The ECG is observed continuously by placing the patient on a bedside (hardwire) monitor or telemetry (battery-operated transmitting device worn by the patient), both of which transmit to a central bank of monitors. The telemetry system is wireless and allows patients to be monitored while ambulating. These forms of monitoring have graded visual and audible alarms that sound when an arrhythmia is detected. However, many of the alarms can be false alarms, caused by artifact that mimics an arrhythmia. Muscular activity, patient movement, electrical interference, or equipment malfunction are common causes of artifact. Nurses dealing with excessive alarms may become desensitized to these sounds and develop alarm fatigue. Alarm fatigue delays the nurse's response time or results in missed alarms. Alarm fatigue has serious consequences as undetected arrhythmias have led to serious adverse events, including death of patients (Honan et al., 2015).

Several nursing interventions facilitate acquisition of accurate data, reduce risk of alarm fatigue, and ensure patient safety when using various forms of cardiac monitoring (Hannibal, 2014; Sendelbach & Funk, 2013; Sendelbach & Jepsen, 2013). Key to the elimination of artifact is using proper skin preparation before applying electrodes and changing the electrode every 24 hours. Continuous ECG monitoring is discussed in Chapter 17.

Patients requiring ECG monitoring need to be informed of the purpose of the monitoring and cautioned that it does not detect symptoms such as dyspnea or chest pain. Therefore, patients need to be advised to report symptoms to the nurse whenever they occur.

Stress Testing

Stress testing is used to evaluate the response of the cardiovascular system to increased demands for oxygen and nutrients. It is used to determine the (1) presence of atherosclerosis in the arteries of the heart and lower extremities, (2) functional capacity of the heart after an MI or heart surgery, and (3) effectiveness of the medical regimen. The

stress test is usually combined with a radionuclide imaging technique or echocardiogram to examine myocardial function during exercise and at rest.

Procedure

During an exercise stress test, the patient walks on a treadmill (most common) or pedals a stationary bicycle. Exercise intensity progresses according to established protocols in which the speed and grade of the treadmill are increased every few minutes. If the patient is unable to exercise, a pharmacologic stress test is performed. Patients undergoing a pharmacologic stress test with radionuclide imaging will receive an infusion of a vasodilating agent (dipyridamole [Persantine], adenosine [Adenocard], or regadenoson [Lexiscan]) to mimic the physiologic effects of exercise. If echocardiography is used, the patient receives an infusion of dobutamine, a synthetic sympathomimetic agent to increase the metabolic demands of the heart.

Throughout the test, the patient is assessed for signs and symptoms of myocardial or leg ischemia (claudication) by monitoring the ECG, BP, physical appearance, perceived exertion, and symptoms, including chest pain, dyspnea, dizziness, leg cramping, and fatigue. The stress test is said to be "positive" if evidence of myocardial ischemia is detected by changes in the patient's ECG or claudication is validated by a decrease in ankle pressure. A positive stress test is an indication for additional testing.

Nursing Interventions

Patients are instructed to fast for 4 hours before the test, avoiding tobacco, caffeine, and other stimulants. Medications may be taken with sips of water. Clothes and rubber-soled shoes suitable for exercising should be worn. The nurse describes the monitoring equipment, symptoms to report, and reviews the exercise protocol and the need for the patient to put forth his or her best efforts to complete the test. If vasodilating agents are used, patients are informed that they may have transient flushing or nausea. If the stress test is to be combined with imaging techniques, information related to these techniques is also reviewed. After the test, patients are monitored for 10 to 15 minutes or until stable, and then patients may resume their usual activities.

Radionuclide Imaging

Radionuclide imaging studies involve the use of radioisotopes to evaluate coronary artery perfusion noninvasively, to detect myocardial ischemia and infarction, and to assess left ventricular function. Radioisotopes are atoms in an unstable form that give off small amounts of energy in the form of gamma rays as they decay. When radioisotopes are injected into the bloodstream, the energy emitted can be detected by a gamma scintillation camera positioned over the body. These radioisotopes are called tracers.

Myocardial Perfusion Imaging

Myocardial perfusion imaging is performed using two types of techniques—single-photon emission computed tomography (SPECT) or positron emission tomography (PET). It is commonly performed after an acute MI to determine if arterial perfusion to the heart is compromised during activity and to evaluate the extent of myocardial damage. It is also used to evaluate if myocardial ischemia from CAD is the cause of chest pain or other CAD-

related symptoms.

These imaging techniques are performed in combination with stress testing to compare images obtained when the heart is resting to images of the heart in a stressed state resulting from exercise or medications. An area of the myocardium that shows no perfusion or reduced perfusion is said to have a "defect" present. Comparing resting images with images taken after the stress test help differentiate ischemic myocardium from infarct-related myocardium. A defect that does not change in size before and after stress is called a fixed defect. Fixed defects indicate that there is no perfusion in that area of the myocardium, which is the case after an MI. Defects that appear or that get larger after the stress test images are taken indicate reduced perfusion to that area of the heart. Because the defect disappears with rest, it is called a reversible defect. Reversible defects constitute positive stress test findings. Typically, cardiac catheterization is recommended after a positive test result to determine the severity of obstructions to blood flow caused by CAD.

SPECT is a painless, noninvasive procedure that involves the injection of one of three commercially available tracers (technetium [Tc]-99m sestamibi, Tc-99m-tetrofosmin, or thallium-201). During SPECT, patients are positioned supine on the table with their arms over their heads. The gamma camera circles around the chest area converting the signals from the traces into pictures of the heart. The procedure takes approximately 30 minutes. The second scan is repeated following the exercise or pharmacologic stress test.

During PET, tracers are administered by injection; one compound is used to determine blood flow in the myocardium, and another determines the metabolic function. The PET camera provides detailed three-dimensional images of the distributed compounds. The viability of the myocardium is determined by comparing the extent of glucose metabolism in the myocardium to the degree of blood flow. For example, ischemic but viable tissue will show decreased blood flow and elevated metabolism. For a patient with this finding, revascularization through surgery or percutaneous coronary interventions will probably be indicated to improve heart function. Restrictions of food intake before the test vary among institutions, but because PET evaluates glucose metabolism, the patient's blood glucose level should be within the normal range before testing.

The patient undergoing nuclear imaging techniques with stress testing should be prepared for the type of stressor to be used (exercise or drug) and the type of imaging technique (SPECT or PET). The patient may be concerned about receiving a radioactive substance and needs to be reassured that these tracers are safe—the radiation exposure is similar to that of other diagnostic x-ray studies. No postprocedure radiation precautions are necessary.

Test of Ventricular Function and Wall Motion

Equilibrium radionuclide angiocardiography (ERNA), also known as multiple-gated acquisition (MUGA) scanning, is a noninvasive technique that uses a conventional scintillation camera interfaced with a computer to record images of the heart during several hundred heartbeats. The computer processes the data and allows for sequential images of the functioning heart. These images are analyzed to evaluate left ventricular function, wall motion, and EF. This scanning procedure can be used to assess for differences in left ventricular function during rest and exercise. The patient is reassured that there is no radiation danger and is instructed to remain motionless during the scan.

Echocardiography

Traditional Echocardiography

Echocardiography, a noninvasive ultrasound test, is used to examine cardiac structures and function.

Procedure. A handheld transducer generates high-frequency sound waves through the chest wall into the heart and records the return signals for display on an oscilloscope and recording on a videotape. An ECG is recorded simultaneously to assist with interpreting the echocardiogram. Two-dimensional or cross-sectional echocardiography, an enhancement of this technique, creates a sophisticated, spatially correct image of the heart. Other techniques, such as Doppler and color flow imaging echocardiography, show the direction and velocity of the blood flow through the heart.

Nursing Interventions. The nurse prepares the patient for the test by explaining that it is a painless procedure and that the transducer emits sound waves as it is moved across the surface of the chest wall. Gel applied to the skin helps transmit the sound waves. Periodically, the patient is asked to turn onto the left side or hold a breath. The test takes about 30 to 45 minutes.

Transesophageal Echocardiography

Procedure. Transesophageal echocardiography (TEE) involves threading a small transducer through the mouth and into the esophagus. This technique provides clearer images than other ultrasound methods because ultrasound waves are passed through less dense tissue. It is an important diagnostic tool for determining if atrial or ventricular thrombi are present in patients with HF, valvular heart disease, and arrhythmias.

A topical anesthetic and moderate sedation are used during a TEE because of the discomfort associated with the positioning of the transducer. Once the patient is sedated, the transducer is inserted into the mouth and the patient is asked to swallow several times until it is positioned in the esophagus.

Complications are uncommon during TEE, but if they do occur they are serious. These complications are caused by sedation and impaired swallowing resulting from the topical anesthesia (respiratory depression and aspiration) and by insertion and manipulation of the transducer into the esophagus and stomach (vasovagal response or esophageal perforation). The patient must be assessed before TEE for a history of dysphagia or radiation therapy to the chest, which increases the risk of complications.

Nursing Interventions. Prior to the test, the nurse provides preprocedure education and ensures that patients have a clear understanding of what the test entails and why it is being performed. Patients are instructed not to eat or drink anything for 6 hours before the study; that an IV will be inserted to administer medications, including a sedative to keep the patient comfortable; and after the removal of dentures, a topical anesthetic agent is used to numb the throat. After the procedure, the nurse informs patients that they will remain in bed with the head of the bed elevated to 45 degrees and will be offered something to drink as soon as they are recovered from the sedation and swallow, cough, and gag reflexes have returned. Patients are reminded that a sore throat may be present for the next 24 hours.

They are to report the presence of a persistent sore throat, shortness of breath, or difficulty swallowing. If the procedure is performed in an outpatient setting, patients must have someone transport them home.

The nurse follows the organization's moderate sedation policy. During the test, the nurse provides emotional support and monitors the patient's comfort level, level of consciousness, BP, ECG, respiration, and oxygen saturation (SpO_2). Liquids and food are withheld until patients are fully alert and the effect of the topical anesthetic agent is reversed; swallowing reflexes may be diminished for several hours. Once the patient begins taking liquids, the patient should be assessed for dysphagia (difficulty swallowing).

Cardiac Catheterization

This invasive diagnostic procedure uses fluoroscopy (an imaging technique that visualizes the heart on an x-ray screen) to guide catheter placement into the heart and to view chambers and coronary arteries. This procedure is usually performed in the outpatient setting, unless the condition of the patient is serious enough to require hospitalization, such as HF or acute MI.

Cardiac catheterization is the gold standard for diagnosing CAD and quantifying the extent of coronary artery obstruction (reported as percentage). Cardiac catheterization is also used to diagnose pulmonary hypertension and valvular heart disease. Results of this procedure are used to determine if revascularization procedures (percutaneous coronary intervention or coronary artery bypass surgery) or valve replacement/repair are indicated.

In preparation for the procedure, patients have blood tests performed to evaluate metabolic function (electrolytes and glucose) and renal function (blood urea nitrogen and creatinine level). Baseline coagulation studies (activated thromboplastin time, international normalized ratio, and prothrombin time) are obtained to guide dosing of anticoagulation during the procedure. Because bleeding and hematoma formation are procedure risks, a complete blood cell count (hematocrit, hemoglobin, platelets) is necessary to establish baseline values. Later these results are compared with postprocedure results to monitor for blood loss. Patients who are managed on warfarin (Coumadin) are informed to discontinue the medication 3 days before the procedure, and the INR is assessed preprocedure. An INR of less than 1.8 is recommended to minimize bleeding, and an INR less than 2.2 is considered acceptable if the radial artery is used (Davidson & Bonow, 2015, p. 366). For patients with diabetes, metformin is discontinued the day before any diagnostic testing because of the potential development of lactic acidosis; normal renal function should be confirmed before the medication is restarted after the procedure.

Patients are NPO for at least 6 hours, and an IV is established for sedation, fluids, heparin, and other medications. BP and multiple ECG leads are monitored to observe for hemodynamic instability and arrhythmias, and pulse oximetry is used to monitor respiratory status. Prior to the procedure, patients having experienced a reaction to contrast agents are premedicated with antihistamines and steroids. Contrast agents can induce contrast-induced nephropathy (CIN), a form of acute kidney failure in patients who have diabetes, HF, renal insufficiency or renal disease, hypotension, dehydration, or are older aged. Patients at risk for CIN receive pre- and postprocedure preventive strategies. IV hydration increases vascular volume and facilitates removal of contrast from the kidneys. Administration of sodium bicarbonate and the antioxidant acetylcysteine (Mucomyst),

both urine-alkalizing agents, aid in protecting the renal tubules from an acidic environment (Jorgensen, 2013). Advise the patient that he or she may feel warm and have a metallic taste and/or a burning sensation for a few seconds behind the eyes or in the jaw, teeth, tongue, or lips during injection of contrast medium (Daniels, 2014). In addition, an important role of the nurse is to prepare the patient and family for the cardiac catheterization. Box 12-4 outlines the information that should be reviewed prior to the procedure.

BOX 12-4 Patient Education

Preparing for a Cardiac Catheterization

Goal: To assure adequate preparation for the procedure

- Ask patients about any concerns or fears they have about the procedure.
- Remind patients to fast for 8 to 12 hours before the procedure.
- Understand the procedure involves lying on a hard table for about an hour.
- Assure patient that medications will be given to maintain comfort.
- Tell patients they may experience palpitations due to extra heartbeats that can occur as the catheter is advanced through the heart. Flushing and a sensation similar to the need to void may occur after injection of the contrast agent, which subsides in 1 minute or less.

Procedure

Right-Heart Catheterization. Right-heart catheterization is performed to evaluate pressures and oxygen saturations in the chambers of the right side of the heart and the function of the tricuspid and pulmonary valves. It involves the passage of a catheter from an antecubital, internal jugular, subclavian, or femoral vein into the right atrium, right ventricle, and PA. Complications, although rare, include arrhythmias, infection, and perforation of the septum or chamber wall.

Left-Heart Catheterization. Left-heart catheterization is performed to evaluate the patency of the coronary arteries and the function of the left ventricle and the mitral and aortic valves. It is performed by the insertion of a catheter into the radial or femoral artery that is advanced into the aorta, left ventricle, and coronary arteries. If the radial artery approach is selected, the Allen test is performed to assess arterial perfusion of the hand (discussed later in this chapter). The radial artery approach is associated with reduction in major bleeding, access-related complications, mortality, and major adverse cardiac events (Mahla, Mahla, Choudhary, & Nahata, 2015; Ruiz-Rodriguez, Asfour, Lolay, Ziada, & Abdel-Latif, 2016). Rare complications include arrhythmias, acute MI, perforation of the heart or great vessels, and systemic embolization.

Angiography. Angiography involves the injection of a contrast agent into the vascular system to visualize the heart and blood vessels. *Coronary angiography* is produced through the injection of the contrast agent into the coronary arteries to determine patency. An *aortogram* is produced through the injection of the contrast agent to highlight the aorta and

its major arteries.

Arterial Hemostasis. Once the arterial catheter is removed, either manual pressure, mechanical compression devices, percutaneously deployed vascular closure devices, or external patches are used to achieve hemostasis. Major benefits of the vascular closure devices include immediate hemostasis and a shorter time on bed rest. Rare complications associated with these devices include bleeding around the closure device, infection, and arterial obstruction.

Nursing Interventions

After cardiac catheterization, the nurse:

- Assesses the catheter access site frequently for bleeding or hematoma formation. If hematoma develops, notify the provider and apply direct pressure with gloved hand for 15 minutes (Daniels, 2014).
- Assesses for arrhythmias using cardiac monitoring or by assessing the apical and peripheral pulses for a pulse deficit. A vagal response, causing bradycardia and hypotension, can be triggered by discomfort from manual pressure used to obtain hemostasis as the arterial or venous catheter is removed. It is reversed by promptly elevating the lower extremities above heart level, infusing IV fluid, and administering IV atropine to treat the bradycardia, as prescribed.
- Maintains the patient on bed rest after the procedure until hemostasis of the involved blood vessels is achieved, which is based upon variables such as catheter insertion site, size of the catheter used, anticoagulation status of the patient, and other patient variables (e.g., advanced age, obesity, bleeding disorder). Variations exist in time on bedrest and range from 2 to 8 hours. If manual or mechanical pressure was used, bed rest is maintained for up to 6 hours with the affected leg straight and the head elevated to 30 degrees. For comfort, the patient may be turned from side to side with the affected extremity straight. If a percutaneous closure device or patch was deployed, the nurse reviews local nursing care standards and anticipates that the patient will have fewer activity restrictions. Analgesic medication is administered for discomfort.
- Instructs the patient to report chest pain and bleeding or sudden discomfort from the catheter insertion sites immediately.
- Assesses for contrast agent–induced renal failure by monitoring for an increase in creatinine levels. IV hydration is used to flush the contrast agent from the urinary tract; accurate intake and output are recorded.
- Assesses peripheral perfusion of the involved limb, including peripheral pulses, capillary refill, and neurovascular status per institution policy until discharge, as embolization is infrequent but can cause limb or end-organ ischemia.
- Ensures patient safety by instructing the patient to ask for help when getting out of bed the first time. The patient is assessed for bleeding from the catheter access site and for orthostatic hypotension.
- Provides patients with additional instructions at time of discharge (see Box 12-5).

BOX 12-5 Patient Education

Self-Management After Cardiac Catheterization

Goal: To assure that patients have information they need to reduce the risk of postprocedure complications and to understand their treatment plan.

- For the next 24 hours, do not bend at the waist, strain, or lift heavy objects.
- If the radial artery was used, avoid sleeping on the affected arm for 24 hours and refrain from repetitive movement of the affected extremity for 24–48 hours.
- Avoid tub baths, but shower as desired.
- Ask your provider about when you may resume your usual activities.
- Call your provider if you have any bleeding, swelling, new bruising, or pain from your procedure puncture site, or a temperature of 101.5°F (38.6°C) or more.
- Talk with your provider about getting assistance with lifestyle changes to reduce your risk for future heart problems. If test results show that you have coronary artery disease, ask your provider to refer you to a local cardiac rehabilitation program.
- Your provider may prescribe new medications. If you suspect that any of these are causing side effects, call your provider immediately. Do not stop taking any medications before talking to your provider.

Hemodynamic Monitoring

Hemodynamic monitoring continuously assesses the cardiovascular function of critically ill patients. It requires a special catheter and pressure monitoring system composed of a continuous flushing device to maintain catheter patency, a transducer to convert the pressure coming from the artery or heart chamber into an electrical signal, and a monitor, which displays the pressure waveform on a bedside oscilloscope.

Procedure

Central Venous Pressure Monitoring. CVP is measured by positioning a catheter in the vena cava (superior or inferior) or right atrium. It reflects right ventricle preload because pressure in the vena cava, right atrium, and right ventricle are all equal at the end of diastole. Normal CVP is 2 to 8 mm Hg. A CVP of greater than 8 mm Hg indicates hypervolemia (excessive fluid circulating in the body) or right-sided HF. On the contrary, a CVP of less than 2 mm Hg indicates a reduction in preload or hypovolemia. Complications of CVP monitoring are infection, pneumothorax, and air embolism.

Pulmonary Artery Pressure Monitoring. PA pressure monitoring involves the use of a balloon-tipped catheter that is inserted through a large vein (subclavian, jugular, or femoral) and connected to the pressure monitoring system (see Fig. 12-10). The catheter is threaded through the right side of the heart into the PA. It is used in critically ill patients to measure the cardiac output and right atrial, PA systolic and diastolic, and pulmonary capillary wedge pressures (see Fig. 12-5, for normal pressures).

The PA diastolic and PA wedge pressures are used most often because they reflect left ventricular preload. These readings are possible because, at the end of diastole, when the ventricle is completely filled and the mitral valve is open, there is equalization of pressure within all left heart chambers and vessels (left ventricle and atrium, pulmonary veins and arteries). The PA diastolic and PA wedge pressures are used to diagnose the etiology of shock and evaluate the response of the patient's cardiovascular system to medical interventions.

The pulmonary capillary wedge pressure is obtained by inflating the balloon tip that causes the catheter to float out into a smaller branch of the PA. This is an occlusive maneuver; therefore, the measurement must be taken immediately, the balloon deflated, and the waveform assessed to ensure that the catheter returned to its normal position in the PA.

Complications of PA pressure monitoring include infection, PA rupture, pulmonary thromboembolism, pulmonary infarction, arrhythmias, and air embolism.

Intra-arterial BP Monitoring. Intra-arterial BP monitoring is used to obtain continuous systolic, diastolic, and mean arterial pressure (MAP) readings and blood samples. MAP is used to reflect the perfusion pressure to major organs. During one cardiac cycle, the heart spends two thirds of the time in diastole, compared with systole. The formula for calculating MAP is: MAP = (2 × diastolic) + systolic/3. The cardiac monitor automatically makes the calculation, or if the BP is taken by cuff pressure, it can be calculated manually. Major organs require an MAP of 65 mm Hg (normal range is 70 to 110 mm Hg).

The Allen test is used to assess for adequate perfusion of the hand via the ulnar artery prior to cannulating the radial artery for pressure monitoring. The Allen test is performed by compressing the radial and ulnar arteries simultaneously and asking the patient to make a fist, which causes the hand to blanch. After the patient opens the fist, the nurse releases the pressure on the ulnar artery while maintaining pressure on the radial artery. The patient's hand will turn pink within 3 to 5 seconds if the ulnar artery is patent (Bickley, 2013). If other arteries are selected for cannulation, a Doppler ultrasound is used to assess perfusion to the involved limb.

Complications associated with arterial monitoring include arterial obstruction with distal ischemia, hemorrhage, air embolism, arteriospasm, and infection.

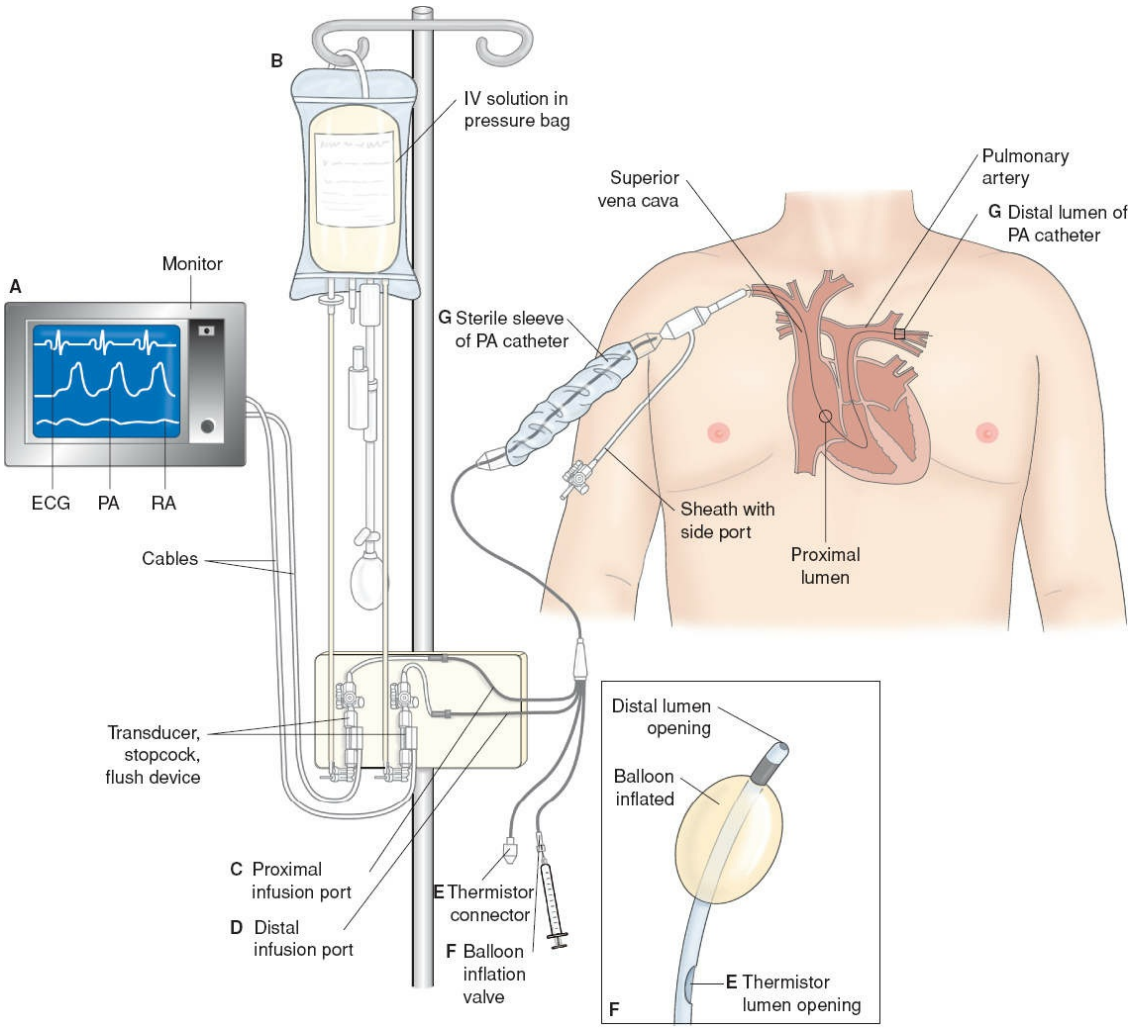

FIGURE 12-10 Pulmonary artery (PA) catheter and pressure monitoring systems. (A) Bedside monitor that connects with cables to (B) the pressure monitoring systems (includes IV solution in a pressure bag, IV tubing, and two transducers with stopcocks and flush devices). This system connects to (C) the proximal infusion port that opens in the right atria and is used to infuse fluids or medications and monitor central venous pressures and (D) the distal infusion port. This port opens in the PA and is used to monitor PA pressures. (E) The thermistor connector is attached to the bedside cardiac monitor to obtain cardiac output. (F) An air filled-syringe is attached to the balloon inflation valve during catheter insertion and measurement of PA wedge pressure. (G) PA catheter positioned in the PA. Note the sterile sleeve over the PA catheter. The PA catheter is threaded through the sheath until it reaches the desired position in the PA. The side port on the sheath is used to infuse medications or fluids. ECG, electrocardiogram; RA, right atrium.

Nursing Interventions

Nurses receive comprehensive training prior to using hemodynamic monitoring technologies. The following guidelines are used to ensure safe and effective care:

- The insertion site is prepared following local hospital policy, which includes clipping excessive hair, cleansing with an antiseptic solution, and using a local anesthetic.
- CVP and PA catheters are used for infusing IV fluids and drugs as well as drawing blood specimens.
- The nurse assures that the system is set up and maintained properly. The pressure

monitoring system must be kept patent, free of air bubbles, and calibrated to atmospheric pressure (referred to as the zero reference point).

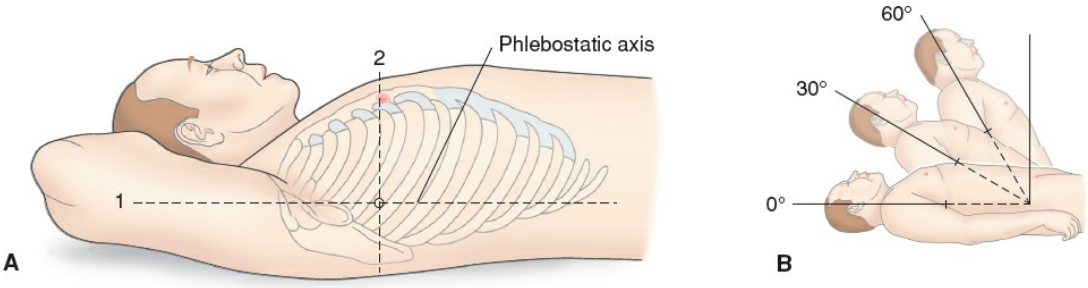

FIGURE 12-11 A. The phlebostatic axis is the reference point for the atrium when the patient is in supine position. It is the intersection of two lines on the left chest wall: (1) the midaxillary line drawn between the anterior and posterior surfaces of the chest and (2) the line drawn through the fourth intercostal space. Its location is identified with a skin marker. The stopcock of the transducer used in hemodynamic monitoring is "leveled" at this mark prior to obtaining pressure measurements. B. Measurements can be taken with the head of the bed (HOB) elevated to 60 degrees. Note the phlebostatic axis changes as the HOB is elevated, so that the stopcock and the transducer must be repositioned after each position change.

- Before the pressure measurements are obtained, the nurse positions the stopcock of the transducer at the phlebostatic axis. Figure 12-11 describes landmarks to use to locate the phlebostatic axis.
- The pressure monitoring system and catheter insertion site dressing are changed according to hospital policy. In general, the dressing is kept dry and air occlusive. Dressing changes are performed using sterile technique.
- CVP and PA catheter placement is confirmed by chest x-ray.
- The nurse monitors the patient for complications associated with the various forms of hemodynamic monitoring and reports findings immediately.

Doppler Ultrasound Flow Studies

Doppler ultrasound studies are most often used to detect obstruction of blood flow to the extremities or head due to a thrombus and determine if atherosclerosis is present in the lower extremities in patients with intermittent claudication. This technology uses a handheld device, called a *transducer,* which sends and receives sound waves that "echo" or bounce off blood cells. The transducer is placed in contact with the skin over the blood vessel being examined. Normally, the transducer detects rhythmic changes in the sound waves that are generated as blood cells flow through patent blood vessels. Obstruction to blood flow is evidenced by no change in sound waves.

Standard Doppler ultrasound studies are combined with computer technology to provide additional information about blood flow. Duplex Doppler ultrasound provides a picture of the blood vessel and a graph describing the speed and direction of blood flow, and color Doppler ultrasound produces colors to visualize these dimensions of blood flow.

When the nurse has difficulty finding a pulse, the continuous wave Doppler, a portable device, can be used. This device is used to hear, rather than feel the pulse. Box 12-6 describes how to use the continuous wave Doppler to evaluate pulses in the lower

extremities.

The continuous wave Doppler is also used to obtain systolic BPs in the extremities to calculate the ankle-brachial index (ABI). This ratio compares the ankle to arm systolic BPs and is an indicator of perfusion to the lower extremities. The ABI for each lower extremity is calculated by selecting the higher of the two ankle systolic pressures (obtained from both the posterior tibial and dorsalis pedis arteries) and dividing it by the higher of the right and left brachial systolic pressures. The ankle systolic pressure is normally the same or slightly higher than the brachial systolic pressure, resulting in an ABI of 1 to 1.1. As PAD progresses, the systolic BP in the ankle of the affected extremity decreases. An ABI of 0.8 to 0.99 indicates mild PAD, 0.5 to 0.79 moderate PAD (claudication present), and less than 0.5 severe PAD (pain at rest).

- Example: The patient's right brachial systolic pressure is 160 mm Hg; the right posterior tibial systolic pressure is 80 mm Hg.

$$80/160 = 0.5 \text{ ABI}$$

BOX 12-6 Evaluating Lower Extremity Pulse Using a Continuous Wave Doppler

The patient is placed in supine position with the head of the bed elevated to 20–30 degrees; the legs are externally rotated to permit adequate access to the medial malleolus. Acoustic gel is applied to the skin to permit uniform transmission of the ultrasound wave (do not use electrocardiogram gel). The tip of the Doppler transducer is positioned at a 45- to 60-degree angle over the expected location of the artery and angled slowly to identify arterial blood flow. Avoid using excessive pressure as diseased arteries can collapse if too much pressure is applied over the artery.

CHAPTER REVIEW

Critical Thinking Exercises

1. The patient you are taking care of in the cardiac intensive care unit has a diagnosis of decompensated heart failure and is having a pulmonary artery catheter inserted to help guide medical therapy. Describe the process you will use to obtain pulmonary artery systolic, diastolic, and wedge pressure measurements. Discuss the correlation between pulmonary artery pressure measurements and the patient's symptoms and physical assessment findings. What is your role in assuring that the pulmonary catheter is properly maintained and that the patient is free from catheter-related complications?
2. You are admitting a 65-year-old woman with rapid atrial fibrillation who will be undergoing a number of tests and treatment for this arrhythmia. She has an order for telemetry, and a transesophageal echocardiography (TEE) is planned for later today. What nursing interventions will you perform to minimize false ECG alarms? How will

you prepare the patient for ECG monitoring? Why is it important for the patient to undergo a TEE? How will you describe this procedure to the patient? What is your role in managing the patient when she returns from having the TEE?

3. You are considering taking a position in an emergency department and plan to observe the triage nurse on the evening shift. You want to prepare for this experience by familiarizing yourself with the common types of patients who present with cardiovascular-related complaints. Name five common cardiovascular diseases and signs and symptoms associated with these disorders. What additional information do you need to consider when quickly assessing patients for a potentially life-threatening illness? Describe how you will focus your physical assessment on the cardiovascular system.

NCLEX-Style Review Questions

1. The nurse is performing a cardiac examination of a patient who has HF. When auscultating over the apical area, the nurse hears an extra sound between S_1 and S_2. This sound may be caused by:
   a. S_3, indicating worsening HF
   b. S_4, indicating the sound of blood moving into a noncompliant left ventricle
   c. A diastolic murmur, suggesting aortic regurgitation
   d. A systolic murmur, indicating a mitral valve regurgitation

2. After which of the following diagnostic tests will the patient need to remain on bedrest for 2 to 6 hours?
   a. Exercise stress test
   b. Cardiac catheterization
   c. Myocardial perfusion imaging
   d. Traditional echocardiography

3. A man was just admitted after experiencing chest pain and shortness of breath. Blood tests were sent while he was in the emergency department, and the nurse is evaluating the results. An elevation in which one of the following blood tests indicates that he is having an acute myocardial infarction?
   a. Troponin
   b. Cholesterol
   c. Brain natriuretic peptide (BNP)
   d. C-reactive protein (CRP)

4. A 45-year-old woman who has a history of diabetes, hypertension, and cigarette smoking walks into the emergency room with shortness of breath, indigestion, and diaphoresis. She should be evaluated immediately for:
   a. Community-acquired pneumonia
   b. Acute coronary syndrome

c. Pulmonary embolus
d. Aortic dissection

5. Which of the following signs or symptoms are indications for performing an ankle-brachial index (ABI)?
   a. Irregular, superficial ulcer along the medial malleolus
   b. 4+ pitting edema to lower extremities
   c. Intermittent claudication
   d. Pulse deficit greater than 20 mm Hg

CHAPTER 13

Nursing Management: Patients with Hypertension

Andrea Rothman Mann

Learning Objectives

After reading this chapter, you will be able to:

1. Compare and contrast the continuum of normotension, prehypertension, hypertension, and hypertensive crisis.
2. Assess for risk factors for primary and secondary hypertension.
3. Correlate pathophysiology of hypertension to complications in target organs.
4. Identify nursing management of patients with prehypertension and hypertension, including lifestyle changes and pharmacologic therapy.
5. Summarize management of the patient experiencing hypertensive crisis.
6. Incorporate current evidence when caring for the client with prehypertension and hypertension.

Currently, about 78 million American adults in the United States have hypertension; that amounts to almost one in three people over 18 years of age. In addition, hypertension affects 1 billion individuals worldwide (NIH, 2013; CDC, 2015). Another one in three American adults has prehypertension—blood pressure higher than the normal 120/80 or lower but not yet in the high blood pressure range. Hypertension is the most common condition causing visits to a health care provider (Krader, 2014). Diagnosis of hypertension may be missed easily as it is asymptomatic and must be measured to be detected; hence the term "silent killer" (Bostock-Cox, 2013). About one in five adults is unaware of having high blood pressure (CDC, 2015). Undiagnosed, untreated, or undertreated hypertension may lead to target organ damage causing myocardial infarction (MI), kidney damage or failure, cerebrovascular accident (CVA), or hypertensive retinopathy.

High blood pressure was a primary or contributing cause of death for more than 360,000 Americans in 2013—that's nearly 1,000 deaths each day. High blood pressure costs the nation $46 billion each year. This total includes the cost of health care services, medications to treat high blood pressure, and missed days of work (CDC, 2015).

Almost 91% of adults aged 18 years and older had their blood pressure measured within the preceding 2 years and could state their blood pressure. The target of Healthy People 2020 is to increase this awareness to 92.6%, for a 2% improvement nationwide. Over the past decade, blood pressure control increased by 55% among adults aged 18 years and above, up from 48.9% in the data from 2009 to 2012. Yet, of individuals treated for hypertension, approximately 50% do not achieve adequate blood pressure (BP) control (ODPHP, 2014; CDC, 2015).

Nursing Alert

Every 10 years, the U.S. Department of Health and Human Services (HHS) provides scientific insights and lessons from the decade, along with new knowledge from current data, trends, and innovations. Healthy People 2020 reflects assessments of major risks to health and wellness, changing public priorities, and emerging issues related to national preparedness and prevention.

HYPERTENSION

The Joint National Committee on Prevention, Detection, Evaluation and Treatment of High BP (JNC7) of the National Institute of Health (2003) defines a BP of less than 120/80 mm Hg diastolic as normal, BP of 120 to 139/80 to 89 mm Hg as prehypertension, and a BP of 140/90 mm Hg or higher as hypertension. The JNC8 of 2014 did not focus on or change classifications but rather introduced evidence-based age and pharmacologic treatment options.

The JNC8 defined diagnosis for hypertension based on those under 60 years of age and those over 60 years of age (Weber, 2014). In addition, JNC8 addressed evidence-based thresholds for initiating pharmacologic therapy (James et al., 2013) and concluded hypertensive persons ages 30 through 59 years without diabetes or chronic kidney disease (CKD) should receive treatment when the BP is greater than 140/90. The panel based the recommendation of maintaining BP of less than 140/90 mm Hg for individuals 59 years of age or less on expert opinion. Treatment threshold for diagnosis of hypertension in those age 60 or older without diabetes or CKD is considered a blood pressure reading above 150/90. All individuals who have diabetes and/or CKD should receive treatment to keep the BP below 140/90 (James et al., 2013). While this may seem like the standards for diagnosis and treatment for hypertension have been relaxed, Weber (2014) points out that evidence-based recommendations need not be applied rigidly. The blood pressure targets and therapies should be based on patient response to treatment and practitioner judgment regardless of age. Further evidence is needed to clarify treatment for patients up to 80 years of age.

TABLE 13-1 Classification of Blood Pressure (BP) for Adults Age 18 and Older[a]

BP Classification[a]	Systolic BP (mm Hg)		Diastolic BP (mm Hg)
Normal	Less than 120	and	Less than 80
Prehypertension	120–139	or	or 80–89
Stage 1 hypertension	140–159	or	90–99
Stage 2 hypertension	160 or higher	or	100 or higher
Hypertensive crisis	Greater than 180		Greater than 120

[a]Based on the average of two or more properly measured, seated readings taken on each of two or more office visits. From the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High BP. (2003). *Hypertension*, *42*(6), 1206–1252; Ferri, 2018.

Hypertension is further classified as stage 1 or 2 depending on its severity (Table 13-1). Stage 1 hypertension occurs when the systolic pressure is 140 to 159 mm Hg or greater and/or the diastolic pressure is 90 to 99 mm Hg or greater. Stage 2 hypertension occurs when the systolic pressure is 160 mm Hg or higher, or the diastolic pressure is 100 mm Hg or higher. Severe hypertension is demonstrated with the systolic BP greater than or equals to 180 mm Hg or the diastolic BP *greater than or equals to* 110 mm Hg (O'Connell, 2014). If the systolic and diastolic pressures are in separate categories, the higher classification is used. The term *resistant hypertension* is used to define patients whose conventional blood

pressure remains uncontrolled by three classes of antihypertensive agents, including a diuretic (Franklin et al., 2013). The terms *refractory* and *resistant* are used interchangeably (Ferri, 2018).

Classifying hypertension on a continuum as opposed to a single value promotes an understanding that elevation in BP from prehypertension through stages 1 and 2 is associated with increasing morbidity and mortality. This health risk rises with elevations of either the systolic or diastolic pressure. Diagnosis of hypertension should be based on the average of two or more accurate BP measurements taken during two or more contacts with a health care provider (D'Amico & Barbenit, 2016).

Blood pressure should be measured accurately in both arms, using the higher reading. The nurse should palpate the brachial pulse prior to measurement and use the correct cuff size. The patient should be seated for at least 5 minutes; smoking and eating should be avoided for 30 minutes. In addition, the arm should be at heart level.

Nursing Alert

As this book is ready to print, the American College of Cardiology and the American Heart Association recommended new guidelines for the definition of elevated blood pressure (Systolic 120 to 129 mm Hg and diastolic <80 mm Hg); and Hypertension (Stage 1 is defined as Systolic 130 to 139 mm Hg or diastolic 80 to 89 mm Hg), and Stage 2 is a Systolic at least 140 mm Hg or diastolic at least 90 mm Hg). While evidence can seem conflicting at this point, it is continually evolving. Awareness of current literature is essential to providing evidenced based care, and since science is continually evolving, nurses must commit to continuous lifelong learning. Current emphasis supports non-pharmacologic interventions, in addition to pharmacologic therapy individualized by the provider.

Pathophysiology

BP is the product of cardiac output (CO) multiplied by peripheral vascular resistance (PVR). CO is the volume of blood being pumped by the heart per minute and is the product of the heart rate (HR) multiplied by the stroke volume (SV), which is the amount of blood pumped out from the ventricles per beat. PVR is related to the diameter of the blood vessel and the viscosity of the blood. The thicker the blood or smaller the radius of the blood vessel, the higher the resistance. Conversely, the larger the diameter of the vessel or thinner the blood, the lower the PVR (Grossman & Porth, 2014). For hypertension to develop, there must be a change in one or more factors affecting PVR or CO (Fig. 13-1). In addition, there must also be a problem with the body's control systems that monitor or regulate pressure. Management of hypertension aims to decrease peripheral resistance or blood volume, or the strength, force, and rate of myocardial contraction.

Circadian variations in blood pressure occur. Blood pressure tends to be highest shortly after awakening and then decreases throughout the day, reaching the lowest point between 2 AM and 5 AM. Individuals who reflect this pattern are known as dippers; those who reflect a pattern of a flattened 24-hour blood pressure profile are referred to as nondippers. Nondippers may be at higher risk for cardiovascular and kidney disease; however, additional research is needed to determine optimal therapy (Grossman & Porth, 2014).

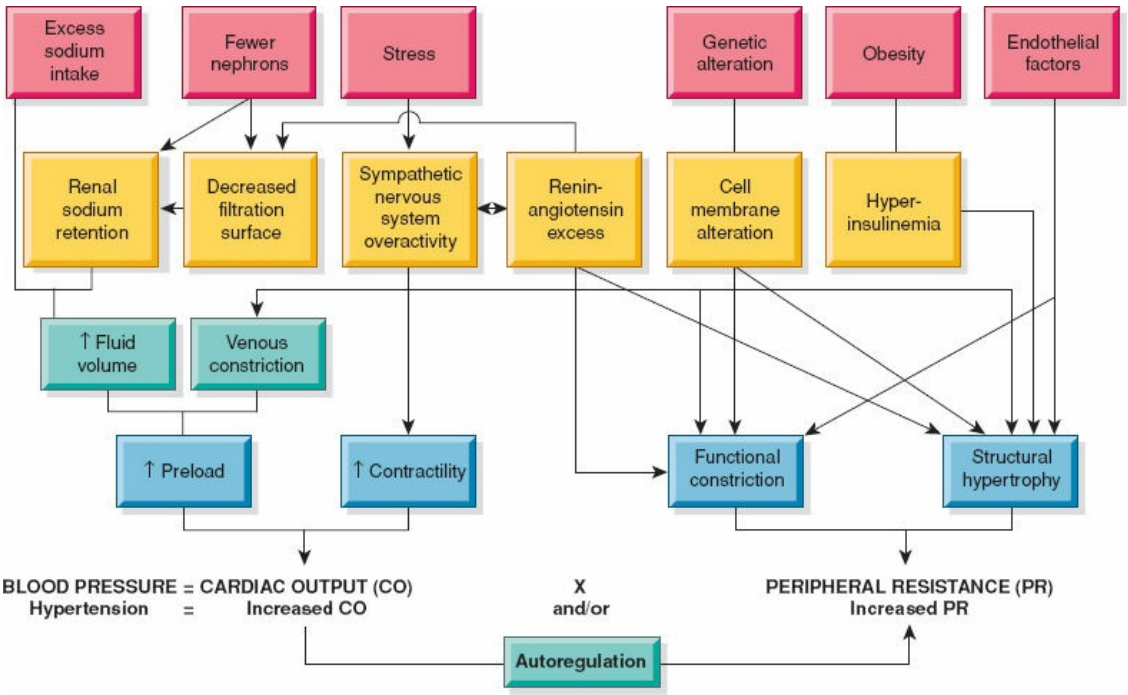

FIGURE 13-1 Factors involved in control of BP. (Adapted from Kaplan, N. M., Lieberman, E., & Neal, W. (2014). *Kaplan's clinical hypertension* (11th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Of patients with hypertension, 90% to 95% have primary hypertension; that is, high BP from an unidentified cause (Felicilda-Reynaldo & Kenneally, 2015; Grossman & Porth, 2014). This type of hypertension has also been called *essential* or *idiopathic* hypertension. The remainder of this group have secondary hypertension, which is high BP related to an

identified cause. These causes include narrowing of the renal arteries or renal artery stenosis, kidney disease, hyperaldosteronism (mineralocorticoid hypertension), medications, pregnancy, and coarctation of the aorta (Grossman & Porth, 2014).

White-coat hypertension and *masked hypertension* are two additional types of hypertension with emerging concern for complications (AHA, 2016a). The patient with white-coat hypertension has normal ambulatory BP readings but elevated pressures (greater than 140/90) in a health care office or clinic. Those identified as having white-coat hypertension should have follow-up with ambulatory home blood pressure monitoring to determine if the situation is, indeed, isolated. Ambulatory monitoring will also determine if masked hypertension exists (discussed below) and if systolic hypertension is present; in addition, it will help to prevent overdiagnosis and treatment, which may cause unnecessary side effects (ACP, 2012; AHA, 2014b; Franklin et al., 2013). Additional studies of individuals with white-coat hypertension demonstrated an increased risk of developing systolic hypertension; 37% developed a diagnosis of hypertension in 2.5 years (Franklin et al., 2013). It is important that these clients receive active follow-up and lifestyle counseling (Sivén, Niiranen, Kantola, & Jula, 2016). Additional evidence suggests that elevations in blood pressure without tachycardia or complaints of pain, can be predictive of developing hypertension later in life (Shiber-Ofer, Shohat, & Grossman, 2015; Grossman & Porth, 2014).

Masked hypertension presents as normal pressure readings in provider settings but elevated BPs at home or work. Masked hypertension is known to be a precursor of sustained hypertension. The prevalence of masked hypertension is known to be as high as 70% in African Americans, a rate significantly higher than the approximately 10% reported in the general population (O'Riordan, 2011). In addition, as many as 10% to 40% of patients who are normotensive by conventional clinic measurement are hypertensive by ambulatory blood pressure monitoring (ABPM) (Kaplan & Townsend, 2016). Masked hypertension may be related to daily stressors at work, smoking or alcohol use, oral contraceptive use, and sedentary habits. The nurse should also suspect masked hypertension in men, those with diabetes or kidney disease, and those with transiently elevated BPs. In addition, masked hypertension may appear in those with nighttime blood pressure elevation using ABPM, those with normal/high-normal daytime ABPM of 130 to 135/80 to 85 mm Hg, and those with obstructive sleep apnea and autonomic dysfunction (Franklin et al., 2013). Those with masked hypertension have an increased prevalence of metabolic risk factors, left ventricular hypertrophy, and carotid plaque, demonstrating the impact of hypertension on organ function. Among baseline-masked hypertensives, hypertension progressed after 5 years to sustained hypertension in approximately one third of patients; about one out of five remained masked. This demonstrates individuals with masked hypertension may be at particular risk for cardiovascular disease because of delays in diagnosis and treatment (Trudel, Milot, & Brisson, 2013).

When the at-risk individual is identified, the nurse advocates for the use of home BP monitoring to confirm the diagnosis and monitor treatment. Engaging the patient in the process of self-care results in improved outcomes.

Risk Factors

Although no precise cause can be identified for most cases of hypertension, it is understood that hypertension is a multifactorial condition. Associated factors for essential hypertension include heredity, obesity, sleep apnea, advancing age, renal changes, and ethnicity/race. Possible factors include diabetes, type A personality, smoking, sedentary lifestyle, and hypothyroidism (Bellestas & Caico, 2014; Weber, 2014). A diet high in sodium and low in potassium may contribute to hypertension especially in those who are sodium sensitive (CDC, 2015). About 5% of individuals have sodium sensitivity that can affect their BP.

Factors contributing to hypertension may include increased sympathetic nervous system activity and increased renal reabsorption of sodium, chloride, and water. Other contributors to hypertension include increased activity of the renin–angiotensin–aldosterone system, causing expansion of extracellular fluid volume and increased SVR, or dysfunction of the vascular endothelium. Resistance to insulin may be a common factor linking hypertension, type 2 diabetes mellitus, hypertriglyceridemia, obesity, and glucose intolerance (Grossman & Porth, 2014).

The prevalence of hypertension increases with aging. A rise in systolic pressure continues throughout life; while diastolic pressure rises until approximately 50 years old, it tends to level off over the next decade, and may remain the same or fall later in life. About 65% of Americans aged 60 or older have hypertension. Those who are normotensive at age 55 have a 90% lifetime risk for developing hypertension. Men and women are equally likely to develop hypertension during their lifetimes. Before age 45, men are more likely to have hypertension than women. When women reach menopause, loss of hormonal protection occurs, at which time the risk for hypertension rises. After age 64, hypertension is more likely to affect women.

Men younger than 55 are more likely to have uncontrolled hypertension than women; after age 65, women are more likely to have uncontrolled high blood pressure (HBP) (NIH, 2015a; Davis, 2015). Black males, Mexican-American males, and younger adults ages 20 to 39 have a higher likelihood of uncontrolled blood pressure (Davis, 2015).

While hypertension can affect anyone, it is more common in African-American adults than in Caucasian adults. African Americans have an earlier onset, higher prevalence, and a greater rate of stage 2 hypertension, leading to higher incidences of nonfatal stroke, death from heart disease, and end-stage kidney disease. In addition, African Americans are less likely than Caucasians to achieve target control levels with treatment. This increases when the African-American individual is male, overweight or obese, physically inactive, smokes, and/or has diabetes. Hypertension risks vary among different groups of Hispanic-American adults. For instance, Puerto Rican-American adults have higher rates of HBP-related death than all other Hispanic groups and Caucasians. However, Cuban Americans have lower rates of HBP-related deaths than Caucasians (NIH, 2015a).

Systolic hypertension is the most common form of hypertension and is a major risk factor for cardiovascular disease. As the "baby boomer" generation ages, its incidence is expected to increase (Grossman & Porth, 2014).

Obesity is one of the common risk factors for the development of hypertension. A rise in childhood obesity forewarns of increasing numbers of hypertensive adults (Bellestas & Caico, 2014; NIH, 2015a). Hypertension, a risk factor for atherosclerotic heart disease,

often coexists with dyslipidemia (see Chapter 14), diabetes mellitus (see Chapter 30), and a sedentary lifestyle. Metabolic syndrome or syndrome X occurs when three of the following symptoms are present simultaneously: BP elevation greater than 130/85, insulin resistance, dyslipidemia, and/or abdominal obesity. Metabolic syndrome places the patient at risk for cardiovascular disease and diabetes (AHA, 2014b). The risk for cardiovascular disease doubles with each increment of 20/10 mm Hg above 115/75 mm Hg.

Oral contraceptive use causes a small increase in systolic and diastolic BP, which, when accompanied by smoking and obesity, results in hypertension three times more often than in those without these risk factors. Cigarette smoking does not cause high BP; however, if a person with hypertension smokes, his or her risk of dying from heart disease or related disorders increases significantly (Grossman & Porth, 2014).

Nursing Alert
Use of oral contraceptive is probably the most common cause of secondary hypertension in women. Question female clients regarding medication use (Grossman & Porth, 2014).

Gerontologic Considerations

The number of people in the United States over 65 years of age is expected to reach 75 million by the year 2040. People over 85 years of age are the fastest growing subset of the US population (Chaudhry, Chavez, Gasowski, Grodzicki, & Messerli, 2012).

The prevalence of hypertension increases with aging; half of individuals aged 60 to 69 and 75% of individuals over age 70 are affected (Grossman & Porth, 2014). Aging causes structural and functional changes in the heart and blood vessels, including atherosclerosis and decreased elasticity of the major blood vessels. Because of increased wall stiffness, the arteries are less able to buffer the pressure created as blood is ejected from the left ventricle and unable to store the energy to exert diastolic pressure. The elderly also are more likely to suffer from the complications of hypertension and are more likely to have uncontrolled disease (Egan, 2016). Isolated systolic hypertension with widened pulse pressure is more common in older adults. This is associated with cardiovascular and cerebrovascular morbidity and mortality, as well as dementia (Grossman & Porth, 2014).

Compared with younger patients with similar blood pressure, elderly hypertensive patients have lower CO, higher peripheral resistance, wider pulse pressure, lower intravascular volume, and lower renal blood flow. These age-related pathophysiologic differences must be considered when treating hypertension in the elderly.

The average elderly American is on more than six medications, putting them at risk for polypharmacy. Not all medications are for high blood pressure, but many interact with antihypertensive medications, such as NSAIDs used for arthritis, which can raise blood pressure. Therefore, the drug regimen of an elderly patient with hypertension should be reviewed carefully at every visit.

An orthostatic decline in blood pressure accompanies advanced age and contributes to an inevitable adverse effect with some antihypertensive drugs (refer to Chapter 12 for details on assessing for orthostatic hypotension). Accordingly, systolic blood pressure lower than 130 and diastolic blood pressure lower than 70 mm Hg are best avoided in octogenarians. An initial goal of less than 140/90 mm Hg is reasonable in elderly patients, and an achieved systolic blood pressure of 140 to 145 mm Hg is acceptable in octogenarians (Chaudhry et al., 2012).

Nursing Alert
When hypertension is treated initially, the nurse monitors the blood pressure to evaluate response to the treatment. It is important to recognize that if the mean BP is lowered more than 40% in the initial 24 hours, then symptoms of cerebral hypoperfusion may occur (Ferri, 2018).

Restricting sodium intake has been shown to lower blood pressure more in older adults than in younger adults. In the DASH trial, systolic blood pressure decreased by 8.1 mm Hg with sodium restriction in hypertensive patients aged 55 to 76 years, compared with 4.8 mm Hg for adults aged 23 to 41 years. Thiazide diuretics should be used with caution in the elderly because of the risk of hyponatremia and volume depletion.

Nursing Alert

Pulse pressure is the difference between the systolic and diastolic pressure; normally, it is approximately 40 mm Hg. As an example, 120/80 equals a pulse pressure of 40 mm Hg. A widened pulse pressure, over 50 mm Hg, is associated with increasing intracranial pressure, atherosclerosis, aortic insufficiency, and fever. It is detected with routine BP measurement. Elevated systolic pressure is a key indicator for the development of coronary heart disease (Franklin & Wong, 2013).

To reduce the cardiovascular and cerebrovascular risks, older adults should begin treatment with lifestyle modifications. If medications are needed to achieve the BP goal, the starting dose should be half that used in younger patients and increased slowly. Many practitioners advocate for "start low and go slow" with medication regimens in the geriatric population. Compliance may be more difficult for the elderly when memory impairment exists or due to the expense of treatment plans. The nurse should ensure that the patient understands the regimen and can see and read instructions, open the medication container, and get the prescription refilled. Family or caregivers should be included in the teaching program so that they can assist with the regimen as necessary, encourage adherence to the treatment plan, and know when and whom to call for questions or problems.

Nursing Alert

The elderly are more sensitive to volume depletion caused by diuretics and to sympathetic inhibition caused by adrenergic antagonists. Teach patients to change positions slowly when moving from a lying or sitting position to a standing position and to use supportive devices, such as handrails and walkers, to prevent falls that could result from dizziness.

Clinical Manifestations and Assessment

Proper technique for assessment of BP is essential. The nurse should ensure proper BP measurement technique is being used (see Box 13-1) and that manometers used are calibrated. The nurse should select a cuff with a length of about 80% of the arm circumference and a width of about 40% of the arm circumference (D'Amico & Barbenito, 2016). To avoid undermeasurement of the SBP with auscultatory gap, the nurse should inflate the cuff to palpate the brachial artery until the pulse is obliterated, deflate the cuff, add 30 mm Hg to the palpated pressure, and then auscultate the BP and record results (D'Amico & Barbenito, 2016).

Automated or semiautomated blood pressure measurement devices are usually less accurate than are trained observers using the auscultatory method. It is recommended their use be limited to when frequency and less accurate methods of blood pressure assessment are needed. Providers should auscultate blood pressure (as described previously) to diagnose and/or evaluate the management of hypertension (Grossman & Porth, 2014).

Nursing Alert

Normally, the BP should vary by no more than 5 mm Hg between arms. If there is a difference, record both initially. Later, record the higher number. A difference of 10 mm Hg or more between the patient's arms may indicate thoracic outlet syndrome or arterial obstruction on the side with the lower value.

Pathophysiology Alert

Thoracic outlet syndrome is a condition where upper extremity symptoms are believed to result from neurovascular compression at the thoracic outlet. Compression may occur in three anatomical structures—arteries, veins, and nerves (Ferri, 2016b). If arterial compression is present, the involved extremity will be cool with a weak or absent pulse. A decrease in blood pressure (on the involved limb) greater than 20 mm Hg compared with the opposite arm is sometimes noted.

BOX 13-1 GUIDELINES FOR NURSING CARE

Measuring BP

Assessment is based on the average of at least two readings. (If two readings differ by more than 5 mm Hg, additional readings are taken and an average reading is calculated from the results.)

Equipment

- Recently calibrated aneroid manometer, or validated electronic device
- Cuff
- Stethoscope

NURSING ACTION	RATIONALE
1. Instruct the patient to: • Avoid smoking cigarettes or ingesting nicotine, exercising, or drinking caffeine for 30 minutes before BP is measured. • Sit quietly for 5 minutes before the measurement. • Sit comfortably with the forearm supported at heart level on a firm surface, palm up, both feet firmly on the ground, back supported; avoid talking while the measurement is being taken. The selected arm should be bare to the shoulder, and if the garment sleeve is raised, it should be loose so blood flow is not impinged.	1. Listening carefully helps ensure an accurate measurement is taken. Stimuli such as food, alcohol, caffeine, nicotine, and exercise within 30 minutes before blood pressure measurement may affect the reading. Crossing legs, talking, and doing mental tasks while the BP is measured increase blood pressure.
2. Select the size of the cuff based upon the size of the patient. (The cuff size should have a bladder width of at least 40% of limb circumference and length at least 80% of limb circumference.) The average adult cuff is 12–14 cm wide and 30 cm long.	2. Using a cuff that is too small will give a higher BP measurement, and using a cuff that is too large results in a lower BP measurement compared to one taken with a properly sized cuff.
3. Wrap the cuff firmly around the arm (half the distance between the acromion [bony process on the shoulder blade] and the olecranon [elbow] is used to determine the midpoint of the arm). Center the cuff bladder approximately 2 cm (–1 in) above the elbow crease, with the midline of the bladder directly over the brachial artery. One finger should fit between the cuff and the patient's arm.	3. Proper setup is required for accurate reading. If the cuff is too loose, a falsely high reading occurs and vice versa.
4. Position the patient's arm at the level of the heart, preferably by resting the arm on a firm surface such as the examination table.	4. Positioning the arm above heart level will give a falsely low reading; a reading when the patient's arm is below heart level will be falsely elevated.
5. Palpate the systolic pressure before auscultating, using the radial or brachial artery (inflate the cuff until the pulse disappears; then deflate the cuff and note the pressure at which the pulse reappears. This is the systolic pressure by palpation).	5. This technique prevents the risks of overinflation, undue patient discomfort, and/or underestimation of systolic blood pressure. It also helps to detect the presence of an auscultatory gap more readily; an auscultatory gap is present when there is intermittent disappearance of the initial Korotkoff sounds after their first appearance (associated with older patients with hypertension), leading to underestimation of systolic blood pressure.
6. Ask the patient to sit quietly while the BP is measured.	6. BP can increase when the patient is engaged in conversation.
7. The nurse positions himself/herself so that the manometer is at the eye level. Tighten the thumbscrew of the pressure bulb and rapidly inflate the cuff to 30 mm Hg above the palpated systolic pressure. Slowly loosen the thumbscrew to deflate the cuff of the sphygmomanometer, releasing the pressure at 2 mm Hg per second. Listen carefully. Note the pressure at which the first sound is auscultated. This is the systolic reading. Continue to listen to the Korotkoff sounds. Determine the pressure when the pulsations disappear completely, this is the diastolic reading.	7. Misalignment between the eye and the mercury meniscus or aneroid manometer may cause the meniscus to be read as higher or lower than the actual position. Listening carefully ensures an accurate measurement.
8. Initially, record BP results of both arms and take subsequent measurements from the arm with the higher BP.	8. A difference of 10–15 mm Hg may indicate arterial obstruction on the side with the lower value.
9. Record the site where the BP was measured and the position of the patient (e.g., right arm).	9. This is especially important when assessing for orthostatic changes.
10. Inform the patient of his or her BP value and what it means. Emphasize the need for periodic reassessment, and encourage patients who measure BP at home to keep a written record of readings.	10. This engages the patient in the teaching process and correlates diet and medication adherence with BP.

Adapted from D'Amico & Barbenito, 2016.

Because there are typically no symptoms of hypertension, physical examination may be unremarkable, other than elevated BP. Rarely patients may report early morning headaches, dull aching headache throughout the day, visual disturbances, orthostatic hypertension or hypotension; fatigue and proteinuria may be found on assessment (Bellestas & Caico, 2014). Many symptoms are associated with target or end-organ damage. The nurse should question the patient asking about anginal pain; shortness of breath; alterations in speech,

vision, or balance; epistaxis (nosebleeds); headaches; dizziness; or nocturia. Further assessment includes asking about personal, social, or financial factors, or unacceptable pharmaceutical side effects that may interfere with the patients' ability to adhere to the medication regimen.

Hypertension may be asymptomatic and remain so for many years; however, when signs and symptoms appear, vascular damage related to the organs served by the involved vessels has occurred (Bellestas & Caico, 2014). Coronary artery disease with angina or MI is a common consequence of hypertension. Left ventricular hypertrophy occurs in response to the increased workload placed on the ventricle as it contracts against higher systemic pressure. When heart damage is extensive, heart failure follows; 90% of the time, hypertension precedes congestive heart failure (Aschenbrenner & Venable, 2012). Pathologic changes in the kidneys, indicated by microalbuminuria, increased blood urea nitrogen (BUN) and serum creatinine levels, and nocturia result. Cerebrovascular involvement may lead to stroke or transient ischemic attack, manifested by alterations in vision or speech, dizziness, weakness, a sudden fall, or hemiplegia. Occasionally, retinal changes such as hemorrhages, exudates (fluid accumulation), arteriolar narrowing, and cotton-wool spots (small infarctions) occur. In severe hypertension, papilledema (swelling of the optic disc) may be seen. A risk factor assessment is needed to classify and guide the treatment of the hypertensive individual at risk for cardiovascular damage. Risk factors and cardiovascular problems related to hypertension are presented in Box 13-2.

Routine laboratory tests evaluate for end-organ damage. These include urinalysis, evaluation for microalbuminuria or proteinuria, blood chemistry (i.e., analysis of sodium, potassium, BUN and creatinine, fasting glucose, and total and high-density lipoprotein [HDL] cholesterol levels), and a 12-lead electrocardiogram (ECG). Left ventricular hypertrophy can be assessed by echocardiography. Additional studies, including creatinine clearance, renin level, urine tests, and 24-hour urine protein, may be performed. The eyes should be assessed for hypertensive retinopathy (Bellestas & Caico, 2014).

BOX 13-2 Risk Factors for Cardiovascular Problems in Hypertensive Patients

Major Risk Factors (in Addition to Hypertension)

- Smoking
- Dyslipidemia (elevated LDL [or total] cholesterol and/or low HDL cholesterol)[a]
- Diabetes mellitus[b]
- Impaired renal function (GFR less than 60 mL/min and/or microalbuminuria)
- Obesity (body mass index [BMI] of 30 kg/m^2 or higher)[c]
- Physical inactivity
- Age (over 55 years for men, 65 years for women)
- Alcohol use
- Family history of cardiovascular disease (in female relative under 65 years or male relative under 55 years)

Target Organ Damage or Clinical Cardiovascular Disease

- Heart disease (left ventricular hypertrophy, angina, or previous myocardial

infarction, previous coronary revascularization, heart failure)
- Stroke (cerebrovascular accident, brain attack) or TIA
- Chronic kidney disease
- Peripheral arterial disease
- Retinopathy

Grossman & Porth, 2014.

[a]These risk factors plus hypertension, elevated triglyceride levels, and abdominal obesity are components of the metabolic syndrome.

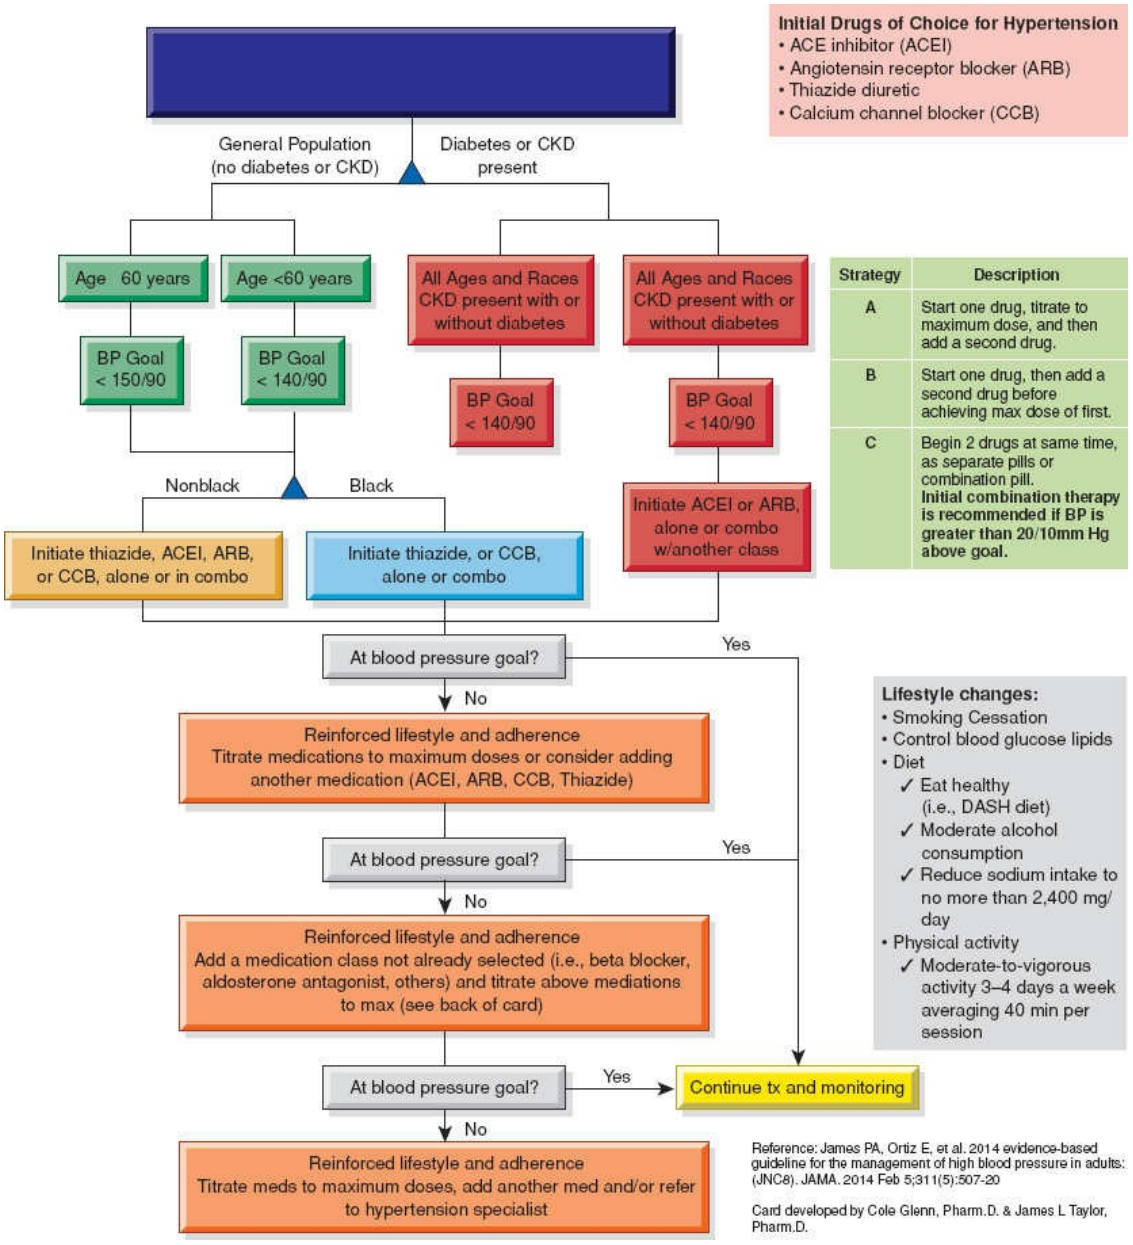
[b]These risk factors plus hypertension, elevated triglyceride levels, and abdominal obesity are components of the metabolic syndrome.

[c]These risk factors plus hypertension and elevated triglyceride levels are components of the metabolic syndrome.

Medical and Nursing Management

The treatment goal for most individuals under 60 years of age with hypertension, regardless of complicating conditions, is a BP of less than 140/90 mm Hg. The aim for individuals with prehypertension and no complicating conditions is to lower BP to normal. To prevent or delay progression to hypertension, JNC7 urges health care providers to encourage people with BPs in the prehypertension category to begin lifestyle modifications, such as dietary changes and exercise (see below). JNC8 recommends that people over the age of 60 begin pharmacologic treatment when the blood pressure is greater than 150/90; lifestyle changes should also be emphasized. Health care providers should monitor these patients every 1 to 3 months until their BP goal is reached and then every 3 to 6 months thereafter. While JNC7 recommended those with diabetes or CKD attain a target pressure of less than 130/80 mm Hg, current JNC8 guidelines call for similar treatment goals for all hypertensive populations, maintaining blood pressure less than 140/90 (Krader, 2014).

The management of hypertension is summarized in the treatment algorithm issued by JNC8 (Fig. 13-2). The clinician uses the treatment algorithm, risk factor assessment data, and the patient's BP category to choose treatment plans for the patient.



Initial Drugs of Choice for Hypertension
• ACE inhibitor (ACEI)
• Angiotensin receptor blocker (ARB)
• Thiazide diuretic
• Calcium channel blocker (CCB)
General Population (no diabetes or CKD)
Diabetes or CKD present
Age 60 years
Age <60 years
All Ages and Races CKD present with or without diabetes
All Ages and Races CKD present with or without diabetes
BP Goal < 150/90
BP Goal < 140/90
BP Goal < 140/90
BP Goal < 140/90
Nonblack
Black
Initiate ACEI or ARB, alone or combo w/another class
Initiate thiazide, ACEI, ARB, or CCB, alone or in combo
Initiate thiazide, or CCB, alone or combo
At blood pressure goal?
Yes
No
Reinforced lifestyle and adherence
Titrate medications to maximum doses or consider adding another medication (ACEI, ARB, CCB, Thiazide)
At blood pressure goal?
Yes
No
Reinforced lifestyle and adherence
Add a medication class not already selected (i.e., beta blocker, aldosterone antagonist, others) and titrate above mediations to max (see back of card)
At blood pressure goal?
Yes
Continue tx and monitoring
No
Reinforced lifestyle and adherence
Titrate meds to maximum doses, add another med and/or refer to hypertension specialist
Strategy
Description
A
Start one drug, titrate to maximum dose, and then add a second drug.
B
Start one drug, then add a second drug before achieving max dose of first.
C
Begin 2 drugs at same time, as separate pills or combination pill.
Initial combination therapy is recommended if BP is greater than 20/10mm Hg above goal.
Lifestyle changes:
• Smoking Cessation
• Control blood glucose lipids
• Diet
✓ Eat healthy (i.e., DASH diet)
✓ Moderate alcohol consumption
✓ Reduce sodium intake to no more than 2,400 mg/day
• Physical activity
✓ Moderate-to-vigorous activity 3–4 days a week averaging 40 min per session

Card developed by Cole Glenn, Pharm.D. & James L Taylor, Pharm.D.

Compelling indications	
Indication	**Treatment Choice**
Heart failure	ACEI/ARB + BB + diuretic + spironolactone
Post-MI/Clinical CAD	ACEI/ARB AND BB
CAD	ACEI, BB, diuretic, CCB
Diabetes	ACEI/ARB, CCB, diuretic
CKD	ACEI/ARB
Recurrent stroke prevention	ACEI, diuretic
Pregnancy	labetolol (first line), nifedipine, methyldopa

Hypertension treatment

Beta-1 Selective Beta-blockers – possibly safer in patients with COPD, asthma, diabetes, and peripheral vascular disease:
- metoprolol
- bisoprolol
- betaxolol
- acebutolol

Drug Class	Sample Dose Ranges	Comments
Diuretics	HCTZ 12.5–50mg, chlorthalidone 12.5–25mg, indapamide 1.25–2.5mg triamterene 100mg *K+ sparing* – spironolactone 25–50mg, amiloride 5–10mg, triamterene 100mg furosemide 20-80mg twice daily, torsemide 10–40mg	Monitor for hypokalemia Most side effects (SE) are metabolic in nature Most effective when combined w/ ACEI Stronger clinical evidence w/chlorthalidone Spironolactone - gynecomastia and hyperkalemia Loop diuretics may be needed when GFR <40mL/min
ACEI/ARM	*ACEI:* lisinopril, benazapril, fosinopril and quinapril 10–40mg, ramipril 5–10mg, trandolapril 2–8mg *ARB:* candesartan 8–32mg, valsartan 80–320mg, losartan 50–100mg, olmesartan 20-40mg, telmisartan 20–80mg	SE: Cough (ACEI only), angioedema (more with ACEI), hyperkalemia Losartan lowers uric acid levels; candesartan may prevent migraine headaches
Beta-blockers	metoprolol succinate 50–100mg and tartrate 50-100mg twice daily, nebivolol 5–10mg, propranolol 40–120mg twice daily, carvedilol 6.25–25mg twice daily, bisoprolol 5–10mg, labetalol 100–300mg twice daily	Not first line agents – reserve for post-MI/CHF Cause fatigue and decreased heart rate Adversely affect glucose; mask hypoglycemic awareness
Calcium channel blockers	*Dihydropyridines:* amlodipine 5–10mg, nifedipine ER 30–90mg, *Non-dihydropyridines:* diltiazem ER 180–360 mg, verapamil 80–120mg 3 times daily or ER 240–480mg	Cause edema; dihydropyridines may be safely combined w/ B-blocker Non-dihydropyridines reduce heart rate and proteinuria
Vasodilators	hydralazine 25–100mg twice daily, minoxidil 5–10mg terazosin 1–5mg, doxazosin 1–4mg given at bedtime	Hydralazine and minoxidil may cause reflex tachycardia and fluid retention – usually require diuretic + B-blocker Alpha-blockers may cause orthostatic hypotension
Centrally-acting agents	clonidine 0.1–0.2mg twice daily, methyldopa 250–500mg twice daily guanfacine 1–3mg	Clonidine available in weekly patch formulation for resistant hypertension

FIGURE 13-2 Algorithm of hypertension treatment. Treatment begins with lifestyle modifications and continues with various medication regimens. ACEI, angiotensin-converting enzyme inhibitor; ALDO ANT, aldosterone antagonist; ARB, angiotensin receptor blocker; BB, beta blocker; CCB, calcium-channel blocker; THIAZ, thiazide diuretic. (From the Eighth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High BP (JNC8).)

