sodium.	Manifestations of hyponatremia depend on the cause, magnitude, and speed with which the deficit occurs. Symptoms include: Anorexia, nausea and vomiting, headache, lethargy, dizziness, confusion, muscle cramps and weakness, muscular twitching, seizures, papilledema, dry skin, ↑ pulse, ↓ BP, weight gain, edema. *Labs indicate:* ↓ Serum sodium; urine sodium level varies depending on the etiology of the hyponatremia
Sodium excess (hypernatremia) Serum sodium >145 mEq/L	Water deprivation in patients unable to drink at will; hypertonic tube feedings without adequate water supplements; diabetes insipidus; heatstroke; hyperventilation; watery diarrhea; burns; and diaphoresis; excess corticosteroid, sodium bicarbonate, and sodium chloride administration; and salt water near-drowning victims.	Thirst, elevated body temperature, swollen dry tongue and sticky mucous membranes, hallucinations, lethargy, restlessness, irritability, focal or grand mal seizures, pulmonary edema, hyperreflexia, twitching, nausea, vomiting, anorexia, ↑ pulse, and ↑ BP *Labs indicate:* ↑ Serum sodium, increased serum osmolality; ↑ urine-specific gravity and osmolality (provided the water loss is from a route other than the kidneys); ↓ CVP

Potassium deficit (hypokalemia) Serum potassium <3.5 mEq/L	Increased output of K^+ (diuretics, diarrhea, vomiting, gastric suction, recent ileostomy, intestinal drains, osmotic diuresis); decreased intake of K^+ (NPO, anorexia, vomiting, alcoholism, fasting diets); or redistribution of K^+ (metabolic alkalosis, insulin administration).	Fatigue, anorexia, nausea and vomiting, muscle weakness, decreased bowel motility, abdominal distention, ileus, ventricular arrhythmias, paresthesias, leg cramps, hypoactive reflexes, increased sensitivity to digitalis *ECG:* Flattened T waves, prominent U waves, ST depression, prolonged PR interval
Potassium excess (hyperkalemia) Serum potassium >5.0 mEq/L	Pseudohyperkalemia, oliguric kidney failure, use of potassium-conserving diuretics in patients with renal insufficiency, metabolic acidosis, Addison disease, crush injury, burns, stored bank blood transfusions, and rapid IV administration of potassium	Vague muscular weakness, tachycardia → bradycardia, arrhythmias, flaccid paralysis, paresthesias, intestinal colic *ECG:* Tall tented T waves, prolonged PR interval and QRS duration, absent P waves, ST depression
Calcium deficit (hypocalcemia) Serum calcium <8.5 mg/dL	Hypoparathyroidism (may follow thyroid surgery or radical neck dissection), malabsorption, pancreatitis, alkalosis, vitamin D deficiency, massive subcutaneous infection, generalized peritonitis, massive transfusion of citrated blood, chronic diarrhea, decreased parathyroid hormone, kidney failure, ↑ PO_4, pancreatic and small bowel fistulas, hypomagnesemia, hypoalbuminemia	Numbness, tingling of fingers, toes, and circumoral region; positive Trousseau sign and Chvostek sign; tetany; seizures, carpopedal spasms, hyperactive deep tendon reflexes, irritability, laryngeal spasm, anxiety. *ECG:* Prolonged QT interval and lengthened ST predisposing to torsades de pointes (form of ventricular tachycardia) *Labs indicate:* Serum calcium concentration is low; ionized serum calcium concentration is also low; ↓ Mg^{++} (inhibits PTH secretion)
Calcium excess (hypercalcemia) Serum calcium >10.5 mg/dL	Hyperparathyroidism, malignant neoplastic disease, prolonged immobilization, overuse of calcium supplements, vitamins A and D excess, oliguric phase of kidney failure, acidosis, thiazide diuretic use	Muscular weakness, confusion, constipation, anorexia, nausea and vomiting, polyuria and polydipsia, dehydration, hypoactive deep tendon reflexes, lethargy, deep bone pain, pathologic fractures, flank pain, and calcium stones. *ECG:* Shortened ST segment and QT interval, bradycardia, heart blocks
Magnesium deficit (hypomagnesemia) Serum magnesium <1.8 mg/dL	Chronic alcoholism, hyperparathyroidism, hyperaldosteronism, diuretic phase of kidney failure, malabsorptive disorders, diabetic ketoacidosis, refeeding after starvation, parenteral nutrition, chronic laxative use, diarrhea, decreased serum K^+ and Ca^{++} and certain pharmacologic agents (such as gentamicin, cisplatin, and cyclosporine)	Neuromuscular irritability, positive Trousseau and Chvostek signs, insomnia, mood changes, anorexia, vomiting, increased tendon reflexes, and potentiation of ventricular and supraventricular arrhythmias. *ECG:* PVCs, flat or inverted T waves, depressed ST segment, prolonged PR interval and widened QRS
Magnesium excess (hypermagnesemia) Serum magnesium >2.7 mg/dL	Renal insufficiency (particularly when magnesium-containing medications are administered IV or excessive ingestion of magnesium-containing antacids or laxatives), adrenal insufficiency	Nausea, vomiting, hypotension, drowsiness, hypoactive reflexes, depressed respirations leading to apnea, bradycardia and hypotension. *ECG:* Prolonged PR interval and QT interval.
Phosphorus deficit (hypophosphatemia) Serum phosphorus <2.5 mg/dL	Refeeding after starvation, alcohol withdrawal, diabetic ketoacidosis, respiratory alkalosis, ↓ magnesium, ↓ potassium, hyperparathyroidism, diarrhea, vitamin D deficiency associated with malabsorptive disorders, burns, acid–base disorders, parenteral nutrition, and diuretic and antacid use	Paresthesias, muscle weakness, bone pain and tenderness, chest pain, confusion, cardiomyopathy, respiratory failure, seizures, tissue hypoxia, and increased susceptibility to infection.

Phosphorus excess (hyperphosphatemia) Serum phosphorus >4.5 mg/dL	Acute and chronic kidney failure, excessive intake of phosphorus, vitamin D excess, respiratory acidosis, hypoparathyroidism, volume depletion, leukemia/lymphoma treated with cytotoxic agents, increased tissue breakdown, rhabdomyolysis	Tetany, signs and symptoms of hypocalcemia; hyperactive reflexes; soft-tissue calcifications in lungs, heart, kidneys, and cornea
Chloride deficit (hypochloremia) Serum chloride <96 mEq/L	GI tube drainage and severe vomiting and diarrhea, laxatives, ileostomy, and fistulas; sodium and potassium deficiency; metabolic alkalosis; loop, osmotic, or thiazide diuretic use; overuse of bicarbonate; rapid removal of ascitic fluid with a high sodium content; intravenous fluids that lack chloride (dextrose and water)	Signs and symptoms of hypochloremia are associated with hyponatremia, hypokalemia, and metabolic alkalosis *Labs indicate:* ↓ Serum chloride, ↓ serum sodium, ↑ pH, ↑ serum bicarbonate, ↑ total carbon dioxide content, ↓ serum potassium
Chloride excess (hyperchloremia) Serum chloride >108 mEq/L	Excessive sodium chloride infusions with water loss; hypernatremia; kidney failure; corticosteroid use; dehydration; severe diarrhea (loss of bicarbonate); respiratory alkalosis; administration of diuretics; overdose of salicylates; Kayexalate, acetazolamide, phenylbutazone, and ammonium chloride use; hyperparathyroidism; metabolic acidosis	Signs and symptoms of hyperchloremia are typically associated with metabolic acidosis (tachypnea, Kussmaul respirations, lethargy, diminished cognitive ability), and hypernatremia (fluid retention, dyspnea, tachycardia, hypertension) *Labs indicate:* ↑ Serum chloride, ↑ serum sodium, ↓ serum pH, ↓ serum bicarbonate, normal anion gap

↑ increased; ↓ decreased; BP, blood pressure; BUN, blood urea nitrogen; CVP, central venous pressure; DKA, diabetic ketoacidosis; GI, gastrointestinal; IV, intravenous; PVCs, premature ventricular contractions; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

Glossary

abduction movement away from the center or median line of the body

ablation purposeful destruction of heart muscle cells, usually in an attempt to control an arrhythmia

abscess localized collection of purulent material surrounded by inflamed tissues, typically associated with signs of infection

absolute neutrophil count (ANC) a mathematical calculation of the actual number of neutrophils in the circulation, derived from the total white blood cells (WBCs) and the percentage of neutrophils counted in a microscope's visual field; provides an estimate of infection risk

absorption phase of the digestive process that occurs when small molecules, vitamins, and minerals pass through the walls of the small and large intestine and into the bloodstream

acanthosis nigricans hyperpigmentation of the skin that typically occurs on the neck, dorsum of hands, axilla, or groin areas

accommodation process by which the eye adjusts for near distance (e.g., reading) by changing the curvature of the lens to focus a clear image on the retina

achalasia absent or ineffective peristalsis (wavelike contraction) of the distal esophagus accompanied by failure of the esophageal sphincter to relax in response to swallowing

achlorhydria lack of hydrochloric acid in digestive secretions of the stomach

acidosis an acid–base imbalance characterized by an increase in H^+ concentration (decreased blood pH); a low arterial pH due to reduced bicarbonate concentration is called metabolic acidosis; a low arterial pH due to increased PCO_2 is respiratory acidosis

acoustic pertaining to sound or the sense of hearing

acromegaly disease process resulting from excessive secretion of somatotropin (growth hormone); causes progressive enlargement of peripheral body parts, commonly the face, head, hands, and feet and enlargement of many body organs

active transport physiologic pump that moves fluid from an area of lower concentration to one of higher concentration; active transport requires adenosine triphosphate (ATP) for energy

acute coronary syndrome (ACS) signs and symptoms that indicate unstable angina or acute myocardial infarction

acute limb ischemia (ACL) sudden decrease in limb arterial perfusion, threatening limb viability

acute lung injury (ALI) an umbrella term for hypoxemic, respiratory failure; ARDS is a severe form of ALI

acute respiratory distress syndrome (ARDS) an inflammatory pulmonary response to a variety of pulmonary and nonpulmonary insults to the lung; characterized by diffuse interstitial infiltrates, alveolar/capillary leak, atelectasis, decreased compliance, refractory

hypoxemia and no signs of cardiogenic heart failure

acute tubular necrosis type of acute kidney failure in which there is actual damage to the kidney tubules

addiction a behavioral pattern of substance use characterized by a compulsion to take the substance (drug or alcohol) primarily to experience its psychic effects

Addison disease chronic adrenocortical insufficiency secondary to destruction of the adrenal glands

addisonian crisis acute adrenocortical insufficiency; commonly characterized by shock (acute hypotension, volume depletion), nausea and vomiting; usual laboratory abnormalities include hyponatremia, hyperkalemia, and perhaps hypoglycemia; often precipitated by stress or abrupt withdrawal of therapeutic glucocorticoids

adduction movement toward the center or median line of the body

adherence the process of faithfully following guidelines or directions

adjuvant chemotherapy use of anticancer medications in addition to other treatments such as surgery, radiation to delay or prevent a recurrence of the disease

adnexa the fallopian tubes and ovaries

adrenalectomy surgical removal of one or both adrenal glands

adrenocorticotropic hormone (ACTH) hormone secreted by the anterior pituitary, essential for growth and development; chief function is to stimulate hormones of the adrenal cortex-glucocorticoids (principally cortisol), mineralocorticosteroids (principally aldosterone) and androgens (sex hormones)

adrenogenital syndrome masculinization in women, feminization in men, or premature sexual development in children; result of abnormal secretion of adrenocortical hormones, especially androgens

afterload the amount of resistance to ejection of blood from the ventricle

agglutination clumping effect occurring when an antibody acts as a cross-link between two antigens

agnosia loss of ability to recognize objects through a particular sensory system; may be visual, auditory, or tactile

agonist a substance that when combined with the receptor produces the drug effect or desired effect; endorphins and morphine are agonists on the opioid receptors

AIDS acquired immunodeficiency syndrome; when a person infected with the human immunodeficiency virus (HIV) develops an opportunistic infection or has a $CD4^+$ lymphocyte count below 200

airway pressure release ventilation (APRV) mode of mechanical ventilation that allows unrestricted, spontaneous breaths throughout the ventilatory cycle; on inspiration, patient receives preset level of continuous positive airway pressure, and pressure is periodically released to aid expiration

akathisia restlessness, urgent need to move around, and agitation

alaryngeal communication alternative modes of speaking that do not involve the normal larynx; used by patients whose larynx has been surgically removed

aldosterone hormone synthesized and released by the adrenal cortex; causes the kidneys to reabsorb sodium (and thus water retention) and potassium loss

algogenic causing pain

alkalosis an acid–base imbalance characterized by a reduction in H^+ concentration (increased blood pH); a high arterial pH with increased bicarbonate concentration is called metabolic alkalosis; a high arterial pH due to reduced PCO_2 is respiratory alkalosis

allergen substance that causes manifestations of allergy

allergy inappropriate and often harmful immune system response to substances that are normally harmless

allograft tissue harvested from a donor for use in another person (*synonym* homograft)

alopecia loss of hair from any cause

alpha$_1$-antitrypsin deficiency a genetic disorder resulting from deficiency of alpha$_1$ antitrypsin, a protective enzyme in the lungs; the deficiency increases the patient's risk for developing emphysema even in the absence of smoking

alpha-interferon protein substance that the body produces in response to infection

altered level of consciousness condition of being less responsive to and aware of environmental stimuli

ambulatory surgery includes outpatient (same-day) surgery that does not require an overnight hospital stay or short stay, with admission to an inpatient hospital setting for less than 24 hours

amenorrhea the absence of menstruation that can be either primary or secondary

amputation the removal of a body part

amylase pancreatic enzyme; aids in the digestion of carbohydrates

anagen phase active phase of hair growth

anaphylactic shock distributive shock state resulting from a severe allergic reaction producing an overwhelming systemic vasodilation and relative hypovolemia in addition to bronchial spasm

anaphylaxis clinical response to an immediate immunologic reaction between a specific antigen and antibody

androgens hormones secreted by the adrenal cortex; stimulate activity of accessory male sex organs and development of male sex characteristics; hormones produced by the ovaries and adrenals that affect many aspects of female health, including follicle development, libido, oiliness of hair and skin, and hair growth

anemia decreased red blood cell (RBC) count

anergy loss or weakening of the body's immunity to an irritating agent or antigen

anesthesia a state of narcosis, analgesia, relaxation, and loss of reflexes

anesthesiologist physician trained to deliver anesthesia and to monitor the patient's condition during surgery

anesthetic the substance, such as a chemical or gas, used to induce anesthesia

anesthetist health care professional, such as a nurse anesthetist, who is trained to deliver anesthesia and to monitor the patient's condition during surgery

aneurysm congenital or acquired localized weakness or dilation of an artery formed at a weak point in the vessel wall

angina pectoris chest pain brought about by myocardial ischemia

angiogenesis formation of new blood vessels, such as in a healing wound or in a malignant tumor

angiography an x-ray picture of a vessel lumen following the injection of a radiopaque contrast material

angioneurotic edema condition characterized by urticaria and diffuse swelling of the deeper layers of the skin

angioplasty an invasive procedure to dilate a stenotic blood vessel

angiotensin-converting enzyme (ACE) inhibitors medications that inhibit the angiotensin-converting enzyme

ankle–brachial index (ABI) ratio of the ankle systolic pressure to the higher of the two brachial systolic pressures; an objective measurement of arterial disease

ankylosis fixation or immobility of a joint

annuloplasty repair of a cardiac valve's outer ring

anovulation lack of ovulation

antagonist a substance that blocks or reverses the effects of the agonist by occupying the receptor site without producing the drug effect; naloxone (Narcan™) is an opioid antagonist

anterior chamber space in the eye bordered anteriorly by the cornea and posteriorly by the iris and pupil

antiarrhythmic a medication that suppresses or prevents an arrhythmia

antibody protein substance developed by the body in response to and interacting with a specific antigen

antidiuretic hormone (ADH) hormone secreted by the posterior pituitary gland; causes the kidneys to reabsorb more water; also called *vasopressin*

antigen substance that induces the production of antibodies

antigenic determinant the specific area of an antigen that binds with an antibody combining site and determines the specificity of the antigen–antibody reaction

antihistamine medication that opposes the action of histamine

antireflux valve valve that prevents return or backward flow of fluid

antrectomy removal of the pyloric (antrum) portion of the stomach with anastomosis (surgical connection) to the duodenum (gastroduodenostomy or Billroth I) or anastomosis to the jejunum (gastrojejunostomy or Billroth II)