The nurse encourages self-management, which may include self BP monitoring, and education to initiate and maintain lifestyle changes. It is important to assess the patient's beliefs about hypertension (Box 13-3). Self-management and education empowers patients to ask questions and voice concerns. These individuals are less likely to be hospitalized, have fewer emergency department and unscheduled medical visits, and have fewer days off from work.

The nurse should routinely ask whether patients take herbal supplements or over-the-counter (OTC) medications that may increase BP. These include caffeine and ephedra, which are stimulants; licorice, which has an aldosterone-like effect; and oral contraceptives, acetaminophen and NSAIDs, which may lead to fluid retention. In addition, certain agents have been touted as BP-lowering agents, such as coenzyme Q10, garlic, vitamin C, and L-arginine. Patients should be cautioned that nutritional supplements are not regulated in the same manner as pharmaceuticals, and all products used should be reported to the health care provider (FDA, 2016).

Lifestyle Changes

Table 13-2 summarizes recommended lifestyle modifications. Research findings

demonstrate that weight loss, reduced alcohol and sodium intake, and regular physical activity for 30 minutes on most days are effective lifestyle adaptations to reduce BP (Grossman & Porth, 2014). Counsel the client that smoking cessation will decrease the risk for heart disease. Treatment of sleep apnea, underlying thyroid disorders, and management of blood glucose are also recommended (Harvard Letter, 2015). The nurse should emphasize the concept of lifelong BP control and adherence to treatment rather than cure and absolute compliance.

Every patient with hypertension should be offered information regarding lifestyle modifications to reduce blood pressure (O'Connell, 2014). Specific information regarding diet, exercise, avoidance of salt/sodium intake and alcohol as well as smoking cessation should be included. Adhering to the American Heart Association's DASH approach (Dietary Approaches to Stop Hypertension) helps decrease BP and lower lipid levels, reducing the risk of cardiovascular diseases (NIH, 2015b). Refer to Table 13-3 for details on DASH diet.

DASH is low in saturated and trans fats as well as rich in potassium, calcium, magnesium, fiber, and protein. Further, the DASH approach emphasizes vegetables, fruits, and fat-free or low-fat dairy products. It includes whole grains, fish, poultry, beans, seeds, nuts, and vegetable oils and limits sodium, sweets, sugary beverages, and red meats, which not only lowers blood pressure but also prevents cardiovascular disease (NIH, 2015c).

BOX 13-3 Nursing Research

Bridging the Gap to Evidence-Based Practice

Using Culturally Sensitive Education to Improve Adherence With Anti-Hypertension Regimen.

Gross, B., Anderson, E., Busby, S., Frith, K., & Panco, C. (2013). Using culturally sensitive education to improve adherence with anti-hypertension regimen. *Journal of Cultural Diversity*, *20*(2), 75–79.

Purpose

The purpose of the project was to assess the outcomes of culturally sensitive education programs for African Americans on antihypertensive treatment regimens.

Design

A culturally sensitive, evidence-based education program was designed to promote adherence to an antihypertensive regimen among African-American patients receiving care at a nonprofit ambulatory walk-in clinic. Thirty-five clinic patients with elevated BP were enrolled initially. The theory of Planned Behavior was used to assess for an association among beliefs, attitudes, social influences and perceived ability to perform the expected behavior. Baseline literacy was assessed using the Newest Vital Sign literary assessment tool. Patients were asked to maintain a medication diary to determine if outcomes were met.

Findings

Economic factors impact adherence to the prescribed diet and exercise, as well as ability to purchase healthy food choices. Eighty percent of the participants were women ages 29–70 years of age. Several patients desired to eat healthfully but expressed concern their families and friends would not eat food prepared with unfamiliar food choices.

Participants made statements such as, "I had to stop eating in restaurants with my friends because they made fun of me when I ordered salads instead of fried and seasoned food." In addition, eating healthfully required participants to travel several miles to a full-service supermarket.

Some patients who were nonadherent to the medical regimen felt home remedies such as "a little cold water on my forehead" could help get blood pressure down. Others stated they took the medication only when they "felt bad."

Of the 10 patients who completed the program, all stated their knowledge of hypertension treatment had increased. Only one maintained the medication diary; the others forgot to bring it to the clinic but stated they followed the regimen. Lifestyle changes such as eating healthier, maintaining a record of weight, smoking cessation, and beginning a safe exercise program were agreed to; however the elderly did not agree to the exercise program due the fear of crime. The 10 patients who completed the program had blood pressure readings within normal limits at the end of the project.

Nursing Implications

Barriers to treatment included friends and families who did not encourage participants to change their diets. Culturally, hypertension may be seen as an episodic, rather than chronic, condition by this group. Fear of being robbed while walking around the neighborhood, even in broad daylight, and lack of financial resources to join a gym or fitness club were reported. Walking in the mall was also difficult as the mall was several miles from home and participants had no transportation. Natural remedies are passed down by family members, and lack of trust of health care providers can impact adherence with prescription medications.

African-American's attitudes regarding health and illness have been influenced by their culture and are often passed on to future generations. Nurses should be conscious of the importance of culture and treatment and ensure the treatment is congruent with the patient's cultural background, income, and religious practices. The authors conclude education programs should be offered in churches and community centers. Churches in the African-American community serve as spiritual as well as social and cultural gathering sites. Education programs that support both spiritual and social support will promote healthy lifestyle modification.

The average daily sodium intake for Americans age 2 years and older is 3,400 mg (CDC, 2016). Consistent with the DASH approach, the target sodium intake should be 2,300 to 2,400 mg daily (1 teaspoon). Those who already have hypertension, diabetes, or CKD as well as African-American individuals and adults aged 51 and over should reduce sodium intake further, to 1,500 mg of sodium daily (Oza & Garcellano, 2015). When salt intake is reduced, blood pressure begins decreasing within weeks (CDC, 2016). About 5% of patients have sodium-sensitive hypertension and should be very cautious with sodium intake, especially the elderly.

A diet high in fruits and vegetables is associated with lower systolic and diastolic blood pressure. Maintaining or attaining normal weight is advised. Obesity may increase the risk of hypertension through overactivation of the sympathetic nervous system, activation of

renin–angiotensin–aldosterone system, sodium retention, and increased HR. Increased inflammatory markers such as C-reactive protein, leads to endothelial dysfunction and abnormal lipid levels. The impaired production of nitric oxide, a potent vasodilator, impairs vasodilation and causes an increased resting blood pressure (O'Connell, 2014). Regular exercise is associated with lower blood pressure regardless of body mass index (BMI). Exercise may improve inflammatory markers and cause an increase in endothelial nitric oxide synthase, a potent vasodilator.

Exercise and lifestyle changes should include the importance of achieving a waist circumference of less than 40 inches for a man and less than 35 inches for a woman and a BMI between 18.5 and 24.9 kg/m^2. For patients not meeting that goal, modification involves caloric restriction and increased physical activity. A weight loss of only 10 lb may result in a 5 to 20 mm Hg reduction in SBP, offering tangible results to the patient. The nurse encourages the patient to formulate a plan for weight loss, consulting a dietician or using support groups if necessary. The bariatric patient may benefit from surgical intervention. Mobile health technology (Fitbit, pedometer, etc.) may assist the patient in increasing his physical activity.

TABLE 13-2 Lifestyle Modifications to Prevent and Manage Hypertension[a]

Modification	Recommendation	Goal of SBP[b] Reduction (Range)[c]
Weight reduction	Maintain normal body weight (body mass index 18.5–24.9 kg/m^2).	5–20 mm Hg/10 kg
Adopt DASH (Dietary Approaches to Stop Hypertension) eating plan	Consume a diet rich in fruits, vegetables, fiber, potassium, and low-fat dairy products, and reduce consumption of animal protein, fat, and saturated fat.	8–14 mm Hg
Dietary sodium reduction	Reduce dietary sodium intake to 2.4-g sodium or 6-g sodium chloride per day.	2–8 mm Hg
Physical activity	Engage in regular aerobic physical activity such as 30 minutes of brisk walking 3–5 days per week	4–9 mm Hg
Moderation of alcohol consumption	Limit consumption to no more than two drinks (e.g., 24-oz beer, 10-oz wine, or 3-oz 80-proof whiskey) per day in most men and to no more than one drink per day in women and lighter-weight people.	2–4 mm Hg

[a]For overall cardiovascular risk reduction, stop smoking.
[b]SBP, Systolic BP.
[c]The effects of implementing these modifications are dose- and time-dependent and could be greater for some individuals.
From the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High BP. (2003). *Hypertension, 42*(6), 1206–1252.

TABLE 13-3 The DASH (Dietary Approaches to Stop Hypertension) Diet

Food Group	Number of Servings Per Day
Grains and grain products	6–8
Vegetables	4 or 5
Fruits	4 or 5
Low-fat or fat-free dairy foods	2 or 3
Meat, fish, and poultry	6 or fewer
Nuts, seeds, and dry beans	4 or 5 weekly
Sodium	2,300 mg/day (1,500 mg if over 51 years of age)
Fats and oils	2–3
Sweets and added sugars	5 or less weekly

The diet is based on 2,000 calories per day.
Retrieved from http://www.nhlbi.nih.gov/health/health-topics/topics/dash/followdash. Last updated June 2014.

Specific information should be provided on reading labels for foods that contain less than 400 mg of sodium per serving and for reducing the intake of table salt to 1 teaspoon (2.3 to 2.4 g of sodium) daily. Most sodium intake comes from packaged, processed, and restaurant foods and, therefore, is in the product at the time of purchase. Teach the patient that it takes 2 to 3 months for the taste buds to adapt to changes in salt intake to encourage perseverance (Dudek, 2014). Recognizing that hypertension is a common cause of morbidity and mortality of cardiovascular disease, the American Public Health Association has published a resolution that food manufacturers and restaurants reduce sodium in the food supply by 50% over the next decade (Jackson, King, Zhao, & Cogswell, 2016) (apha.org, 2014).

Nursing Alert
Reducing table salt to about 1 teaspoon per day, or 2.3 to 2.4 g of sodium, can reduce systolic BP by 2 to 8 mm Hg.

While moderate alcohol consumption has shown to lower blood pressure, those who do not drink alcohol already should not start for the purpose of lowering blood pressure (Oza & Garcellano, 2015). Limiting one's daily alcohol intake to 24 oz of beer, 10 oz of wine, or

3 oz of whiskey for men, and half that for women, is recommended (AHA, 2016a). Smoking cessation is encouraged in all hypertensive patients because it can significantly increase the progression of renal insufficiency as measured by the serum creatinine concentration, which rose from 1.5 to 1.9 mg/dL in a study conducted over 35 months (Kaplan, 2016). There has been some concern regarding the impact of nicotine replacement therapy (NRT) on blood pressure in patients with hypertension; a recent study conducted with patients with hypertension, CAD, and/or MI revealed no significant clinical change in blood pressure or HR during the use of NRT and/or bupropion (Zevin & Pacheco, 2016). Based on these data, nurses may advocate for behavioral therapies and/or pharmacotherapies for those interested in quitting smoking.

Alternate Therapies

Complementary and alternative medicine therapies and mind–body interventions are potentially effective in reducing BP. Relaxation, meditation, guided imagery, hypnosis, biofeedback, yoga, and Tai Chi are some examples of these therapies. Yoga has been shown to have beneficial effects on the cardiovascular system. Physical activity and exercise has been demonstrated to reduce morbidity and mortality for coronary heart disease, hypertension, obesity, diabetes, and osteoporosis as well as have a positive effect on the patient's psychological well-being (Lo, Yeh, Chang, Sung, & Smith, 2012; Oza & Garcellano, 2015).

Blood Pressure Monitoring

The nurse must ensure that follow-up is provided for any person identified as having an elevated BP level. Each person should be given a written record of his or her BP at the screening. The American Heart Association and the National Heart, Lung, and Blood Institute provide printed and electronic patient education materials (see reference resources web addresses). Reductions in BP are greater when patients are partners and participate in self-management; some options include diaries and technology-based applications (smartphone products, web-based self-monitoring programs).

Pharmacologic Therapy

The nurse collaborates with the patient to support adherence to the medication regimen. Studies have shown consistently that 20% to 30% of medication prescriptions are never filled and that, on average, 50% of medications for chronic disease are not taken as prescribed (AHRQ, 2012). In addition, patients with limited income as well as those who do not have health insurance are at high risk for not purchasing their medication after receiving a prescription (Adams & Urban, 2016). Motivation for adherence to the prescribed regimen improves when patients have positive experiences with and trust in the clinician. Empathy and culturally sensitive education build trust and is a potent motivator to achieve better outcomes with medication adherence and lifestyle changes (Gross, Anderson, Busby, Frith, & Panco, 2013). Cene et al. (2013) identified African-American men with depressive symptoms, psychosocial stressors, and substance abuse as a population at high risk for nonadherence to treatment. Screening for such symptoms should be undertaken when nonadherence is noted along with referral to appropriate resources (Cene

et al., 2013).

Evidence-based guidelines for management of hypertension from JNC8 suggests the general population aged over 60 years initiates pharmacologic therapy to lower BP when systolic BP is over 150 mm Hg or diastolic BP is over 90 mm Hg (James et al., 2013; Felicilda-Reynaldo & Kenneally, 2015). While exact target range for B/P control vary for subgroups such as the elderly or those with kidney disease, current evidence suggests more intensive control of B/P is warranted because of the association between higher BP and increased CVD risk. Most recent guidelines recommend a systolic pressure of 130 mm Hg is the upper limit of normal at all ages (ACC/AHA, 2017). In the general population, including those with diabetes but excluding all African Americans, initial antihypertensive treatment should include a thiazide-like diuretic, calcium-channel blocker (CCB), angiotensin-converting enzyme inhibitor (ACEI), or angiotensin-receptor blocker (ARB). In the general African American population, including those with diabetes, initial antihypertensive treatment should include a thiazide-type diuretic or CCB. In the population aged 18 or older, regardless of race or presence of diabetes, those who have CKD as well as initial or added antihypertensive treatment should include an ACEI or ARB to improve kidney outcome.

The main objective of hypertension treatment is to attain and maintain goal BP. If the goal is not attained within 1 month of treatment, increasing the dose of the first drug or adding a second drug from one of the classes was recommended (thiazide-type diuretic, CCB, ACEI, or ARB). The advantage of adding a medication, rather than increasing the dose of the first medication, is that side effects may be avoided. Most patients requiring pharmacologic intervention need two medications for effective treatment as hypertension is caused by multiple factors.

Blood pressure should be assessed and the treatment adjusted until the goal is reached. If the goal is not met with two medications, a third drug is added and titrated; note that an ACEI and ARB are not recommended for use at the same time. A third drug from another class may be added as needed (Krader, 2014).

There is a recommendation against use of beta-blockers for the initial treatment of hypertension (Krader, 2014), since evidence suggested a higher rate of cardiovascular death, MI, or stroke when compared to use of an ARB. The following are not recommended as first-line therapy: dual $alpha_1$- + beta-blocking agents (e.g., carvedilol), vasodilating beta-blockers (e.g., nebivolol), central $alpha_2$-adrenergic agonists (e.g., clonidine), direct vasodilators (e.g., hydralazine), aldosterone receptor antagonists (e.g., spironolactone), adrenergic neuronal depleting agents (e.g., reserpine), and loop diuretics (e.g., furosemide) (James, 2014).

Thiazide diuretics are useful in the elderly and in patients with osteoporosis because they decrease bone breakdown and preserve bone integrity. ACEIs or angiotensin receptor blockers (ARBs) protect and preserve kidney function and protect the vascular endothelium (Felicilda-Reynaldo & Kenneally, 2015). CCBs, such as amlodipine, exert their major effect on blood vessels and are recommended for the treatment of hypertension, while medications that affect HR, such as diltiazem, are better suited to rhythm control.

Drug Alert!
The JNC8 recommends initial therapy with thiazide diuretics and CCBs for African-American individuals. They provide the greatest blood pressure reduction in this population (Adams & Urban, 2016).

Drug Alert!
Use of NSAIDs with ACEIs and ARBs may decrease antihypertensive effects due to prostaglandin inhibition and fluid retention.

Drug Alert!
Maximum antihypertensive effect from thiazide diuretics used for hypertension is delayed and does not occur for 3 to 4 weeks. Inform patients of this information to decrease risk of nonadherence to therapy (Felicilda-Reynaldo & Kenneally, 2015).

Drug Alert!
ACEIs exert their therapeutic effect within 1 hour of administration, and the risk for severe hypotension is increased during the first 5 hours. To prevent first-dose hypotension and the risk for falls, the patient should be in a supine position for the first dose and have blood pressure assessed (Felicilda-Reynaldo & Kenneally, 2015).

Drug Alert!
Observe patients receiving ACEIs for the first time for angioedema, a dangerous adverse effect. Symptoms include difficulty breathing or swelling in the face, neck, or tongue (Felicilda-Reynaldo & Kenneally, 2015).

When the BP is at goal for at least 1 year, gradual reduction of the types and doses of medication is indicated. To promote persistence (adherence), clinicians try to prescribe the simplest treatment schedule possible, ideally one or two pills daily. The nurse needs to emphasize and support both pharmacologic and nonpharmacologic strategies; contracting, goal-setting, counseling, referral to support groups, and use of web-based technology are some of the strategies used. If a patient who is diagnosed with resistant hypertension fails to reach goal BP when adhering to a three-drug regimen that includes a diuretic and the patient has multiple drug intolerances or contraindications, a referral to a hypertension specialist is indicated (Ferri, 2016a). Obstructive sleep apnea has been recognized as one of the most common risk factors for resistant hypertension (Oza & Garcellano, 2015).

Table 13-4 describes the pharmacologic agents that are recommended for the treatment of hypertension.

The nurse should include education when medication for other risk factors is combined with antihypertensive therapy. For example, a statin to lower cholesterol is prescribed if the patient has a cardiovascular disease risk or has target organ damage. The nurse teaches the patient that high cholesterol does not directly increase BP but can increase vascular damage leading to cardiovascular complication (Harvard Health Letter, 2015). Low-dose aspirin therapy may be indicated once BP is controlled to limit cardiovascular complications. There is evidence that depression is associated with poor adherence to medication regimens and that posttraumatic stress disorder (PTSD) is associated with hypertension, thus

directing the nurse to develop further psychosocial interventions and reinforce collaborative pharmacologic interventions (Kibler, Joshi, & Ma, 2008).

The nurse provides written information about the expected effects and side effects of antihypertensive medications, warning the patient not to stop medications abruptly because rebound hypertension may occur. As always, the patient should be encouraged to provide honest feedback to the health care provider to achieve optimum BP control. Patients should be cautioned to avoid OTC medications, especially nasal decongestants containing vasoconstrictors, which can further elevate BP.

Medication compliance increases when patients actively participate in self-care, including self-monitoring of BP, diet, and exercise—possibly because patients receive immediate feedback and have a greater sense of control. Evidence demonstrates that compliance further increases when the provider takes time in counseling, takes into account cultural perspectives on causes and treatment of hypertension, and avoids viewing the patient as responsible for treatment failures.

Complications

Prolonged BP elevation damages blood vessels, particularly in target organs such as the heart, kidneys, brain, and eyes. The consequences of prolonged, uncontrolled hypertension are MI, heart failure, left ventricular hypertrophy, kidney failure, stroke, and impaired vision. An acute elevation in BP associated with end-organ damage is termed *hypertensive emergency*.

HYPERTENSIVE CRISES

Hypertensive crisis is defined as a diastolic BP of higher than 180/120 mm Hg. Approximately 1% of individuals with hypertension will have a hypertensive crisis at some point. Hypertensive crises occur when hypertension is untreated or has been poorly controlled as well as in those who have discontinued their medications. These crises are more common in men, older adults, and African Americans (Adams & Urban, 2016). Other causes of hypertensive crises include head injury, pheochromocytoma (a tumor of the adrenal medulla that causes excess secretion of catecholamines), food–drug interactions (such as tyramine combined with a monamine oxidase [MAO] inhibitors), eclampsia or preeclampsia, substance abuse (e.g., cocaine intoxication), and kidney disease (Adams & Urban, 2016).

TABLE 13-4 Medication Therapy for Hypertension

Medication	Major Action	Considerations
Diuretics (Thiazide and Thiazide-Like, Loop, Potassium-Sparing)		
Hydrochlorothiazide and metolazone, furosemide, spironolactone	Decreases blood volume, renal blood flow, and cardiac output Natriuresis, negative sodium balance Directly affects vascular smooth muscle	Side effects: Dry mouth, thirst, nausea, weakness, drowsiness, postural hypotension Considerations: Monitor for signs of sodium, potassium, and magnesium imbalance.
Central Alpha$_2$-Agonists and Other Centrally Acting Drugs—No Longer Recommended as First-Line Treatment		
Clonidine, methyldopa	Impairs synthesis and reuptake of norepinephrine Displaces norepinephrine from storage sites Stimulates central alpha$_2$-adrenergic receptors	Side effects: Hypotension, postural hypotension, bradycardia, dizziness, drowsiness, dry mouth, depression, nasal congestion, rebound hypertension, impotence
Beta Blockers—No Longer Recommended as First-Line Treatment in Any Subgroup (Krader, 2014)		
Atenolol, propranolol, metoprolol, nadolol, timolol	Blocks beta adrenergic receptors of sympathetic nervous system causing vasodilation, decreased cardiac output and heart rate	Side effects: Hypotension, bradycardia, congestive heart failure, fatigue, depression, weakness, impotence, rebound hypertension, hypoglycemia Contraindications: Asthma, COPD
Alpha$_1$ Blockers—No Longer Recommended as First-Line Treatment in Any Subgroup (Krader, 2014)		
Doxazosin, prazosin hydrochloride, terazosin	Peripherally acting vasodilator	Side effects: Vomiting and diarrhea, urinary frequency, and tachycardia if not controlled with beta blocker, drowsiness

Combined Alpha and Beta Blockers—No Longer Recommended as First-Line Treatment in Any Subgroup (Krader, 2014)		
Carvedilol, labetalol hydrochloride	Blocks alpha- and beta-adrenergic receptors; causes peripheral dilation and decreases peripheral vascular resistance	Side effects: Orthostatic hypotension, tachycardia or bradycardia Contraindications: Asthma and COPD
Vasodilators		
Fenoldopam mesylate	Stimulates dopamine and alpha$_2$-adrenergic receptors	Side effects: Headache, flushing, hypotension, sweating
Hydralazine	Decreases peripheral resistance; concurrently elevates cardiac output; acts directly on smooth muscle of blood vessels	Side effects: Headache, tachycardia, flushing, and dyspnea, lupus erythematosus–like syndrome
Minoxidil	Direct-acting arterial vasodilator	Side effects: Hirsutism, dizziness, headache, nausea, edema, tachycardia, profound hypotension, thiocyanate toxicity
Sodium nitroprusside	Peripheral vasodilation by relaxation of smooth muscle	Side effects: Hypotension, tachycardia, flushing, headache
Angiotensin-Converting Enzyme (ACE$_1$) Inhibitors		
Captopril, enalaprilat/enalapril, fosinopril, lisinopril, quinapril, ramipril	Inhibits conversion of angiotensin I to angiotensin II; reduces peripheral resistance	Side effects: Hypotension, tachycardia, hyperkalemia, azotemia, angioedema (rare but life threatening) Contraindications: Pregnancy
Angiotensin II Receptor Blockers (ARBs)		
Candesartan irbesartan, losartan olmesartan, telmisartan, valsartan	Blocks the effects of angiotensin II at the receptor; reduces peripheral resistance	Side effects: Hypotension, hyperkalemia Contraindications: Pregnancy
Calcium-Channel Blockers		
Nondihydropyridines Diltiazem, verapamil **Dihydropyridines** Amlodipine, felodipine, isradipine, nifedipine	Inhibits calcium ion influx; reduces cardiac afterload, workload	Do not discontinue suddenly. Side effects: Hypotension, bradycardia, CHF dizziness, edema Contraindications: Sick sinus syndrome, heart blocks
Direct renin inhibitor (DRI)	Not considered first-line agent for treatment	
Aliskiren		Side effect, diarrhea, cough, flulike symptoms, and rash. DRI aliskiren can injure or be fatal to the developing fetus.

COPD, chronic obstructive pulmonary disease; CHF, congestive heart failure; DRI, direct renin inhibitor.

Once the crisis has been managed, the nurse strategizes with the patient and provider to take control of his or her BP and prevent recurrence. There are two classes of hypertensive crisis that require immediate intervention: hypertensive emergency and hypertensive urgency (Adams & Urban, 2016).

A hypertensive emergency is a situation in which diastolic BP is greater than 120 mm Hg and must be lowered quickly to halt or prevent damage to the target organs (Adams & Urban, 2016; Grossman & Porth, 2014). Conditions associated with hypertensive emergency include eclampsia or preeclampsia, MI, dissecting aortic aneurysm, intracranial hemorrhage, and hyperthyroidism or thyroid storm. In hypertensive emergencies, patients present with severe elevations in blood pressure, accompanied by rapidly progressive target organ dysfunction, such as myocardial or cerebral ischemia or infarction, pulmonary edema, or kidney failure (Victor, 2016). Patient complaints include headaches, confusion, blurred vision, nausea and vomiting, seizures, pulmonary edema, oliguria, and hypertensive retinopathy (Victor, 2016, p. 394). The therapeutic goals are a controlled, gradual

reduction of the BP by 10% in the first hour and by an additional 15% during the next 3 to 12 hours to a blood pressure of no less than 160/110 mm Hg (Victor, 2016). Additional gradual reductions are made over the next 48 hours until blood pressure normalizes. It is important not to become overeager and lower the BP too quickly (cerebral hypoperfusion may occur if the mean BP is lowered more than 40% in the initial 24 hours); because of hypoperfusion to the brain, heart, kidneys, and retina an MI or CVA could result (Ferri, 2016a). The exceptions include aortic dissection and postoperative bleeding from vascular suture lines, in which a more rapid normalization of blood pressure is required (Victor, 2016). A patient experiencing hypertensive emergency most likely will receive care in the intensive care unit with BP measured every 5 minutes while unstable. The nurse evaluates the patient for a precipitous drop in BP, which requires immediate action to restore BP and perfusion to normal levels.

Hypertensive urgency describes a situation in which BP is severely elevated, but there is no evidence of impending or progressive target organ damage (Adams & Urban, 2016). Elevated BPs associated with severe headache, epistaxis, or anxiety are classified as urgencies. Reducing blood pressure can be accomplished by increasing the dose of the patient's current medications or by adding a second medication. Oral medications with rapid onset of action may be used, including clonidine (Catapres), captopril (Capoten), or labetalol (Trandate). This can be accomplished by keeping the patient in the emergency department for several hours, followed by outpatient assessment within 1 to 3 days (Adams & Urban, 2016).

Pharmacologic Management of Hypertensive Crises

The medications of choice in hypertensive emergencies are best managed with continuous IV infusion of a short-acting titratable antihypertensive agent. The nurse avoids the sublingual and IM routes as their absorption and dynamics are unpredictable. Medications may include clevidipine hydrochloride, fenoldopam mesylate, enalaprilat, esmolol, hydralazine, nicardipine, or sodium nitroprusside, which have immediate, short-lived actions. Nitroprusside should be used cautiously due to thiocyanate toxicity, erratic responses, and risk for severe hypotension (Adams & Urban, 2016). For more information about these medications, see Table 13-4.

Oral doses of fast-acting agents such as clonidine or labetalol are recommended for the treatment of hypertensive urgencies (see Table 13-4).

Drug Alert!
ACEIs and ARBs block aldosterone and may cause hyperkalemia when used with potassium-sparing diuretics or salt substitutes that contain potassium. The nurse should monitor the potassium level and teach the patient to avoid salt substitutes.

The nurse follows up with teaching about a hypertensive crisis and encourages the patient to take charge of managing hypertension.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 72-year-old man arrives in the emergency department with a laceration of his right forearm from a minor gardening injury, which will require suturing. The patient's BP on his left arm is 184/96 and his heart rate is 82 and regular. You express concern to the patient that his BP is high. He shrugs and tells you, "The top number is always elevated, but it's nothing to worry about." Based on current evidence, what teaching should the nurse provide regarding untreated hypertension? What other information do you plan to gather from this patient? What plan of action might you initiate?

2. You are volunteering at a church-sponsored BP screening offered after Sunday services, in tandem with a fund-raising buffet breakfast. The pastor approaches you and notes that the breakfast buffet contains a variety of egg dishes, hash browns, sausage patties, bacon, and pastries. He asks you what effects, if any, this food may have on his parishioners' BPs. What effect might this type of diet have on the parishioners' BPs today? Discuss the evidence that supports specific dietary strategies aimed at preventing and treating hypertension and its complications. Include the DASH approach.

NCLEX-Style Review Questions

1. The nurse is reviewing the vital signs of a patient admitted with cellulitis whose BP is

136/86. Which of the following should the nurse teach the patient about this BP reading?

a. "Your BP is in the normal range, you don't need to worry."
b. "This BP shows prehypertension; try to cut down on sodium and see your health care provider."
c. "I will notify the provider of your BP; a BP of 136/86 indicates you have hypertension."
d. "You are at risk for organ damage; this BP indicates a hypertensive urgency."

2. During routine screening, the nurse notes a BP of 172/96. The patient states, "I feel fine—what's the big deal?" Which of the following indicates the best response by the nurse?

a. "As long as you are feeling well and you are under 60 years old, there is no need to worry."
b. "Untreated high BP may result in kidney failure, heart attack, or stroke."
c. "This BP elevation indicates you have not been compliant with your medication."
d. "Have you had any unusual nosebleeds or headaches lately?"

3. A patient is admitted with angina and hypertensive crisis. On admission, the BP is 240/120. The nurse recognizes which of the following is consistent with current BP management strategies?

a. In 2 hours, the target BP is 140/90.
b. In 1 hour, the patient's target BP should be 180/90.
c. Lowering the BP too quickly may lead to rebound hypertension.
d. The nurse should anticipate using oral medications for hypertensive crisis.

4. The nurse is teaching a patient about BP self-monitoring. What direction should be included in the plan of care?

a. You may sit or stand when taking your BP.
b. Do not eat or drink for at least 2 hours before measuring your BP.
c. Make sure the cuff is loose enough to avoid squeezing your arm too tightly.
d. Keep your arm at heart level and avoid talking during BP measurement.

5. A nurse is completing medication teaching for a patient diagnosed with hypertension. What directive is important to include in the plan to prevent rebound hypertension?

a. Caution the client about the use of OTC vitamins.
b. Inform the client that beta blockers can cause sexual dysfunction.
c. Avoid abruptly stopping antihypertensive medication.
d. Teach the patient/client to arise slowly.

CHAPTER 14

Nursing Management: Patients with Coronary Vascular Disorders

Mary G. Pierson

Learning Objectives

After reading this chapter, you will be able to:

1. Summarize the pathophysiology, risk factors, clinical manifestations, and treatment of coronary atherosclerosis.
2. Summarize the pathophysiology, clinical manifestations, and treatment of angina pectoris.
3. Describe percutaneous coronary intervention (PCI) and coronary artery revascularization procedures.
4. Explain the nursing care of a patient who has had a PCI procedure for treatment of coronary artery disease.
5. Describe the nursing care of a patient who has undergone cardiac surgery.
6. Summarize the pathophysiology, clinical manifestations, and treatment of myocardial infarction.

Cardiovascular disease (CVD) is the leading cause of death in the United States and globally, and accounts for more than 17.3 million deaths per year, a number that is expected to increase to more than 23.6 million by 2030 (Mozaffarian et al., 2016). About one of every three deaths in America and 31% of all deaths globally can be attributed to CVD, affecting all segments of the population. Coronary artery disease (CAD) is the most prevalent type of CVD in adults. For this reason, it is important for nurses to become familiar with various manifestations of coronary artery conditions and methods for assessing, preventing, and treating these disorders medically and surgically.

CORONARY ATHEROSCLEROSIS

The most common cause of CVD in the United States is atherosclerosis, an abnormal accumulation of lipid or fatty substances and fibrous tissue in the lining of arterial blood vessel walls. These substances create blockages and narrow the coronary vessels in a way that reduces blood flow to the myocardium. It is now known that atherosclerosis involves a repetitious inflammatory response to injury to the artery wall and subsequent alteration in the structural and biochemical properties of the arterial walls.

Pathophysiology

Atherosclerosis begins as fatty streaks of lipids that are deposited in the intima of the arterial wall. These lesions commonly begin early in life, perhaps even in childhood. Not all fatty streaks develop into more advanced lesions later. Genetics and environmental factors influence the progression of these lesions. The continued development of atherosclerosis involves an inflammatory response, which begins with injury to the vascular endothelium. The injury may be initiated by smoking, hypertension (HTN), and other factors. The presence of inflammation has multiple effects on the arterial wall, including the attraction of inflammatory cells (including macrophages or monocytes, white blood cells [WBCs]) (Swirski & Nahrendorf, 2013). The macrophages infiltrate the injured vascular endothelium and ingest lipids, which turns them into what are called "foam cells." These foam cells are present in all stages of atherosclerotic plaque formation (Porth, 2015). Activated macrophages also release biochemical substances that can further damage the endothelium, attracting platelets and initiating clotting.

Smooth muscle cells within the vessel wall subsequently proliferate and form a fibrous cap over a center that is filled with lipid and inflammatory infiltrate. These deposits, called atheromas or plaques, protrude into the lumen of the vessel, narrowing it and obstructing blood flow (Fig. 14-1). If the fibrous cap of the plaque is thick and the lipid pool remains relatively stable, it can resist the stress from blood flow and vessel movement. If the cap is thin and inflammation is ongoing, the lipid core may grow, causing it to rupture, and this ruptured plaque is a focus for thrombus formation. Then the thrombus may obstruct blood flow, leading to sudden cardiac death or an acute myocardial infarction (MI), which is the death of a portion of the heart muscle. Thus, atherosclerosis can produce narrowing of the lumen of a blood vessel, sudden obstruction of a blood vessel due to plaque rupture, and weakening of a blood vessel, resulting in aneurysm formation or emboli formation because of direct damage to the endothelium.

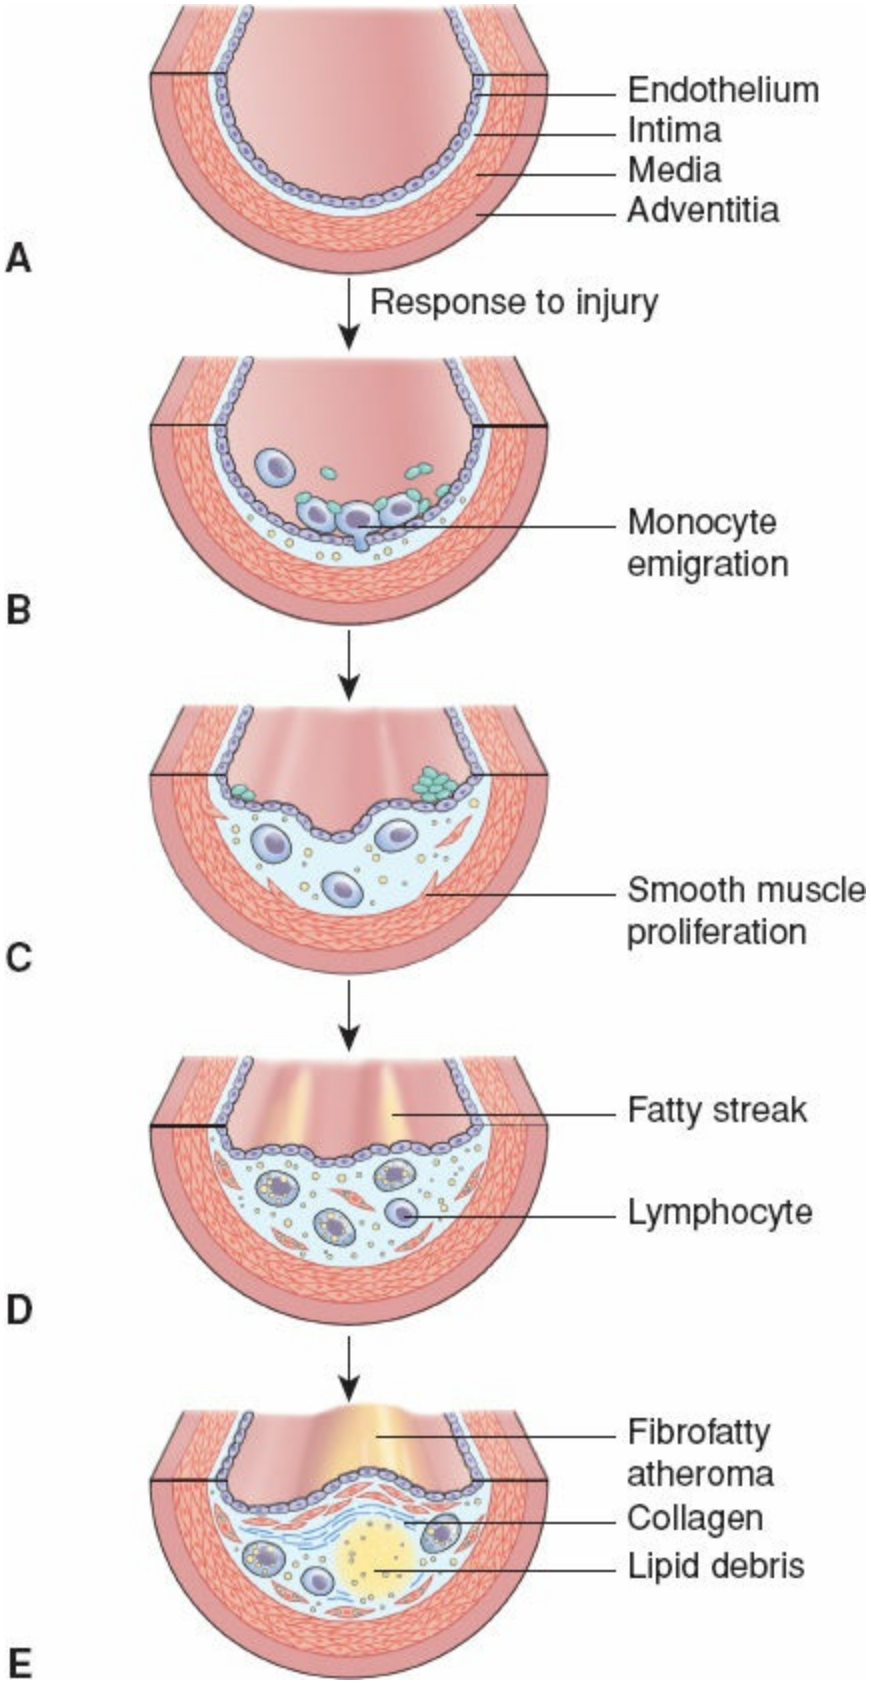

FIGURE 14-1 Atherosclerosis begins as monocytes and lipids enter the intima of an injured vessel (A, B). Smooth muscle cells proliferate within the vessel wall (C) contributing to the development of fatty accumulations and atheroma (D). As the plaque enlarges, the vessel narrows and blood flow decreases (E). The plaque may rupture and a thrombus might form, obstructing blood flow.

The anatomic structure of the coronary arteries makes them particularly susceptible to the mechanisms of atherosclerosis. There are three major coronary arteries and they have multiple branches; atherosclerotic lesions most often form where the vessels branch (Fig. 14-2). Although heart disease is most often caused by atherosclerosis of the coronary arteries, other phenomena may also decrease blood flow to the heart. Examples include vasospasm (sudden constriction or narrowing) of a coronary artery, myocardial trauma from internal or external forces, structural disease, congenital anomalies, decreased oxygen supply (e.g., from acute blood loss, anemia, or low blood pressure), and increased oxygen demand (e.g., from rapid heart rate, thyrotoxicosis, or use of cocaine).

Risk Factors

Epidemiologic studies point to several factors that increase the probability that CAD will develop in a person. Some risk factors are uncontrollable, including:

- Age (men over 45 years old, women over 55 years old)
- Gender (in people less than 55 years of age, men are at a greater risk; after 55 years of age, men and women have the same risk; or women under 55 years of age who have premature menopause without estrogen replacement therapy)
- Race (African Americans, Mexican Americans, Native Americans, and some Asian Americans demonstrate increased risk)
- Family history of first-degree relative with premature diagnosis of heart disease

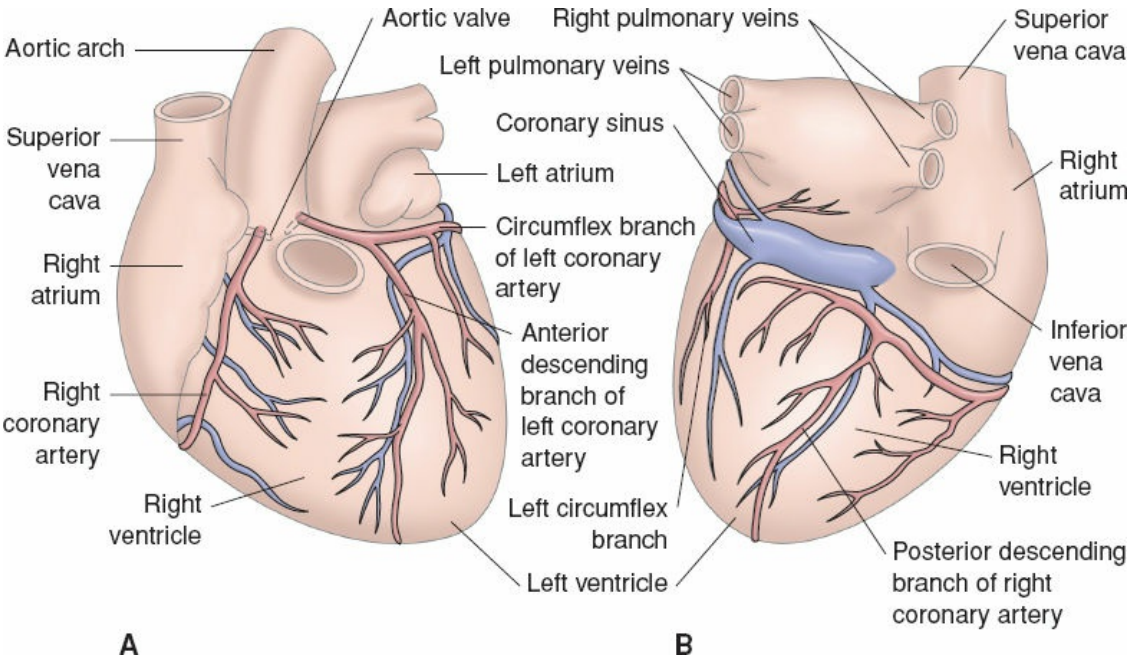

FIGURE 14-2 The coronary arteries supply the heart muscle with oxygenated blood, adjusting the flow according to metabolic needs: (A) anterior view and (B) posterior view of heart.

Known modifiable risk factors include diabetes and prediabetes, HTN, smoking, obesity, physical inactivity, high blood cholesterol, unhealthy diet, and stress (National Heart, Lung, and Blood Institute [NHLBI], 2016).

Risk factors identified more recently include sleep apnea, metabolic syndrome (discussed below), increased body mass index (BMI), chronic kidney disease, chronic infections (Hui, Leung, & Padwal, 2015), nonalcoholic fatty liver disease (NAFLD) (Targher & Byrne, 2013), and influenza; additional risk factors may include conditions thought to be proinflammatory (e.g., rheumatoid arthritis) (Udel et al., 2013; Wilson, 2016).

Nursing Alert

Obesity (BMI of 35% or higher) in and of itself is associated with all-cause mortality regardless of level of physical activity. Questions exist regarding whether obesity itself

is a risk factor for CAD or cardiovascular events, or if it is the relationship of obesity to glucose intolerance, insulin resistance, HTN, physical inactivity, and dyslipidemia that increases risk. Given the significant risk that diabetes, HTN, and hyperlipidemia impose on coronary disease, nurses need to make efforts toward increasing awareness of the crucial role that these disorders have on cardiovascular mortality and morbidity.

A cluster of metabolic abnormalities now known as metabolic syndrome is known to be a major risk factor for CAD (Fig. 14-3). A diagnosis of this syndrome includes any combination of three of the following conditions:

- Insulin resistance (fasting glucose greater than 110 mg/dL or abnormal glucose tolerance test) (Har, 2016)
- Abdominal obesity (waist circumference greater than 35 inches in women, greater than 40 inches in men)
- Dyslipidemia (triglycerides greater than 150 mg/dL; HDL less than 50 mg/dL in women, less than 40 mg/dL in men)
- HTN (at least 130/85 mm Hg) (Har, 2016)
- Proinflammatory state (high levels of C-reactive protein [CRP])
- Prothrombotic state (high fibrinogen)

Many people with type-2 diabetes mellitus fit this clinical picture. Measurement of lipoprotein, homocysteine (an amino acid associated with cardiac disease), and CRP may also be appropriate in people who are identified as being at risk (Koenig, 2013).

Nursing Alert
CRP is a protein that is released in the blood during inflammatory states. The high-sensitivity CRP (hs-CRP) may be useful in assessing the risk of a cardiac event (Yousuf et al., 2013). A normal level is less than 0.1 mg/dL or less than 1 mg/L (Kaptoge, Di Angelantonio, & Pennells, 2012; Koenig, 2013).

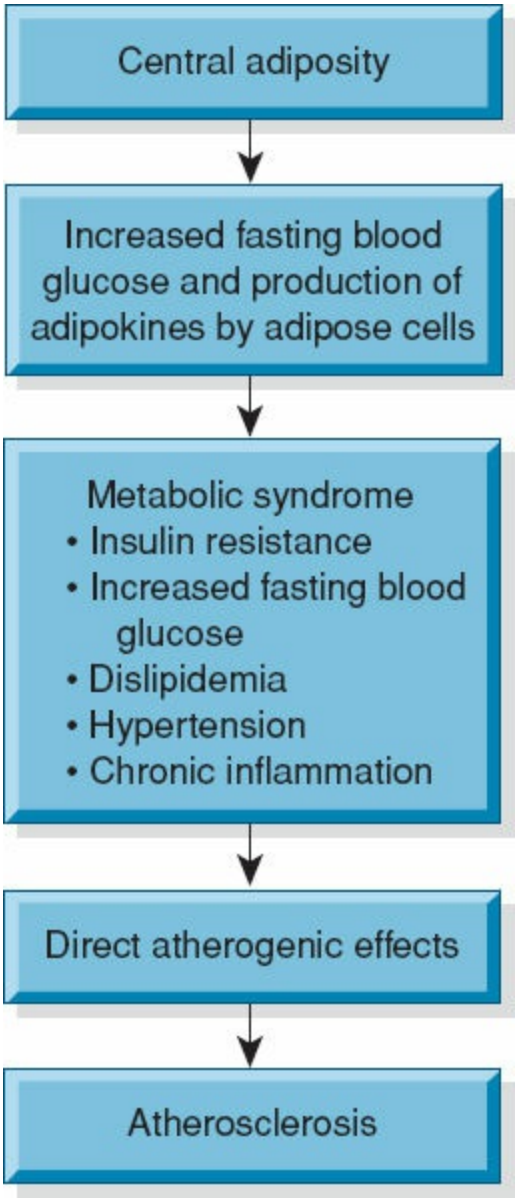

FIGURE 14-3 Pathophysiology of CVD in metabolic syndrome. Both central adiposity and the immune system play a role in the development of metabolic syndrome. Adipokines (such as leptin) and cytokines (such as tumor necrosis factor) are thought to contribute to the development of metabolic abnormalities. The eventual effect of these processes is the promotion of atherosclerosis.

Additionally, a risk equivalent is a condition that places patients at high risk for experiencing a cardiac event, such as an MI. Having one or more of the conditions listed as contributing to metabolic syndrome may place patients at the same risk of having a cardiac event as someone who has already experienced one (Lackland et al., 2012). Risk equivalents for cardiac events are detailed in Box 14-1.

Clinical Manifestations and Assessment

Coronary atherosclerosis produces symptoms and complications according to the location and degree of narrowing of the arterial lumen, thrombus formation, and obstruction of blood flow to the myocardium (Libby, 2013). This impediment to blood flow is usually progressive, causing an inadequate blood supply that deprives the cardiac muscle cells of oxygen needed for their survival. The condition is known as ischemia. Angina pectoris refers to chest pain that is brought about by myocardial ischemia. If the decrease in blood supply is significant enough, of long enough duration, or both, death of myocardial cells, or MI, may result. Over time, irreversibly damaged myocardium undergoes degeneration and is replaced by scar tissue, causing various degrees of myocardial dysfunction. Significant myocardial damage may result in persistently low cardiac output (CO), and if the heart cannot support the body's needs for oxygenated blood, the result is heart failure. Myocardial hypoxia due to CAD may also lead to lethal cardiac rhythm disturbances that may result in sudden cardiac death.

BOX 14-1 Coronary Artery Disease Risk Equivalents

Individuals at highest risk for a cardiac event within 10 years are those with known existing coronary artery disease (CAD) who have experienced a cardiac event, and those without a known history of cardiac event but have any one or more of the following diseases, which are called CAD risk equivalents (Lackland et al., 2012). Risk equivalents are essentially disease processes that involve atherosclerotic disease.

- Diabetes
- Peripheral arterial disease
- Abdominal aortic aneurysm
- Carotid artery disease
- Chronic kidney disease (CKD)
- Large vessel atherosclerotic ischemic stroke

Nursing Alert
Classic signs and symptoms of myocardial ischemia include acute onset of chest pain (often described as crushing pain, usually substernal but may be in other areas of the chest, jaw, back, or arms), shortness of breath (SOB) (dyspnea [particularly in the elderly]), extreme fatigue, diaphoresis, and nausea and vomiting. The pain of an MI may be differentiated from angina by persistence of the pain despite rest and nitroglycerine. Women often complain of atypical chest pain and nonspecific signs and symptoms.

In the elderly, sometimes there will not be a classic presentation of symptoms (referred to as "silent" ischemia), making recognition and diagnosis a clinical challenge. Elderly patients should be encouraged to recognize their chest pain–like symptom (anginal

equivalent), for example, weakness, as an indication that they should rest or take prescribed medications and contact their provider with concerns. Pharmacologic stress testing may be used to diagnose CAD in elderly patients or those who have a limited ability to exercise because of other conditions (e.g., peripheral vascular disease, arthritis, degenerative disk disease, physical disability, foot problems).

Prevention and Medical and Nursing Management

Controlling cholesterol, treating hyperlipidemia, and managing HTN and diabetes mellitus are discussed here; additional medical and nursing management is discussed under angina.

Controlling Cholesterol Abnormalities

The association of a high blood cholesterol level with CAD is well established. The metabolism of fats is an important contributor to the development of CAD. Fats, which are insoluble in water, are encased in water-soluble lipoproteins that allow them to be transported within the circulatory system. The various lipoproteins are categorized by their protein content, which is measured in density. The density increases when more protein is present. Four elements of fat metabolism—total cholesterol, LDL, HDL, and triglycerides—affect the development of heart disease. Cholesterol is processed by the GI tract into lipoprotein globules called *chylomicrons.* These are reprocessed by the liver as lipoproteins (Fig. 14-4). This is a physiologic process necessary for the formation of lipoprotein-based cell membranes and other important metabolic processes. When an excess of LDL is produced, LDL particles adhere to vulnerable points in the arterial endothelium. Here, macrophages ingest them, leading to the formation of foam cells and the beginning of plaque formation.

All adults 20 years of age or older should have a fasting lipid profile (total cholesterol, LDL, HDL, and triglyceride) performed at least once every 5 years and more often if the profile is abnormal. Patients younger than 20 years of age with known family history of hyperlipidemia and/or vascular disease should probably be tested earlier. Patients who have had an acute event (e.g., MI), a percutaneous coronary intervention (PCI), or a coronary artery bypass graft (CABG) require assessment of the LDL cholesterol level within a few months of the event or procedure because LDL levels may be low immediately after the acute event or procedure. Subsequently, lipids should be monitored regularly until the desired level is achieved.

LDL exerts a harmful effect on the coronary vasculature because the small LDL particles can be transported easily into the vessel lining. In contrast, HDL promotes the use of total cholesterol by transporting LDL to the liver, where it is biodegraded and then excreted. The level of HDL should exceed 40 mg/dL and ideally should be more than 60 mg/dL. A high HDL level is a strong negative risk factor for heart disease (i.e., it protects against disease). In 2013, the guidelines for the treatment of high blood cholesterol levels were updated by the American College of Cardiology and the American Heart Association (ACC-AHA) Task Force on Practice Guidelines. The current guidelines represent a substantial change from previous recommendations, which promoted specific lipid-level goals for patients that were dependent on the patient's level of risk. Patients now fall into a group dependent upon risk, their factors, and history rather than on their LDL level. The groups who would benefit from statin therapy (cholesterol lowering medications) are those:

1. With clinically evident atherosclerotic CVD
2. With primary low-density lipoprotein (LDL) cholesterol levels of at least 190 mg/dL
3. With type-1 or type-2 diabetes (ages 40 to 75 years) and an LDL cholesterol level of 70

mg/dL or higher, without clinically evident atherosclerotic CVD

4. Without clinically evident atherosclerotic CVD or diabetes with an LDL cholesterol level range of 70 to 189 mg/dL and an estimated 10-year risk of atherosclerotic CVD of at least 7.5% (Note: A downloadable spreadsheet enabling estimation of 10-year and lifetime risk for atherosclerotic CVD and a web-based calculator are available at http://my.americanheart.org/cvriskcalculator and http://www.cardiosource.org/science-and-quality/practice-guidelines-and-quality-standards/2013-prevention-guideline-tools.aspx).

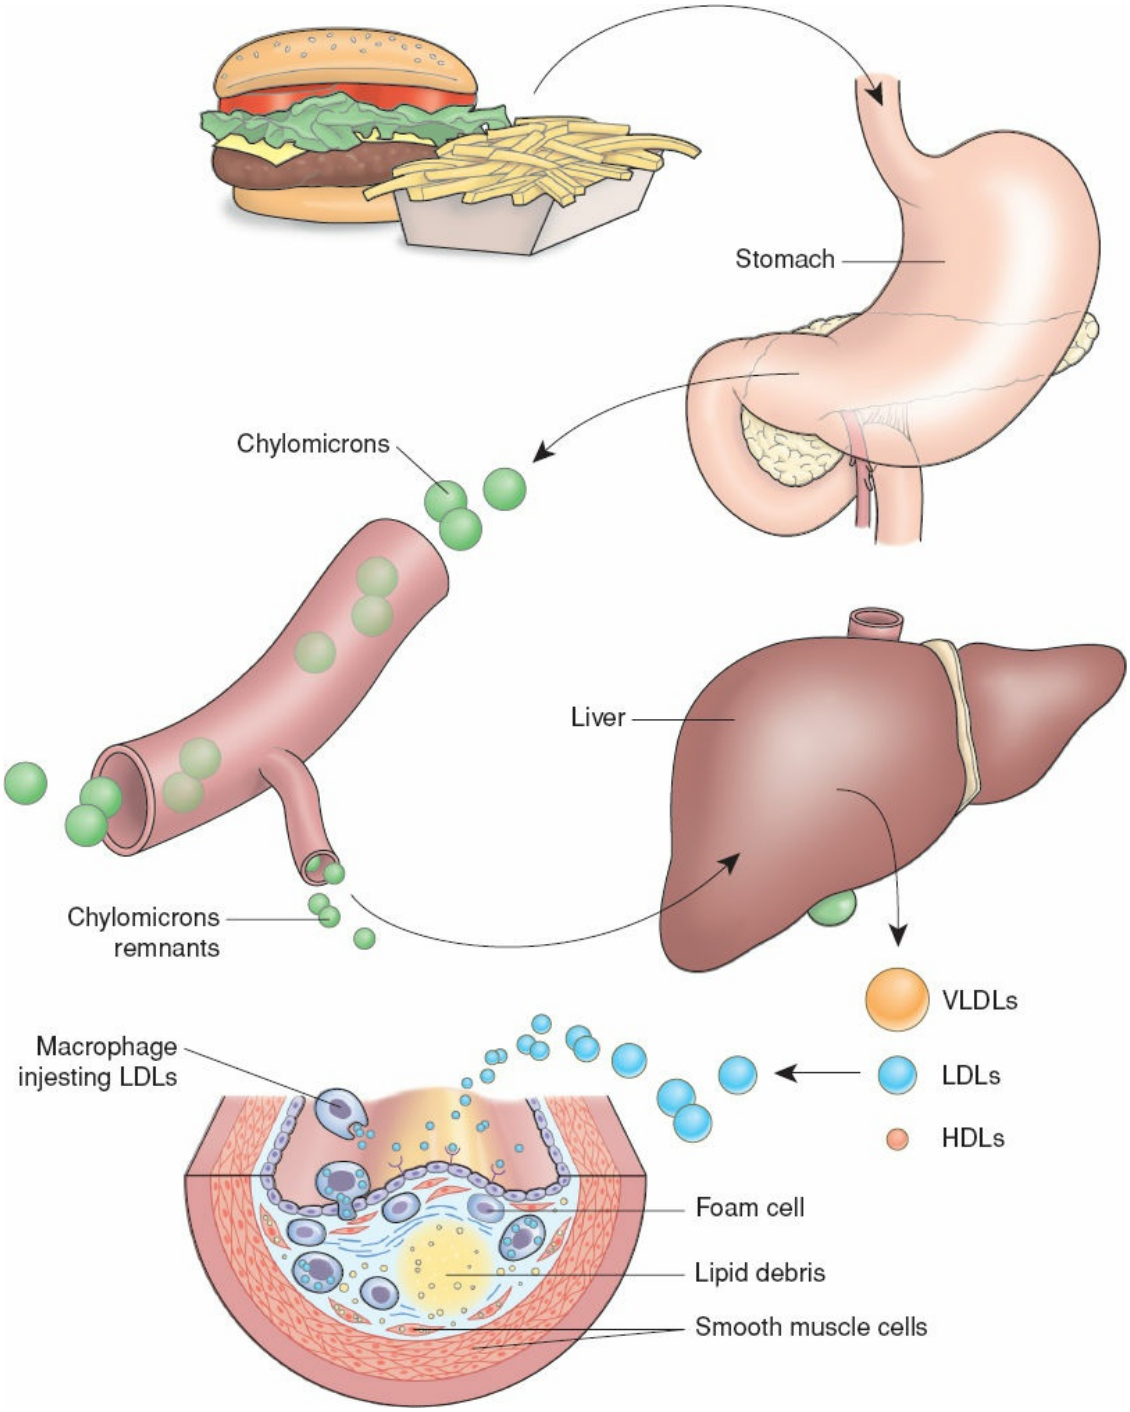

FIGURE 14-4 Lipoproteins and the development of atherosclerosis. As dietary cholesterol and saturated fat are processed by the GI tract, chylomicrons enter the blood. They are broken down into chylomicron remnants in the capillaries. The liver processes them into lipoproteins. When these are released into the circulation, excess low-density lipoproteins (LDLs) adhere to receptors on the intimal wall. Macrophages also ingest LDLs and transport them into the vessel wall, beginning the process of plaque formation. HDLs, high-density lipoproteins; VLDL, very-low-density lipoprotein.

TABLE 14-1 Medications Affecting Lipoprotein Metabolism

Medication	Lipid/Lipoprotein Effects	Side Effects	Contraindications
HMG-CoA Reductase Inhibitors (Statins)			
Lovastatin (Mevacor®) Pravastatin (Pravachol®) Simvastatin (Zocor®) Fluvastatin (Lescol®) Atorvastatin (Lipitor®)[a] Rosuvastatin (Crestor®)[a] Pitavastatin (Livalo®)	LDL ↓ 18–55% HDL ↑ 5–15% TG ↓ 7–30%	Myopathy, myalgias, increased liver enzyme levels, ↑ blood sugar	**Absolute:** Active liver disease, pregnancy, lactation **Relative:** Drug–drug interactions can increase the risk of adverse events—refer to pharmacist.
Nicotinic Acid			
Niacin (Niacor®, Niaspan®) Immediate-release nicotinic acid Extended-release nicotinic acid Sustained-release nicotinic acid	LDL ↓ 5–25% HDL ↑ 15–35% TG ↓ 20–50%	Flushing, hyperglycemia, hyperuricemia (or gout), upper GI distress, hepatotoxicity	**Absolute:** Chronic liver disease, severe gout **Relative:** Diabetes, hyperuricemia, peptic ulcer disease
Fibric Acids			
Fenofibrate (TriCor®, Trilipix®, Lipofen®, Fenoglide®, Antara®, Lofibra®) Gemfibrozil (Lopid®) Fenofibric acid (Fibricor®)	LDL ↓ 5–20% (may be increased in patients with high TG) HDL ↑ 10–20% TG ↓ 20–50%	Dyspepsia, rash, pruritis, gallstones, myopathy, unexplained non-CHD deaths	**Absolute:** Severe kidney disease, severe liver disease
Bile Acid Sequestrants			
Cholestyramine (LoCholest®, Questran®, Prevalite®) Colesevelam (WelChol®) Colestipol HCl (Colestid®)	LDL ↓ 15–30% TG no change or increase	GI distress, constipation, vitamin K deficiency, Decreased uptake of fat-soluble vitamins, drug interactions (binds to other drugs and prevents absorption)	**Absolute:** dysbetalipoproteinemia, TG > 400 mg/dL, bowel obstruction, TG induced pancreatitis **Relative:** TG > 200 mg/dL
Omega-3 Fatty Acids *eicosapentaenoic acid/ docosahexaenoic acid (EPA/DHA)*	TG ↓ 25–30% LDL ↑ 5–10% (with dose of 4 g/day)	Flushing, elevated liver enzymes, bleeding risk eructation, and gastric irritation (taste perversion, dyspepsia) and allergic reactions (fish); When used in amounts greater than 3 g/day, EPA is POSSIBLY UNSAFE, and can thin the blood and increase the risk for bleeding.	**Absolute:** hypersensitivity to any component of this medication Use caution if hypersensitivity to fish/shellfish, bleeding risk, active liver disease
PCSK9 INHIBITOR Evolocumab (Repatha®) Alirocumab (Praluent®) (self-injected under the skin with a prefilled, single-use SureClick® Autoinjector)	↓ LDL 58–71%	Allergic reaction; flu-like symptoms; back pain; redness, pain, or bruising at the injection site	**Absolute:** hypersensitivity reaction to evolocumab
Cholesterol Absorption Inhibitor Ezetimibe (Zetia®)	↓ LDL (–18%), ↑ HDL 1–4%, ↓ TG 5–10%	Allergic reaction, arthralgia, diarrhea, back pain, stomach or abdominal pain, fever, sore throat	Allergy to ezetimibe; active liver disease

Note: Statin therapy are considered first line agents; the other agents listed below are generally reserved for patients with tolerability issues or hypertriglyceridemia.
HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LDL, low-density lipoprotein; HDL, high-density lipoprotein; TG, triglycerides; ↓, decrease; ↑, increase; CHD, coronary heart disease.
[a]Atorvastatin (Lipitor) and Rosuvastatin (Crestor) are both "High-Intensity Statins", High-Intensity Statins daily dose lowers LDL-C by approx ≥50% and are the most commonly prescribed (Foley et al., 2017).

In these patient groups, high-intensity statin therapy (designed to reduce LDL cholesterol levels by as much as 50% or more) is generally recommended; it is believed that the benefit outweighs the risk. Research has demonstrated that primary prevention with statins reduces total mortality as well as nonfatal atherosclerotic cardiovascular events (see Table 14-1 for commonly prescribed medications affecting lipoprotein metabolism).

Moderate-intensity statin therapy (aims for a reduction of 30% to less than 50% in LDL

cholesterol levels) is recommended for patients who cannot tolerate high-intensity treatment or patients with diabetes and a 10-year risk of atherosclerotic CVD of less than 7.5%. People receiving statin therapy should be monitored for muscle and hepatic injury and for new-onset diabetes.

Serum cholesterol and LDL levels often can also be influenced by diet and physical activity. Depending on the patient's LDL level and risk of CAD, medication to treat hyperlipidemia may also be prescribed. Medication should be used in conjunction with a heart-healthy diet and an exercise program (Keaney, Curfman, & Jarcho, 2014). Refer to Table 14-1.

Treating Hyperlipidemia

Lipid-lowering medications can reduce CAD mortality in patients with elevated lipid levels and in at-risk patients with normal lipid levels. Patients with elevated cholesterol levels should be monitored for adherence to the therapeutic plan, the effect of cholesterol-lowering medications, and the development of side effects. Lipid levels are obtained and adjustments made to the diet and medication every 6 weeks until the lipid goal or maximum dose is achieved and then every 6 months thereafter (Morris, Ballantyne, Birtcher, Dunn, & Urbina, 2014). Lifestyle changes need to be incorporated into any treatment regimen and include:

- Dietary measures include a heart-healthy diet (monitor and treat hyperlipidemia if dietary control is not enough).
  - Increase physical activity;150 minutes of moderate exercise weekly (i.e., brisk walking) or about 75 minutes of vigorous exercise weekly (i.e., running) (Ridker, Libby, & Buring, 2015)
- Smoking cessation (people who stop smoking reduce their risk of heart disease 30% to 50% within the first year, and the risk continues to decline thereafter)
- Stress management
- HTN management
- Diabetes management

Managing Hypertension

The risk of CVD increases as blood pressure increases. Elevated blood pressure may result in increased stiffness of the vessel walls, leading to vessel injury and a resulting inflammatory response within the intima. Inflammatory mediators then lead to the release of growth-promoting factors that cause vessel hypertrophy and hyperresponsiveness. These changes result in acceleration and aggravation of atherosclerosis. HTN also increases the work of the left ventricle, which must pump harder to eject blood into the arteries. Over time, the increased workload causes the heart to enlarge and thicken and may, eventually, lead to cardiac failure.

Early detection of high blood pressure and adherence to a therapeutic regimen can prevent the serious consequences associated with untreated elevated blood pressure. HTN is discussed in detail in Chapter 13.

Controlling Diabetes Mellitus

The relationship between diabetes mellitus and heart disease has been confirmed. Patients with diabetes are two to four times more likely than nondiabetic patients to experience development of CVD (Ferri, 2016). And diabetes is considered equivalent to existing CAD as a risk factor for a secondary cardiac event (Lackland et al., 2012). For 50% to 75% of patients with diabetes, CVD is identified as the cause of death (Grossman & Porth, 2014).

Hyperglycemia fosters dyslipidemia, increased platelet aggregation, and altered red blood cell function, which can lead to thrombus formation. Effective treatment with appropriate anti-hyperglycemic agents and diet has shown improvement in endothelial function and improved endothelial-dependent dilation (Strain & Smith, 2016). Thus, control of diabetes is essential in preventing or modulating the development of CAD. Diabetes is discussed in detail in Chapter 30.

Unfolding Patient Stories: Carl Shapiro • Part 1

Carl Shapiro, who has a family history of atherosclerotic CVD, is diagnosed with HTN and hyperlipidemia during a routine visit to his primary provider. He is overweight, smokes a half pack of cigarettes per day, and describes his job as stressful. What questions can the nurse ask Carl Shapiro to help develop a plan for patient education? What topics are important for the nurse to address, and how can the information be presented? (Carl Shapiro's story continues in Chapter 56.)

Care for Carl and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in (thepoint.lww.com/DocuCareEHR).

ANGINA PECTORIS

Angina pectoris is a clinical syndrome usually characterized by episodes or paroxysms of pain, pressure, or discomfort in the chest, jaw, shoulder, back, or arm that is caused by myocardial ischemia (Ferri, 2016). The cause is insufficient coronary blood flow (usually caused by atherosclerotic disease), resulting in a decreased oxygen supply when there is increased myocardial demand for oxygen in response to physical exertion or emotional stress. In other words, the demand for oxygen exceeds the supply. The severity of angina is based on the precipitating activity and its effect on activities of daily living. Types of angina are listed in Box 14-2.

Pathophysiology

Angina is usually caused by atherosclerotic disease. Almost invariably, angina is associated with a significant obstruction of a major coronary artery. Normally, the myocardium extracts a large amount of oxygen from the coronary circulation to meet its continuous demands. When there is an increase in demand, flow through the coronary arteries needs to be increased. When there is blockage in a coronary artery, flow cannot be increased, and ischemia results. Because angina is a symptom of coronary atherosclerosis, the risk factors are the same.

BOX 14-2 Types of Angina

- *Stable angina:* Predictable and consistent pain that occurs on exertion and is relieved by rest
- *Unstable angina* (also called preinfarction angina or crescendo angina): Symptoms occur more frequently and last longer than in stable angina. The threshold for pain is lower, and pain may occur at rest.
- *Intractable or refractory angina:* Severe incapacitating chest pain
- *Variant angina* (also called Prinzmetal's angina): Pain at rest with reversible ST-segment elevation; thought to be caused by coronary artery vasospasm
- *Silent ischemia:* Objective evidence of ischemia (such as electrocardiogram changes with a stress test), but patient reports no symptoms

Clinical Manifestations and Assessment

Ischemia of the heart muscle may produce pain or other symptoms, varying in severity from mild indigestion to a choking or heavy sensation in the upper chest that ranges from discomfort to agonizing pain accompanied by severe apprehension and a feeling of impending death. Typically, the pain or discomfort is poorly localized and may radiate to the neck, jaw, shoulders, and inner aspects of the upper arms, usually the left arm. The patient often feels tightness or a heavy, choking, or strangling sensation that has a vise-like, insistent quality. The patient with diabetes mellitus may not have severe pain with angina because diabetic neuropathy can dull the perception of pain. A woman may have different symptoms than a man, because coronary disease in women tends to be more diffuse and affects long segments of the artery rather than discrete segments. Table 14-2 discusses anginal pain.

The nurse is alert for complaints of unusual fatigue; weakness or numbness in the arms, wrists, and hands; SOB; pallor; diaphoresis; anxiety; dizziness or lightheadedness; and nausea and vomiting that may accompany the pain (called *associated signs and symptoms*). Angina may subside with rest or nitroglycerin. In many patients, anginal symptoms follow a stable, predictable pattern.

The diagnosis of angina begins with the patient's history related to the clinical manifestations of ischemia. A 12-lead electrocardiogram (ECG) and blood laboratory biomarker values help in making the diagnosis. The patient may undergo an exercise or pharmacologic stress test in which the heart is monitored by ECG, echocardiogram, or both. The patient may also be referred for a nuclear scan or invasive procedure (e.g., cardiac catheterization, coronary artery angiography).

Medical Management

The objectives of the medical management of CAD and angina are to decrease the oxygen demand of the myocardium and to increase the oxygen supply. Medically, these objectives are met through pharmacologic therapy and control of risk factors. Alternatively, reperfusion procedures may be used to restore the blood supply to the myocardium. These include PCI procedures (e.g., percutaneous transluminal coronary angioplasty [PTCA] with intracoronary stent placement, atherectomy) and CABG. PCI is currently the preferred method of treatment for patients with simple coronary artery lesions (Iqbal, Serruys, & Taggert, 2013).

TABLE 14-2 Assessing Angina

Acronym	Factors About Pain That Need To Be Assessed	Assessment Questions
P	Position/Location Provocation/Palliation	"Where is the pain? Can you point to it?" "What were you doing when the pain began?" "What makes it worse?" "What makes it better?"
Q	Quality Quantity	"How would you describe the pain?" "Is it like any pain you had before?" "Has the pain been constant?"
R	Radiation	"Can you feel the pain anywhere else?"
S	Severity Symptoms	"How would you rate the pain on a 0–10 scale, with 0 being no pain and 10 being the most amount of pain?" (or use visual analog scale or adjective rating scale) "Did you notice any other symptoms with the pain?" (such as nausea, vomiting, diaphoresis)
T	Timing	"How long ago did the pain start?"

Adapted from Bickley, L. S. (2013). *Bates' guide to physical examination and history taking* (11th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Pharmacologic Therapy

Several types of drugs are used to treat coronary vascular disease:

- *Positive inotrope:* A medication that increases myocardial contractility (force of contraction)
- *Negative inotrope:* A medication that decreases myocardial contractility
- *Positive chronotrope:* A medication that increases heart rate
- *Negative chronotrope:* A medication that decreases heart rate

Nitrates

Nitrates remain the mainstay for treatment of coronary ischemia. A vasoactive agent (Nitroglycerin, Nitrostat, Nitrol, Nitro-Bid, Nitro-paste) is administered to reduce myocardial oxygen consumption, which decreases ischemia and relieves pain. Nitroglycerin dilates primarily the veins and, in higher doses, also the arteries. Dilation of the veins causes venous pooling of blood throughout the body. As a result, less blood returns to the heart, and filling pressure (preload) is reduced. If the patient is hypovolemic (does not have adequate circulating blood volume), the decrease in filling pressure can cause a significant

decrease in CO and blood pressure; thus it is important for the nurse to monitor the patient's response to nitrates. Nitrates also relax the systemic arteriolar bed and increase oxygen supply, bringing about a more favorable balance between supply and demand.

Nursing Alert
The nurse must evaluate for hypotension before administering nitrates. Once hypotension is excluded, a sublingual nitroglycerin tablet is administered. Vital signs are monitored while evaluating for resolution of symptoms since even small doses can produce sudden hypotension and bradycardia. Usually this reaction can be reversed with intravenous atropine (Mega & Morrow, 2015).

When nitroglycerin is administered sublingually (SL), the patient's response is assessed (relief of chest pain and effect on blood pressure and heart rate). If the chest pain is unchanged or is lessened but still present, nitroglycerin SL administration is repeated up to a total of three doses. Each time, blood pressure, heart rate, and the ST segment (if the patient is on a monitor with ST-segment monitoring capability) are assessed. If the pain is significant and continues after these interventions, the patient is evaluated further for acute MI and further intervention is necessary.

Nursing Alert
As with any medication, the nurse should always check the expiration dates on the bottle of nitroglycerin tablets.

Most patients with angina pectoris must self-administer nitroglycerin on an as-needed basis. A key nursing role in such cases is educating patients about the medication and how to take it (Box 14-3). SL nitroglycerin comes in tablet and spray forms.

Beta-Adrenergic Blocking Agents

Beta-blockers such as metoprolol (Lopressor, Toprol) and atenolol (Tenormin) reduce myocardial oxygen consumption by blocking beta-adrenergic sympathetic stimulation to the heart. The result is a reduction in heart rate, slowed conduction of impulses through the conduction system, decreased blood pressure, and reduced myocardial contractility (negative chronotrope and negative inotrope) to balance the myocardial oxygen needs (demands) and the amount of oxygen available (supply). This helps control chest pain and delays the onset of ischemia during work or exercise. Beta-blockers reduce the incidence of recurrent angina, infarction, and cardiac mortality. Patients taking beta-blockers are cautioned not to stop taking them abruptly because angina may worsen and MI may develop.

BOX 14-3 Patient Education

Self-Administration of Nitroglycerin

- Instruct the patient to make sure the mouth is moist, the tongue is still, and saliva is not swallowed until the nitroglycerin tablet dissolves. Place the tablet under the tongue or between the cheek and gum, and let it dissolve.

- Advise the patient to carry the medication at all times as a precaution. However, because nitroglycerin is very unstable, it should be carried securely in its original container (e.g., capped, dark, glass bottle); tablets should never be removed and stored in metal or plastic pillboxes.
- Explain that nitroglycerin is volatile and is inactivated by heat, moisture, air, light, and time. Instruct the patient to renew the nitroglycerin supply every 6 months.
- Inform the patient that the medication should be taken in anticipation of any activity that may produce pain. Because nitroglycerin increases tolerance for exercise and stress when taken prophylactically (i.e., before angina-producing activity, such as exercise, stair-climbing, or sexual intercourse), it is best taken before pain develops.
- Recommend that the patient note how long it takes for the nitroglycerin to relieve the discomfort. Advise the patient that if pain persists after taking three sublingual tablets at 5-minute intervals, emergency medical services should be called.
- Discuss possible side effects of nitroglycerin, including flushing, throbbing headache, hypotension, and tachycardia.
- Advise the patient to sit down for a few minutes when taking nitroglycerin to avoid hypotension and syncope.

Calcium-Channel Blocking Agents

Calcium-channel blockers (calcium ion antagonists such as Norvasc, Cardizem) have a variety of effects. These agents decrease sinoatrial node automaticity and atrioventricular node conduction, resulting in a slower heart rate and a decrease in the strength of the heart muscle contraction (negative inotropic and negative chronotropic effects). These effects decrease the workload of the heart. Calcium-channel blockers also relax the blood vessels, causing a decrease in blood pressure and an increase in coronary artery perfusion. Calcium-channel blockers increase myocardial oxygen supply by dilating the smooth muscle wall of the coronary arterioles; they decrease myocardial oxygen demand by reducing systemic arterial pressure and the workload of the left ventricle. They may be prescribed to prevent and treat vasospasm (as in variant angina).

The calcium-channel blockers most commonly used are amlodipine (Norvasc) and diltiazem (Cardizem, Tiazac).

Antiplatelet and Anticoagulant Medications

Antiplatelet medications are administered to prevent platelet aggregation and subsequent thrombosis, which impedes blood flow. The patient receiving anticoagulation therapy should be monitored for signs and symptoms of external and internal bleeding, such as low blood pressure, increased heart rate, and decreased serum hemoglobin and hematocrit. The patient should be placed on bleeding precautions, which include:

- Applying pressure to the site of any needle puncture for a longer time than usual
- Avoiding intramuscular (IM) injections
- Avoiding tissue injury and bruising from trauma or use of constrictive devices (e.g.,

continuous use of an automatic blood pressure cuff)

Examples of antiplatelet and anticoagulant medications include aspirin, clopidogrel, heparin, and glycoprotein and IIb/IIIa inhibitors.

Aspirin prevents platelet activation and reduces the incidence of MI and death in patients with CAD.

Clopidogrel (Plavix) or ticlopidine (Ticlid) is given to patients who are allergic to aspirin or is given in addition to aspirin in patients at high risk for MI. Unlike aspirin, these medications take a few days to achieve their antiplatelet effect. They also may cause GI upset.

IV unfractionated heparin (UFH) prevents the formation of new blood clots. Treating patients with unstable angina with heparin reduces the occurrence of MI. A decrease in platelet count or evidence of thrombosis may indicate a serious complication called *heparin-induced thrombocytopenia* (HIT), an antibody-mediated reaction to heparin that may result in thrombosis. Patients who have received heparin within the past 3 months and those who have been receiving UFH for 5 to 15 days are at high risk for HIT.

Nursing Alert

HIT is a complication of anticoagulation with UFH or low–molecular-weight heparin (LMWH). It is an immune-mediated disorder in which antibodies form against the heparin-platelet factor 4 complex. The antibody complex attaches to the platelet, causing its aggregation. The reticuloendothelial system destroys activated platelets, thus resulting in decreased platelet counts. Frequently, procoagulants are also generated, resulting in thrombosis. A complication of HIT is heparin-associated thrombocytopenia and thrombosis (HITT). In the presence of unexplained thrombocytopenia, or venous or arterial thrombosis associated with thrombocytopenia, HIT should be considered. Discontinuation of heparin as soon as diagnosis is suspected is warranted (Lee & Arepally, 2013).

IV administration of glycoprotein (*GP*) *IIb/IIIa agents* (abciximab [ReoPro], tirofiban [Aggrastat], and eptifibatide [Integrilin]) is indicated for hospitalized patients with unstable angina and as adjunct therapy for PCI. These agents prevent platelet aggregation by blocking the GPIIb/IIIa receptors on the platelets, preventing adhesion of fibrinogen and other factors that cross-link platelets to each other and thereby would normally allow platelets to form a thrombus (clot). As with heparin, bleeding is the major side effect, and bleeding precautions should be initiated.

Oxygen Administration

Oxygen therapy is usually initiated at the onset of chest pain in an attempt to increase the amount of oxygen delivered to the myocardium and to decrease pain. Blood oxygen saturation is monitored by pulse oximetry; the normal oxygen saturation (SpO_2) level is greater than 95%.

Percutaneous Coronary Interventions

PCIs to treat angina and CAD most commonly include balloon angioplasty with intracoronary stent implantation. The patient in whom an acute MI is suspected may be

referred for an immediate intervention, in which case the occluded coronary artery is opened and reperfusion to the area that had been deprived of oxygen is re-established. The duration of oxygen deprivation is directly related to the number of cells that die; therefore, the time from the patient's arrival in the emergency department to the time PCI is performed is critical and should be less than 60 minutes (time is muscle!). This is frequently referred to as *door-to-balloon time,* "*DTB,*" *or* "*time to device.*" A cardiac catheterization laboratory and staff must be available 24 hours a day, 7 days a week if an emergent PCI is to be performed within this short time.

Nursing Alert

It is imperative that an accurate assessment of a patient's peripheral vascular system is documented preprocedurally. This data will be used to evaluate postoperative vascular status. The assessment should include extremities color, sensation, temperature, capillary refill, and peripheral perfusion using the grading scale common to the nurse's institution. The affected extremity is assessed every 15 minutes for the first hour and then according to hospital protocol.

Diagnostic Cardiac Catheterization and Percutaneous Coronary Intervention

A cardiac catheterization is a diagnostic procedure carried out in the cardiac catheterization laboratory where a vascular catheter is inserted in an artery (mostly radial or femoral) and threaded through your blood vessels to your heart; dye that is seen on fluoroscopy (x-ray) is then injected, and the structures of the heart and the patency of the coronary arteries are visualized. Coronary vessels with blockages are definitively identified, and often during the same procedure, are opened by a PCI. During PCI, the vascular catheter that is balloon-tipped is used to open blocked coronary arteries. Most often a stent is then deployed to maintain patency of the artery. PCI is used in patients with angina and as an intervention for acute MI. Catheter-based interventions can also be used to open blocked CABGs.

PCI is used more often now than ever before; it is the fifth most common procedure carried out yearly in the United States (Mullin, 2014). Hollow catheters called *sheaths* are inserted usually via the radial or femoral artery and occasionally the brachial artery. Catheters are then threaded through the sheaths, up through the aorta, and into the coronary arteries. Angiography is performed using injected radiopaque contrast agents (commonly called *dye*) to identify the location and extent of the blockage. A balloon-tipped dilation catheter is passed through the sheath and positioned over the lesion. The physician determines the catheter position by examining markers on the balloon that can be seen with fluoroscopy. When the catheter is positioned properly, the balloon is inflated with high pressure for several seconds and then deflated. The pressure compresses and possibly "cracks" the atheroma (Fig. 14-5). The media and adventitia of the coronary artery are also stretched. The appropriate stent is then put into place to keep the artery open (see Fig. 14-6).

Nursing Alert

It is critical that an "Allen's test" is assessed pre-intervention to ensure ulnar arterial flow to the hand since adequacy will permit a radial artery approach for a PCI procedure (refer to Chapter 12). The radial approach provides direct access to the

ascending aorta and allows for immediate mobilization following PCI.

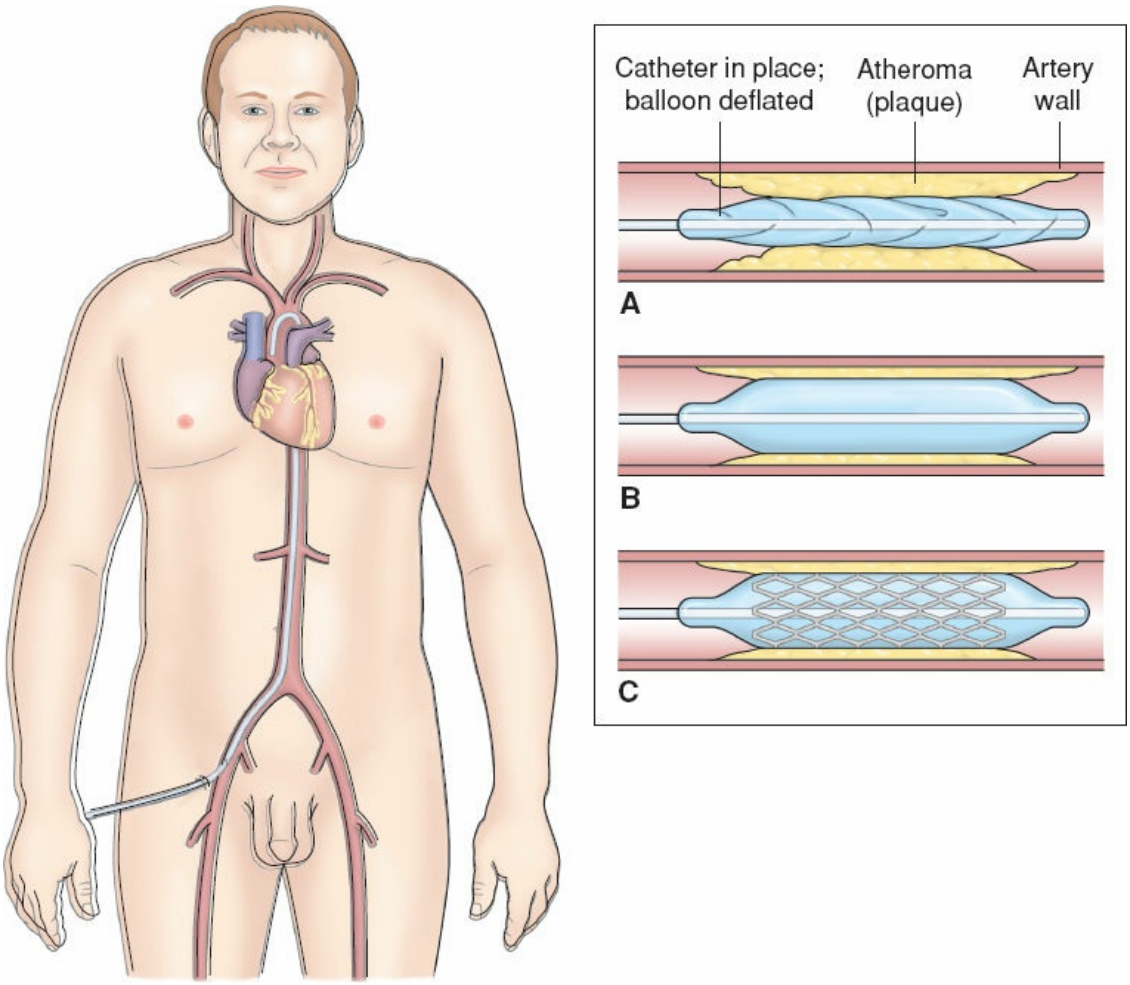

FIGURE 14-5 Percutaneous coronary intervention. A. A balloon-tipped catheter is passed into the affected coronary artery and placed across the area of the atheroma (plaque). B. The balloon is then rapidly inflated and deflated with controlled pressure. C. A stent is placed to maintain patency of the artery, and the balloon is removed.

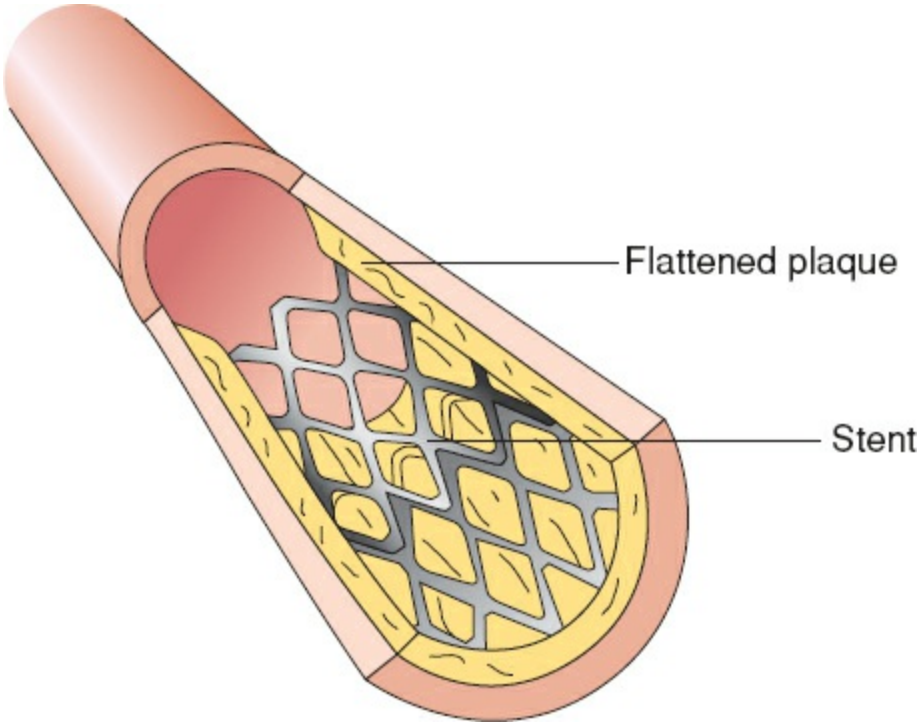

FIGURE 14-6 Vascular stent.

Several inflations and several balloon sizes may be required to achieve the goal, usually defined as an improvement in blood flow and a residual stenosis of less than 20%. Other measures of the success of a PCI are an increase in the artery's lumen, a difference of less than 20 mm Hg in blood pressure from one side of the lesion to the other, and no clinically obvious arterial trauma. Because the blood supply to the coronary artery decreases while the balloon is inflated, the patient may complain of chest pain and the ECG may display significant ST-segment changes. Intracoronary stents are usually positioned in the intima of the vessel to maintain patency after the balloon is withdrawn. PCI procedures have a success rate of greater than 95%; the only exception is a chronic total coronary (100%) obstruction of the lumen, where the ability to negotiate a guidewire through the blockage is only about 50% to 90% (and varies substantially with the operator's expertise) (Teirstein & Lytle, 2016). Refer to Table 14-3 for complications after PCI.

Coronary Artery Stent

After PCI, the area that has been treated may potentially close off partially or completely, a process called *restenosis.* The intima of the coronary artery has been injured and responds by initiating an acute inflammatory process. This process may include release of mediators that lead to vasoconstriction, clotting, and scar tissue formation. A coronary artery stent is placed to overcome these risks. Restenosis happens in 10% to 50% of patients with PCI after balloon angioplasty *without* stenting, usually within 6 months (Teirstein & Lytle, 2016). A stent is a metal mesh that provides structural support to a vessel at risk of acute closure. Either bare metal or "drug eluting" stents are used; there are guidelines in place to aid in determining which the cardiologist should choose. Stents have been shown to improve long-term outcomes of PCI (Grossman & Porth, 2014). The stent is positioned over the angioplasty balloon. When the balloon is inflated, the mesh expands and presses against the vessel wall, holding the artery open. The balloon is withdrawn, but the stent is

left permanently in place within the artery; eventually endothelium covers the stent, and it is incorporated into the vessel wall. Because of the risk of thrombus formation in the stent, the patient receives antiplatelet medications (examples are clopidogrel [Plavix] and aspirin). These medications are routinely continued for at least 3 to 6 months to decrease the risk of thrombus formation.

Complications that can occur during a PCI procedure include dissection, perforation, abrupt closure, or vasospasm of the coronary artery; acute MI; acute arrhythmias (e.g., ventricular tachycardia); and cardiac arrest. These may require emergency surgical treatment. Complications after the procedure may include abrupt closure of the coronary artery and vascular complications, such as bleeding at the insertion site, retroperitoneal bleeding, hematoma, pseudo-aneurysm, arteriovenous fistula, or arterial thrombosis and distal embolization, as well as acute kidney failure. Risk factors for the aforementioned complications include older age, female gender, larger vascular sheath size, low BMI, renal insufficiency, and degree of anticoagulation during the procedure (Mauri & Bhatt, 2015).

Nursing Alert

Severe kidney failure is associated with post-PCI procedural mortality and is directly related to the extent of the patient's baseline kidney disease (Mauri & Bhatt, 2016). Patients admitted with mild kidney dysfunction are at a higher risk for kidney failure and more adverse cardiac events (MACE) after PCI; therefore, monitoring of urinary output and renal function tests is particularly critical in this patient population. There is a 20% higher risk for death at 1 year following PCI than in those with preserved renal function (Mauri & Bhatt, 2016). The risk for nephropathy is dependent on the dose of contrast dye used and level of hydration. Ensuring adequate intravenous hydration surrounding the procedure can help protect against renal compromise.

Postprocedure Care

Patient care is similar to that for a cardiac catheterization. Many patients are admitted to the hospital the day of the PCI and discharged the next day; increasingly selected patients are treated as outpatients and released 6 to 12 hours after the procedure without an overnight stay (Teirstein & Lytle, 2016). When the PCI is performed emergently to relieve acute coronary syndrome (ACS), the patient will usually go to a critical care unit to be monitored closely for a slightly longer period of time. During the PCI, patients receive IV heparin and are monitored for signs of bleeding. Patients may also receive a GPIIb/IIIa agent (e.g., eptifibatide [Integrilin]) for several hours following the PCI to prevent platelet aggregation and thrombus formation in the coronary artery and stent. Hemostasis at the access site is achieved, and sheaths may be removed at the end of the procedure by using a vascular closure device (e.g., Angio-Seal, VasoSeal) or a device that sutures the vessels. Hemostasis after sheath removal may also be achieved by direct manual pressure, a mechanical compression device (e.g., C-shaped clamp), or a pneumatic compression device (e.g., FemoStop® or TR band®).

TABLE 14-3 Complications After Percutaneous Coronary Intervention (PCI)

Complication	Signs and Symptoms	Possible Causes	Nursing Actions
Bleeding or hematoma	Expanding mass surrounding puncture site; hard lump or bluish tinge at sheath insertion site	Anticoagulant therapy, coughing, vomiting, bending leg or hip, obesity, bladder distention, high blood pressure	Keep the patient on bed rest. Apply manual pressure at site of sheath insertion. Outline extent of hematoma with a marking pen. Monitor results of complete blood cell count and vital signs. If bleeding does not stop, notify physician or nurse practitioner. Anticipate interruption of anticoagulant and antiplatelet therapies. Blood transfusion may be indicated.
Lost or weakened pulse distal to sheath insertion site	Extremity cool, cyanotic, pale, or painful	Arterial thrombus or embolus	Assess peripheral circulation by comparing bilateral pulses; note temperature, capillary refill, sensation, and movement, as well as color of the affected extremity. Notify physician or nurse practitioner. Anticipate surgery and anticoagulation or thrombolytic therapy.
Pseudoaneurysm and arteriovenous fistula; if they rupture, sudden massive swelling and severe pain will be seen.	A large painful pulsatile mass felt or bruit heard near sheath insertion site	Vessel trauma during procedure	Notify physician or nurse practitioner. Anticipate ultrasound-guided compression. If the pseudoaneurysm is small (less than 2 cm), it may be observed and monitored clinically. Assess circulation, sensation, and motility of involved extremity. Prepare patient for surgery to close fistula if indicated.
Retroperitoneal bleeding (blood collecting in the retroperitoneal space may not produce obvious swelling or skin color changes)	Back or flank pain Unexplained hypotension Tachycardia Restlessness and agitation Decreased hemoglobin/hematocrit Cullen sign (bluish to purplish periumbilical discoloration) and Grey Turner sign (flank discoloration) may be noted with retroperitoneal bleed (see Fig. 27-10 on page 843).	Arterial tear causing bleeding into flank area	Notify physician or nurse practitioner immediately. Stop any anticoagulation medication. Anticipate need for IV fluids and/or administration of blood.
Acute kidney failure	Decreased urine output, elevated blood urea nitrogen (BUN), creatinine	Nephrotoxic contrast agent	Provide hydration to promote excretion of contrast material. Monitor urine output. Monitor BUN and creatinine. Administer renal protective agents (e.g., acetylcysteine [Mucomyst] before and after procedure as prescribed.

Allergic reaction	Urticaria, hives, sneezing, and bronchospasm	Allergic reaction to dye is higher in patients allergic to penicillin or shellfish and in those with known prior reaction to contrast material.	Anticipate administering prednisone, antihistamines, and H_2 blockers before the coronary procedure for patients with known prior reaction to contrast material or shellfish. If anaphylaxis occurs, the nurse anticipates administering epinephrine and IV saline for hydration.
Cardiac tamponade	Tachypnea, tachycardia, hypotension, jugular venous distention, and muffled heart sounds; cool extremities from hypoperfusion in some patients	Most common cause is perforation due to rupture of a coronary artery.	Anticipate a pericardiocentesis in patients with compromised hemodynamic status.
Chest pain/acute ischemic event/spasm	Complaints of chest pain	Benign stent sensation, acute stent thrombosis, abrupt vessel closure, transient coronary spasms, side branch occlusion, and distal embolization of debris	Notify the provider when patient complains of chest pain. Monitor vital signs, O_2 sat, and lung and cardiac sounds. Assess peripheral perfusion. Monitor electrocardiogram (ECG). Perform serial tests for cardiac markers. Measure troponin. Obtain a 12-lead ECG with any episodes of chest pain.

Adapted from Gomes, B. B. (2015). Care of the patient undergoing radial approach heart catheterization: Implications for medical-surgical nurses. *Medsurg Nursing*, *24*(3), 173–176; Mullin, M. (2014). Transradial approach versus transfemoral approach for coronary angiography and coronary angioplasty. *Critical Care Nursing Quarterly*, *37*(2), 159–169.

Occasionally, the patient may return to the nursing unit with the femoral or brachial vascular access sheaths in place. This may happen if there is a planned trip back to the catheterization lab or if the activated clotting time (ACT) is too high to remove the sheath safely. The sheaths are removed when blood studies (e.g., ACT) indicate that the heparin is no longer active and the clotting time is within an acceptable range. This usually takes a few hours, depending on the amount of heparin given during the procedure. As long as a sheath is in place, the patient must remain in bed and avoid bending the affected limb. The head of bed (HOB) is not elevated beyond 30 degrees if there is a femoral sheath in place. After the sheath removal, the patient maintains bed rest for 3 to 6 hours according to the hospital's policy. Sheath removal and the application of pressure on the vessel insertion site may cause the heart rate to slow and the blood pressure to decrease (vasovagal response). An IV bolus of atropine is usually given to treat this response. If the radial approach was used, the patient will have fewer restrictions on mobility but should not bend or put pressure on the affected area; the nurse should follow institutional policy for specific restrictions. Refer to Box 14-4 for care of patient after radial artery approach.

Some patients with unstable lesions and at high risk for abrupt vessel closure are restarted on heparin after sheath removal, or they receive an IV infusion of a GPIIb/IIIa inhibitor. These patients are monitored more closely and may recover more slowly.

Nursing Alert

Post PCI, IV fluids may be administered to promote excretion of the contrast medium. The nurse is alert for signs of fluid volume excess that may include complaints of SOB at rest or with exertion, orthopnea, paroxysmal nocturnal dyspnea, cough, development or increased crackles in the lungs, S_3 gallop, jugular vein distention

(JVD), and pulsus alternans (characterized by alternating strong and weak peripheral pulses). Changes in vital signs will vary depending on whether CO is increased (HTN) or reduced (hypotension).

BOX 14-4 Nursing Care After Cardiac Cath/PCI via Radial Approach

Assessment

- Monitor vital signs (including pulse oximetry*), neurovascular checks**, site and limb assessment per policy and/or provider's order (expect Q15 minutes x4, Q30 minutes x4, Q1 hour x4, and then Q4 hours or routine).
- Observe site for any bleeding, ecchymosis or hematoma. Observe appearance of skin under and around the compression device (i.e., TR band®).
- Avoid use of affected arm for blood pressure and blood draws for 24 hours.
- After a diagnostic cardiac catheterization, the TR band® is likely to remain in place for a minimum of 1 hour (follow provider's order).
- After an interventional procedure (angioplasty with stent placement) the TR band® is likely to remain in place for a minimum of 2 hours (follow provider's order).

*The Pulse oximetry probe should be on either the thumb or index finger of the affected hand because impaired radial artery circulation will be revealed in these digits.
**Neurovascular checks include color, temperature, sensation (presence or absence of numbness and tingling), pulses (radial and ulnar of the affected limb), and capillary refill.

Activity

- The patient may be out of bed with assistance (per provider's order) while the radial artery compression device is in place. Typically there is no restriction on head of bed elevation; the affected arm is kept straight and no pressure is applied to the limb. An ace wrap or an arm board can be applied to prevent wrist flexing. As noted above, avoid blood pressures and blood draws from the procedural arm for 24 hours.
- When removing the Radial compression device, the nurse should position the patient either in a bed or stretcher or in a chair that allows for elevation of legs in the event of a vagal response (drop in blood pressure and/or heart rate).

Reportable to the Provider

- Changes in sensation or pain in affected extremity, hematoma, bleeding, ecchymosis, blistering of the skin, appearance of mottling, absence of radial or ulnar pulse
- Any variance of the patient's vital signs

Patient and Family Education

- Report any symptoms of pain, numbness, or tingling in the affected extremity, as well as redness or streaking, swelling, and discharge from the site.

- For 24 hours after procedure, minimize manipulation of the affected wrist (no flexing), including no weight-bearing on wrist when rising from bed/chair. Elevating the affected arm and applying ice will promote comfort and decrease swelling.
- Do not drive.
- Remove occlusive dressing after 24 hours and leave open to air. If minor oozing occurs, apply dressing for 12 more hours; the site may be washed with mild soap and water. Avoid excess moisture to the access site, especially submerging the hand in water. and flexing the wrist for 72 hours after procedure.
- If bleeding should occur: sit down and hold pressure at the site for 10 minutes. If bleeding stops, sit with the wrist straight for 2 hours and notify the provider. If bleeding does not stop after 10 minutes or a large amount of bleeding is noted, call 911 and lie down. DO NOT drive yourself to the hospital.
- Avoid heavy lifting (over 5 lbs.).
- Do not operate heavy equipment.
- Avoid excessive wrist movement.
- Avoid vigorous exercise using arm.
- Plan for a follow-up appointment within 1 to 2 weeks; use the call-back number with 24-hour service if needed.

Adapted from Gomes, B. B. (2015). Care of the patient undergoing radial approach heart catheterization: Implications for medical-surgical nurses. Medsurg Nursing, *24*(3), 173–176; Mullin, M. (2014). Transradial approach versus transfemoral approach for coronary angiography and coronary angioplasty. Critical Care Nursing Quarterly, *37*(2), 159–169.

After hemostasis is achieved, a pressure dressing is applied to the site. Patients resume self-care and ambulate unassisted within a few hours of the procedure. The duration of immobilization depends on the size and location of the sheath inserted, the amount of anticoagulant administered, the method of hemostasis, the patient's underlying condition, and the physician's preference. On the day after the procedure, the site is inspected and the dressing replaced with an adhesive bandage. The nurse teaches the patient to monitor the site for bleeding or development of a hard mass indicative of hematoma. On discharge, heavy lifting is discouraged for several days if the femoral artery was used, and intense aerobic exercise is typically discouraged for 2 to 4 weeks (especially after stent implantation). There is usually no driving for 24 hours (Teirstein & Lytle, 2016).

Surgical Procedures: Coronary Artery Revascularization

Advances in diagnostics, medical management, and surgical and anesthesia techniques, as well as the care provided in critical care and surgical units, home care, and rehabilitation programs, have continued to make surgery a viable treatment option for patients with CAD. CABG has been done for nearly 50 years now, with techniques ever evolving and improving. CABG is a surgical procedure in which a blood vessel is grafted to the occluded coronary artery so that blood can flow beyond the occlusion; it is also called a bypass graft.

Major indications for CABG include:

- Alleviation of angina that cannot be controlled with medication or PCI
- Treatment of multivessel CAD and complicated lesions
- Prevention and treatment of MI, arrhythmias, or heart failure
- Treatment for complications from an unsuccessful PCI

The recommendation for CABG is determined by a number of factors, including the number of diseased coronary vessels, the location complexity of the lesions (blockages), the degree of left ventricular dysfunction, the presence of comorbidities, the patient's symptoms, and any previous treatment. CABG surgery remains the standard of care for patients with complex CAD, although technological advancements in both PCI and in CABG surgery make it difficult to compare these interventions historically. Cardiologists and cardiac surgeons work together to determine the most appropriate treatment for an individual patient (Iqbal et al., 2013).

For a patient to be considered for CABG, the coronary arteries to be bypassed must have approximately a 70% occlusion (60% if in the left main coronary artery). If significant blockage is not present, the flow through the artery will compete with the flow through the bypass, and circulation to the ischemic area of myocardium may not be improved. It is also necessary that the artery be patent beyond the area of blockage or the flow through the bypass will be impeded.

Vessels commonly used for CABG are the greater saphenous vein, followed by the lesser saphenous vein (other veins may also be used) as well as the internal thoracic arteries (Fig. 14-7). If a vein is be used, it is removed from its original location and grafted to the ascending aorta and to the coronary artery distal to the lesion. The saphenous veins are used in emergency CABG procedures because they can be obtained quickly by one surgeon while another performs the chest surgery. A common adverse effect of vein removal is edema in the extremity from which the vein was taken. The degree of edema varies and usually diminishes over time. Within 5 to 10 years, atherosclerotic changes often develop in saphenous vein grafts.

The right and left internal mammary arteries and, less frequently, the radial arteries are also used for CABG. Arterial grafts are preferred to venous grafts because they do not develop atherosclerotic changes as quickly and remain patent longer. The surgeon leaves the proximal end of the mammary artery intact and detaches the distal end of the artery from the chest wall. This end of the artery is then grafted to the coronary artery distal to the occlusion. The internal mammary arteries may not be long enough to use for multiple bypasses. Because of this, many CABG procedures are performed with a combination of venous (reversed segments of veins [reversed because of venous valves]) and arterial grafts.

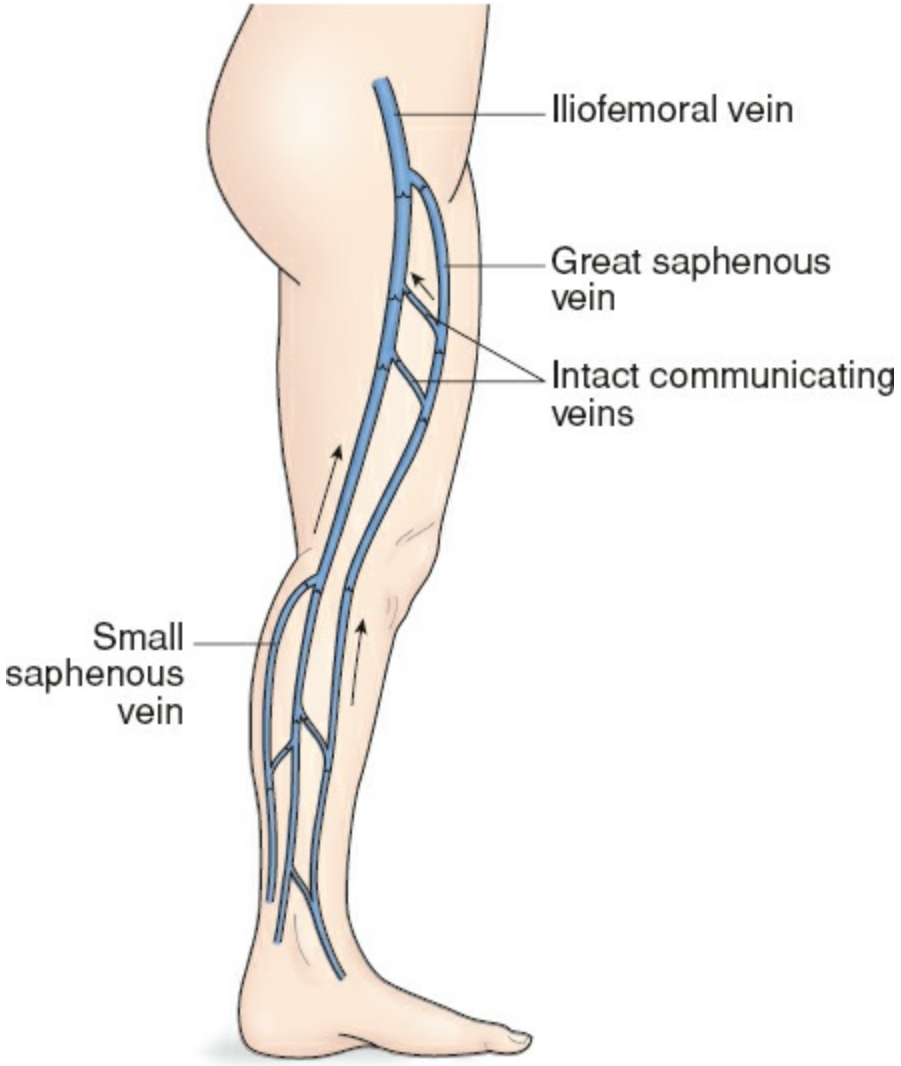

FIGURE 14-7 The greater and lesser saphenous veins are commonly used in bypass graft procedures.

After CABG, as many as 63% to 89% of patients develop pleural effusions (fluid collection within the pleural space) in the immediate postoperative period (Heffner, 2016), which is associated with a variety of etiologies, including accumulation of pleural fluid because of congestive heart failure, surgical tissue trauma, hemorrhage from harvesting of the IMA, postoperative atelectasis and diaphragmatic dysfunction, or chylothorax (lymphatic fluid in the pleural space) because of unintended thoracic duct injury during the operative event. Signs and symptoms vary based upon the etiology; however, the nurse is alert for dyspnea, cough, orthopnea (SOB when lying flat), splinting, dullness to percussion, decreased breath sounds, and decreased respiratory excursion on the affected side (for further details, refer to Chapter 10).

Coronary Artery Bypass Graft Surgery

Traditional Technique. The traditional CABG procedure is performed with the patient under general anesthesia. The surgeon makes a median sternotomy incision and connects the patient to the cardiopulmonary bypass (CPB) machine (discussed below). Next, a blood vessel from another part of the patient's body (e.g., saphenous vein, left internal mammary artery) is grafted distal to the coronary artery lesion, bypassing the obstruction (Fig. 14-8).

Then CPB is discontinued, chest tubes and epicardial pacing wires are placed, and the incision is closed. Next, the patient is admitted to a critical care unit and typically stays for about 24 hours before being transferred to the step-down unit.

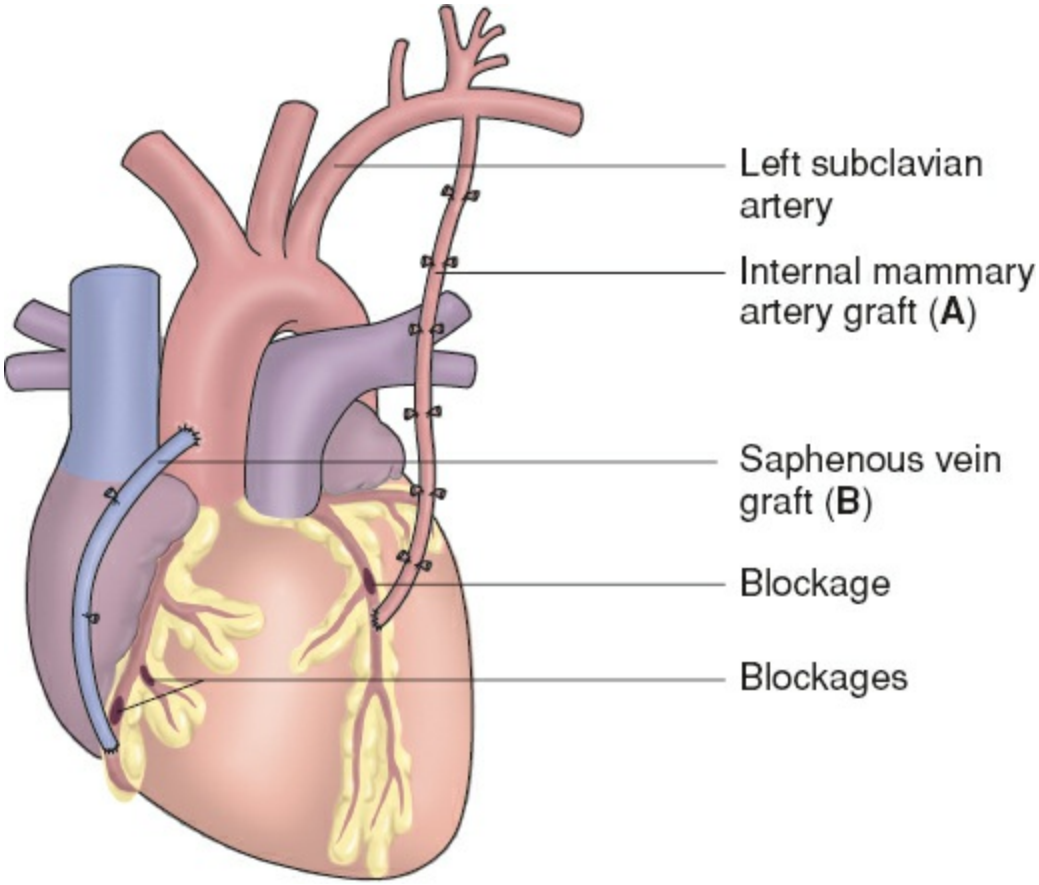

FIGURE 14-8 Coronary artery bypass grafts. One or more procedures may be performed using various veins and arteries. A. Left internal mammary artery, used frequently because of its functional longevity. B. Saphenous vein, also used as bypass graft.

Many cardiac surgical procedures are possible because of CPB (i.e., extracorporeal circulation) (Fig. 14-9). The procedure mechanically circulates and oxygenates blood for the body while bypassing the heart and lungs. CPB maintains perfusion to body organs and tissues, and allows the surgeon to complete the anastomoses in a motionless, bloodless surgical field.

CPB is accomplished by placing a cannula in the right atrium, vena cava, or femoral vein to withdraw blood from the body. The cannula is connected to tubing filled with an isotonic crystalloid solution (usually 5% dextrose in lactated Ringer's solution). Venous blood removed from the body by the cannula is filtered, oxygenated, cooled or warmed by the machine, and then returned to the body. The cannula used to return the oxygenated blood is usually inserted in the ascending aorta, or it may be inserted in the femoral artery. The heart is stopped by the injection of cardioplegia solution, which is high in potassium, into the coronary arteries. The patient receives heparin to prevent clotting and thrombus formation in the bypass circuit when blood comes in contact with the foreign surfaces of the tubing. At the end of the procedure, when the patient is disconnected from the bypass machine, protamine sulfate is administered to reverse the effects of heparin.

During the procedure, hypothermia is maintained, usually 28° to 32°C (82.4° to 89.6°F). The blood is cooled during CPB and returned to the body. The cooled blood slows the body's basal metabolic rate, thereby decreasing the demand for oxygen. Cooled blood usually has a higher viscosity, but the crystalloid solution used to prime the bypass tubing dilutes the blood. When the surgical procedure is completed, the blood is rewarmed as it passes through the CPB circuit. Urine output, arterial blood gases (ABGs), electrolytes, and coagulation studies are monitored to assess the patient's status during CPB.

Alternate Technique. Another type of CABG procedure often done today is the "off pump" CABG or "OPCAB." The potential benefits of OPCAB include a decrease in the incidence of stroke and other neurologic complications, reduced blood usage, less kidney failure, and fewer cardiac rhythm disturbances. Also done today is the "MIDCAB," or minimally invasive coronary artery bypass surgery. The MIDCAB is performed on a beating heart via a thoracotomy incision and is only suitable for certain lesions that are located in the arteries on the anterior portions of the heart. Patients undergoing any type of CABG surgery will go to the intensive care unit for approximately 24 hours, and then transfer to the step-down unit. The average overall hospital stay for CABG surgery is anticipated at 5 days.

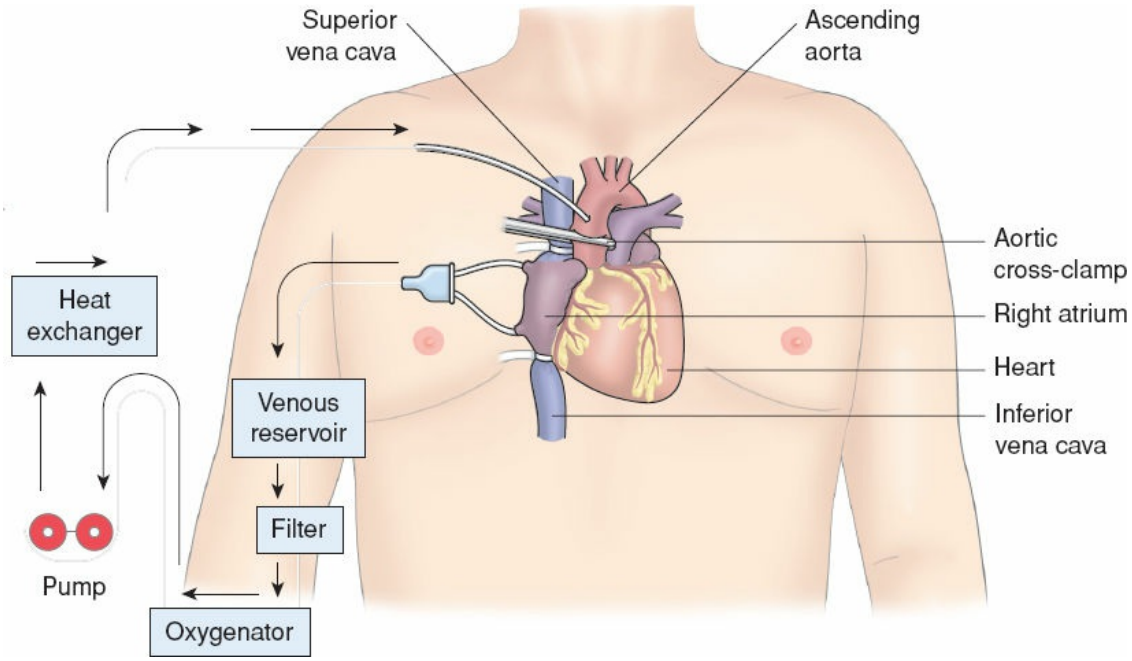

FIGURE 14-9 The cardiopulmonary bypass (CPB) system, in which cannulas are placed through the right atrium into the superior and inferior vena cavae to divert blood from the body and into the bypass system. The pump system creates a vacuum, pulling blood into the venous reservoir. The blood is cleared of air bubbles, clots, and particulates by the filter and then is passed through the oxygenator, releasing carbon dioxide and obtaining oxygen. Next, the blood is pulled to the pump and pushed out to the heat exchanger, where its temperature is regulated. Then the blood is returned to the body via the ascending aorta.

Complications of Coronary Artery Bypass Graft

CABG may result in complications such as MI, arrhythmias, hemorrhage, and kidney dysfunction. Table 14-4 presents an overview of the potential complications in the

postoperative cardiac surgical patient. Although most patients improve symptomatically following surgery, CABG is not a cure for CAD, and angina, exercise intolerance, or other symptoms experienced before CABG may recur. Medications required before surgery may need to be continued. Lifestyle modifications recommended before surgery remain important to treat the underlying CAD and for the continued viability of the newly implanted grafts.

TABLE 14-4 Potential Complications of Cardiac Surgery

Complication	Description	Assessment and Management
Cardiac Complications		
Decreased Cardiac Output		
Hypovolemia (most common cause of decreased cardiac output after cardiac surgery)	• Net loss of blood and intravascular volume • Surgical hypothermia (as the reduced body temperature rises after surgery, blood vessels dilate and more volume is needed to fill the vessels). • IV fluid loss to the interstitial spaces because surgery and anesthesia make capillary beds more permeable. • Increased heart rate, arterial hypotension, low pulmonary artery wedge pressure (PAWP), and low central venous pressures (CVP) often are seen.	• Fluid replacement may be prescribed. Replacement fluids include: Colloid (albumin, heta-starch), packed red blood cells, or crystalloid solution (normal saline, lactated Ringer's solution).
Persistent bleeding	• Cardiopulmonary bypass may cause platelet dysfunction, and hypothermia alters clotting mechanisms. • Surgical trauma causing tissues and blood vessels to ooze bloody drainage. • Intraoperative anticoagulant (heparin) therapy • Postoperative coagulopathy may also result from liver dysfunction and depletion of clotting components.	• Accurate measurement of wound bleeding and chest tube blood is essential. Bloody drainage should not exceed 200 mL/hr for the first 4 to 6 hours. Drainage should decrease and stop within a few days, while progressing from sanguineous to seros anguineous and serous drainage. • Protamine sulfate may be administered to neutralize unfractionated heparin; vitamin K and blood products may be used to treat hematologic deficiencies. • If bleeding persists, the patient may return to the operating room.
Cardiac tamponade	• Fluid and clots accumulate in the pericardial sac, which compresses the heart, preventing blood from filling the ventricles. • Signs and symptoms include arterial hypotension, tachycardia, muffled heart sounds, decreasing urine output, and ↑ CVP. Additional signs and symptoms: arterial pressure waveform demonstrating a pulsus paradoxus (decrease of more than 10 mm Hg during inspiration) and decreased chest tube drainage (suggesting that the drainage is trapped or clotted in the mediastinum).	• The chest drainage system is checked to eliminate possible kinks or obstructions in the tubing. • Patency of the tubing in the chest drainage system must be maintained, the nurse can facilitate movement of the fluid by adjusting the position of the tubing therefore helping with forward flow. • Chest x-ray may show a widening mediastinum. • Emergency medical management is required; may include pericardiocentesis or return to surgery.
Fluid overload	• High PAWP, CVP, and pulmonary artery diastolic pressures, as well as crackles indicate fluid overload.	• Diuretics are prescribed and the rate of IV fluid administration is reduced. • Alternative treatments include continuous renal replacement therapy and dialysis.
Hypothermia	• Low body temperature leads to vasoconstriction, shivering, and arterial hypertension.	• Patient is rewarmed gradually after surgery, decreasing vasoconstriction.

Hypertension	• Results from postoperative vasoconstriction. It may stretch suture lines and cause postoperative bleeding. The condition may be transient.	• Vasodilators (nitroglycerin [Tridil], nitroprusside [Nipride, Nitropress]) may be used to treat hypertension. Administer cautiously to avoid hypotension.
Tachyarrhythmias	• Increased heart rate is common with perioperative volume changes. Uncontrolled atrial fibrillation commonly occurs during the first few days postoperatively.	• If a tachyarrhythmia is the primary problem, the heart rhythm is assessed and medications (e.g., adenosine [Adenocard, Adenoscan], amiodarone [Cordarone], digoxin [Lanoxin], diltiazem [Cardizem], esmolol [Brevibloc], lidocaine [Xylocaine], procainamide [Pronestyl]), may be prescribed. Patients may be prescribed antiarrhythmics before coronary artery bypass graft (CABG) to minimize the risk of postoperative tachyarrhythmias. • Carotid massage may be performed by a provider to assist with diagnosing or treating the arrhythmia. • Cardioversion and defibrillation are alternatives for symptomatic tachyarrhythmias. • For patients who cannot attain normal sinus rhythm, an alternate goal may be to establish a stable rhythm that produces a sufficient cardiac output.
Bradycardias	• Decreased heart rate	• Many postoperative patients will have temporary pacer wires that can be attached to a pulse generator (pacemaker) to stimulate the heart to beat faster. Less commonly, atropine, epinephrine, or isoproterenol may be used to increase heart rate.
Cardiac failure (decreased cardiac output)	• Myocardial contractility may be decreased perioperatively.	• The nurse observes for and reports falling mean arterial pressure; rising PAWP, pulmonary artery diastolic pressure, and CVP; increasing tachycardia; restlessness and agitation; peripheral cyanosis; venous distention; labored respirations; and edema. • Medical management includes diuretics, digoxin, and IV inotropic agents.
MI (may occur intraoperatively or postoperatively)	• Portion of the cardiac muscle dies; therefore, contractility decreases. Impaired ventricular wall motion further decreases cardiac output. Symptoms may be masked by the postoperative surgical discomfort or the anesthesia–analgesia regimen.	• Careful assessment to determine the type of pain the patient is experiencing; myocardial infarction (MI) suspected if the mean blood pressure is low with normal preload. • Serial electrocardiograms (ECGs) and cardiac biomarkers assist in making the diagnosis (alterations may be due to the surgical intervention). Analgesics are prescribed in small amounts while the patient's blood pressure and respiratory rate are monitored (because vasodilation secondary to analgesics or decreasing pain may occur and compound the hypotension). • Activity progression depends on the patient's activity tolerance.
Pulmonary Complications		
Impaired gas exchange	• During and after anesthesia, patients require mechanical assistance to breathe. • Potential exists for postoperative atelectasis. • Anesthetic agents stimulate production of mucus, and chest incision pain may decrease the effectiveness of ventilation.	• Pulmonary complications are often detected during assessment of breath sounds, oxygen saturation levels, arterial blood gases, and when monitoring peak pressure and exhaled tidal volumes on the ventilator. • Extended periods of mechanical ventilation may be required while complications are treated.

Fluid Volume Complications		
Hemorrhage	• Untoward and excessive bleeding may be life-threatening.	• Serial hemoglobin, hematocrit, and coagulation studies are performed to guide therapy. • Administration of fluids, colloids, and blood products: packed red blood cells, fresh frozen plasma, platelet concentrate. • Administration of aprotinin (Trasylol) perioperatively to reduce blood transfusion needs. • Administration of desmopressin acetate (DDAVP) to enhance platelet function.
Neurologic Complications		
Neurologic changes; stroke	• Inability to follow simple commands within 6 hours of recovery from anesthetic; different capabilities on right or left side of body	• Neurologically, most patients begin to recover from anesthesia in the operating room. • Patients who are elderly or who have kidney or hepatic failure may take longer to recover. • Patient should be evaluated for stroke when neurologic changes are evident.
Kidney Failure and Electrolyte Imbalance		
Kidney failure	• Usually acute and resolves within 3 months but may become chronic and require ongoing dialysis	• May respond to diuretics or may require continuous renal replacement therapy (CRRT) or dialysis
Acute kidney Injury	• Often results from hypoperfusion of the kidneys or from injury to the renal tubules by nephrotoxic medications	• Fluids, electrolytes, BUN, creatinine, and urine output are monitored frequently. Follow your medical center's protocol for postprocedure hydration
Electrolyte imbalance	• Postoperative imbalances in potassium, magnesium, sodium, calcium, and blood glucose are related to surgical losses, metabolic changes, and the administration of medications and IV fluids.	• Monitor electrolytes and basic metabolic studies frequently. • Implement treatment to correct electrolyte imbalance promptly
Other Complications		
Hepatic failure	• Most common in patients with cirrhosis, hepatitis, or prolonged right-sided heart failure	• Use of medications metabolized by the liver must be minimized. • Bilirubin, albumin, and amylase levels are monitored, and nutritional support must be provided.
Infection	• Surgery and anesthesia alter the patient's immune system. Many invasive devices are used to monitor and support the patient's recovery and may serve as a source of infection.	• The following must be monitored to detect signs of possible infection: body temperature, white blood cell (WBC) counts and differential counts, incision and puncture sites, cardiac output and systemic vascular resistance, urine (clarity, color, and odor), bilateral breath sounds, sputum (color, odor, amount), as well as nasogastric secretions. • Antibiotic therapy may be expanded or modified as necessary. • Invasive devices must be discontinued as soon as they are no longer required. Institutional protocols for maintaining and replacing invasive lines and devices must be followed to minimize the patient's risk for infection.

Note: The patient may require interventions for more than one complication at a time. Collaboration among nurses, physicians, pharmacists, respiratory therapists, and dietitians is necessary to achieve the desired patient outcomes.

NURSING PROCESS

The Postoperative Cardiac Surgery Patient

Initial postoperative care focuses on achieving or maintaining hemodynamic stability and recovery from general anesthesia. Care will be provided in the PACU or intensive care unit, with the patient transferred to the step-down or progressive care unit usually within 24 hours. Care focuses on the monitoring of cardiopulmonary status, pain management, wound care, progressive activity, and nutrition. Education about medications and risk factor modification is emphasized. Discharge from the hospital may occur 3 to 5 days after CABG in patients without complications.

The immediate postoperative period for the patient who has undergone cardiac surgery presents many challenges to the health care team. Specific information about the surgical procedure and important factors about postoperative management are communicated by the surgical team and anesthesia personnel to the critical care nurse, who then assumes responsibility for the patient's care. A plan of nursing care for the patient after cardiac surgery is available online at http://thepoint.lww.com/Honan2e.

ASSESSMENT

In the critical care environment, a complete assessment of all systems is performed hourly for at least 12 hours to determine the postoperative status of the patient compared with the preoperative baseline and to identify anticipated changes since surgery. The following parameters are assessed:

- *Neurologic status:* Level of responsiveness, pupil size and reaction to light, reflexes, facial symmetry, movement and strength of upper and lower extremities
- *Cardiac/hemodynamic status:* Heart rate and rhythm, heart sounds, pacemaker status, arterial blood pressure, central venous pressure (CVP), pulmonary artery pressure, pulmonary artery wedge pressure (PAWP), waveforms from the invasive blood pressure lines, cardiac output (CO) or index, systemic and pulmonary vascular resistance, pulmonary artery oxygen saturation (SvO_2), and bleeding (from mediastinal chest tubes). Refer to Chapter 55 for a detailed description of hemodynamic monitoring.
- *Respiratory status:* Chest movement, breath sounds, ventilator settings, respiratory rate, peak inspiratory pressure, arterial oxygen saturation (SaO_2), percutaneous oxygen saturation (SpO_2), end-tidal CO_2, ABGs
- *Peripheral vascular status:* Peripheral pulses; color of skin, nail beds, mucosa, lips, and earlobes; skin temperature; edema; condition of dressings and invasive lines
- *Kidney function:* Urinary output; urine-specific gravity and osmolality may be assessed,

serum blood urea nitrogen (BUN) and creatinine
- *Fluid and electrolyte status:* Intake, output from all drainage tubes, all CO parameters, mucous membranes, skin turgor, presence of edema, and analysis of laboratory values including electrolytes, calcium, and magnesium
- *Pain:* Nature, type, location, and duration (incisional pain must be differentiated from anginal pain); apprehension; response to analgesics

Assessment also includes observing all equipment and tubes to determine whether they are functioning properly (Fig. 14-10).

As the patient regains consciousness and progresses through the postoperative period, the nurse also assesses indicators of psychological and emotional status. The patient may exhibit behavior that reflects denial or depression or may experience postcardiotomy delirium. Characteristic signs of delirium include transient perceptual illusions, visual and auditory hallucinations, disorientation, and paranoid delusions.

DIAGNOSIS

Appropriate nursing diagnoses of the patient recovering from cardiac surgery may include:

- Decreased CO/tissue perfusion
- Fluid volume and electrolyte imbalance
- Impaired gas exchange
- Impaired cerebral circulation
- Pain

PLANNING

The goal after CABG surgery is to maintain hemodynamic stability, adequate gas exchange, fluid volume balance, and cerebral perfusion. As the patient progresses toward hospital discharge, patient education and activity progression must be included in the plan of care.

NURSING INTERVENTIONS

RESTORING CARDIAC OUTPUT

To evaluate the patient's cardiac status, the nurse primarily determines the effectiveness of the CO through clinical observations and routine measurements: serial readings of blood pressure, heart rate, CVP, arterial pressure, and pulmonary artery pressures.

Kidney function is related to cardiac function as blood pressure and heart rate drive glomerular filtration; therefore, urinary output is measured and recorded. Urine output of less than 30 mL/hr or 0.5 mL/kg/hr may indicate a decrease in CO. Body tissues depend on adequate CO to provide a continuous supply of oxygenated blood to meet the changing demands of the organs and body systems. Because the buccal mucosa, nail beds, lips, and earlobes are sites with rich capillary beds, they should be observed for cyanosis or

duskiness as possible signs of reduced CO. The nurse notes distention of the neck veins along with an elevated CVP, signaling right-sided heart failure. Generally, if cardiac output has decreased, the skin becomes cool, moist, and cyanotic or mottled.

Arrhythmias may develop when perfusion of the heart is poor. Common arrhythmias encountered during the postoperative period are atrial fibrillation (Afib), bradycardias, tachycardias, and ectopic beats. Afib is one of the most frequently encountered arrhythmias of CABG, occurring in up to 40% of patients, typically within 2 to 3 days (Morrow & Boden, 2015). Afib increases the risk of clot formation and embolization (two- to threefold increase in incidence of postoperative stroke); therefore, patients at risk for this arrhythmia may be prescribed prophylactic beta-blocking agents (Morrow & Boden, 2015). Risk factors for developing postoperative Afib are older, hypertensive, previous Afib, and heart failure. Epicardial pacing wires are typically placed during the surgery, and the nurse and provider work collaboratively if pacing is needed postoperatively to stabilize a rhythm. Continuous observation of the cardiac monitor for arrhythmias is essential.

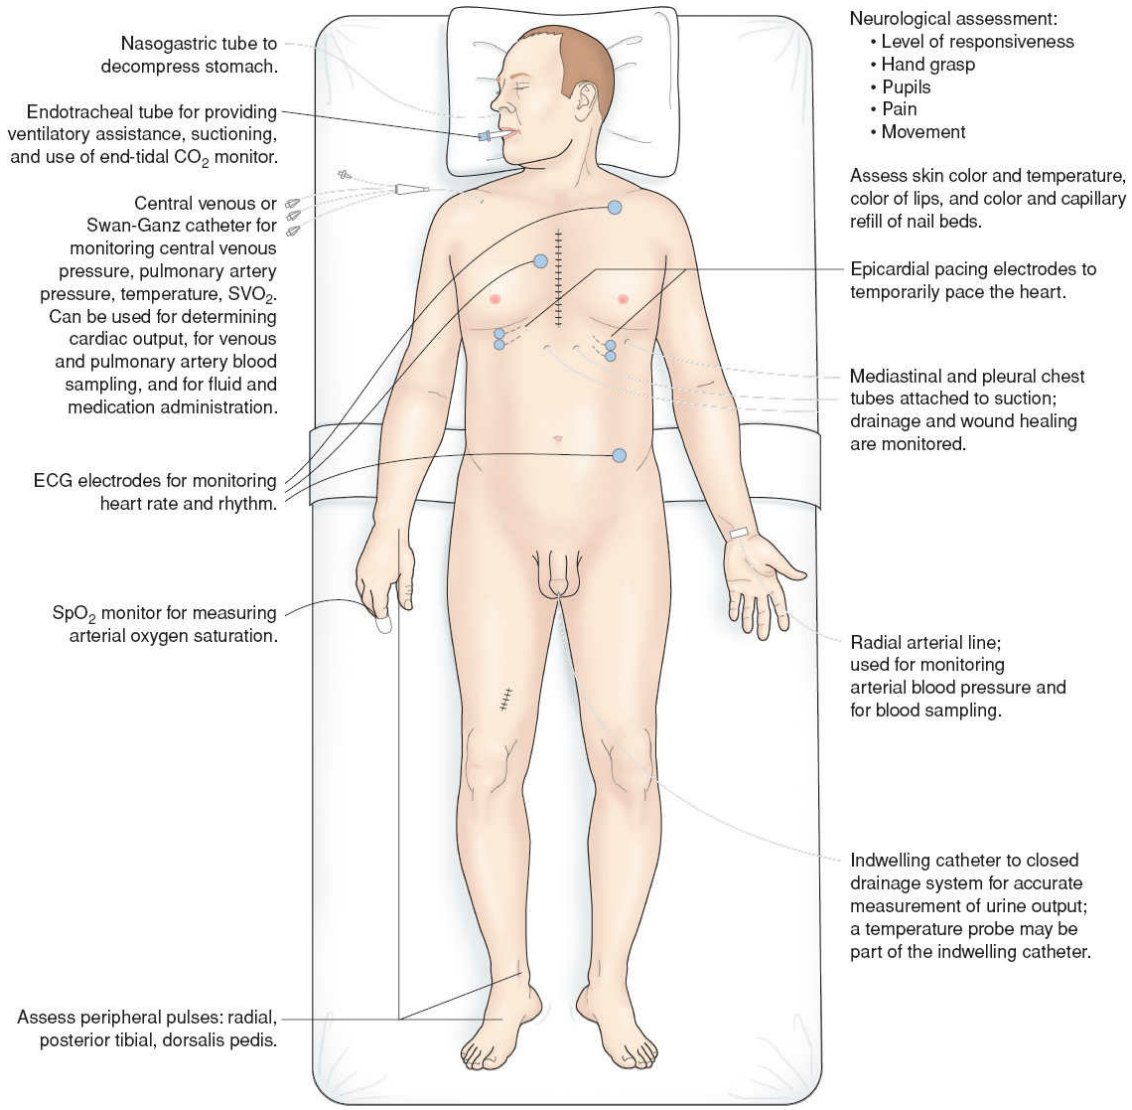

FIGURE 14-10 Postoperative care of the cardiac surgical patient requires the nurse to be proficient in interpreting hemodynamics, correlating physical assessments with laboratory results, sequencing interventions, and evaluating progress toward desired outcomes.

Any indications of decreased CO are reported promptly to the provider. These assessment data and results of diagnostic tests are used to determine the cause of the problem. After a diagnosis has been made, the provider and the nurse work together to restore CO and prevent further complications.

MAINTAINING ADEQUATE TISSUE PERFUSION

Thromboemboli formation also can result from injury to the intima of the blood vessels, dislodging a clot from a damaged valve, loosening of mural thrombi, or coagulation problems. Air embolism can result from CPB or central venous cannulation. Symptoms of embolization vary according to site. The usual embolic sites are the lungs, coronary arteries, mesentery, spleen, extremities, kidneys, and brain. The patient is observed for onset of the following:

- Chest pain and respiratory distress from pulmonary embolus or MI

- Severe abdominal or back pain, bowel emptying, or nausea and vomiting from mesenteric emboli
- Pain, cessation of pulses, blanching, numbness, or coldness in an extremity
- Decreased urine output from renal emboli
- One-sided weakness and pupillary changes, as occur in stroke

All such symptoms are reported promptly to the provider. After surgery, the following measures are taken to prevent venous stasis, which can cause deep venous thrombosis and subsequent pulmonary embolism:

- Applying elastic bandage wraps, elastic stocking, and/or sequential pneumatic compression wraps
- Discouraging crossing of legs
- Early and frequent ambulation

Inadequate kidney perfusion can occur as a complication of cardiac surgery. One possible cause is low CO. Trauma to blood cells during CPB can cause hemolysis of red blood cells, which then occlude the renal glomeruli. Additionally, the use of vasopressor agents to increase blood pressure may constrict the renal arterioles and reduce blood flow to the kidneys.

Nursing management includes accurate measurement of urine output. An output of less than 30 mL/hr or 0.5 mL/kg/hr may indicate hypovolemia or renal insufficiency. Fluids may be prescribed to increase CO and renal blood flow. IV diuretics may be administered to increase urine output. The nurse should be aware of the patient's BUN, serum creatinine, and urine and serum electrolyte levels. Abnormal levels are reported promptly because it may be necessary to adjust fluids and the dose or type of medication administered. If efforts to maintain kidney perfusion are ineffective, the patient may require continuous renal replacement therapy (CRRT) or dialysis (refer to Chapter 27).

MAINTAINING NORMAL BODY TEMPERATURE

Patients are usually hypothermic when admitted to the critical care unit following the cardiac surgical procedure if their surgery was done using CPB. The patient must be warmed to a normal temperature gradually. This is accomplished partially by the patient's own basal metabolic processes and often with the assistance of warmed ventilator air, warm air via a warming system, blankets, or heat lamps. While the patient is hypothermic, the clotting process is less efficient, the heart is prone to arrhythmias, and oxygen does not readily transfer from the hemoglobin to the tissues. Because anesthesia and hypothermia suppress normal basal metabolism, oxygen supply usually meets the cellular demand.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Infection. Common sites of infection postoperatively include the lungs, urinary tract,

incisions, and intravascular catheters. Foley catheters should be removed as early as possible to prevent infection (postop Day 1 if possible). There is no evidence that wound dressings after 48 hours are protective against surgical site infection (SSI). The incidence of SSIs post-CABG ranges from 0.35 to 8.49 per 100 operations where the majority of the infections are superficial. Prophylaxis with an antimicrobial reduces the occurrence of SSI up to fivefold (Anderson, 2016). Aseptic technique is used when changing dressings and when providing endotracheal tube (ETT) and catheter care. Closed systems are used to maintain all IV and arterial lines. All invasive equipment is discontinued as soon as possible after surgery.

Clearance of pulmonary secretions is accomplished by frequently repositioning the patient, suctioning, chest percussion and/or vibration, as well as teaching and encouraging the patient to breathe deeply, cough, and use the incentive spirometer frequently. Prevention of atelectasis is achieved through these interventions.

Postpericardiotomy syndrome may occur in patients who undergo cardiac surgery (Hoit, 2016). This complication develops in as many as 15% of patients undergoing cardiac surgery (LeWinter & Hopkins, 2015). It is thought to be related to the production of antiheart antibodies in response to myocardial injury. The syndrome is characterized by fever, pericardial pain, pleural pain, dyspnea, pericardial effusion, pericardial friction rub, and arthralgia. These signs and symptoms may occur in combination with leukocytosis (elevated WBCs) and elevation of the erythrocyte sedimentation rate and CRP. These signs frequently appear after the patient is discharged from the hospital. Anti-inflammatory agents (NSAIDs) often produce a dramatic improvement in symptoms within 48 hours.

Fluid Volume and Electrolyte Imbalance. Fluid and electrolyte imbalance may occur after cardiac surgery. Nursing assessment includes monitoring of intake and output, weight, hemodynamic parameters, hematocrit levels, distention of neck veins, edema, breath sounds, and electrolyte levels. Changes in serum electrolytes are reported promptly so that treatment can be instituted. Especially important are high or low levels of potassium, magnesium, sodium, and calcium. Elevated blood glucose levels are common in the postoperative period. Administration of insulin may be required in patients both with and without diabetes to achieve the glycemic control necessary for promoting wound healing.

Impaired Gas Exchange. Impaired gas exchange is another possible complication after cardiac surgery. All body tissues require an adequate supply of oxygen for survival. To achieve this after surgery, an ETT with ventilator assistance will be needed initially postop (for an average of about 6 hours). The assisted ventilation is continued until the patient's blood gas measurements are acceptable and the patient demonstrates the ability to breathe independently. To ensure adequate gas exchange, the nurse assesses and maintains the patency of the ETT. The patient is suctioned when necessary. Because a patent airway is essential for oxygen and carbon dioxide exchange, the ETT must be secured to prevent it from slipping into the right mainstem bronchus or accidental dislodgment. The patient is

weaned from the ventilator and extubated as soon as possible, usually within 6 hours of CABG. Physical assessment and ABG results guide the process. Before being extubated, the patient should have cough and gag reflexes and stable vital signs; be able to lift the head off the bed or give firm hand grasps; have adequate vital capacity, negative inspiratory force, and minute volume appropriate for body size; and have acceptable ABG levels while breathing without the assistance of the ventilator. Refer to Chapter 55 for additional information related to ventilators and weaning.

During this time, the nurse assists with the weaning process and eventually with the removal of the ETT. Deep breathing and coughing are encouraged at least every 1 to 2 hours after extubation to open the alveolar sacs and provide for increased ventilation as well as to clear secretions (preventing atelectasis).

The patient is assessed continuously for signs of impaired gas exchange: restlessness, anxiety, cyanosis of mucous membranes and peripheral tissues, and tachycardia. Breath sounds are assessed frequently, as well as ABGs, oxygen saturation, and end-tidal CO_2. Following extubation, aggressive pulmonary interventions, such as turning, coughing of secretions, using incentive spirometer, and deep breathing, are necessary to prevent atelectasis and pneumonia.

When the patient's condition stabilizes, body position is changed every 1 to 2 hours. Frequent changes of patient position provide for optimal pulmonary ventilation and perfusion by allowing the lungs to expand more fully.

Impaired Cerebral Circulation. Brain function depends on a continuous supply of oxygenated blood. The brain does not have the capacity to store oxygen and must rely on adequate continuous perfusion by the heart. Hypoperfusion or microemboli may produce central nervous system injury after cardiac surgery.

It is important to observe the patient for any symptoms of hypoxia: restlessness, headache, confusion, dyspnea, hypotension, and cyanosis. An assessment of the patient's neurologic status includes level of consciousness (LOC), response to verbal commands and painful stimuli, pupil size and reaction to light, facial symmetry, movement of the extremities, and hand grip strength. Any indication of a change in status is immediately reported to the provider and documented in the medical record.

MINIMIZING SENSORY-PERCEPTION IMBALANCE

Some patients exhibit abnormal behaviors that occur with varying intensity and duration. In the early years of cardiac surgery, this phenomenon occurred more frequently than it does today. Advances in surgical techniques and in the delivery of anesthetic agents have significantly decreased the incidence of postoperative delirium. However, incident rates of 3% to 32% of delirium after cardiac surgery are seen in those with pre-existing organic mental disorders (e.g., stroke, dementia), significant prior alcohol consumption, advanced age, or intracranial cerebral artery disease (McGarvey, Cheung, & Stecker, 2016). In those without the aforementioned risk factors, the nurse should consider etiologies of anxiety, sleep deprivation, increased sensory input, medications, and physiologic problems

such as hypoxemia. Delirium may appear after a 2- to 5-day stay in an intensive care environment and is associated with increased morbidity and mortality, including postoperative complications of respiratory insufficiency and sternal instability, prolonged length of stay, increased need for skilled nursing facility placement, and reduced cognitive and functional recovery, making early recognition and response crucial. Treatment of postoperative delirium requires an assessment for the etiology and correction of potentially reversible causes (McGarvey et al., 2016).

Careful explanations of all procedures and of the need for cooperation help keep the patient oriented throughout the postoperative course. Continuity of care is desirable; a familiar face and a nursing staff with a consistent approach help the patient feel safe. The patient's family should be welcomed at the bedside. Some patients have difficulty learning and retaining information after cardiac surgery. Many patients have difficulties in cognitive function after cardiac surgery, a phenomenon that does not occur after other types of major surgery. The patient may experience recent memory loss, short attention span, difficulty with simple math, poor handwriting, and visual disturbances. Patients with these difficulties often become frustrated when they try to resume normal activities and learn how to care for themselves at home. The patient and family are reassured that the difficulty usually resolves gradually and most patients will return to their preoperative baseline by 3 to 12 months after surgery (McGarvey et al., 2016). A well-designed plan of nursing care can assist the nursing team in coordinating their efforts for the emotional well-being of the patient.

RELIEVING PAIN

Deep pain may not be felt in the peri-incisional area but may occur in a broader, more diffuse area. Patients who have had cardiac surgery experience pain caused by the interruption of intercostal nerves along the incision route and irritation of the pleura by the chest catheters. Incisional pain may also be experienced from peripheral vein or artery graft harvest sites. IV and oral NSAIDs decrease the amount of opioids required for pain relief and increase patient comfort. Patients report the most pain during coughing, turning, and moving. Physical support of the incision with a folded bath blanket or small pillow during deep breathing and coughing helps to minimize pain (often referred to as "splinting"). Then the patient should be able to participate in respiratory exercises and increase self-care progressively. Patient comfort improves after removal of the chest tubes. The patient is observed for any adverse effects of opioids, which may include respiratory depression, hypotension, ileus, or urinary retention. If serious side effects occur, an opioid antagonist (e.g., naloxone [Narcan]) may be used.

EVALUATION

Expected patient outcomes may include:

- Maintains adequate CO
- Maintains adequate gas exchange

- Maintains fluid and electrolyte balance
- Experiences decreased symptoms of sensory-perception disturbances
- Experiences relief of pain
- Maintains adequate tissue perfusion
- Maintains normal body temperature
- Incisions are well healed
- Performs self-care activities
- Engages in follow-up care with health care providers and cardiac rehabilitation services
- Adheres to recommendations for diet and lifestyle changes to maintain optimal future health
- Exhibits no complications

MYOCARDIAL INFARCTION (MI)

Coronary occlusion, heart attack, and MI are terms used synonymously, but the preferred term is MI.

Pathophysiology

In an MI, an area of the myocardium is permanently destroyed. MI is usually caused by reduced blood flow in a coronary artery due to rupture of an atherosclerotic plaque and subsequent occlusion of the artery by a thrombus. In unstable angina, the plaque ruptures, but the artery is not completely occluded. Because unstable angina and acute MI are considered to be the same process but occurring at different points along a continuum, the term acute coronary syndrome (ACS) may be used in lieu of these diagnoses. Other causes of MI include vasospasm (sudden constriction or narrowing) of a coronary artery, decreased oxygen supply (e.g., from acute blood loss, anemia, or low blood pressure), and increased demand for oxygen (e.g., from a rapid heart rate, thyrotoxicosis, or ingestion of cocaine). In each case, a profound imbalance exists between myocardial oxygen supply and demand.

The area of infarction develops over minutes to hours. As the cells are deprived of oxygen, ischemia develops, cellular injury occurs, and the lack of oxygen results in infarction, or the death of cells. The expression "time is muscle" reflects the urgency of appropriate treatment to improve patient outcomes. Each year in the United States, more than 1,500,000 people die from acute MIs; it is the most common cause of death in those over 40 years (Ferri, 2016). Half of those who die never reach a hospital.

Various descriptions are used to further identify an MI: the type of MI (ST-segment elevation, non–ST-segment elevation), the location of the injury to the ventricular wall (anterior, inferior, posterior, or lateral wall), the point in time within the process of infarction (acute, evolving, or old), and the extent of the damage to the myocardium caused by the MI (partial or full thickness). Partial infarcts are associated with severely narrow coronary arteries and present as non–ST-segment elevation, while full-thickness infarcts commonly occur with obstruction of a single coronary artery and present as ST elevation on ECG readings (Porth, 2015).

The ECG usually identifies the type and location, and other ECG indicators such as a Q wave and patient history identify the timing. Regardless of the location of the infarction of cardiac muscle, the goal of medical therapy is to prevent or minimize myocardial tissue death and to prevent complications.

Risk Factors

Risk factors for MI are the same as those described for atherosclerosis and angina.

Clinical Manifestations and Assessment

Chest pain that occurs suddenly and continues despite rest and medication is the presenting symptom in most patients with an MI. Although patients with diabetic neuropathy may not experience chest pain, a high degree of suspicion must be maintained for an MI in diabetic patients admitted with associated symptoms of dyspnea, syncope, fatigue, diaphoresis, or lightheadedness. Up to 30% of patients with ST elevation myocardial infarction (STEMI) have prodromal (early nonspecific) symptoms. Box 14-5 discusses assessment parameters. In many cases, the signs and symptoms of MI cannot be distinguished from those of unstable angina. The diagnosis of MI is generally based on the presenting symptoms, physical findings, ECG, and laboratory test results (e.g., serial cardiac biomarker values). The prognosis depends on the severity of coronary artery obstruction and the extent of myocardial damage.