anuria total urine output less than 50 mL in 24 hours

anus last section of the GI tract; outlet for waste products from the system

aortic valve semilunar valve located between the left ventricle and the aorta

aphasia impairment of language (including speaking, reading, writing, or comprehension) due to an injury of the brain

aphonia impaired ability to use one's voice due to disease or injury to the larynx

apical impulse also called *point of maximum impulse* (PMI); impulse normally palpated at the fifth intercostal space, left midclavicular line (or 7 to 9 cm from the left sternal border); caused by contraction of the left ventricle

aplasia lack of cellular development (e.g., of cells within the bone marrow)

apnea cessation of breathing/airflow for at least 10 seconds

apoptosis programmed cell death

apraxia inability to perform previously learned purposeful motor acts on a voluntary basis

aromatase inhibitors medications that block the production of estrogens by the adrenal glands

arrhythmia also referred to as *dysrhythmia;* disorder of the formation or conduction (or both) of the electrical impulse within the heart, altering the heart rate, heart rhythm, or both and potentially causing altered perfusion

arterial bypass surgical rerouting of blood around an obstructed artery, using a graft

arteriovenous fistula type of vascular access for dialysis; created by surgically connecting an artery to a vein

arteriovenous graft type of surgically created vascular access for dialysis by which a piece of biologic, semibiologic, or synthetic graft material connects the patient's artery to a vein

arthrocentesis needle aspiration of synovial fluid

arthrodesis surgical fusion of a joint

arthroplasty the repair of joint problems through the operating arthroscope (an instrument that allows the surgeon to operate within a joint without a large incision) or through open joint surgery

arthroscope surgical instrument used to examine internal joint structures

articulation a joint; the site of close approximation of two or more bones

asbestosis diffuse lung fibrosis resulting from exposure to asbestos fibers

ascites fluid accumulation in the abdominal cavity

aspiration removal of substance by suction; breathing of fluids or foods into the trachea and lungs

assist-control ventilation (A/C) mode of mechanical ventilation in which the patient's breathing pattern may trigger the ventilator to deliver a preset tidal volume; in the absence of spontaneous breathing, the machine delivers a controlled breath at a preset minimum rate and tidal volume

assisted suicide use of pharmacologic agents to hasten the death of a terminally ill patient; illegal in most states

asterixis involuntary flapping movements of the hands associated with metabolic liver dysfunction

asthma a disease with multiple precipitating mechanisms characterized by the interaction between underlying inflammation, airway hyperresponsiveness, and obstruction to airflow

astigmatism refractive error in which light rays are spread over a diffuse area rather than sharply focused on the retina; a condition caused by differences in the curvature of the cornea and lens

ataxia inability to coordinate muscle movements, resulting in difficulty in walking, talking, and performing self-care activities; irregular, uncoordinated movements

atelectasis collapse or airless condition of the alveoli caused by hypoventilation, obstruction to the airways, or compression

atheroma fibrous cap composed of smooth muscle cells that forms over lipid deposits within arterial vessels and that protrudes into the lumen of the vessel, narrowing the lumen and obstructing blood flow; also called *plaque*

atherosclerosis disease process involving the accumulation of lipids, calcium, blood components, carbohydrates, and fibrous tissue on the intimal layer of arteries

atonic without tone; denervated muscle that atrophies

atony lack of normal muscle tone

atopic dermatitis type I hypersensitivity involving inflammation of the skin evidenced by itching, redness, and a variety of skin lesions

atrophy shrinkage-like decrease in the size of a muscle

atypical hyperplasia abnormal increase in the number of cells in a specific area within the ductal or lobular areas of the breast; this abnormal proliferation increases the risk for cancer

auscultatory gap a silent interval between systolic and diastolic Korotkoff sounds, causing an underestimation of the systolic pressure

autograft a graft derived from one part of a patient's body and used on another part of that same patient's body

autonomic dysreflexia also called autonomic hyperreflexia; a life-threatening emergency in spinal cord injury patients that causes a hypertensive emergency, occurs in patients with an injury at or above T6

autonomic nervous system division of the nervous system that regulates the involuntary body functions

autonomy self-determination; in the health care context, the right of the individual to make choices about the use and discontinuation of medical treatment

autoregulation ability of cerebral blood vessels to dilate or constrict to maintain stable cerebral blood flow despite changes in systemic arterial blood pressure

avascular necrosis death of tissue due to insufficient blood supply

axon portion of the neuron that conducts impulses away from the cell body

azotemia concentration of urea and other nitrogenous wastes in the blood

Babinski reflex (sign) a reflex action of the toes, indicative of abnormalities in the motor control pathways leading from the cerebral cortex

bacterial vaginosis a vaginal infection caused by an overgrowth of anaerobic bacteria

bacteriuria bacteria in the urine; bacterial count higher than 100,000 colonies/mL

balanced analgesia using more than one form of analgesia concurrently to obtain more pain relief with fewer side effects

balloon angioplasty a technique using a balloon, attached to a catheter, inflated to restore blood flow in blocked arteries

balloon tamponade use of balloons placed within the esophagus and proximal portion of the stomach and inflated to compress bleeding vessels (esophageal and gastric varices)

balneotherapy a bath with therapeutic additives

band cell slightly immature neutrophil

bandemia an excess of immature white blood cells released by the bone marrow into the blood; signifies infection or inflammation

bariatric term that comes from two Greek words meaning "weight" and "treatment"

baroreceptors nerve fibers located in the aortic arch and carotid arteries that are responsible for reflex control of the blood pressure

basal metabolic rate chemical reactions occurring when the body is at rest

basophil type of granulocyte; involved in the inflammatory response

B cells cells that are important for producing a humoral immune response

benign proliferative breast disease various types of atypical, yet noncancerous, breast tissue that increase the risk for breast cancer

benign prostatic hyperplasia (BPH) noncancerous enlargement or hypertrophy of the prostate; BPH is the most common pathologic condition in older men and the second most common cause of surgical intervention in men older than 60 years of age

bereavement period during which mourning for a loss takes place

Biliary tract defined as the organs and ducts that create and store bile and release it into the duodenum (the small intestine)

biologic response modifier (BRM) therapy use of agents or treatment methods that can alter the immunologic relationship between the tumor and the host to provide a therapeutic benefit

biologic warfare use of a biologic agent, such as anthrax, as a weapon of mass destruction

biopsy a diagnostic procedure to remove a small sample of tissue to be examined microscopically to detect malignant cells

blast cell primitive white blood cell

blindness inability to see, usually defined as corrected visual acuity of 20/400 or less, or a visual field of no more than 20 degrees in the better eye

bolus a feeding administered into the stomach in large amounts and at designated intervals

bone graft the placement of bone tissue (autologous or homologous grafts) to promote healing, to stabilize, or to replace diseased bone

borborygmus rumbling noise caused by the movement of gas through the intestines

brace externally applied device to support the body or a body part, control movement, and prevent injury

brachytherapy delivery of radiation therapy through internal implants

bradykinesia very slow voluntary movements and speech

brain death irreversible loss of all brain function, including the brainstem

brain injury an injury to the skull or brain that is severe enough to interfere with normal functioning

BRCA-1 and BRCA-2 genes on chromosome 17 that, when damaged or mutated, place a woman at greater risk for breast cancer and/or ovarian cancer compared with women who do not have the mutation

breakthrough pain a sudden and temporary increase in pain occurring in a patient being managed with opioid analgesia

breast conservation treatment surgery to remove a breast tumor and a margin of tissue around the tumor without removing any other part of the breast; may or may not include lymph node removal and radiation therapy

bronchoscopy direct examination of larynx, trachea, and bronchi using an endoscope

bruit sound produced by turbulent blood flow through an irregular, tortuous, stenotic, or dilated vessel

Budd–Chiari syndrome hepatic vein thrombosis resulting in noncirrhotic portal hypertension

bulbar paralysis immobility of muscles innervated by cranial nerves with their cell bodies in the lower portion of the brainstem

bursa fluid-filled sac found in connective tissue, usually in the area of joints

bursitis inflammation of a fluid-filled sac in a joint

calcitonin hormone secreted by the parafollicular cells of the thyroid gland; participates in calcium regulation (lowers blood calcium and phosphate level)

callus cartilaginous/fibrous tissue at fracture site

cancellous bone lattice-like bone structure; trabecular bone

cancer a disease process whereby cells proliferate abnormally, ignoring growth-regulating signals in the environment surrounding the cells

carboxyhemoglobin hemoglobin that is bound to carbon monoxide and therefore is unable to bind with oxygen, resulting in hypoxemia

carcinogenesis process of transforming normal cells into malignant cells

cardiac output amount of blood pumped by each ventricle in liters per minute; normal cardiac output is 4 to 6 L/min in the resting adult heart

cardiogenic shock shock state resulting from impairment or failure of the myocardium

cardiomyopathy disease of the heart muscle

cardioversion electrical current administered in synchrony with the patient's own QRS complex to stop arrhythmia

cartilage tough, elastic, avascular tissue at ends of bone

cast rigid external immobilizing device molded to contours of body part

CCR5 coreceptor or cell surface molecule needed along with the $CD4^+$ molecule for HIV to infect the host's immune system cells

cellular density the number of living cells in a unit

cellular immune response the immune system's third line of defense, involving the attack of pathogens by T cells

central cyanosis bluish discoloration of the skin or mucous membranes due to hemoglobin carrying reduced amounts of oxygen; often a late sign of hypoxia

central venous access device (CVAD) a device designed and used for long-term administration of medications and fluids into central veins

cerebral contusion bruising of the brain surface

cerebral edema swelling of the brain

cerumen yellow or brown, waxlike secretion found in the external auditory canal

cervical stenosis a narrowing or incomplete opening of the cervical os

cervix bottom (inferior) part of the uterus that is located in the vagina

chemical warfare use of a chemical agent, such as chlorine, as a weapon of mass destruction (WMD)

chemosis edema of the conjunctiva

chemotherapy use of medications to kill tumor cells by interfering with cellular functions and reproduction

chest drainage system use of a chest tube and closed drainage system to reexpand the lung and to remove excess air, fluid, and blood

chest percussion manually cupping over the chest wall to mobilize secretions by mechanically dislodging viscous or adherent secretions in the lungs

chest physiotherapy (CPT) therapy used to remove bronchial secretions, improve ventilation,

and increase the efficiency of the respiratory muscles; types include postural drainage, chest percussion, and vibration

cholecystectomy removal of the gallbladder

cholecystitis inflammation of the gallbladder

cholecystokinin-pancreozymin (CCK-PZ) hormone; major stimulus for digestive enzyme secretion; stimulates contraction of the gallbladder

cholelithiasis the presence of calculi in the gallbladder

cholesteatoma tumor of the middle ear or mastoid, or both, that can destroy structures of the temporal bone

cholesterol a lipid that is an integral constituent of cell membranes, transported in the circulatory system bound to low-density and high-density lipoproteins

chordoplasty repair of the tendinous fibers that connect the edges of the atrioventricular valve leaflets to the papillary muscles

choroidal neovascularization new growth of new blood vessels beneath the retina; considered to be abnormal

chronic conditions medical or health problems with associated symptoms or disabilities that require long-term management (3 months or longer)

chronic obstructive bronchitis a disease of the airways defined as the presence of cough and sputum production for at least a combined total of 3 months in each of 2 consecutive years with obstruction to airflow; a category of COPD

chronic obstructive pulmonary disease (COPD) disease state characterized by airflow limitation that is not fully reversible; sometimes referred to as *chronic airway obstruction* or *chronic obstructive lung disease*

chyme mixture of food with saliva, salivary enzymes, and gastric secretions that is produced as the food passes through the mouth, esophagus, and stomach

cilia short hairs that provide a constant whipping motion that serves to propel mucus and foreign substances away from the lung toward the larynx

circulating nurse (or circulator) registered nurse who coordinates and documents patient care in the operating room

cirrhosis a chronic liver disease characterized by fibrotic changes and the formation of dense connective tissue within the liver, subsequent degenerative changes, and loss of functioning cells

clonus abnormal movement marked by alternating contraction and relaxation of a muscle occurring in rapid succession

CMS Center for Medicare Services; the federal agency that administers Medicare, Medicaid, and the Children's Health Insurance programs

cochlea the winding, snail-shaped bony tube that forms a portion of the inner ear and contains the organ of Corti, the transducer for hearing

cochlear (acoustic) nerve the division of the eighth cranial (vestibulocochlear) nerve, which goes to the cochlea

collagen a protein present in skin, tendon, bone, cartilage, and connective tissue

collateral small vessels that may enlarge to carry blood around a blocked vessel

colloids intravenous solutions that contain molecules that are too large to pass through capillary membranes

colonization microorganisms present in or on a host, without host interference or interaction and without eliciting symptoms in the host

colposcopy microscopic examination of the lower genital tract using a magnifying instrument called a colposcope

coma prolonged state of unconsciousness

commissurotomy splitting or separating fused cardiac valve leaflets

community an interacting population of individuals living together within a larger society

compartment syndrome increasing pressure in a muscle compartment causing impaired nerve and blood vessel function

complement series of enzymatic proteins in the serum that, when activated, destroy bacteria and other cells

complete spinal cord lesion a condition that involves total loss of sensation and voluntary muscle control below the lesion in the spinal cord

computed tomographic angiography (CTA) three-dimensional image created by specialized x-ray technique to visualize blood flow

concussion a temporary neurologic dysfunction caused by trauma to the head, classified as mild or classic based on symptoms (mild, without loss of consciousness or memory; classic, includes loss of consciousness and memory)

conduction transmission of electrical impulses from one cell to another

conductive hearing loss loss of hearing in which efficient sound transmission to the inner ear is interrupted by some obstruction or disease process

condyloma external genital warts carrying the human papilloma virus

cones retinal photoreceptor cells essential for visual acuity and color discrimination

congestive heart failure (CHF) a fluid overload condition (congestion) associated with heart failure

consolidation lung tissue that has become more solid in nature due to collapse of alveoli or infectious process (pneumonia)

constructional apraxia inability to draw figures in two or three dimensions

continent urinary diversion (Kock or Charleston pouch) transplantation of the ureters to a segment of bowel with construction of an effective continence mechanism or valve

continuous ambulatory peritoneal dialysis (CAPD) method of peritoneal dialysis whereby a patient performs four or five complete exchanges or cycles throughout the day

continuous cyclic peritoneal dialysis (CCPD) method of peritoneal dialysis in which a peritoneal dialysis machine (cycler) automatically performs exchanges, usually while the patient sleeps

continuous glucose monitoring system (CGMS) a device worn for 72 hours that continuously monitors blood glucose levels; the data are downloaded and analyzed for blood glucose patterns for that time period; presently used diagnostically to elicit patterns and tailor treatment

continuous passive motion (CPM) device a device that promotes range of motion, circulation, and healing

continuous positive airway pressure (CPAP) positive pressure applied throughout the respiratory cycle to a spontaneously breathing patient to promote alveolar and airway stability; may be administered with endotracheal or tracheostomy tube or by mask

continuous renal replacement therapy (CRRT) variety of methods used to replace normal kidney function by circulating the patient's blood through a filter and returning it to the patient

continuous subcutaneous insulin infusion a small device that delivers insulin on a 24-hour basis as basal insulin; it is also programmed by the patient to deliver a bolus dose before eating a meal in an attempt to mimic normal pancreatic function

continuous venovenous hemodialysis (CVVH or CVVHD) form of continuous renal replacement therapy that results in removal of fluid and waste products; venous blood circulates through a hemofilter and returns to the patient

contractility ability of the cardiac muscle to shorten in response to an electrical impulse

contracture abnormal shortening of muscle or joint, or both; fibrosis

control containment of the growth of cancer cells

contusion blunt force injury to soft tissue

cor pulmonale right heart failure due to elevated pulmonary artery pressures or lung disease

coronary artery bypass graft (CABG) a surgical procedure in which a blood vessel from another part of the body is grafted onto the occluded coronary artery below the occlusion in such a way that blood flow bypasses the blockage

corpus luteum site of a follicle that changes after ovulation to produce progesterone

corrosive poison alkaline or acidic agent; causes tissue destruction after contact

cortical bone compact bone

corticosteroids hormones produced by the adrenal cortex or their synthetic equivalents; also referred to as adrenal-cortical hormone and adrenocorticosteroid

crackles soft, high-pitched, discontinuous popping sounds during inspiration caused by delayed reopening of the airways

creatine kinase (CK) an enzyme found in human tissues; one of the three types of CK is specific to heart muscle and may be used as an indicator of heart muscle injury

creatinine endogenous waste product of muscle energy metabolism

crepitus grating or crackling sound or sensation; may occur with movement of ends of a broken bone or irregular joint surface

cricothyroidotomy surgical opening of the cricothyroid membrane to obtain an airway that is maintained with a tracheostomy or endotracheal tube

critical limb ischemia (CLI) chronic severe arterial obstruction with severe pain

cryosurgery of the prostate localized treatment of the prostate by application of freezing temperatures

crystalloids intravenous electrolyte solutions that move freely between the intravascular compartment and interstitial spaces

cure prolonged survival and disappearance of all evidence of disease so that the patient has the same life expectancy as anyone else in his or her age group