Nursing Alert
Women often present with symptoms different from those seen in men; in fact, 50% of women with an MI do not complain of chest pain (Chesler, Ho, & Ramkissoon, 2014). Therefore, a high level of suspicion is associated with vague complaints such as fatigue, shoulder blade discomfort, and/or SOB (Chesler et al., 2014).

Patient History

The patient history has two parts: the description of the presenting symptom(s) (e.g., pain) and the history of previous illnesses and family history of heart disease. The patient's risk factors for heart disease should also be evaluated.

BOX 14-5 Focused Assessment

Acute Myocardial Infarction (MI) or Acute Coronary Syndrome (ACS)

Be alert for the following signs and symptoms:

Cardiovascular

- Chest pain or discomfort, palpitations
- S_3, S_4, and new onset of a murmur
- Increased jugular venous distention (may be seen if the MI has caused heart failure)
- Elevated blood pressure (because of sympathetic stimulation) or decreased blood pressure (because of decreased contractility, impending cardiogenic shock, or medications)
- Pulse deficit, indicating atrial fibrillation
- In addition to ST-segment and T-wave changes, tachycardia, bradycardia, or arrhythmias on electrocardiogram (ECG)

Respiratory

- Shortness of breath, dyspnea, tachypnea, and crackles if MI has caused pulmonary congestion
- Pulmonary edema

Gastrointestinal
- Nausea and vomiting

Genitourinary
- Decreased urinary output (may indicate cardiogenic shock)

Skin
- Cool, clammy, diaphoretic, and pale appearance (due to sympathetic stimulation, may indicate cardiogenic shock)

Neurologic
- Anxiety, restlessness, and lightheadedness (may indicate increased sympathetic stimulation or a decrease in contractility and cerebral oxygenation or cardiogenic shock)

Psychological
- Fear with feeling of impending doom
- Denial

Electrocardiogram

The ECG provides information that assists in diagnosing acute MI. It should be obtained within 10 minutes from the time a patient reports pain or arrives in the emergency department. By monitoring serial ECG changes over time, the location, evolution, and resolution of an MI can be identified and monitored. The ECG changes that occur with an MI are seen in the leads that view the involved surface of the heart. The extent of ischemia and resultant injury through the various layers of the heart determine the type of ECG changes seen. The classic ECG changes are T-wave inversion, ST-segment elevation, and development of an abnormal Q wave (Fig. 14-11). The first ECG signs of an acute MI occur as a result of myocardial ischemia and injury. As the area becomes ischemic, myocardial repolarization is delayed, causing the T wave (representing ventricular depolarization) to invert. The ischemic region may remain depolarized while adjacent areas of the myocardium return to the resting state. As ischemia progresses to injury, the T wave becomes enlarged and symmetric. Myocardial injury also causes ST-segment changes. The ST segment may rise at least 1 mm above the isoelectric line (area between the T wave and the next P wave is used as the reference for the isoelectric line), or there may be non–ST-segment elevation. Remember that there may be a combination of ischemia, injury, and infarction occurring simultaneously, thus resulting in mixed ECG patterns.

Nursing Alert

Because lethal arrhythmias can appear suddenly in patients with MIs (most deaths with STEMI

occur within the first hour of its onset and usually result from ventricular fibrillation [Mega & Morrow, 2015]), all patients should have bedside monitoring of the ECG and intravenous access!

The beginning of the ST segment is usually identified by a change in the thickness or angle of the terminal portion of the QRS complex and is called the *J point* (Fig. 14-12). The J point is the end of ventricular depolarization (QRS) and the beginning of the ventricular repolarization (ST segment) and is identified by a change from an essentially vertical angle (QRS) to a more horizontal angle (ST segment). This J point is normally on the baseline, and elevation in the ST segment in two contiguous leads is a key diagnostic indicator for MI. The nurse assesses for ST elevation, as it relates to the isoelectric line, at a point 0.08 seconds past the J point.

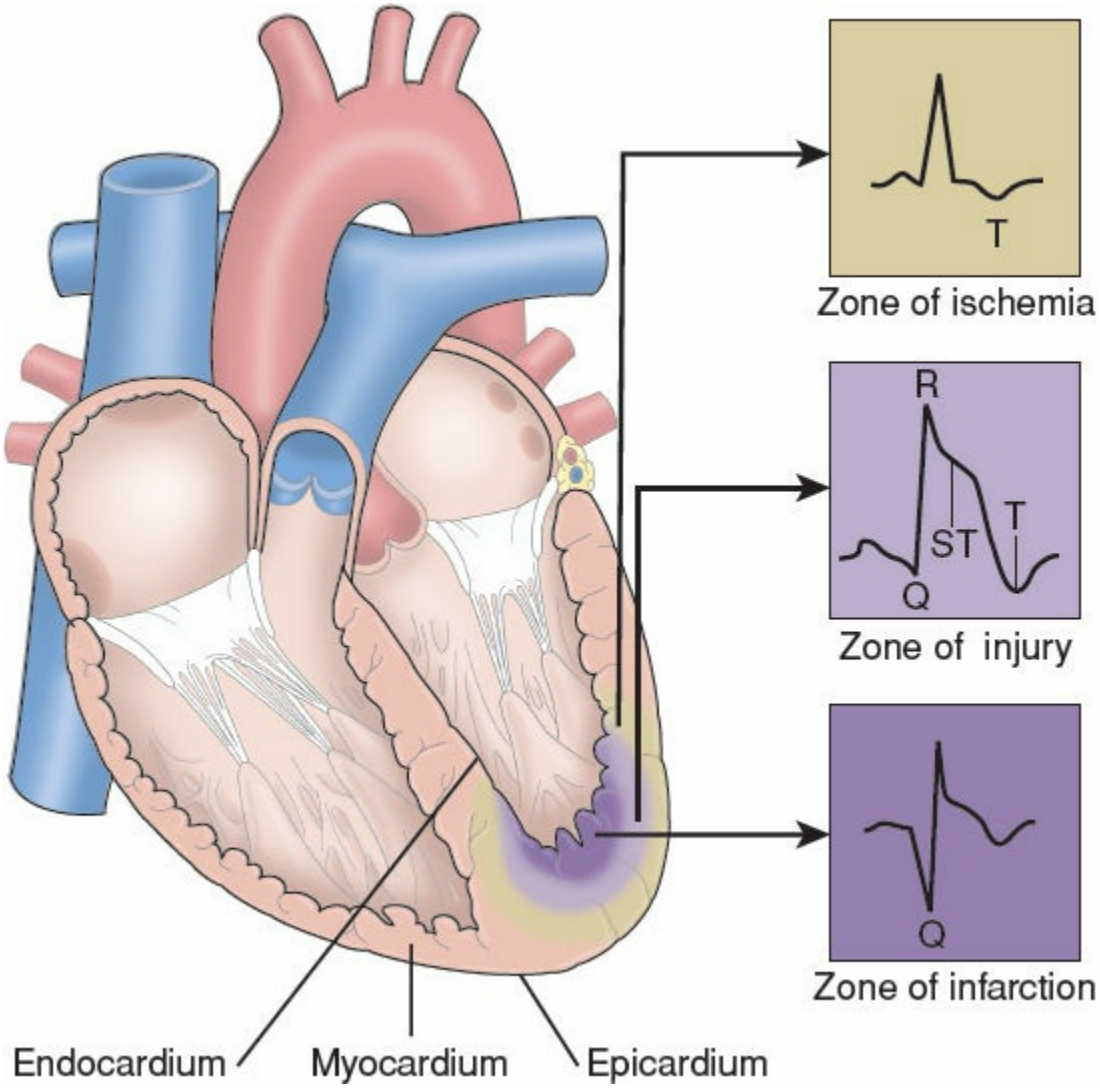

FIGURE 14-11 Effects of ischemia, injury, and infarction on an electrocardiogram (ECG) recording. Ischemia causes inversion of the T wave because of altered repolarization. Cardiac muscle injury causes elevation of the ST segment and tall, symmetrical T waves. Later, Q waves develop because of the absence of depolarization current from the necrotic tissue and opposing currents from other parts of the heart.

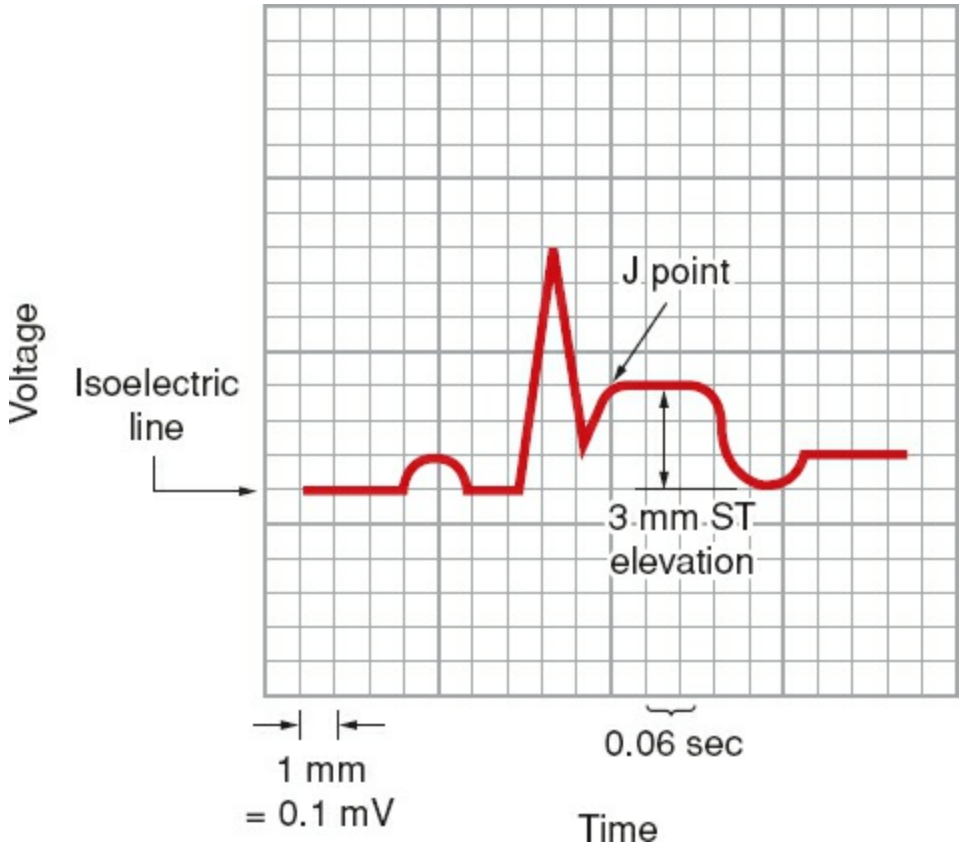

FIGURE 14-12 Using the electrocardiogram (ECG) to diagnose acute myocardial infarction (MI). (ST-segment elevation is measured 0.06 to 0.08 seconds after the J point. An elevation of more than 1 mm in contiguous leads is indicative of acute MI.)

The appearance of abnormal Q waves is another indication of MI. A Q wave is a negative deflection that signals the beginning of ventricular depolarization; however, abnormal Q waves represent myocardial necrosis and can develop within 1 to 3 days of an MI. A pathological Q wave is identified by an abnormal depth and duration of the Q wave or the appearance of "new" Q waves not previously seen in ECG tracings. The pathological Q wave, therefore, reflects the conduction from other parts of the heart because of necrotic tissue. An abnormal Q wave is 0.04 seconds or longer, 25% of the R-wave depth (provided the R wave exceeds a depth of 5 mm), or did not exist before the event. An acute MI may also cause a significant decrease in the height of the R wave. During an acute MI, injury and ischemic changes are usually present. An abnormal Q wave may be present without ST-segment and T-wave changes, which indicates an old, not acute, MI. For some patients, there are no persistent ECG changes, and the MI is diagnosed by blood levels of cardiac biomarkers.

Using the above information, patients are diagnosed with one of the following forms of ACS:

- *Unstable angina:* The patient has clinical manifestations of coronary ischemia, but ECG or cardiac biomarkers show no evidence of acute MI.
- *STEMI:* The patient has ECG evidence of acute MI with characteristic changes in two contiguous leads on a 12-lead ECG. In this type of MI, significant damage to the myocardium occurs.

- *Non-STEMI:* The patient has elevated cardiac biomarkers but no definite ECG evidence of acute MI.

During recovery from an MI, the ST segment often is the first ECG indicator to return to normal (in 1 to 6 weeks). The T wave becomes large and symmetric for 24 hours, and it then inverts within 1 to 3 days for 1 to 2 weeks. Q-wave alterations are usually permanent. An old ST-segment elevation MI is usually indicated by an abnormal Q wave or decreased height of the R wave without ST-segment and T-wave changes.

Echocardiogram

The echocardiogram is used to evaluate ventricular function. It may be used to assist in diagnosing an MI, especially when the ECG is nondiagnostic. The echocardiogram can detect hypokinetic and akinetic wall motion, can determine the ejection fraction, and can also assess valvular function.

Laboratory Tests

Laboratory tests called *cardiac biomarkers* are used to diagnose an MI (Table 14-5). Newer laboratory tests with faster results, and thus producing earlier diagnosis, include troponin analysis. These tests are based on the release of cellular contents into the circulation when myocardial cells die.

Creatine Kinase and Its Isoenzymes

Creatinine kinase–myocardial band (CK-MB) is the cardiac-specific isoenzyme; CK-MB is found mainly in cardiac cells and, therefore, increases only when there has been damage to these cells. Elevated CK-MB assessed by mass assay is an indicator of acute MI; its level begins to increase within a few hours and peaks within 24 hours of an MI. A normal CK-MB is 0 to 3 ng/mL or 1 to 3 μg/L. If the patient has cardiac complaints and negative CK-MB for more than 48 hours, then etiologies for the symptoms outside of an MI will be assessed.

TABLE 14-5 Biomarkers of Acute Myocardial Infarction

Serum Test	Earliest Increase (hours)	Test Running Time (minutes)	Peak (hours)	Return to Normal
Total creatinine kinase (CK)	3–6	30–60	24–36	3 days
CK-MB:isoenzyme	4–8	30–60	12–24	3–4 days
Mass assay	2–3	30–60	10–18	3–4 days
Myoglobin	1–3	30–60	4–12	12 hours
Troponin T or I	3–4	30–60	4–24	1–3 weeks

Myoglobin

Myoglobin is a hemeprotein that helps transport oxygen. Like CK-MB enzyme, myoglobin is found in cardiac and skeletal muscle. A normal level is 5 to 70 ng/mL or 5 to 70 μg/L. The myoglobin level starts to increase within 1 to 3 hours and peaks within 12 hours after the onset of symptoms. An increase in myoglobin is not very specific in indicating an acute

cardiac event; however, negative results are an excellent parameter for ruling out an acute MI.

Troponin

Troponin, a protein found in the myocardium, regulates the myocardial contractile process. There are three isomers of troponin: C, I, and T. Troponin C binds calcium to activate muscle contraction, while troponins I and T are specific for cardiac muscle, and are currently recognized as reliable and critical biomarkers of myocardial injury. A normal troponin I level is less than 0.5 ng/mL. An increase in the level of troponin in the serum can be detected within a few hours during acute MI. It remains elevated for a long period, often as long as 3 weeks, and it, therefore, can be used to detect recent myocardial damage.

Nursing Alert

Troponin I levels of greater than 1.5 ng/mL or greater than 1.5 mg/L *are critical.*

Medical Management

The goals of medical management are to minimize myocardial damage, preserve myocardial function, and prevent complications. These goals are facilitated by the use of guidelines developed by the American College of Cardiology and American Heart Association (Box 14-6). They may be achieved by reperfusing the area with the emergency PCI or use of thrombolytic medications in a medical center not capable of doing a PCI. Minimizing myocardial damage is also accomplished by reducing myocardial oxygen demand and increasing oxygen supply with medications, oxygen administration, and bed rest. The resolution of pain and ECG changes indicate that demand and supply are in equilibrium; they may also indicate reperfusion. Visualization of blood flow through an open vessel in the catheterization laboratory is evidence of reperfusion.

Pharmacologic Therapy

The patient with suspected MI is given aspirin, nitroglycerin, morphine, a beta-blocker, and other medications as indicated, while the diagnosis is being confirmed. Patients should receive a beta-blocker initially, throughout the hospitalization, and upon discharge. Also on discharge, there needs to be documentation that the patient was discharged on a statin, an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin-receptor blocking agent (ARB), and aspirin. These are "quality indicators" for ACS treatment and are now publicly reported measures. Remember SAAB: *s*tatin, *a*ce or arb, *a*spirin, *b*eta-blocker. If any of these are not prescribed, clear documentation as to why not must be provided.

BOX 14-6 Medical Treatment Guidelines for Acute Myocardial Infarction

Use rapid transit to the hospital.

Obtain 12-lead electrocardiogram (ECG) to be read within 10 minutes.

Obtain laboratory blood specimens of cardiac biomarkers, including troponin.

Obtain other diagnostics to clarify the diagnosis.

Begin routine medical interventions:

- Supplemental oxygen
- Nitroglycerin
- Morphine
- Aspirin 162 to 325 mg
- Beta-blocker
- Angiotensin-converting enzyme inhibitor or angiotensin-receptor blocker within 24 hours

Evaluate for indications for reperfusion therapy:

- Percutaneous coronary intervention
- Thrombolytic therapy

Continue therapy as indicated:

- IV heparin or low–molecular-weight heparin
- Clopidogrel (Plavix) or antiplatelet-like agent
- Glycoprotein IIb/IIIa inhibitor

Thrombolytics

In non–PCI-capable hospitals, initial assessment of patients should include evaluation of the contraindications to administration of a thrombolytic agent. The purpose of thrombolytics is to dissolve and lyse the thrombus in a coronary artery (thrombolysis), allowing blood to flow through the coronary artery again (reperfusion), minimizing the size of the infarction, and preserving ventricular function. Hospitals monitor their ability to administer these medications within 30 minutes from the time the patient arrives in the emergency department. This is called *door-to-needle time* or "*time to needle.*" The thrombolytic agents used most often are alteplase (t-PA, Activase) and reteplase (r-PA, TNKase). Box 14-7 discusses administration of and contraindications for thrombolytic therapy.

Analgesics

The analgesic of choice for acute MI is morphine sulfate administered in IV boluses to reduce pain and anxiety. It reduces preload and afterload (peripheral arterial and venous dilation), which decreases the workload of the heart. Morphine also relaxes bronchioles to enhance oxygenation. The cardiovascular response to morphine is monitored carefully, particularly the blood pressure, which can decrease, and the respiratory rate, which can be depressed. Because morphine decreases the sensation of pain, ST-segment monitoring may be a better indicator of subsequent ischemia than assessment of pain.

BOX 14-7 Administration of Thrombolytic Therapy

Indications

- No PCI-capable center available in the next 120 minutes (O'Gara et al., 2013)
- Chest pain for longer than 20 minutes, unrelieved by nitroglycerin
- ST-segment elevation in at least two leads that face the same area of the heart
- Less than 6 hours from onset of pain

Absolute Contraindications

- Active bleeding (excluding menses)
- Known bleeding disorder
- History of hemorrhagic stroke
- History of intracranial vessel malformation
- Known malignant intracranial neoplasm
- Ischemic stroke within 3 months (except acute ischemic stroke within 4.5 hours)

- Recent major surgery or trauma
- Uncontrolled hypertension
- Suspected aortic dissection
- Pregnancy

Nursing Considerations

- Minimize the number of times the patient's skin is punctured.
- Avoid intramuscular injections.
- Draw blood for laboratory tests when starting the IV line.
- Start IV lines before thrombolytic therapy; designate one line to use for blood draws.
- Avoid continual use of noninvasive blood pressure cuff.
- Monitor for acute arrhythmias and hypotension.
- Monitor for reperfusion; resolution of angina or acute ST-segment changes on the EKG.
- Check for signs and symptoms of bleeding: decrease in hematocrit and hemoglobin values, decrease in blood pressure, increase in heart rate, oozing or bulging at sites of invasive procedure, back pain, muscle weakness, changes in level of consciousness, complaints of headache.
- Treat major bleeding by discontinuing thrombolytic therapy and any anticoagulants; apply direct pressure and notify the provider immediately.
- Treat minor bleeding by applying direct pressure if accessible and appropriate; continue to monitor for bleeding.

Note: If possible, a patient should always be transferred to a hospital with PCI capability within 2 hours.

O'Gara, P. T., Kushner, F. G., Ascheim, D. D., et al. (2013). ACCF/AHA guideline for the management of ST-elevation myocardial infarction: A report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Journal of the American College of Cardiology*, *61*, e78.

Nursing Alert

Maintaining the patient in a supine position and elevating the lower extremities if blood pressure falls can minimize hypotension following the administration of nitroglycerin and morphine. Such positioning is undesirable in patients with pulmonary edema, but morphine rarely produces hypotension in these circumstances (Mega & Morrow, 2015).

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors prevent the conversion of angiotensin I to angiotensin II. In the absence of angiotensin II, the blood pressure decreases and the kidneys excrete sodium and fluid (diuresis), decreasing the oxygen demand of the heart. Use of ACE inhibitors in patients after MI decreases mortality rates and prevents remodeling of myocardial cells, which is associated with the onset of heart failure. It is important to ensure that the patient is not hypotensive, hyponatremic, hypovolemic, or hyperkalemic before administering ACE

inhibitors. Blood pressure; urine output; and levels of serum sodium, potassium, and creatinine need to be monitored closely. An ARB can be used in lieu of an ACE inhibitor.

Nursing Alert
The nurse remembers the mnemonic MONA when treating potential MI patients: morphine, oxygen, nitrates, and aspirin.

Reperfusion Procedures

Reperfusion procedures may be used to restore the blood supply to the myocardium. These include PCI procedures (e.g., intracoronary stents, atherectomy), and CABG. See discussion under "angina pectoris" section for detailed descriptions.

Cardiac Rehabilitation

After the MI patient is free of symptoms, an active rehabilitation program is initiated. Cardiac rehabilitation is a program that targets risk reduction by means of education, individual and group support, and physical activity. Most insurance programs, including Medicare, cover the cost of cardiac rehabilitation. The nurse needs to encourage the patient and ensure that referral from the hospital for outpatient cardiac rehabilitation is accomplished.

Cardiac rehabilitation is categorized in three phases. Phase I begins with the diagnosis of atherosclerosis, which may occur when the patient is admitted to the hospital for ACS (e.g., unstable angina or acute MI). It includes any postprocedural activity that occurs during the hospitalization. Phase I consists of low-level activities and initial education for the patient and family.

Phase II occurs after the patient has been discharged. It usually lasts for 4 to 6 weeks but may extend to 6 months. This outpatient program consists of supervised, often ECG-monitored, exercise training that is individualized based on the results of an exercise stress test.

Phase III focuses on maintaining cardiovascular stability and long-term conditioning. The patient is usually self-directed during this phase and does not require a supervised program, although it may be offered. The goals of each phase build on the accomplishments of the previous phase. Health promotion is discussed in Box 14-8.

Nursing Management

Relieving Pain and Other Signs and Symptoms of Ischemia

Balancing myocardial oxygen supply with demand (e.g., as evidenced by the relief of chest pain) is the top priority in the care of the patient with an acute MI. Although medication therapy is required to accomplish this goal, nursing interventions are also important.

The recommended treatment for acute MI is reperfusion with thrombolytic therapy (*time to needle*) or emergent PCI (*time to device*) for patients who present to the health care facility immediately and who have no major contraindications. These therapies are important because, in addition to relieving symptoms, they aid in minimizing or avoiding permanent injury to the myocardium. With or without reperfusion, administration of aspirin, an IV beta-blocker, and nitroglycerin is indicated. Use of a GPIIb/IIIa agent or heparin may also be indicated. Aspirin (300 mg) should be administered unless already given (e.g., by emergency services or home treatment) or contraindicated (known allergy). A previous history of gastritis or indigestion is not a contraindication to the use of aspirin in ACS (Kelly, 2015). Since the goal is rapid therapeutic aspirin level in the blood, the patient should chew the tablet to promote buccal absorption rather than absorption through the gastric mucosa (Mega & Morrow, 2015). The nurse administers morphine to relieve pain and anxiety and to promote vasodilation, reducing preload and afterload.

BOX 14-8 Health Promotion

Promoting Health After Myocardial Infarction and Other Acute Coronary Syndromes

To extend and improve the quality of life, a patient who has had an MI must learn to adjust his or her lifestyle to promote heart-healthy living. With this in mind, the nurse and patient develop a program to help the patient achieve desired outcomes.

Changing Lifestyle During Convalescence and Healing

Adaptation to an MI is an ongoing process and usually requires some modification of lifestyle. Some specific modifications include:

- Avoiding any activity that produces chest pain, extreme dyspnea, or undue fatigue
- Avoiding extremes of heat and cold and walking against the wind
- Losing weight, if indicated
- Stopping smoking and use of tobacco; avoiding secondhand smoke
- Using personal strengths to support lifestyle changes
- Developing heart-healthy eating patterns, including avoiding large meals and hurrying while eating
- Modifying meals to align with the Therapeutic Lifestyle Changes (TLC) or the Dietary Approaches to Stopping Hypertension (DASH) diet
- Adhering to medical regimen, especially in taking medications

- Following recommendations that ensure blood pressure and blood glucose are in control
- Pursuing activities that relieve and reduce stress

Adopting an Activity Program

Additionally, the patient needs to undertake an *orderly* program of increasing activity and exercise for long-term rehabilitation as follows:

- Engaging in a regimen of physical conditioning with a gradual increase in activity duration and then a gradual increase in activity intensity
- Walking daily, increasing distance and time as prescribed
- Monitoring pulse rate during physical activity until the maximum level of activity is attained
- Avoiding activities that tense the muscles: isometric exercise, weight-lifting, any activity that requires sudden bursts of energy
- Avoiding physical exercise immediately after a meal
- Alternating activity with rest periods (some fatigue is normal and expected during convalescence)
- Participating in a daily program of exercise that develops into a program of regular exercise for a lifetime

Managing Symptoms

The patient must learn to recognize and take appropriate action for possible recurrences of symptoms as follows:

- Call 911 if chest pressure or pain (or anginal equivalent) is not relieved in 15 minutes by nitroglycerin.
- Contact the provider if any of the following occur: shortness of breath, fainting, slow or rapid heartbeat, swelling of feet and ankles.

Nursing Alert

Bleeding complications are most common after thrombolytic therapy, and intracranial hemorrhage is the most serious complication (frequency is generally less than 1%); therefore, any change in the LOC, cranial nerve changes, motor weakness, etc. is reported immediately to the provider.

Oxygen should be administered along with medication therapy to assist with relief of symptoms. Administration of oxygen, even in low doses, raises the circulating level of oxygen to reduce pain associated with low levels of myocardial oxygen. The route of administration, usually by nasal cannula, and the oxygen flow rate are documented. A flow rate of 2 to 4 L/min is usually adequate to maintain oxygen saturation levels of 96% to 100% if no other disease is present.

Vital signs are assessed frequently as long as the patient is experiencing pain and other signs or symptoms of acute ischemia. Physical rest in bed with the backrest elevated (semi-

Fowler's position) helps decrease chest discomfort and dyspnea. Elevation of the head and torso is beneficial for the following reasons:

- Tidal volume improves because of reduced pressure from abdominal contents on the diaphragm and better lung expansion and gas exchange.
- Drainage of the upper lung lobes improves.
- Venous return to the heart (preload) decreases, reducing the work of the heart.

Nursing Alert
HOB elevation is beneficial for patients with cardiac disease; however, if the patient becomes hypotensive, the patient may be placed in the supine position with legs elevated to increase venous return.

Improving Respiratory Function

Regular and careful assessment of respiratory function can help the nurse detect early signs of pulmonary complications. Scrupulous attention to fluid volume status prevents overloading the heart and lungs.

Promoting Adequate Tissue Perfusion

Limiting the patient to bed or chair rest during the initial phase of treatment is particularly helpful in reducing myocardial oxygen consumption. This limitation should remain until the patient is pain-free and hemodynamically stable. Checking skin temperature and peripheral pulses frequently is important in monitoring tissue perfusion. Pulse oximetry should be in use, and efforts toward minimizing myocardial oxygen consumption should be in place. Maintaining the patient at rest both physically and emotionally by providing a quiet atmosphere and mild anxiolytic medications may be considered in some cases.

Reducing Anxiety

Alleviating anxiety and decreasing fear are important nursing functions that reduce the sympathetic stress response. Decreased sympathetic stimulation decreases the workload of the heart, which may relieve pain and other signs and symptoms of ischemia.

Monitoring and Managing Potential Complications

Complications that can occur after acute MI are caused by the damage that occurs to the myocardium and to the conduction system as a result of the reduced coronary blood flow. Because these complications can be life-threatening, close monitoring for and early identification of their signs and symptoms are critical. Refer to Chapter 54 for details of cardiogenic shock.

The nurse closely monitors and reports changes in cardiac rate/rhythm, heart and lung sounds, blood pressure, pain, respiratory status, urinary output, skin color/temperature, LOC, ECG changes, and laboratory values. Also, stool softeners should be considered to prevent constipation and straining. The nurse institutes emergency measures when necessary.

CHAPTER REVIEW

Critical Thinking Exercises

1. You are working in a cardiology office and you receive a phone call from a patient who had an MI 2 years ago. She reports that she is experiencing some SOB and mild back pain. What evidence base is there to suggest that symptoms of an MI may be different for women than men? Discuss the strength of this evidence and its significance in determining assessment criteria to be used for women and men. What questions would you ask this patient? What would you instruct her to do? Provide rationale for your instructions.

2. You are taking over the care of a patient who returned from the catheterization laboratory 2 hours ago following a successful PCI. He was reported to be stable on bed rest, with no bleeding from the right femoral site. The patient appears very pale and complains of right flank pain. Identify the key parameters that need to be assessed. Describe the actions you would take and state why.

3. You are caring for a patient who has been hospitalized awaiting CABG surgery. As you deliver his morning medications, he states that he is feeling "pressure" in the lower sternal area, but he thinks it is just "nerves." What questions would you ask and what would you assess? What would your next actions be?

NCLEX-Style Review Questions

1. A patient arrives in the emergency room complaining of nausea, diaphoresis, SOB, and squeezing substernal chest pain that radiates to the left shoulder and jaw. The nurse should perform which interventions?
   a. Complete admission registration, alert the catheter laboratory team, establish an IV access, and record all vital signs
   b. Alert the catheter laboratory team, administer oxygen, obtain blood work, and notify the health care provider
   c. Establish an IV, give sublingual nitroglycerin as ordered, insert a Foley catheter, and alert the catheter laboratory team
   d. Administer oxygen, apply a cardiac monitor, record patient's vital signs, and give sublingual nitroglycerin as ordered

2. What does the nurse recognize as an absolute contraindication for thrombolytic therapy?
   a. Active bleeding
   b. Current anticoagulant therapy
   c. Over age 75
   d. Severe hepatic disease

3. The nurse is caring for a nonsmoking female patient with the diagnosis of coronary

atherosclerosis who has been admitted to the hospital with angina. The patient states that she never experiences chest pain going down her arm or in the middle of her chest. The nurse is not surprised at this statement and explains to the patient that:

a. Women who have ischemia are usually totally asymptomatic.
b. Women have been found to have more atypical symptoms such as dyspnea, nausea, and weakness.
c. Chest pain occurs only with strenuous exercise.
d. Cigarette smoking is usually the contributing factor to chest pain.

4. Two hours after cardiac catheterization that was accessed via the right femoral artery route, an adult client complains of numbness and pain in the right foot. What action should the nurse take first?

a. Call the provider immediately.
b. Check the client's peripheral pulses (pedal/posterior tibial).
c. Take the client's blood pressure.
d. Recognize that this is an expected response and reassess the patient in 1 hour.

5. A 54-year-old man comes to triage complaining of severe, left-sided, pressure-like chest pain and left arm numbness. The pain began 2 hours ago and is unrelieved by rest. The patient is anxious, diaphoretic, and complaining of nausea. Cardiac monitoring is begun, and oxygen is given at 2 L/min. An intermittent infusion device (IID) is in place, and vital signs are as follows: BP of 128/68 mm Hg; pulse, 76 beats/min; respirations easy and regular at 20 breaths/min. ECG reveals normal sinus rhythm with occasional unifocal premature ventricular contractions (PVCs).

The nurse suspects an MI based on an elevation in the which lab study?

a. CK-MB and LDH
b. LDH and troponin I
c. CK-MB and troponin I
d. Troponin I and SGPT

CHAPTER 15

Nursing Management: Patients with Complications from Heart Disease

Jessica Shank Coviello

Learning Objectives

After reading this chapter, you will be able to:

1. Compare and contrast diastolic and systolic heart failure (HF), including pathophysiology and clinical manifestations.
2. Describe the management of patients with HF.
3. Develop a teaching plan for patients with HF.
4. Describe the assessment and management of patients with pulmonary edema.
5. Describe the management of patients with cardiogenic shock.
6. Describe the management of patients with pericardial effusion.
7. Describe emergency management of patients with cardiac arrest.

Today, patients with heart disease can be assisted to live longer and achieve a higher quality of life than they could even a decade ago. Through advances in diagnostic procedures that allow earlier and more accurate diagnoses, treatment can begin well before significant debilitation occurs. Newer treatments, technologies, and pharmacotherapies are being developed rapidly. However, heart disease remains a chronic condition, and complications may develop. This chapter presents the complications most often resulting from heart diseases and the treatments provided by the health care team for these complications.

HEART FAILURE

Heart failure (HF) is the inability of the heart to pump sufficient blood to meet the needs of the tissues for oxygen and nutrients. In the past, HF was often referred to as congestive heart failure (CHF), because many patients experience pulmonary or peripheral congestion. Currently HF is recognized as a clinical syndrome characterized by signs and symptoms of fluid overload or of inadequate tissue perfusion. Fluid overload and decreased tissue perfusion result when the heart cannot generate a cardiac output (CO) sufficient to meet the body's demands (see Chapter 12 for a review of cardiac hemodynamics). The term *heart failure* indicates myocardial disease in which there is a problem with contraction of the heart (systolic dysfunction) or filling of the heart (diastolic dysfunction) that may or

may not cause pulmonary or systemic congestion. Some cases of HF are reversible, depending on the cause. Most often, HF is a progressive, lifelong diagnosis that is managed with lifestyle changes and medications to prevent acute congestive episodes.

CHRONIC HEART FAILURE

As with coronary artery disease (CAD), the incidence of chronic heart failure increases with age. The nature of chronic heart failure can be either systolic or diastolic with systolic failure the most common at 60% (Hobbs & Boyle, 2014). In the United States, the lifetime risk of developing HF is 20% for those *age* 40 years and older. Currently, over 5.7 million people *age 20 years or older* in the United States have HF, and 650,000 new cases are diagnosed each year (Muzaffarian et al., 2015). Although HF can affect people of all ages, the incidence increases from approximately 20 per 1000 individuals 65 to 69 years of age to more than 80 per 1000 among those age 85 years or older. HF is the most common reason for hospitalization of people older than 65 years of age and the second most common reason for visits to a health care provider. The rate of hospital readmission remains staggeringly high. The economic burden caused by HF is estimated to rise from $30.7 billion in 2012 to $69.7 billion in 2030 (Muzaffarian et al., 2015).

The increase in the incidence of HF reflects the increased number of elderly people and improvements in treatment of cardiac diseases, resulting in increased survival rates. Many hospitalizations could be prevented by appropriate outpatient care. Prevention and early intervention to arrest the progression of HF are major health initiatives in the United States.

Types and Classification

There are two types of HF, which are identified by assessment of left ventricular functioning, usually by echocardiogram. The more common type is an alteration in ventricular contraction called systolic heart failure, which is characterized by a weakened heart muscle. The less common alteration is diastolic heart failure, which is characterized by a stiff and noncompliant heart muscle, making it difficult for the ventricle to fill. An assessment of the ejection fraction (EF) is performed to assist in determining the type of HF. EF, an indication of the volume of blood ejected with each contraction, is calculated by subtracting the amount of blood at the end of systole from the amount at the end of diastole and calculating the percentage of blood that is ejected. A normal EF is 50% to 70% of the ventricular volume; the ventricle does not empty completely between contractions. The EF is normal in diastolic HF but severely reduced in systolic HF.

Pathophysiology Alert

In diastolic heart failure there is a normal EF; therefore, a normal EF does not mean or equate to normal CO. A normal EF is not a reliable gauge of normal CO. The nurse is aware that a low CO is the fundamental pathophysiologic abnormality of all HF.

Although a low EF is a hallmark of HF, the severity of HF is frequently classified according to the patient's symptoms. In 2008, the American College of Cardiology and the American Heart Association (Schocken et al.) developed a classification system for HF that incorporates a patient's clinical status and pathophysiology of the disease in its classification. Stages of HF (A–D) were defined for use in understanding and managing the progression of HF, including risk factors for HF and primary prevention strategies; the stage classifications continue to be used today. Additionally, Figure 15-1 considers the natural history and progressive nature of HF. Treatment guidelines have been developed for each stage.

Pathophysiology

HF results from a variety of cardiovascular (CV) conditions (including chronic hypertension [HTN], CAD, valvular disease, congenital heart defects, and arrhythmias) as well as from conditions such as diabetes mellitus, fever, infection, thyrotoxicosis, iron overload, hypoxia, anemia, and pulmonary embolus (Mann, Zipes, Libby, & Bonow, 2014). These conditions can result in decreased contraction (systole), decreased filling (diastole), or both. Significant myocardial dysfunction most often occurs before the patient experiences signs and symptoms of HF, such as shortness of breath, edema, or fatigue.

As HF develops, the body activates neurohormonal compensatory mechanisms. These mechanisms represent the body's attempt to cope with the HF and are responsible for the signs and symptoms that eventually develop. Understanding these mechanisms is important because the treatment of HF is aimed at relieving them (Fig. 15-2).

Systolic HF results in a decrease in the volume of blood being ejected from the ventricle. The decreased ventricular stretch is sensed by baroreceptors (sensors in blood vessels that respond to perfusion pressure of blood flow) in the aortic and carotid bodies (Mann et al., 2014). The sympathetic nervous system is stimulated to release epinephrine and norepinephrine. The purpose of this initial response is to increase heart rate and contractility and support the failing myocardium, but the continued response has multiple negative effects. Sympathetic stimulation causes vasoconstriction of the skin, gastrointestinal tract, and kidneys. A decrease in renal perfusion due to low CO and vasoconstriction then causes the release of renin by the kidney. Renin promotes the formation of angiotensin I, a benign, inactive substance. Angiotensin-converting enzyme (ACE) in the lumen of pulmonary blood vessels converts angiotensin I to angiotensin II, a potent vasoconstrictor, which then increases the blood pressure and afterload (see alert below). Angiotensin II also stimulates the release of aldosterone from the adrenal cortex, resulting in retention of sodium and fluid, excretion of potassium (K^+) by the renal tubules, and stimulation of the thirst center. This leads to the fluid volume overload commonly seen in HF. Angiotensin, aldosterone, and other neurohormones (e.g., endothelin, prostacyclin) lead to an increase in preload (see alert below) and afterload, which increases stress on the ventricular wall, causing an increase in the workload of the heart. Additionally, the combination of medication treatments for HF coupled with the release of aldosterone predisposes patients with HF to hypokalemia. A counter-regulatory mechanism is attempted through the release of natriuretic peptides. Atrial natriuretic peptide (ANP) and B-type natriuretic peptide (BNP) are released from the over distended cardiac chambers (Fig. 15-3). These substances promote vasodilation and diuresis. However, their effect is usually not strong enough to overcome the negative effects of the other mechanisms.

Nursing Alert

Preload should be considered as the stretching of the cardiac muscle prior to contraction. Ventricular preload is determined by the volume of blood in the ventricle prior to the onset of systole and is a function of both venous return and end-systolic volume of the chamber. For example, when venous return or volume of blood entering the heart is increased, preload increases. In contrast, if there is a loss of blood due to hemorrhage, less

blood returns to the atria and this leads to decreased ventricular filling and reduced preload. Regardless of the chamber (atria or ventricle), preload is related to the volume just prior to contraction. Afterload should be considered as resistance to flow (the pressure gradient that the ventricles must overcome to pump blood out the ventricles to either the lungs or systemic circulation).

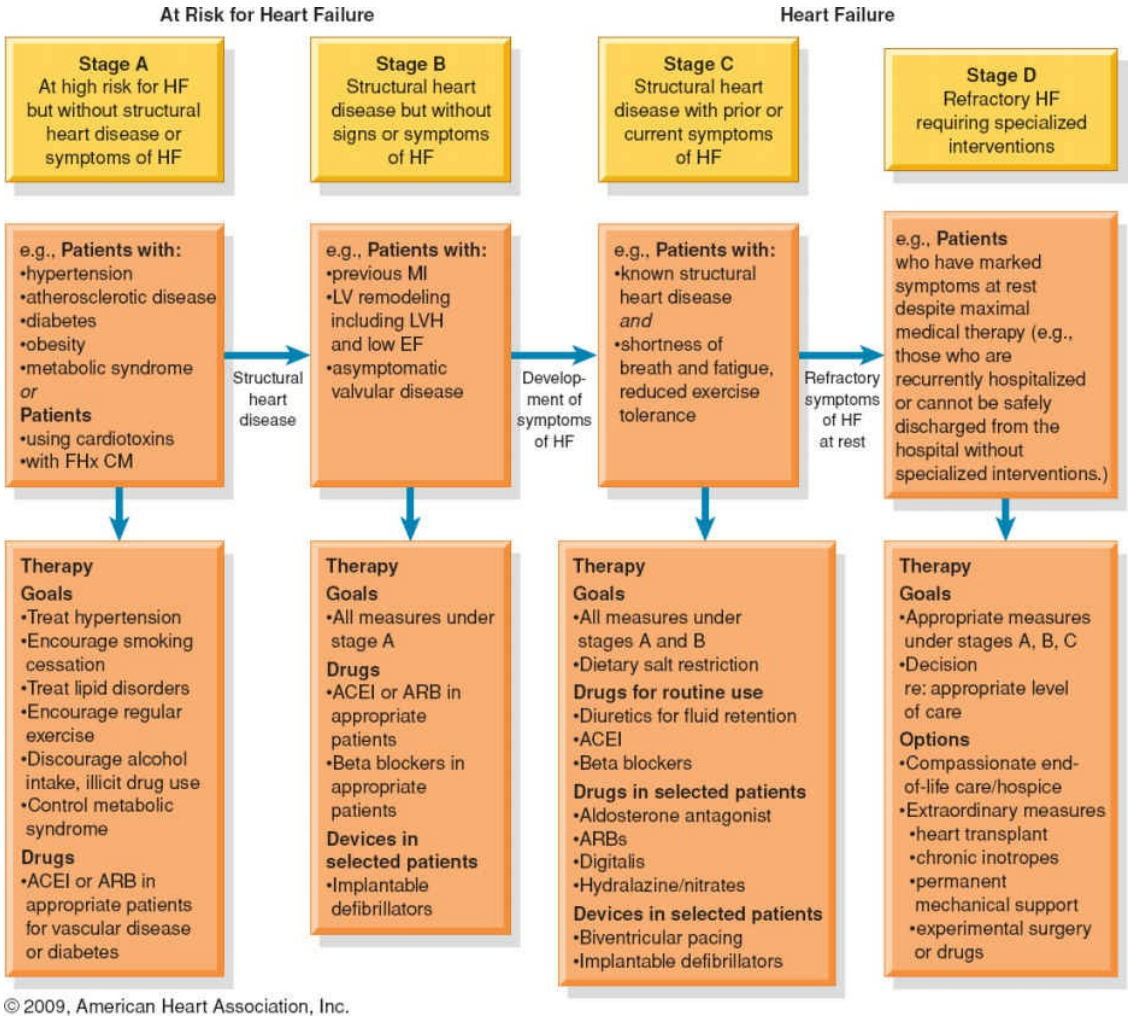

FIGURE 15-1 Stages in the development of heart failure. ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; EF, ejection fraction; FHx CM, family history of cardiomyopathy; LV, left ventricle; LVH, left ventricular hypertrophy; MI, myocardial infarction. (From American Heart Association (AHA). (2009). *Circulation*, *119*, 1977–2016. Reprinted with permission.)

As the heart's workload increases, contractility of the myocardial muscle fibers decreases. Decreased contractility results in an increase in end-diastolic blood volume (preload) in the ventricle, stretching the myocardial muscle fibers and increasing the size of the ventricle (ventricular dilation). The increased size of the ventricle further increases the stress on the ventricular wall, adding to the workload of the heart. One way the heart compensates for the increased workload is to increase the thickness of the heart muscle (ventricular hypertrophy). However, hypertrophy results in an abnormal proliferation of myocardial cells, a process known as *ventricular remodeling*. Under the influence of neurohormones (e.g., angiotensin II), large myocardial cells are produced that are dysfunctional and die

early, leaving the other normal myocardial cells to struggle to maintain CO (Mann et al., 2014). The heart does not pump sufficient blood to the body, which causes the body to stimulate the heart to work harder; the heart cannot respond, and failure becomes worse. This cycle repeats itself, thus contributing to an ongoing process of further cardiac decline.

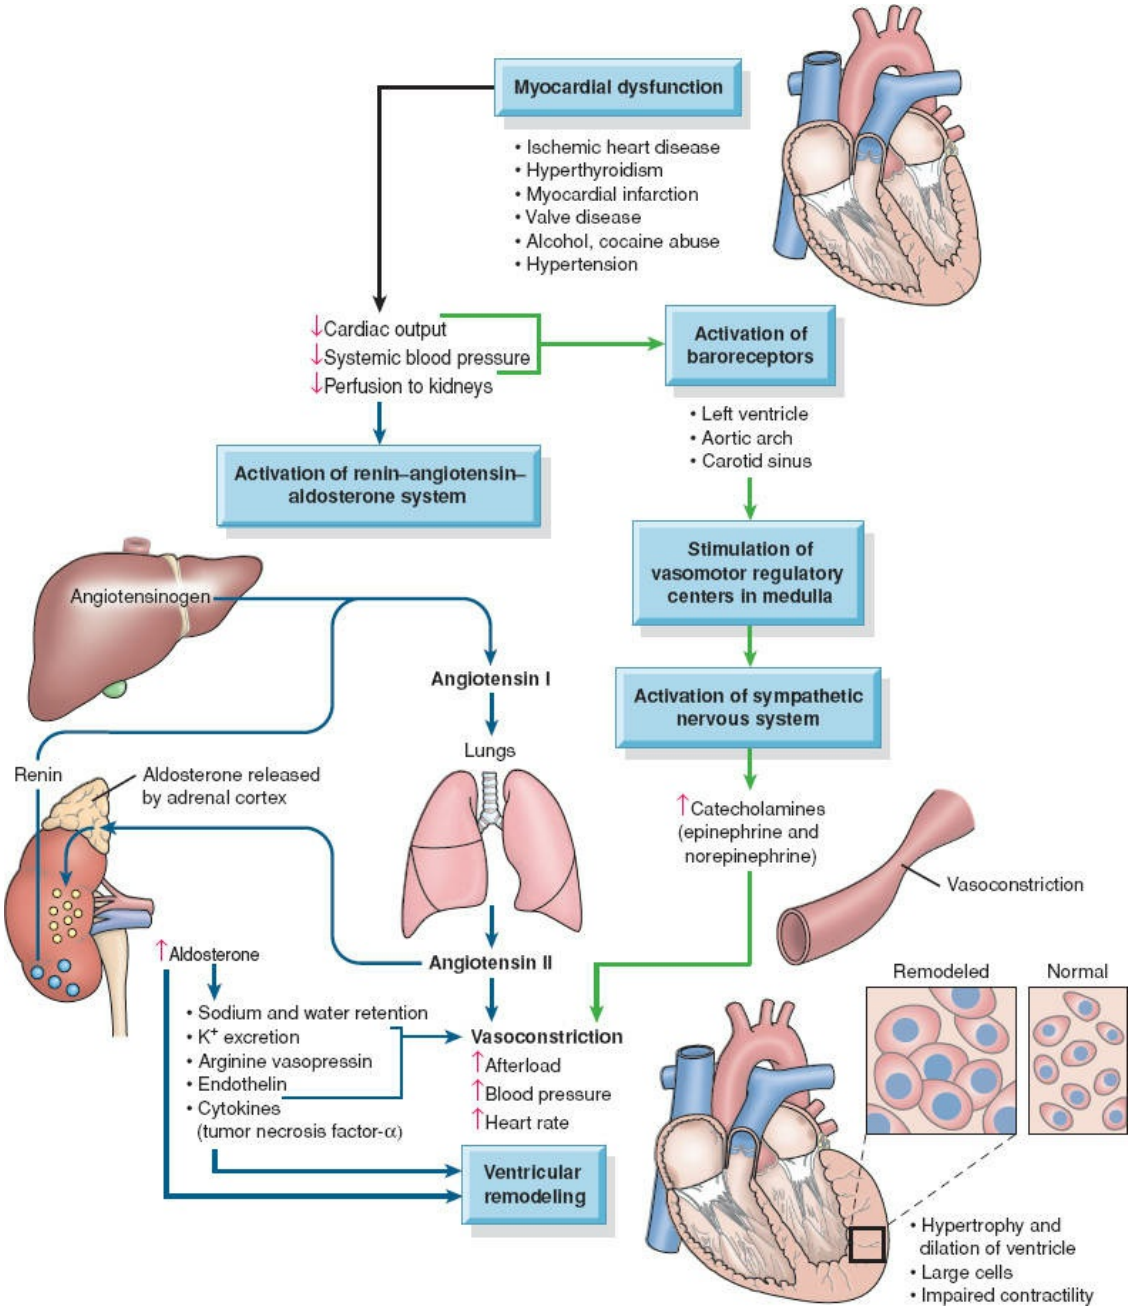

FIGURE 15-2 The pathophysiology of heart failure. A decrease in cardiac output activates multiple neurohormonal mechanisms that ultimately result in the signs and symptoms of HF.

Diastolic HF develops because of continued increased workload on the heart, which responds by increasing the number and size of myocardial cells (i.e., ventricular hypertrophy and altered cellular functioning). These responses cause resistance to ventricular filling, which increases ventricular filling pressures despite a normal or reduced blood volume. Less blood in the ventricles causes decreased CO. The low CO and high

ventricular filling pressures can cause the same neurohormonal responses as described for systolic HF. Table 15-1 provides a comparison of systolic and diastolic HF (Van Wacher & Edelmann, 2014).

Additionally, HF may present as right sided versus left sided (Table 15-2).

Risk Factors

There are important risk factors for HF that can be modified before actual structural heart disease occurs. Early identification and treatment of these risk factors, or comorbidities may prevent or decrease the occurrence of the onset of HF. Risk factors that are asymptomatic for HF are included in stage A HF.

An example of such an HF risk factor is HTN. HTN is a risk for both men and women, but it is more profound in women. In fact, it is the primary etiology of HF in women. The incidence of HF increases as blood pressure increases, duration increases, and the patient's age increases. Long-term treatment of HTN reduces the risk by 50% (Yancy et al., 2013). It has been estimated that the lifetime risk of HTN in the United States is more than 75%. It is, therefore, an important risk factor to treat early, and patients should be encouraged to maintain their blood pressure below 140/90 mm Hg consistently (Yancy et al., 2013).

Those with diabetes mellitus or metabolic syndrome are at greater risk of HF. Remember metabolic syndrome is confirmed in patients who have any three of the following: abdominal obesity, elevated triglyceride levels (over 150 mg/dL), decreased high-density lipoprotein (HDL) (<40 mg/dL for men, <50 mg/dL for women) HTN, and elevated fasting glucose. These comorbidities also negatively affect outcomes for those with HF (Yancy et al., 2013).

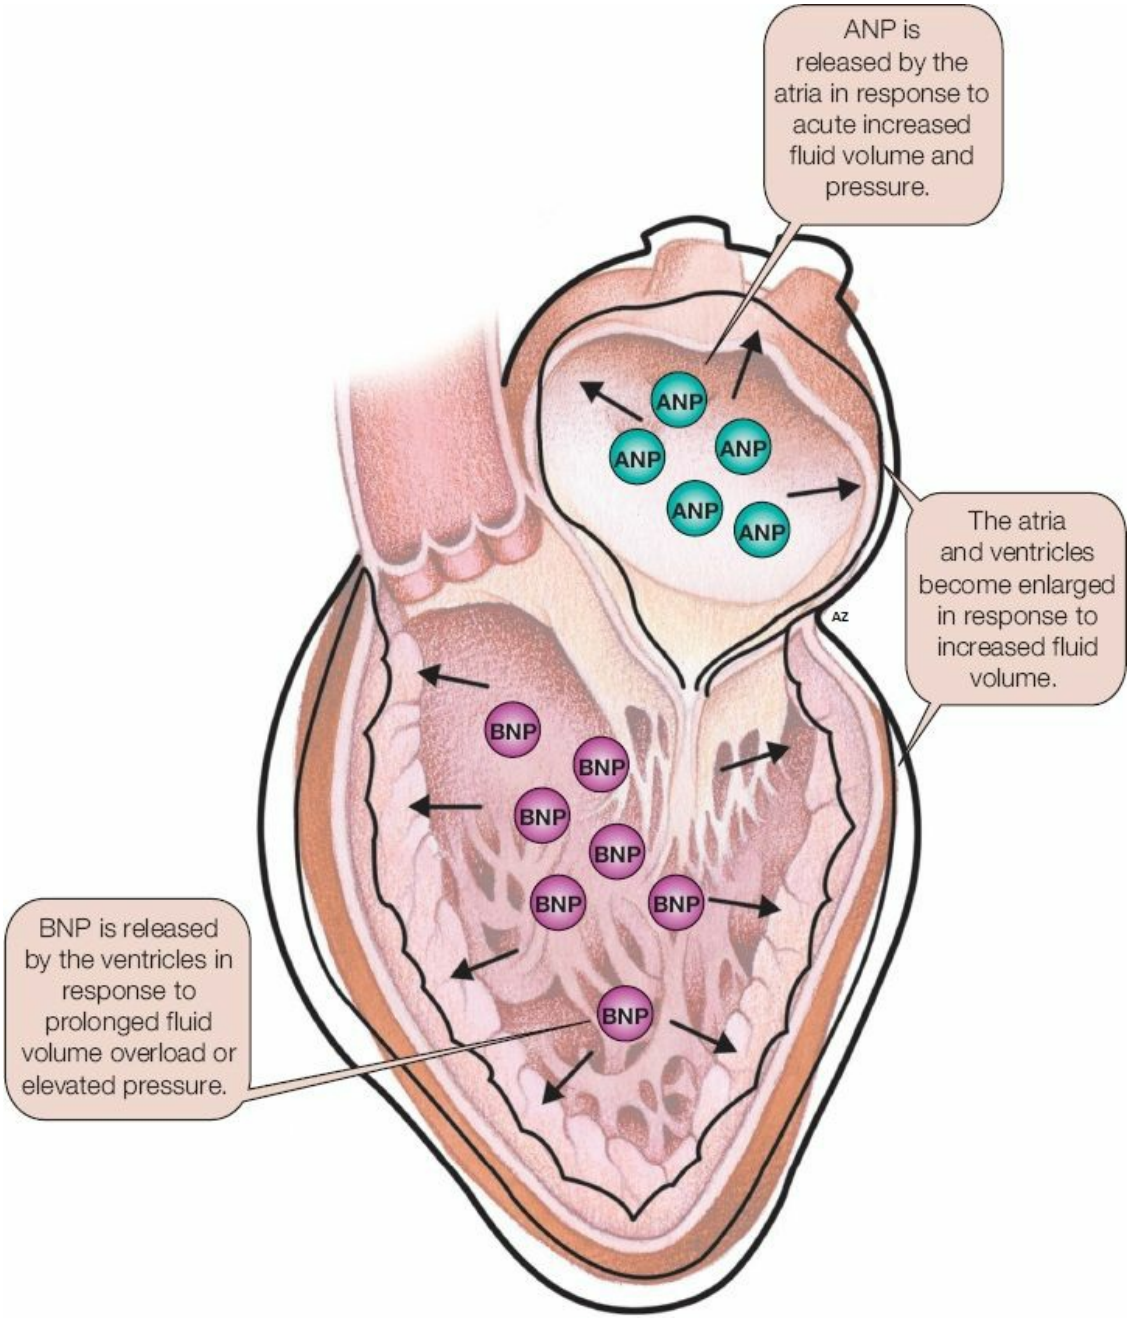

FIGURE 15-3 A-type natriuretic peptide (ANP) and B-type natriuretic peptide (BNP). Disruptions in intravascular fluid balance trigger the release of ANP and BNP. (From Lippincott Williams & Wilkins. (2010). *Cardiovascular care made incredibly visual* (2nd ed., p. 50). Philadelphia, PA: Lippincott Williams & Wilkins.)

Finally, those diagnosed with atherosclerotic disease (CAD, stroke, or peripheral vascular disease) are likely to develop HF without adequate control of CV risk. It is important to note that the primary cause of HF in men is CAD (Schocken et al., 2008; Yancy et al., 2013; Goff et al., 2013; Katz, 2015; van Deursen et al., 2014a).

TABLE 15-1 Comparison of Systolic and Diastolic Heart Failure

	Systolic Failure	Diastolic Failure
Pathophysiology	• Impaired ventricular pumping of blood during systole • Characterized by reduced stroke volume, incomplete ventricular emptying, cardiac dilation, and elevated left ventricular diastolic pressure • Reduced cardiac output evokes compensatory neurohormonal responses that increase heart rate, sodium and water retention, and vasoconstriction	• Impaired ventricular relaxation filling during diastole • Characterized by a stiffened left ventricle that cannot relax and fill sufficiently at normal diastolic pressure • The result is either decreased left ventricular end-diastolic volume (leading to decreased cardiac output) or a compensatory rise in left ventricular filling pressure, which can lead to pulmonary venous hypertension
Causes/etiology	Usually caused by ischemic or idiopathic dilated cardiomyopathy, when the left ventricle cannot adequately contract or squeeze out its contents, so that preload increases and stroke volume decreases	Usually caused by hypertensive, hypertrophic, or restrictive cardiomyopathy

TABLE 15-2 Symptom Comparison of Left- Versus Right-Sided Heart Failure

	Left-Sided HF	Right-Sided HF
Pathophysiology	• Pulmonary congestion from impaired left ventricle (LV) function • LV cannot pump blood out of the ventricle effectively into the aorta and the systemic circulation • Pulmonary venous blood volume and pressure increase, forcing fluid from the pulmonary capillaries into the pulmonary tissues and alveoli, causing pulmonary interstitial edema and impaired gas exchange	• Right ventricle pump failure leading to congestion in the peripheral tissues and the viscera • Right side of the heart cannot eject blood and cannot accommodate all the blood that normally returns to it from the venous circulation • Increased venous pressure leads to jugular vein distension (JVD) and increased hydrostatic pressure throughout the venous system. Normal central venous pressure (CVP) is 2–8 mm Hg. A CVP greater than 8 mm Hg associated with hypervolemia (excessive fluid circulating in the body) or right-sided HF

Clinical Manifestations and Assessment

Systolic and diastolic HF share similar clinical findings. Overt signs of HF include resting dyspnea, cyanosis, and cachexia (physical wasting), resulting from long-standing heart disease. A baseline height and weight should be documented on admission and weight rechecked each morning. Obtaining daily weights and tracking trends in weight, along with an accurate intake and output log, provide an easy and accurate way to monitor fluid balance. Fluid balance is an important surveillance strategy in controlling HF symptoms.

Nursing Alert
Daily weights should be at the same time, on the same scale, and with the patient wearing the same clothes for accuracy. The nurse is aware that when calculating new gain or loss that 500 mL approximates 1 lb, or 1000 mL approximates 1 kg (2.2 lb).

A thorough CV assessment is performed, which includes blood pressure measurement in both sitting and standing positions in order to detect orthostatic hypotension.

Tachycardia (heart rate over 120 bpm) may signal worsening HF. When the heart rate is rapid, the stroke volume (SV) decreases because the ventricle has less time to fill. This, in turn, produces increased pressure in the atria and, eventually, in the pulmonary vascular bed. A weak, thready pulse and *pulsus alternans* (pulse is regular but force of amplitude varies with alternating beats from large to small) are signs of decreased left ventricular function.

Left ventricular hypertrophy (LVH) may displace the apical pulse left and downward from its normal location at the fifth intercostal space, medial to the midclavicular line. Right-sided HF may present with an elevation in jugular venous pressure greater than 4 cm above the sternal angle. This is an estimate, not a precise measurement, of central venous pressure.

An S_3 heart sound is a sign that the heart is beginning to fail and that increased blood volume is filling the ventricle with each beat. Other sounds may include mitral and tricuspid regurgitation murmurs. The nurse may detect an S_4 sound if the patient has increased resistance to ventricular filling because of increased stiffness of the ventricular myocardium.

The nurse assesses the lungs. Crackles (formerly called rales) are discrete, discontinuous crackling sounds heard at the end of inspiration. They are produced by the sudden delayed reopening of edematous small airways and alveoli and are not cleared with coughing. It is recommended that the nurse begins auscultation at the base of the lungs to detect crackles in HF patients and notes the extent. Typically crackles start at the lung bases and are heard progressively higher in the lungs as HF worsens. Wheezing may also be heard in some patients. The rate and depth of respirations are also documented. Dullness to percussion may indicate pleural effusions due to HF.

The nurse assesses dependent parts of the patient's body for perfusion and edema. With significant decreases in SV, there is a decrease in perfusion to the periphery, causing the skin to feel cool and to appear pale or cyanotic. If the patient is sitting upright, the feet and

lower legs are examined for edema; if the patient is supine in bed, the sacrum and back are also assessed for edema. Fingers and hands may also become edematous. The nurse notes the location and extent of the edema and assesses for evidence of pitting edema (refer to Chapter 12).

Hepatomegaly, hepatojugular reflux, and ascites can occur with venous congestion due to right-sided HF. Recall with right-sided HF, there is accumulation of fluid in the systemic venous circulation. To assess for hepatojugular reflux, the patient is positioned in bed so that the nurse can observe the blood column of the jugular veins above the clavicle. The patient is asked to breathe normally while manual pressure is applied over the right upper quadrant of the abdomen for at least 5 seconds (Kusumoto Heart Disease, 2013). If the top of the jugular venous column in the neck rises and persists as long as the abdominal pressure is continued, it is considered positive hepatojugular reflux, which indicates that the right ventricle cannot accommodate the additional volume of displaced blood; when the right ventricle cannot accommodate this additional volume, an increase in jugular venous pressure is seen. A positive hepatojugular reflux is associated with right HF and constrictive pericarditis.

BOX 15-1 Focus on Assessment

Left-Sided Versus Right-Sided Heart Failure

Be alert for the following signs and symptoms:

Left-Sided HF

- Dyspnea, orthopnea, PND
- Cough
- Pulmonary crackles (rales)
- Decrease O_2 saturation levels
- S_3 ventricular gallop
- Oliguria, if kidney perfusion is diminished (Note: Nocturia may occur when perfusion improves with sleeping due to improved perfusion at rest.)
- Decreased perfusion to other systemic organs (advanced failure):
  - Sluggish GI motility
  - Dizziness, lightheadedness, confusion, restlessness
  - Anxiety
  - Skin cool and clammy
  - Decrease in EF
  - Tachycardia and/or weak/thready pulse
  - Fatigue or activity intolerance

Right-Sided HF

- Lower extremity dependent edema (dependent edema is swelling that follows the position of the body):

- Legs and feet
- May progress to thighs, external genitalia, lower trunk, abdomen, and sacral edema (in a bed-bound patient)
- Pitting edema (indentations in the skin remain even after slight compression with the fingertips)

- Hepatomegaly (enlargement of the liver)
- Ascites (accumulation of fluid in the peritoneal cavity)
- Anorexia and nausea
- Weight gain due to retention of fluid
- Weakness/fatigue from reduced CO and impaired cognition
- Decreased perfusion to other systemic organs (advanced failure)

Sensorium and level of consciousness must be evaluated. As the volume of blood ejected by the heart decreases, so does the amount of oxygen transported to the brain. Patients may complain of dizziness or lightheadedness. Box 15-1 compares and contrasts assessment findings in left- and right-sided HF.

Diagnostic evaluation includes:

- A chest x-ray can determine the presence and extent of cardiac enlargement or pulmonary congestion and can help identify pulmonary disease. Cardiomegaly indicates systolic dysfunction; a normal heart size suggests diastolic dysfunction.
- A 12-lead electrocardiogram (ECG) determines the presence of cardiac arrhythmias, LVH, and previous or current myocardial infarction (MI). If the patient has left ventricular dysfunction, the ECG usually indicates a left ventricular electrical abnormality specific to ventricular dilation or hypertrophy.
- A two-dimensional (2D) echocardiogram with Doppler flow study is a noninvasive test to look for structural cardiac abnormalities and to measure EF. An EF of less than 40% indicates systolic dysfunction; an EF of greater than 40% with signs and symptoms of HF and impaired ventricular relaxation indicates diastolic dysfunction.
- Although the 2D echocardiogram remains the more common approach to assessing left ventricular function, three-dimensional (3D) echocardiogram with strain (-20% plus or minus 2 SD) measurements is quickly replacing the 2D mode due to greater accuracy (Jasilyte et al., 2013; Yingchoncharoen, Agarwal, Popvic, & Marwick, 2013).
- Cardiac magnetic resonance testing is now considered the gold standard for assessing cardiac function. It is a more expensive test than both the 2D and 3D with strain and can be found only in large or regional medical facilities (Manolis, Chamodraka, & Zacharopoulou, 2015).
- Laboratory tests that may help diagnose HF include complete blood cell count, electrolyte levels (including calcium and magnesium), blood urea nitrogen, creatinine, serum glucose, serum albumin, liver function tests, thyroid-stimulating hormone, urinalysis, and BNP levels. High BNP levels (greater than 100 pg/mL) indicate

abnormal ventricular function or symptomatic HF.

- A right-sided heart catheterization also can be performed to determine the heart's preload pressures and pulmonary pressures to determine the degree of HF and the need for further intervention. A patient with angina who is a candidate for coronary revascularization may undergo a full cardiac catheterization with coronary arteriography.

Medical Management

Treatment begins with prevention. Identifying patients at risk is the first step in the care and treatment of HF.

The overall goals of management of HF are to relieve patient symptoms, improve functional status and quality of life, and extend survival. Treatment is based on the type, severity, and cause of HF. Specific objectives include the following:

- Eliminate or reduce any etiologic contributory factors, especially those that may be reversible (e.g., atrial fibrillation, excessive alcohol ingestion, uncontrolled HTN).
- Reduce the workload on the heart by reducing afterload and preload.
- Optimize all therapeutic regimens.
- Prevent exacerbations of HF.

Treatment options vary according to the severity of the patient's condition (see Fig. 15-1).

Lifestyle Changes

Managing the patient with HF includes providing general education and counseling to the patient and family. It is important that the patient and family understand the nature of HF and the importance of their participation in the treatment regimen. Lifestyle recommendations include restriction of dietary sodium; avoidance of excessive fluid intake, alcohol, and smoking; weight reduction when indicated; and regular exercise. The patient must know how to recognize signs and symptoms that need to be reported to the health care professional such as weight gain, increasing shortness of breath, fatigue, and edema.

Pharmacologic Therapy

Several medications (Table 15-3) are prescribed routinely for systolic HF, including ACE inhibitors, beta blockers, diuretics, and digoxin. Medications for diastolic failure depend on the underlying condition, such as HTN or valvular dysfunction.

TABLE 15-3 Pharmacologic Treatment of Heart Failure

Drug Class	Pharmacokinetics	Indications and Nursing Implications
Diuretics	Diuretics prompt the kidneys to excrete sodium, chloride, and water, reducing fluid volume. They are a preload reducer.	• Diuretics should never be used alone to treat HF because they don't prevent further myocardial damage. • Loop diuretics such as furosemide, bumetanide, and torsemide, are the preferred first-line diuretics because of their efficacy in patients with and without kidney impairment. • Low-dose spironolactone may be added to a patient's regimen if he or she has recent or recurrent symptoms at rest despite therapy with angiotensin-converting enzyme (ACE) inhibitors, beta blockers, digoxin, and diuretics.
Inotropes	Inotropes affect the force of myocardial contraction. Positive inotropes increase force of myocardial contraction and also increase workload of heart and oxygen demand. Negative inotropes decrease force of myocardial contraction and decrease workload of heart and oxygen demand.	• Digoxin increases the heart's ability to contract and improves HF symptoms and exercise tolerance in patients with mild to moderate HF. • Major adverse reactions to positive inotropes include arrhythmias; gastrointestinal problems, such as anorexia; and neurologic symptoms, such as confusion (Adams et al., 2014). • IV-positive inotropes, such as dobutamine, dopamine, and milrinone, can also be used for long-term support (e.g., patients awaiting cardiac transplant) via a tunneled central venous catheter or peripherally inserted central catheter.
ACE inhibitors	ACE inhibitors, such as captopril and enalapril, block the conversion of angiotensin I to angiotensin II, a vasoconstrictor that can raise blood pressure. These drugs alleviate HF symptoms by causing vasodilation and decreasing myocardial workload. They are preload and afterload reducers that provide renal protection.	• The most common adverse reaction to ACE inhibitors is a dry cough. Other adverse reactions include hypotension, worsening kidney function, and potassium retention.
Angiotensin-II receptor blockers	Angiotensin-II receptor antagonists selectively block the binding of angiotensin II to specific tissue receptors in vascular smooth muscle and the adrenal glands. Overall effects include: blocking the vasoconstricting effect of the renin–angiotensin system; blocking aldosterone release, leading to a reduction in sodium and water retention; they have little effect on potassium. They are preload and afterload reducers.	• Patients who cannot take ACE inhibitors may be prescribed angiotensin receptor blockers instead. This therapy reduces the effects of sodium and water retention, vasoconstriction, and myocardial remodeling.
Aldosterone receptor antagonists	Aldosterone receptor antagonists, such as eplerenone, block aldosterone from binding to receptors in the kidneys. This allows the kidneys to eliminate excess sodium and water. They are a preload reducer.	• Aldosterone receptor antagonists are similar to ACE inhibitors for nursing implications. Evidence suggests patients may not exhibit the side effect of a cough as they do with ACE inhibitors.
Beta blockers	Beta-adrenergic blockers, such as bisoprolol, metoprolol, and carvedilol, block the effects of catecholamines, resulting in reduction of heart rate, decreased peripheral vasoconstriction and decreased myocardial demand. Beta blockers can interfere with the passage of air into the lungs. However, selective beta blockers avoid this problem. They are a negative inotrope.	• Long-term therapy reduces HF symptoms and improves the patient's functional status.
Nesiritide	Nesiritide (Natrecor) is a preparation of human B-type natriuretic peptide (BNP) that mimics the action of endogenous BNP, causing diuresis and vasodilation, reduced BP, and improved cardiac output. It is a preload and afterload reducer.	• It is given via the IV route only. **The use of nesiritide has come into question recently with outcomes similar to those of diuretics (van Deursen et al., 2014b).**
Vasodilators/ nitrates	Vasodilators/nitrates are used for arterial and venous smooth muscle relaxation. They are preload and afterload reducers.	• The combination of hydralazine and nitrates is recommended to improve outcomes for patients self-described as African American (Khazanie et al., 2016) with moderate–severe HF symptoms who are on optimal ACE inhibitors, beta blockers, and diuretics.

Additional Therapies

Additional therapy and surgical treatment are described in Table 15-4. Box 15-2 discusses the psychological impact of these therapies.

Nursing Management

Despite advances in medical and surgical approaches to HF, mortality remains high. Nurses can make a major difference in promoting positive outcomes. Caring for patients with HF requires a collaborative, interdisciplinary team approach. Nurses play a pivotal role in the care and ongoing teaching of this patient population (Danna, Garbee, & Kensler, 2014).

Assessing the Patient

The nursing assessment for the patient with HF focuses on observing for effectiveness of therapy and for the patient's ability to understand and implement self-management strategies. Signs and symptoms of pulmonary and systemic fluid overload are recorded and reported immediately so that adjustments can be made in therapy. The nurse also explores the patient's emotional response to the diagnosis of HF, a chronic and often progressive condition.

The health history focuses on the signs and symptoms of HF, such as shortness of breath, dyspnea on exertion (DOE), (shortness of breath that occurs with exertion), and cough. Sleep disturbances, particularly sleep suddenly interrupted by shortness of breath termed *paroxysmal nocturnal dyspnea* (PND), may be reported. The nurse also asks about the number of pillows needed for sleep (an indication of orthopnea—shortness of breath while lying flat), edema, abdominal symptoms, altered mental status, activities of daily living, daily weight, and the activities that cause fatigue. The nurse explores the patient's understanding of HF, self-management strategies, and the desire to adhere to those strategies. The nurse helps patients identify the impact the illness has had on their quality of life and successful coping skills that they have used. Often family and significant others are included in these discussions.

Monitoring Intake and Output

If the patient is hospitalized, the nurse measures output carefully to establish a baseline against which to assess the effectiveness of diuretic therapy. Intake and output records are rigorously maintained. It is important to know whether the patient has ingested more fluid than he or she has excreted (positive fluid balance), which then is correlated with a gain in weight. The patient must be monitored for oliguria (diminished urine output, less than 400 mL/24 hours) or anuria (urine output less than 100 mL/24 hours).

The patient is weighed daily in the hospital or at home, at the same time of day, with the same type of clothing, and on the same scale. If there is a significant change in weight (i.e., 2 to 3 lb increase in a day or 5 lb increase in a week), the patient is instructed to notify his or her provider or to adjust the medications (e.g., increase the diuretic dose) per the provider's directions.

TABLE 15-4 Modalities for Treatment of Heart Failure

Modality	Indications	Description/Procedure
Ultrafiltration (UF)	Eases symptoms for patients in decompensated HF and can help some patients to respond again to conventional drug therapy; it is a low-volume extracorporeal process that removes fluid from the intravascular compartment. Recent studies show inconsistent findings on the benefit of UF vs. standard diuretic therapy (Mehra, 2015; Marenzi, Kazory, & Agostoni, 2015).	• Uses a mechanical pump and a hemofilter to remove a specified amount of fluid with each treatment, alleviating the patient's symptoms. • Treatment time varies depending on patient needs. • During treatment, the intravascular fluid volume remains stable, since fluid shifts from the interstitial space to replace fluid lost in treatment, which reduces edema and third-spacing. Typically, patients do not become hypotensive or hypovolemic with this treatment (Klein, 2014).
Cardiac resynchronization therapy (CRT)	In the patient with HF who does not improve with standard therapy, CRT may be beneficial. CRT involves the use of a biventricular pacemaker to treat electrical conduction defects. Left bundle branch block is a feature of delayed conduction that is frequently seen in patients with HF that results in dyssynchronous conduction and contraction of the right and left ventricles, which can further decrease EF (Yancy et al., 2013).	• Use of a pacing device with leads placed in the right atrium, right ventricle, and left ventricular can synchronize the contractions of the right and left ventricles. This intervention has been shown to improve cardiac output, optimize myocardial energy consumption, reduce mitral regurgitation, and slow the ventricular remodeling process. For selected patients, this results in fewer symptoms and increased functional status (Yancy et al., 2013; Krishnamoorthy & Felker, 2014). For patients who require CRT and an implantable cardiac defibrillator (ICD), combination devices are available.
Implantable cardiac defibrillators (ICDs)	Patients with HF are at high risk for arrhythmias. In patients with life-threatening arrhythmias, placement of an ICD can prevent sudden cardiac death and extend survival.	• ICDs can provide a range of therapies that include cardioversion, defibrillation, and pacing. A lead or leads are placed in the appropriate chamber's endocardium and attached to a generator box that can be implanted in the right or left side of the chest, under the clavicle. • Wearable cardioverter defibrillators have recently been used as a bridge to implantable defibrillators (Chung, 2014).
Ventricular access devices/destination therapy	Patients with end-stage HF may require a ventricular assist device (VAD) for greater support for the failing ventricle(s). A VAD can reduce myocardial ischemia and workload, limit permanent cardiac damage, and restore adequate organ perfusion. Indications for use include: as a bridge to myocardial recovery in acute ventricular failure (e.g., shock, acute MI, etc.), as a bridge to heart transplantation in chronic ventricular failure, and for permanent therapy for end-stage chronic HF. VADs are also known as *destination therapy.*	• VADs are mechanical blood pumps that work by augmenting or replacing the function of either the left or right ventricle. • There are currently four FDA-approved devices that are used as bridges to transplantation in adults. One of the four is also approved for use as destination therapy or as long-term mechanical support of the heart. The devises may be pulsatile or continuous flow (nonpulsatile) (Sunagawa et al., 2017). • All shares a common problem with infectious complications, risk for thromboembolic complications, and possibility of mechanical failure common to any machine.
Heart transplant	For some patients with end-stage HF, cardiac transplantation is the only option for long-term survival. Some of these patients require mechanical circulatory assistance with an implanted ventricular assist device as a bridge therapy to cardiac transplantation. Research continues toward perfection of a totally implantable artificial heart that may be used as an alternative to transplantation.	• Heart transplantation involves replacing a person's diseased heart with a donor heart. This is an option for advanced HF patients when all other therapies have failed (Ammirate et al., 2014).

BOX 15-2 Nursing Research

Bridging the Gap to Evidence-Based Practice

What are the evidence-based approaches and key factors associated with successful outcomes in teaching patients with heart failure?

Rasmusson, K., Flattery, M., Baas, L. S. (2015). American Association of Heart Failure Nurses position paper on educating patients with heart failure. Heart & Lung, 44(2),

173–177.

Purpose
To provide supporting evidence associated with successful educational approaches for patients with heart failure.

Design
This is a position paper. Position papers represent a policy or opinion of a panel of experts representing an organization (e.g., American Heart Association). They are based on a synthesis and analysis of the literature and expert testimony.

Nursing Implications
The nurse's approach to teaching self-care measures to heart failure patients should be guideline directed and evidence based. It should include:

- Early instruction reinforced through the hospital stay and at discharge (Andrikopoulou, Abbate, & Whellan, 2014)
- Assessment of patient's health literacy, educational preferences, and knowledge of heart failure tailored to the patient's needs, including preferred language and learning style (visual, verbal, and/or multimedia)
- Sixty minutes of heart failure education, which has demonstrated a reduction in 30-day readmission (Koelling, Johnson, Cody, & Aaronson, 2005)
- Teach-back methods (White, Garbez, Carroll, Brinker, & Howie-Esquivel, 2013)
- Family and caregivers (Agren, Evangelista, Hjelm, & Stromber, 2012; Hwang, Fleischmann, Howie-Esquivel, Stotts, & Dracup, 2011; Kurylo, Elliot, & Deviro, 2004)
- Evidence-based and novel teaching techniques to enhance knowledge as well as build skills and confidence (Yancy et al., 2013; Lindenfeld et al., 2010)
- Clarification with patient of who will be providing posthospitalization management and then communication of the plan to that provider in order to coordinate care, reduce polypharmacy, and reduce readmissions
- Assessment of learning after discharge through telephone follow-up and repeating information at each outpatient visit (Andrikopoulou et al., 2014)
- Assessment of patient's adherence with self-care monitoring at each outpatient visit and addressing factors that limit adherence
- Community-based classes, groups, or other creative programming

ACUTE HEART FAILURE AND PULMONARY EDEMA

Pulmonary edema is the abnormal accumulation of fluid in the lungs. The fluid may accumulate in the interstitial spaces and in the alveoli. Pulmonary edema can be categorized into two subsets depending on the etiology: cardiogenic and noncardiogenic (Sovari, 2014; Givertz et al., 2014).

Pathophysiology

Cardiogenic pulmonary edema is an acute event that results from HF. It can occur acutely, such as with MI, or it can occur as an exacerbation of chronic HF. Myocardial scarring as a result of ischemia can limit the dispensability of the ventricle and render it vulnerable to a sudden increase in workload. With increased resistance to left ventricular filling, blood backs up into the pulmonary circulation. The patient quickly develops pulmonary edema, sometimes called *flash pulmonary edema,* from the blood volume overload in the lungs. Pulmonary edema can also be caused by noncardiac disorders, such as kidney failure, liver failure, and oncologic conditions that cause the body to retain fluid. The pathophysiology is similar to that seen in HF, in that the left ventricle cannot handle the volume overload, and blood volume and pressure build up in the left atrium. The rapid increase in atrial pressure results in an acute increase in pulmonary venous pressure, which produces an increase in hydrostatic pressure that forces fluid out of the pulmonary capillaries into the interstitial spaces and alveoli.

Impaired lymphatic drainage also contributes to the accumulation of fluid in the lung tissues. The fluid within the alveoli mixes with air, creating "bubbles" that are expelled from the mouth and nose, producing the classic symptom of pulmonary edema: frothy sputum; alveoli are flooded with fluid from the capillaries, producing thin secretions containing air bubbles that frequently are colored with hemoglobin (LeBlond, Brown, Suneja, & Szot, 2015). Because of the fluid within the alveoli, air cannot enter, and gas exchange is impaired. The result is hypoxemia, which is often severe. The onset may be preceded by premonitory symptoms of pulmonary congestion, but it also may develop quickly in the patient with a ventricle that has little reserve to meet increased oxygen needs.

Clinical Manifestations and Assessment

As a result of decreased cerebral oxygenation, the patient becomes increasingly restless and anxious. Clinical manifestations include a sudden onset of breathlessness, sense of suffocation, cough that produces a large amount of frothy sputum (that may be blood tinged), cold and moist skin, cyanotic (bluish) nail beds, a weak and rapid pulse, pulmonary crackles (rales), expiratory wheezing, and distended neck veins.

Additionally oxygen demand increases, yet oxygen saturation is significantly decreased. The patient, nearly suffocated by the blood-tinged, frothy fluid filling the alveoli, is literally drowning in secretions. The situation demands immediate action.

Medical and Nursing Management

Although the etiology of pulmonary edema may vary, management of symptoms follows the similar clinical management plan for treating acute decompensated HF (oxygen, diuretics, pharmacologic preload [volume] and afterload [resistance to flow] reduction, and, possibly, hemodynamic monitoring). Additional therapies may include early rescue with noninvasive mask ventilation and bronchodilator therapy with select $beta_2$ agonist medications like albuterol (Lazzari et al., 2016).

CARDIOGENIC SHOCK

Cardiogenic shock occurs when decreased CO leads to inadequate tissue perfusion and initiation of the shock syndrome. Cardiogenic shock may occur following MI, when a large area of myocardium becomes ischemic, necrotic, and hypokinetic (slow or diminished muscle motion). It also can occur as a result of end-stage HF, cardiac tamponade, pulmonary embolism (PE), cardiomyopathy, and arrhythmias. Cardiogenic shock is a life-threatening condition with a high mortality rate.

Pathophysiology

The signs and symptoms of cardiogenic shock reflect the circular nature of the pathophysiology of HF. The degree of shock is proportional to the extent of left ventricular dysfunction. The heart muscle loses its contractile power, resulting in a marked reduction in SV and CO. The decreased CO, in turn, reduces arterial blood pressure and tissue perfusion in the vital organs (heart, brain, lung, kidneys). Flow to the coronary arteries is reduced, resulting in decreased oxygen supply to the myocardium, which increases ischemia and further reduces the heart's ability to pump. Inadequate emptying of the ventricle also leads to increased pulmonary pressures, pulmonary congestion, and pulmonary edema, exacerbating the hypoxia, causing ischemia of vital organs, and setting a vicious cycle in motion.

Clinical Manifestations and Assessment

The classic signs of cardiogenic shock are those of tissue hypoperfusion and result from HF and the overall shock state. They include cerebral hypoxia (restlessness, confusion, agitation), low blood pressure, rapid and weak pulse, cold and clammy skin, tachypnea with respiratory crackles, and decreased urinary output. Initially, arterial blood gas (ABG) analysis may show respiratory alkalosis related to the tachypnea. Arrhythmias are common and result from myocardial ischemia.

The patient with cardiogenic shock is managed in an intensive care unit. A pulmonary artery catheter may be inserted to measure CO and other hemodynamic parameters that are used to assess the severity of the problem and to guide patient management. The pulmonary artery wedge pressure (indirect estimate of left atrial pressure or left ventricular preload) is elevated and the CO is decreased as the left ventricle loses its ability to pump. The systemic vascular resistance is elevated because of the sympathetic nervous system stimulation that occurs as a compensatory response to the decrease in blood pressure. The decreased blood flow to the kidneys causes a hormonal response (i.e., activation of the renin–angiotensin–aldosterone system) that causes fluid retention and further vasoconstriction. Increases in HR, circulating volume, and vasoconstriction occur to maintain circulation to the brain, heart, kidneys, and lungs but at a cost: an increase in the workload of the heart.

The reduction in blood volume delivered to the tissues results in an increase in the amount of oxygen extracted from the blood that is delivered to the tissues (to try to meet the cellular demand for oxygen). The increased systemic oxygen extraction results in decreased venous (mixed and central) oxygen saturation. When the cellular oxygen needs cannot be met, anaerobic metabolism and buildup of lactic acid occur. As a result, ABGs would reveal metabolic acidosis. Continuous central venous oximetry and measurement of blood lactic acid levels may help assess the severity of the shock as well as the effectiveness of treatment. Refer to Chapter 55 for further discussion on lactic acid levels.

Continued cellular hypoperfusion eventually results in organ failure. The patient becomes unresponsive, severe hypotension ensues, and the patient develops shallow respirations and cold, cyanotic or mottled skin. Laboratory tests results indicate organ dysfunction.

Medical Management

The most important approach to treating cardiogenic shock is to correct the underlying problem, reduce any further demand on the heart, improve oxygenation, and restore tissue perfusion. For example, if the ventricular failure is the result of an acute MI, emergency percutaneous coronary intervention may be indicated. Major arrhythmias are corrected because they may have caused or contributed to the shock. If the patient has hypervolemia, diuresis is indicated. Diuretics, vasodilators, and mechanical therapies, such as continuous renal replacement therapy, have been used to reduce the circulating blood volume. If hypovolemia (low intravascular volume) is suspected or detected through hemodynamic pressure readings, the patient is given IV volume expanders (e.g., normal saline solution, lactated Ringer solution, albumin) to increase the amount of circulating fluid. The patient is placed on strict bed rest to conserve energy. If the patient has hypoxemia, as detected by pulse oximetry or ABG analysis, oxygen administration is increased, often under positive pressure when regular flow is insufficient to meet tissue demands. Intubation and sedation may be necessary to maintain oxygenation. The settings for mechanical ventilation are adjusted according to the patient's oxygenation status and the need for conserving energy. Ventilator management is discussed in Chapter 55.

PERICARDIAL EFFUSION AND CARDIAC TAMPONADE

Pericardial effusion (accumulation of fluid in the pericardial sac) may accompany pericarditis, advanced HF, metastatic carcinoma, chemotherapy, cardiac surgery, or trauma.

Pathophysiology

Normally, the pericardial sac contains less than 50 mL of fluid, which is needed to decrease friction for the beating heart. An increase in pericardial fluid raises the pressure within the pericardial sac and compresses the heart. This has the following effects:

- Increased right ventricular end-diastolic pressure (RVEDP) and left ventricular end-diastolic pressure (LVEDP)
- Decreased venous return
- Inability of the ventricles to distend and fill adequately

Pericardial fluid may accumulate slowly without causing noticeable symptoms until a large amount accumulates. However, a rapidly developing effusion can stretch the pericardium to its maximum size and, because of increased pericardial pressure, venous return to the heart is obstructed and the amount of blood pumped out with each contraction is reduced, which decreases CO. The result is cardiac tamponade (e.g., compression of the heart).

Clinical Manifestations and Assessment

The patient may report a feeling of fullness within the chest or may have substantial or ill-defined pain. The feeling of pressure in the chest may result from stretching of the pericardial sac. Because of increased pressure within the pericardium, venous pressure tends to increase, as evidenced by engorged neck veins during inspiration. This rise in venous pressure and vein distension during inspiration is known as Kussmaul sign (Mansoor & Karlapuclir, 2015). If hemodynamic pressures are monitored, the nurse will note equivalent diastolic pressures in all chambers, so that right and left atrial pressures, RVEDP, LVEDP, and pulmonary artery diastolic pressures become equal or nearly equal (a difference of less than 3 to 5 mm Hg) (Imazio, 2014). Other signs include dyspnea, cough, and labile or low blood pressure. Systolic blood pressure that is markedly lower during inhalation is called pulsus paradoxus. The difference in systolic pressure between the point that is heard during exhalation and the point that is heard during inhalation is measured. Pulsus paradoxus exceeding 10 mm Hg is abnormal. A pericardial friction rub may be heard. The cardinal signs of cardiac tamponade are falling systolic blood pressure, narrowing pulse pressure (difference between the systolic and diastolic pressure, should normally be above 40 mm Hg), rising venous pressure (increased JVD) during inspiration, and distant (muffled) heart sounds (Fig. 15-4). If untreated, shock and death can result.

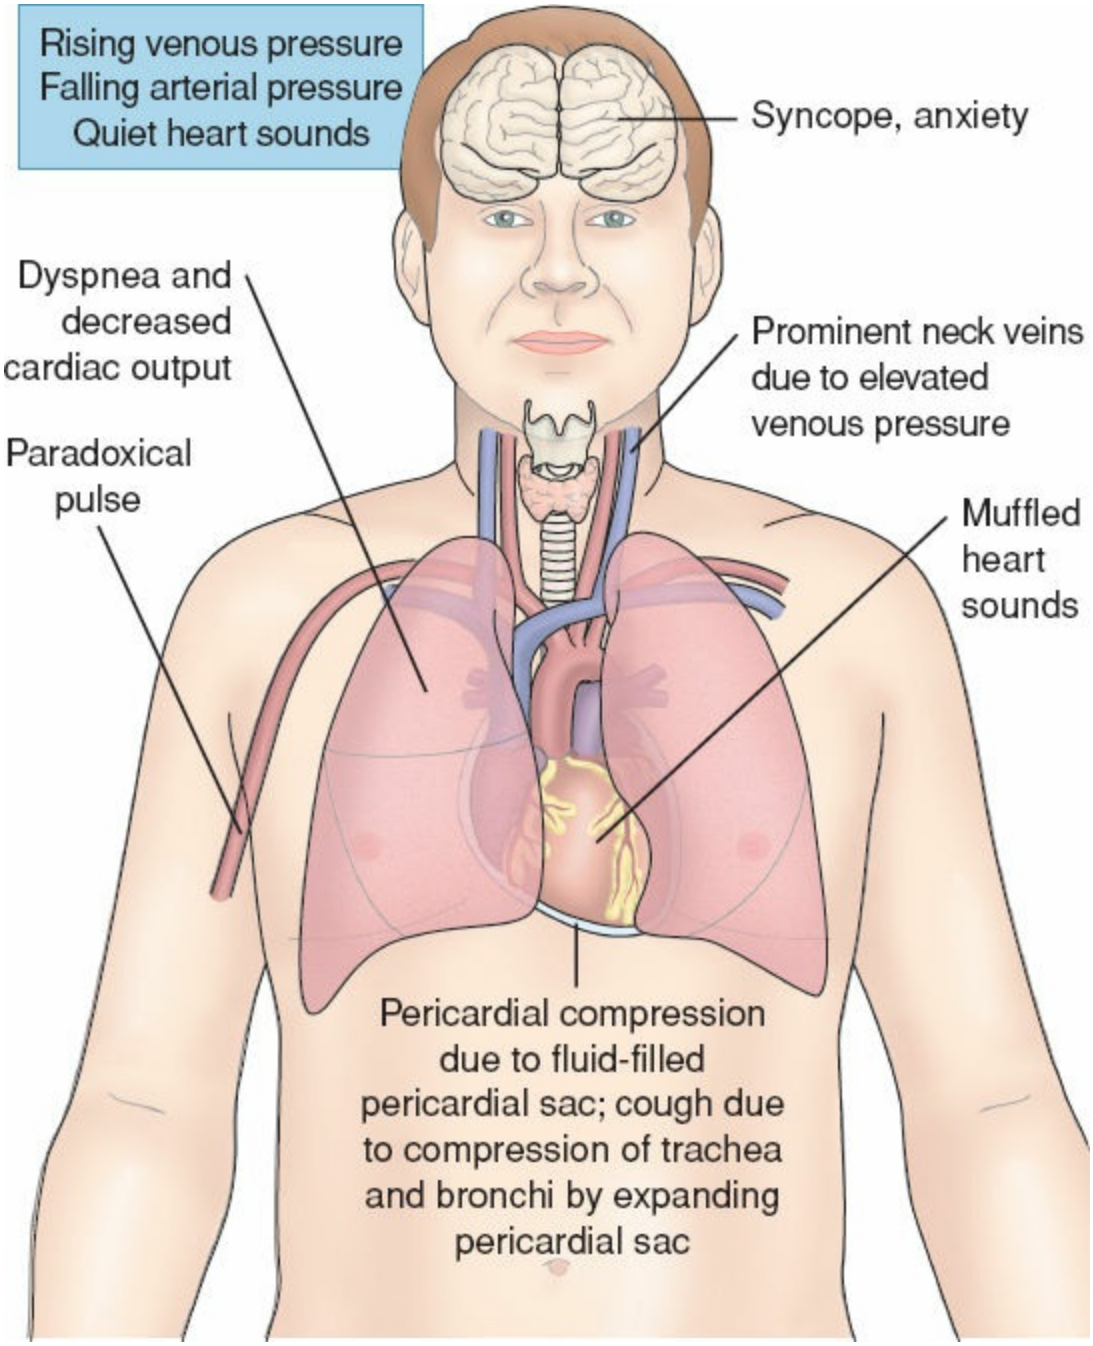

FIGURE 15-4 Assessment findings in cardiac tamponade resulting from pericardial effusion include feelings of faintness, shortness of breath, and anxiety from decreased cardiac output; cough from pressure created in the trachea from swelling of the pericardial sac; distended neck veins from rising venous pressure; Kussmaul sign; paradoxical pulse; and muffled or distant heart sounds.

A chest x-ray shows a large pericardial effusion. An echocardiogram is performed to confirm the diagnosis.

Medical and Nursing Management

Pericardiocentesis

If cardiac function becomes seriously impaired as a result of pericardial effusion, pericardiocentesis (puncture of the pericardial sac to aspirate pericardial fluid) is performed to remove fluid from the pericardial sac (Fig. 15-5). The major goal of this procedure is to prevent cardiac tamponade, which restricts normal heart filling and contraction.

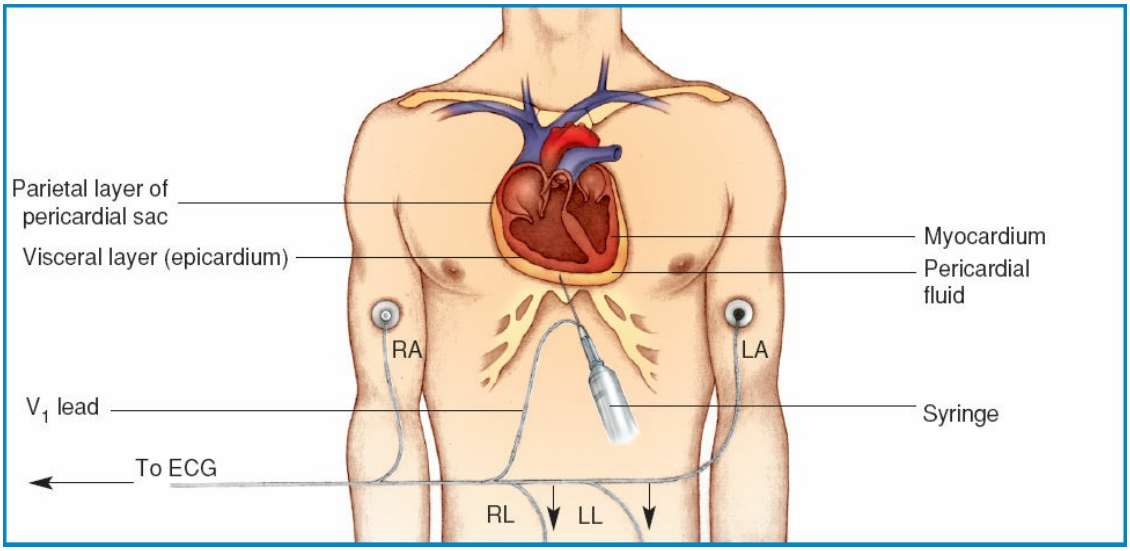

FIGURE 15-5 Pericardiocentesis. (From Lippincott Williams & Wilkins. (2010). *Cardiovascular care made incredibly visual* (2nd ed., p. 231). Philadelphia, PA: Lippincott Williams & Wilkins.)

During the procedure, vital signs, oxygen saturation, ECG and, if applicable, hemodynamic pressures are measured. Emergency resuscitation equipment should be readily available. The head of the bed is elevated to 45 to 60 degrees, placing the heart in proximity to the chest wall so that the needle can be inserted into the pericardial sac more easily. If a peripheral IV line is not already in place, one is inserted, and a slow IV infusion is started in case it becomes necessary to administer emergency medications or blood products.

The pericardial aspiration needle is attached to a 50-mL syringe by a three-way stopcock. Several possible sites are used for pericardial aspiration. Typically, ultrasound imaging is used to guide placement of the needle into the pericardial space. The needle is advanced slowly until it has entered the pericardium and fluid is obtained.

A resulting decrease in central venous pressure and an associated increase in blood pressure after withdrawal of pericardial fluid indicate that the cardiac tamponade has been relieved. The patient almost always feels immediate relief. If there is a substantial amount of pericardial fluid, a small catheter may be left in place to drain recurrent accumulation of blood or fluid. Pericardial fluid is sent to the laboratory for examination for tumor cells, bacterial culture, chemical and serologic analysis, and differential blood cell count.

Complications of pericardiocentesis include ventricular or coronary artery puncture, arrhythmias, pleural laceration, gastric puncture, and myocardial trauma. After pericardiocentesis, the patient's heart rhythm, blood pressure, venous pressure, and heart

sounds are monitored to detect possible recurrence of cardiac tamponade. If it recurs, repeated aspiration is necessary. Cardiac tamponade may require surgical treatment by open pericardial drainage called a pericardiotomy.

Pericardiotomy

Recurrent pericardial effusions, usually associated with neoplastic disease, may be treated by a pericardiotomy (pericardial window). Under general anesthesia, a portion of the pericardium is excised to permit the pericardial fluid to drain continuously into the mediastinum and is reabsorbed via lymphatics (Imazio, 2014). The nursing care is the same as that for other cardiac surgery (see Chapter 14).

CARDIAC ARREST

Cardiac arrest occurs when the heart ceases to produce an effective pulse and circulate blood.

Pathophysiology

Cardiac arrest may be caused by a cardiac electrical event such as ventricular fibrillation, progressive profound bradycardia, or when there is no heart rhythm at all (asystole). Cardiac arrest may follow respiratory arrest; it may also occur when electrical activity is present but there is ineffective cardiac contraction or circulating volume, which is called pulseless electrical activity (PEA). PEA can be caused by hypovolemia (e.g., with excessive bleeding), hypoxia, hypothermia, hyperkalemia, massive PE, MI, and medication overdose (e.g., beta blockers, calcium-channel blockers).

Clinical Manifestations and Assessment

In cardiac arrest, consciousness, pulse, and blood pressure are lost immediately. Ineffective respiratory gasping may occur. The pupils of the eyes begin dilating within 45 seconds. Seizures may or may not occur.

The risk of irreversible brain damage and death increases with every minute from the time that circulation ceases. The interval varies with the age and underlying condition of the patient. During this period, the diagnosis of cardiac arrest must be made, and measures must be taken immediately to restore circulation.

Emergency Management: Cardiopulmonary Resuscitation

Cardiopulmonary resuscitation (CPR) provides blood flow to vital organs until effective circulation can be reestablished. Once loss of consciousness has been established, the resuscitation priority for the adult in most cases is placing a phone call to activate the code team or the emergency medical system (EMS). The "A-B-Cs" (airway, breathing, and circulation) of CPR were replaced with a new standard from the American Heart Association in 2010 and continued in 2015. "C-A-B" (compression, airway, and breathing) is the new sequence for CPR in basic life support (Box 15-3). Compressions are performed first. Exceptions to this include near-drowning and respiratory arrest situations for which 2 minutes of conventional CPR (A-B-C) with rescue breathing should be performed before activating the EMS (Hazinski, 2010, 2015).

Resuscitation of adults consists of the following steps:

1. Establish unresponsiveness: no breathing or no normal breathing (gasping). Activate EMS and get defibrillator or automatic external defibrillator (AED).
2. Check pulse at carotid artery for no more than 10 seconds.
3. Perform chest compressions to a depth of at least 2 in for 30 times allowing for chest recoil after each compression.
4. Airway/breathing: Open airway, give 2 quick breathes followed by 30 compressions.
5. Defibrillation: Shock with standard defibrillator or AED for ventricular tachycardia and ventricular fibrillation.

BOX 15-3 Performing One-Person CPR

1. Establish unresponsiveness by asking, "Are you okay?" Tap or gently shake the patient along with recognition of no breathing or no normal breathing (i.e., only gasping).
2. After initiating the emergency response team or calling for a defibrillator when a patient is unresponsive, position the patient supine on a hard surface.

Unless a definite pulse is felt, initiate chest compressions.

3. Place one hand on top of the other on the lower half of the sternum between the nipples, with elbows locked. Compress the chest 2 in (or one third the depth of the chest) at a rate of 100–120 compressions per minute, keeping your hands on the chest. Allow equal time for compressions and full chest recoil. Continue for 30 compressions, then give 2 ventilations and resume compressions quickly for 5 cycles (2 minutes) before rechecking the pulse.

If the patient is already being monitored or is immediately placed on the monitor using the multifunction pads or the quick-look paddles (found on most defibrillators) and the ECG shows ventricular tachycardia or ventricular fibrillation, immediate defibrillation rather than CPR is the treatment of choice (Boggust, 2016). Survival from pulseless ventricular tachycardia or ventricular fibrillation is inversely related to the time interval between its onset and termination. Optimization occurs with CPR and advanced cardiac life support, including defibrillation and drug therapy, if they are provided at the earliest opportunity (Ornato, 2016). If the patient has not been defibrillated within 10 minutes, the chance of survival is close to zero. Refer to Chapter 17 for more details on

defibrillation.

Recent research on CPR performed in the field for persons in out-of-hospital cardiac arrest by bystanders supports eliminating mouth to mouth or rescue breathing and using "hands-only" cardiac compression only. No differences in patient survival were seen when bystanders received emergency dispatcher instructions for compression-only versus compression-plus rescue breathing CPR (Myerburg & Castellanos, 2015).

CHAPTER REVIEW

Critical Thinking Exercises

1. Compare the pathophysiology of systolic and diastolic failure.
2. Describe the effect of ACE inhibitors and angiotensin receptor blockers on the renin–angiotensin–aldosterone system (RAAS) and its therapeutic effect for HF.

NCLEX-Style Review Questions

1. Which outcome best demonstrates the effectiveness of treatment for a patient with right ventricular failure?
   a. Clear breath sounds
   b. Oxygen saturation greater than 96%
   c. Moist mucous membranes
   d. Central venous pressure of 4 mm Hg
2. The nurse is caring for a patient with right ventricular failure. What symptom will the patient most likely exhibit?
   a. Crackles on auscultation
   b. Jugular vein distention
   c. Pulmonary edema
   d. Normal CVP
3. A patient with CHF is being discharged home. What instruction will the nurse likely give this patient to assess fluid balance?
   a. Monitor blood pressure
   b. Assess radial pulses
   c. Monitor weight daily
   d. Monitor bowel movements
4. What condition includes the classic signs and symptoms of jugular vein distention, muffled heart sounds, and decreasing systolic pressure?
   a. HF
   b. Pericardial tamponade
   c. Pulmonary edema
   d. Cardiogenic shock

5. What medication is commonly used to treat cardiogenic shock related to hypervolemia?
   a. Diuretics
   b. Beta blockers
   c. Vasoconstrictors
   d. Inotropes

CHAPTER 16

Nursing Management: Patients with Structural, Inflammatory and Infectious Cardiac Disorders

Jeanine L. May

Learning Objectives

After reading this chapter, you will be able to:

1. Define valvular disorders of the heart and describe the pathophysiology, clinical manifestations, and management of patients with mitral and aortic regurgitation and/or stenosis.
2. Describe types of cardiac valve repair and replacement procedures used to treat valvular problems and the care needed by patients who undergo these procedures.
3. Describe the pathophysiology, clinical manifestations, and management of patients with the intracardiac septal defects.
4. Describe the pathophysiology, clinical manifestations, and management of patients with cardiomyopathy.
5. Describe the pathophysiology, clinical manifestations, and management of patients with infections of the heart.
6. Describe the rationale for prophylactic antibiotic therapy for patients with valvular heart disease, rheumatic heart disease, and infective endocarditis.

Structural disorders of the heart present many challenges for the patient, family, and health care team. Dysfunctional heart valves, intracardiac septal defects, cardiomyopathies, and inflammatory and infectious diseases of the heart muscle alter cardiac output (CO) and interfere with the heart's ability to pump blood sufficiently to meet the body's demand for oxygen. Nursing care for patients with these disorders requires an understanding of cardiac anatomy; structure and physiology (function) of heart valves, pericardium, myocardium, and endocardium; as well as knowledge of the causes and management of each disorder. Noninvasive and invasive treatments include options such as medication management, supportive care, valve repair or replacement, septal repair, mechanical circulatory assist devices, and cardiac transplantation. Nurses play an integral role in the care of patients with structural, infectious, and inflammatory cardiac conditions.

VALVULAR DISEASE

Properly functioning heart valves allow blood to flow in one direction through the heart and vasculature. Acquired valvular heart disease is a chronic, progressive disorder that develops slowly, although it can occur acutely in certain conditions. Compensatory mechanisms can maintain equilibrium for an extended period of time, and it may be years before the disease progresses, the patient becomes symptomatic, and require treatment. Common causes include degenerative disease, rheumatic heart disease, and infective endocarditis (inflammation of the inner lining of the heart, the endocardium).

Progression of valvular heart disease can result in heart failure, arrhythmias, stroke, and sudden death. Interventions for the management and treatment of acquired valvular heart disease are aimed at preventing the sequelae of atrial fibrillation (AF), thromboembolism, pulmonary artery hypertension, and heart failure, and significant advances in treatment and outcomes have been made in the past several decades. This is primarily due to the development of management guidelines, improvements in noninvasive monitoring of cardiac function, advancements in valvular reconstruction procedures, and improved prosthetic valves.

A detailed review of normal cardiac valvular anatomy is found in Chapter 12 and shown in Figure 16-1. When heart valves do not close or open properly, blood flow is affected. The turbulent flow of blood through a heart valve opening results in a murmur, as described in Table 16-1. Characteristic stenosis occurs when the opening of the valve is narrowed, valve leaflets fail to open properly and the forward flow of blood through the valve is reduced, as shown in Figure 16-2A. The increase in resistance results in turbulent blood flow. The volume of blood in the chamber increases and the heart is forced to work harder to eject blood through the narrowed valve, resulting in increased afterload and eventually, decreased CO. Refer to Figure 16-3 for pathophysiology of heart failure related to valvular heart disease.

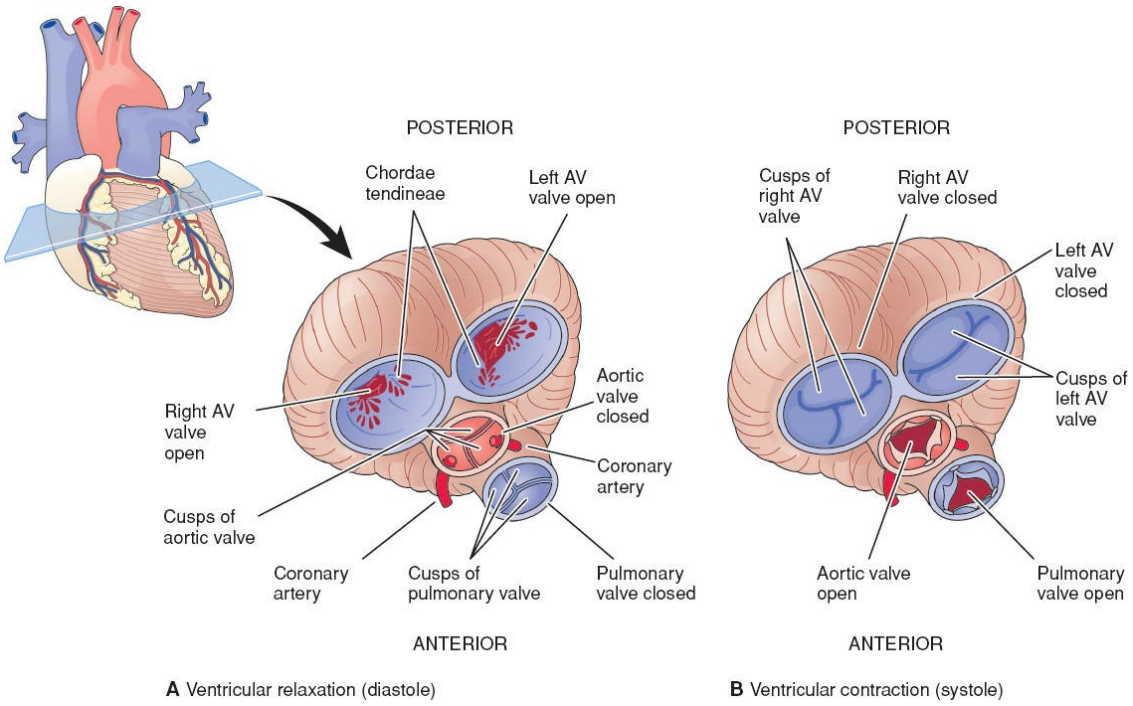

FIGURE 16-1 Heart valves (superior view from anterior, atria removed). Valves keep blood flowing in a forward direction through the heart. A. When the heart is relaxed (diastole), the AV valves are open and blood flows freely from the atria to the ventricles. The pulmonary and aortic valves are closed. B. When the ventricles contract (systole), the AV valves close and blood pumped out of the ventricles opens the pulmonary and aortic valves. ZOOMING IN How many cusps does the right AV valve have? The left? Answer the right AV valve has three cusp (Tricuspid valve) versus two on the left or mitral valve.

Regurgitation, or valvular insufficiency, occurs when valves do not close completely and blood flows backward through the valve, as shown in Figure 16-2. If the aortic valve is affected, blood will flow backward into the left ventricle (LV) during diastole, and if the mitral valve is affected, blood will flow back into the left atrium (LA) during systole. Preload is increased. Mitral valve prolapse (MVP) occurs when the mitral valve does not close properly and the valve leaflets balloon back into the LA during systole. An understanding of the structure and function of heart valves, pathophysiology, as shown in Figures 16-2 and 16-3, and the causes and management of valvular disorders is necessary in order to provide appropriate nursing care for patients with valvular heart disease. Valvular disorders may require surgical repair or replacement of the valve to correct the problem, depending on the severity of symptoms.

TABLE 16-1 Heart Murmurs

Murmur	Timing	Description	Auscultation Site
Mitral Stenosis	Diastole (S2)	Low-pitched, rumbling, decrescendo	Apex
Mitral Regurgitation	Systole (S1)	High-pitched, loud, rumbling	Apex
Aortic Stenosis	Midsystolic (S1)	Loud, crescendo-decrescendo	2nd ICS right sternal border; may radiate into the neck
Aortic Regurgitation	Early Diastole (S2)	High-pitched blowing sound, decrescendo	Left sternal border, at the 3rd ICS

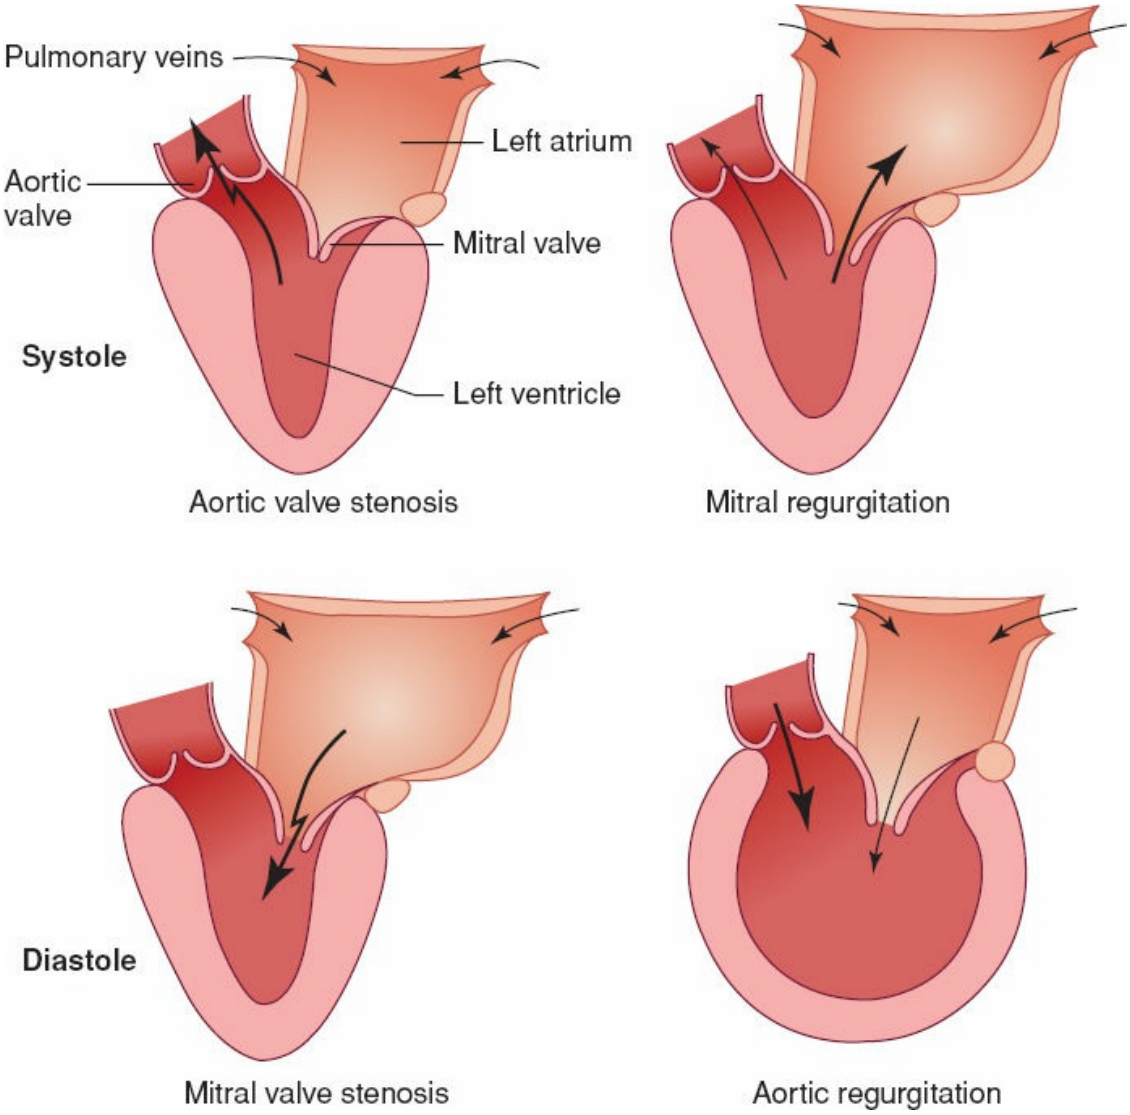

FIGURE 16-2 Alterations in hemodynamic function that accompany aortic valve stenosis, mitral valve regurgitation, mitral valve stenosis, and aortic valve regurgitation. The *thin arrows* indicate the direction of normal flow, and *thick arrows* show the direction of abnormal flow.

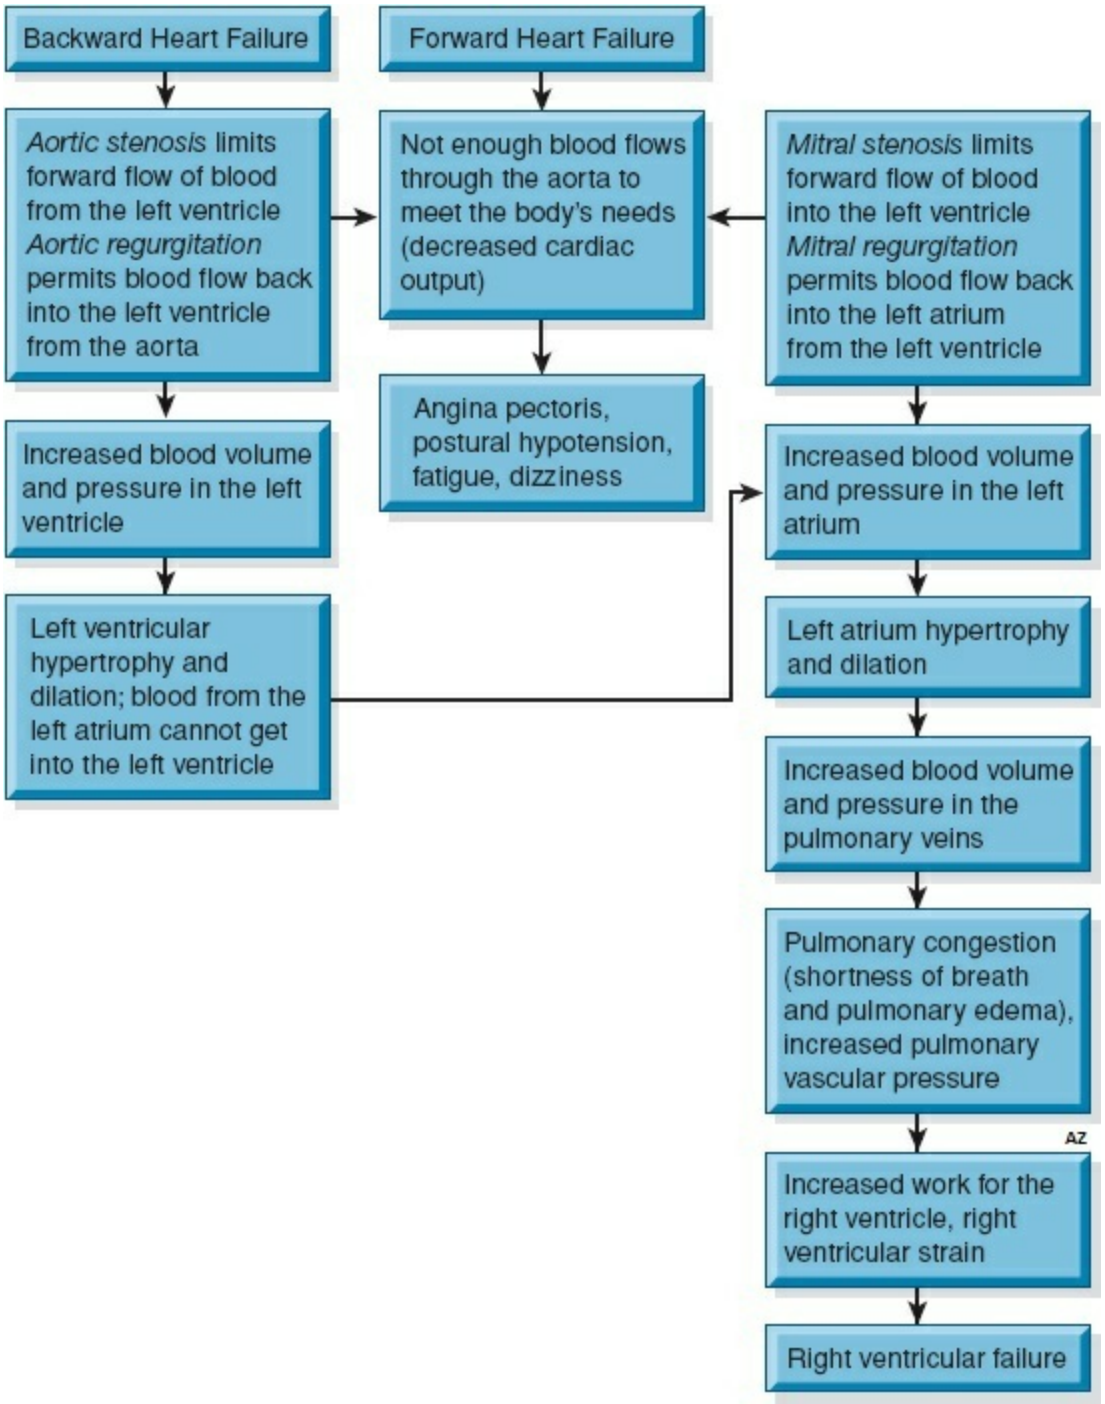

FIGURE 16-3 Pathophysiology: Left-sided heart failure as a result of aortic and mitral valvular heart disease and the development of right ventricular failure.

Pulmonic and tricuspid valve disorders also occur, although with less frequency and usually with fewer symptoms and complications. Tricuspid regurgitation usually occurs with mitral stenosis because of the increased volume and pressure load on the right side of the heart but also can result from infective endocarditis. Tricuspid valve repair is done only if there is severe regurgitation. Tricuspid valve replacement is uncommon. Multivalvular disease is possible: regurgitation and stenosis may occur at the same time in the same or different valves, or one disease may occur in two or more valves.

Nursing Alert
Stenosis is a pressure problem, and regurgitation is a volume problem. Blood volume and pressures are increased behind the affected valve and reduced in front of the affected valve.

MITRAL STENOSIS

In mitral stenosis (MS), the valve opening is narrowed, and blood flow from the LA into the LV is slowed during diastole. MS is slow and progressive. Symptoms may take decades to appear. Over time, heart failure will develop.

Pathophysiology

Normally, the mitral valve opening is 4 to 6 cm^2, but over time as fibrous tissue replaces normal valve tissue, the leaflets begin to thicken and fuse. In cases of marked stenosis, the opening narrows to the width of 1 cm^2 or less. Left atrial pressure increases because of the resistance caused by slowed blood flow into the LV through the narrowed orifice. The LA dilates and hypertrophies because of the increased blood volume. Sluggish atrial blood flow can lead to clot formation and thromboembolism. Because there is no functional valve to protect the pulmonary veins from the backward flow of blood from the atrium, pulmonary venous pressure rises and circulation becomes congested. As a result, the right ventricle (RV) must contract against an abnormally high pulmonary pressure. Pulmonary hypertension increases the work of the RV, and the RV and right atrium become enlarged. Eventually, this results in right-sided heart failure.

Risk Factors

Most often MS is caused by rheumatic fever (RF) or endocarditis, which gradually causes the mitral valve leaflets to thicken and can result in leaflet fusion. Typically MS occurs 20 to 40 years after RF, and symptoms do not develop for another 10 years. Although rheumatic disease is rare in developed countries, MS is still prevalent in developing nations where RF is common (Carabello, 2016). Radiation therapy to the chest area also can result in MS. It is more common in women than in men. Rarely, it can result from a congenital defect.

Clinical Manifestations and Assessment

Although patients with MS can remain asymptomatic, symptoms usually develop when the pressure in the LA becomes greater than that of the LV, after the valve opening is reduced by one third to one half its usual size. Dyspnea on exertion (DOE) results from pulmonary congestion. Patients become progressively fatigued as a result of low CO. Palpitations, chest pain, and paroxysmal nocturnal dyspnea (PND) can occur. As the LA becomes more distended, palpitations, premature beats, AF, and paroxysmal atrial tachycardia may occur. AF is common in people with symptomatic MS, and AF increases the risk of developing a stroke. Dyspnea at rest is likely with severe MS. Other symptoms include cough, sometimes with hemoptysis from ruptured pulmonary veins, hoarseness from the dilated atrium impinging on the left recurrent laryngeal nerve, palpitations, orthopnea, and recurrent respiratory infections. Later, symptoms of right heart failure, including peripheral edema and ascites, occur.

A loud S1 and an opening snap can be heard because of the elevated left atrial pressure. The opening snap is a high-pitched sound heard in early diastole (S2) by the opening of a stenotic valve. The murmur is caused by turbulent blood flow through the abnormally tight valve opening from the LA into the LV. Due to the increased blood volume and pressure, the atrium dilates and becomes electrically unstable, leading to atrial arrhythmias. The pulse can be irregular because of AF. Echocardiography is the most sensitive and specific noninvasive method to diagnose MS and is used to evaluate valve morphology and to measure cardiac pressures. Cardiac catheterization is not indicated unless clinical findings and echo results are discordant.

MITRAL VALVE PROLAPSE

In MVP, a portion of one or both mitral valve leaflets bulge back into the LA during systole, usually with little or no mitral regurgitation (MR). Rarely, the leaflet stretches to the point where the valve does not remain closed during systole and then blood flows from the LV back into the LA.

Pathophysiology

Myxomatous degeneration (pathologic weakening of connective tissue) can cause one or both of the valve leaflets to become enlarged and floppy, causing them to billow into the LA during systole. Over time, as the leaflets prolapse, they can stretch to a degree where the leaflet edges do not fully coapt, or close, resulting in MR.

Risk Factors

Female gender and family history are associated with MVP. It often occurs in people with Marfan syndrome, a connective tissue disorder.

Clinical Manifestations and Assessment

MVP is commonly asymptomatic. However, over time, fatigue, dyspnea, palpitations, and chest pain may develop. Atypical chest pain is not related to activity and may be caused by abnormal stress placed on the chordae tendineae and papillary muscles. Shortness of breath (SOB) is not correlated with activity levels or pulmonary function.

Cardiac auscultation may reveal a mitral midsystolic click. This is a sign that a valve leaflet is ballooning into the LA. A late systolic murmur may be heard if progressive valve leaflet stretching and regurgitation have occurred. Echocardiography is used to diagnose and monitor the progression of MVP.

MITRAL REGURGITATION

MR, also termed *mitral insufficiency,* is the backward flow of blood from the LV into the LA during systole because the valve fails to close completely. Disease processes, including MVP, that alter valve leaflets, mitral annulus, chordae tendineae, and the papillary muscle may result in MR.

Pathophysiology

When the mitral valve leaflets thicken, fibrose, and contract, they cannot close completely. With each heartbeat, blood is forced backward into the LA during systole. Regurgitation of blood into the LA causes left atrial pressure to rise. The LA stretches to accommodate the increased volume, and left atrial dilation occurs. During diastole, regurgitant blood from the LV increases volume load in the LA. With chronic MR, hemodynamic changes occur slowly. Over time, compensatory left ventricular dilation and hypertrophy occur to maintain a normal CO. Eventually this leads to left ventricular failure. The backward flow of blood from the LV reduces blood volume flowing into the atrium from the lungs, and pulmonary venous pressure increases. Pulmonary congestion results, elevating pulmonary artery pressure; this adds further strain on the RV, causing enlargement and right ventricular failure.

Risk Factors

MR is more common in older adults and can result over time from normal aging. Having MVP or mitral valve stenosis can lead to the development of chronic primary MR, although most people with MVP never develop severe regurgitation. Rheumatic heart disease can result in a thick, rigid mitral valve that does not open and close completely, leading to MR.

Clinical Manifestations and Assessment

Patients with chronic MR can remain asymptomatic for years; symptoms develop gradually. As the LV becomes progressively impaired and CO diminishes, fatigue, tachycardia, and weakness can occur. As left atrial pressure increases, orthopnea, DOE, and PND result from pulmonary congestion. Palpitations are related to a hyperdynamic LV and/or AF. Peripheral edema and ascites occur when the RV fails. Acute MR (discussed shortly) manifests as severe left-sided heart failure. Patients may report a sudden inability to breathe accompanied by chest pain.

Physical examination may reveal a hyperdynamic point of maximal impulse, displaced leftward and downward because of the hypertrophied LV. A holosystolic (pansystolic) murmur is heard as a high-pitched, blowing sound at the apex; radiation to the axilla is possible. An S3 may be present because of increased, rapid blood flow into the ventricle during diastole.

Chest x-ray may reveal left ventricular and left atrial enlargement. An echocardiogram provides information regarding left ventricular size and function, left atrial size, and pulmonary artery pressures as well as the anatomy of the valve. Also, echocardiography is used to monitor the severity and progression of MR. Cardiac catheterization may be used if there is a discrepancy between clinical and noninvasive findings to determine the severity of MR.

ACUTE MITRAL REGURGITATION

Acute MR occurs abruptly, when papillary muscle rupture occurs as a complication of myocardial infarction (MI) or if infective endocarditis or trauma leads to rupture of the chordae tendineae. This is a cardiac emergency because of the sudden and severe hemodynamic compromise. It is almost always symptomatic.

Pathophysiology

An acute MI can damage the ventricular wall and disrupt the attachment of the papillary muscle or the chordae tendineae, resulting in acute MR. Without a normally functioning valve to direct the flow of blood forward, a large amount of blood from the LV flows backward into the LA. This compromises forward flow of blood and CO is diminished, which can lead to cardiogenic shock. Compensatory mechanisms lead to an increase in systemic vascular resistance (SVR), which can worsen regurgitation. At the same time, additional blood flows back into the LA causes an increase in left atrial pressure and forces blood back into the pulmonary circulation.

Clinical Manifestations and Assessment

Signs of left- and right-sided heart failure are seen in acute MR: severe SOB, pallor, tachycardia, crackles, and hypotension, as well as peripheral edema, jugular venous distention (JVD), and ascites. Poor tissue perfusion is common as is acute pulmonary decompensation.

Rapid assessment with an echocardiogram is necessary to establish a diagnosis. Often the LA and ventricle are normal in size, and systolic function can be hyperdynamic or normal; also a flail leaflet may be seen.

AORTIC STENOSIS

Aortic stenosis (AS) is narrowing of the valve opening between the LV and the aorta, resulting in obstruction of blood flow across the valve.

Pathophysiology

Progressive narrowing of the valve orifice develops gradually over several years to several decades, increasing afterload. Because the narrowing occurs slowly, the LV is able to adapt by contracting more slowly and stronger than normal, forcibly squeezing the blood through the smaller opening. Normal blood volume in the LV is maintained for a while, but, eventually, left ventricular pressure increases, causing the ventricular wall to hypertrophy to maintain CO. Diastolic dysfunction leads to increased work of the heart, which results in left ventricular failure. This results in elevated left atrial pressure, pulmonary congestion, and, ultimately, heart failure.

Risk Factors

The buildup of calcium deposits on heart valves is the most common cause of AS. As calcification progresses, valve leaflets become more rigid and outflow from the LV becomes obstructed. Acquired AS is common in those over 70 years of age, particularly in males. Besides degeneration of the valve, rheumatic heart disease also can lead to AS. Having a congenital malformation, such as a bicuspid aortic valve, is another risk factor.

Clinical Manifestations and Assessment

Since it develops slowly, and the LV is able to compensate, AS can be asymptomatic for decades. Exertional dyspnea or decreased exercise tolerance can be early signs. The triad of symptoms associated with AS includes angina due to LV hypertrophy and diminished coronary blood flow; dyspnea due to increased pulmonary venous pressure from LV failure; and syncope, usually with exertion, due to a reduction in cerebral blood flow that occurs when vasodilation leads to a decrease in arterial pressure in the setting of fixed CO. With AS, the heart rate will increase in an attempt to increase CO, but CO does not improve. Symptomatic AS has a poor prognosis if untreated.

Nursing Alert
Patients with AS have SAD symptoms: syncope, angina, and dyspnea.

On physical examination, a thrill, or a vibration, may be felt. The vibration is caused by turbulent blood flow across the narrowed valve orifice. A loud, systolic ejection murmur may be heard over the aortic area (second intercostal space, right sternal border) and may radiate into the neck. This is caused by blood flowing through the narrowed opening of the stenotic valve. The patient should be instructed to lean forward during auscultation, especially upon exhalation, to accentuate the murmur. An S4 gallop may be heard.

Echocardiography is used to diagnose and monitor the progression of AS and will demonstrate calcification of the valve or decreased mobility of valve cusps, as well as size and function of LV. Cardiac catheterization can measure the severity of AS when noninvasive testing is inconclusive.

AORTIC REGURGITATION

AR, also referred to as aortic insufficiency, is the backward flow of blood into the LV from the aorta during diastole. This occurs when the valve leaflets do not close completely.

Pathophysiology

When the aortic valve is incompetent, blood from the aorta returns to the LV during diastole in addition to the blood normally delivered by the LA. The LV dilates in an attempt to accommodate blood volume overload, causing hypertrophy. Dilatation and hypertrophy allow the LV to expel more blood with above-normal force, increasing afterload and, as a result, systolic blood pressure, while maintaining a normal ejection fraction (EF). The arteries attempt to compensate for the higher pressures by reflex vasodilation; the peripheral arterioles relax, reducing peripheral resistance and diastolic blood pressure. Although compensatory mechanisms allow patients to remain asymptomatic for some time despite pressure and volume overload, when left ventricular dysfunction develops, symptoms appear.

Risk Factors

Calcific valve disease and bicuspid aortic valve are the most common risk factors for AR. Because they affect the valve leaflets, rheumatic heart disease and infective endocarditis can cause AR. Disorders affecting the aortic root, such as Marfan syndrome and dissecting aortic aneurysms, can lead to AR, as can chronic hypertension (Nishimura et al., 2014a, 2014b; Otto & Bonow, 2015).

Clinical Manifestations and Assessment

AR is asymptomatic for years, but as the disease progresses, symptoms related to increased stroke volume become apparent. Palpitations, particularly when lying down, and visible neck vein pulsations are a result of the increased force and volume of the blood ejected from the hypertrophied LV. Later symptoms, including dyspnea, fatigue, angina, orthopnea, and pulmonary congestion, signify decreased cardiac reserve and LV failure.

Pulse pressure, the difference between systolic and diastolic pressures, widens, resulting in high systolic and low diastolic blood pressure. Another characteristic sign of AR is the water-hammer pulse, in which the pulse has a rapid upstroke and collapses. Systolic blood pressure in the lower extremities is higher than in the upper extremities. A decrescendo diastolic murmur is heard as a high-pitched blowing sound at the 3rd or (4th) intercostal space (ICS) at the left sternal border with the patient sitting up and leaning forward. If the AR is severe, the murmur may be holodiastolic (throughout the S2) and radiate widely along the left sternal border.

Diagnosis is confirmed by echocardiography; valve morphology, degree of LV hypertrophy, and functional capacity are determined. Cardiac catheterization is not necessary in most patients with AR. Patients with symptoms usually have echocardiograms every 4 to 6 months, and those without symptoms have annual echocardiograms. Exercise stress testing will assess functional capacity and symptom response.

MEDICAL AND NURSING MANAGEMENT OF VALVULAR DISORDERS

Patients with any of the valvular diseases discussed thus far in the chapter share some commonalities in medical and nursing management of their varying conditions. No treatment is required for asymptomatic patients with valvular pathology. The goal of medical therapy is not curative; it is symptom relief. Definitive therapy for a valvular problem is mechanical restoration of valve function. Management is guided by findings on the echocardiogram and is aimed at the specific valvular problem, i.e., decreasing regurgitant volume, improving CO, and reducing pulmonary congestion. Beta-blockers (BBs) and calcium channel blockers (CCBs) may be used for rate control, to treat palpitations, for chest discomfort, and for anxiety, and are particularly useful when there is concomitant coronary artery disease. Less commonly, digoxin is given to increase contractility and slow rapid rates to allow for improved ventricular filling. Antiarrhythmics and electrical cardioversion are utilized to restore sinus rhythm, and anticoagulation is indicated if AF is persistent. Diuretics, vasodilators, and sodium restriction may be used to reduce preload and pulmonary congestion. Because patients with severe AS are dependent on preload to maintain CO, diuretics should be used with caution. Angiotensin-converting enzyme inhibitors (ACE-Is) are prescribed to reduce preload, afterload, and hypertension by causing vasodilation. ACE-Is are commonly prescribed for patients with concomitant hypertension but may be avoided in patients with AS because the vasodilation reduces pressure distal to the obstruction without increasing CO and may cause syncope. Afterload reduction may be managed with angiotensin blockers (ARBs), nitrates, or hydralazine. In

acute cases of decompensation, intravenous nitroprusside is the vasodilator used most commonly for afterload reduction, but nitrates should be used with great caution with AS because their use can result in reduced CO.

Nursing Alert
Venous dilation that results from nitroglycerin decreases blood return to the heart, thus decreasing CO and increasing the risk of syncope and decreased coronary artery blood flow. The nurse teaches the patient about the importance of attempting to relieve chest pain with rest before taking nitroglycerin and to anticipate the potential adverse effects (orthostatic hypotension and syncope).

Nursing Alert
Although diuretics and nitrates are used to treat decompensated heart failure in patients with incompetent valves, the nurse understands that caution must be taken if diuretics or nitrates are ordered for a patient with AS. The risk associated with these medications is that preload will be critically reduced and/or systemic arterial blood pressure (with administration of diuretics and nitrates). The treatment for symptomatic AS is valve replacement.

Valvular problems increase the patient's risk of developing bacterial endocarditis. Thrombi may occur on the valve leaflets and, if they embolize, transient ischemic attacks (TIAs) can occur. Daily aspirin is recommended for people who have had documented TIA, even when they are in sinus rhythm. Elimination of caffeine and alcohol may control or reduce symptoms, and the nurse encourages the patient to read labels on over-the-counter products, such as cough medicine, because these products may contain alcohol, caffeine, ephedrine, and epinephrine, which may produce arrhythmias and other symptoms. Symptoms may appear or worsen when the heart rate increases, such as during exercise, and also may be triggered by pregnancy or other stress on the body, such as a pulmonary infection. Strenuous activity is avoided since it increases workload of the heart.

Treatment of arrhythmias, heart failure, or other complications is described in Chapters 15 and 17. If symptoms develop on optimal medical therapy, then surgical repair with valvuloplasty or valve replacement should be considered before ventricular dysfunction worsens. Intra-aortic balloon counterpulsation may be considered as it aids afterload reduction until surgery is performed; however, it is contraindicated in AR because it increases regurgitation.

Assessing Valvular Heart Disorders

Heart and lung sounds are auscultated and peripheral pulses palpated. The nurse assesses the patient with valvular heart disease for signs and symptoms of heart failure, arrhythmias, and other symptoms such as dizziness, syncope, weakness, or chest pain. The nurse teaches the patient about the diagnosis, the progressive nature of valvular disease, and treatment, and also teaches the patient to report new symptoms or changes in symptoms to the health care provider. Treatment is not required until the patient becomes symptomatic. Management should include cardiovascular risk reduction of hyperlipidemia, hypertension, tobacco use, physical inactivity, and weight. Patients should be monitored for signs of activity intolerance, including excessive fatigue, palpitations, diaphoresis, pallor, dyspnea, and tachycardia, and should be instructed to rest if symptoms occur.

Nursing Alert
Evaluating the patient's response to physical activity is important because a decrease in activity tolerance may indicate deterioration in cardiac function, not overexertion. This occurs when the heart can no longer increase CO sufficiently to meet the oxygen demands associated with exercise.

VALVE REPAIR AND REPLACEMENT PROCEDURES

Most patients with valvular heart disease are managed medically until symptoms become unmanageable or the ventricles begin to fail. However, medication cannot cure valve disease. If the condition worsens, or if medication fails to control symptoms, a percutaneous intervention or surgery is indicated to repair or replace diseased heart valves. Percutaneous balloon valvotomy is a nonsurgical procedure used to increase the opening of a stenotic (narrowed) valve, typically performed in the cardiac catheterization laboratory. Although the balloon valvotomy is available for AS, research reveals it is relatively ineffective in improving aortic flow and has a mortality rate postprocedure that is similar to that in untreated patients. Thus, balloon aortic valvotomy generally has been abandoned but may be used when immediate temporary relief is required (Carabello, 2016). For a percutaneous balloon mitral valvotomy, a guide wire is advanced percutaneously from the femoral vein to the right atrium, through a puncture in the septum to the mitral valve, as shown in Figure 16-4. A balloon catheter is placed over the guide wire and positioned so that the balloon tip is directly inside the narrowed valve. The balloon is inflated and deflated several times to widen the valve opening. During the procedure, an echocardiogram may be done to determine the mobility of the valve leaflets and function of the valve. The procedure is contraindicated for patients with heavily calcified valves, left atrial thrombus, or moderate to severe coexisting MR. Patients may have some MR after the procedure. Other potential complications include left-to-right atrial shunts through an atrial septal defect caused by the procedure and emboli from dislodged left atrial thrombus.

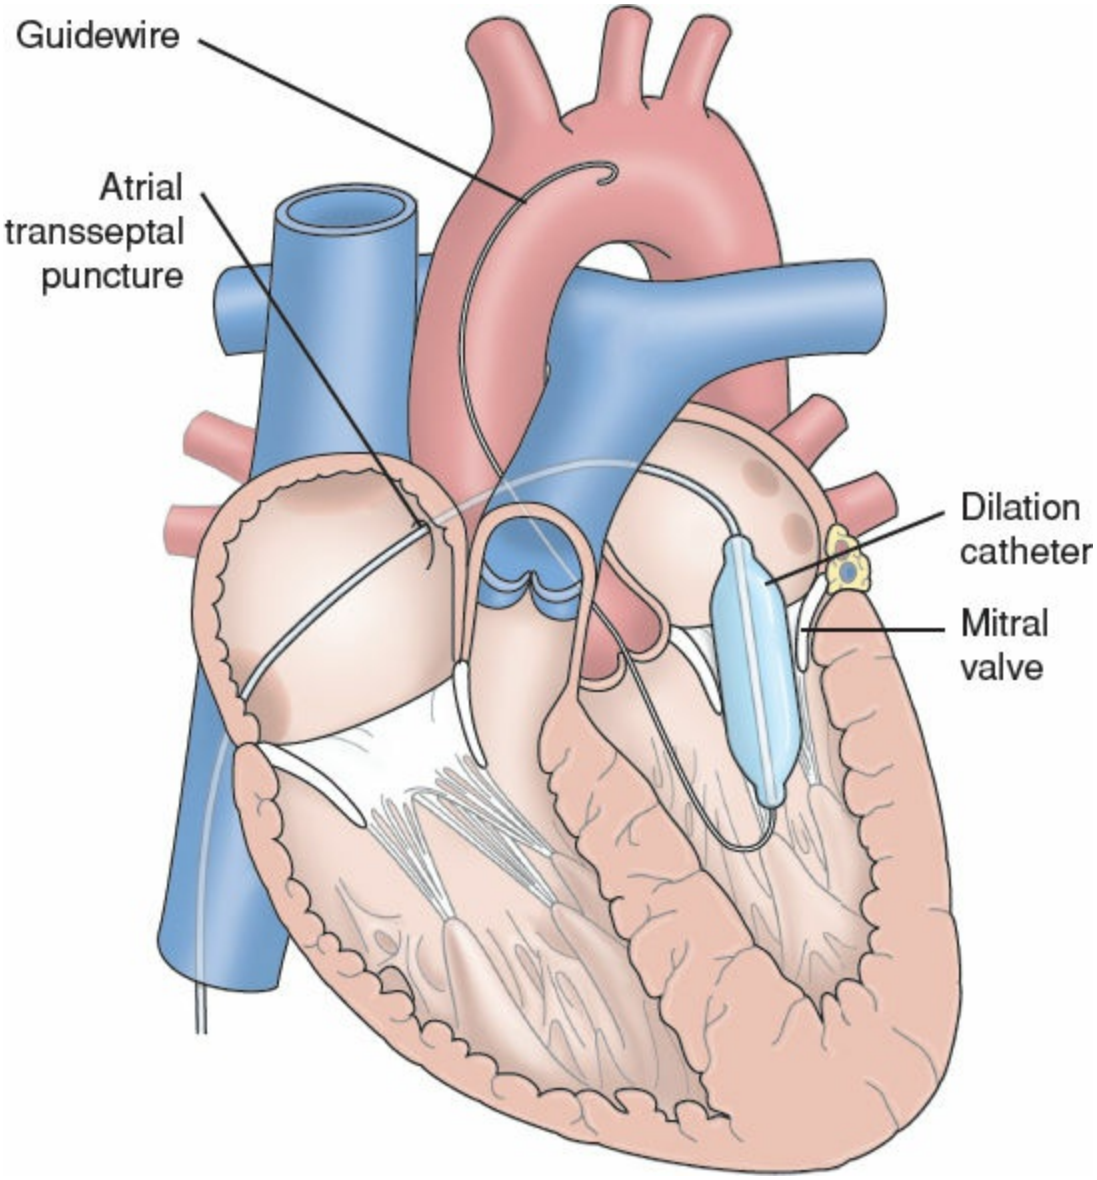

FIGURE 16-4 Balloon valvuloplasty: Cross section of heart illustrating the guide wire and dilation catheter placed through an atrial transseptal puncture and across the mitral valve. The guide wire is extended out from the aortic valve into the aorta for catheter support.

Concept Mastery Alert

Commissurotomy is the splitting or separating of fused cardiac valve leaflets. Valvuloplasty is a general term for repairing a stenosed or regurgitant cardiac valve by commissurotomy, annuloplasty (repair of a cardiac valve's outer ring), leaflet repair, or chordoplasty.

The decision to proceed with a transcatheter versus surgical approach and valve repair or replacement should be made after a detailed discussion between the patient and medical team, and the discussion should include the patient's preferences, risks of anticoagulant therapy, and the possible need for and risk of a repeat surgery (Nishimura et al., 2014a, 2014b).

Regurgitation can be treated surgically by annuloplasty (repair of a cardiac valve's outer

ring) (see Fig. 16-5), valve leaflet repair (see Fig. 16-6), and chordoplasty (repair of the tendinous fibers that connect the edges of the atrioventricular valve leaflets to the papillary muscles). Mitral annuloplasty narrows the diameter of the valve's orifice to treat valvular regurgitation. An annuloplasty ring prosthesis is sutured to the annulus and leaflets, creating an annulus of the desired size, as shown in Figure 16-5.

Leaflet repair, as shown in Figure 16-5, includes removal of excess leaflet tissue and the repair of leaflet damage from stretching or tearing by using pericardial or synthetic patches.

For example, mitral valve leaflets are often repaired by chordoplasty. Stretched chordae tendineae can be shortened, lengthened, or replaced with synthetic chordae. Torn chordae can be reattached to the leaflet. Generally valvular repair is preferred over valve replacement since it avoids the risks associated with cardiopulmonary bypass, anticoagulation for artificial mechanical valve, and lessens pain and recovery time.

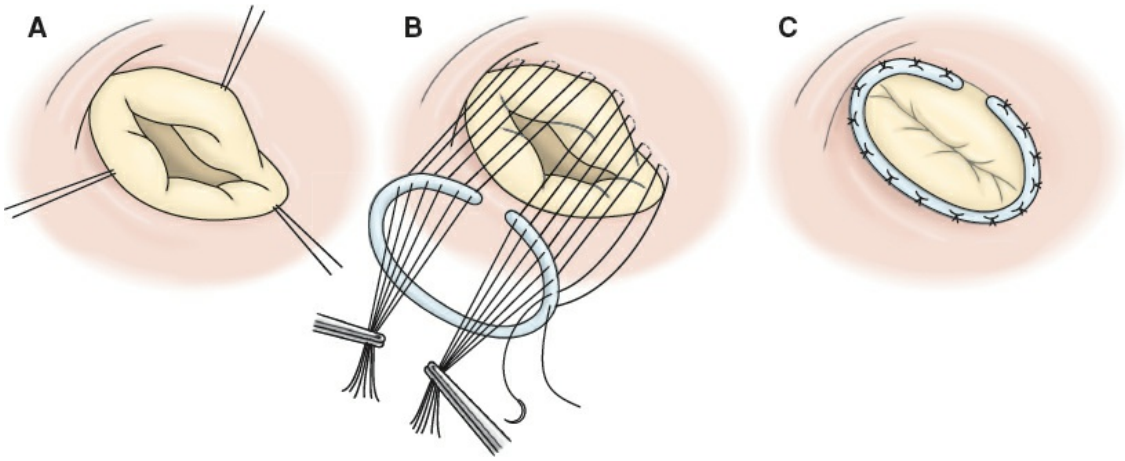

FIGURE 16-5 Annuloplasty ring insertion. A. Mitral valve regurgitation; leaflets do not close. B. Insertion of an annuloplasty ring. C. Completed valvuloplasty; leaflets close.

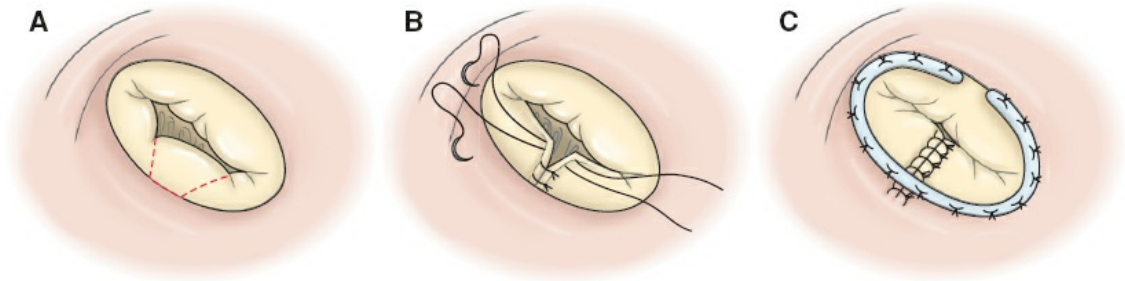

FIGURE 16-6 Valve leaflet resection and repair with a ring annuloplasty. A. Mitral valve regurgitation; the section indicated by dashed lines is excised. B. Approximation of edges and suturing. C. Completed valvuloplasty, leaflet repair, and annuloplasty ring.