Cushing response a compensatory response that attempts to restore blood flow by increasing arterial pressure to overcome the increased intracranial pressure; this includes rising systolic pressure, widening pulse pressure, and bradycardia

Cushing syndrome symptoms resulting from excess free circulating cortisol from the adrenal cortex; characterized by truncal obesity, "moon face," acne, abdominal striae, and hypertension

Cushing triad three classic signs—bradycardia, hypertension, and bradypnea—that represent a loss of compensatory mechanism; a presentation of brainstem dysfunction

cystectomy removal of the urinary bladder

cystitis inflammation of the urinary bladder

cystocele weakness of the anterior vaginal wall that allows the bladder to protrude into the vagina

cytokines hormones produced by leukocytes that are vital to regulation of hematopoiesis, apoptosis, and immune responses; generic term for non-antibody proteins that act as intercellular mediators, as in the generation of immune response

cytologic studies examination of tissue samples (including body fluid) under a microscope, noting the structure, formation, and/or pathology of cells

cytotoxic destructive of cells

cytotoxic T cells lymphocytes that lyse cells infected with virus; also play a role in graft rejection

D-dimer test that measures fibrin breakdown; considered to be more specific than fibrin degradation products in the diagnosis of disseminated intravascular coagulation (DIC)

deafness partial or complete loss of the ability to hear

débridement removal of foreign material and devitalized tissue until surrounding healthy tissue is exposed

debulking surgical removal of all visible tumor in the abdomen

decerebration an abnormal posture associated with severe brain injury, characterized by extreme extension of the upper and lower extremities (extension, adduction and internal rotation of the arm and flexion of the wrist and fingers, extension of the legs, and plantarflexion of the feet)

decompression (intestinal) removal of intestinal contents to prevent gas and fluid from distending the coils of the intestine

decontamination process of removing, or rendering harmless, contaminants that have accumulated on personnel, patients, and equipment

decortication an abnormal posture associated with severe brain injury, characterized by abnormal flexion of the upper extremities (adduction at the shoulder, flexion at the elbow and wrist) and extension of the lower extremities (including hips and knees)

defibrillation electrical current administered to stop an arrhythmia, not synchronized with the patient's QRS complex

dehiscence partial or complete separation of wound edges

delayed union prolongation of expected healing time for a fracture

delirium transient loss of intellectual function, usually due to systemic problems

dementia a progressive organic mental disorder characterized by personality changes, confusion, disorientation, and deterioration of intellect associated with impaired memory and judgment

dendrite portion of the neuron that conducts impulses toward the cell body

dependence occurs when a patient who has been taking opioids experiences a withdrawal syndrome when the opioids are discontinued; often occurs with opioid tolerance and does not indicate an addiction

depolarization electrical stimulation that causes contraction of heart muscle

dermatosis any abnormal skin condition

dermis the second layer of skin containing sweat glands, hair follicles, and nerves

diabetes insipidus condition in which abnormally large volumes of dilute urine are excreted as a result of deficient production of vasopressin (ADH)

diabetes mellitus a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both

diabetic ketoacidosis (DKA) a metabolic derangement in type 1 diabetes that results from a deficiency of insulin; highly acidic ketone bodies are formed, resulting in acidosis; usually requires hospitalization for treatment and is usually caused by nonadherence to the insulin regimen, concurrent illness, or infection

diagnostic peritoneal lavage instillation of lactated Ringer's or normal saline solution into the abdominal cavity to detect red blood cells, white blood cells, bile, bacteria, amylase, or gastrointestinal contents indicative of abdominal injury

dialysate solution that circulates through the dialyzer in hemodialysis and through the peritoneal membrane in peritoneal dialysis

dialyzer "artificial kidney" or dialysis machine; contains a semipermeable membrane through which particles of a certain size can pass

diaphysis shaft of long bone

diastole period of ventricular relaxation resulting in ventricular filling

diastolic heart failure the inability of the heart to pump sufficiently because of an alteration in the ability of the heart to fill; current term used to describe a type of heart failure

differentiation development of functions and characteristics that are different from those of the parent stem cell

diffusion movement of solutes (waste products) from an area of higher concentration to an area of lower concentration *or* exchange of gas molecules from areas of high concentration to areas of low concentration

digestion phase of the digestive process that occurs when digestive enzymes and secretions mix with ingested food and when proteins, fats, and sugars are broken down into their component smaller molecules

dilutional hyponatremia sodium deficiency that develops as a result of fluid retention; associated with excessive antidiuretic hormone secretion in patients with syndrome of inappropriate antidiuretic hormone (SIADH) secretion

diplopia double vision, or the awareness of two images of the same object occurring in one or both eyes

disability restriction or lack of ability to perform an activity in a normal manner; the consequences of impairment in terms of an individual's functional performance and activity; disabilities represent disturbances at the level of the person (e.g., bathing, dressing, communication, walking, grooming)

disarticulation amputation through a joint

dislocation separation of joint surfaces

distributive shock shock state resulting from displacement of blood volume creating a relative hypovolemia and inadequate delivery of oxygen to the cells

diverticulitis inflammation of a diverticulum from obstruction (by fecal matter)

diverticulosis presence of several diverticula in the intestine; common in middle age

dizziness altered sensation of orientation in space

donor site the area from which skin is taken to provide a skin graft for another part of the body

Doppler ultrasonography noninvasive diagnostic procedure to assess blood flow direction, velocity, and turbulence

DRG diagnostic related group; diagnostic categories used by Medicare to classify patients when prospectively paying health care organizations for patient care

dry powder inhaler (DPI) inhalation devices used to deliver medications to the lungs as suspended dry powder

ductal carcinoma in situ (DCIS) cancer cells that start in the ductal system of the breast but have not penetrated the surrounding tissue

dumping syndrome rapid emptying of the stomach contents into the small intestine; characterized by sweating and weakness

duodenum the first part of the small intestine, which connects with the pylorus of the stomach and extends to the jejunum

duplex ultrasound combines grayscale tissue imaging with velocity changes

dysarthria defects of articulation of language (slurred speech)

dyschezia pain with defecation

dyskinesia impaired ability to execute voluntary movements

dyslipidemia abnormal blood lipid levels, including high total, LDL, and triglyceride levels, as well as low HDL levels

dysmenorrhea painful menstruation that is not associated with any type of pathologic process

dyspareunia painful sexual intercourse

dysphagia difficulty swallowing, causing the patient to be at risk for aspiration

dysphonia abnormal voice quality caused by weakness and incoordination of muscles responsible for speech

dysplasia bizarre cell growth resulting in cells that differ in size, shape, or arrangement from other cells of the same type of tissue

dyspnea labored breathing or shortness of breath

dyspnea on exertion (DOE) shortness of breath that occurs with exertion

dysuria painful or difficult urination

ecchymosis bruise

ectopic pregnancy fertilized egg implants anywhere outside of body of the uterus, commonly the fallopian tube

edema soft tissue swelling due to fluid accumulation

effusion excess fluid in joint

EIA (enzyme immunoassay) a blood test that can determine the presence of antibodies to HIV in the blood or saliva; also referred as *enzyme-linked immunosorbent assay* (ELISA); positive results are verified with a Western blot test

ejection fraction percentage of the end-diastolic blood volume ejected from the ventricle with each heartbeat; normal is between 55% and 70%

elimination phase of digestive process that occurs after digestion and absorption, when waste products are evacuated from the body

embolus a piece of thrombus that travels through a vessel and blocks a smaller vessel

emergent triage category signifying potentially life-threatening injuries or illnesses requiring immediate treatment

emmetropia absence of refractive error

emphysema a disease of the airways characterized by destruction of the walls of over distended alveoli; a category of COPD

emptysis the coughing up of blood from the lower respiratory tract

empyema accumulation of purulent material in the pleural space

endocrine secreting internally; hormonal secretion of a ductless gland

endolymphatic hydrops dilation of the endolymphatic space of the inner ear; the pathologic correlate of Ménière disease

endometrial ablation procedure performed through a hysteroscope in which the lining of the uterus is burned away or ablated to treat abnormal uterine bleeding

endometriosis the growth of cells similar to the endometrial lining outside of the uterus causing heavy and painful menses

endometrium lining of the uterus

endorphins, enkephalins, and dynorphins morphine-like substances produced by the body; primarily found in the central nervous system; they have the potential to reduce pain

endoscopic retrograde cholangiopancreatography (ERCP) an endoscopic procedure using fiberoptic technology to visualize the biliary system

endosteum a thin, vascular membrane covering the marrow cavity of long bones and the spaces in cancellous bone

endotracheal intubation insertion of a breathing tube through the nose or mouth into the trachea

end-stage renal disease (ESRD) progressive, irreversible deterioration in renal function that results in retention of uremic waste products

enteroclysis fluoroscopic x-ray of the small intestine; a tube is placed from the nose or mouth through the esophagus and the stomach to the duodenum, a barium-based liquid contrast material is infused through the tube, and x-rays are taken as it travels through the duodenum

enterostomal therapist nurse specially educated in appropriate skin, wound, ostomy, and continence care; often referred to as wound-care specialist or wound–ostomy–continence nurse (WOCN)

enucleation complete removal of the eyeball and part of the optic nerve

eosinophil type of granulocyte; involved in allergic reactions

epidermis the outermost layer of skin

epidermopoiesis development of epidermal cells

epididymitis infection of the epididymis that usually descends from an infected prostate or urinary tract; also may develop as a complication of gonorrhea

epilepsy a group of syndromes characterized by paroxysmal transient disturbances of brain function

epiphysis end of long bone

epistaxis hemorrhage from the nose due to rupture of tiny, distended vessels in the mucous membrane of any area of the nose

epitope any component of an antigen molecule that functions as an antigenetic determinant by permitting the attachment of certain antibodies

erectile dysfunction also called *impotence;* the inability to either achieve or maintain an erection sufficient to accomplish sexual intercourse

erythema redness of the skin caused by congestion of the capillaries

erythrocyte *see* red blood cell

erythrocyte sedimentation rate (ESR) laboratory test that measures the rate of settling of red blood cells; elevation is indicative of inflammation; also called the *sed rate*

erythropoiesis process of red blood cell formation

erythropoietin hormone produced primarily by the kidney; necessary for erythropoiesis

eschar devitalized tissue resulting from a burn

escharotomy a linear excision made through eschar to release constriction of underlying tissue

esophagogastroduodenoscopy (EGD) passage of a fiberoptic tube through the mouth and throat into the digestive tract for visualization of the esophagus, stomach, and small intestine; biopsies can be performed

esophagus collapsible tube connecting the mouth to the stomach, through which food passes as it is ingested

estrogen hormone that develops and maintains the female reproductive system

eustachian tube the 3- to 4-cm tube that extends from the middle ear to the nasopharynx

euthanasia Greek for "good death"; has evolved to mean the intentional killing by act or omission of a dependent human being for his or her alleged benefit

euthyroid state of normal thyroid hormone production

evisceration (eye) removal of the intraocular contents through a corneal or scleral incision; the optic nerve, sclera, extraocular muscles, and sometimes, the cornea are left intact

evisceration (wound) protrusion of organs through the surgical incision

excision surgical removal of tissue

exenteration surgical removal of the entire contents of the orbit, including the eyeball and lids

exocrine secreting externally; hormonal secretion from excretory ducts

exophthalmos abnormal protrusion of one or both eyeballs; produces a startled expression; usually due to hyperthyroidism

expressive aphasia difficulty expressing thoughts through speech or written language; inability to express oneself; often associated with damage to the left frontal lobe area (also known as Broca aphasia)

external auditory canal the canal leading from the external auditory meatus to the tympanic membrane; about 2.5 cm in length

external ear the portion of the ear that consists of the auricle and external auditory canal; it is separated from the middle ear by the tympanic membrane

external fixator external metal frame attached to bone fragments to stabilize them

extravasation leakage of medication from the veins into the subcutaneous tissues

fascia (epimysium) fibrous tissue that covers, supports, and separates muscles

fasciculation involuntary twitch of muscle fibers

fasciotomy the incision and diversion of the muscle fascia to relieve muscle constriction, as in compartment syndrome, or to reduce fascia contracture

fasting plasma glucose (FPG) blood glucose determination obtained in the laboratory after fasting for more than 8 hours; although plasma levels are specified in diagnostic criteria, blood glucose levels, which are slightly higher than plasma levels, are more commonly used

feedback the return of information about the results of input given to a person or a system

female-to-male (FTM) a biologic female who is becoming a male

fetor hepaticus sweet, slightly fecal odor to the breath, presumed to be of intestinal origin; prevalent with the extensive collateral portal circulation in chronic liver disease

fibrin filamentous protein; basis of thrombus and blood clot

fibrinogen protein converted into fibrin to form thrombus and clot

fibrinolysis process of breakdown of fibrin clot

fibrinolytic a substance that acts to break up fibrin, the fine filaments of blood clots

fibrocystic breast changes term used to describe certain benign changes in the breast, typically associated with palpable nodularity, lumpiness, swelling, or pain

fibroscopy (gastrointestinal) intubation of a part of the GI system with a flexible, lighted tube to assist in diagnosis and treatment of diseases of that area

fine-needle aspiration insertion of a needle through the chest wall to obtain cells of a mass or tumor; usually performed under fluoroscopy or chest CT guidance

first-intention healing method of healing in which wound edges are surgically approximated and integumentary continuity is restored without granulation

flaccid displaying lack of muscle tone; limp, floppy

follicle-stimulating hormone (FSH) hormone released by the pituitary gland to stimulate estrogen production and ovulation

fornix upper part of the vagina

fraction of inspired oxygen (FiO_2) concentration of oxygen delivered (1.0 = 100% oxygen)

fracture a break in the continuity of a bone

fracture reduction restoration of fracture fragments into anatomic alignment and rotation

frequency voiding more frequently than every 3 hours

fulminant hepatic failure sudden, severe onset of acute liver failure that occurs within 8 weeks after the first symptoms of jaundice

functional incontinence physical impairments make it difficult or impossible for the patient to reach the toilet in time for voiding

fundus body of the uterus *or* the interior surface of the eye, opposite the lens, and includes the retina, optic disc, macula and fovea, and posterior pole

gangrene dead tissue

gastric refers to the stomach

gastric outlet obstruction (GOO) any condition that mechanically impedes normal gastric emptying; there is obstruction of the channel of the pylorus and duodenum through which the stomach empties

gastritis inflammation of the stomach

gastroesophageal reflux back-flow of gastric or duodenal contents into the esophagus

gastrostomy surgical creation of an opening into the stomach for the purpose of administering foods and fluids

genetics engineering emerging technology designed to enable replacement of missing or defective genes

gestational diabetes mellitus (GDM) any degree of glucose intolerance with its onset during pregnancy

glomerular filtration rate (GFR) volume of plasma filtered at the glomerulus into the kidney tubules each minute; normal rate is approximately 120 mL/min

glomerulonephritis inflammation of the glomerular capillaries

glomerulus tuft of capillaries forming part of the nephron through which filtration occurs

glucagon a hormone secreted by the alpha cells of the islets of Langerhans of the pancreas that increases the blood glucose by stimulating the liver to convert stored glycogen to glucose

glucocorticoids steroid hormones (i.e., cortisol, cortisone, and corticosterone) secreted by the adrenal cortex in response to ACTH; produces a rise of liver glycogen and blood glucose and counteracts inflammatory responses

glycated hemoglobin (glycosylated hemoglobin, Hgb A_{1C} or A1C) a long-term measure of glucose control that is a result of glucose attaching to hemoglobin for the life of the red blood cell (120 days); the goal of diabetes therapy is a normal to near-normal level of glycolated hemoglobin, the same as in the nondiabetic population

goiter enlargement of the thyroid gland; usually caused by an iodine-deficient diet

graafian follicle ovarian cells that form into a structure on the surface of the ovary that houses the ovum or unfertilized egg

grading identification of the type of tissue from which the tumor originated and the degree to which the tumor cells retain the functional and structural characteristics of the tissue of origin

graft-versus-host disease (GVHD) an immune response initiated by T lymphocytes of donor tissue against the recipient's tissues (skin, gastrointestinal tract, liver); an undesirable response

graft-versus-tumor effect the donor cell response against the malignancy; a desirable response

granulocyte granulated white blood cell (neutrophil, eosinophil, basophil); sometimes used synonymously with neutrophil

granulomas cells surrounded by lymphocytes, which can be found in all layers of the bowel; if present, they strongly suggest Crohn disease