Surgery is too risky for some patients. A minimally invasive treatment option, called the MitraClip, was recently approved by the FDA to treat high-risk patients with MR. A small clip is attached to the leaky mitral valve, allowing it to close more completely (https://mitraclip.com/can_the_mitraclip_procedure_help_me; accessed September 17, 2016). This transcatheter mitral valve repair (TMVr) procedure may be used in people with severe degenerative MR who are not candidates for surgery. Patients who are older, symptomatic, and very high risk or not surgical candidates may benefit from a minimally invasive procedure. A transcatheter aortic valve replacement (TAVR) also can be performed

for aortic valve pathology. A collapsible artificial valve is inserted into the stenotic aortic valve through a catheter that is inserted either into the femoral artery (transcatheter) or through a small incision in the chest wall allowing insertion through the LV (transapical). Then the replacement valve is positioned in the damaged valve, and, as it expands, it pushes the damaged valve leaflets aside and becomes the functional valve. Rarely, percutaneous aortic balloon valvuloplasty is used as a bridge to valve replacement surgery in an unstable patient. Aortic balloon valvuloplasty is performed by introducing a balloon catheter across the aortic valve and into the LV. As the balloon is inflated, the calcified leaflets are cracked and split open and the valve ring is stretched. Potential complications include AR, emboli, ventricular perforation, rupture of the aortic valve annulus, ventricular arrhythmias, mitral valve damage, and bleeding from the catheter insertion sites.

Surgical procedures include an open commissurotomy (splitting or separating fused cardiac valve leaflets), which is performed to increase the size of the specific valve orifice when the valve is not calcified. Although some valves can be repaired by commissurotomy, most require replacement because of significant calcification or regurgitation.

Surgical valve replacement is the definitive treatment for symptomatic AS. However, surgical valve replacement for MS is indicated when the valvular problem is not amenable to a percutaneous procedure, percutaneous valvotomy failed, or when there is another indication for surgery, such as coronary artery disease, aortic valve disease, or concomitant mitral or tricuspid regurgitation (Nishimura et al., 2014a, 2014b).

Valvuloplasty, the repair of a cardiac valve, can be done percutaneously or surgically. Percutaneous balloon dilatation of stenotic valves is an appropriate alternative to surgical valve replacement or repair in some patients with valvular heart disease. In general, patients do not require continuous anticoagulation when they undergo valvuloplasty.

When surgical valve replacement is indicated, a decision must be made to use either a mechanical or a bioprosthetic (tissue, biologic) valve. Figure 16-7 shows a prosthetic valve replacement surgery. Consideration must be given to durability, risk of thrombosis, survival rates, and technical issues.

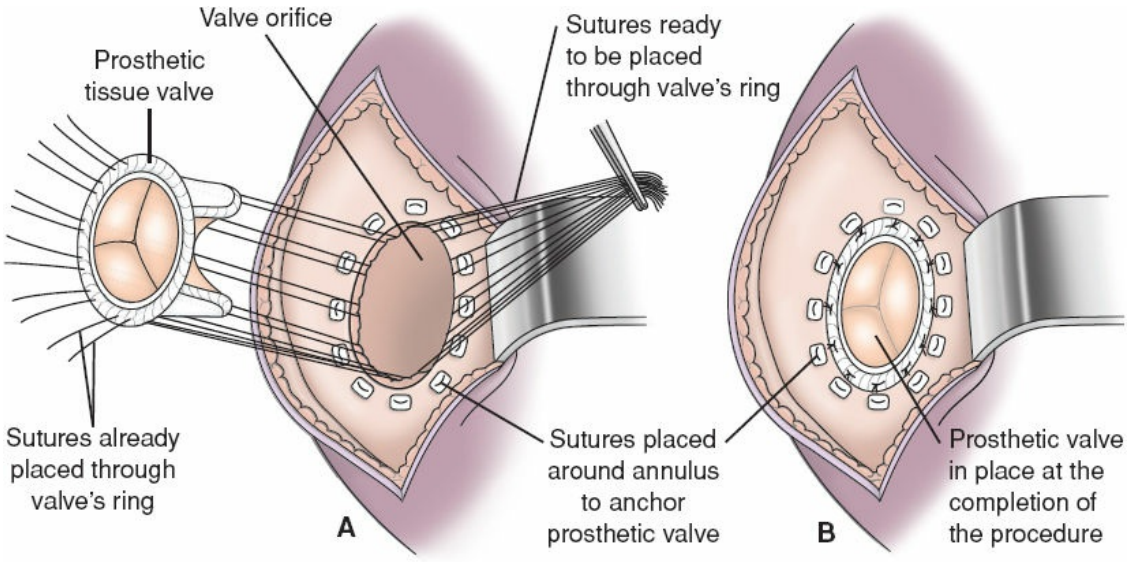

FIGURE 16-7 Valve replacement. A. The native valve is trimmed, and the prosthetic valve is sutured in place. B. Once all sutures are placed through the ring, the surgeon slides the prosthetic valve down the sutures and into the natural orifice. The sutures are then tied off and trimmed.

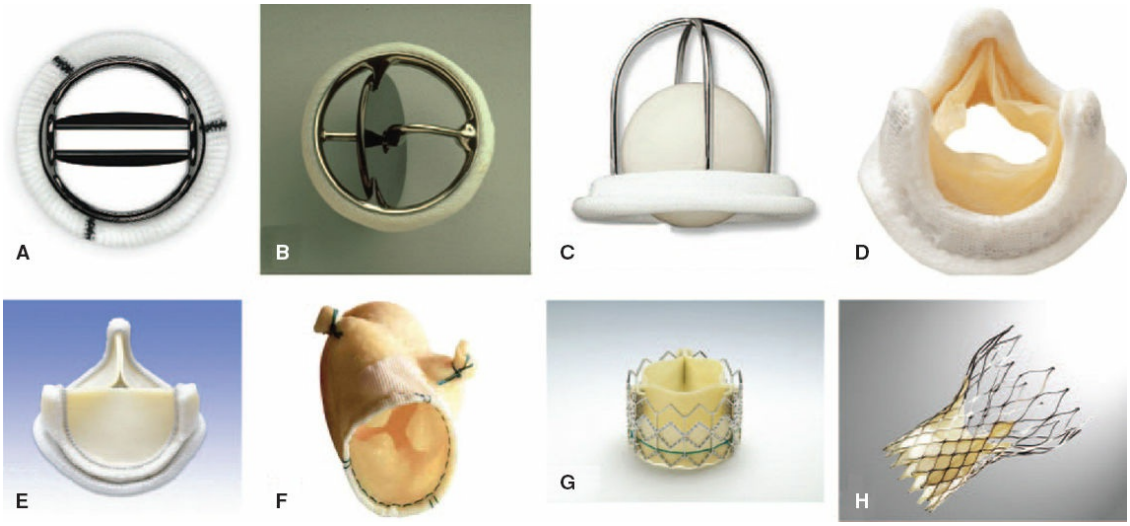

FIGURE 16-8 Common mechanical and tissue valve replacements. Different types of prosthetic heart valves. A. Bileaflet mechanical valve (St. Jude's); this is the most commonly used prosthetic valve, which consists of two semicircular leaflets that pivot on hinges. The leaflets swing partially open and are designed to close so that an acceptable amount of regurgitant blood flow is permitted. B. Monoleaflet, tilting disk mechanical valve (Medtronic Hall). C. Caged ball valve (Starr-Edwards); this valve was discontinued in 2007; however, you may care for patients who had this valve implanted. D. Stented porcine bioprosthesis (Medtronic Mosaic). E. Stented pericardial bioprosthesis (Carpentier-Edwards Magna). F. Stentless porcine bioprosthesis (Medtronic Freestyle). G. Percutaneous bioprosthesis expanded over a balloon (Edwards Sapien). H. Self-expandable percutaneous bioprosthesis (CoreValve).

Types of Valve Prostheses

Two types of valve prostheses are available: mechanical and bioprosthetic (tissue, biological) and are depicted in Figure 16-8. The advantage of a mechanical valve is durability. The major disadvantage is the need for anticoagulation. Bioprosthetic valves have the advantage that they do not require anticoagulation; however, they are less durable. Age, lifestyle, medical history, and valve location are factors that determine whether a mechanical or biologic valve is used.

Mechanical Valves

Three major types of mechanical valves exist: (a) bi-leaflet valve, (b) tilting disk, and (c) caged-ball. The bi-leaflet valve, manufactured by St. Jude, CarboMedics, and On-X, and the single-tilting disc valve (e.g., Medtronic Hall) are used today; the caged-ball valve (Starr-Edwards) is no longer used because of the higher risk of thromboembolism associated with it.

The age and life expectancy of the patient determine the need for durability of a bioprosthetic valve. Mechanical valves are more durable than bioprosthetic valves and may be more likely to be used in a younger patient. However, patients with mechanical valves require lifelong anticoagulation due to the risk of thromboembolism and valve thrombosis, and with this comes the additional risk of bleeding complications.

Bioprosthetic Valves

Bioprosthetic valves are less durable than mechanical valves because of the structural degeneration that occurs over time. This can lead to the need for reoperation. Generally, older patients have shorter anticipated survival, so the risk of reoperation is less than it would be for a younger person. Because long-term anticoagulation generally is not recommended for bioprosthetic valves after the first 3 months of implantation, these valves are used when anticoagulation is contraindicated or should be avoided, such as in women of childbearing age, patients who are noncompliant with medications and follow-up, patients with a history of bleeding disorders, and others who cannot tolerate long-term anticoagulation. The major disadvantage of tissue valves is that they lack longevity.

Types of bioprosthetic valves include homograft (preserved human cadaver), pericardial, and xenograft (bovine, porcine, or equine). Generally homografts are used for the treatment of valve endocarditis. Newer tissue valves demonstrate improved hemodynamics compared with older models. Refer to Figure 16-8 for additional images of bioprosthetic valves.

Nursing Management: Valvuloplasty and Replacement

Before surgery, compensatory mechanisms allowed the heart to adjust gradually to the valvular pathology; surgery abruptly "corrects" blood flow through the heart. Complications unique to valve replacement are related to the sudden changes in intracardiac blood pressures. With valve replacement for a stenotic valve, blood flow through the heart is improved. Symptoms of the backward heart failure resolve in hours to days. With valve replacement for a regurgitant valve, it may take months for the chamber into which blood had been regurgitating to achieve its optimal postoperative function. Signs and symptoms of heart failure resolve as heart function improves.

Patients with percutaneous valvuloplasty procedures must be assessed for signs and symptoms of emboli and heart failure. Postprocedure care is the same as for patients having percutaneous coronary intervention and is discussed in Chapter 14.

Patient care following valve repair or replacement is similar to that of a patient recovering from coronary artery bypass surgery and is discussed in Chapter 14. In the immediate postoperative phase, attention is given to hemodynamic stabilization: augmenting preload, reducing afterload, and enhancing contractility, recognizing that the heart is adjusting to improved function. Patients are at risk for postoperative complications, including thromboembolism, bleeding, infective endocarditis, arrhythmias, structural deterioration (bioprosthetic valves), and hemolytic anemia.

Thromboembolism is the most common complication of prosthetic valves and can lead to hemodynamic compromise by occluding the valve orifice. Long-term anticoagulation with warfarin, a vitamin K antagonist, is indicated after mechanical valve replacement. Heparin is used as a "bridge" until an acceptable level of anticoagulation is achieved with warfarin. Frequently low-dose aspirin is used with warfarin. Newer oral anticoagulants, such as dabigatran, rivaroxaban, and apixaban, are not used (Nishimura et al., 2014a, 2014b).

The risk of thromboembolism is lower in patients with bioprosthetic valves. Usually low-dose (75 to 100 mg daily) aspirin is recommended. For patients with additional thrombotic risk factors, such as concurrent AF, anticoagulation with warfarin generally is prescribed for 3 months postoperatively. The nurse educates the patient about long-term anticoagulant therapy, including the risks associated with it as well as the need for frequent follow-up appointments and blood laboratory studies. Patients receiving warfarin will have individualized target international normalized ratios (INRs), typically between 2 and 3.5 seconds, and will vary based upon the type of valve.

Prosthetic valve endocarditis occurs more often with tissue valves. It can occur early, within the first 60 days after surgery, or later. Signs include fever, heart failure, embolic events, and new murmur. In general, for a patient with a prosthetic heart valve, if the temperature is higher than 100°F, endocarditis must be excluded by blood culture; whereas for fever with signs of sepsis, broad-spectrum antibiotics must be begun while awaiting culture results (Carabello, 2016). Hemolytic anemia results from the destruction of red blood cells by the movement of the prosthetic valve disk or caged ball.

Conduction disturbances and atrial arrhythmias occur frequently following valve surgery, likely due to circulating catecholamines, myocardial inflammation, and electrolyte imbalances. Digoxin, BBs, and CCBs may be used for the treatment of arrhythmias.

The nurse provides teaching about all prescribed medications: Patients with prosthetic valves require education to prevent infective endocarditis with antibiotic prophylaxis. The American Heart Association (AHA) recommends antibiotic prophylaxis for dental procedures that involve manipulation of gingival tissue, the periapical region of teeth, or perforation of the oral mucosa, not for routine cleaning (Nishimura et al., 2014a, 2014b).

INTRACARDIAC SEPTAL DEFECTS AND REPAIR

The atrial or ventricular septum may have an abnormal opening between the right and left sides of the heart, causing oxygenated blood to be shunted from the left side of the heart, which is under greater pressure, to the right. A small septal defect will be asymptomatic and have minimal effect on heart function, but larger ones may require repair to prevent problems related to excess blood volume in the right side of the heart. Over time, a large defect can cause pulmonary congestion, which can cause elevated right heart pressure; eventually this may cause right heart failure and pulmonary hypertension.

Most large septal defects are repaired during infancy or childhood to prevent later problems. A patent foramen ovale (PFO) is a small atrial septal wall defect (ASD) that may not be detected in an adult until the patient presents with symptoms of a TIA or a stroke. Normally thrombi are filtered out of the blood by the lungs. With an ASD, however, there is a risk that the clot could bypass the lungs and travel directly to the brain, causing a TIA or stroke. AF is common in patients with ASDs and further increases risk of stroke. Closure of the PFO is usually a percutaneous procedure to implant a device to plug the opening. Often anticoagulation with aspirin is prescribed. Small ventricular septal defects (VSDs) are rarely closed in adults unless there is evidence of endocarditis or if valve function is compromised due to the location of the defect. A stitch or pericardial or synthetic patch is used to close the opening. Atrial septal defect repairs have low morbidity and mortality rates. Patients should be taught the importance of infective endocarditis antibiotic prophylaxis for 6 months after the repair.

CARDIOMYOPATHY

Cardiomyopathies are diseases of the myocardium (heart muscle) characterized by mechanical and electrical dysfunction and structural abnormalities. Cardiomyopathy is *not* the result of another disease or dysfunction of the heart (such as valve disease). Cardiomyopathy results from various etiologies that are most frequently genetic and is characterized by abnormal hypertrophy or dilatation of the ventricles. Other causes include autoimmune disorders, excessive alcohol intake, pregnancy, chemotherapeutic agents, or infection (usually viral). Regardless of cause, cardiomyopathy results in impaired CO. Decreased stroke volume stimulates the sympathetic nervous system and the renin–angiotensin–aldosterone response, resulting in increased SVR and increased sodium and fluid retention, which places an increased workload on the heart. These alterations lead to severe heart failure, lethal arrhythmias, myocardial destruction, and death.

DILATED CARDIOMYOPATHY

Dilated cardiomyopathy (DCM) is the most common cardiomyopathy and is distinguished by significant irreversible dilation of the ventricles and systolic dysfunction without hypertrophy. It is a common cause of heart failure and the major reason for cardiac transplantation. The ventricles have increased systolic and diastolic volumes with decreased left ventricular function. As the LV becomes dilated (enlarged), contractility is impaired and becomes less forceful. The LV is unable to pump blood out of the heart effectively because of impaired contractility, and this often results in heart failure, ventricular arrhythmias, and sudden cardiac death (SCD). DCM occurs more often in men than in women and is generally seen between 20 and 60 years of age. As much as 40% of DCM is thought to be familial (Lakdawal, Winterfield, & Funke, 2013).

Pathophysiology

Microscopic examination of cardiac muscle tissue shows both atrophic and hypertrophic myocardial fibers with diffuse necrosis of myocardial cells and interstitial fibrosis. The result is poor systolic function. Structural changes (ventricular dilation) decrease the amount of blood ejected from the ventricle with systole, increasing the amount of blood remaining in the ventricle after contraction. Then less blood is able to enter the ventricle during diastole, increasing end-diastolic pressure and eventually increasing pulmonary and systemic venous pressures.

Clinical Manifestations and Assessment

Initial presentation is often with heart failure; symptoms of dyspnea, fatigue, weight gain, and volume overload are most common and are progressive. Arrhythmias and SCD frequently occur. Altered valve function, usually regurgitation, can result from an enlarged stretched ventricle. Poor blood flow through the ventricle also may cause ventricular or atrial thrombi, which can embolize to other locations in the body. A persistent gallop rhythm, JVD, and a holosystolic murmur due to severe MR may be present. An echocardiogram is the preferred diagnostic tool as it can evaluate LV function and size, as well as valvular abnormalities. Cardiac catheterization is important to exclude coronary artery disease.

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy (HCM) is characterized by a hypertrophied, nondilated LV that can lead to obstruction of left ventricular outflow. HCM is an inherited autosomal dominant heart muscle disorder and is one of the most common types of cardiomyopathy, occurring in 1 out of 500 people. It is the most common cause of SCD in young athletes.

Pathophysiology

Cardiac muscle cells normally lay parallel to and end-to-end with each other. However, in HCM, the hypertrophied myofibrils are in disarray, and interstitial fibrosis develops. The heart muscle enlarges and asymmetrically thickens, especially along the septum. The increased thickness of the heart muscle reduces the size of the ventricles, making it more difficult to pump blood. The walls of the ventricle stiffen, and, as a result, the ventricle is less able to relax and fill with blood. The smaller-than-normal ventricular chamber creates a higher velocity flow of blood out of the LV into the aorta. Left ventricular outflow tract obstruction may occur if the mitral valve presses on the septum and blocks blood flow. This causes high systolic pressure in the LV that leads to prolonged ventricular relaxation and diminished CO, resulting in impaired diastolic filling. This decreases the effectiveness of contractions and increases the risk of ventricular arrhythmias.

Clinical Manifestations and Assessment

Clinical presentation varies widely: Many patients with HCM remain asymptomatic or experience only minor symptoms. Others may exhibit dyspnea with exercise or at rest, fatigue, chest pain, palpitations, dizziness, or presyncope and syncope. Some present with ventricular arrhythmias, SCD, or end-stage heart failure requiring cardiac transplantation. AF is common and may result from atrial enlargement. Patients with HCM may have systolic ejection murmurs that become more pronounced when the patient moves from standing to a squatting position. Mitral murmurs occur because of regurgitation. Echocardiography is used to detect HCM; a hypertrophied LV confirms diagnosis when other causes are excluded.

RESTRICTIVE CARDIOMYOPATHY

Restrictive cardiomyopathy (RCM) is characterized by diastolic dysfunction and impaired ventricular filling during diastole. RCM is rare and frequently idiopathic. Other causes of RCM are amyloidosis sarcoidosis and radiation fibrosis. It can occur after a heart transplant. Abnormal myocardial relaxation with interstitial fibrosis and calcifications are the fundamental abnormalities of restrictive cardiomyopathies.

Pathophysiology

Abnormally rigid ventricular walls result in poor ventricular compliance. Stiff ventricular walls lack ventricular stretch, or flexibility, to expand as they fill with blood. Typically, there is normal ventricular wall thickness and the ventricular chambers are not dilated. Systolic function (contractility) is normal or near normal. Atrial enlargement may be present. Impaired diastolic filling occurs because the rigid ventricular walls do not relax and fill with normal blood volume. CO can be increased by an increase in heart rate but, eventually, becomes ineffective due to shortened filling time. As the disease progresses, diastolic heart failure occurs.

Clinical Manifestations and Assessment

Signs and symptoms of RCM are similar to constrictive pericarditis: dyspnea, orthopnea, nonproductive cough, PND, and chest pain. Peripheral edema, fatigue, and hepatomegaly may be present. Echocardiography typically demonstrates normal ventricular dimensions with normal or nearly normal systolic function. With disease progression, edema worsens, and ascites, anasarca, or pulmonary edema may develop. Signs and symptoms of heart failure appear. Often JVD is present on physical examination, and an S3 and S4 can be heard with auscultation.

ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY/DYSPLASIA

Arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC/D) is an inherited cardiomyopathy, often with an autosomal dominant trait. It is a disease of the RV characterized by ventricular tachycardia and right heart failure; however, it may be seen in the left or both ventricles. Although relatively rare, ARVC/D accounts for up to 20% of cases of SCD primarily in young athletes, making it the second leading cause of SCD after DCM (Romero, Mejia-Lopez, Manrique, & Lucariello, 2013).

Presenting symptoms range from palpitations and syncope to SCD. ARVC/D myocardial electrical instability comprises the main clinical manifestation with ventricular ectopy and ventricular tachycardia. Biventricular or RV failure is less common and observed mainly in patients with long-term disease protected from SCD by implantable cardioverter defibrillator (ICD) implantation.

Pathophysiology

ARVC/D occurs when the RV is progressively infiltrated and replaced with fibrous scar and fatty tissue. Initially, localized areas of the RV are affected, but, as the disease progresses, the entire heart can be affected. Eventually, the RV dilates and develops poor contractility, and arrhythmias occur.

Clinical Manifestations and Assessment

Usually presentation is in early adulthood, with symptoms ranging from palpitations and syncope to supraventricular and ventricular arrhythmias or right-sided heart failure. Ventricular tachycardia originating in the RV (left bundle branch block morphology) is the classic presentation. SCD may be the initial presentation. ARVC/D should be suspected in patients with palpitations, syncope, or ventricular tachycardia originating in the RV or SCD, especially among previously symptom-free athletes. Family history, electrocardiogram (ECG), and a history of arrhythmias can help establish a diagnosis of ARVC/D.

STRESS-INDUCED (TAKOTSUBO) CARDIOMYOPATHY

Stress-induced (Takotsubo) cardiomyopathy is a syndrome of acute, reversible LV dysfunction that is frequently, but not always, precipitated by profound emotional, psychological, or physical distress. Ventricular function fully returns within several days to several months. LV morphology, as seen with echocardiography or ventriculogram, demonstrates apical and midventricular contractile abnormalities (akinesis) with sparing of the base as well as resultant ballooning of the ventricle that is seen with angiography. Stress-induced cardiomyopathy has been identified predominantly in white, postmenopausal women. Noncardiac comorbidities, such as anxiety, chronic pulmonary disease, and thyroid disease, are associated.

Pathophysiology

The pathophysiology of stress-induced cardiomyopathy is not completely understood. Catecholamine release triggered by activation of the sympathetic system during sudden stress is thought to result in stress-induced cardiomyopathy. Very happy events, such as the birth of a grandchild, also can cause Takotsubo cardiomyopathy, and it is thought that happy events may increase activation of the sympathetic and parasympathetic systems, acting similarly to stressful events (Ghadri et al., 2016). There are also cases of stress-induced cardiomyopathy occurring from iatrogenic causes, such as during catecholamine administration for dobutamine stress echocardiography (Lyon et al., 2016).

Clinical Manifestations and Assessment

Clinical presentation of stress-induced cardiomyopathy is similar to that of ST-segment elevation myocardial infarction (STEMI). Acute presentation may be severe and reportedly can include life-threatening arrhythmias, pulmonary edema, heart failure, cardiogenic shock, and SCD (Liang, Cha, Oh, & Prasad, 2013). Typically, patients present with acute substernal pain and SOB following an emotionally or physically stressful trigger. Palpitations induced from tachycardia or arrhythmia may be present. ST-segment elevation may be present on ECG, and cardiac enzymes may be mildly elevated, although disproportionately low to levels seen with acute MI. Conversely, serum brain natriuretic peptide (BNP) is extremely elevated. The diagnosis of Takotsubo cardiomyopathy should be suspected in postmenopausal women with acute heart failure or cariogenic shock following an emotionally stressful event. Typically, patients are treated as if they are having an acute MI and undergo urgent cardiac catheterization. An absence of significant coronary artery disease with ballooning of the LV seen during ventriculography, with rapid and complete recovery, is the hallmark feature of stress-induced cardiomyopathy. See Table 16-2.

Nursing Alert
DCM is a floppy heart; HCM is an enlarged, thickened heart; RCM is a stiff, rigid heart; ARVC/D is an arrhythmia-prone heart; and Takotsubo cardiomyopathy is a stressed heart.

MEDICAL AND NURSING MANAGEMENT OF CARDIOMYOPATHY

The echocardiogram is used in the evaluation of cardiomyopathy because it allows assessment of both the structure and function of the ventricles, including valvular abnormalities and EF. A chest x-ray can identify the extent of cardiac enlargement and the presence of pulmonary congestion, an electrocardiogram (ECG) can confirm the presence of arrhythmias, and cardiac catheterization can detect the presence of coronary artery disease. Endomyocardial biopsy may be performed; analysis of myocardial tissue may be used to guide therapy or to establish a precipitating cause, if unknown. Because genetic factors may be involved, detailed and careful family history, should be obtained. Screening of first-degree blood relatives (e.g., parents, siblings, and children) for HCM, DCM, and ARVC/D with echocardiography (echo), and ECG should be considered, as early diagnosis and treatment can prevent or delay significant symptoms and SCD.

Regardless of the type of cardiomyopathy, symptoms are primarily those associated with heart failure. Treatment is supportive and is focused on symptom management. In addition to symptom relief, treatment priorities are prevention of complications, including prevention of lethal arrhythmias to reduce the risk of SCD. Specific treatment for the underlying cause is given if it is known.

Supportive care with standard heart failure therapy, including ACE inhibitors, aldosterone receptor antagonists (ARBs), BB and diuretics, should be administered for all

cardiomyopathies. BBs and CCBs reduce catecholamine response and decrease heart rate. ACE inhibitors are prescribed to reduce preload, afterload, and hypertension by causing vasodilation. ARBs reduce afterload by blocking the action of Angiotensin II, resulting in vasodilation, which subsequently decreases preload and helps regulate fluid and electrolyte balance. Diuretics remove excess sodium and fluid to reduce pulmonary congestion. Nitrates and dehydration should be avoided in HCM to maintain CO. Systemic anticoagulation may be needed to prevent thromboembolic events. Because mural thrombi (a thrombus formed on and attached to a diseased patch of endocardium, not on a valve or on one side of a large blood vessel) are also a risk, the patient's neurologic status should be monitored carefully. Often antiarrhythmic medications are initiated to prevent and treat arrhythmias. For stress-induced cardiomyopathy, accurate diagnosis and differentiation from STEMI is critical to avoid unnecessary treatments, such as administration of thrombolytics, which can cause harm to the patient.

Unstable patients may require positive inotropic medications, vasopressors and intra-aortic balloon pumps (IABPs), implantable devices, or surgery. Pacemakers are used to correct conduction abnormalities and control heart rate when tachyarrhythmias or bradyarrythmias are present. Cardiac resynchronization therapy with biventricular pacing can resynchronize the ventricles to improve contractility. ICDs are recommended when there is a high risk for life-threatening arrhythmias, particularly with ARVC/D. IABP (described in Chapter 55), septal myectomy (removal of hypertrophied portion of the septum that is obstructing the flow of blood from the LV to the aorta) or alcohol septal ablation, left ventricular assist devices (VADs), and heart transplantation may be necessary in the most severe cases.

Nursing management of cardiomyopathy includes careful cardiovascular assessment for signs of worsening heart failure, particularly dyspnea, congested lungs, peripheral edema, and the presence of abnormal heart sounds.

Nursing Alert

The nurse should assess for changes in mentation; pallor; cyanosis; cool, clammy skin; arrhythmias; and a decrease in urine output. These are manifestations of diminished tissue perfusion and suggest reduced CO.

Arrhythmias occur frequently; continuous cardiac monitoring is recommended with personnel and equipment readily available to treat life-threatening arrhythmias. Bed rest is maintained to decrease cardiac workload. Physical activity is increased slowly, and the patient is asked to report symptoms that occur with increasing activity. For stress-induced cardiomyopathy, the nurse must evaluate for the presence of anxiety and guide stress management practices. Encouraging a heart-healthy lifestyle by maintaining a healthy weight and physical activity, smoking cessation, and stress reduction, is integral.

TABLE 16-2 Cardiomyopathies

Type	Description	Etiology	Pathophysiology	Clinical Manifestations
Dilated Cardiomyopathy (DCM)  	Significant, irreversible dilation of the ventricles Systolic dysfunction without hypertrophy Increased ventricular systolic and diastolic volumes with decreased left ventricular (LV) function Impaired contractility may result in HF, ventricular arrhythmias, and sudden cardiac death.	As much as 40% of DCM is thought to be familial. It occurs most often in adults 20 to 60 years of age, and men are affected more than women.	Reduced ventricular wall thickness and increased myocardial mass result in poor systolic function. Decreased blood volume ejected from the ventricle during systole increases blood volume remaining in the ventricle after contraction. Then less blood is able to enter the ventricle during diastole, increasing end-diastolic pressure and, eventually, increasing pulmonary and systemic venous pressures. Valvular regurgitation can result from an enlarged stretched ventricle. Poor blood flow through the ventricle may cause ventricular or atrial thrombi, which may embolize to other locations in the body.	Symptoms are progressive and include dyspnea, fatigue, volume overload, weight gain, chest pain due to coronary artery disease or pulmonary embolism, or abdominal discomfort from hepatomegaly. Signs include: holosystolic murmur (heard on S1) due to MR, thromboembolism, ventricular arrhythmias, and sudden cardiac death. HF may be the initial presentation.
Hypertrophic Cardiomyopathy (HCM)  	Hypertrophied, nondilated LV leads to obstruction of left ventricular outflow, without cardiac or systemic disease	HCM is an inherited autosomal dominant heart muscle disorder and one of the most common types of cardiomyopathy. It is the most common cause of sudden cardiac death (SCD) in young athletes.	Heart muscle asymmetrically increases in mass, especially along the septum, and increased thickness reduces the size of the ventricular cavities, taking longer to relax after systole. During diastole, ventricular filling is impaired; atrial contraction at the end of diastole becomes critical for filling and systolic contraction. Smaller-than-normal LV cavity creates high-velocity blood flow from the LV into the aorta. Left ventricular outflow tract obstruction causes high systolic pressure in the LV that leads to prolonged ventricular relaxation and diminished cardiac output, resulting in diastolic dysfunction. Systolic function is normal or high, resulting in an above-normal ejection fraction.	Most patients with HCM are asymptomatic, but some present with ventricular arrhythmias, SCD, or other symptoms: syncope, dyspnea, or chest pain. Atrial fibrillation commonly occurs from atrial enlargement. Systolic ejection murmurs (heard on S1) do not radiate to the neck. Mitral murmurs result from regurgitation.

Restrictive Cardiomyopathy (RCM)  	Characterized by diastolic dysfunction that negatively affects or "restricts" the heart's ability to fill with blood Uncommon cardiomyopathy	Frequently idiopathic Associated with amyloidosis and endomyocardial fibrosis (scarring of the heart) Often occurs after a heart transplant	Stiff ventricular walls lack ventricular stretch (flexibility to expand as they fill with blood). This impairs diastolic filling, resulting in diastolic HF. Normal, or slightly increased, ventricular wall thickness and atrial enlargement with normal systolic function are characteristic. Atrioventricular block and symptomatic bradycardia can occur.	Symptoms are similar to constrictive pericarditis: dyspnea, nonproductive cough, chest pain, and exercise intolerance. Signs may include jugular venous distention, edema, ascites, anasarca, pulmonary edema, and an S3 and S4 can be heard with auscultation.
Arrhythmogenic Right Ventricular Cardiomyopathy/ Dysplasia (ARVC/D)  	Rare but increasingly recognized condition ARVC/D should be suspected in patients with ventricular tachycardia originating in the right ventricle (i.e., left bundle branch block on ECG) or SCD, especially among previously symptom-free athletes.	Familial in more than 50% of patients and usually occurs in early adulthood	ARVC/D occurs when the right ventricle is progressively infiltrated and replaced with fibrous scar and adipose tissue. Initially, only localized areas of the right ventricle are affected, but, as the disease progresses, the entire heart is affected. Eventually, the right ventricle dilates and develops poor contractility, and arrhythmias occur.	Symptoms are consistent with right HF. Supraventricular arrhythmias may occur. Ventricular arrhythmias and SCD may be the initial presentation, and often diagnosis is made postmortem. Family history, ECG, and a history of arrhythmias can help establish a diagnosis of ARVC/D.
Stress-induced (Takotsubo) Cardiomyopathy  	Syndrome of transient LV dysfunction. Ventricular function fully returns within weeks. LV morphology, seen with echocardiography or ventriculogram, demonstrates apical akinesis (absence of or decreased movement) with sparing of the base and resultant ballooning of the ventricle. It has been identified predominantly in white, postmenopausal women. Noncardiac comorbidities, such as anxiety, chronic pulmonary disease, and thyroid disease are associated.	Precipitated by emotional or physical distress	The pathophysiology of stress-induced cardiomyopathy remains unclear. One theory gaining acceptance is catecholamine excess triggered by activation of the sympathetic system.	Clinical presentation is identical to that of acute ST-segment elevation MI: acute substernal pain and shortness of breath following an emotionally or physically stressful trigger. ST-segment elevation may be present on ECG, and cardiac enzymes may be mildly elevated, disproportionate to levels seen with acute MI. Acute presentation may be severe; arrhythmias, HF, pulmonary edema, and cardiogenic shock have been reported in the absence of significant coronary artery disease. Ballooning of the LV, with rapid and complete recovery, is the hallmark feature.

SURGICAL INTERVENTIONS FOR CARDIOMYOPATHY

When heart failure progresses and medical treatment is no longer effective, surgical intervention, including cardiac transplantation, is considered.

Septal Myectomy and Alcohol Septal Ablation

Septal myectomy generally is used for younger patients with obstructive HCM and severe symptoms refractory to medical management. Removing part of the thickened septum that is bulging into the LV improves blood flow through the heart and out to the body.

Septal ablation is the destruction of the hypertrophied septum caused by injecting alcohol into the artery that supplies blood to that area. Alcohol septal ablation can improve symptoms, but possible complications with this procedure include permanent heart block, which can occur in as many as 10% of the cases and requires implantation of a pacemaker. Generally this is thought to be an acceptable alternative to myectomy when concomitant cardiac surgery is not necessary, coronary anatomy is appropriate, in older patients at risk for operative morbidity, or for those with a strong desire to avoid surgery (Maron & Nishimura, 2014a, 2014b).

Mechanical Circulatory Support

Mechanical circulatory support (MCS) has evolved greatly, and its use has increased dramatically since the late 1960s when a VAD was first used for postcardiotomy shock (McLarty, 2015). MCS has three main functions: (a) reduce or assume the workload of the heart, (b) support systemic circulation, completely or partially, and (c) improve myocardial oxygenation. Patients who cannot be weaned from cardiopulmonary bypass, patients in cardiogenic shock, and patients with refractory heart failure may benefit from short-term (hours to days) MCS for the management of hemodynamically unstable acute, decompensated heart failure while the patient's own heart recovers. Typically, an IABP, described in Chapter 55, or an extracorporeal membrane oxygenator (ECMO) is used to provide support in these cases.

Intra-aortic Balloon Pump Counterpulsation

The IABP decreases the workload of the heart by reducing left ventricular afterload. Additionally, it improves coronary artery blood flow by increasing coronary artery perfusion pressure. The IABP is used pre- and postoperatively in patients with severely compromised left ventricular function, in patients with myocardial ischemia undergoing complex percutaneous coronary interventions, and for patients with complications resulting from acute myocardial infarction, such as papillary muscle rupture, awaiting surgical repair. Bleeding, limb ischemia, infection, and vascular injury are potential complications of IABP, and monitoring the patient for compromised circulation and hemodynamic instability is a priority for nursing management.

Extracorporeal Membrane Oxygenator

ECMO uses a pump to circulate blood through an oxygenator outside the body to provide both cardiac and respiratory support by artificially removing the carbon dioxide and re-oxygenating red blood cells. The purpose of ECMO is to allow time for intrinsic recovery of the lungs and heart; a standard cardiopulmonary bypass provides support during various types of cardiac surgical procedures.

Increasingly, MCS is used long term (months to years) for the management of advanced heart failure from causes including cardiomyopathy (heart failure is described in detail in Chapter 15). Investigation continues for devices for permanent use (Yancy et al., 2013a, 2013b).

Ventricular Assist Devices

VADs can support a failing heart by generating blood flow to the systemic circulation and unloading the ventricle. Most patients receive a left VAD, but some may receive a biventricular device (BiVAD) or a total artificial heart (TAH). Initially this therapy was used temporarily for patients with difficulty weaning from cardiopulmonary bypass following cardiothoracic surgery, VADs were mainly a bridge to recovery. Nondurable (temporary) support indications include cardiogenic shock, acute myocarditis (discussed shortly), and acute, reversible heart failure. Another nondurable indication is the use of a

VAD as a bridge to the decision regarding candidacy for transplantation or to a more permanent VAD when the patient becomes more clinically stable.

Durable or long-term indications include using a VAD as a bridge to transplantation, to sustain life until a donor heart becomes available, or as destination therapy (DT) in patients with end-stage heart failure who are ineligible for transplantation and for whom ventricular recovery is not possible. Increasingly, VADs are being used as DT. See Figure 16-9 for an example of a long-term use of VAD. VAD therapies are also categorized as a bridge to decision (BTD) and a bridge to bridge (BTB). VADs used for a BTD allow time to evaluate whether a transplant or other treatment is most suited to a patient. Similarly, a BTB VAD is used when emergent stabilization is necessary, with a plan to transition to a longer-term device when the patient becomes more clinically stable. Long-term indications include using a VAD as a bridge to transplant (BTT) in patients failing on maximal medical therapy, or for DT in patients with end-stage heart failure who are not transplant candidates.

These devices can have pumps that are outside the body (extracorporeal) or implantable and can be broadly classified as pulsatile volume displacement or continuous flow (axial flow, centrifugal). Most are surgically inserted via sternotomy, but some short-term use VADs can be inserted percutaneously. First-generation volume-displacement pumps provided good hemodynamic support but were limited by lack of long-term durability, an extensive surgical procedure for insertion, and a large external driveline that was prone to infection. These are rarely implanted today.

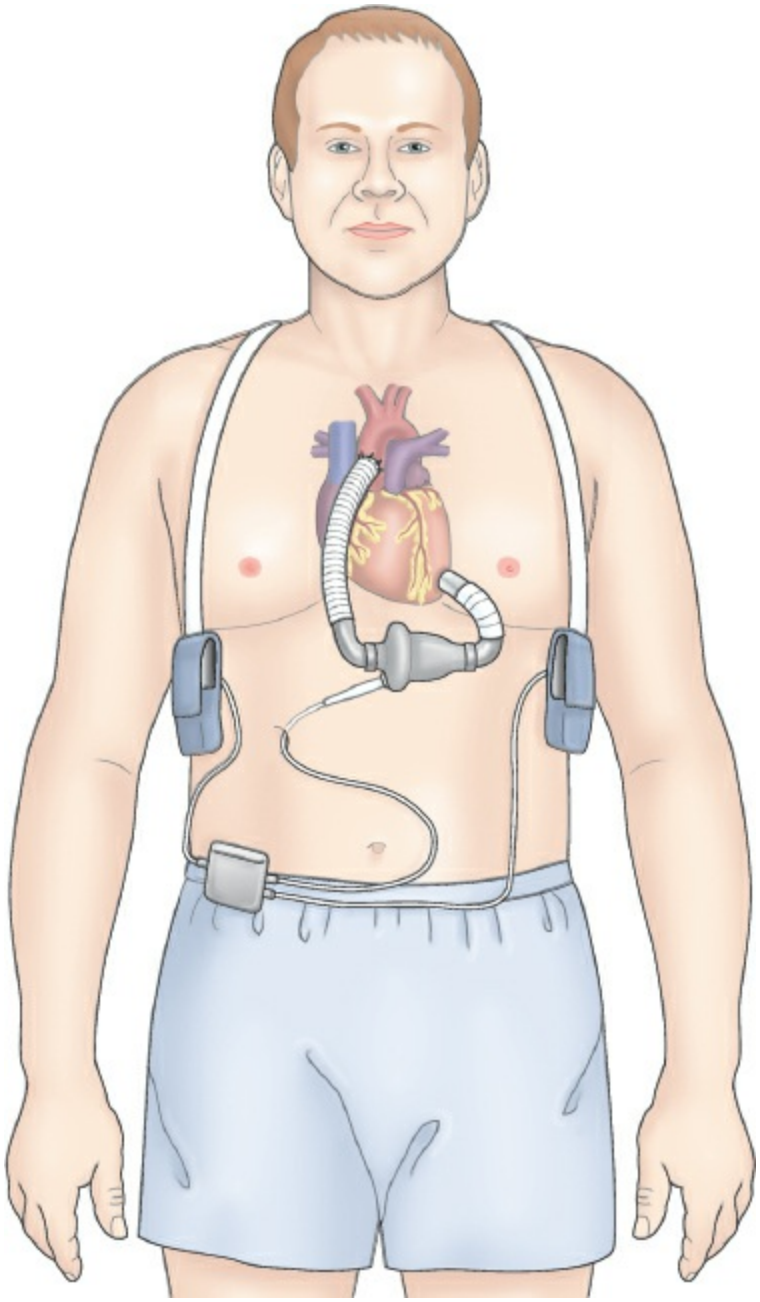

FIGURE 16-9 Left ventricular assist device.

Second- and third-generation LVADs are continuous flow pumps and have only one moving part, making them more durable. Because they have smaller drivelines, the risk of infection and surgical trauma is reduced. Second-generation axial flow pumps contain a spinning impeller that generates a continuous, nonpulsatile flow by a rotor spinning around a central shaft and return blood to the aorta at a constant rate. Third-generation centrifugal VADs generate centrifugal force from the spinning cone-shaped rotor, resulting in a nonpulsatile flow of blood and have been designed for long-term use. Compared with earlier LVADs, the third-generation VADs optimize blood flow to reduce the risk of thrombus formation and are smaller in size to facilitate surgical implantation.

Long-term use of VADs has been shown to improve survival in patients with symptomatic late-stage heart failure; however, it is not without adverse events and an

impact on quality of life. Some researchers had suggested that potential survival benefit would offset the increased rates of adverse effects (Rose et al., 2001). More recently, researchers have acknowledged that although LVADs pose significant risks, they have been shown to improve both quantity and quality of life of patients living with Stage D heart failure and have sought to describe and explain patients' preimplantation decision-making and pre- and postimplantation expectations regarding LVADs, as seen in Box 16-1 (Kitko, Hupcey, Birriel, & Alonso, 2016).

Nursing Alert

The nurse understands that there is no palpable pulse or measurable "normal" systolic or diastolic blood pressure in patients with continuous flow LVADs where the majority of blood flow is through the LVAD. The nurse can attempt to palpate the pulse as occasionally some patients may have a weak pulsation. Obtain a traditional manual blood pressure cuff and, using a Doppler, assess the VAD pressure at the brachial artery, often referred to as the MAP (mean arterial pressure, although with LVAD, it is not the traditional MAP). Refer to your health care facility's target VAD pressure (generally 65 to 80 mm Hg, NOT TO EXCEED 90 mm Hg). The nurse auscultates below the heart to hear the hum of the device running. Use level of consciousness, skin color, respiratory rate, and temperature, and assess the system controller for messages. Observe for the cables, being careful not to put undue stress on them. Additionally for patients that will be discharged with a VAD, patient education focuses on contingency plans, including ensuring uninterrupted electrical access, ensuring access to a working telephone for emergencies, and understanding the limitations of battery life (Devore, Mentz, & Patel, 2014).

Total Artificial Hearts

TAHs are designed to replace both ventricles. The SynCardia Temporary Total Artificial Heart has been FDA-approved for use since 2004 as a BTT in patients waiting for a donor heart who have biventricular failure unresponsive to other therapies and who are at imminent risk of death (U.S. Food and Drug Administration website. Syncardia Systems, Inc. CardioWest total artificial heart (TAH): directions for use. http://www.fda.gov/ohrms/dockets/ac/04/briefing/4029b1_final.pdf. Accessed September 3, 2017). More than 1100 patients have been supported by this device, the longest duration being 1374 days before the patient received a donor heart. In December 2014, Syncardia received FDA approval for this device to be tested in a clinical trial evaluating its effectiveness as DT (http://www.syncardia.com/2015-multimedia-releases/fda-approves-the-syncardia-total-artificial-heart-for-destination-therapy-study/itemid-1737.html).

Complications

Complications of VADs and TAHs include infection, ventricular arrhythmias, thrombus, thromboemboli, hemolysis, hemorrhage, right heart failure, multisystem failure, and mechanical failure of the device. Appropriate anticoagulation to reduce the risk of thrombus formation and thromboembolism, while avoiding the risk of bleeding, is a challenge, and anticoagulation therapy depends on device type, patient history, and platelet responsiveness. Infection is another major complication, particularly with extracorporeal

devices as the percutaneous driveline exit site commonly becomes infected. Infection at this site can spread quickly through the entire system causing sepsis, a systemic infection.

BOX 16-1 Nursing Research

Kitko, L. A., Hupcey, J. E., Birriel, B., & Alonso, W. (2016). Patients' decision-making process and expectations of a left ventricular assist device (LVAD) pre- and postimplantation. Heart and Lung: The Journal of Acute and Critical Care, *45*, 95–99.

Purpose

Five percent to 10% of the nearly 6 million Americans with heart failure have advanced (Stage D) heart failure (HF) with progressive signs and symptoms despite optimal medical, device, and surgical management. Increasing, left ventricular assist devices (LVADs) are being used as a treatment for advanced heart failure. Although LVADs have been shown to improve both the quantity and quality of life in patients living with Stage D HF, they also pose significant risks. Most patients will experience a significant adverse event within 2 years, including malfunctioning pump, infection, bleeding arrhythmias, and stroke. The purpose of this research was to examine patients' preimplantation decision-making and pre- and postimplantation expectations of LVADs.

Design

Thematic analysis of semi-structured, serial interviews of 15 patients with Stage D HF and LVADs was used in this longitudinal, qualitative study to obtain a strong understanding of the decision-making process of patients undergoing LVAD placement and their postimplant expectations.

Findings

"No choice" was the main theme among patients in the preimplantation period. Postimplantation, two themes emerged: "I thought I would be doing better" and "I feel good, but now what." Evidence from preimplantation to postimplantation suggested that patients' perceived expectations of quality-of-life improvement were not met.

Nursing Implications

Faced with rapidly declining health, most patients felt that death, an unacceptable option, was their only alternative to LVAD implantation. Ongoing discussion of treatment goals and all treatment options, including the benefits and risks of each, is critical prior to implantation. In the postimplantation period, patients expected greater improvements in their quality of life. This strongly suggests that postimplantation, ongoing palliative care is necessary as are evidence-based guidelines for discussions of goals of care that include detailed and realistic expectations.

Nursing care for patients with mechanical assist devices (MAD) focuses on the assessment of and minimization of complications as well as providing emotional support and education about the mechanical assist device and the underlying cardiac disease. If a durable VAD is being considered, the patient's ability to manage the VAD should be assessed. When assessing the patient with a VAD, it is important to remember that there may not be any palpable pulse because blood flow throughout the cardiac cycle is continuous, not pulsatile. Pulse oximetry may be unmeasurable or unreliable, and obtaining VAD pressure may be difficult or not possible. It is recommended that a Doppler ultrasound be used with a sphygmomanometer to obtain a VAD pressure.

Heart Transplantation

The first human-to-human heart transplant was performed in 1967. Since then, transplant procedures, equipment, and medications continue to improve. In 1983, when cyclosporine became available, transplantation became an option for patients with end-stage heart disease. Cyclosporine is an immunosuppressant that significantly decreases the body's rejection of transplanted organs. The use of tacrolimus, another immunosuppressant drug, and better methods for monitoring rejection have greatly improved survival rate and expanded selection criteria.

There is a critical shortage of donor hearts; in 2014, 2655 cardiac transplants were performed in the United States, and as of July 2015, there were more than 4100 people on the transplant list awaiting a heart (Mozaffarian et al., 2016). For cardiac transplants occurring between 2009 and 2010, the one-year survival rate after cardiac transplantation was more than 90.8% for men and 90.6% for women (Mozaffarian et al., 2016, p. e345). Typical candidates have advanced heart failure, severe symptoms and functional limitations uncontrolled by medical therapy, no other surgical options, and a poor life expectancy from heart disease. As discussed earlier, VADs serve as a "BTT," for patients waiting for a heart transplant.

A multidisciplinary team screens the candidate before recommending the transplantation procedure. A primary factor to be considered is the candidate's prognosis after transplantation. Function of major organ systems (lungs, liver, and kidneys), chronic health conditions, infections, history of other transplantations, psychosocial status, family support, compliance, and current health status are evaluated (Mancini & Naka, 2016).

Transplant candidates cannot have irreversible pulmonary hypertension as this would lead to right ventricular failure of the transplanted heart. Other contraindications include malignancy and active infection as both of these can worsen as a result of the antirejection medications.

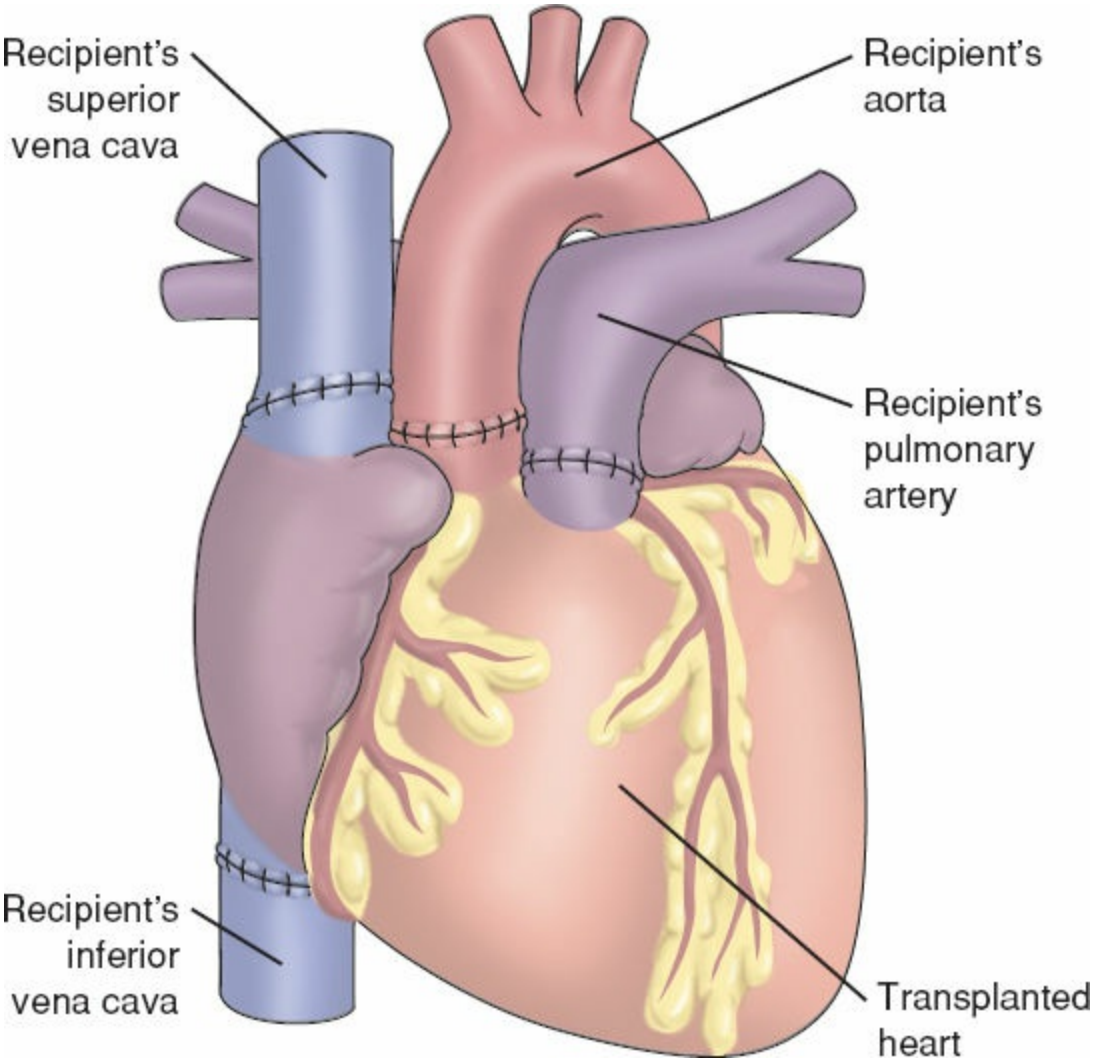

FIGURE 16-10 Orthotopic method of heart transplantation.

In addition to having severely compromised physical health, patients also struggle with psychosocial issues. Waiting for a donor heart is stressful for the patient and family. Much unpredictability and uncertainty exist regarding when or whether a donor heart will become available.

Orthotopic Transplantation

Orthotopic transplantation, as depicted in Figure 16-10, is the most common surgical procedure for cardiac transplantation. The recipient's heart is removed, leaving a portion of the recipient's atria with the vena cava and pulmonary veins in place. The donor heart, which usually has been preserved in ice, is prepared for implant by cutting away a small section of the atria that corresponds with the sections of the recipient's heart that were left in place. The donor heart is implanted by suturing the donor atria to the residual atrial tissue of the recipient's heart. After the venous or atrial anastomoses are complete, the recipient's pulmonary artery and aorta are sutured to those of the donor heart.

Rarely (less than 1%), a heterotopic cardiac transplant may be performed because of significant pulmonary hypertension, small donor heart, or expected poor function of the donor heart. In this case, the recipient's heart is left in place and the donor heart is placed

next to it and they are joined together.

Postoperative Course

Patients who have had heart transplants constantly balance the risk of rejection with the risk of infection. They must adhere to a complex regimen of diet, medications, activity, follow-up laboratory studies, biopsies of the transplanted heart (to diagnose rejection), and clinic visits. Commonly, patients receive cyclosporine or tacrolimus, azathioprine or mycophenolate mofetil (CellCept), and corticosteroids to minimize rejection.

The transplanted heart is denervated; it has no nerve connections to the recipient's body, and the sympathetic and vagus nerves do not affect the transplanted heart. The resting rate of the transplanted heart is approximately 70 to 90 beats/minute, but it increases gradually if catecholamines are in the circulation. Patients must gradually increase and decrease their exercise (i.e., extended warm-up and cool-down periods), because 20 to 30 minutes may be required to achieve the desired heart rate. Atropine does not increase the heart rate of transplanted hearts.

Rejection is most common in the first 3 to 6 months following transplant, although the risk of infection continues to be a significant risk even after the first year because of the immunosuppressant medications. In addition to rejection and infection, other complications include posttransplant lymphoproliferative disease and the development of allograft vasculopathy or rapidly progressing atherosclerosis in the arteries of the transplanted heart. Osteoporosis frequently occurs as a side effect of the anti-rejection medications and pretransplantation dietary insufficiency and long-term sedentary lifestyle. Immunosuppressants and corticosteroids can cause weight gain, diabetes, dyslipidemia, kidney failure, and disturbances of the central nervous and gastrointestinal systems, and toxicity from immunosuppressants can occur.

Transplant recipients face a number of stressors, including (a) coping with complications such as graft rejection; (b) managing a complex posttransplant regimen consisting of multiple medications; exercise and dietary prescriptions; regular medical follow-up evaluations and laboratory tests; lifestyle restrictions related to smoking, alcohol, and other potentially harmful substances; (c) transitioning from their roles as critically ill or dying patients to roles and lifestyles that are less illness-focused; (d) psychological acceptance of the transplant and the fact that someone else lost their life when the patient regained his or hers; and (e) coping with financial issues, such as the cost of surgery and medications.

INFLAMMATORY DISEASES OF THE HEART

Any of the heart's three layers can become inflamed or affected by a variety of causes including infections (viral, bacterial, fungal), inflammatory disorders (connective tissue disorders, inflammatory bowel disease, drug-induced, postoperative (heart and lung surgeries), or idiopathic (no specific cause can be found). The diseases are named for the layer of the heart most involved in the infectious process: endocarditis (endocardium), myocarditis (myocardium), and pericarditis (pericardium) (see Fig. 16-11). These diseases may damage heart muscle, valves, or pericardium and impact cardiac function and, indirectly, quality of life. The ideal management for all infectious diseases is prevention.

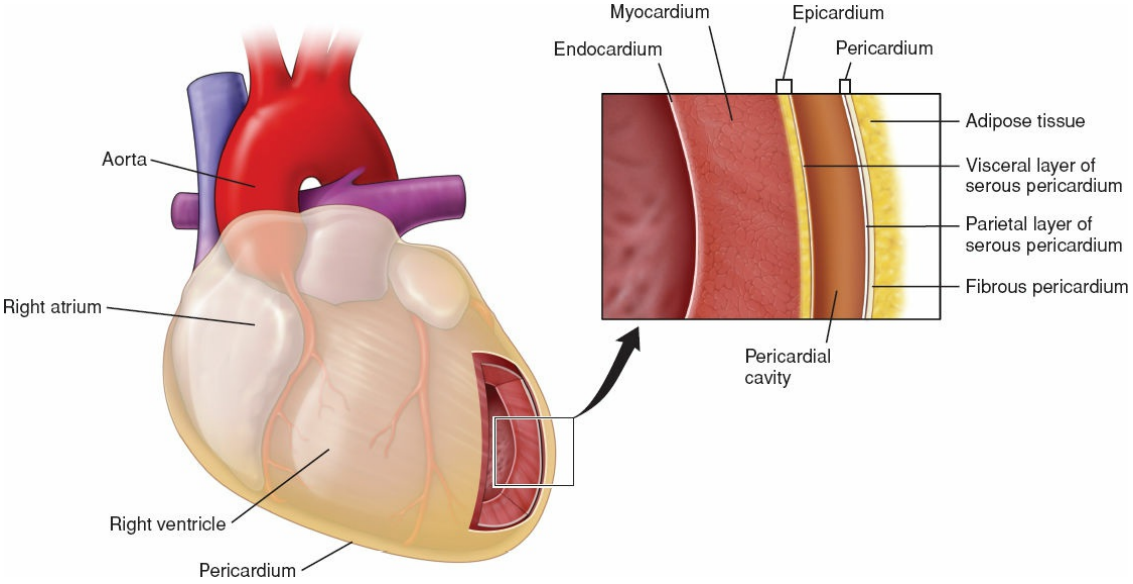

FIGURE 16-11 The layers of the heart. Layers of the heart and pericardium. This schematic diagram shows the anatomic relationship between the layers of the heart. In the middle mediastinum, the heart and roots of the great vessels are surrounded by the pericardium, which is often covered by highly variable amounts of adipose tissue. The pericardium has two layers: a tough external fibrous layer called the fibrous pericardium and a parietal layer of serous pericardium that lines its inner surface. The parietal layer of the serous pericardium is reflected back at the great vessels entering and leaving the heart as the visceral layer of the serous pericardium or epicardium. The epicardium lines the outer surface of the heart. The pericardial cavity is a space between the visceral and parietal layers of the serous pericardium, and it is lined by the mesothelial cells. Deep within the epicardium is the myocardium, which consists of cardiac muscle. Note the small amount of adipose tissue of the epicardium, which contains the coronary arteries and cardiac veins. The inner layer of the myocardium is called the endocardium, which is lined by the mesothelium with an underlying thin layer of connective tissue.

RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

Rheumatic fever (RF) is a systemic inflammatory condition that is a complication of Group A beta-hemolytic streptococcal (GAS) pharyngitis, commonly known as strep throat. RF almost always occurs in children or adolescents; however, because suspected strep throat is

treated swiftly with antibiotics, RF now occurs rarely in the United States.

Pathophysiology

RF results in damage to connective tissues, especially in the heart, brain, joints, and skin. It is triggered by the body's immune response to GAS bacteria. It is thought that the immune system is unable to distinguish between the invading bacteria and its own host tissues, resulting in inflammation and tissue damage. Rheumatic heart disease is a condition in which permanent damage to the heart valves occurs from a prior episode of RF.

Clinical Manifestations and Assessment

Symptoms of RF include sore throat, fever, headache, weakness, diaphoresis, nausea, irritability, and swollen glands. Other manifestations result from the inflammatory process in the affected structures. Polyarthritis occurs in 75% of cases, and swollen, tender, painful joints can persist for up to 4 weeks. Erythema marginatum is a nonitchy macular rash on the trunk and proximal extremities that blanches with pressure, is not indurated, and does not scar. It often occurs with subcutaneous nodules: round, firm, painless bumps beneath the skin that usually disappear after 1 to 2 weeks. Patients also may develop chorea, which is characterized by spontaneous, purposeless movements of the trunk and extremities. Typically self-limiting, chorea can last for weeks to months. The existence and extent of cardiac damage may not be apparent during the acute phase of RF but will manifest later in life as rheumatic heart disease.

Rheumatic carditis is inflammation of the pericardium, myocardium, or endocardium, separately or in combination. Rheumatic myocarditis can temporarily weaken the pumping ability of the heart and cause conduction abnormalities. Rheumatic pericarditis occurs during the acute illness and may result in accumulation of fluid in the pericardial sac. Myocardial and pericardial inflammation usually resolves without sequelae, but rheumatic endocardial inflammation often results in permanent adverse effects. Heart valves become swollen, and tiny vegetations or growths develop on the valve leaflets. They can lead to thickening of the leaflets, causing them to shorten and preventing them from closing completely. As a result, blood regurgitates backward through the valve. The most common site of valvular regurgitation is the mitral valve, although any of the heart valves may be affected. Heart murmurs characteristic of valvular regurgitation, stenosis, or both become audible on auscultation. Since most patients with rheumatic heart disease develop mitral insufficiency, a blowing, high-pitched holosystolic murmur is frequently heard. Diastolic murmurs are heard if AR occurs. The myocardium compensates for some time, but as the valvular pathology progresses, compensatory mechanisms fail, and heart failure can develop.

Medical and Nursing Management

Throat cultures are necessary to diagnose the presence of a GAS infection. If group A beta-hemolytic streptococcus (GAS) is identified, aggressive treatment with penicillin for a 10-day course of therapy is prescribed. Clarithromycin or clindamycin may be prescribed for patients who are penicillin-allergic. Aspirin, or other anti-inflammatory medicines, is usually prescribed.

Since no diagnostic studies are specific for rheumatic endocarditis and symptoms may not develop until years after the RF, the Jones criteria help standardize the diagnosis of RF by classifying the signs of RF into major and minor categories. Having two major (e.g., polyarthritis, carditis, subcutaneous nodules, erythema marginata, or chorea) or one major and two minor (e.g., fever, elevated erythrocyte sedimentation rate [ESR] or serum C-reactive protein level) clinical findings with a throat culture indicating recent infection with GAS pharyngitis indicates a high probability of RF. Although the Jones criteria were developed in the 1940s, they have been revised several times. The most recent review by the AHA in 2015 recommended the expanded use of echocardiography to aid in diagnosis, even in the absence of confirmed heart murmur.

After acute RF has resolved, the long-term risks are related to the risk of developing rheumatic heart disease. Long-term antibiotic prophylaxis against group A strep is indicated in cases of known RF or rheumatic heart disease because recurrent RF is associated with worsening rheumatic heart disease. Recommended antibiotic prophylaxis for RF is shown in Box 16-2 (Nishimuri et al., 2014a, 2014b). People who have recovered from RF should have annual cardiac evaluations to identify the presence of new heart murmurs, which suggest the presence of rheumatic heart disease. Echocardiograms should be done to determine whether rheumatic valvular disease is developing. When a new murmur is detected in a patient with a systemic infection, endocarditis should be suspected.

BOX 16-2 Duration of Antibiotic Prophylaxis for Rheumatic Fever/Rheumatic Heart Disease

Rheumatic fever without carditis:	5 years or until age 21 (whichever is longer)
Rheumatic fever with carditis:	10 years or until age 21 (whichever is longer)
Rheumatic fever with valvular heart disease:	10 years or until age 40 (whichever is longer)

Patients who have rheumatic endocarditis with mild valvular dysfunction may require no further treatment. However, there is a risk of recurrent attacks of acute RF; bacterial endocarditis; embolism from vegetations or mural thrombi to the lung, kidney, spleen, brain, or peripheral vessels; and cardiac failure. The nurse monitors the patient for signs and symptoms of valvular disease, heart failure, thromboemboli, and arrhythmias.

Rheumatic heart disease may be prevented through early recognition and adequate treatment of oropharyngeal streptococcal infections to prevent RF.

INFECTIVE ENDOCARDITIS

Endocarditis is a serious infection of the endocardium, the membrane that lines the interior chambers of the heart and forms the valves. Certain factors, such as the presence of a prosthetic heart valve, a structural cardiac defect, an implantable device, or a previous episode of endocarditis, account for the majority of infectious endocarditis (IE). Other conditions, such as immunosuppression, neutropenia, malignancy, intravenous drug use (IVDU), and nosocomial hospital exposures, such as the presence of an indwelling central venous catheter, can predispose the patient to IE because they can introduce bacteria into the bloodstream. The risk of exposure to antibiotic-resistant bacteria is greater in the hospital and can result in a more virulent infection.

Pathophysiology

Most IE is caused by staphylococci, followed by streptococci and enterococci bacteria. IE also can be fungal. Systemic infection can result in IE, but pathogens also can enter the bloodstream because of surgical or dental procedures or through direct contamination, such as through an injection by IVDUs. Then the microbes colonize at the site of an abnormality or injury of the endocardium, such as a prolapsed mitral valve or a prosthetic valve site. Inflammation and infection result in endothelial damage; platelets, fibrin, blood cells, and the pathogens cluster as vegetations on the endocardium. The infection may erode through the endocardium into the underlying structures (e.g., valve leaflets), causing tears or deformities of valve leaflets, dehiscence of prosthetic valves, deformity of the chordae tendineae, or paravalvular abscesses. The vegetations are friable and fragments can break off, move through the bloodstream, and cause systemic or pulmonary embolization.

Acute IE has a rapid onset, occurring within days to weeks, and often is accompanied by high fever and chills. Subacute IE occurs gradually and is notable by low-grade fever, malaise, and lethargy, and its course is prolonged. Often, the onset of IE is insidious, and signs and symptoms slowly develop from inflammation, destruction of the heart valves, and embolization of the vegetative growths on the heart.

Risk Factors

Pre-existing heart disease increases the risk of developing IE. A cardiac valve with epithelial damage will attract bacteria to its surface, and this can result in endocardial infection. This injury may be the result of rheumatic heart disease, previous endocarditis, a prosthetic valve, a congenital abnormality such as a bicuspid aortic valve, a structural abnormality such as MVP, or it may be age-related, degenerative valvular changes. Central venous access devices and long-term indwelling catheters, such as those used for hemodialysis, are associated with the hospital-acquired IE. IVDU and body piercing are risk factors for IE (see Box 16-3).

Clinical Manifestations and Assessment

The clinical presentation of IE varies and diagnosis may be difficult, as symptoms are often vague and may include anorexia, myalgias, fever, chills, weight loss, back and joint pain, and night sweats. Fever is common, but may be intermittent or absent, especially in patients who are receiving antibiotics or corticosteroids, in the elderly, or in those who have heart failure or kidney failure. A heart murmur may be absent initially but develops in almost all patients. Murmurs that worsen over time are indicative of progressive damage from vegetations or perforation of the valve or chordae tendineae.

BOX 16-3 Risk Factors for Infective Endocarditis

- Acquired valvular dysfunction
- Atrial septal defect (unrepaired or repaired)
- Bicuspid aortic valve
- Body piercing
- Coarctation of the aorta
- Complex cyanotic congenital malformations
- Degenerative valve disease
- History of infective endocarditis
- Indwelling, long-term hemodialysis catheters
- IV drug use
- Mitral regurgitation
- MVP with valvular regurgitation or thickened leaflets
- Nosocomial endocarditis
- Parenteral nutrition lines or IV lines into the right atrium
- Health care exposure
- Patent ductus arteriosus
- Prosthetic cardiac valves
- Ventricular septal defect

In addition to fever and heart murmur, Osler nodes, Janeway lesions, and Roth spots are distinguishing signs of IE, and are the result of microembolization (see Fig. 16-12). Osler nodes are painful, erythematous nodules present on the pads of fingers or toes. Janeway lesions are painless, red or purple macules found on the palms and soles. Roth spots, seen on fundoscopic exam, are oval retinal hemorrhages with pale centers. Splinter hemorrhages may be seen under the fingernails and toenails, and petechiae may appear on the neck, chest, abdomen, conjunctiva, and mucous membranes. Central nervous system manifestations of IE include headache, transient cerebral ischemia, and strokes, which may be caused by emboli to the cerebral arteries. Embolization may be a presenting symptom; it may occur at any time and may involve other organ systems. Cardiomegaly, heart failure, tachycardia, or splenomegaly may occur. Abdominal discomfort, particularly in the left

upper quadrant, is suggestive of splenic embolization or infarction. It is notable that because of earlier diagnosis and improved treatment, these classic signs of IE (with the exception of conjunctival hemorrhages and petechiae) are now seen in less than 10% of patients with IE (Murdoch et al., 2009).

Positive blood cultures are highly sensitive for diagnosis; however, negative blood cultures do not definitely rule out infective endocarditis, especially if a patient has received antibiotics or if slow-growing bacteria are present. Three sets of blood cultures should be obtained 24 hours apart before administration of any antimicrobial agents.

The modified Duke Criteria are used to aid in the diagnosis of IE. Major clinical criteria are positive blood cultures and evidence of endocardial involvement. When these are supplemented by minor clinical criteria, such as predisposing cardiac conditions or IVDU, persistent fever without an alternative cause, systemic or pulmonary embolism, Osler nodes, or Roth spots, a diagnosis of IE can be made. A diagnosis of IE is established with two major criteria or one major and three minor criteria, or five minor criteria. A possible diagnosis of IE is made when one major and one minor or three minor criteria are present (Fowler, Bayer, & Baddour, 2016).

Echocardiography can detect the presence of vegetations or abscesses, prosthetic valve dehiscence, new regurgitation, or heart failure, and is recommended for all patients with suspected IE. Other abnormal findings include anemia, elevated white blood cell (WBC) count, elevated sedimentation rate (ESR), and elevated C-reactive protein. Abnormal electrocardiographic (ECG) findings include atrioventricular blocks, bundle branch blocks, and fascicular blocks.

FIGURE 16-12 Common peripheral manifestations of infective endocarditis. Splinter hemorrhages (A)

are normally seen under the fingernails or toenails. They are usually linear and red for the first 2 to 3 days and brownish thereafter. Osler's nodes (B) are tender subcutaneous nodules, often in the pulp of the digits or the thenar eminence (the fleshy prominence at the base of the thumb). C. Conjunctival petechiae. Janeway's lesions (D) are nontender erythematous, hemorrhagic, or pustular lesions, often on the palms or soles. (From Mylonakis, E. & Calderwood, S. B. (2001). Infective endocarditis in adults. *New England Journal of Medicine, 345,* 1318–1330.)

Medical and Nursing Management

Treatment of IE focuses on eliminating the infection and preventing complications. Treatment with long-term intravenous antibiotic therapy is targeted to the pathogen identified by the blood cultures. It is administered for a significant period, often up to 6 weeks, in doses that produce a high serum concentration to ensure eradication of the infection. Antibiotics are initiated as soon as blood cultures have been obtained. Many patients have peripherally inserted central catheters (PICC) or other long-term IV access. Nursing management of patients with endocarditis includes prevention of the complications of long-term IV therapy. Invasive lines and wounds must be assessed for erythema (redness), tenderness, warmth, swelling, drainage, or other signs of infection. Blood cultures are taken periodically to monitor the effect of therapy, and serum levels of the selected antibiotic are monitored to ensure the serum demonstrates bactericidal activity. Even if the patient responds to therapy, endocarditis can be destructive to the heart and other organs. Nurses should be alert for complications such as persistent infection, heart failure, kidney failure, or emboli. A new or worsening murmur may indicate dehiscence of a prosthetic valve, rupture of an abscess, or injury to valve leaflets. When IE is complicated by persistent or recurrent infection, heart failure, systemic emboli, neurologic complication, myocardial abscess, or fungal endocarditis, surgery is indicated. Most patients who have prosthetic valve endocarditis require valve replacement. If the patient has undergone surgical treatment, the nurse provides postoperative care and instructions.

The patient should be taught to recognize the symptoms of endocarditis and to seek medical assistance should symptoms recur. The patient and family should be instructed about medications as well as signs and symptoms of infection. The nurse provides the patient and family with emotional support and facilitates coping strategies during the prolonged course of the infection and antibiotic treatment. The nurse instructs all patients with IE about the importance of excellent daily dental hygiene and the highest-risk patients about the need for prophylactic before certain dental procedures.

BOX 16-4 Indications for Infective Endocarditis Antibiotic Prophylaxis

- Prosthetic heart valve
- Previous infective endocarditis
- Cardiac transplant recipients with a structurally abnormal valve with regurgitation.
- Congenital heart disease with persistent risk of IE:
  - Unrepaired cyanotic congenital abnormalities
    - Completely repaired congenital defects with prosthetic material, during first 6 months after surgery
  - Repaired congenital defects with residual defect adjacent to prosthetic material

Dental Procedures for Which Endocarditis Prophylaxis Is Recommended for High-Risk Patients (see the below list) All dental procedures that involve manipulation of

gingival tissue or the periapical region of teeth or perforation of the oral mucosa *except* the following:

- Routine anesthetic injections through noninfected tissue
- Taking dental radiographs
- Placement of removable prosthodontic or orthodontic appliances
- Adjustment of orthodontic appliances
- Placement of orthodontic brackets
- Shedding of deciduous teeth and bleeding from trauma to the lips or oral mucosa

Adapted from Baddour, L. M., Freeman, W. K., Suri, R. M., & Wilson, W. R. (2015). Cardiovascular Infections. In Braunwald's heart disease: A textbook of cardiovascular medicine (Vol. 64, pp. 1524–1550). Philadelphia, PA: Elsevier Saunders.

Infectious Endocarditis Prophylaxis

Prevention of IE is important, and antibiotic prophylaxis is recommended prior to dental procedures for only the subset of patients who are at highest risk of adverse outcomes. For patients with a (1) prosthetic cardiac valve, (2) history of infective endocarditis, (3) congenital heart disease with persistent risk of IE, and (4) heart transplantation with valvular disease, antibiotic prophylaxis is warranted for dental procedures that involve manipulation of gingival tissue, the periapical region of teeth, or perforation of the oral mucosa. Antibiotic prophylaxis is not recommended for (1) routine anesthetic injections through noninfected tissue, (2) taking dental radiographs, or (3) placement or adjustment of removable prosthodontic or orthodontic appliances (Nishimura et al., 2014a, 2014b). A summary of indications for infective endocarditis antibiotic prophylaxis is found in Box 16-4.

MYOCARDITIS

Myocarditis is an inflammation of the heart muscle (myocardium), commonly resulting from viral infection. It also may be caused by bacterial infections, immune-mediated mechanisms, and toxic agents. Frequently, the cause is unknown. It can be acute or chronic. Mortality varies with the severity of symptoms. Mild cases with few symptoms may resolve without treatment, while more serious cases result in cardiogenic shock and death.

Pathophysiology

Cardiac muscle inflammation that results in myocyte necrosis (e.g., cardiac cell death) is the hallmark of myocarditis. Acute myocarditis is characterized by myocyte damage from viral infection, autoimmunity, or other precipitating event. Myocyte antigens and cytokines are released. In the subacute phase (days 4 through 14), T and B lymphocytes infiltrate the myocardium, and the virus is cleared. The immune response continues, and infected myocytes are lysed. Myocyte necrosis results in fibrosis. During the chronic phase, myocyte injury continues and can lead to DCM, left ventricular failure, and ventricular arrhythmias.

Clinical Manifestations and Assessment

Clinical presentation can vary widely; symptoms can range from mild systemic findings of fever, myalgias, fatigue, and dyspnea to ventricular arrhythmias, cardiogenic shock, and DCM. Other signs and symptoms include an S3 gallop, tachycardia, tachypnea, JVD, edema, ECG abnormalities, orthopnea, and palpitations. Fulminant heart failure or SCD can develop quickly.

A minority of patients will have elevated cardiac enzymes and WBC count. ESR will be elevated approximately 60% of the time. Echocardiography is widely used when myocarditis is suspected and may show nonspecific findings or demonstrate impaired heart muscle function or pericardial effusion. Endomyocardial biopsy is used to confirm diagnosis.

Medical and Nursing Management

For patients with myocarditis, supportive care is of primary importance with a goal of maintaining hemodynamic stability and improving symptoms. ACE-Is, ARBs, BBs, and diuretics may be prescribed to treat heart failure symptoms. Self-limiting, mild cases may resolve with bed rest and supplemental oxygen, while more severe cases will require hemodynamic support. Surgical options, such as the placement of a VAD or TAH or heart transplantation, should be considered when there is no improvement in symptoms or hemodynamic status despite maximal medical therapy.

Nursing care of the patient with myocarditis includes an assessment whether the patient's symptoms are improving or worsening. In addition to monitoring vital signs, heart sounds, lung sounds, and peripheral perfusion, the nurse must assess hemodynamic, oxygenation, and fluid status. Nurses should be prepared to use emergency equipment as there is a high risk for life-threatening ventricular arrhythmias. Nurses must also provide emotional support to the patient and family; myocarditis can be particularly stressful due to its variable presentation and course.

PERICARDITIS

Pericarditis is an inflammation of the pericardium, the membranous sac surrounding the heart. The pericardium holds the heart in place, prevents it from over-expanding if blood volume increases, and protects the heart from infection and malignancy (see Figs. 16-11 and 16-13). Pericarditis can be infectious (viral, bacterial, or fungal) or noninfectious. Approximately 80% to 90% of pericarditis is idiopathic and assumed to be caused by viral infection (Imazio, Gaita, & LeWinter, 2015). Causes of the less common, noninfectious pericarditis include acute myocardial infarction, chest trauma or cardiac surgery, autoimmune disorders, medications (e.g., isoniazid, hydralazine), and malignancy. A list of the most frequently occurring causes of pericarditis is provided in Box 16-5.

Pathophysiology

The pericardial sac consists of two layers, the parietal (outer) layer and the visceral (inner) layer that is affixed to the heart. A small amount of fluid (15 to 50 mL) separates the layers. Acute pericarditis develops rapidly, occurring when the pericardial sac becomes inflamed. Pericarditis may lead to an accumulation of fluid in this space, called *pericardial effusion*. This may result in increased pressure on the heart, leading to cardiac tamponade (refer to Chapter 15).

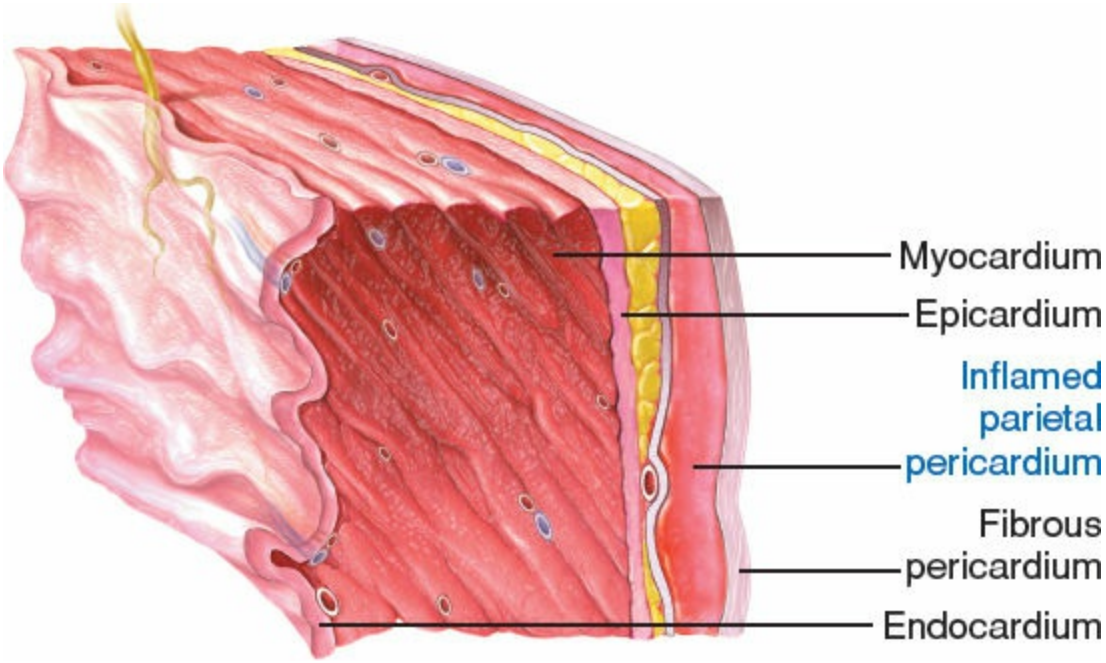

FIGURE 16-13 Tissue changes in pericarditis. Normally, the epicardium and pericardium slide over each other easily because they are lubricated by a small amount of fluid. Thicker material replaces this fluid in pericarditis.

BOX 16-5 Causes of Pericarditis

- Acute myocardial infarction (MI)
- Bacterial infection (e.g., streptococci, staphylococci, meningococci)
- Cancer, particularly metastasis to the heart from lung or breast tumors or lymphoma
- Chest Trauma: chest injury, invasive cardiac procedures, such as implantation of pacemaker or defibrillator (ICD) or cardiac surgery,
- Disorders of adjacent structures: dissecting aneurysm, pulmonary disease (e.g., pneumonia)
- Fungal infection (e.g., *Aspergillus, Candida, Histoplasma*)
- Idiopathic
- Medications (e.g., procainamide, hydralyzine, and isoniazid)
- Metabolic disorders, primarily kidney failure and uremia

- Radiation therapy of chest and upper torso, especially for breast cancer, lung cancer, or lymphoma (peak occurrence 5 to 9 months after treatment)

Rheumatic diseases (systemic lupus erythematosus, rheumatoid arthritis, and mixed connective tissue disease)

- Viral infection (e.g., coxsackie, hepatitis B, influenza, mononucleosis, mumps, varicella)

Pericarditis that reappears 4 to 6 weeks after an episode of acute pericarditis is termed *recurrent pericarditis*. In chronic *effusive* pericarditis, fluid slowly accumulates in the pericardial space, between the two layers of the pericardium.

Chronic *constrictive* pericarditis is rare. Frequent or prolonged episodes of pericarditis can lead to thickening and decreased elasticity of the pericardium, and scarring may fuse the visceral and parietal pericardium. This compresses the heart and restricts its ability to fill with blood. Over time, the pericardium may become calcified, further restricting ventricular expansion during diastole. With less filling, the ventricles pump less blood, leading to decreased CO and signs and symptoms of heart failure. Because higher pressure is required to fill the compressed heart, pressure increases in the veins that return blood to the heart. This increased systemic venous pressure will lead to peripheral edema and liver failure.

Clinical Manifestations and Assessment

The clinical presentation of pericarditis can range from minor chest pain to cardiogenic shock. However, the most common symptom is chest pain. Irritation of the pericardium causes pain that is typically persistent, sharp, pleuritic, and retrosternal. Although usually felt in the midchest, it may radiate to the neck, shoulders, or arms, making it difficult to differentiate from chest pain associated with an MI. However, in contrast to myocardial ischemic pain, the discomfort is usually aggravated by deep inspiration, coughing, lying down, or turning. It is characteristically relieved with a forward-leaning or sitting position because that position reduces pressure on the parietal pericardium. Although not heard in all patients with pericarditis, a common finding is a creaky or scratchy friction rub.

Nursing Alert

A pericardial friction rub is diagnostic of pericarditis. It has a creaky or scratchy sound and is louder at the end of exhalation. Nurses can assess for the presence of a pericardial friction rub by placing the diaphragm of the stethoscope tightly against the thorax and auscultating the left lower sternal border in the fourth intercostal space, the site where the pericardium comes into contact with the left chest wall. The rub is best heard when the patient is sitting and leaning forward. The friction rub is caused by the inflamed layers of the pericardium rubbing against each other and is often intermittent.

Other signs may include a mild fever, increased WBC count, anemia, and an elevated ESR or C-reactive protein level. Patients may have a nonproductive cough. Dyspnea unrelated to exertion is typical of pericarditis; SOB occurs as a result of pericardial compression from cardiac tamponade.

A diagnosis of pericarditis can be made if two of the following are present: pleuritic chest pain, pericardial friction rub, 12-lead ECG demonstrating widespread ST elevation without reciprocal changes or T-wave inversion, and pericardial effusion. Echocardiography is done to assess for pericardial effusion or tamponade, but the absence of effusion does not exclude pericarditis.

Medical and Nursing Management

The goals of management are to provide symptom relief and detect signs and symptoms of cardiac tamponade. If the underlying cause is known, it should be treated; however, typically it is not necessary to confirm the etiology as most pericarditis is viral in nature and resolves without sequelae. Nonsteroidal anti-inflammatory medications (NSAIDs) and aspirin constitute first-line treatment. In the past, corticosteroids were commonly prescribed if a pericardial effusion was present or if the patient did not respond to NSAIDs, but more recently, it has been shown that corticosteroids may prolong the course of recovery or can increase the risk of a recurrent pericarditis (Imazio et al., 2015; Snyder, Bepko, & White, 2014). Colchicine is used to treat recurrent pericarditis, and recent research suggests it may be beneficial when added to NSAIDs for initial management of acute pericarditis (Adler, Charron, & Imazio, 2015). In cases of constrictive pericarditis, surgical removal of the pericardium (pericardectomy) may be necessary to provide relief from restrictive inflammation and scarring.

In addition to pain management, patients with acute pericarditis benefit from positioning: sitting upright and leaning forward will relieve pressure on the pericardium. Patients with chest pain often benefit from psychological support, education, and reassurance that the chest pain they are experiencing is not a heart attack.

Complications

Nurses caring for patients with pericarditis must be aware of the potential of serious complications. The two major complications of pericarditis are pericardial effusion, the accumulation of fluid in the pericardial sac, and cardiac tamponade, compression of the heart from excessive fluid buildup (refer to Chapter 15).

NURSING PROCESS

The Patient with Pericarditis

ASSESSMENT

Pain is the primary symptom of the patient with pericarditis, and it is assessed while repositioning the patient. The nurse tries to identify whether the pain is influenced by inspiration or expiration; breath holding; flexion, extension, or rotation of the spine and neck; by movements of the shoulders and arms; and by coughing or swallowing. Recognizing that deep inspiration or coughing intensifies pain may help to differentiate the pain of pericarditis from the pain of MI. To distinguish a pericardial friction rub from a pleural friction rub, the patient is asked to hold his or her breath; a pericardial friction rub will continue. A pericardial friction rub occurs when the pericardial surfaces lose their lubricating fluid because of inflammation. The rub is audible on auscultation and is synchronous with the heartbeat but is often intermittent and does not always occur. The patient's temperature is monitored frequently. Pericarditis may cause an abrupt onset of fever in a patient who has been afebrile.

DIAGNOSIS

Based on the assessment data, a major nursing diagnosis may be:

- Acute pain related to inflammation of the pericardium

PLANNING

The nursing plan focuses on two goals: pain relief and absence of complications.

NURSING INTERVENTIONS

PAIN RELIEF

Relief of pain is achieved by chair rest because sitting upright and leaning forward is the posture that tends to relieve pain. It is important to instruct the patient to restrict activity until the pain subsides. As the chest pain and friction rub abate, activities of daily living may be resumed gradually. If the patient is taking analgesics or colchicine for the pericarditis, his or her responses are monitored and recorded. Patients taking NSAIDs are assessed for gastrointestinal adverse effects. If chest pain and friction rub recur, bed rest or chair rest is resumed.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Pericardial Effusion. Fluid that accumulates between the pericardial linings or in the pericardial sac is called *pericardial effusion* (see Chapter 15). The fluid can constrict the myocardium and impair its ability to pump. CO declines with each contraction. Failure to identify and treat this problem can lead to cardiac tamponade and possible sudden death.

Cardiac Tamponade. The first symptoms of cardiac tamponade are often SOB, chest tightness, dizziness, or restlessness. Assessment of blood pressure may reveal a pulsus paradoxus, a decrease of 10 mm Hg or more in the systolic blood pressure during inspiration. Usually, the systolic pressure decreases and the diastolic pressure remains stable; hence, pulse pressure narrows. The patient may have tachycardia, and the ECG voltage may be decreased or the QRS complexes may alternate in height (electrical alternans). Heart sounds may progress from distant to imperceptible. Neck vein distention and other signs of rising central venous pressure develop. These signs occur as the fluid-filled pericardial sac compresses the myocardium. Blood continues to return to the heart from the periphery but cannot flow into the heart to be pumped back into the circulation. The nurse notifies the provider immediately and prepares to assist with diagnostic echocardiography and pericardiocentesis (see Chapter 15). The nurse stays with the patient and continues to assess and record signs and symptoms while intervening to decrease patient anxiety.

EVALUATION

Expected patient outcomes include:

1. Freedom from pain
    a. Performs activities of daily living without pain, fatigue, or SOB
    b. Temperature returns to normal range
    c. Exhibits no pericardial friction rub
2. Absence of complications
    a. Sustains blood pressure in normal range
    b. Has heart sounds that are strong and can be auscultated

c. No evidence of effusion or tamponade

CHAPTER REVIEW

Critical Thinking Exercises

1. A friend tells you she does not like to take drugs and does not plan to adhere to advice from her health care providers to use antibiotics before routine dental checkups. You know your friend has had a heterograft mitral valve replacement. How would you respond to your friend? On what evidence do you base your response? What is the strength of that evidence?

2. A 19-year-old man with HCM is being discharged from the hospital. He lives alone and states he really needs to get back to the gym to resume his weight training. Based on your knowledge about the developmental tasks of 19-year olds, what do you anticipate his psychosocial needs would be? His family came to the hospital during the first 2 days of his hospital stay, but they live out of town and have returned home. Should they be included in the plan of care? The cardiologist has requested a consult with transplant services. How will this consult be included in the plan of care?

3. A 68-year-old man with AF, who is recovering from an aortic valve replacement for AS and three coronary artery bypass grafts, has been prescribed a BB, an ACE inhibitor, digoxin, and warfarin. The cardiologist advises the patient to continue to carry nitroglycerin spray for treatment of angina, should it occur. What are the teaching and discharge planning needs? As you care for the patient on the third postoperative day, you assess that the patient has short-term memory deficits. What are your plans to achieve discharge as expected on postoperative day 5 to 7?

NCLEX-Style Review Questions

1. Incomplete closure of the mitral valve results in backflow of blood from the:
   a. RV to the right atrium
   b. Right atrium to RV
   c. LV to LA
   d. LA to LV

2. Severe AS is consistent with all of the following *except:*
   a. Pulmonary edema
   b. Increased CO
   c. Right-sided heart failure
   d. Left ventricular hypertrophy

3. The following are symptoms associated with AS:
   a. Angina, syncope, dyspnea

b. Diastolic murmur, syncope, dyspnea
c. Syncope, diastolic murmur, angina
d. Dyspnea, angina, diastolic murmur

4. Which diagnostic test is preferred for evaluation of heart function?
a. Electrocardiogram
b. Chest x-ray
c. Echocardiogram
d. Cardiac catheterization

5. Management of patients with cardiomyopathy is directed at preventing and treating heart failure. The treatment of heart failure includes (*select all that apply*):
a. Reducing circulating blood volume
b. Reducing myocardial oxygen needs
c. Increasing CO by improving contractility or reducing peripheral resistance
d. Increasing preload

6. All of the following are indications for a VAD to be used as a bridge to recovery *except:*
a. Acute myocarditis
b. Cardiogenic shock following an acute myocardial infarction
c. End-stage heart failure
d. Failure to wean from cardiopulmonary bypass following cardiac surgery

7. A patient presents with chest pain. Acute myocardial infarction is excluded and the patient is diagnosed with pericarditis. Which of the following medications would the provider be most likely to prescribe initially? *Select all that apply*.
a. Acetaminophen (Tylenol)
b. Ibuprofen (Motrin)
c. Colchicine
d. Broad Spectrum Antibiotic
e. Coumadin (Warfarin)

8. Which of the following describes the best place to auscultate for the presence of a pericardial friction rub?
a. Left lower sternal border in the fourth intercostal space
b. Right lower sternal border in the fourth intercostal space
c. Left lower sternal border in the second intercostal space
d. Right lower sternal border in the second intercostal space

9. What condition requires IE prophylaxis?
a. MVP
b. Rheumatic heart disease
c. Bicuspid valve disease
d. Prosthetic valve

CHAPTER 17

Nursing Management: Patients with Arrhythmias and Conduction Problems

Catherine G. Winkler

Learning Objectives

After reading this chapter, you will be able to:

1. Describe methods to monitor, diagnose, and treat arrhythmias.
2. Analyze elements of an electrocardiogram (ECG) rhythm strip: atrial and ventricular rate, atrial and ventricular rhythm, P wave and shape, PR interval, the QRS complex and shape, QRS duration and QT interval, and the ST interval.
3. Identify the ECG criteria, causes, and management of several arrhythmias, including conduction disturbances.
4. Use the nursing process as a framework for care of patients with arrhythmias.
5. Compare the different types of electrical therapies, their uses, possible complications, and nursing implications.
6. Describe the key points of using a defibrillator and the associated waveforms.
7. Identify the clinical indications for pacemakers and implantable cardioverter defibrillators (ICD).
8. Identify the electrophysiology diagnostic studies and interventional procedures that patients undergo to treat arrhythmias (e.g., catheter ablation).
9. Describe the patient education that is indicated for patients who experience arrhythmias.
10. Consider the importance of the ethical implications of deactivation of cardiovascular implantable electronic devices (CIEDs) at end of life.

Arrhythmias (also called *dysrhythmias*) are disorders of the electrical impulse within the heart that cause disturbances of heart rate, heart rhythm, or both. Without a normal rate and regular rhythm, the heart does not perform efficiently as a pump to circulate oxygenated blood. Arrhythmias may initially produce symptoms related to the hemodynamic effect they cause, such as a decrease in cardiac output. Refer to Table 17-1 for signs and symptoms of a decreased cardiac output. In addition to decreasing the cardiac output, some arrhythmias increase the risk of clot formation within the chambers of the heart. Arrhythmias are named according to the site of origin of the impulse (e.g., atria or ventricle) and the mechanism of formation or conduction involved (e.g., bradycardia [too slow], tachycardia [too fast], premature [early], etc.). Their presence is confirmed by an electrocardiogram.

THE ELECTROCARDIOGRAM

The electrical impulse that travels through the heart can be viewed by means of an electrocardiogram (ECG). Each phase of the cardiac cycle is reflected by specific waveforms (discussed later in the chapter). The number and placement of the electrodes used depend on the type of ECG needed. The electrodes record waveforms that appear on the paper or monitor and represent the electrical current in relation to the two electrodes (Fig. 17-1). Heart rate and rhythm may be monitored effectively through only two electrodes; however, the use of 10 electrodes (resulting in 12 leads) provides more detailed information and is the basis for understanding other types of electrocardiographic monitoring. The difference between electrodes, wires, and leads is described in Box 17-1.

TABLE 17-1 Signs and Symptoms of Decreased Cardiac Output

System	Signs and Symptoms of Decreased Cardiac Output
Respiratory	Tachypnea, shortness of breath (SOB), orthopnea, dyspnea on exertion (DOE), hypoxemia, crackles on lung auscultation, wheeze, dry or productive cough
Cardiac and peripheral vascular	Edema, jugular vein distention (JVD), displaced point of maximum impulse (PMI), S_3 gallop rhythm, tricuspid and/or mitral regurgitation murmurs, hypotension, decreased mean arterial pressure (MAP), narrow pulse pressure, cool skin and extremities, delayed capillary refill, tachycardia
Renal	Decreased urinary output, oliguria, rising creatinine
Gastrointestinal	Abdominal distention, ascites, liver engorgement, positive abdominojugular reflex
Central nervous	Dizziness, decreased sensorium, syncope, fatigue
Behavioral/ emotional	Anxiety, restlessness

THE 12-LEAD ELECTROCARDIOGRAM

An ECG contains information about the contraction and relaxation of heart chambers. This diagnostic information could change due to various cardiovascular diseases (Dandapat, Sharma, & Tripathy, 2015). The 12-lead ECG is a diagnostic tool that uses 10 electrodes: one placed on each limb and six placed on the chest (precordial). In combination, these 10 electrodes produce 12 different waveforms (or leads). These 12 leads include three bipolar leads (I, II, III) and nine unipolar leads (aVR, aVL, aVF, V_1–V_6). Bipolar leads measure electrical activity traveling between a positive and negative electrode, while unipolar leads record electrical activity from a single reference point. Together, the 12 leads show electrical activity in both a frontal plane and a transverse plane. When viewed together, these two planes provide important diagnostic information beyond heart rate and rhythm, including conduction abnormalities such as bundle branch block (BBB), heart chamber enlargement, localization of ischemia or infarction, and even noncardiac conditions such as electrolyte imbalances caused by hypocalcemia, hyperkalemia, or hypomagnesemia (Hale & Hovey, 2014; Winkler, 2015). Consider taking a picture of a statue from 12 different angles: When merged, a composite picture of the entire statue is achievable, but the viewer is also capable of analyzing unique details of the picture when selecting to view a specific angle—this is the same principle behind ECG monitoring. The 12-lead ECG produces an image of the heart, whereas particular leads view specific areas of the heart.

BOX 17-1 Understanding Electrodes, Wires, and Leads

Electrodes

Electrodes are electrical contacts that are placed on the patient's skin. They come in various shapes. Today's electrodes are disposable for single patient use. They all contain conductive gel and a connector for a wire.

Wires

The electrode is connected to a recording device by a set of wires or cables. The wires are color coded, although the coding system is not internationally consistent. For 12-lead ECGs, there are 10 wires, one for each electrode. For continuous monitoring, there may be anywhere from three to five wires. Three- and four-wire systems allow monitoring of limb leads only, whereas five-wire systems allow monitoring of limb leads plus a chest lead. Some wires come preattached to the electrodes and are disposable; others need to be attached to the electrode and are reusable.

Leads

Leads are the images the nurse sees on the paper or monitor. They represent an examination of the heart from a specific viewpoint. The direction of the ECG complex varies depending on which lead is viewed. The direction of the electric current determines how the waveforms appear on paper.

Electrode placement for a 12-lead ECG must be accurate and consistent as misplacement can result in altered waveforms, which can lead to an inaccurate diagnosis and treatment. Electrode placement is important in arrhythmia identification and is crucial in identifying changes related to ischemia (decreased blood flow often due to atherosclerosis), infarction (cellular damage or death because of limited blood supply), and many arrhythmias. In addition, electrode placement is important in terms of customization to the patient to ensure that clinically relevant data is obtained through placing electrodes strategically on the patient to capture or view the best clinical ECG data.

The four limb electrodes are placed on the lower legs, near the ankles, and on the arms, near the wrists. The remaining six electrodes are placed across the left side of the chest. Locating the specific anatomical landmark is critical for correct chest electrode placement (Box 17-2). If the patient needs a series of ECGs, consistency of electrode placement is also important. In some cases, the chest electrodes are left in place or the correct location is marked with an indelible pen to ensure the identical placement for follow-up ECGs.

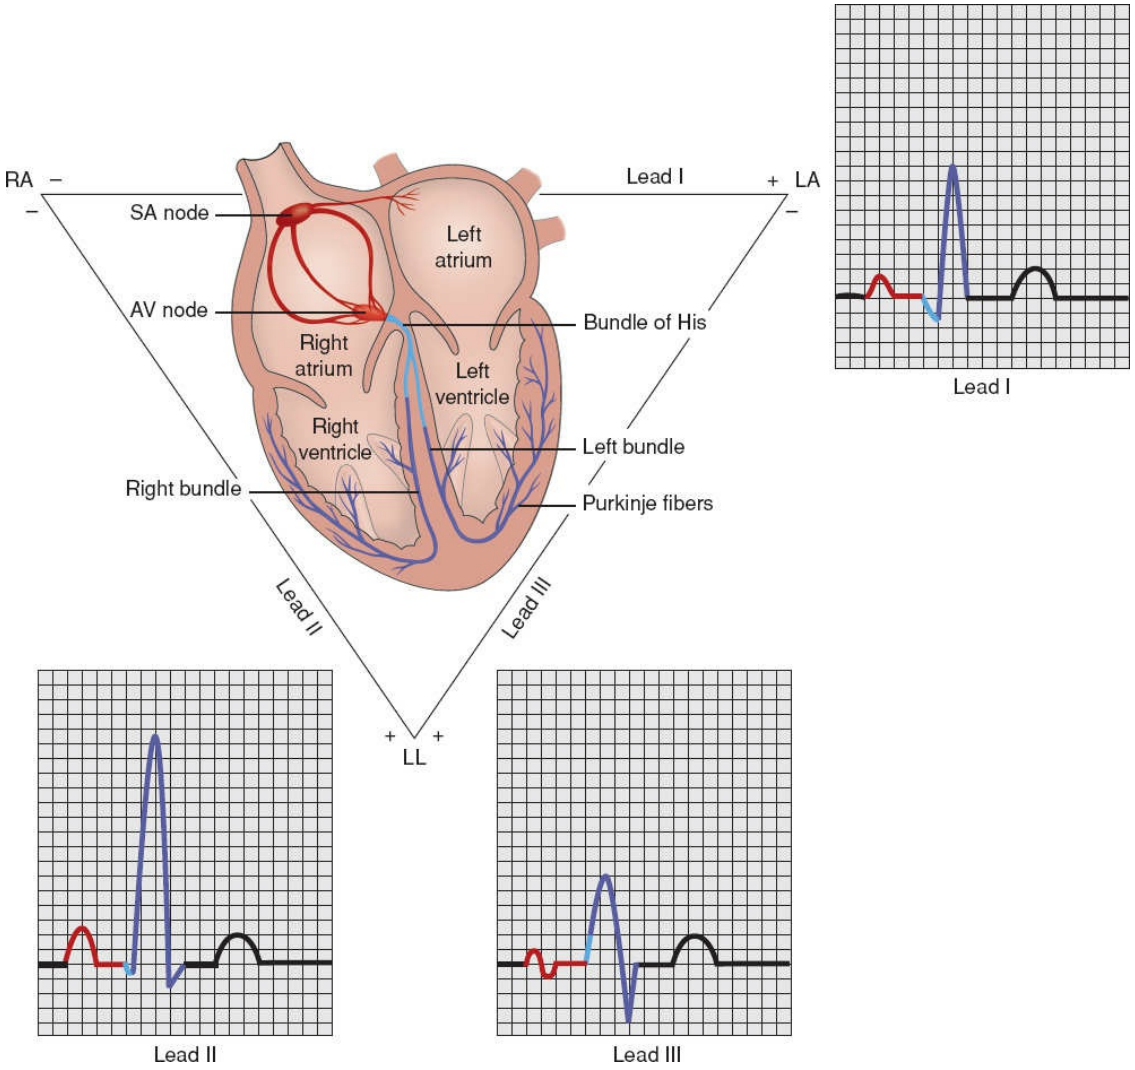

FIGURE 17-1 Relationship of electrocardiogram (ECG) complex, lead system, and electrical impulse. The heart conducts electrical activity, which the ECG measures and records. The configurations of electrical activity displayed on the ECG vary depending on the lead (or view) of the ECG and on the rhythm of the heart. Therefore, the configuration of a normal rhythm tracing from lead I will differ from the configuration of a normal rhythm tracing from lead II, lead II will differ from lead III, and so on. The same is true for abnormal rhythms and cardiac disorders. To make an accurate assessment of the heart's electrical activity or to identify where, when, and what abnormalities occur, the ECG needs to be evaluated from every lead, not just from lead II. Here the different areas of electrical activity are identified by color. RA, right arm; LA, left arm; SA, sinoatrial; AV, atrioventricular; LL, left leg.

The specific locations for electrode placement are shown in Figure 17-2.

V_1 Right side of the sternum, fourth intercostal space

V_2 Left side of the sternum, fourth intercostal space

V_3 Midway between V_2 and V_4

V_4 Midclavicular line, fifth intercostal space (under the breast in women)

V_5 Left anterior axillary line, same level as V_4

V_6 Left midaxillary line, same level as V_4 (Davies & Scott, 2014)

The precordial (anterior surface over the heart) leads reflect the electrical activity primarily in the left ventricle. In some circumstances, an alternative electrode placement

may be required. For example, in patients with suspected right-sided heart damage, right-sided chest leads are required to evaluate the right ventricle (see Fig. 17-2). Electrodes for V_1R (R refers to the right side of the chest) through V_6R are placed in the mirror image of the electrodes on the left side of the chest as detailed here:

V_1R Left side of the sternum, fourth intercostal space
V_2R Right side of the sternum, fourth intercostal space
V_3R Midway between V_2 and V_4
V_4R Midclavicular line, fifth intercostal space (under the breast in women)
V_5R Right anterior axillary line, same level as V_4
V_6R Right midaxillary line, same level as V_4

BOX 17-2 Correct Electrode Placement

Too often, arbitrary markings are used to determine rib positions, such as the areola of the breast. Valid ECG monitoring requires counting ribs for correct placement of electrodes. Begin by finding the sternal notch and slowly move your finger down the manubrium, until a rise is noted. Next, move your hand laterally from the rise until you note the rib at the sternal margin; this is the second rib. Underneath this rib is the second intercostal space (ICS). Count down two more ribs to the fourth ICS and place V_1 electrode on right side of sternum and V_2 on left side of sternum. V3 electrode will be placed midway between V_2 and V_4. The V_4 electrode is placed at the fifth ICS at the midclavicular line. The V_5 electrode is placed at the same level of V_4 at the left anterior axillary line, and the V_6 electrode is at same level as V_4 and V_5 at the left midaxillary line. It may be helpful to mark this placement for consistent ECG placements in the future.

CONTINUOUS MONITORING

Targeted or patient-centric ECG monitoring is best applied when an immediate assessment of the patient can be made to determine the optimal monitoring level. Based on the admission diagnosis and changes in the clinical course during hospitalization, ongoing medical decisions are predicated on the goals of care and specific interventions. Patients are monitored for a variety of reasons: to detect changes in the patient's clinical condition, to diagnose a problem, to assess a response to an intervention, to prevent an undesirable event, and for surveillance before and after cardiac surgery (Winkler, 2015).

The American Heart Association (AHA) practice standards for ECG monitoring in the hospital setting were last published in 2004 by Drew and colleagues and provide direction in deciding which patients are best served by cardiac monitoring during an episode of illness. The practice standards group patients into the following classes:

- Class I: indicated for all patients such as those who have been resuscitated from cardiac arrest
- Class II: possibly indicated, but not essential, which includes patients who are post-acute myocardial infarction (MI) for 24 to 48 hours for ECG monitoring of arrhythmia, ST-segment ischemia, and/or QTc interval, and
- Class III: not indicated because risk is so low for patients such as those who have permanent, rate-controlled atrial fibrillation (AF).

FIGURE 17-2 ECG electrode placement. The standard left precordial leads are V_1—fourth intercostal space, right sternal border; V_2—fourth intercostal space, left sternal border; V_3—diagonally between V_2 and V_4; V_4—fifth intercostal space, left midclavicular line; V_5—same level as V_4, anterior axillary line; V_6 (not illustrated)—same level as V_4 and V_5, midaxillary line. The right precordial leads, placed across the right side of the chest, are the mirror opposite of the left leads. RA, right arm; LA, left arm; RL, right leg; LL, left leg. (Adapted from Molle, E. A., Kronenberger, J., West-Stack, C., & Durham, L. S. (2005). *Lippincott Williams & Wilkins' Pocket Guide to Medical Assisting* (2nd ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

After a decision is made regarding the class of ECG monitoring and the intensity that is required for the patient, the specific inpatient setting and the timeframe for monitoring are selected. Monitoring is an important diagnostic tool for heart disease and changes in health status. Important clinical decisions are made based on the data, to include medication therapy, device (pacemaker, ICD) adjustments, further diagnostic testing, referral for cardiac consultation, unit transfers, and length of stay (Winkler, 2015).

However, as important as understanding when a patient does require ECG monitoring is recognizing when the patient does not. Unnecessary monitoring increases health care costs, diverts nursing and medical staff from other important work, and may give the patient an incorrect message about his or her cardiac health (i.e., that the patient is more ill than he or she actually is). In addition, the ubiquitous nature of alarms in hospitals has been associated with compromised patient safety to such an extent that the Joint Commission has deemed alarm management a National Patient Safety Goal (2013).

Accordingly, ECG monitoring with human oversight of the patient remains indispensable but needs to be evaluated continuously because the standard of care evolves over time and the aim needs to be to deliver the right "type" and "dose" of cardiac monitoring (Winkler, 2015). Through an understanding of the patient's underlying condition and the pathology, the nurse can select the leads that will supply the most clinically significant information.

ECG monitoring systems vary in sophistication but, in general, can do the following:

- Monitor one limb lead or one limb lead plus one chest lead
- Monitor ST segments (ST-segment depression is a marker of myocardial ischemia; ST-segment elevation provides evidence of an evolving MI)
- Monitor QT segments for prolongation
- Provide graded visual and audible alarms (based on priority, asystole would be highest)
- Provide computerized rhythm monitoring (arrhythmias are interpreted and stored in the memory of the monitoring system)
- Produce a graphical recording
- Interface with the electronic medical record (as applicable)

Continuous monitoring systems have anywhere from three to five electrodes with capability of viewing two to ten leads. Box 17-3 provides helpful hints on how to apply these electrodes. In continuous monitoring, although limb electrodes are still used, they are positioned on the torso as opposed to the lower legs and arms, as in a 12-lead ECG. This allows for greater patient movement and comfort and reduced interference from skeletal muscle artifact. The four disposable electrodes are positioned in specific locations on the

patient's chest, and a cable is connected to the monitor or telemetry device in the following arrangement: the right arm (RA) electrode placed on the right upper chest (below the clavicle) and the RA wire (usually white) attached; the left arm (LA) electrode placed on the left upper chest (below the clavicle) and the LA wire (usually black) attached; the left leg (LL) electrode placed on the left torso below the rib cage and on the left side of the abdomen and the LL wire (usually red) attached; the right leg (RL) electrode placed on the right torso and the RL wire (usually green) attached. A maxim used to recall placement is "white on right (snow over grass [green]) and smoke (black) over fire (red)." The color-coding of wires is not an international standard. To reduce interference from skeletal muscle when placing electrodes, it is helpful to avoid boney prominences or areas that have significant movement. It is also important to ensure that the electrodes have not expired (expiration date on package) and, if the package has been opened, that the electrodes have not dried out. In addition, the electrodes need to be applied properly to the skin by prepping the skin according to manufacturer's directions and removing excessive chest hair. Expert opinion and research support proper skin preparation to reduce the number of false alarms. Walsh-Irwin and Jurgens (2015) found that electrocardiographic alarms decreased significantly (p <0.05) after proper skin preparation and electrode placement (95% confidence interval). Reducing alarm frequency or the number of false alarms is central to decreasing alarm fatigue and increasing patient safety in the inpatient environment (Walsh-Irwin & Jurgens, 2015).

BOX 17-3 Helpful Hits for Applying Electrodes

These guidelines optimize skin adherence and the conduction of electrical currents.

- Have the patient positioned supine with the head of the bed at an angle of 30–40 degrees. This will make it easier to find the intercostal spaces for electrode placement. Provide as much privacy for the patient as possible.
- Débride the skin surface of dead cells with soap and water, and dry well. This decreases skin impedance and increases conductivity.
- Clip (do not shave) hair from around the electrode site if needed.
- If the patient is diaphoretic, apply a small amount of benzoin to the skin or wipe with alcohol, avoiding the area under the center of the electrode. (These are controversial recommendations. Benzoin, like alcohol, may increase the risk of burns if the patient requires cardioversion or defibrillation.)
- Connect the electrodes to the lead wires prior to placing them on the chest; peel the backing off the electrode and make sure the center is moist with electrode gel.
- Locate the landmarks for lead placement and use light, consistent pressure to secure the electrode.
- Change the electrodes every 24–48 hours (or as recommended by the manufacturer), examine the skin for irritation, and apply the electrodes to different locations. This, too, is debatable although evidence suggests that changing the electrodes daily decreases the number of "false alarms" according to the AACN Practice Alert on Alarm Management (Sendelbach & Jepsen, 2013).

- If the patient is sensitive to the electrodes, use hypoallergenic electrodes.

The signals are transmitted either directly to a bedside monitor (hardwire) or by radio waves from a small transmitter box to a central monitoring station (telemetry).

The most basic monitoring system uses three electrodes to allow monitoring in one of three bipolar limb leads. Leads that can be monitored are lead I (positive electrode on the LA, negative electrode on the RA), lead II (positive electrode on the LL and negative electrode on the RA), and lead III (positive electrode on the LL and negative electrode on the LA). These are useful for heart rate and basic rhythm recognition. They are inadequate for accurately identifying many arrhythmias, especially tachycardias (increased heart rate) with a wide QRS. Bipolar limb lead monitoring systems are often found on portable monitors, defibrillators, and some telemetry ECG devices.

TABLE 17-2 Monitoring Recommendations, Vessels, and Recommended Leads

Type of Monitoring	Coronary Vessel Involved	Lead Selection
Arrhythmia monitoring Primary lead	LAD	V_1—intraventricular septum
Arrhythmia monitoring Secondary lead	Left circumflex	V_6—lateral wall
Ischemia monitoring	LAD	V_3—anterior wall V_1, V_2, V_4
Ischemia monitoring	RCA	III—inferior wall II, aVF
Ischemia monitoring	Left circumflex	V_5 and V_6—lateral wall I, aVL—sometimes no change V_1, V_2, or V_3 for reciprocal changes posterior wall
If ischemic footprint unknown	LAD and RCA	V_3 and III—anterior and inferior leads
Demand ischemia	Left circumflex	V_5—lateral wall
QT-interval monitoring	N/A	Monitor in the lead with best defined T wave

LAD, left anterior descending; RCA, right coronary artery.

Five-electrode monitoring systems use four electrodes placed as above, in the LA, RA, LL, and RL positions, as well as one chest electrode that can be placed in any one of the precordial locations (V_1–V_6). Monitoring systems with five electrodes permit the nurse to decide which leads will be monitored based on the patient's diagnosis and condition. Five-electrode systems have a display that allows two leads to be monitored simultaneously; typically, the nurse chooses one limb lead and one precordial lead to be viewed. The ability to monitor a limb lead and precordial lead simultaneously is often necessary for accurate

identification of many arrhythmias, including arrhythmias with a wide QRS complex (BBBs, ventricular pacemaker rhythms, and wide QRS tachycardias). Two leads commonly used for continuous monitoring are leads II and V_1. Lead II provides the best visualization of atrial depolarization (represented by the P wave) and is preferred for monitoring atrial activity and heart rate. Lead V_1 best records ventricular depolarization and is most helpful when monitoring the patient for tachycardias. The AACN Practice Alert for dysrhythmia monitoring and the AHA Practice Standards for ECG monitoring recommend V_1 as the preferred lead to monitor for wide QRS complex tachycardia. The next best lead is V_6. Monitoring for ST-segment changes is also important in terms of detecting ischemia. If the patient's history is known, it is best to monitor the patient in a more directed way using the leads that reflect the vessels involved in the ischemic event. Refer to the monitoring recommendations in Table 17-2 when the patient's history is known.

Further, patients who have or are at risk for prolongation of the QT interval should also be monitored. Prolongation of the QT interval can occur because of a genetic predisposition or through acquired abnormalities such as kidney failure, hypokalemia, and acute pancreatitis. However, in the acute care setting, QT prolongation is often due to medications, such as some antibiotics, antipsychotics, antiarrhythmics, and antiemetics (Ferri, 2016a). The QTc is considered prolonged when it is above 0.47 second in males and 0.48 second in females. If the QTc is above 0.50 second in anyone, it can be associated with a higher risk of torsade de pointes (Roden, 2015).

Ambulatory Electrocardiography

Ambulatory ECG is a continuous form of monitoring used in the outpatient setting to identify the etiology of distressing symptoms (pre-syncope, syncope, palpitations) that may be caused by arrhythmias, myocardial ischemia, or pacemaker dysfunction. In addition to monitoring for arrhythmias and evaluation of silent ischemia, ambulatory monitoring is used to evaluate arrhythmia and device therapy as well as prognosis and risk stratification of various cardiac populations. Ambulatory ECG monitoring may also be used in patients who have had a cryptogenic stroke (strokes that cannot be attributable to any specific cause) where paroxysmal AF is suspected (Afzal et al., 2015) or with hypertrophic cardiomyopathy, or in patients with variant angina. The patient wears a portable recording device (i.e., Holter monitor) that is connected to the chest by electrodes and lead wires. The patient keeps a diary while wearing this device, noting the type and time of symptoms or performance of unusual activities. The patient may also wear an event loop monitor or an implantable loop recorder, which are categorized as intermittent recorders and selected when patients have infrequent symptoms. The monitoring period may be as short as 24 to 48 hours or as long as several months.

Transtelephonic Monitoring

Transtelephonic monitoring (TTM), a form of outpatient ECG monitoring, transmits ECG signals via the telephone. Chest electrodes are connected to a transmitter box. To send the ECG, the telephone mouthpiece is placed over the transmitter box, and the ECG is evaluated at another location. This method is used for diagnosing arrhythmias and evaluating permanent cardiac pacemakers. It is a patient-activated recording that can be sent directly over the phone line and captures data when symptoms present during activities of daily living.

Wireless Mobile Cardiac Monitoring Systems

This outpatient monitoring system, mobile cardiac telemetry (MCT), uses a small sensing device worn by the patient; it transmits the ECG signal to a monitor. When an arrhythmia is detected, the system transmits the ECG to a monitoring center via a telephone line or a wireless communication system. This system enhances detection and early treatment of arrhythmias.

INTERPRETING THE ELECTROCARDIOGRAM

ECG waveforms are printed on graph paper that is divided by light and dark vertical and horizontal lines at standard intervals (Fig. 17-3). Time and rate are measured on the horizontal axis of the graph, and amplitude or voltage is measured on the vertical axis. Each small block on the graph paper equals 0.04 second, and five small blocks form a large block, which equals 0.2 second. When an ECG waveform moves toward the top of the paper, it is called a *positive deflection.* When it moves toward the bottom of the paper, it is called a *negative deflection.*

The ECG is composed of waveforms (including the P wave, the QRS complex, the T wave, and possibly a U wave) and of segments or intervals (PR interval, the ST segment, and the QT interval) (see Fig. 17-3).

The P wave represents the electrical impulse starting in the sinus node and spreading through the atria (atrial depolarization leading to atrial contraction).

The PR interval is measured from the beginning of the P wave to the beginning of the QRS complex and represents the time needed for sinus node stimulation, atrial depolarization, and conduction through the AV node before ventricular depolarization. In adults, the normal range for the PR is 0.12 to 0.20 second.

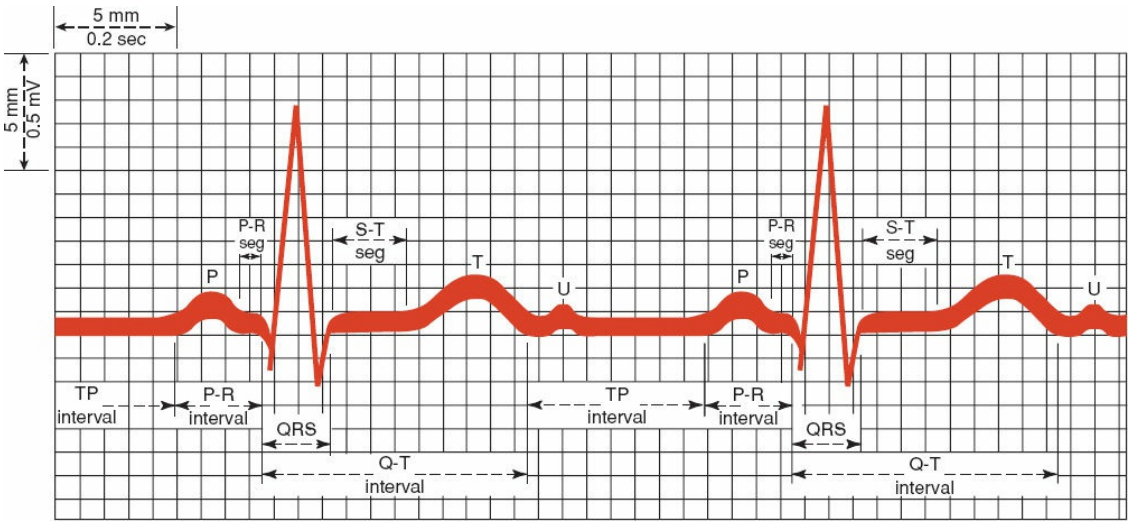

FIGURE 17-3 ECG and commonly measured components. Each small box represents 0.04 second on the horizontal axis and 1 mm or 0.1 millivolt on the vertical axis. The PR interval is measured from the beginning of the P wave to the beginning of the QRS complex; the QRS complex is measured from the beginning of the Q wave to the end of the S wave; the QT interval is measured from the beginning of the Q wave to the end of the T wave; and the TP interval is measured from the end of the T wave to the beginning of the next P wave.

The QRS complex represents ventricular depolarization. Not all QRS complexes have all three waveforms. The Q wave is the first negative deflection after the P wave. The R wave is the first positive deflection after the P wave, and the S wave is the first negative deflection after the R wave. The QRS complex is normally less than 0.10 second in duration (2.5 small boxes).

The T wave represents ventricular repolarization or electrical recovery. It follows the

QRS complex and is usually in the same direction as the QRS complex. Atrial repolarization also occurs but is not visible on the ECG because it occurs at the same time as the QRS.

The U wave may or may not be present and is thought to represent repolarization of the Purkinje fibers; it is, however, sometimes seen in patients with hypokalemia (low potassium levels), hypertension, or heart disease. If present, the U wave follows the T wave and is usually smaller than the P wave. If tall, it may be mistaken for an extra P wave.

The ST segment, which represents early ventricular repolarization, lasts from the end of the QRS complex to the beginning of the T wave. The beginning of the ST segment is usually identified by a change in the thickness or angle of the terminal portion of the QRS complex and is called the *J point*. The end of the ST segment may be more difficult to identify because it merges into the T wave. The ST segment is analyzed to identify whether it is above or below the isoelectric line, which may be, among other signs and symptoms, a sign of cardiac ischemia.

Nursing Alert

Nurses should note ST-segment changes and obtain a 12-lead ECG because:

- *ST-segment depression is seen with ischemia*
- *ST-segment elevation is seen with injury*
- *Q waves are seen with necrosis and infarction*
- *Patients sometimes have silent myocardial ischemia with no associated symptoms such as chest pain. Often silent ischemia occurs in patients with diabetes. Therefore, ST-segment changes viewed on an ECG may be the only way to know that there is a significant cardiac problem.*

The QT interval, which represents the total time for ventricular depolarization and repolarization, is measured from the beginning of the QRS complex to the end of the T wave. The QT interval varies with heart rate, gender, and age. If the QT interval becomes prolonged, the patient may be at risk for a lethal ventricular arrhythmia called *torsade de pointes.* The corrected QT (QTc) is calculated based on heart rate and is a determinant of risk for torsade de pointes arrhythmia. The nurse should measure the QT interval every 8 to 12 hours and calculate the QTc on printouts of rhythm strips from the bedside or telemetry monitor for patients at risk for torsade de pointes. An alternative is to use the cardiac monitoring system QT measurement if your hospital system has it as a feature. As referenced earlier, QTc greater than 0.47 second for males or greater than 0.48 second for females is indicative of increased risk of torsade de pointes, and a QTc of more than 0.50 second is considered dangerously prolonged (Ferri, 2016).

Nursing Alert

The QT interval (QTc) using the Bazett formula: QT interval divided by the square root of the RR interval. The RR interval is measured from one R wave to the next R wave that comes before the QT interval being measured (Bazett, 1920).

The PP and RR intervals are measured from the beginning of one P or R wave to the beginning of the next P or R wave. The PP interval is used to determine atrial rate and rhythm. The RR interval is measured from one QRS complex to the next QRS complex.

The RR interval is used to determine ventricular rate and rhythm (Fig. 17-4).

ANALYZING THE ELECTROCARDIOGRAM RHYTHM STRIP

The ECG must be analyzed in a systematic manner to determine the patient's cardiac rhythm and to detect arrhythmias and conduction disorders. If continuous ST-segment monitoring is in use, evidence of myocardial ischemia, injury, and infarction may also be detected.

Box 17-4 is an example of a method that can be used to analyze the patient's rhythm.

Normal sinus rhythm occurs when the electrical impulse starts at the sinus node and travels through the normal conduction pathway. Normal sinus rhythm serves as a baseline for comparison in identifying all other arrhythmias. ECG characteristics are as follows:

Rate: 60 to 100 in the adult
Rhythm: Regular
P wave: Normal and consistent shape; always in front of the QRS
PR interval: Consistent interval between 0.12 and 0.20 second
QRS duration: Less than 0.10 second

See Figure 17-5.

ARRHYTHMIAS

As our population grows older, where we now define elder groups who range from youngest old (65 to 74 years of age) to elite old (centenarians), the normative aging processes coupled with high incidences of heart disease and polypharmacy with frequent drug–drug interactions show that arrhythmias will continue to be a growing health care concern requiring monitoring, ongoing assessment, and treatment. Nurses are in a unique position to be the ones who first discover the arrhythmia and, later, to educate the patient on the management of this condition to preserve and support a good quality of life.

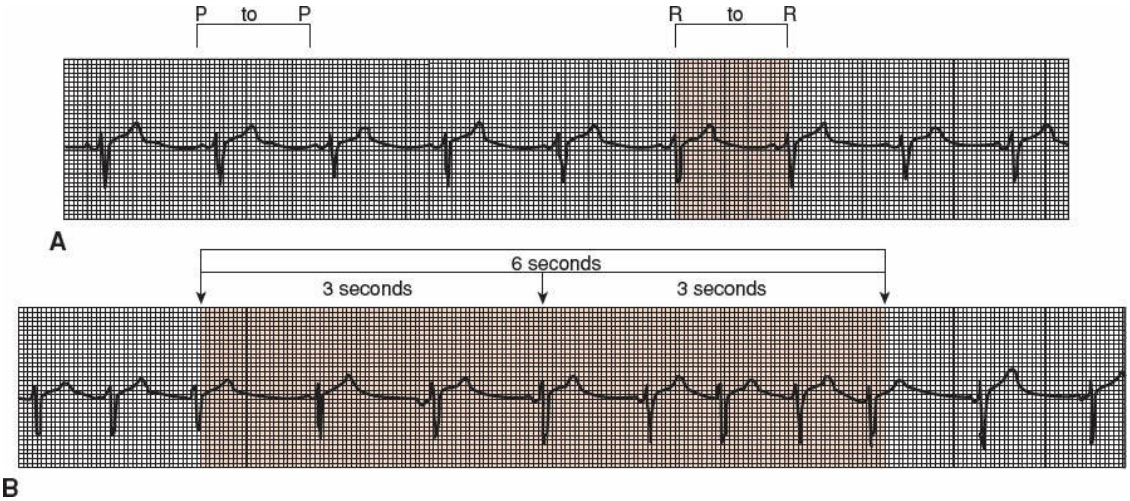

FIGURE 17-4 A. Ventricular and atrial heart rate determination with a regular rhythm: 1,500 divided by the number of small boxes between two P waves (atrial rate) or between two R waves (ventricular rate). In this example, there are 25 small boxes between both the R waves and the P waves, so the heart rate is 60 bpm. B. Heart rate determination if the rhythm is irregular. There are approximately 7 RR intervals in 6 seconds, so there are about 70 RR intervals in 60 seconds (7 × 10 = 70). The ventricular heart rate is 70 bpm.

BOX 17-4 Interpreting Arrhythmias: Systematic Analysis of the Electrocardiogram

Step 1: Determine the Heart Rate

The heart rate is usually visible on the monitor display or on the printed rhythm strip. However, the monitor will also record "artifact," which may alter the heart rate. The heart rate should always be confirmed by one of the following methods.

Note: the term artifact refers to "noise" that is not related to the heart and produces a "fuzzy" or obscured waveforms. It may be associated with electrical interference by outside sources, poor electrode contact, patient tremors, and malfunction of equipment.

Six-second Method

Locate the 3-second markers along the top or bottom of the ECG paper. Count the number of R waves (ventricular rate) or P waves (atrial rate) occurring between two 3-

second markers (thus total time is 6 seconds) and multiply by 10 (thus, 60 seconds or 1 minute).

Large-box Method

Count the number of large boxes between two consecutive R waves (ventricular rate) or P waves (atrial rate) and divide into 300. If, for example, there are four large boxes between two R waves, the heart rate is 300/4, or 75.

Small-box Method

Count the number of small boxes between two consecutive R (ventricular rate) or P waves (atrial rate) waves and divide into 1,500. If, for example, there are 10 small boxes between two R waves, the heart rate is 1500/10, or 150 (see Fig. 17-4).

The normal heart rate is between 60 and 100. The term *bradycardia* is used when the heart rate is below 60, whereas *tachycardia* refers to rates above 100.

Step 2: Determine the Rhythm Regularity

Measure the distance between two consecutive R waves (ventricular regularity) or between two consecutive P waves (atrial regularity). Compare the distance between other RR or PP intervals. If the distance is consistent, the rhythm is regular; if the distance varies, the rhythm is irregular. The normal rhythm is regular.

Step 3: Determine if the Rhythm Originated in the SA Node

Look for a P wave and determine if there is one P wave for every QRS. Determine if the size and shape of the P wave is consistent. The normal rhythm has one P wave for every QRS complex. Because P waves represent the contraction across both atria, irregularities in shape are noted with conduction defect within the atrium, atrial enlargement, or hypertrophy.

Step 4: Evaluate Conduction

Measure the PR interval and the QRS duration. The normal PR interval is between 0.12 (three small boxes) and 0.20 (five small boxes) second. The normal QRS interval is less than 0.10 second (2.5 small boxes). QRS duration of more than 0.10 is termed "wide QRS" and is indicative of abnormal ventricular conduction, such as BBBs or ventricular tachycardia.

Step 5: Evaluate the Appearance of the Rhythm

Look for premature beats or elevated or depressed ST segments. ST elevation/depression is associated with ventricular injury/ischemia.

Step 6: Interpret the Rhythm

Compare the findings to the defining characteristics of specified arrhythmias.

Step 7: If a change is noted from the patient's baseline, evaluate the patient, consider obtaining a 12-lead ECG, and report the change to the provider as appropriate.

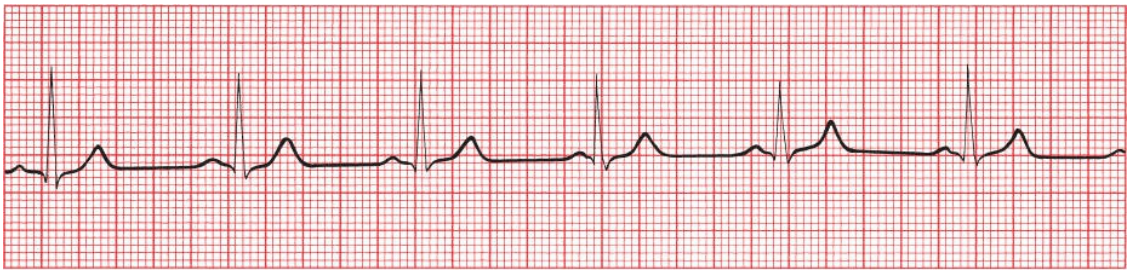

FIGURE 17-5 A typical rhythm strip. It can be as short or as long as you need to decipher the rhythm. This particular strip represents a continuous recording of lead II in a patient with normal sinus rhythm, the normal rhythm of the heart.

SINUS NODE ARRHYTHMIAS

SINUS ARRHYTHMIA

Sinus arrhythmia occurs when the sinus node creates an impulse at an irregular rhythm. Sometimes the irregularity is associated with the respiratory cycle. The rate increases with inspiration and decreases with expiration because the SA node fires more quickly with inspiration. Sinus arrhythmia does not cause any significant hemodynamic effect and is not clinically significant. It occurs frequently in the young and decreases in frequency with age.

SINUS BRADYCARDIA

Pathophysiology

Sinus bradycardia occurs when the sinus node creates an impulse at a slower-than-normal rate. The causes include lower metabolic needs (e.g., sleep, athletic training, hypothyroidism), vagal stimulation (e.g., from vomiting, suctioning, severe pain, extreme emotions), medications (e.g., calcium-channel blockers, amiodarone, beta blockers), increased intracranial pressure (ICP), and MI specifically the inferior wall (10% to 15% of patients with inferior MIs develop sinus bradycardia) (Olgin & Zipes, 2015).

Clinical Manifestations and Assessment

Sinus bradycardia often does not cause symptoms though the context or etiology may be important to treat. The patient is assessed to determine the hemodynamic effect, if any, and the possible cause of the arrhythmia.

ECG characteristics are:

Rate: Less than 60 beats per minute (bpm)
Rhythm: Regular
P wave: Present before each QRS and consistent in size and shape
PR interval: Normal
QRS duration: Normal

See Figure 17-6.

Medical and Nursing Management

Only bradycardias that cause serious signs and symptoms (altered mental status, ongoing chest pain, hypotension, or shock) require immediate treatment. Treatment of symptomatic bradycardia includes transcutaneous pacing and atropine. If pacing is unavailable or ineffective, a dopamine or epinephrine infusion may be considered (Neumar et al., 2015). If significant bradycardia is due to medications, the medications should be withheld while their necessity is re-evaluated.

Nursing Alert

For new-onset syncope and bradycardia, the nurse asks the patient about recent medications during patient admission history, since medications are the cause of most cases of symptomatic bradycardia. Consider a wide variety of medications, including beta-adrenergic blocking eye drops for the treatment of glaucoma. Recall that if the puncta is not occluded with administration, the medication can drain into tear ducts and be systemically absorbed, resulting in syncope secondary to bradycardia (Miller & Zipes, 2015).

SINUS TACHYCARDIA

Pathophysiology

Sinus tachycardia occurs when the sinus node creates an impulse at a faster-than-normal rate. Causes may include the following:

- Physiologic or psychological stress (e.g., acute blood loss, anemia, shock, hypervolemia, hypovolemia, heart failure, pain, pulmonary emboli, hypermetabolic states, fever, exercise, anxiety)

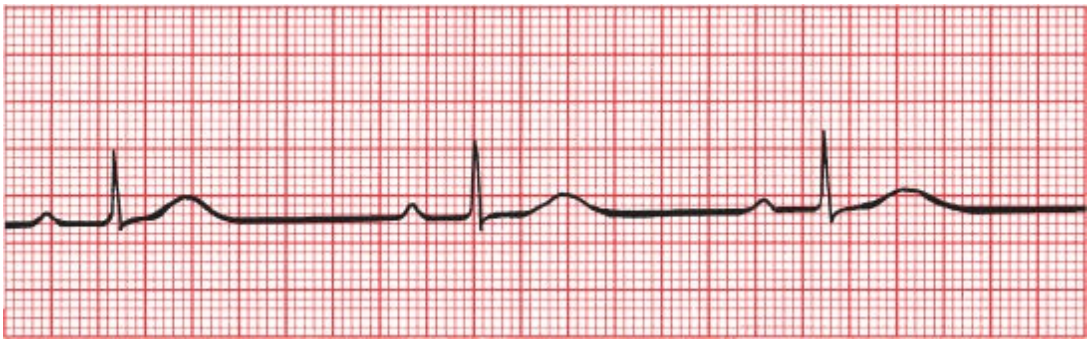

FIGURE 17-6 Sinus bradycardia. More than seven large squares separate each beat, and the rate is 40 to 45 beats per minute.

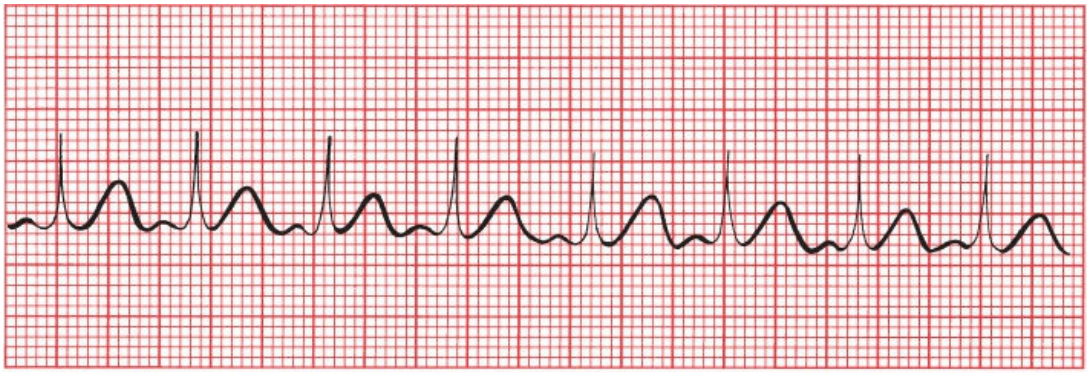

FIGURE 17-7 Sinus tachycardia. Each beat is separated by two and one half large squares for a rate of 120 beats per minute.

- Medications that stimulate the sympathetic response (e.g., catecholamines, aminophylline, atropine, thyroid medications), stimulants (e.g., caffeine, alcohol, nicotine), and illicit drugs (e.g., amphetamines, cocaine, ecstasy)

Clinical Manifestations and Assessment

Sinus tachycardia often does not cause symptoms like bradycardia, the context is important to determine if an intervention is clinically indicated. As the heart rate increases, the diastolic filling time decreases, possibly resulting in reduced cardiac output and associated symptoms (refer to Table 17-1). If the rapid rate persists and the heart can no longer compensate for the decreased ventricular filling, the patient may develop acute pulmonary edema or cardiac ischemia.

ECG characteristics are:

Rate: Greater than 100 bpm
Rhythm: Regular
P wave: Present before each QRS and consistent in size and shape
PR interval: Normal
QRS duration: Normal

See Figure 17-7.

Medical and Nursing Management

Treatment of sinus tachycardia is usually determined by the severity of symptoms and directed at identifying and treating its cause. For example, tachycardia caused by acute blood loss would be treated with intravenous (IV) fluid replacement and blood transfusion. Common causes of sinus tachycardia in hospitalized patients include agitation, hemorrhage, or sepsis; in outpatient settings consider hyperthyroidism, anemia, infection or inflammation, and hypovolemia (Olgin & Zipes, 2015).

ATRIAL ARRHYTHMIAS

PREMATURE ATRIAL COMPLEX

Pathophysiology

A premature atrial complex (PAC) is a single ECG complex that occurs when an electrical impulse starts in the atrium before the next normal impulse of the sinus node. The PAC may be caused by caffeine, alcohol, nicotine, stretched atrial myocardium (e.g., as in hypervolemia), anxiety, hypokalemia (low potassium level), hypermetabolic states (e.g., with pregnancy), hypoxemia, or atrial ischemia, injury, or infarction.

Clinical Manifestations and Assessment

PACs are common ECG findings, often found without cardiac pathology. The patient may report, "My heart skipped a beat"; however, many times the patient is asymptomatic.

ECG characteristics are:

Rate: Depends on the underlying rhythm

Rhythm: Irregular

P wave: Size and shape of the P wave associated with the premature beat is different from sinus node–generated P wave

PR interval: The PR interval of the premature beat is greater than 0.12 second but shorter than the sinus generated PR interval

QRS duration: Normal

See Figure 17-8.

Medical and Nursing Management

If PACs are infrequent, no treatment is necessary since hemodynamic stability is maintained. If they are frequent (more than six per minute), this may be a sign of a worsening condition or the onset of more serious arrhythmias, such as AF, and further work-up may be clinically indicated.

ATRIAL FLUTTER

Pathophysiology

Atrial flutter occurs in the atrium and creates impulses at a rapid but regular atrial rate between 220 and 350 times per minute. Because the atrial rate is faster than the atrioventricular (AV) node can conduct, not all atrial impulses are conducted into the ventricle. This is an important feature of this arrhythmia because if all atrial impulses were conducted to the ventricle, the ventricular rate would also be 220 to 350, which would result in a life-threatening arrhythmia. Causes include coronary artery disease (CAD), hypertension, mitral or tricuspid valve disease, hyperthyroidism or thyrotoxicosis, chronic lung disease, cor pulmonale (right ventricular failure), pulmonary emboli, previous extensive atrial ablation, and cardiomyopathy. A clinical relationship between atrial flutter and AF can be appreciated often in the same patient post open heart surgery (Olgin & Zipes, 2015).

Clinical Manifestations and Assessment

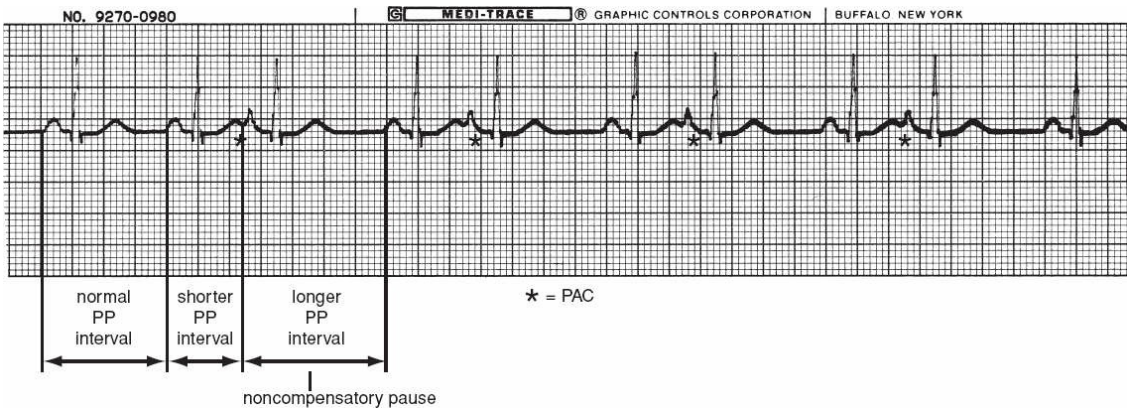

FIGURE 17-8 Premature atrial complex (PAC). Normal sinus rhythm with one premature atrial contraction (PAC).

Atrial flutter may not cause any symptoms or, instead, may cause serious signs and symptoms, such as fatigue, lightheadedness, chest pain, shortness of breath, and low blood pressure. The risk of mural (wall) emboli forming in the atria increases with this arrhythmia because without a strong atrial contraction, stasis of blood occurs; therefore, the nurse remains alert for signs of pulmonary or systemic emboli.

ECG characteristics are:

Rate: Atrial rate ranges between 220 and 350 bpm; ventricular rate usually ranges between 75 and 150 depending on AV node conduction

Rhythm: Usually regular but may be irregular because of a change in the AV conduction

P wave: Flutter waves in a characteristic "sawtooth" pattern

PR interval: Not measurable

QRS duration: Normal

See Figure 17-9.

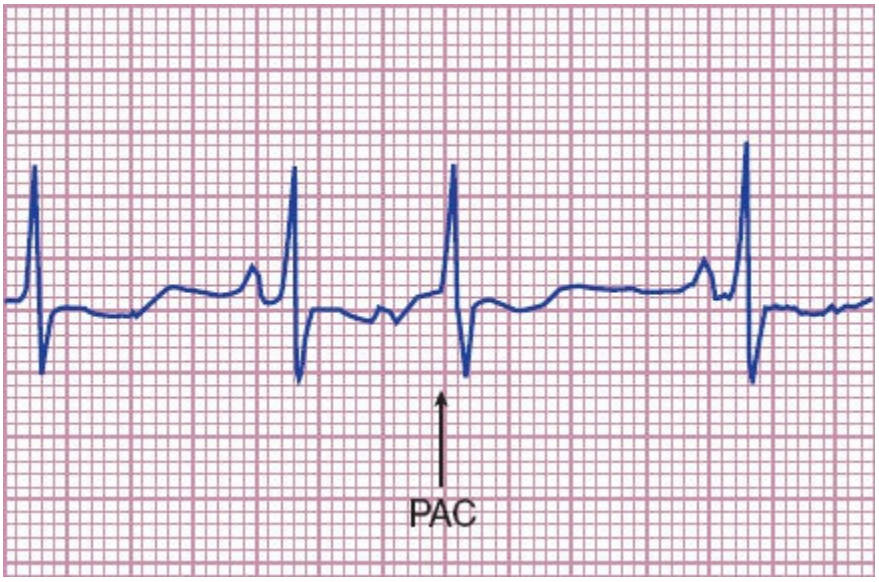

FIGURE 17-9 The classic saw-toothed pattern of atrial flutter.

Medical and Nursing Management

As noted in the 2014 AHA/ACC/HRS Guidelines, the initial treatment for atrial flutter commonly is cardioversion or radiofrequency ablation (discussed later in this chapter) to terminate it and restore NSR (January et al., 2014). If the patient is unstable, urgent electrical cardioversion is usually indicated (discussed later in this chapter). For patients who have atrial flutter, antithrombotic therapy is recommended per the same risk profile used for AF (AHA/ACC/HRS, 2014). In addition, flecainide, dofetilide, propafenone, and intravenous ibutilide are useful for pharmacologic cardioversion of AF or atrial flutter, provided there are no contraindications to the selected medication (AHA/ACC/HRS, 2014). Refer to Table 17-3 for medication management of AF.

ATRIAL FIBRILLATION

Pathophysiology

AF should be distinguished from atrial flutter. AF causes rapid, disorganized, and uncoordinated electrical activity within the atria. AF may be transient, starting and stopping suddenly and occurring for a very short time (paroxysmal), or it may be persistent, requiring treatment to terminate the rhythm or to control the ventricular rate. Further, AF may be described in terms of duration of episodes, such as long-standing, permanent, or nonvalvular AF. Long-standing persistent AF is continuous or AF lasting longer than 12 months in duration; permanent AF is used when the physician and patient together decide to stop further attempts to restore and maintain NSR. Finally, the term nonvalvular AF is used when AF exists in the absence of rheumatic mitral stenosis, a mechanical or bioprosthetic heart valve, or mitral valve repair (AHA/ACC/HRS, 2014). The erratic atrial contraction promotes formation of thrombi within the atria, increasing the risk for an embolic event such as stroke (brain attack). In fact, patients with AF have a fivefold increase in the risk for stroke and a twofold increase in mortality (Morady & Zipes, 2015). AF is usually associated with increasing age, valvular heart disease, CAD, hypertension, heart failure, cardiomyopathy, diabetes, obstructive sleep apnea, obesity, hyperthyroidism, pulmonary disease, chronic lung disease, and surgery (especially open heart surgery). Physiologic stressors, such as hypoxia, infection, and hypoglycemia; as well as the use of caffeine, alcohol, or sympathomimetic drugs; and smoking are also associated with AF. An additional risk factor for AF is psoriasis, which, if severe, triples the risk for AF in patients younger than 50 years (Morady & Zipes, 2015, p. 800). It is important to note that sometimes AF occurs in people without any underlying pathophysiology.

TABLE 17-3 Common Medication Dosage for Rate Control of AF

	Intravenous Administration	Usual Oral Maintenance Dose
Beta Blockers		
Metoprolol tartrate	2.5–5.0 mg IV bolus over 2 minutes; up to 3 doses	25–100 mg BID
Metoprolol XL (succinate)	N/A	50–400 mg QD
Atenolol	N/A	25–100 mg QD
Esmolol	500 mcg/kg IV bolus over 1 minute, then 50–300 mcg/kg/min IV	N/A
Propranolol	1 mg IV over 1 minute, up to 3 doses at 2-minute intervals	10–40 mg TID or QID
Nadolol	N/A	10–240 mg QD
Carvedilol	N/A	3.125–25 mg BID
Bisoprolol	N/A	2.5–10 mg QD
Nondihydropyridine Calcium-Channel Antagonists		
Verapamil	0.075–0.15 mg/kg IV bolus over 2 minutes; may give an additional 10.0 mg after 30 minutes if no response, then 0.005 mg/kg/min infusion	180–480 mg QD (ER)
Diltiazem	0.25 mg/kg IV bolus over 2 minutes, then 5–15 mg/hr	120–360 mg QD (ER)
Digitalis Glycosides		
Digoxin	0.25 mg IV with repeat dosing to a maximum of 1.5 mg over 24 hours	0.125–0.25 mg QD
Others		
Amiodarone[a]	300 mg IV over 1 hour, then 10–50 mg/hr over 24 hours	100–200 mg QD

[a]Multiple dosing schemes exist for the use of amiodarone.
AF, atrial fibrillation; BID, twice daily; ER, extended release; IV, intravenous; N/A, not applicable, QD, once daily; QID, 4 times a day; TID, 3 times a day.
January, C. T., Wann, L. S., Alpert, J. S., Calkins, H., Cigarroa, J. E., Cleveland, J. C.,…Yancy, C. W. (2014). 2014 AHA/ACC/HRS Guideline for the Management of Patients With Atrial Fibrillation: Executive Summary. *Circulation*, *130*, 2071–2104.

Clinical Manifestations and Assessment

Some people with AF may be asymptomatic. However, there is a rapid ventricular response, which reduces the time for ventricular filling, resulting in a smaller stroke volume. In addition, loss of the atrial contraction (sometimes referred to as *atrial kick*) reduces ventricular filling volume and reduces cardiac output by 25%. This often leads to symptoms of fatigue and malaise. The shorter time in diastole reduces the time available for coronary artery perfusion, thereby increasing the risk for myocardial ischemia. In addition, patients are at risk for the development of heart failure (Morady & Zipes, 2015).

ECG characteristics are:

Rate: Atrial rate is 300 to 400, with a variable ventricular response rate (typically rapid)
Rhythm: Irregular
P wave: No discernible P waves; irregular undulating waves may be seen and are referred to as *fibrillatory waves*
PR interval: Not measurable
QRS duration: Normal

See Figure 17-10.

Nursing Alert
The three cornerstones of AF management include rate control, rhythm control, and prevention of thromboembolism.

FIGURE 17-10 Atrial fibrillation with a slow, irregular ventricular rate.