Graves' disease a form of hyperthyroidism; characterized by a diffuse goiter and exophthalmos

grief the personal feelings that accompany an anticipated or actual loss

Hashimoto disease thyroiditis (inflammation of the thyroid gland) characterized by high levels of antimicrosomal antibodies; an autoimmune disorder that is the most common cause of hypothyroidism in the United States

head injury an injury to the scalp, skull, and/or brain

health education a variety of learning experiences designed to promote behaviors that facilitate health

health promotion the art and science of assisting people to change their lifestyle toward a higher state of wellness

hearing loss dysfunction of any component of the auditory system (conductive hearing loss, sensorineural hearing loss, mixed hearing loss)

heart failure (HF) the inability of the heart to pump sufficient blood to meet the needs of the tissues for oxygen and nutrients; signs and symptoms of pulmonary and systemic congestion may or may not be present

Helicobacter pylori a spiral-shaped gram-negative bacterium that colonizes the gastric mucosa; involved in most cases of peptic ulcer disease

helper T cells lymphocytes that attack foreign pathogens (antigens) directly

hematemesis vomiting of blood

hematocrit percentage of total blood volume consisting of red blood cells

hematopoiesis complex process of the formation and maturation of blood cells

hematuria red blood cells in the urine

hemianopsia blindness in half of the field of vision in one or both eyes

hemiarthroplasty the replacement of one of the articular surfaces (e.g., in a hip hemiarthroplasty, the femoral head and neck are replaced with a femoral prosthesis—the acetabulum is not replaced)

hemiplegia/hemiparesis paralysis/weakness on one side of the body, or part or it, due to an injury to the motor areas of the brain

hemodialysis procedure during which a patient's blood is circulated through a dialyzer to remove waste products and excess fluid

hemodynamic monitoring use of devices to measure cardiovascular function

hemoglobin iron-containing protein of red blood cells; delivers oxygen to tissues

hemolysis destruction of red blood cells; can occur within or outside of the vasculature

hemorrhagic stroke a stroke that results from bleeding into the brain tissue itself or into the subarachnoid space or ventricles

hemostasis a dynamic process that involves the cessation of bleeding from an injured vessel, which requires activity of blood vessels, platelets, coagulation, and fibrinolytic systems; intricate balance between clot formation and clot dissolution

hemothorax partial or complete collapse of the lung due to blood accumulating in the pleural space; may occur after surgery or trauma

hepatic encephalopathy central nervous system dysfunction resulting from liver disease; frequently associated with elevated ammonia levels that produce changes in mental status, altered level of consciousness, and coma

hernia protrusion of an organ or part of an organ through the wall of the cavity that normally contains it

herniation abnormal protrusion of tissue through a defect or natural opening

herpes simplex cold sore (cutaneous viral infection with painful vesicles and erosions on the tongue, palate, gingiva, buccal membranes, or lips)

high-density lipoprotein (HDL) a protein-bound lipid that transports cholesterol to the liver for excretion in the bile; composed of a higher proportion of protein to lipid than low-density lipoprotein; exerts a beneficial effect on the arterial wall

hirsutism the condition of having excessive hair growth

histamine substance in the body that causes increased gastric secretion, dilation of capillaries, and constriction of the bronchial smooth muscle

histamine-2 (H_2) receptor antagonist a pharmacologic agent that inhibits histamine action at the H_2 receptors of the stomach, resulting in inhibition of gastric acid secretion

HIV-1 retrovirus isolated and recognized as the etiologic agent of AIDS

HIV-2 virus closely related to HIV-1 that also causes AIDS, predominantly found in West Africa

homeostasis maintenance of a constant internal equilibrium in a biologic system that involves positive and negative feedback mechanisms

hormones chemical transmitter substances produced in one organ or part of the body and carried by the bloodstream to other cells or organs on which they have a specific regulatory effect; produced mainly by endocrine glands (e.g., pituitary, thyroid, gonads)

hospice a coordinated program of interdisciplinary care and services provided primarily in the home to terminally ill patients and their families

humoral immune response the immune system's second line of defense; often termed the *antibody response*

hydrocele a collection of fluid, generally in the tunica vaginalis of the testis, although it also may collect within the spermatic cord

hydrocephalus excessive cerebrospinal fluid (CSF) in the intracranial cavity, commonly due to obstruction of flow in the ventricular system or subarachnoid space

hydrochloric acid acid secreted by the glands in the stomach; mixes with chyme to break it down into absorbable molecules and to aid in the destruction of bacteria

hydrophilic a material that absorbs moisture

hydrostatic pressure the pressure created by the weight of fluid against the wall that contains it; in the body, hydrostatic pressure in blood vessels results from the weight of fluid itself and the force resulting from cardiac contraction

hygroscopic a material that absorbs moisture from the air

hymen tissue that covers the vaginal opening partially or completely before vaginal penetration

hyperemia "red eye" resulting from dilation of the vasculature of the conjunctiva

hyperglycemia elevated blood glucose level; fasting level greater than 110 mg/dL (6.1 mmol/L); 2-hour postprandial level greater than 140 mg/dL (7.8 mmol/L)

hyperglycemic hyperosmolar nonketotic syndrome (HHNS) a metabolic disorder of type 2 diabetes resulting from a relative insulin deficiency initiated by an intercurrent illness that raises the demand for insulin; associated with polyuria and severe dehydration

hyperopia farsightedness; a refractive error in which the focus of light rays from a distant object is behind the retina

hyperpigmentation increase in the melanin of the skin, resulting in an increase in pigmentation

hyperplasia abnormally increased proliferation of normal cells

hypersensitivity abnormal heightened reaction to a stimulus of any kind

hypertension blood pressure of 140/90 mm Hg or greater

hypertensive emergency a situation in which blood pressure is severely elevated and there is evidence of actual or probable target organ damage

hypertensive urgency a situation in which blood pressure is severely elevated but there is no evidence of target organ damage
hypertonic solution a solution with an osmolality higher than that of serum
hypertrophy enlargement; increase in size of muscle
hyphema blood in the anterior chamber
hypochromia pallor within the red blood cell caused by decreased hemoglobin content
hypoglycemia low blood glucose level (<60 mg/dL [<2.7 mmol/L])
hypophysectomy surgical removal of all or part of the pituitary gland
hypopigmentation decrease in the melanin of the skin, resulting in a loss of pigmentation
hyposmia impairment of the sense of smell
hypotension a decrease in blood pressure to less than 90/60 mm Hg
hypotonic solution a solution with an osmolality lower than that of serum
hypovolemic shock shock state resulting from decreased intravascular volume due to fluid loss or deficit; causes include hemorrhage and dehydration
hypoxemia decrease in arterial oxygen tension in the blood
hypoxia decrease in oxygen supply to the tissues and cells

iatrogenic incontinence the involuntary loss of urine due to extrinsic medical factors, predominantly medications
ileal conduit transplantation of the ureters to an isolated section of the terminal ileum, with one end of the ureters brought to the abdominal wall
ileus decreased motility of the GI tract, often the result of irritation of the peritoneum; signs and symptoms include diffuse abdominal discomfort, nausea, vomiting, abdominal distention, hypoactive or absent bowel sounds, absent bowel movement/flatus
immunity the body's specific protective response to an invading foreign agent or organism
immunopathology study of diseases resulting in dysfunctions within the immune system
immunoregulation complex system of checks and balances that regulates or controls immune responses
impaired fasting glucose (IFG), impaired glucose tolerance (IGT) a metabolic stage intermediate between normal glucose homeostasis and diabetes; not clinical entities in their own right but risk factors for future diabetes and cardiovascular disease
impairment loss or abnormality of psychological, physiologic, or anatomic structure or function at the organ level (e.g., dysphagia, hemiparesis); an abnormality of body structure, appearance, and organ or system function resulting from any cause
imperforate hymen membrane at the vaginal opening, or introitus, that is still intact and causing obstruction
implantable cardioverter defibrillator (ICD) a device implanted into the chest to treat arrhythmias
incentive spirometry method of deep breathing that provides visual feedback to help the patient inhale deeply and slowly and achieve maximum lung inflation
incomplete spinal cord lesion a condition where there is preservation of the sensory or motor fibers, or both, below the lesion in the spinal cord
incus the second of the three ossicles in the middle ear; it articulates with the malleus and stapes; the anvil

induration an abnormally hard lesion or reaction, as in a positive tuberculin skin test

infection condition in which the host interacts physiologically and immunologically with a microorganism

infectious disease the consequences that result from invasion of the body by microorganisms that can produce harm to the body and potentially death

informed consent the patient's autonomous decision about whether to undergo a surgical procedure; based on the nature of the condition, the treatment options, and the risks and benefits involved

ingestion phase of the digestive process that occurs when food is taken into the GI tract via the mouth and esophagus

injection congestion of blood vessels

inner ear the portion of the ear that consists of the cochlea, vestibule, and semicircular canals

insulin a hormone secreted by the beta cells of the islets of Langerhans of the pancreas that is necessary for the metabolism of carbohydrates, proteins, and fats

interdisciplinary collaboration communication and cooperation among members of diverse health care disciplines jointly to plan, implement, and evaluate care

interferons proteins formed when cells are exposed to viral or foreign agents; capable of activating other components of the immune system

intermittent claudication a muscular, cramp-like pain in the extremities consistently reproduced with the same degree of exercise or activity and relieved by rest

intermittent mandatory ventilation (IMV) mode of mechanical ventilation that provides a combination of mechanically assisted breaths and spontaneous breaths

internal auditory canal a canal in the petrous portion of the temporal bone that houses the facial and vestibulocochlear nerves (cranial nerves VII and VIII)

internal fixation the stabilization of the reduced fracture by the use of metal screws, plates, wires, nails, and pins

international normalized ratio (INR) a standard method for monitoring prothrombin levels in patients receiving oral anticoagulation (warfarin), eliminating the variation in test results from laboratory to laboratory

interstitial cystitis inflammation of the bladder wall that eventually causes disintegration of the lining and loss of bladder elasticity

interstitial nephritis inflammation within the renal tissue

intracranial pressure pressure exerted by the volume of the intracranial contents within the cranial vault

intraoperative phase period of time from when the patient is transferred to the operating room table to when he or she is admitted to the postanesthesia care unit (PACU)

intrathecal chemotherapy chemotherapeutic agents injected directly into the subarachnoid space

intrinsic factor a gastric secretion that combines with vitamin B_{12} so that the vitamin can be absorbed

introitus perineal opening to the vagina

involucrum new bone growth around a sequestrum

ischemia insufficient tissue oxygenation

ischemic stroke stroke that results from inadequate blood supply to the brain due to partial or

complete occlusion of an artery

islet cell transplantation an investigational procedure in which purified islet cells from cadaver donors are injected into the portal vein of the liver, with the goal of having these cells secrete insulin and cure type 1 diabetes

isoelectric line the baseline or flat part of the electrocardiogram (ECG), frequently noted between the T and P waves, or between the P wave and the QRS complex; ST-segment elevation or depression is noted by observing the relationship of the ST-segment to the isoelectric line (above or below)

isometric contraction muscle tension increased, length unchanged, no joint motion

isotonic contraction muscle tension unchanged, muscle shortened, joint moved

isotonic solution a solution with the same osmolality as serum and other body fluids; osmolality falls within normal range for serum (280 to 300 mOsm/kg)

jaundice yellowing discoloration of the skin by abnormally high levels of bilirubin in the blood

jejunum second portion of the small intestine, extending from the duodenum to the ileum

JNC 7 Seventh Joint National Committee on the Prevention, Detection, Evaluation, and Treatment of High Blood Pressure; committee established to study and make recommendations about hypertension in the United States; findings and recommendations of JNC 7 are contained in an extensive report published in 2003

joint area where bone ends meet; provides for motion and flexibility

joint arthroplasty or replacement the replacement of joint surfaces with metal or synthetic materials

joint capsule fibrous tissue that encloses bone ends and other joint surfaces

joint effusion the escape of fluid from the blood vessels or lymphatics into the joint space

Kegel exercises exercises that contract and relax the pelvic floor muscle, helping to strengthen it

keratin an insoluble, fibrous protein that forms the outer layer of skin

ketone a highly acidic substance formed when the liver breaks down free fatty acids in the absence of insulin

Kock pouch a type of ileostomy in which the surgeon forms an artificial rectum from a section of the ileum

Kussmaul respirations increase in respiration, particularly the tidal volume associated with metabolic acidosis

kyphosis increase in the convex curvature of the spine

lactobacilli vaginal bacteria that limit the growth of other bacteria by producing hydrogen peroxide

lamellae mature compact bone structures that form concentric rings of bone matrix; lamellar bone

laminectomy excision of the posterior arches and spinous processes of a vertebra

Langerhans cells dendritic clear cells in the epidermis that carry surface receptors for immunoglobulin and that are active participants in delayed hypersensitivity of the skin;

in addition, these cells are responsible for carrying invading bacteria to lymphocytes in lymph glands where they are neutralized

laparoscopic cholecystectomy removal of gallbladder through endoscopic procedure

large intestine the portion of the GI tract into which waste material from the small intestine passes as absorption continues and elimination begins; consists of several parts—ascending segment, transverse segment, descending segment, sigmoid colon, and rectum

laryngectomy removal of all or part of the larynx and surrounding structures

laryngitis inflammation of the larynx; may be caused by voice abuse, exposure to irritants, or infectious organisms

latency time interval after primary infection when a microorganism lives within the host without producing clinical evidence

lavage flushing of the stomach via the gastric tube with water or other fluids to clear it

leaflet repair repair of a cardiac valve's movable "flaps" (leaflets)

learning the act of gaining knowledge and skill

learning readiness the optimum time for learning to occur; usually corresponds to the learner's perceived need and desire to obtain specific knowledge

leukemia a progressive, malignant disease characterized by uncontrolled proliferation of white blood cells

leukocyte *see* white blood cell

leukopenia less than normal amount of white blood cells in circulation

lichenification thickening of the horny layer of the skin

ligament fibrous band connecting bones

limbus junction of the cornea and sclera

liniments lotions with added oil for increased softening of the skin

lipase an enzyme that aids in the digestion of fats

lobular carcinoma in situ (LCIS) atypical change and proliferation of the lobular cells of the breast; previously considered a premalignant condition but now considered a marker of increased risk for invasive breast cancer

locked-in syndrome condition due to a lesion at or below the pons or midbrain, which results in the inability to movement while consciousness is preserved; communication is severely limited

lordosis increase in lumbar curvature of the spine

low-density lipoprotein (LDL) a protein-bound lipid that transports cholesterol to tissues in the body; composed of a lower proportion of protein to lipid than high-density lipoprotein; exerts a harmful effect on the arterial wall

low-profile gastrostomy device (LPGD, G-button) an enteral feeding access device that is flush with the skin and is used for long-term feeding

luteal phase the second half or secretory phase of the menstrual cycle that occurs after ovulation

luteinizing hormone (LH) hormone released by the pituitary gland that stimulates progesterone production

lymphedema chronic swelling of an extremity due to interrupted lymphatic circulation,

typically from an axillary lymph node dissection

lymphocyte form of white blood cell involved in immune functions

lymphoid pertaining to lymphocytes

lymphokines substances released by sensitized lymphocytes when they come in contact with specific antigens

lysis destruction of cells

macrophage cells of the reticuloendothelial system (RES) that are capable of phagocytosis

magnetic resonance angiography (MRA) the use of magnetic fields and radio waves to produce two- or three-dimensional images of blood vessels

male-to-female (MTF) a biologic male who is becoming a female

malignant having cells or processes that are characteristic of cancer

malleus the first (most lateral) and largest of the three ossicles in the middle ear; it is connected to the tympanic membrane laterally and articulates with the incus; the hammer

malunion healing of a fractured bone in a malaligned position

mammoplasty surgical procedure to reconstruct or change the size or shape of the breast; can be performed for reduction or augmentation

mass casualty incident (MCI) situation in which the number of casualties exceeds the number of resources

mastalgia breast pain, usually related to hormonal fluctuations or irritation of a nerve

mechanical ventilation a positive- or negative-pressure breathing device that supports ventilation and oxygenation

Medicare Hospice Benefit a Medicare entitlement that provides for comprehensive, interdisciplinary palliative care and services for eligible beneficiaries who have a terminal illness and a life expectancy of less than 6 months

megacolon an acquired or congenital abnormal enlargement of the colon

melanin the substance responsible for melanin

melanocytes cells of the skin that produce coloration of the skin

melena tarry or black stools; indicative of blood in stools

memory cells cells that are responsible for recognizing antigens from previous exposure and mounting an immune response

menarche beginning of menstrual function

Ménière disease condition of the inner ear characterized by a triad of symptoms episodic vertigo, tinnitus, and fluctuating sensorineural hearing loss

meniscectomy the excision of damaged joint fibrocartilage

menopause permanent cessation of menstruation resulting from the loss of ovarian follicular activity

menorrhagia excessive bleeding that occurs in regular cycles

menstruation sloughing and discharge of the lining of the uterus if conception does not take place

Merkel cells cells of the epidermis that play a role in transmission of sensory messages

metabolic syndrome a cluster of metabolic abnormalities including insulin resistance, obesity,

dyslipidemia, and hypertension that increase the risk of cardiovascular disease

metaplasia conversion of one type of mature cell into another type of cell

metastasis spread of cancer cells from the primary tumor to distant sites

metered-dose inhaler (MDI) patient-activated medication canister that provides aerosolized medication that the patient inhales into the lungs

metrorrhagia irregular vaginal bleeding that is heavy and prolonged

microcytosis smaller than normal red blood cells

micrographia small and often illegible handwriting

micturition urination or voiding

middle ear the small, air-filled cavity in the temporal bone that contains the three ossicles

migraine headache a severe, unrelenting headache often accompanied by symptoms such as nausea, vomiting, and visual disturbances

mineralocorticoid steroid of the adrenal cortex; primarily aldosterone, which promotes retention of sodium and therefore water and excretion of potassium

minor triage category signifying non–life-threatening injuries or illnesses that can be routinely managed in a clinic or physician's office or that require no medical care

miotics medications that cause pupillary constriction

mitral valve atrioventricular valve located between the left atrium and left ventricle

mittelschmerz midcycle ovulatory pain caused by a ruptured corpus luteum

moderate sedation use of sedation to depress the level of consciousness without altering the patient's ability to maintain a patent airway and to respond to physical stimuli and verbal commands, previously referred to as *conscious sedation*

modified radical mastectomy removal of the breast tissue, nipple–areola complex, and a portion of the axillary lymph nodes

monitored anesthesia care (MAC) moderate sedation administered by an anesthesiologist or anesthetist

monocyte large white blood cell that develop into a macrophage when transported to tissues

Monro–Kellie hypothesis theory that states that due to limited space for expansion within the skull, an increase in volume of any one of the cranial contents—brain tissue, blood, or CSF—must be compensated for by a decrease in volume of another

morbid obesity more than twice ideal body weight, 100 lb or more over ideal body weight, or body mass index (BMI) exceeding 30 kg/m^2

mourning individual, family, group, and cultural expressions of grief and associated behaviors

mouth first portion of the GI tract, through which food is ingested

murmurs sounds created by abnormal, turbulent flow of blood in the heart

mydriatics medications instilled in the eyes that cause pupillary dilation

myeloid pertaining to nonlymphoid blood cells that differentiate into red blood cells, platelets, monocytes and macrophages, neutrophils, eosinophils, basophils, and mast cells

myelopoiesis formation and maturation of cells derived from myeloid stem cell

myelosuppression suppression of the blood cell–producing function of the bone marrow

myocardial infarction (MI) death of heart tissue caused by lack of oxygenated blood flow; if acute, abbreviated as AMI

myocardium muscle layer of the heart responsible for the pumping action of the heart
myoglobinuria iron-containing protein from muscle cells in the urine often following trauma
myomectomy surgical excision of uterine fibroids that preserves fertility
myopia nearsightedness; a refractive error in which the focus of light rays from a distant object is anterior to the retina
myxedema refers to the soft tissue changes in subcutaneous and other interstitial tissues in a person with hypothyroidism

nadir lowest point of white blood cell depression after therapy that has toxic effects on the bone marrow
nasoduodenal tube tube inserted through the nose into the beginning of the small intestine (duodenum)
nasogastric (NG) tube tube inserted through the nose into the stomach
nasojejunal tube tube inserted through the nose into the second portion of the small intestine (jejunum)
natural killer cells (NK cells) lymphocytes that defend against microorganisms and malignant cells
negative feedback regulating mechanism in which an increase or decrease in the level of a substance decreases or increases the function of the organ producing the substance
neoadjuvant chemotherapy preoperative chemotherapy; it is administered preoperatively to shrink a large tumor
neoplasm/tumor/lesion an abnormal mass of tissues, which can be benign or malignant in nature
nephron structural and functional unit of the kidney responsible for urine formation
nephropathy a long-term complication of diabetes in which the kidney cells are damaged; characterized by microalbuminuria in early stages and progressing to end-stage renal disease
nephrosclerosis atherosclerosis of renal arteries causing fibrosis, glomerular damage, ischemia
neurodegenerative a disease, process, or condition that leads to deterioration of normal cells or function of the nervous system
neurogenic bladder bladder dysfunction that results from a disorder or dysfunction of the nervous system; may result in either urinary retention or bladder overactivity, resulting in urinary urgency and urge incontinence
neurogenic shock a type of distributive shock state resulting from loss of sympathetic vascular tone causing low blood pressure
neuropathy a long-term complication of diabetes resulting from damage to the nerve cell
neurovascular status neurologic (motor and sensory components) and circulatory functioning of a body part
neutropenia abnormally low absolute neutrophil count
neutrophil fully mature white blood cell capable of phagocytosis; primary defense against bacterial infection
nociception activation of sensory transduction in nerves by thermal, mechanical, or chemical energy impinging on specialized nerve endings; the nerves involved convey information about tissue damage to the central nervous system

nociceptor a receptor preferentially sensitive to a noxious stimulus
nocturia awakening at night to urinate
nonunion failure of fragments of a fractured bone to heal together
nonurgent triage category signifying episodic or minor injury or illness in which treatment may be delayed several hours or longer without increased morbidity
normal flora persistent nonpathogenic organisms colonizing a host
normal heart sounds referred to as S_1 and S_2, are produced by closure of the atrioventricular (AV) valves (tricuspid, mitral valves) and semilunar valves (pulmonic, aortic valves), respectively
normochromic normal red blood cell color, indicating normal amount of hemoglobin
normocytic normal size of red blood cells
nosocomial pertaining to or originating from a hospitalization; not present at the time of hospital admission
nuchal rigidity stiffness of the neck or inability to bend the neck
nucleated RBC immature form of red blood cell; portion of nucleus remains within the red cell; not normally seen in circulating blood
nucleic acid amplification tests (NAAT) a test that uses nucleic acid to assess for specific pathogens
null lymphocytes lymphocytes that destroy antigens already coated with the antibody
nutrition the science that deals with food and nourishment in humans
nystagmus involuntary oscillation of the eyeball

obstructive shock shock state resulting from the obstruction of the great vessels or heart itself; examples include cardiac tamponade, tension pneumothorax, pulmonary embolism, and abdominal compartment syndrome
odynophagia pain on swallowing
oligomenorrhea infrequent or light menses sometimes occurring at intervals of greater than 35 days
oliguria total urine output less than 400 mL in 24 hours
omentum fold of the peritoneum that surrounds the stomach and other organs of the abdomen
oncology field or study of cancer
oophorectomy surgical removal of the ovaries
open lung biopsy biopsy of lung tissue performed through a limited thoracotomy incision
open reduction the correction and alignment of the fracture after surgical dissection and exposure of the fracture
open reduction with internal fixation (ORIF) open surgical procedure to repair and stabilize a fracture
opioid a morphine-like compound that produces bodily effects including pain relief, sedation, constipation, and respiratory depression; this term is preferred rather than the term *narcotic*
opportunistic infection illness caused by various organisms, some of which usually do not cause disease in persons with normal immune systems
opsonization the coating of antigen–antibody molecules with a sticky substance to facilitate

phagocytosis

optic chiasm the area of the brain where optic nerve (CN II) fibers partially cross

orchiectomy surgical removal of one or both of the testes

orchitis inflammation of the testes (testicular congestion) caused by pyogenic, viral, spirochetal, parasitic, traumatic, chemical, or unknown factors

organ of Corti the end organ of hearing, located in the cochlea

orthopnea shortness of breath when lying flat

orthotopic liver transplantation (OLT) grafting of a donor liver into the normal anatomic location, with removal of the diseased native liver

orthotopic transplantation the recipient's heart is removed, and a donor heart is grafted into its normal position in the body of the recipient; the patient has one heart

OSHA Occupational Safety and Health Administration; the federal agency providing oversight to organizations that ensure the safety of employees at work

osmolality the number of osmoles (the standard unit of osmotic pressure) per kilogram of solution, expressed as mOsm/kg; used more often in clinical practice than the term *osmolarity* to evaluate serum and urine; in addition to urea and glucose, sodium contributes the largest number of particles to osmolality

osmolarity the number of osmoles, the standard unit of osmotic pressure per liter of solution, expressed as milliosmoles per liter (mOsm/L); describes the concentration of solutes or dissolved particles

osmosis the process by which fluid moves across a semipermeable membrane from an area of low solute concentration to an area of high solute concentration; the process continues until the solute concentrations are equal on both sides of the membrane

ossicle a small bone; there are three in the middle ear malleus, incus, and stapes

ossification process in which minerals (calcium) are deposited in bone matrix

osteoarthritis degenerative joint disease characterized by destruction of the articular cartilage and overgrowth of bone

osteoblast bone-forming cell

osteoclast bone resorption cell

osteocyte mature bone cell

osteogenesis bone formation

osteoid pertaining to bone matrix tissue; "pre-bone"

osteomyelitis infection of the bone

osteon microscopic functional bone unit

osteophyte a bony outgrowth or protuberance; spur

osteoporosis a disorder in which bones lose density and become porous and fragile

otalgia sensation of fullness or pain in the ear

otitis externa (i.e., external otitis) inflammation of the external auditory canal

otitis media inflammation of the middle ear; may be acute lasting less than 6 weeks or chronic, causing irreversible tissue damage and persistent tympanic membrane perforation

otoconia debris of the inner ear comprised from small, crystalline stones of calcium carbonate

otorrhea drainage from the ear

otosclerosis a condition characterized by abnormal spongy bone formation around the stapes
oval window a fenestra (aperture) between the vestibule of the inner ear and the middle ear, occupied by the base of the stapes
ovaries almond-shaped reproductive organs that produce eggs at ovulation and play a major role in hormone production
overflow incontinence involuntary urine loss associated with overdistention of the bladder due to mechanical or anatomic bladder outlet obstruction
oxyhemoglobin combined form of oxygen and hemoglobin; found in arterial blood
oxytocin hormone secreted by the posterior pituitary; causes myometrial contraction at term and milk release during lactation

P wave the part of an electrocardiogram (ECG) that reflects conduction of an electrical impulse through the atrium; atrial depolarization (contraction)
pain an unpleasant sensory and emotional experience resulting from actual or potential tissue damage
pain threshold the point at which a stimulus is perceived as painful
pain tolerance the maximum intensity or duration of pain that a person is able to endure
palliation relief of symptoms associated with cancer
palliative care comprehensive care for patients whose disease is not responsive to cure; care also extends to patients' families
palliative sedation use of pharmacologic agents, at the request of the terminally ill patient, to induce sedation when symptoms have not responded to other management measures; the purpose is not to hasten the patient's death but to relieve intractable symptoms
pancreaticojejunostomy joining of the pancreatic duct to the jejunum by side-to-side anastomosis; allows drainage of the pancreatic secretions into the jejunum
pancreatitis inflammation of the pancreas; may be acute or chronic
pancytopenia abnormal decrease in white blood cells, red blood cells, and platelets
pannus proliferation of newly formed synovial tissue infiltrated with inflammatory cells
papilledema swelling of the optic disc
paralysis absence of muscle movement suggesting nerve damage
paraplegia paralysis of the lower extremities with dysfunction of the bowel and bladder from a lesion in the thoracic, lumbar, or sacral regions of the spinal cord
parasympathetic nervous system division of the autonomic nervous system active primarily during nonstressful conditions, controlling mostly visceral functions
parenteral nutrition (PN) method of supplying nutrients to the body by an intravenous route
paresthesia abnormal touch sensation (e.g., burning, tingling, numbness)
parotitis inflammation of the parotid gland
paroxysmal an arrhythmia that has a sudden onset and/or termination and is usually of short duration
patient-controlled analgesia (PCA) self-administration of analgesic agents by a patient instructed about the procedure
pelvic inflammatory disease (PID) infection of uterus and fallopian tubes, usually from a sexually transmitted disease

penis male organ for copulation and urination; consists of glans penis, body, and root

penumbra area of ischemic brain tissue surrounding the core infarct that is potentially viable (and therefore an important concept for treatment options for patients with an evolving ischemic stroke)

pepsin a gastric enzyme that is important in protein digestion

percutaneous coronary intervention (PCI) an invasive procedure in which a catheter is placed in a coronary artery, and one of several methods is employed to remove or reduce a blockage within the artery

percutaneous endoscopic gastrostomy (PEG) an endoscopic procedure for inserting a feeding tube into the stomach in order to provide long-term nutritional support

percutaneous thrombectomy endovascular technique to remove thrombus

percutaneous transluminal coronary angioplasty (PTCA) a type of percutaneous coronary intervention in which a balloon is inflated within a coronary artery to break an atheroma and open the vessel lumen, improving coronary artery blood flow

performance status patient activity level; ability to perform activities of daily living (ADLs), work, ambulate; multiple tools exist to measure performance status

pericardiocentesis procedure that involves aspiration of fluid from the pericardial sac

pericardiotomy surgically created opening of the pericardium

perimenopause the period immediately prior to menopause and the first year after menopause

perioperative phase period of time that constitutes the surgical experience; includes the preoperative, intraoperative, and postoperative phases of nursing care

periosteum fibrous connective tissue covering bone

peripheral arterial disease (PAD) process of blood flow reduced to tissue

peripherally inserted central catheter (PICC) a device used for intermediate-term intravenous therapy

peristalsis wavelike movement that occurs involuntarily in the alimentary canal and assists the passage of food through the bowel

peritoneal dialysis procedure that uses the lining of the patient's peritoneal cavity as the semipermeable membrane for exchange of fluid and solutes

peritoneum thin membrane that lines the inside of the wall of the abdomen and covers all the abdominal organs

peritonitis inflammation of the lining of the abdominal cavity, usually as a result of a bacterial infection of an area in the gastrointestinal tract with leakage of contents into the abdominal cavity

personal protective equipment (PPE) equipment beyond standard precautions; may include level A, B, C, and D equipment

pessary a plastic, silicone, rubber, or latex device that is inserted into the vagina

petechiae pinpoint, nonblanchable red spots that appear on the skin as a result of blood leakage into the skin

phagocytic cells cells that engulf, ingest, and destroy foreign bodies or toxins

phagocytic immune response the immune system's first line of defense, involving white blood cells that have the ability to ingest foreign particles

phagocytosis process of ingestion and digestion of bacteria by cells

phantom limb pain pain perceived as being in the amputated limb

pharyngitis inflammation of the throat; usually viral or bacterial in origin

phase I PACU area designated for care of surgical patients immediately after surgery and for patients whose condition warrants close monitoring

phase II PACU area designated for care of surgical patients who have been transferred from a phase I PACU because their condition no longer requires the close monitoring provided in a phase I PACU

phase III PACU setting in which the patient is cared for in the immediate postoperative period and then prepared for discharge from the facility

pheochromocytoma chromaffin cell tumor, usually benign, located in the adrenal medulla; characterized by secretion of catecholamines, resulting in hypertension, severe headache, profuse sweating, visual blurring, anxiety, and nausea

phimosis condition in which the foreskin is constricted so that it cannot be retracted over the glans; can occur congenitally or from inflammation and edema

photophobia ocular pain on exposure to light

physical fitness the condition of being physically healthy as a result of proper exercise and nutrition

pinna the outer part of the external ear, which collects and directs sound waves into the external auditory canal; the auricle

placebo effect analgesia that results from the expectation that a substance will work, not from the actual substance itself

plasma liquid portion of blood

plasmapheresis removal of whole blood from the body, separation of its cellular elements by centrifugation, and reinfusion of them suspended in saline or some other plasma substitute, thereby depleting the body's own plasma without depleting its cells

plasminogen protein that is converted to plasmin to dissolve thrombi and clots

platelet thrombocyte; a cellular component of blood involved in blood coagulation

pleural effusion abnormal accumulation of fluid in the pleural space

pleural space the area between the parietal and visceral pleurae; a potential space

pneumothorax partial or complete collapse of the lung due to positive pressure in the pleural space

podagra gout, especially of the great toe

polycystic ovarian syndrome (PCOS) most common endocrine disorder affecting women of reproductive age that may also cause overproduction of estrogen and testosterone resulting in abnormal thickening of the uterine lining, very heavy and/or irregular periods, as well as acne and facial hair

polycythemia increase in the red blood cell concentration in the blood; in chronic obstructive pulmonary disease (COPD), the body attempts to improve oxygen-carrying capacity by producing increasing amounts of red blood cells

polymenorrhea frequent menstruation occurring 21 days or less

polymerase chain reaction (PCR) a sensitive laboratory technique that can detect and quantify HIV in a person's blood or lymph nodes

polyuria total urine output greater than 3 L in 24 hours

portal hypertension elevated pressure in the portal circulation resulting from obstruction of

venous flow into and through the liver

position (postural) sense awareness of position of parts of the body without looking at them; also referred to as *proprioception*

positive end-expiratory pressure (PEEP) positive pressure maintained by the ventilator at the end of exhalation (instead of a normal zero pressure) to increase functional residual capacity and open collapsed alveoli; improves oxygenation with lower FiO_2

postanesthesia care unit (PACU) area where postoperative patients are monitored as they recover from anesthesia; formerly referred to as the *recovery room* or *postanesthesia recovery room*

posterior chamber space between the iris and vitreous

postoperative phase period of time that begins with the admission of the patient to the PACU and ends after a follow-up evaluation in the clinical setting or home

postural drainage positioning the patient to allow drainage from all the lobes of the lungs and airways

postural (orthostatic) hypotension a decrease in systolic blood pressure (SBP) of at least 20 mm Hg or diastolic blood pressure (DBP) of at least 10 mm Hg within 3 minutes of sitting or standing, associated with dizziness, lightheadedness, or syncope

PR interval the part of an electrocardiogram (ECG) that reflects conduction of an electrical impulse from the sinoatrial (SA) node through the atrioventricular (AV) node

preadmission testing (PAT) diagnostic testing performed before admission to the hospital

prediabetes a condition of impaired carbohydrate metabolism that increases the risk of developing diabetes

prehypertension blood pressure 120 to 129/80 to 89 mm Hg

preload degree of stretch of the cardiac muscle fibers at the end of diastole

premenstrual dysphoric disorder (PMDD) a more severe form of PMS that occurs in late luteal phase and recurs cyclically

premenstrual syndrome (PMS) a constellation of symptoms associated with fluctuation of hormones during the luteal phase of the menstrual cycle

preoperative phase period of time from when the decision for surgical intervention is made to when the patient is transferred to the operating room table

presbycusis progressive hearing loss associated with aging

presbyopia describes the condition in which the eye exhibits a progressively diminished ability to focus on near objects with age

pressure support ventilation (PSV) mode of mechanical ventilation in which preset positive pressure is delivered with spontaneous breaths to decrease work of breathing

priapism an uncontrolled, persistent erection of the penis from either neural or vascular causes, including medications, sickle cell thrombosis, leukemic cell infiltration, spinal cord tumors, and tumor invasion of the penis or its vessels

primary amenorrhea the absence of menstruation by age 16 or absence of secondary sex characteristics and menarche by age 14

primary headache a headache for which no specific organic cause can be found

primary hypertension also called essential hypertension; denotes high blood pressure from an unidentified cause

primary infection 4- to 7-week period of rapid viral replication immediately following infection; also known as acute HIV infection

progesterone hormone produced by the corpus luteum

prolapse (of a valve) stretching of an atrioventricular heart valve leaflet into the atrium during systole

prolapse an organ that slips or falls out of place

prophylactic mastectomy removal of the breast to reduce the risk of breast cancer in women considered to be at high risk for development of the disease

proportional assist ventilation (PAV) mode of mechanical ventilation that provides partial ventilatory support in proportion to the patient's inspiratory efforts; decreases the work of breathing

proptosis downward displacement of the eyeball resulting from an inflammatory condition of the orbit or a mass within the orbital cavity

prostaglandins a hormone-like substance that causes rhythmic contraction and relaxation of smooth muscle

prostate gland gland that lies just below the neck of the bladder, surrounds the urethra, and is traversed by the ejaculatory duct, a continuation of the vas deferens; produces a secretion that is chemically and physiologically suitable to the needs of the spermatozoa in their passage from the testes

prostate-specific antigen (PSA) substance that is produced by the prostate gland and measured in a blood specimen; PSA levels are increased with prostate cancer; the PSA test is used in combination with digital rectal examination to detect prostate cancer

prostatitis inflammation of the prostate gland

protease inhibitor medication that inhibits the function of protease, an enzyme needed for HIV replication

proteinuria protein in the urine

proton pump inhibitors pharmacologic agents that block acid secretion by irreversibly binding to and inhibiting the hydrogen–potassium adenosine triphosphatase pump system at the secretory surface of gastric parietal cells; most potent inhibitors of gastric acid secretion

provirus viral genetic material in the form of DNA that has been integrated into the host genome; when it is dormant in human cells, HIV is in a proviral form

ptosis drooping eyelid

pulmonary edema increase in the amount of extravascular fluid in the lung

pulmonary embolism obstruction of the pulmonary vasculature with an embolus; embolus may be due to blood clot, air bubbles, or fat droplets

pulmonary perfusion blood flow through the pulmonary vasculature

pulmonary vascular resistance resistance created by the vasculature of the lungs to the ejection of blood from the right ventricle

pulmonic valve semilunar valve located between the right ventricle and the pulmonary artery

pulseless electrical activity (PEA) condition in which electrical activity is present but there is not an adequate pulse or blood pressure because of ineffective cardiac contraction or circulating blood volume

pulsus paradoxus systolic blood pressure of more than 10 mm Hg higher during exhalation than during inspiration; difference is normally less than 10 mm Hg

purulent consisting of, containing, or discharging pus

pyelonephritis inflammation of the renal pelvis
pyloroplasty surgical procedure to increase the opening of the pyloric orifice
pylorus opening between the stomach and the duodenum
pyrosis heartburn
pyuria white blood cells in the urine

QA/QI quality assurance/quality improvement; a system of continuous monitoring and evaluation of products or services to order to maintain and/or improve quality
QRS complex the part of an electrocardiogram (ECG) that reflects conduction of an electrical impulse through the ventricles; ventricular depolarization (contraction)
QT interval the part of an electrocardiogram (ECG) that reflects the time from ventricular depolarization through repolarization (resting state)

radiation therapy use of ionizing radiation to interrupt the growth of malignant cells
radicular pain pain that radiates along the nerve, caused from irritation or pressure of the nerve root
radiculopathy disease of a nerve root
radioimmunoassay radioisotope-labeled antigen measurement of hormone or other substance
radioisotopes unstable atoms that emit small amounts of energy in the form of gamma rays; used in cardiac nuclear medicine studies
rebound hypertension pressure that is controlled with therapy and that becomes abnormally high with the discontinuation (usually abrupt) of therapy
receptive aphasia difficulty understanding spoken or written language; often associated with damage to the temporal lobe area (Wernicke aphasia)
rectocele weakness of the posterior vaginal wall that allows the rectal cavity to protrude into the submucosa of the vagina
red blood cell (RBC) also *erythrocyte;* a cellular component of blood involved in the transport of oxygen and carbon dioxide
red reflex the reddish-orange reflection from the eye's retina that is observed using an ophthalmoscope under dimly lit or dark conditions
referred pain pain perceived as coming from an area different from that in which the pathology is occurring
reflex an automatic response to stimuli
reflex incontinence involuntary loss of urine due to hyperreflexia or involuntary urethral relaxation in the absence of normal sensations; usually associated with micturition (voiding)
regurgitation backward flow of blood through a heart valve
reinforcement the process of strengthening a given response or behavior to increase the likelihood that the behavior will continue
remodeling process that ensures bone maintenance through simultaneous bone resorption and formation
renal clearance volume of plasma that the kidneys can clear of a specific solute (e.g., creatinine); expressed in milliliters per minute
renal glycosuria recurring or persistent excretion of glucose in the urine

renal replacement therapy term used to encompass life-supporting treatments for renal failure; includes hemodialysis, peritoneal dialysis, hemofiltration, and renal transplantation

repolarization return of the cell to resting state, caused by reentry of potassium into the cell while sodium exits the cell

residual urine urine that remains in the bladder after voiding

resorption removal/destruction of tissue, such as bone

respiration gas exchange between atmospheric air and the blood, and between the blood and cells of the body

respiratory weaning process of gradual, systematic withdrawal or removal of ventilator, breathing tube, and oxygen

rest pain a persistent pain in the foot at rest that can worsen at night and indicates significant arterial insufficiency

restricted zone area in the operating room where scrub attire and surgical masks are required; includes operating room and sterile core areas

restrictive lung disease disease of the lung that causes a decrease in lung volumes

resuscitation triage category signifying life-threatening injuries or illnesses requiring immediate intervention

rete ridges undulations and furrows that appear at the dermis–epidermis junction and are responsible for cementing together the two layers

reticulocytes slightly immature red blood cells (RBCs), usually only 1% of total circulating RBCs

reticuloendothelial system (RES) complex system of cells throughout body capable of phagocytosis

retinopathy a long-term complication of diabetes in which the microvascular system of the eye is damaged

retrovirus a virus that carries genetic material in RNA instead of DNA and contains reverse transcriptase

reverse transcriptase enzyme that transforms single-stranded RNA into a double-stranded DNA

rhabdomyolysis accumulation of byproducts of skeletal muscle destruction in renal tubule

rhinitis inflammation of the mucous membranes of the nose; may be infectious, allergic, or inflammatory in origin

rhinorrhea drainage of a large amount of fluid from the nose

rhinosinusitis inflammation of the sinuses; may be acute or chronic; may be viral, bacterial, or fungal in origin

RICE acronym for *R*est, *I*ce, *C*ompression, *E*levation

rigidity increase in muscle tone at rest characterized by increased resistance to passive stretch

rods retinal photoreceptor cells essential for bright and dim light

Romberg test test for cerebellar dysfunction requiring the patient to stand with feet together, eyes closed, and arms extended; inability to maintain the position, with either significant stagger or sway, is a positive test

rotator cuff shoulder muscles (supraspinatus, subscapularis, infraspinatus, and teres minor) and their tendons

round window a fenestra between the middle ear and the inner ear at the base of the cochlea,

occupied by the round window membrane

rubor reddish blue skin discoloration occurring in skin in dependent position

rule of nines method for calculating body surface area burned by dividing the body into multiples of nine

sciatica inflammation of the sciatic nerve, resulting in pain and tenderness along the nerve through the thigh and leg

sclerotherapy the injection of substances into or around esophagogastric varices to cause constriction, thickening, and hardening of the vessel and thus to stop bleeding

scoliosis lateral curving of the spine

scotomas blind or partially blind areas in the visual field

scrub role registered nurse, licensed practical nurse, or surgical technologist who scrubs and dons sterile surgical attire, prepares instruments and supplies, and hands instruments to the surgeon during the procedure

sebaceous glands glands that exist within the epidermis and secrete sebum to keep the skin soft and pliable

sebum fatty secretion of the sebaceous glands

secondary amenorrhea the absence of menses for 6 or more months after a regular cycle of menstruation has been established

secondary conditions or disorders preventable physical, mental, or social disorders resulting directly or indirectly from an initial disabling condition

secondary headache headache identified as a symptom of another organic disorder (e.g., brain tumor, hypertension)

secondary hypertension high blood pressure from an identified cause, such as renal disease

second-intention healing method of healing in which wound edges are not surgically approximated and integumentary continuity is restored by the process known as granulation

secretin hormone responsible for stimulating secretion of pancreatic juice; also used as an aid in diagnosing pancreatic exocrine disease and in obtaining desquamated pancreatic cells for cytologic examination

seizures paroxysmal transient disturbance of the brain resulting from a discharge of abnormal electrical activity

self-monitoring of blood glucose (SMBG) a method of capillary blood glucose testing in which a drop of blood is applied to a test strip that is read by a meter

self-responsibility personal accountability for one's actions or behavior

semicircular canals the superior, posterior, and lateral bony tubes that form part of the inner ear; contain the receptor organs for balance

semirestricted zone area in the operating room where scrub attire is required; may include areas where surgical instruments are processed

sensitization a heightened response seen after exposure to a noxious stimulus; response to the same stimulus is to feel more pain

sensorineural hearing loss loss of hearing related to damage of the end organ for hearing or cranial nerve VIII, or both

sentinel lymph node first lymph node(s) in the lymphatic basin that receives drainage from the

primary tumor in the breast; identified by a radioisotope and/or blue dye

septic shock distributive shock state resulting from combination of infectious trigger and impaired host response, resulting in decreased tissue perfusion

sequestrum dead bone in abscess cavity

serosa thin membrane that forms the outer layer of the stomach

serum portion of blood remaining after coagulation occurs

shock physiologic state in which there is inadequate tissue perfusion

sialadenitis inflammation of the salivary glands

sinoatrial (SA) node primary pacemaker of the heart, located in the right atrium

sinus rhythm electrical activity of the heart initiated by the sinoatrial (SA) node

sling bandage used to support an arm

small intestine longest portion of the GI tract, consisting of three parts—duodenum, jejunum, and ileum—through which food mixed with all secretions and enzymes passes as it continues to be digested and begins to be absorbed into the bloodstream

spacer device a device used to attach to a metered-dose inhaler (MDI) that may improve patients' ability to use their MDI correctly

spastic having greater than normal muscle tone

spasticity sustained increase in tension of a muscle when it is passively lengthened or stretched with exaggeration of the tendon reflexes

spermatogenesis production of sperm in the testes

spinal cord compression tumor extension into the epidural space

spinal cord injury (SCI) an injury to the spinal cord, vertebral column, supporting soft tissue, or intervertebral disks caused by trauma

spirituality personal belief systems that focus on a search for meaning and purpose in life, intangible elements that impart meaning and vitality to life, and a connectedness to a higher or transcendent dimension

spirometry pulmonary function tests that measure specific lung volumes (e.g., FEV_1, forced expired volume in 1 second), capacities (e.g., FVC, forced vital capacity), and flow rates; may be measured before and after bronchodilator administration

splint device designed specifically to support and immobilize a body part in a desired position

spondylosis ankylosis or stiffening of the cervical or lumbar vertebrae

sprain an injury to ligaments and other soft tissues at a joint

ST segment the part of an electrocardiogram (ECG) from the end of the QRS complex to the beginning of the T wave

staging process of determining the size and spread, or metastasis, of a tumor

stapes the third (most medial) ossicle of the middle ear; it articulates with the incus, and its footplate fits into the oval window; the stirrup

status epilepticus episode in which the patient experiences multiple seizure bursts with no recovery time in between

steatorrhea frothy, foul-smelling stools with a high fat content; results from impaired digestion of proteins and fats due to a lack of pancreatic juice in the intestine

stem cell primitive cell, capable of self-replication and differentiation into myeloid or

lymphoid stem cell

stenosis narrowing or tightening of an opening or passage in the body

stent a woven mesh that provides structural support to a coronary vessel, preventing its closure

stent-graft tube composed of fabric supported by a metal mesh

stereotactic biopsy computer-guided method of core needle biopsy that is useful when masses in the breast cannot be felt but can be visualized using mammography

stoma artificially created opening between a body cavity (e.g., intestine) and the body surface

stomach distensible pouch into which the food bolus passes to be digested by gastric enzymes

stomatitis inflammation of the oral mucosa

strain a musculotendinous injury

stress incontinence involuntary loss of urine through an intact urethra as a result of a sudden increase in intra-abdominal pressure

stress management behaviors and techniques used to strengthen a person's resources against stress

stress test a test used to evaluate the functioning of the cardiovascular system during a period of increased oxygen demand simulated by walking on a treadmill or medications that mimic the body's physiologic response to exercise

striae band-like streaks on the skin, distinguished by color, texture, depression, or elevation from the tissue in which they are found; usually purplish or white

stroke a syndrome characterized by death of brain cells that occurs when there is a disruption of cerebral blood flow

stroke volume (SV) amount of blood ejected from the ventricle per heartbeat

subarachnoid screw or bolt device placed into the subarachnoid space to measure intracranial pressure

subluxation partial separation or dislocation of joint surfaces

subtotal or supracervical hysterectomy removal of the uterus, fallopian tubes, and ovaries with retention of the cervix

sudden cardiac death immediate cessation of effective heart activity

suppressor T cells lymphocytes that decrease B-cell activity to a level at which the immune system is compatible with life

suprapubic catheter a urinary catheter that is inserted through a suprapubic incision into the bladder

surgical asepsis absence of microorganisms in the surgical environment to reduce the risk for infection

surgical biopsy procedure in which an entire mass or a portion of it is surgically removed for examination under a microscope by a pathologist

suspensions liquid preparations in which powder is suspended, requiring shaking before use

sympathetic nervous system division of the autonomic nervous system with predominantly excitatory responses; the "fight-or-flight" system

sympathetic ophthalmia an inflammatory condition created in the fellow eye by the affected eye (without useful vision); the condition may become chronic and result in blindness (of the fellow eye)

synchronized intermittent mandatory ventilation (SIMV) mode of mechanical ventilation in which the ventilator allows the patient to breathe spontaneously while providing a preset number of breaths to ensure adequate ventilation; ventilated breaths are synchronized with spontaneous breathing

syndrome of inappropriate antidiuretic hormone (SIADH) secretion excessive secretion of antidiuretic hormone (ADH) from the pituitary gland, despite low serum osmolality level, resulting in hyponatremia

synovial pertaining to a complex joint bounded by joint capsule and containing synovial fluid

synovitis inflammation of the synovial membrane

synovium membrane in joint that secretes lubricating fluid

systemic inflammatory response syndrome (SIRS) overwhelming inflammatory response in the absence of known infection causing decreased tissue perfusion

systemic vascular resistance resistance caused by the peripheral circulation to the ejection of blood from the left ventricle

systole period during the cardiac cycle when the ventricles contract, resulting in ejection of blood from the right and left ventricles into the pulmonary artery and aorta

systolic heart failure inability of the heart to pump sufficiently because of an alteration in the ability of the heart to contract; current term used to describe a type of heart failure

T wave the part of an electrocardiogram (ECG) that reflects repolarization of the ventricles

targeted therapies cancer treatments that seek to minimize the negative effects on healthy tissues by disrupting specific cancer cell functions, such as malignant transformation, communication pathways, processes for growth and metastasis, and genetic coding

T cells cells that are important for producing a cellular immune response

teaching the imparting of knowledge

telangiectases spider-like red marks on the skin caused by distention of the superficial blood vessels that blanch on pressure

telemetry ambulatory electrocardiographic monitoring using a battery-operated transmitting device worn by the patient

temporal bone a bone on both sides of the skull at its base; composed of the squamous, mastoid, and petrous portions

temporomandibular disorders a group of conditions that cause pain or dysfunction of the temporomandibular joint (TMJ) and surrounding structures

tendinitis inflammation of a tendon

tendon cord of fibrous tissue connecting muscle to bone

tendon transfer a surgical procedure in which a tendon is incised at its insertion and placed at a site distant from the original insertion site in order to restore or correct the function of a muscle

tenesmus ineffective and sometimes painful straining to eliminate either feces or urine resulting in abscess formation

tension pneumothorax pneumothorax characterized by increasing positive pressure in the pleural space with each breath; this is an emergency situation and the positive pressure needs to be decompressed or released immediately

terminal illness progressive, irreversible illness that despite cure-focused medical treatment will result in the patient's death

testes the ovoid sex glands encased in the scrotum; the testes produce sperm

testicular cancer the most common cancer in men 15 to 35 years of age and the second most common malignancy in those 35 to 39 years of age; its cause is unknown

testosterone male sex hormone secreted by the testes; induces and preserves the male sex characteristics

tetraplegia (formerly quadriplegia) paralysis of both arms and legs, with dysfunction of bowel and bladder from a lesion of the cervical segments of the spinal cord

therapeutic regimen a routine that promotes health and healing

third-intention healing method of healing in which surgical approximation of wound edges is delayed due to contamination and the wound heals initially by second intention (granulation), and later when the wound appears to be clean it is closed surgically

thoracentesis insertion of a needle into the pleural space to remove fluid that has accumulated and decrease pressure on the lung tissue; may also be used diagnostically to identify potential causes of a pleural effusion

thoracotomy surgical opening into the chest cavity

thrombin enzyme necessary to convert fibrinogen into fibrin clot

thrombocyte *see* platelet

thrombocytopenia decrease in the number of platelets

thrombocytosis higher than normal platelet count

thrombolysis breakdown of thrombus by pharmacologic means

thrombolytic an agent or process that breaks down blood clots

thyroid storm severe life-threatening form of hyperthyroidism precipitated by stress; usually of abrupt onset; characterized by high fever, extreme tachycardia, and altered mental state

thyroidectomy surgical removal of all or part of the thyroid gland

thyroiditis inflammation of the thyroid gland; may lead to chronic hypothyroidism or may resolve spontaneously

thyroid-stimulating hormone (TSH) released from the pituitary gland; causes stimulation of the thyroid gland, resulting in release of T_3 and T_4

thyrotoxicosis a hypermetabolic response caused by excessive endogenous (T_3 and/or T_4 hormone) or exogenous thyroid hormone

thyroxine (T_4) thyroid hormone; active iodine compound formed and stored in the thyroid; deiodinated in peripheral tissues to form triiodothyronine (T_3); maintains body metabolism in a steady state

tinea a superficial fungal infection on the skin or scalp

tinnitus subjective perception of sound with internal origin; unwanted noises in the head or ear

tolerance occurs when a person who has been taking opioids becomes less sensitive to their analgesic properties (and usually side effects); characterized by the need for increasing doses to maintain the same level of pain relief

tone (tonus) normal tension (resistance to stretch) in resting muscle

tonicity the measurement of the osmotic pressure of a solution; another term for *osmolality*

tophi accumulation of crystalline deposits in articular surfaces, bones, soft tissue, and cartilage

total artificial heart mechanical device used to aid a failing heart, assists both the right and left ventricles

total joint arthroplasty or replacement the replacement of both articular surfaces within a joint with metal or synthetic materials

total mastectomy removal of the breast tissue and nipple–areola complex

total nutrient admixture (TNA) an admixture of lipid emulsions, proteins, carbohydrates, electrolytes, vitamins, trace minerals, and water

trabeculae lattice-like bone structure; cancellous bone

tracheostomy tube indwelling tube inserted directly into the trachea to assist with ventilation

tracheotomy surgical opening into the trachea

trachoma a bilateral chronic follicular conjunctivitis of childhood that leads to blindness during adulthood, if left untreated

traction application of a pulling force to a part of the body

transbronchial through the bronchial wall, as in a transbronchial lung biopsy

transection severing of the spinal cord itself; transection can be complete (all the way through the cord) or incomplete (partially through)

transgender a person who identifies his or her gender with that of the opposite sex

transient ischemic attack (TIA) a brief episode of neurologic dysfunction caused by focal brain or retinal ischemia with clinical symptoms typically lasting less than 1 hour and without evidence of acute infarction

transurethral resection of the prostate (TUR or TURP) resection of the prostate through endoscopy; the surgical and optical instrument is introduced directly through the urethra to the prostate, and the gland is then removed in small chips with an electrical cutting loop

transverse rectus abdominis myocutaneous (TRAM) flap method of breast reconstruction in which a flap of skin, fat, and muscle from the lower abdomen, with its attached blood supply, is rotated to the mastectomy site

trapeze overhead assistive device to promote patient mobility in bed

triage process of assessing patients to determine management priorities

tricuspid valve atrioventricular valve located between the right atrium and right ventricle

triggered in reference to pacemakers, term used to describe the release of an impulse in response to some stimulus

triiodothyronine (T_3) thyroid hormone; formed and stored in the thyroid; released in smaller quantities, biologically more active and with faster onset of action than thyroxine (T_4); widespread effect on cellular metabolism, influences every major organ system

troponin myocardial protein; measurement is used to assess heart muscle injury

trypsin pancreatic enzyme; aids in digestion of proteins

tubular reabsorption movement of a substance from the kidney tubule into the blood in the peritubular capillaries or vasa recta

tubular secretion movement of a substance from the blood in the peritubular capillaries or vasa recta into the kidney tubule

Turner syndrome a female genetic disorder due to a missing or incomplete X chromosome

tympanic membrane the membrane that separates the middle ear from the external auditory canal; also referred to as the *eardrum*

tympanoplasty surgical repair of the tympanic membrane

type 1 diabetes a metabolic disorder characterized by an absence of insulin production and secretion from autoimmune destruction of the beta cells of the islets of Langerhans in the pancreas; formerly called *insulin-dependent* or *juvenile* diabetes

type 2 diabetes a metabolic disorder characterized by the relative deficiency of insulin production and a decreased insulin action and increased insulin resistance; formerly called *non–insulin-dependent* or *adult-onset* diabetes

U wave the part of an electrocardiogram (ECG) that may reflect Purkinje fiber repolarization; usually, it is not seen unless a patient's serum potassium level is low

ulcer an area of tissue erosion or an open sore

ultrafiltration process whereby water is removed from the blood by means of a pressure gradient between the patient's blood and the dialysate

ultrasonography imaging method using high-frequency sound waves to diagnose whether masses are solid or fluid-filled

unrestricted zone area in the operating room that interfaces with other departments; includes patient reception area and holding area

urea nitrogen nitrogenous end product of protein metabolism

uremia the clinical syndrome associated with an excess of urea and other nitrogenous wastes in the blood (fluid and electrolyte, hormonal, and metabolic imbalances)

ureterosigmoidostomy transplantation of the ureters into the sigmoid colon, allowing urine to flow through the colon and out the rectum

ureterovesical or vesicoureteral reflux backward flow of urine from the bladder into one or both ureters

urethritis inflammation of the urethra

urethrovesical reflux backward flow of urine from the urethra into the bladder

urge incontinence involuntary loss of urine associated with urinary urgency due to hypersensory disorders of the bladder, motor instability, or both

urgent triage category signifying serious illness or injury that is not immediately life threatening

urinary casts proteins secreted by damaged kidney tubules

urinary incontinence involuntary or uncontrolled loss of urine from the bladder sufficient to cause a social or hygienic problem

urosepsis sepsis resulting from infected urine, most often a urinary tract infection (UTI)

urticaria hives

uterine prolapse relaxation of pelvic tone that allows the cervix and uterus to descend into the lower vagina

uvulopalatopharyngoplasty (UPPP) surgical removal of the uvula, tonsils, and part of the soft palate to create a larger posterior oropharynx as treatment for obstructive sleep apnea

vagotomy syndrome dumping syndrome; gastrointestinal symptoms, such as diarrhea and abdominal cramping, resulting from rapid gastric emptying

Valsalva maneuver forcible exhalation against a closed glottis followed by a rise in intrathoracic pressure and subsequent possible dramatic rise in arterial pressure; may occur during straining at stool

valve replacement insertion of a prosthetic valve at the site of a malfunctioning heart valve to restore blood flow in one direction through the heart

valvuloplasty repair of a stenosed or regurgitant cardiac valve by commissurotomy, annuloplasty, leaflet repair, or chordoplasty (or a combination of procedures)

variceal banding procedure that involves the endoscopic placement of a rubber band-like device over esophageal varices to ligate the area and stop bleeding

varicocele an abnormal dilation of the veins of the pampiniform venous plexus in the scrotum (the network of veins from the testis and the epididymis, which constitute part of the spermatic cord)

vasculitis inflammation of a blood vessel or lymph vessel

vasoactive medications medications that act on the vessels to either constrict or dilate, resulting in either increased or decreased blood pressure and/or heart rate

vasopressin antidiuretic hormone (ADH) secreted by the posterior pituitary; causes retention of water and raises blood pressure by contraction of smooth muscle, particularly blood vessels

ventilation movement of air in and out of airways

ventilation–perfusion ratio the ratio between ventilation and perfusion in the lung; matching of ventilation to perfusion optimizes gas exchange

ventricular assist device mechanical device used to aid a failing right or left ventricle

ventricular tachycardia (VT) a rapid rhythm that originates in the ventricles

ventriculostomy a catheter placed in one of the lateral ventricles of the brain to measure intracranial pressure and allow for drainage of cerebrospinal fluid (CSF) or blood

vertigo an illusion of movement in which the individual or the surroundings are sensed as moving, usually rotation

vesicant substance that can cause tissue necrosis and damage, particularly when extravasated

vestibulocochlear nerve cranial nerve VIII; contains the cochlear (acoustic) portion and the vestibular portion

vibration a type of massage administered by quickly tapping the chest with the fingertips or alternating the fingers in a rhythmic manner, or by using a mechanical device to assist in mobilizing lung secretions

viral load test measures the quantity of HIV RNA in the blood

viral set point amount of virus present in the blood after the initial burst of viremia and the immune response that follows

vitiligo a localized or widespread condition characterized by destruction of the melanocytes in circumscribed areas of the skin, resulting in white patches

vitreous humor gelatinous material (transparent and colorless) that fills the eyeball behind the lens

volvulus abnormal twisting of the intestines resulting in intestinal obstruction

vulvovaginal candidiasis a vaginal infection caused by fungus or yeast

weapons of mass destruction (WMD) weapons used to cause widespread death and destruction

wellness a condition of good physical and emotional health sustained by a healthy lifestyle

wheezes continuous musical sounds associated with airway narrowing or partial obstruction

white blood cell (WBC) also *leukocytes;* cellular components of blood involved in defense of the body; subtypes include neutrophils, eosinophils, basophils, monocytes, and lymphocytes

window period time from infection with HIV until seroconversion detected on HIV antibody test

wound care specialist a nurse specially educated in appropriate skin, wound, ostomy, and continence care; often referred to as an *enterostomal therapist* or a *wound-ostomy-continence nurse* (WOCN)

xenograft heart valve replacement made of tissue from an animal heart valve (*synonym* heterograft)

xerosis overly dry skin

xerostomia dry oral cavity resulting from decreased function of salivary glands

Zollinger–Ellison tumor hypersecretion of gastric acid that produces peptic ulcers as a result of a non–beta cell tumor of the pancreatic islets

Suggested Answers to Unit Case Studies

UNIT ONE
Basics of Adult Health Nursing

a. Important areas of health education include:
   - Adherence to therapeutic regimen
   - Willingness to learn
   - Health literacy skills
   - Learning needs
   - Learner readiness

b. Variables that could effect medication compliance include:
   - Sensory deficits, such as hearing and visualizing
   - Financial constraints
   - Inadequate support systems
   - Life-time treatment with OTC medications
   - Mobility impairments
   - Inadequate cognitive, psychomotor, or language skills
   - Fear of loss of control in decision making

c. Teaching strategies for this patient include:
   - Knowledge of side effects of prescribed medications
   - Teaching strategies to accommodate decreased visual and hearing acuity
   - Small amounts of material at one time, frequent repetition of information, use of reinforcement techniques
   - Minimize distraction

UNIT TWO
Concepts and Challenges in Patient Management

a. Psychosocial aspects of this diagnosis include:
   - Body image
   - Self-esteem
   - Functional and cognitive abilities
   - Plan for postoperative rehabilitation
   - Prognosis

b. Potential postoperative complications may include:
   - Infection
   - Bleeding

- Impaired wound healing
- Altered pulmonary or kidney function
- Development of a deep vein thrombosis
- Increased intracranial pressure
- Seizures

c. Special needs of the patient undergoing chemotherapy include:
- Monitoring for nausea, vomiting, fatigue, and depression
- Monitoring white blood cell, hemoglobin, hematocrit, and platelet counts
- Safe administration of chemotherapy
- Monitoring for signs of bone marrow suppression including bleeding, infection, and anemia
- Nutritional status
- Teaching of self-care

UNIT THREE
Problems Related to Gas Exchange and Respiratory Function

a. Potential complications that may arise following a total laryngectomy include:
- Respiratory distress, hypoxia
- Hemorrhage
- Infection
- Wound breakdown
- Aspiration
- Tracheostomal stenosis anxiety and depression

b. Patient teaching areas of self-care include:
- Proper hand hygiene
- Adequate dietary intake
- Safe hygiene, prevention of water entering stoma during a shower
- Signs of infection, indications for notifying provider
- Avoidance of strenuous activities and fatigue
- Carry medical identification
- Performing oral care
- Importance of regular physical examinations
- Tracheostomy suctioning if necessary
- Need for home care

c. Support groups for laryngectomy patients include:
- International Association of Laryngectomees (IAL)
- I Can Cope (American Cancer Society)
- Local area support groups

UNIT FOUR
Problems Related to Cardiovascular and Circulatory Function

a. Current and potential problems related to the patient's nonadherence to medication include:
   - Obesity
   - Nonadherence with medication regimen
   - Smoking
   - Congestive heart failure

b. Important areas of teaching to emphasize include:
   - Lifestyle changes (smoking cessation, weight loss, regular physical activity)
   - Emphasize concept of lifelong blood pressure control rather than cure
   - Waist circumference of less than 40 in
   - DASH diet
   - Limiting alcohol ingestion
   - Compliance with medication regimen
   - Follow-up appointments

c. Target organs/systems that may be affected by the patient's nonadherence include:
   - Heart-Cardiac (MI)
   - Kidneys-Renal (kidney failure, elevated BUN, elevated creatinine)
   - Brain-Cerebrovascular (TIA or Stroke)

UNIT FIVE
Problems Related to Hematologic

a. The only curative treatment for CML is allogeneic stem cell transplantation.
   - The efficacy of imatinib is first-line treatment.
   - Treatment-related mortality of stem cell transplant limits use of transplant to patients with high risk or relapsed disease, or in those patients who did not respond to therapy with TKI.

b. The three phases of CML include:
   - Chronic phase: There is usually adequate numbers of health cells to fight infection; the expected outcome is correction of the chromosomal abnormality.
   - Accelerated Phase: Abnormal cells present in higher numbers.
   - Blast crisis: The predominant cell type is immature; treatment may resemble induction therapy for acute leukemia, using the same medications as for AML or ALL.
   - Most patients are diagnosed in the chronic phase.

c. Nursing considerations of the patient undergoing chemotherapy (Gleevec):
   - Monitoring side effects of chemotherapy such as fluid retention.
   - Monitoring CBC.
   - Monitoring patient for infection; educating patient on signs of infections that would warrant notification of provider.
   - Educate patients that antacids and grapefruit juice may limit drug absorption.

UNIT SIX
Problems Related to Digestive, Gastrointestinal, and Metabolic Function

a. Patient selection criteria for bariatric surgery include:
   - Table 23-5 Selection Criteria for Bariatric Surgery
   - Failure of previous nonsurgical attempts at weight reduction
   - Expectation that patient will adhere to postoperative care
   - BMI greater than or equal to 35 with obesity-associated comorbidity
   - BMI greater than or equal to 40 with no comorbidities

b. Potential lifestyle changes include:
   - Box 23-2 Dietary Guidelines for the Patient Who Has Had Bariatric Surgery
   - Do not eat and drink at the same time.
   - Eat slowly and include two protein snacks per day.
   - Patients need extensive counseling before and after the surgery.
   - All patients require lifelong monitoring of weight loss, comorbidities, metabolic and nutritional status, and dietary and activity behaviors because they are at risk for developing malnutrition and weight gain.

c. Complications that may be associated with bariatric surgery include:
   - Bleeding, blood clots, bowel obstruction, incisional or ventral hernias, and infection
   - Peritonitis, stomal obstruction, and stomal ulcers
   - Atelectasis and pneumonia
   - Nausea, dumping syndrome, diarrhea, and constipation
   - Long-term complications are related to nutritional deficiency.

UNIT SEVEN
Problems Related to Urinary Tract Function

a. Areas of teaching for this patient should include:
   - Lifestyle changes
   - Dietary restrictions
   - Encouragement of self-management
   - Patient and family teaching regarding the symptoms of worsening renal function; frequent, clear explanations and information
   - Dialysis education
   - Care of the vascular access; patients with fistulae or grafts are taught to check daily for a thrill over the graft (vibrating or buzzing sensation) and to notify health care provider or dialysis center if absent.

b. Treatment modalities for this patient population include:
   - Pharmacologic therapies, which include calcium, phosphorous binders, antihypertensives, antiseizure agents, erythropoietin, and agents to treat metabolic acidosis
   - Nutritional therapy and fluid restriction
   - Potential blood transfusions

c. Nursing management would include:
   - Prevention of infection due to invasive line and catheters
   - Meticulous skin care
   - Psychosocial care; teaching in brief 10- to 15-minute sessions
   - Nutritional and fluid therapy; monitoring fluid and electrolyte balance
   - Monitoring weight
   - Teaching regarding dietary restrictions
   - Monitoring for complications of chronic kidney failure

UNIT EIGHT
Problems Related to Endocrine Function

a. Questions to ask the patient regarding his fluctuating blood sugar levels include:
   - What times do you take your blood sugar?
   - Have you been sick lately?
   - Have you started taking any new medications?
   - Do you have all the supplies you need to take your blood sugar?
   - Describe a typical meal.
   - Tell me what you do for exercise.

b. Areas of teaching with regard to the foot wound for this patient should include:
   - Inspect your feet daily; use a mirror to check the bottom of your feet.
   - Wash your feet in warm, not hot, water and dry them well.
   - Wear shoes and socks at all times; never walk barefoot.
   - Put your feet up while sitting.
   - Contact your health care provider if you have a cut, sore, blister, or bruise on your foot that does not heal within 3 days or sooner if you see signs of infection.
   - Remember that because you have diabetes, it will take longer for you to heal.
   - Because you have diabetes, you may experience decreased sensation in your lower legs and feet.
   - Maintaining optimal glucose control will aid healing and help to prevent infection.
   - Monitor your food intake by using a meal planning guide and by monitoring carbohydrate intake.

c. Aids to assist patient in keeping more accurate records of his blood sugar include:
   - Keeping a blood sugar log
   - Obtaining blood sugar levels at the same time each day
   - Taking blood sugar prior to meals

UNIT NINE
Problems Related to Reproductive Function

a. Risk factors associated with cervical cancer include:
   - Lesbian women are at higher risk for cervical cancer due to misinformation, insufficient knowledge and screening.

- The human papillomavirus (HPV) has been implicated.
- Intercourse with an uncircumcised male, high parity, cigarette smoking, multiple sexual partners.
- See also Box 33-11 Risk Factors for Cervical Cancer.

b. Clinical manifestations that the patient may have had prior to the diagnosis include:
- Irregular vaginal bleeding and pelvic pain and pressure
- Malodorous vaginal discharge, which occurs as a result of tumor necrosis
- Dyspareunia and rectal pressure are also common as the tumor increases in size and extent invading surrounding tissue causing other symptoms to develop.

c. The purpose of a colposcopy is:
- To magnify the cervix which has had acetic acid solution applied to it to help differentiate the cervical cells. Biopsies are taken in areas of visible abnormal vascular patterns.
- Approximately 50% of newly diagnosed women with cervical cancer will present with stage I disease.

d. Medical management of cervical cancer includes:
- Cervical conization or cone biopsy
- Cold knife conization and loop electrosurgical excision procedure (LEEP) are other procedures that may be performed to treat high- or low-grade squamous intraepithelial lesions, which are precursors to cervical cancer.
- Cervical conization alone is adequate for those women who want to preserve childbearing ability.
- Patients diagnosed with a stage IB or IIA undergo a radical hysterectomy: removal of the uterus and upper one third of the vagina, including the cervix, but sparing the ovaries. Pelvic radiation and chemotherapy may follow but depends on the size and extent of the tumor.
- Stage IB carries an increased risk of recurrence.
- Neoadjuvant chemotherapy has demonstrated success in decreasing tumor size and increasing survival when used prior to a radical hysterectomy.

UNIT TEN
Problems Related to Immunologic Function

a. The nurse could expect that the following medications may be ordered for this patient:
- Nonsteroidal anti-inflammatory drugs (indomethacin or ibuprofen) are considered agents of first choice for an acute attack.
- Indomethacin or ibuprofen with colchicines as an alternative or in combination may be considered.
- Low-dose colchicine has been used for prophylaxis after resolution of attacks; not as preventative of accumulation in joints.
- Allopurinol (Zyloprim) is considered the drug of choice for preventing the precipitation of an attack and tophi formation and promoting the regression of

existing tophi.
- Uricosuric agents, such as probenecid (Benemid), correct hyperuricemia by inhibiting renal reabsorption and increasing urinary excretion.
- When reduction of the serum urate level is indicated, uricosuric agents are the medications of choice.
- Febuxostat (Uloric) has been approved for the treatment of gout that does not respond to usual treatment. Newer urate-lowering agents, such as uricase, are currently under investigation and show promise for successful gout treatment.
- Corticosteroids are useful for short-term therapy of acute gout and may be used on patients who have no response to other therapy.

b. The two phases of medical management of gout include:
- Management of acute gouty inflammation
- Long-term management to prevent flare-ups and to control hyperuricemia

c. Nursing management of gout includes:
- Pain management is the primary concern during the acute phase of an attack. The joint should be rested and application of ice, not heat, may help with reducing discomfort.
- Patients should be taught to limit alcohol intake and to avoid fad starvation diets, foods high in purines and high in fructose.
- The patient should drink plenty of fluids, at least 2,000 mL daily, to lessen renal involvement and the development of urinary stones.
- Dietary restriction of sodium, fat, and cholesterol can lead to a reduction in gout symptoms and decrease effects associated with coexisting metabolic syndrome.
- Review Table 39-3 Medications Used in Rheumatic Diseases and Table 39-4 Medications Used to Treat Gout

d. Nursing diagnoses for this patient may include:
- Acute and chronic pain related to inflammation and/or progression of joint deterioration.
- Self-care deficits (specify) related to limitations secondary to progression of disease, pain, fatigue, contractures, and loss of motion.
- Risk for injury related to adverse effects of medications and potential complications.
- Insomnia related to pain, anxiety/stress, depression, and medications.

UNIT ELEVEN
Problems Related to Musculoskeletal Function

a. Evaluative data would include:
- A focus on history and physical examination, including general observation of the patient, back examination, and neurologic testing (reflexes, sensory impairment, muscle strength, straight-leg raising, and muscle atrophy).
- The patient may report pain radiating down the leg, which is known as radiculopathy or sciatica.

- The patient's gait, spinal mobility, reflexes, leg length, leg motor strength, and sensory perception may be affected.

b. Diagnostic procedures that could lead to a definitive diagnosis include:
   - X-ray of the spine, CT, MRI, EMG
   - See Box 41-1 Diagnostic Procedures for Low Back Pain

c. Medical and nursing management of this patient includes:
   - Management focuses on relief of pain and discomfort, activity modification, use of back-conserving techniques of body mechanics, improved self-esteem, and weight reduction.
   - Most back pain is self-limited and resolves within 4 weeks with analgesics, rest, stress reduction, and relaxation.
   - Pain-guided imagery, nonprescription analgesics, diaphragmatic breathing, and relaxation.
   - Mobility-position changes should be made slowly and carried out with assistance as required; avoid twisting and jarring movements; alternate lying, sitting, and walking activities frequently; avoid sitting, standing, or walking for long periods.
   - As patient achieves comfort, activities are gradually resumed, and an exercise program is initiated (see Box 41-2, p. 1187).

UNIT TWELVE
Problems Related to Neurologic Function

a. Emergency management of stroke includes:
   - Acute stroke care can be divided into two phases: hyperacute phase (the first 24 hours of care) and phase 2 (acute care during the hospitalization).
   - An algorithm is used in the hyperacute phase for the initial workup of a patient presenting with acute stroke symptoms (see Fig. 47-6, p. 1363).
   - The diagnosis is made by history, neurologic examination, and neuroimaging. An initial head CT will determine whether the patient is experiencing a hemorrhagic stroke.
   - The National Institutes of Health Stroke Scale (NIHSS) has become an accepted assessment tool to quantify stroke severity and to assess patient outcome after stroke treatment (see Table 47-4, p. 1366).
   - Review Table 47-2 Comparison of Major Types of Stroke.
   - Review Box 47-1 Stroke Chain of Survival: The 7 D's.

b. The type of stroke that the patient may be experiencing is an ischemic stroke
   - In an ischemic stroke, disruption of the cerebral blood flow due to an obstruction of a blood vessel initiates a complex series of metabolic events referred to as the ischemic cascade.

c. Standardized performance measures for ischemic stroke care include:
   - Nonambulatory patients should start receiving DVT prophylaxis by the end of day 2.
   - Patient is prescribed antithrombotic therapy at discharge.

- Patients with atrial fibrillation are discharged on anticoagulation.
- Patients with acute ischemic stroke who arrive at the hospital within 180 minutes of time last known well may receive tPA.
- Stroke education, cholesterol-lowering medication.
- Review Table 47-1 Stroke Performance Measures.

d. Nursing considerations for the patient receiving t-PA include:
- The penumbra area may be revitalized by administration of tissue plasminogen activator (tPA), which selectively binds fibrin-converting plasminogen to plasmin, causing clot lysis.
- The initial expedited diagnostic workup and treatment of ischemic stroke is driven by time-dependent pharmacologic and clot retrieval device options.
- Thrombolysis with recombinant tissue plasminogen activator (rtPA) is currently the only FDA-approved drug for acute ischemic stroke within a 3-hour window of symptom onset.
- Once a hemorrhage has been ruled out and the clinical diagnosis of ischemic stroke is made, the acute stroke team must review the eligibility criteria for tPA administration
- Review inclusion/exclusion criteria in Figure 47-7 Acute Stroke Protocol.
- Table 47-5 Schedule of Neurologic Assessment and Vital Signs and Other Acute Care Assessments in Thrombolysis-Treated and Nonthrombolysis-Treated Patients summarizes the nursing care for thrombolysis treatment for patients with acute ischemic stroke.

UNIT THIRTEEN
Problems Related to Sensorineural Function

a. Criterion for a cochlear implant includes:
- At least 1 year of age
- Selected after careful screening by otologic history, physical examination, audiologic testing, x-rays, and psychological testing Those that benefit from a cochlear implant include:
- Profound sensorineural hearing loss in both ears
- Inability to hear and recognize speech well with hearing aids
- No medical contraindication to a cochlear implant or general anesthesia
- Indications that being able to hear would enhance the patient's life

b. A cochlear implant involves:
- Implantation of a small receiver in the temporal bone through a postauricular incision and placing electrodes into the inner ear
- The microphone and transmitter are worn on the external ear

c. The rehabilitation period includes:
- Extensive cochlear rehabilitation with the multidisciplinary team, which includes an audiologist and speech pathologist.
- Several months may be needed to interpret the sounds heard.

- Children and adults who lost their hearing before they learned to speak take much longer to acquire speech.

UNIT FOURTEEN
Problems Related to Integumentary Function

a. Nursing management for this patient during the emergent phase of burn injury includes:
   - ABCs
   - In high-voltage electrical injury, spinal cord injury can result; cervical spine immobilization
   - Arrhythmias can occur from electrical injury; cardiac monitoring
   - Neurologic assessment
   - Management of fluid and electrolyte loss and shock (refer to Table 53-4, p. 1498)
   - Secondary head-to-toe assessment
   - Note time of injury, source of the burn, how the burn was treated at the scene, and any history of falling with the injury
   - History of pre-existing disease, allergies, medications, and the use of drugs, alcohol, and tobacco
   - IV analgesia
   - Assessment of TBSA and depth of injury
   - Baseline height, weight, and labs

b. Graft site care includes:
   - Position and turn carefully to avoid disturbing the graft or putting pressure on the graft site.
   - Elevate extremity to minimize edema.
   - Occlusive dressings may be used to immobilize the graft.

   Donor site care includes:
   - A moist gauze dressing is applied at the time of surgery to maintain pressure and to stop any bleeding
   - During healing, site must remain clean, dry, and free of pressure
   - Heals spontaneously within 7 to 14 days
   - Pain management

c. Long-term complications for this patient include:
   - Hypertrophic scarring
   - Immobility
   - Loss of body image due to disfigurement
   - Psychological and economic impact
   - Pain

UNIT FIFTEEN
Other Acute Problems

a. Treatment measures to reverse MODS are aimed at:
   - Controlling the initiating event
   - Promoting adequate organ perfusion
   - Providing nutritional support
   - The nurse is aware that mortality rates are 40% when two organ systems are involved and persistent dysfunction (>72 hours) in three organ systems can result in a mortality risk of 80%. Commonly affected organs are the kidneys (acute kidney failure) and lungs (acute respiratory distress syndrome).

b. Patient populations at increased risk for developing MODS include:
   - Elderly, those with chronic illness, malnutrition, immunosuppression, or surgical or traumatic wounds
   - Early detection and documentation of initial signs of infection are essential in managing MODS in elderly patients. Subtle changes in mentation and a gradual rise in temperature are early warning signs.

c. Nursing management of the patient with MODS includes:
   - The general plan of nursing care for patient with MODS is the same as that for patients in septic shock.
   - Primary nursing interventions are aimed at supporting the patient and monitoring organ perfusion until primary organ insults are halted.
   - Providing information and support to family members is a critical role of the nurse. The health care team needs to address end-of-life decisions to ensure that supportive therapies are congruent with the patient's wishes.