Medical and Nursing Management

Treatment of AF depends on its cause and duration and the patient's symptoms, age, and comorbidities. Once the pattern, clinical history, and symptoms are established, it is important to then assess for the presence of structural heart disease and identification of any correctable secondary causes, such as sleep apnea or substance abuse. The management of AF includes controlling the ventricular rate and achieving rhythm conversion to sinus rhythm if possible. Cardioversion of AF can be done either by medication or an electrical shock. Direct-current cardioversion is more effective than pharmacologic cardioversion (Knight, 2013). It is important to consider that when AF onset is more recent, then pharmacologic cardioversion will be more effective. However, electrical cardioversion is indicated when a patient with new-onset AF is hemodynamically unstable (Knight, 2013). Shocks are delivered in sync with the QRS wave. Biphasic defibrillators are used more often with less energy required (150 to 200 J) than when using the older, monophasic defibrillators with higher-energy settings. Pharmacologic cardioversion is done with intravenous (IV) ibutilide, procainamide, or amiodarone. For AF episodes shorter than 48 to 72 hours duration, the efficacy of ibutilide is approximately 60% to 70%, whereas amiodarone's efficacy is approximately 40% to 50%, and procainamide's efficacy is 30% to 40% (Morady & Zipes, 2015). Commonly used oral medications include flecainide and propafenone. For ventricular rate control, the medications that are used are beta blockers and calcium-channel antagonists along with Digoxin (reserved for those patients who are sedentary or with systolic HF). For rhythm control after cardioversion, patients will often be placed on dofetilide, amiodarone, or dronedarone (Knight, 2013).

Nursing Alert

For a patient with new-onset AF for over 48 hours, or when the onset is unknown, the nurse is aware that a transesophageal echocardiography (TEE) should be performed before cardioversion to rule out a left atrial thrombus. The rationale behind this is that with cardioversion, if the patient converts to a sinus rhythm, the risk increases for embolization of the clot resulting in a potential CVA. If no thrombi are present, then cardioversion can be performed safely; however, the patient needs to be educated that 4 weeks of anticoagulation will be maintained after cardioversion to prevent thromboembolism (Morady & Zipes, 2015).

If delayed cardioversion is selected rather than emergent cardioversion, then the patient typically receives 3 weeks of therapeutic anticoagulation (Knight, 2013) to prevent a thrombus and a TEE should be performed prior to cardioversion. Accordingly, all patients with AF, regardless of whether a rhythm or rate control plan is chosen, should be treated with antithrombotic therapy.

If the QRS is wide and the ventricular rhythm is irregular, AF with an accessory pathway, such as Wolff–Parkinson–White syndrome, should be suspected. Medications that block AV conduction (e.g., adenosine [Adenocard], digoxin, diltiazem [Cardizem], and verapamil [Calan]) should be avoided because they may actually cause an increase in ventricular rate given that conduction is via an alternative pathway rather than via the AV node. Expert consultation

will be required to determine appropriate treatment.

Antithrombotic therapy prevents thromboembolism, and long-term anticoagulant therapy is prescribed using warfarin, or warfarin alternatives—factor Xa inhibitor (rivaroxaban or apixaban) or direct thrombin inhibitor (dabigatran). These therapies are indicated if the patient with AF is at high risk for stroke using the CHADS 2 scoring system (i.e., over 75 years of age or has hypertension, diabetes, heart failure, or history of stroke). There are no effective reversal agents for these warfarin-alternative agents. If immediate anticoagulation is necessary, the patient may be placed on heparin until the warfarin level is therapeutic (AHA/ACC/HRS, 2014).

Nursing Alert

No therapy, cardiac medications or cardioversion may be used to convert lone AF (also referred to as idiopathic AF [where there is no clear cause for the rhythm]) for patients over 65 years of age without heart disease. If there are no contraindications, anticoagulation therapy may be started without direct treatment of arrhythmia itself. If warfarin is used, the international normalized ratio (INR) should be 2.0 to 3.0 with a target of 2.5. An INR below 2.0 is not effective at preventing strokes. If the patient has a mechanical valve, then the target INR should be 2.5 (Knight, 2013).

Pacemaker implantation or catheter ablation is sometimes indicated for patients who are unresponsive to medications. Catheter ablation is a minimally invasive procedure during which high-frequency radio waves are applied to destroy the tissue at the site of the arrhythmia. Ablation procedures are usually performed in electrophysiology (EP) laboratories and are similar to other types of heart catheterization procedures in that a catheter is used. However, the differences include longer procedure times (approximately 6 to 8 hours) for ablation, the catheter delivers high energy to stop an arrhythmia, and it is indicated for conduction diagnosis and treatment alone—not for diagnosis and treatment of disease in the coronary arteries. During a catheter ablation, long, thin, flexible tubes are placed in the heart via the vascular system. A diagnostic catheter determines where the abnormal tissue that is causing the arrhythmia is located. High-frequency energy is sent into the tissue, creating a lesion or scar. The area is now ablated (destroyed), thus facilitating normal electrical conduction. Cryoballoon ablation is a new procedure that has been effective in preventing paroxysmal AF in patients who were unable to be medically managed with antiarrhythmic medications (Packer et al., 2013). Pulmonary vein isolation using cryoablation can be achieved in most people with shorter procedure times. However, the potential complications of this procedure include phrenic nerve injury or stroke (Packer et al., 2013).

Several approaches are effective in preventing the occurrence of postoperative AF, including preoperative administration of a beta blocker or immediate postoperative administration of IV amiodarone (AHA/ACC/HRS, 2014).

SUPRAVENTRICULAR TACHYCARDIA

Pathophysiology

Supraventricular tachycardia (SVT) is a broad term used to describe tachycardias where the atrial and/or the ventricular rates exceed 100 bpm at rest (Page et al., 2016). The mechanism involves an electrical impulse originating above the ventricles, commonly from tissue at the HIS bundle and above (AV node). The heart rate is increases by an abnormal electrical impulse starting in the atria, and the ventricular rate follows the atrial impulse resulting in this "tachy" arrhythmia. Broadly, SVT includes sinus tachycardia, focal and multifocal atrial tachycardias, junctional tachycardias, AV nodal re-entry tachycardia (AVNRT), and various other accessory pathway-mediated reentrant tachycardias. Technically, AF is an SVT, but it is not grouped this way in the AHA guidelines and was addressed separately. SVTs even without AF included are among the most common arrhythmias that require treatment. Conduction abnormalities may occur because of aberrant conduction, a pre-existing BBB, or an accessory pathway that results in pre-excitation (Page et al., 2015). Further, the presence of AV dissociation (where the ventricular rate is faster than the atrial rate or in other cases where fusion complexes occur that represent the dissociation of supraventricular impulses from ventricular) provides assistance with diagnosis of VT versus SVT. It is sometimes difficult to differentiate between the two without a 12-lead ECG.

Clinical Manifestation

SVTs effect on a patient's quality of life varies; the degree of impact is often affected by the frequency of episodes, the duration, and the timing of the SVT (whether with exercise or also at rest). Symptoms vary depending on the rhythm and the patient, with reports of palpitations, chest pain, shortness of breath, dizziness, and syncope, along with panic and anxiety, which heighten the degree of symptoms and confounds the diagnosis of SVT (Page et al., 2015).

ECG characteristics are:

Rate: over 100 bpm
Rhythm: Regular
P wave: If visible, inverted P waves sometimes seen after the QRS
PR interval: Not measurable
QRS duration: In paroxysmal SVT, the QRS is normal.

See Figure 17-11.

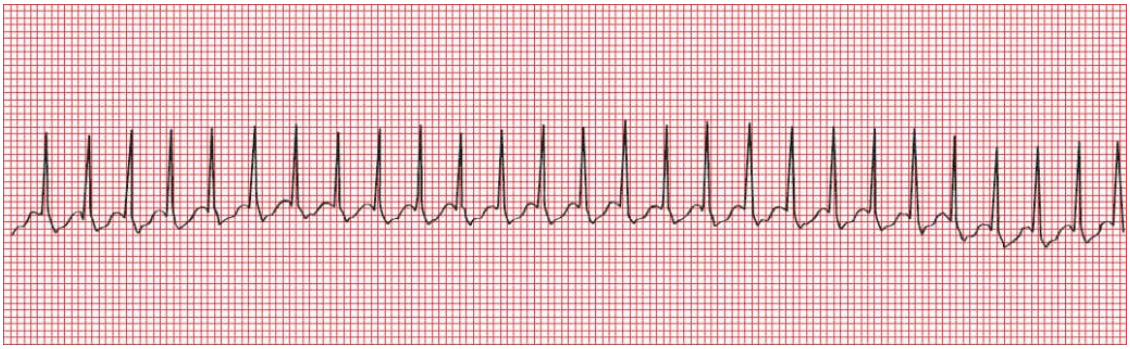

FIGURE 17-11 Supraventricular tachycardia: note rate above 220, abnormal P waves, no beat-to-beat variability.

Medical and Nursing Management

Treatment of atrial SVT depends on its cause and duration and the patient's symptoms, age, and comorbidities. Vagal maneuvers are recommended as a first step to discontinue the rhythm in patients who are hemodynamically stable. Often this intervention does not work or only works in the short term. Medical management in the short term in a patient who is stable with a regular SVT is with adenosine. If the patient becomes hemodynamically unstable, cannot be rate controlled with medication or it is ineffective, the treatment recommendation is synchronized cardioversion. Intravenous beta blockers, IV diltiazem, or IV verapamil (class IIa) can also be used to convert the patient's rhythm to NSR (Page et al., 2015).

For ongoing management, patients are placed on oral beta blockers, diltiazem, or verapamil and taught how to do the vasovagal maneuver. Antiarrhythmic medications do carry the potential for adverse side effects. Therefore, today more often patients are referred for catheter ablation with a high degree of success and low rate of complications (Page et al., 2015).

JUNCTIONAL ARRHYTHMIAS

JUNCTION RHYTHM

Pathophysiology

Junctional rhythm occurs when the AV node, instead of the sinus node, becomes the pacemaker of the heart. When the sinus node slows (e.g., from increased vagal tone) or when the impulse cannot be conducted through the AV node (e.g., because of complete heart block), the AV node automatically discharges an impulse. Junctional escape rhythm may be caused by acute coronary syndromes; valvular disease; hypoxia; increased parasympathetic tone; or the effects of medication, including digoxin, beta blockers, and calcium-channel blockers.

Clinical Manifestations and Assessment

The patient may be asymptomatic or experience signs and symptoms associated with a decreased cardiac output.

ECG characteristics are:

Rate: 40 to 60 bpm
Rhythm: Regular
P wave: If visible, may be before, during, or after the QRS
PR interval: If a P wave is visible, less than 0.12 second
QRS duration: Normal

See Figure 17-12.

Medical and Nursing Management

If the patient is symptomatic, the treatment is the same as for bradycardia; the patient may be paced (temporary or permanent) or is given IV atropine or epinephrine.

VENTRICULAR ARRHYTHMIAS

ABNORMAL VENTRICULAR CONDUCTION (BBB)

Pathophysiology

If there is a delay or defect in the conduction system within the ventricles (right and left bundle branches), the QRS complex will be prolonged or widened (greater than 0.12 second). A BBB may be described as right or left and complete or incomplete. They may occasionally be present in otherwise healthy individuals; however, they may also be caused by ventricular enlargement (ventricular hypertrophy or cardiomyopathy) or anteroseptal myocardial ischemia or infarction. A BBB may be clinically insignificant, though it can be serious when associated with an acute MI.

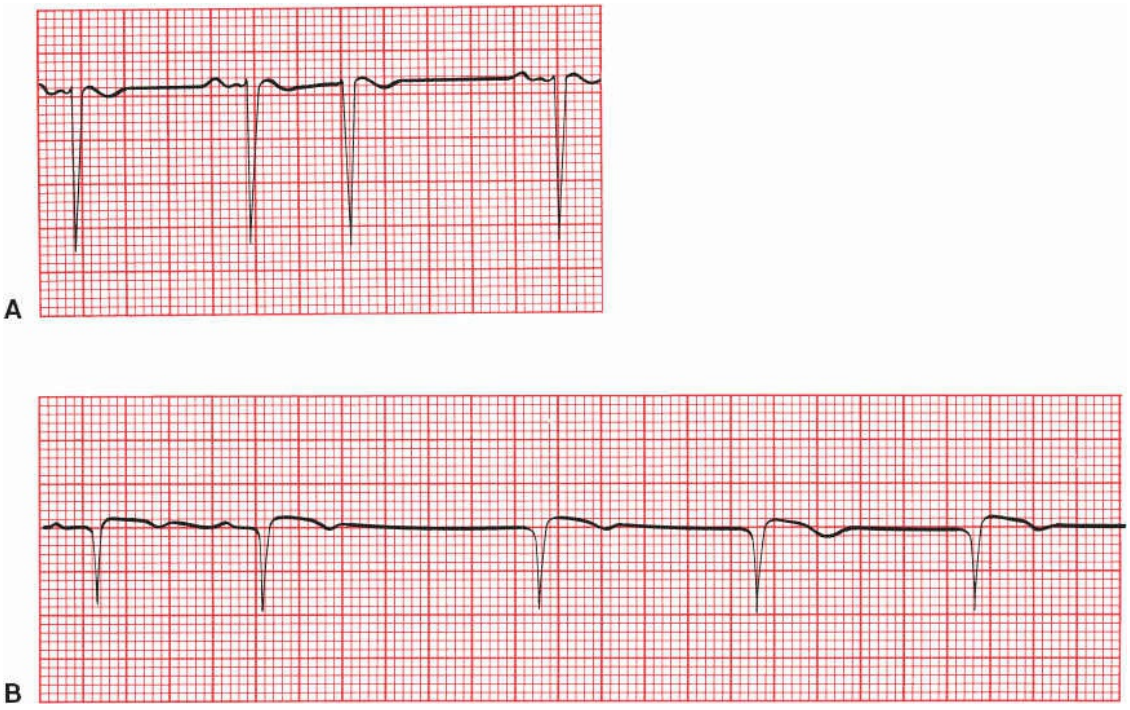

FIGURE 17-12 Junctional rhythm note short PR intervals. A. A junctional premature beat. The third beat is obviously premature, and there is no P wave preceding the QRS complex. B. The third beat is a junctional escape beat, establishing a sustained junctional rhythm. It looks just like a junctional premature beat, but it occurs late, following a prolonged pause, rather than prematurely.

Medical and Nursing Management

The goal is to treat the underlying cause of the BBB when possible, such as by maximizing medical management of CAD or cardiomyopathy. However, in the presence of an acute MI, BBB may progress to complete heart block, which may require temporary pacing during the acute phase of illness.

PREMATURE VENTRICULAR COMPLEX

Pathophysiology

A premature ventricular complex (PVC) is an impulse that starts in a ventricle and is conducted through the ventricles before the next normal sinus impulse. Premature ventricular contractions can occur in healthy people, especially with intake of caffeine, nicotine, or alcohol. They are also caused by cardiac ischemia or infarction, increased workload on the heart (e.g., exercise, fever, hypervolemia, heart failure, tachycardia), digitalis toxicity, hypoxia, acidosis, or electrolyte imbalances, especially hypokalemia. Prevalence of PVCs increases with age, in males, and with hypokalemia (Olgin & Zipes, 2015). New research suggests that PVCs may be an early marker for the development of heart failure. In a population-based study by Dukes et al. (2015) a higher frequency of PVCs was associated with a decrease in left ventricular ejection fraction (LVEF, which is the amount of blood ejected out of the left ventricle per each ventricular contraction), an increase in incident CHF, and increased mortality. More studies are needed to refine and evaluate efficacy for both preventative therapies and treatment options for PVCs. What is clear is that prevention of PVCs through ablation is possible, thus the future may include PVCs as a modifiable risk factor for HF (Dukes et al., 2015).

Clinical Manifestations and Assessment

The patient may be asymptomatic or complain that their heart "skipped a beat." The effect of a PVC depends on its timing in the cardiac cycle and how much blood was in the ventricles when they contracted. *Bigeminy* is a rhythm in which every other complex is a PVC. In *trigeminy,* every third complex is a PVC, and in *quadrigeminy*, every fourth complex is a PVC. PVCs may present singly or in pairs (often referred to as couplets). Three or more successive PVCs are termed *ventricular tachycardia* (VT) (discussed next).

ECG characteristics are:

Rate: Depends on the underlying rhythm

Rhythm: Regular

P wave: Visibility of P wave depends on the timing of the PVC; may be absent (hidden in the QRS or T wave) or in front of the QRS. If the P wave follows the QRS, the shape of the P wave may be different.

PR interval: If the P wave is in front of the QRS, the PR interval is less than 0.12 second.

QRS duration: Duration of the QRS in a PVC is 0.12 second or longer (wide); shape is bizarre and abnormal.

See Figure 17-13.

C
D
E

FIGURE 17-13 Dangerous forms of premature ventricular contractions (PVCs): (A) bigeminy, (B) couplets, (C) run, (D) multifocal, and (E) R-on-T phenomenon.

Medical and Nursing Management

Initial treatment is aimed at correcting the cause of the arrhythmia (e.g., treat hypokalemia). Long-term pharmacotherapy for PVCs is not indicated unless the patient is symptomatic. In the absence of disease, PVCs usually are not serious. In the patient with an acute MI or in the context of HF, PVCs may be more frequent and reflect the underlying heart disease or represent an early modifiable risk factor for heart failure.

Unfolding Patient Stories: Kenneth Bronson • Part 2

Recall from Chapter 10 Kenneth Bronson, who came to the emergency department with difficulty breathing after a week of flu-like symptoms, productive cough, and high fever. He was diagnosed with a right lower lobe pneumonia. Sinus tachycardia with occasional unifocal premature ventricular contractions (PVCs) is seen on the cardiac monitor. What are potential causes for the tachycardia and PVCs that the nurse should investigate when considering his age of 27 years, symptoms experienced over the last week, and the clinical manifestations associated with his diagnosis?

Care for Kenneth and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in (thepoint.lww.com/DocuCareEHR).

VENTRICULAR TACHYCARDIA

Pathophysiology

Ventricular tachycardia is defined as three or more consecutive ventricular beats occurring at a rate exceeding 100 bpm. The causes are similar to those of PVCs. Ultimately, those causes will determine the course of treatment with consideration to the underlying disease; the projected, associated risk; the period of time that the risk exists; and the benefits and risks as well as tolerance of the planned treatment. VT is usually associated with ACS but can also occur in specific clinical conditions:

- after an MI,
- with inherited primary arrhythmia syndromes, such as long QT syndrome,
- with electrolyte imbalances,
- cardiomyopathies,
- structural heart disease, and
- due to proarrhythmic medications that may precede ventricular fibrillation.

Untreated VT can deteriorate into ventricular fibrillation, a lethal arrhythmia and sudden cardiac death.

Clinical Manifestations and Assessment

The patient can experience a range of symptoms related to decreased cardiac output, such as hypotension or syncope, pulselessness, and unresponsiveness. In contrast, some patients may be initially asymptomatic but usually will decompensate hemodynamically.

ECG characteristics are:

Rate: 100 to 250 bpm
Rhythm: Regular
P wave: Usually not visible; if visible are not associated with the QRS complex (called *dissociation*)
PR interval: None
QRS duration: Greater than 0.12 second

See Figure 17-14.

Medical and Nursing Management

The patient's tolerance for this rapid rhythm depends on the ventricular rate and underlying disease. Several factors together with the ventricular rate and the etiology determine the initial treatment, including the following: identifying the rhythm as monomorphic (having a consistent QRS shape and rate) or polymorphic (having varying QRS shapes and rhythms); determining the existence of a prolonged QT interval before the initiation of VT; and ascertaining the patient's heart function. If the patient is stable, continuing the assessment, especially obtaining a 12-lead ECG, may be the only action necessary.

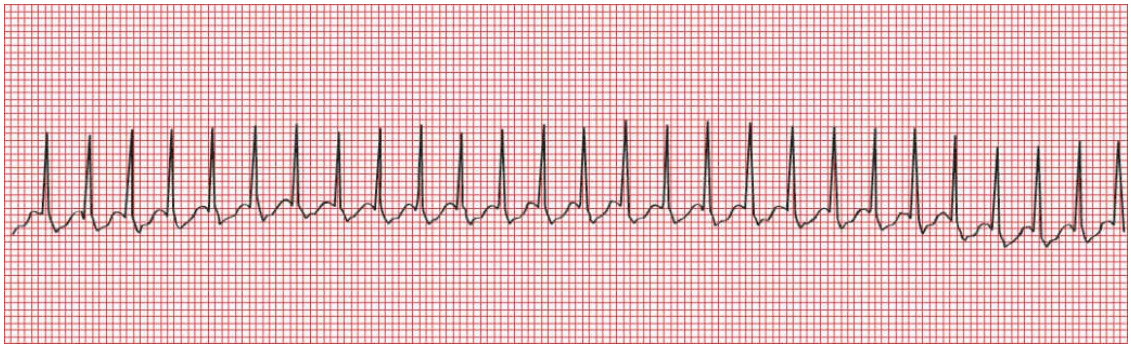

FIGURE 17-14 Ventricular tachycardia: rapid and regular rhythm, wide QRS complex without P waves.

Vasopressin with epinephrine is no longer administered to patients in cardiac arrest because the evidence does not support it, according to the AHA Guidelines Update (Hazinski et al., 2015). However, per these guidelines, epinephrine alone should be considered to establish a rhythm that can be treated in the event that the initial rhythm is a nonshockable one. Amiodarone administered IV is often the antiarrhythmic medication of choice for a stable patient with VT. Cardioversion is the treatment of choice for monophasic VT in a symptomatic patient. However, many antiarrhythmic drugs other than beta blockers have not been shown to be effective in the treatment of primary ventricular arrhythmia or in sudden cardiac death prevention but may be helpful as an adjunct therapy in management of patients who are arrhythmia prone (Priori et al., 2015). Importantly, AF should be suspected as the cause of a wide, complex tachycardia with an irregular rhythm, and it should be treated appropriately.

Nursing Alert

The nurse observes the patient's response hemodynamically to the VT. Obtain vital signs, auscultate lungs and heart, monitor urine output, and assess the patient's level of consciousness. If a patient demonstrates hypotension, shock, angina, symptoms of congestive heart failure (crackles, decreasing oxygen saturation, SOB [left-sided HF] or edema, jugular vein distention [right-sided HF]), or symptoms of cerebral hypoperfusion, the nurse prepares for cardioversion.

Torsade de pointes (Fig. 17-15) is a polymorphic VT usually preceded by a prolonged

QT interval that can be congenital or acquired and is relatively uncommon. Acquired torsades is frequently associated with drug therapy, hypokalemia, or hypomagnesemia (Berul, Seslar, Zimetbaum, & Josephson, 2016). Risk factors for torsade de pointes are described in Box 17-5 which includes some of the QT-prolonging medications. Since QT-prolonging agents can be found in all classes of medications, a website has been established for patients and health care professionals (e.g., www.QTdrugs.org). Up-to-date information is provided at this site regarding QT-prolonging medications and drug-to-drug interactions that can also affect the QT interval. Because this rhythm is likely to cause the patient to deteriorate and become pulseless, immediate treatment is usually required. Standard antiarrhythmic agents may be administered with temporary pacing, but treatment will depend on the cause of torsades and management should focus on removing the etiology of this arrhythmia. For example, in acquired torsades, intravenous magnesium is the initial treatment of choice followed by temporary ventricular or atrial pacing (Olgin & Zipes, 2015, p. 783). Any type of VT in a patient who is unconscious and without a pulse is treated in the same manner as ventricular fibrillation: immediate defibrillation is the action of choice. In addition, it is important in the hospital setting to monitor patients closely, noting those who have a QTc above 500 ms and discontinuing the offending medications.

BOX 17-5 Risk Factors for Torsade de Pointes

1. QT interval prolongation
2. Female gender
   a. Risk increased two- to threefold
3. Electrolyte imbalance
   a. Primarily hypokalemia
4. Structural heart disease
   a. Ischemic heart disease
   b. Cardiomyopathy
5. Pharmacologic factors
   a. Antiarrhythmic medications—most potent QT interval prolonging
      i. Ia Class—quinidine and procainamide
      ii. III Class—dofetilide, ibutilide, sotalol, and amiodarone
         - More than 50 drugs medications are noted to prolong the QT interval
   b. Other medications with ability to prolong QT have been found in almost every other class of therapeutic agent.
6. Congenital
   a. Congenital severe bradycardia (long QT syndrome)
   b. Autosomal-dominant syndromes
   c. Autosomal-recessive cases
7. Other

a. Intracranial events (e.g., subarachnoid hemorrhage) may be as high as 8% if associated with hypokalemia

b. Cocaine

c. Hypothermia

d. HIV infection

Nursing Alert

When caring for a patient experiencing an emergent cardiac arrhythmia, consider the following.

1. *Assess the patient's condition.*
2. *If patient has a loss of respirations, a loss of pulse, a decrease in level of consciousness, or significant change in blood pressure, call a cardiac arrest code. If the patient is alert without a significant change in vital signs, call for a rapid response team (RRT) or alert the provider stat to the patient's change in condition. Speak with the patient as it applies to keep the patient informed and calm.*
3. *While awaiting arrival of the medical team, continue to assess the patient, apply supplemental oxygen, ensure adequate IV access, and bring emergency equipment and a bedside monitor to the patient's bedside.*

VENTRICULAR FIBRILLATION

Pathophysiology

Ventricular fibrillation is a rapid, disorganized ventricular rhythm that causes ineffective quivering of the ventricles. No atrial activity is seen on the ECG. Causes of ventricular fibrillation are the same as for VT; it may also result from untreated or unsuccessfully treated VT.

Clinical Manifestations and Assessment

Clinical manifestations include absence of an audible heartbeat, a palpable pulse, and respirations. Cardiac arrest and death are imminent.

ECG characteristics are:

Rate: Often cannot be determined, but is greater than 220 bpm
Rhythm: Irregular
P wave: Not visible
PR interval: Not visible
QRS duration: Not visible

See Figure 17-16.

Medical and Nursing Management

Treatment of choice is immediate defibrillation if available, immediate cardiopulmonary resuscitation (CPR), and activation of emergency services. After the initial defibrillation, five cycles of CPR, alternating with a rhythm check and defibrillation, are used to convert ventricular fibrillation to an electrical rhythm that produces a pulse. Vasoactive medications (epinephrine) should be administered as soon as possible after the second rhythm check (immediately before or after the second defibrillation). Often antiarrhythmic medications (amiodarone, lidocaine, or possibly magnesium) will be administered though there is lack of evidence to support their routine use after a cardiac arrest (AHA, 2015). Once the patient is intubated, CPR should be administered continuously with one breath every 6 seconds and a compression rate of 100 to 120 per minute. In addition, underlying and contributing factors are identified and eliminated throughout the event (AHA, 2015).

IDIOVENTRICULAR RHYTHM

Pathophysiology

Idioventricular rhythm, also called *ventricular escape rhythm*, occurs when the impulse starts in the conduction system below the AV node. When the sinus node fails to create an impulse (e.g., from increased vagal tone) or when the impulse is created but cannot be conducted through the AV node (e.g., due to complete AV block), the Purkinje fibers automatically discharge an impulse.

FIGURE 17-17 Idioventricular rhythm. There are no P waves, the QRS complexes are wide, and the rate is about 75 beats per minute.

Clinical Manifestations and Assessment

Idioventricular rhythm commonly causes the patient to lose consciousness and experience other signs and symptoms of reduced cardiac output.

ECG characteristics are:

Rate: 20 to 40; if the rate exceeds 40, the rhythm is known as *accelerated idioventricular rhythm* (AIVR)
Rhythm: Regular
P wave: Not visible
PR interval: Not visible
QRS duration: Duration is 0.12 second or more

See Figure 17-17.

Medical and Nursing Management

If the patient is in cardiac arrest, treatment is the same as for asystole (absence of electrical activity and pulse); if the patient is not in cardiac arrest, treatment is the same as for bradycardia. Interventions include identifying the underlying cause, administering IV atropine and vasopressor medications, and initiating emergency pacing. In some cases, idioventricular rhythm may cause no symptoms of reduced cardiac output.

VENTRICULAR ASYSTOLE

Pathophysiology

Commonly called *flatline*, ventricular asystole is characterized by absent QRS complexes confirmed in two different leads. Asystole is seen in the absence of cardiac electrical activity; because there is no contraction, there is no perfusion.

Clinical Manifestations and Assessment

There is no heartbeat, no palpable pulse, and no respiration. Without immediate treatment, ventricular asystole is fatal.

ECG characteristics are:

Rate: Not measurable
Rhythm: Not measurable
P wave: Usually not visible
PR interval: Not measurable
QRS duration: Absent

See Figure 17-18.

Medical and Nursing Management

Asystole is treated by focusing on high-quality CPR with minimal interruptions and identifying underlying and contributing factors. The guidelines for advanced cardiac life support (AHA, 2015) state that the key to successful treatment is rapid assessment to identify a possible cause, which may be hypoxia, acidosis, severe electrolyte imbalance, drug overdose, hypovolemia, cardiac tamponade, tension pneumothorax, coronary or pulmonary thrombosis, trauma, or hypothermia. Because of the poor prognosis associated with asystole, if the patient does not respond to CPR, medical management, and other interventions aimed at correcting underlying causes, resuscitation efforts are usually ended ("the code is called") unless special circumstances (e.g., hypothermia, transportation to a hospital is required) exist.

PULSELESS ELECTRICAL ACTIVITY

In some situations, the patient may have an organized electrical rhythm visible on the monitor display but is unresponsive, not breathing, and pulseless. This is termed *pulseless electrical activity* (PEA) and is considered a cardiac arrest. The patient should receive immediate CPR and life support.

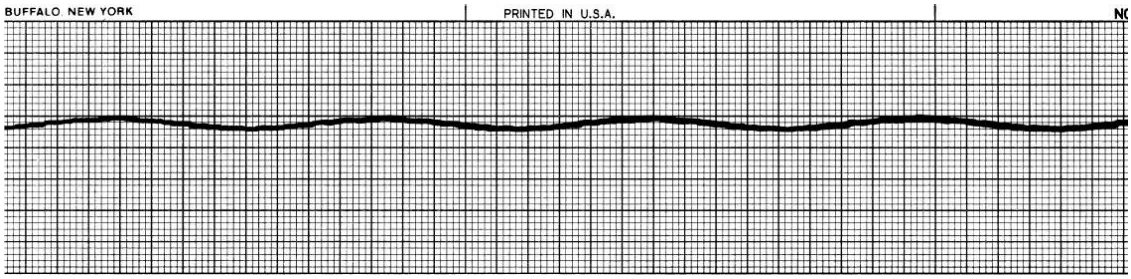

FIGURE 17-18 Asystole. Always check two different leads to confirm rhythm.

CONDUCTION ABNORMALITIES

AV blocks occur when the conduction of the impulse through the AV nodal area is decreased or stopped. These blocks can be caused by medications (e.g., digitalis, calcium-channel blockers, beta blockers), myocardial ischemia and infarction, valvular disorders, or myocarditis.

The clinical signs and symptoms of a heart block vary with the ventricular rate and the severity of any underlying disease processes. Whereas first-degree AV block rarely causes any hemodynamic effect, the other blocks may result in decreased heart rate, causing a reduction in perfusion to vital organs, such as the brain, heart, kidneys, lungs, and skin. A patient with third-degree AV block caused by digitalis toxicity may be stable; another patient with the same rhythm caused by acute MI may be unstable. Therefore the context and general condition of the patient are factors. Health care providers must always keep in mind the need to treat the patient, not the rhythm. The treatment is based on the hemodynamic effect of the rhythm.

FIRST-DEGREE ATRIOVENTRICULAR BLOCK

First-degree AV block occurs when atrial conduction is delayed through the AV node, resulting in a prolonged PR interval.

Pathophysiology

First-degree block may occur without an underlying pathophysiology or may be the result of medications such as beta blockers, calcium-channel blockers, or digoxin. It can also result from conditions that increase parasympathetic (vagal) tone, such as vomiting or Valsalva maneuver.

Clinical Manifestations and Assessment

The patient is usually asymptomatic.

ECG characteristics are:

Rate: Depends on underlying rhythm
Rhythm: Regular
P wave: Present before each QRS and consistent in size and shape
PR interval: Greater than 0.20 second
QRS duration: Normal

See Figure 17-19.

Medical and Nursing Management

The patient with first-degree AV block is only treated if symptoms related to bradycardia are present. If the AV block is new, the patient should be observed for potential progression to second-degree block.

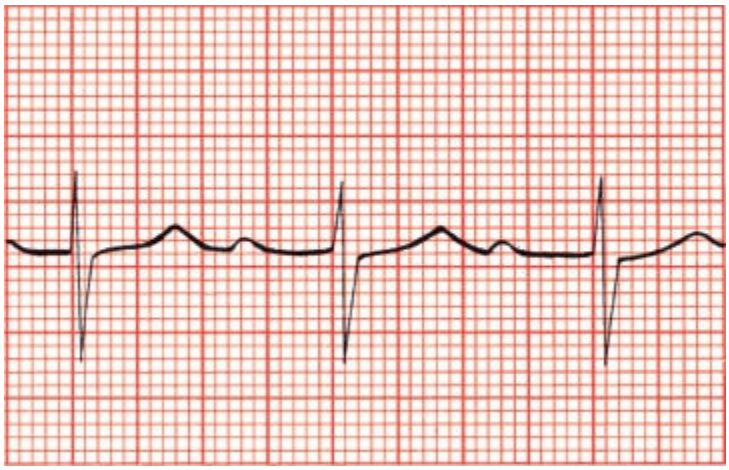

FIGURE 17-19 First-degree AV block. Note the prolonged PR interval.

SECOND-DEGREE ATRIOVENTRICULAR BLOCK, TYPE I (WENCKEBACH)

Second-degree AV block, type I, occurs when there is a repeating pattern in which all but one of a series of atrial impulses are conducted through the AV node into the ventricles (e.g., every four of five atrial impulses are not conducted). Each atrial impulse takes a longer time for conduction than the one before, until one impulse is fully blocked, thus an increasing PR interval is seen with each successive beat until a P wave is seen without a resulting QRS. Because the AV node is not depolarized by the blocked atrial impulse, the AV node has time to fully repolarize so that the next atrial impulse can be conducted within the shortest amount of time.

Pathophysiology

Second-degree AV block, type I, is caused by a gradual and progressive conduction delay through the AV node. It may be related to increased parasympathetic (vagal) tone, ischemia, or medications that slow conduction, such as beta blockers, calcium-channel blockers, and digoxin.

Clinical Manifestations and Assessment

Signs and symptoms are related to bradycardia and may include chest discomfort, dyspnea, and hypotension.

ECG characteristics are:

Rate: Atrial rate faster than ventricular rate

Rhythm: The atrial rhythm is usually regular; the ventricular rhythm is usually irregular.

P wave: Size and shape normal

PR interval: PR interval becomes longer with each succeeding ECG complex until there is a P wave not followed by a QRS

QRS duration: Normal

See Figure 17-20.

Medical and Nursing Management

If the patient has symptomatic bradycardia, treatment with atropine or transcutaneous pacing is indicated.

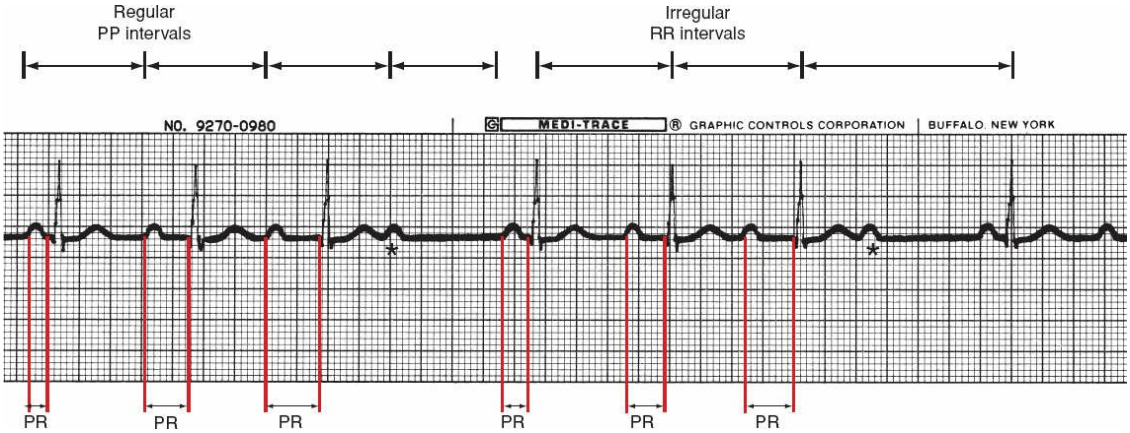

FIGURE 17-20 Mobitz type I second-degree AV block (Wenckebach block). The PR intervals become progressively longer until one QRS complex is dropped.

SECOND-DEGREE ATRIOVENTRICULAR BLOCK, TYPE II

Second-degree AV block, type II, occurs when only some of the atrial impulses are conducted through the AV node into the ventricles. The ECG will reveal P waves not followed by a QRS. It is less common but more severe as it can progress to complete third-degree heart block.

Pathophysiology

Conduction is blocked below the AV node. It is caused by ischemia, usually due to blockage of the left coronary artery.

Clinical Manifestations and Assessment

Signs and symptoms are related to bradycardia and may include chest discomfort, dyspnea, and hypotension.

ECG characteristics are:

Rate: Atrial rate 60 to 100 bpm; ventricular rate less than atrial rate

Rhythm: Atrial rhythm is regular (constant PP interval); ventricular rhythm is irregular.

P wave: Normal

PR interval: Constant, no progressive prolongation with conducted beats

QRS duration: Normal or wide depending on the location of the block relative to the AV node

See Figure 17-21.

Medical and Nursing Management

If the patient has symptomatic bradycardia, treatment with atropine or pacing is indicated.

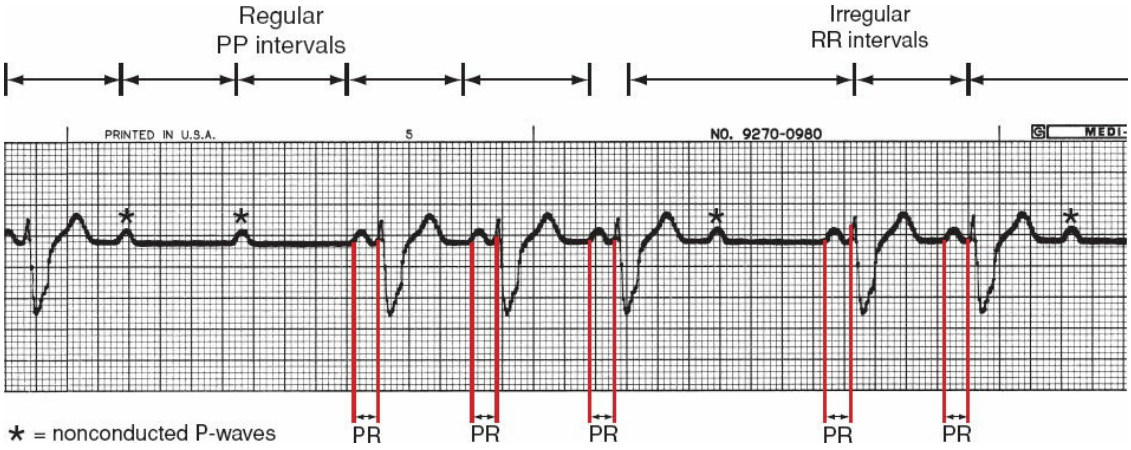

FIGURE 17-21 Mobitz type II second-degree AV block. On this EKG, each third P wave is not followed by a QRS complex (dropped beat).

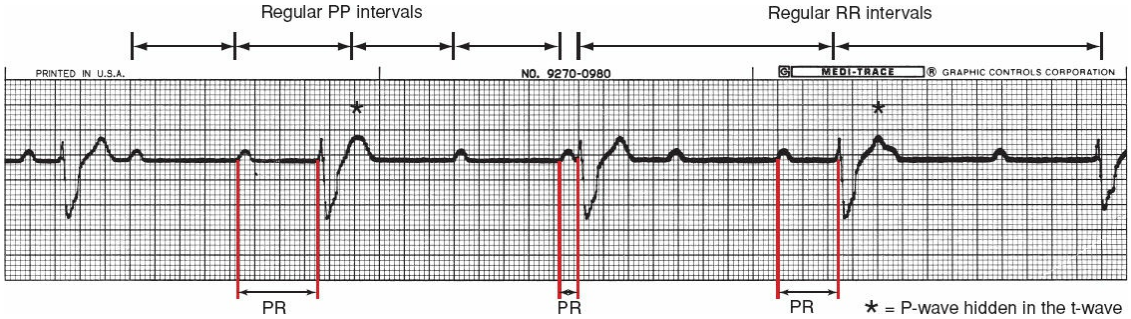

FIGURE 17-22 Third-degree AV block. The P waves appear at regular intervals, as do the QRS complexes, but they have nothing to do with one another. The QRS complexes are wide, implying a ventricular origin.

THIRD-DEGREE ATRIOVENTRICULAR BLOCK

Third-degree AV block occurs when no atrial impulse is conducted through the AV node into the ventricles. In third-degree AV block, two separate impulses stimulate the heart: one stimulates the atria, represented by the P wave, and one stimulates the ventricles, represented by the QRS complex, but there is no relationship or synchrony between the atrial and the ventricular contraction. Each is beating at its own inherent rate and independent of each other, thus the cardiac output is affected. P waves may be seen, but the atrial electrical activity is not conducted down into the ventricles. This is called *AV dissociation.*

Pathophysiology

Complete heart block is caused by injury to the conduction system so that there is no conduction between the atria and the ventricles.

Clinical Manifestations and Assessment

Signs and symptoms are related to bradycardia and may include syncope, chest discomfort, angina, dyspnea, and hypotension.

ECG characteristics are:

Rate: Atrial rate 60 to 100 bpm, ventricular rate 20 to 40 bpm

Rhythm: Atrial and ventricular rhythms are both regular but independent of each other.

P wave: Normal, more P waves than QRS complexes

PR interval: Not present; no relationship between the P wave and the R wave

QRS duration: Normal or wide depending on the location of the block relative to the AV node

See Figure 17-22.

Medical and Nursing Management

If the patient has symptomatic bradycardia, treatment with atropine or pacing is indicated.

NURSING PROCESS

The Patient with an Arrhythmia

ASSESSMENT

Major areas of assessment include possible causes of the arrhythmia, contributing factors, the associated risks, and the arrhythmia's effect on the heart's ability to pump an adequate blood volume.

A health history is obtained to identify any previous occurrences of possible decreased cardiac output, such as near-syncope or syncope (fainting), light-headedness, dizziness, fatigue, chest discomfort, shortness of breath, and/or palpitations. Comorbidities or coexisting conditions that could be a possible cause of the arrhythmia (e.g., heart disease, chronic obstructive pulmonary disease, pre-existing thyroid disease or Lyme disease) may also be identified. All medications, prescribed and over-the-counter, are reviewed. Laboratory results are reviewed to assess levels of medications, as well as factors that could contribute to the arrhythmia (e.g., anemia, hypokalemia, hypomagnesemia). A psychosocial assessment is performed to identify the possible effects of the arrhythmia, the patient's perception of the arrhythmia, and whether anxiety is a significant contributing factor.

During physical assessment, the nurse assesses the patient's skin, which may be pale and cool. Signs of fluid retention, such as neck vein distention and crackles and wheezes auscultated in the lungs, may be detected. The presence of peripheral edema is assessed as well as its extent and whether it is pitting or not. The rate and rhythm of apical and peripheral pulses are also assessed, and any pulse deficit (see Chapter 12) is noted. The nurse auscultates for extra heart sounds (especially S_3 and S_4) and for heart murmurs, evaluates blood pressure, and assesses the patient's usual versus current weight.

Nursing Alert

Cardiac output is calculated as heart rate (HR) × stroke volume (SV). Stroke volume is the amount of blood ejected by the left ventricle with each contraction. If an arrhythmia occurs, the HR and SV can be affected, decreasing the filling times for the ventricle and, ultimately, causing a decreased cardiac output. The nurse is alert

for patient complaints of dizziness, syncope, shortness of breath, peripheral edema, weight gain, crackles, fatigue, chest pain, or discomfort.

DIAGNOSIS

Appropriate nursing diagnoses of the patient with an arrhythmia may include:

- Cardiac output, decreased
- Anxiety related to fear of the unknown
- Knowledge deficit regarding the arrhythmia and its treatment

Potential complications may include the following:

- Cardiac arrest (see Chapter 15)
- Heart failure (see Chapter 15)
- Thromboembolic event, especially with AF (see Chapter 15)

PLANNING

The major goals for the patient would include eliminating or decreasing the occurrence of the arrhythmia, minimizing anxiety, and acquiring knowledge about the arrhythmia and its treatment.

NURSING INTERVENTIONS

MONITORING AND MANAGING THE ARRHYTHMIA

The nurse regularly evaluates the patient's blood pressure, pulse rate and rhythm, rate and depth of respirations, breath sounds, and daily weights. The nurse also asks the patient about episodes of chest pain, syncope, light-headedness, dizziness, or fainting as part of the ongoing assessment as well as frequency of palpitations and overall level of fatigue. If a patient with an arrhythmia is hospitalized, the nurse may obtain a 12-lead ECG, continuously monitor the patient, and analyze rhythm strips to track and trend the arrhythmia. The patient should have vascular access and supplemental oxygen at the bedside.

The nurse assesses and observes for the beneficial and adverse effects of each antiarrhythmic medication. The nurse also manages medication administration carefully so that a constant serum blood level of the medication is maintained.

In addition to medication, the nurse assesses for factors that contribute to the arrhythmia, such as caffeine and stress, and assists the patient in developing a plan to make lifestyle changes that eliminate or reduce these factors.

MINIMIZING ANXIETY

When the patient experiences episodes of arrhythmia, the nurse maintains a calm and reassuring attitude. This assists in reducing anxiety (reducing the sympathetic response)

and fosters a trusting relationship with the patient. In addition, the nurse can help the patient develop a system to identify possible causative, influencing, and alleviating factors (e.g., keeping a diary). The nursing goal is to maximize the patient's control and to make the episode less threatening. In addition, involving family members can also be beneficial for the patient; the family can be involved in providing an educated support system and a plan of action if the patient experiences a hemodynamically unstable rhythm.

TEACHING PATIENTS SELF-CARE

The nurse explains the importance of maintaining therapeutic serum levels of antiarrhythmic medications so that the patient understands why medications should be taken regularly each day. If the patient has a potentially lethal arrhythmia, it is also important to establish with the patient and family a plan of action to take in case of an emergency. Family members should be encouraged to learn CPR as well as how to use an automated external defibrillator (AED). Occasionally patients wear a defibrillator vest to manage arrhythmias in the short term while allowing time to determine if the patient's cardiac output will improve post-MI or while trying to diagnose the cause of a clinically significant arrhythmia. This wearable defibrillator is worn only for a period of a few weeks to months, and then, depending on the patient's progress, the device is discontinued with no further device used or a permanent ICD is placed (discussed shortly) (Figs. 17-23 and 17-24). The patient and family should also be taught about potential effects or presentation of the arrhythmia and the signs and symptoms. This information allows the patient and family to feel more in control and better prepared for possible events.

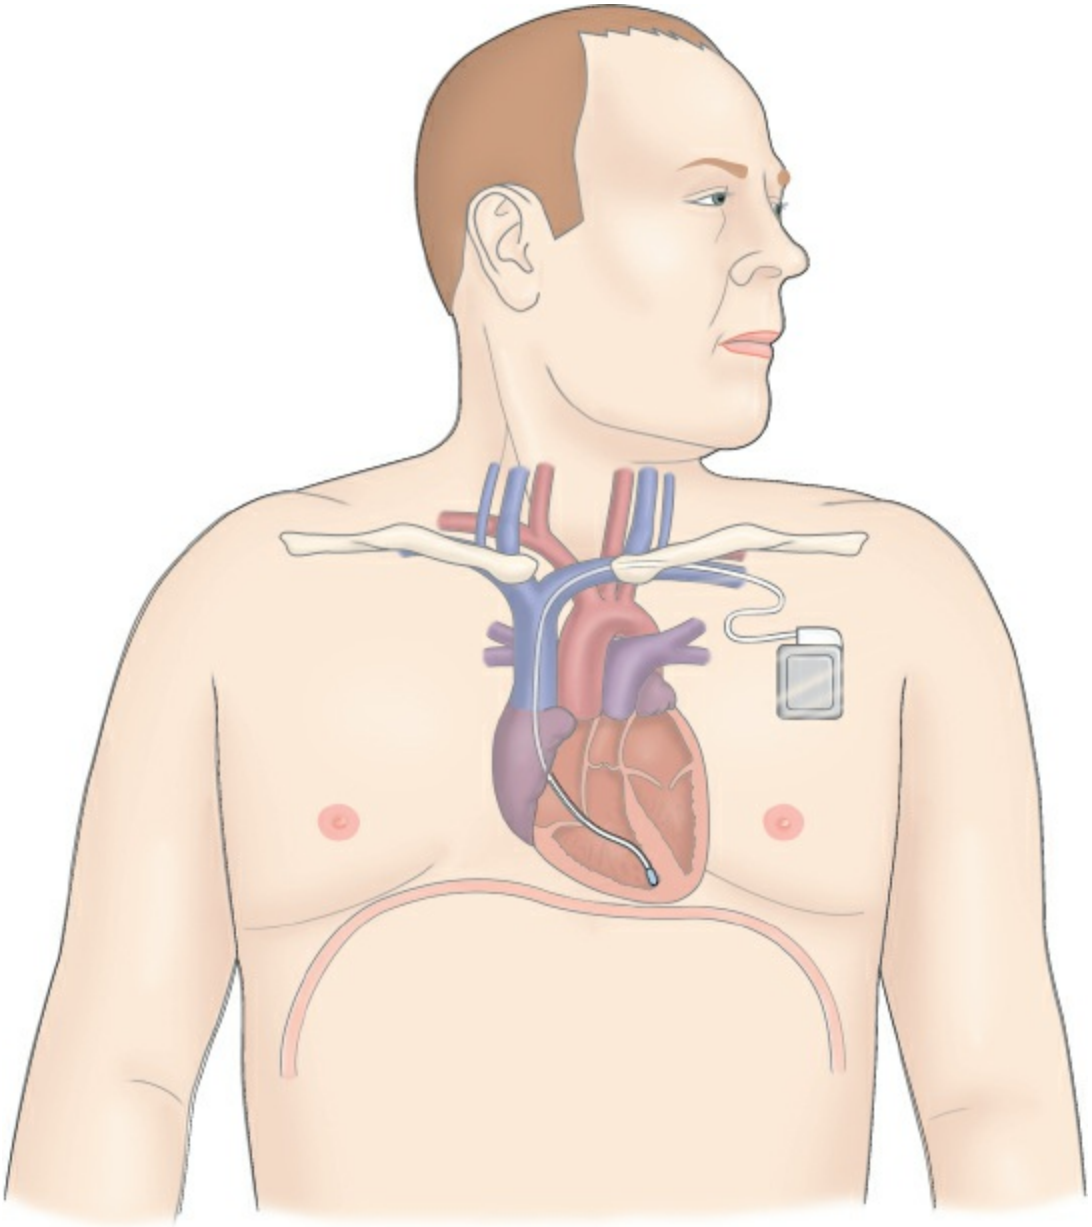

FIGURE 17-23 The implantable cardioverter defibrillator (ICD) consists of a generator and a sensing/pacing/defibrillating electrode.

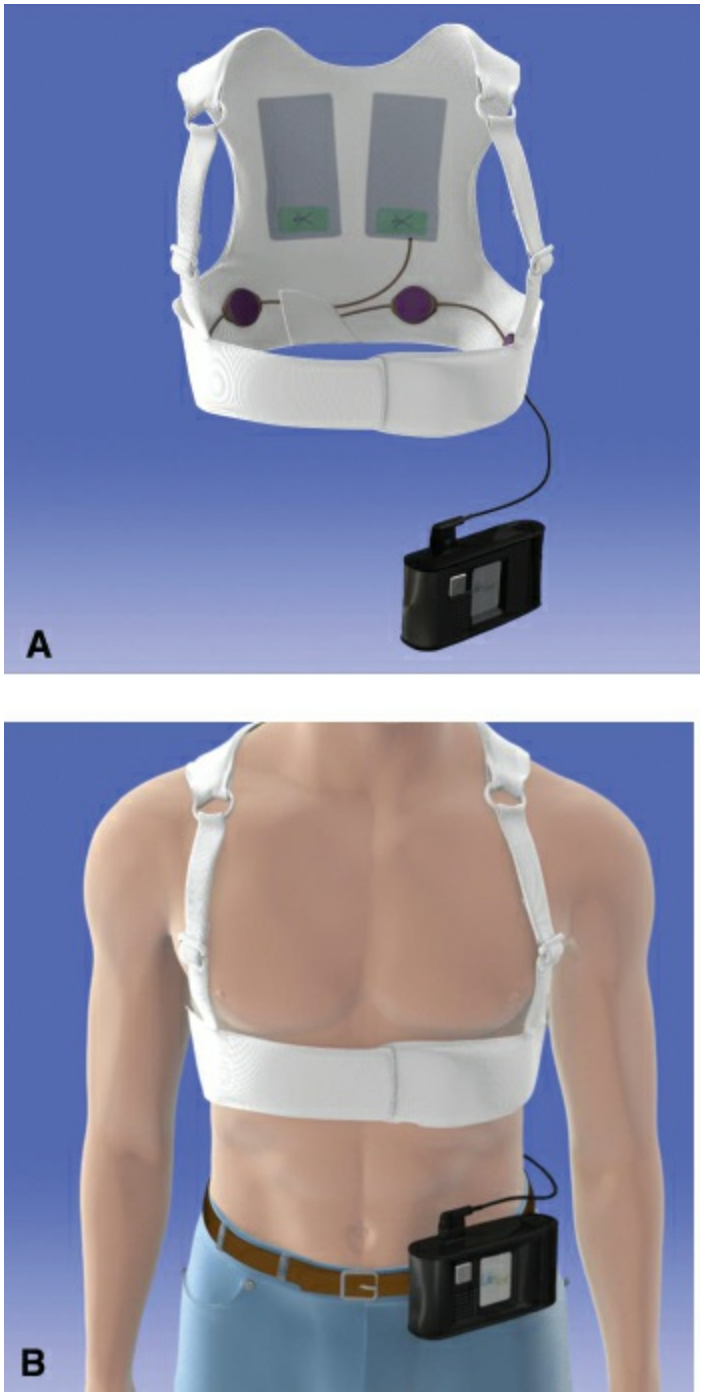

FIGURE 17-24 The LifeVest is a wearable defibrillator. Unlike an implantable cardioverter defibrillator (ICD), the LifeVest is worn outside the body rather than implanted in the chest. This device continuously monitors the patient's heart with dry, nonadhesive sensing electrodes to detect life-threatening abnormal heart rhythms. If a life-threatening rhythm is detected, the device alerts the patient prior to delivering a treatment shock, and thus allows a conscious patient to delay the treatment shock. If the patient becomes unconscious, the device releases a Blue™ gel over the therapy electrodes and delivers an electrical shock to restore normal rhythm. Dry, non-adhesive sensing electrodes on this electrode belt continuously monitor patient's heart (A). This monitor is worn in a holster around the waist and collects ECG data from the sensing electrodes which can later be sent to a provider via modem (B).

CONTINUING CARE

Home care is warranted if the patient has significant comorbidities, socioeconomic issues, or limited self-management skills that could increase the risk for nonadherence to the therapeutic regimen.

EVALUATION

Expected patient outcomes may include:

1. Maintains cardiac output:
    a. Demonstrates heart rate, blood pressure, respiratory rate, and level of consciousness within normal ranges
    b. Demonstrates no or decreased episodes of arrhythmia
2. Experiences reduced anxiety:
    a. Expresses a positive attitude about living with the arrhythmia
    b. Expresses confidence in ability to take appropriate actions in an emergency
3. Expresses understanding of the arrhythmia and its treatment:
    a. Explains the arrhythmia and its effects
    b. Describes the medication regimen and its rationale
    c. Explains the need to maintain a therapeutic serum level of the medication
    d. Describes a plan to eliminate or limit factors that contribute to the arrhythmia
    e. States actions to take in the event of an emergency

ADJUNCTIVE MODALITIES AND MANAGEMENT

Acute arrhythmias may be treated with medications or with electrical therapy (emergency defibrillation, cardioversion, or pacing), or, in many cases, both are used concurrently and sequentially to prevent the occurrence of arrhythmias. Many antiarrhythmic medications are used to treat atrial and ventricular tachyarrhythmias. The choice of medication depends on the specific arrhythmia and its duration, the presence of heart failure and other diseases, and the patient's response to previous treatment. Electrical therapies include cardioversion and defibrillation for acute tachyarrhythmia, and implantable devices (pacemakers for bradycardias and implantable cardioverter defibrillator [ICD] for chronic tachyarrhythmias). These devices are often referred to as cardiovascular implantable electronic devices (CIEDs). Catheter ablation is also available depending on the type of arrhythmia. The nurse is responsible for assessing the patient's understanding of and response to therapy, as well as the patient's self-management abilities.

CARDIOVERSION AND DEFIBRILLATION

Cardioversion and defibrillation are used to treat tachyarrhythmias by delivering an electrical current that depolarizes a critical mass of myocardial cells. When the cells repolarize, the sinus node is usually able to recapture its role as the heart's pacemaker. One major difference between cardioversion and defibrillation is the timing of the delivery of electrical current. In cardioversion, the delivery of the electrical current is synchronized with the patient's intrinsic rhythm; in defibrillation, the delivery of the current is unsynchronized or delivered independent of the patient's intrinsic rhythm.

The electrical current may be delivered externally through the skin with the use of paddles or with electrode pads, or it may be delivered internally as part of open heart surgery. The paddles or pads may be placed on the front of the chest (Fig. 17-25) (standard paddle placement), or one paddle may be placed on the front of the chest and the other connected to an adapter with a long handle and placed under the patient's back (anteroposterior placement) (Fig. 17-26). Whether using pads or paddles, the nurse must observe two safety measures. First, good contact must be maintained between the pads or paddles and the patient's skin (with a conductive medium in between them) to prevent electrical current from leaking into the air (arcing) when the defibrillator is discharged. Second, no one is to be in contact with the patient or with anything that is touching the patient when the defibrillator is discharged, to minimize the chance that electrical current will be conducted to anyone other than the patient. Box 17-6 lists key points for assisting with cardioversion or defibrillation.

FIGURE 17-25 Standard paddle placement for defibrillation and for pads.

Nursing Alert
Two types of defibrillators are used today for external cardioversion and defibrillation: the older, monophasic sinusoidal waveform and the newer, biphasic

truncated waveform. The new biphasic defibrillators use less energy to convert arrhythmias to normal sinus rhythm, which is a benefit. These defibrillators work through automatically adjusting to the patient's transthoracic impedance. The nurse understands that the amount of energy delivered to the heart is inversely related to transthoracic resistance so lowering the resistance helps to deliver optimal current to "shock" the heart. Refer to recommendations in Box 17-6 for further details.

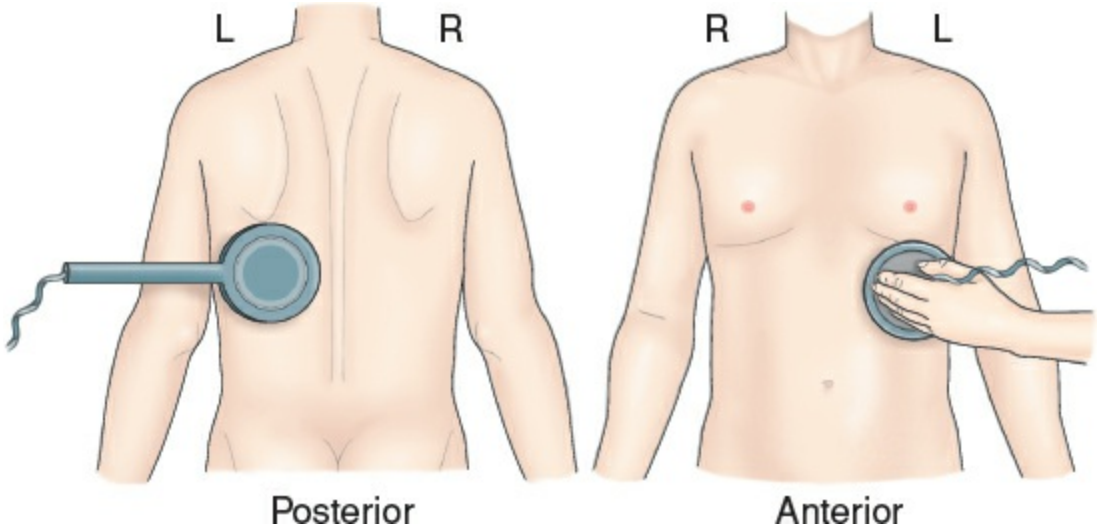

FIGURE 17-26 Anteroposterior paddle placement for defibrillation.

BOX 17-6 Assisting with External Cardioversion or Defibrillation

When assisting with external cardioversion or defibrillation, the nurse should remember these key points:

- Use multifunction conductor pads or paddles with a conducting medium between the paddles and the skin (the conducting medium is available as a sheet, gel, or paste). Do not use gels or pastes with poor electrical conductivity (e.g., ultrasound gel). Conductive electrode gel has been noted to reduce the transthoracic resistance by approximately 30% (Open Anesthesia, 2013).
- Place paddles or pads so that they do not touch the patient's clothing or bed linen and are not near medication patches or direct oxygen flow.
- If using paddles, exert 20–25 lb of pressure to ensure good skin contact. This lowers the transthoracic resistance.
- Before pressing the discharge button, call "Clear!" three times. Ensure that you and everyone else are not touching the patient, bed, or equipment. Perform a final visual check to ensure that you, and everyone else, are clear of the patient and anything touching the patient.
- Record the delivered energy.
- After the event is complete, inspect the skin under the pads or paddles for burns; if any are detected, consult with the physician or a wound care nurse about treatment.

- If cardioverting, ensure that the monitor leads are attached to the patient and that the defibrillator is in the synchronized mode ("sync"). If defibrillating, ensure that the defibrillator is not in the synchronized mode (most machines default to the "not-sync" mode).

Electrical Cardioversion

Electrical cardioversion involves the delivery of a "timed" electrical current to terminate a tachyarrhythmia. In cardioversion, the defibrillator is set to synchronize with the ECG on a cardiac monitor so that the electrical impulse discharges during ventricular depolarization (QRS complex). The synchronization prevents the discharge from occurring during the vulnerable period of repolarization (T wave), which could result in VT or ventricular fibrillation. When the synchronizer is on, no electrical current is delivered if the defibrillator does not discern a QRS complex. Because there may be a short delay until recognition of the QRS, the discharge buttons of an external defibrillator must be held down until the shock has been delivered.

If the cardioversion is elective and the arrhythmia has lasted longer than 48 hours, anticoagulation for a few weeks before cardioversion may be indicated. Digoxin is usually withheld for 48 hours before cardioversion to ensure the resumption of sinus rhythm with normal conduction. The patient is instructed not to eat or drink for at least 4 hours before the procedure. Before cardioversion, the patient receives IV moderate sedation as well as an analgesic medication or anesthesia. The amount of voltage used varies, depending on the defibrillator's technology and the type of arrhythmia.

Nursing Alert
When the heart returns to a normal sinus rhythm after cardioversion, the atria beat forcefully. If a clot has formed in the atria, systemic emboli may result, thus anticoagulation is needed if the arrhythmia has lasted over 48 hours. The nurse is alert for systemic signs of embolization, such as sudden onset shortness of breath with pulmonary emboli or neurologic changes (visual, motor, sensory, headache, etc.; refer to Chapter 47) with cerebral emboli.

Defibrillation

Defibrillation is used in emergency situations as the treatment of choice for ventricular fibrillation and pulseless VT. Defibrillation is not used on patients who are conscious or have a pulse. It has been established that early defibrillation is the major determinant of survival in cardiac arrest and is recommended in the guidelines as the first step when there is access to a defibrillator (AHA, 2015).

The electrical voltage required to defibrillate the heart is usually greater than that required for cardioversion and may cause more myocardial damage. Defibrillators are classified as monophasic or biphasic as discussed in the Alert. Monophasic defibrillators deliver current in only one direction and require increased energy loads; they are rarely used today. Newer biphasic defibrillators deliver the electrical charge to the positive paddle, which then reverses back to the originating paddle. The recommended energy levels for defibrillation vary according to the type of waveform and the manufacturer of the defibrillator. Following defibrillation, CPR is initiated immediately if a rhythm resulted that did not resume perfusion, and other advanced life support treatments are begun. This treatment with continuous CPR, medication administration, and defibrillation continues until a stable rhythm resumes or it is determined that the patient cannot be revived.

Often AEDs are used today by both laypersons and health care providers where the device once attached to the patient interprets the rhythm. Based on an algorithm when the patients' rhythm is determined to be "shockable," the defibrillator will guide the operator's or rescuer's action to discharge a shock. The AEDs are commonly placed in locations where large groups of people meet and/or in remote locations. They are often found in schools, airports, stadiums, on board aircraft, and in hospitals. The assignment of AEDs in the hospital setting makes sense to facilitate early rescue by providers who—although they are clinically oriented—are not necessarily proficient in interpreting arrhythmias due to infrequent occurrences of lethal arrhythmias, such as on a maternal child health unit.

Implantable Cardioverter Defibrillator

Often patients will have ICD/Pacemaker devices placed if they have tachyarrhythmias to manage both the rapid and slow rates. The ICD is a device that detects and terminates life-threatening episodes of tachycardia or fibrillation. ICDs are used for patients who have survived sudden cardiac death syndrome, usually caused by ventricular fibrillation, or have experienced symptomatic VT. Other people at risk of sudden cardiac death include those with dilated cardiomyopathy, hypertrophic cardiomyopathy, arrhythmogenic (capable of inducing an arrhythmia) right ventricular dysfunction, and prolonged QT syndrome. In addition, patients with moderate to severe left ventricular dysfunction, with a low ejection fraction (less than 30%), or with or without nonsustained VT are at high risk for cardiac arrest; therefore, prophylactic implantation may be indicated. ICDs may also be implanted in patients with symptomatic, recurrent, medication-refractory AF.

An ICD consists of a generator and at least one lead that can sense intrinsic electrical activity and deliver an electrical impulse. The device is usually implanted much like a pacemaker (Fig. 17-23). ICDs are designed to respond to two criteria: a rate that exceeds a predetermined level, and a change in the isoelectric line segments. When an arrhythmia occurs, the device automatically charges and delivers the programmed charge through the lead to the heart. ICD surveillance is similar to that of the pacemaker; however, it includes information about the number and frequency of shocks that have been delivered. Each device offers a different delivery sequence, but all are capable of delivering high-energy defibrillation to treat a tachycardia (atrial or ventricular). Antiarrhythmic medication usually is administered with this technology to minimize the occurrence of the tachyarrhythmia and to reduce the frequency of ICD discharge. In patients who have SVT, there is a choice between a single- and dual-chamber ICD dependent on the patient's clinical condition. The dual-chamber algorithm senses and interprets data from the atrium and ventricle to classify the rhythm and treat. However, early nonrandomized and small studies have not shown the dual chamber to be superior to single chamber at this time probably due to atrial sensing malfunctions (Madhavan & Friedman, 2013).

Some ICDs can respond with antitachycardia pacing or overdrive, in which the device delivers electrical impulses at a fast rate in an attempt to disrupt the tachycardia or by low-energy (low-intensity) cardioversion or by defibrillation. Antitachycardia pacing is used to terminate tachycardias caused by a conduction disturbance called *re-entry.* Some ICDs also have pacemaker capability if the patient develops bradycardia, which sometimes occurs after treatment of the tachycardia. In addition, many ICDs have other functions, such as storage of detected arrhythmias and the ability to perform electrophysiologic testing.

Nursing Alert

Patients who have ICDs must take care when coming into contact with devices that have strong magnetic fields. These devices may interfere with ICD function especially with prolonged exposure.

It is important for the nurse to refer the patient to the AHA website: http://www.heart.org/ to learn more about the potential environmental issues associated with ICDs so that the patient can take the necessary precautions.

The primary complication associated with the ICD is surgery-related infection. A few complications are associated with the technical aspects of the equipment, such as premature battery depletion and dislodged or fractured leads. In original research by Stoier, Preben, and Berg (2013), the findings suggest that patients who receive an ICD as secondary prevention experience an increase in negative emotions to include sadness, disgust, anger, and surprise. Accordingly, the literature also suggests that more research and work need to be done in the area of communication with the patient about the ICD prior to implantation. Patient–provider communication about the ICD has been reported to be unclear with omission of information considered important to the patient, use of medical jargon, and lack of attention to the psychological burden of the device and the impact on patient's quality of life (Hauptman, Chibnall, Guild, & Armbrecht, 2013). Nurses should advocate for patients and their families to ensure that informed consent is achieved before implantation of an ICD.

Support may need to be provided to assist individuals with adjustment to the uncertainty and psychological distress related to ICD delivering a shock. In past research, inappropriate shocks occurred in 13% of ICD patients, usually due to misinterpretation of an SVT (vanRees et al., 2011). However, newer features in modern ICDs (e.g., antitachycardia pacing therapy) coupled with the broad goals of both preventing inappropriate shocks and delivering shocks for symptomatic ventricular arrhythmias are offering advances in providing medical devices safely to such patients (Rickard & Wilkoff, 2016). Patients who have ICDs are clinically monitored, and their devices can be interrogated remotely and in-person to program them to meet the specific clinical indications (Wilcoff et al., 2015).

Deactivation of the ICD at End of Life

When a patient is in the terminal phases of illness, the ICD is no longer an appropriate intervention in the management of clinical care, and thoughtful consideration is required of the deactivation plan. Ideally, the conversation regarding the ICD and the possible need to deactivate it in a terminal illness should be discussed before the device is even implanted in the patient. Guidelines or protocols are needed in the United States to provide both patients and providers with direction for management of this lifesaving device in the context of life-ending disease along with ethical and legal implications. Further, both pacemakers and ICDs should be considered fully as they relate to the end of life to then estimate the potential benefits and harm associated with the device while allowing death with dignity. Pacemakers are not as controversial because in contrast with the ICD, there are no associated painful discharges of shocks to treat an arrhythmia in a patient who is dying. Deactivation of an ICD would not cause the death of a patient; rather this will allow a natural death to occur. Nurses, along with the interdisciplinary team, will need to collaborate to address the ethical challenges associated with withdrawal of life-sustaining treatments, such as the CIEDs (Wiegand, MacMillan, Rogrigues dos Santos, & Bousso, 2015).

PACEMAKER THERAPY

A pacemaker is an electronic device that delivers electrical stimulation to the heart to regulate the heart rate when a patient has a slower-than-normal heart rate or conduction disturbance. They may also be used to control some tachyarrhythmias or to treat advanced heart failure that does not respond to medication. Pacemakers may be temporary or permanent. Temporary pacemakers may be transvenous, transcutaneous, or epicardial.

Pacemaker Design and Types

Pacemakers consist of two components: an electronic pulse generator and pacemaker electrodes, or leads. The generator contains the energy source that determines the rate (measured in bpm) and the strength or output (measured in milliamperes [mA]) of the electrical stimulus delivered to the heart. The generator can be programmed to detect the heart's intrinsic electrical activity and to cause an appropriate response; this component of pacing is called *sensitivity* and is measured in millivolts (mV). Leads can be threaded through a major vein into the right ventricle (endocardial leads), or they can be lightly sutured onto the outside of the heart and brought through the chest wall during open heart surgery (epicardial wires). The endocardial leads may be placed temporarily with catheters through a great vessel (transvenous wires), usually guided by fluoroscopy. The endocardial and epicardial wires are connected to a temporary external generator.

Endocardial leads may also be placed permanently, usually through the external jugular vein, and connected to a permanent generator. The generator is implanted in a subcutaneous pocket created in the pectoral region below the clavicle (Fig. 17-27). The procedure usually takes about 1 hour, and it is performed in a cardiac catheterization or EP laboratory using a local anesthetic. Batteries need replacement after approximately 10 years; and battery replacement is usually performed using a local anesthetic.

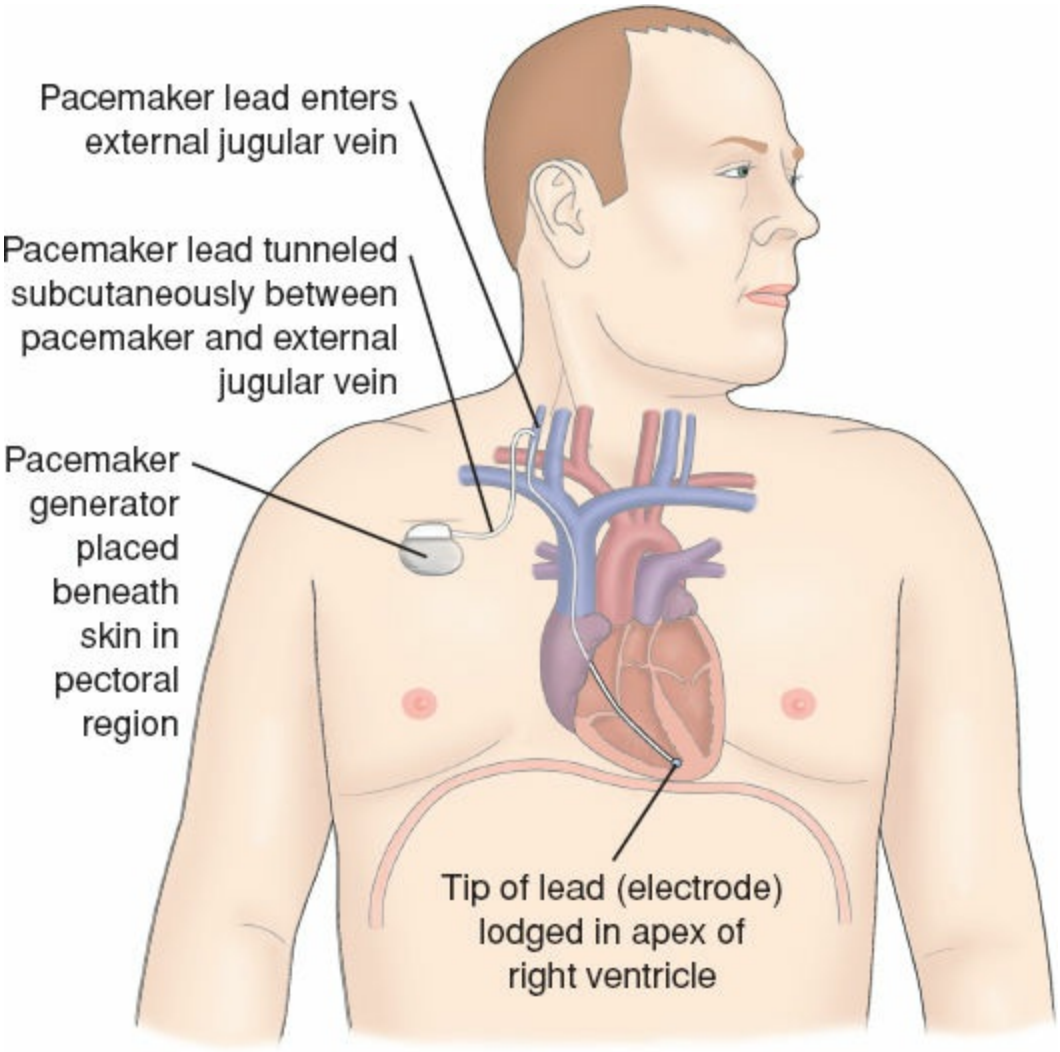

FIGURE 17-27 Implanted transvenous pacing lead (with electrode) and pacemaker generator.

If a patient suddenly develops a symptomatic bradycardia, emergency pacing may be started with transcutaneous pacing. Large pacing ECG electrodes (pads) are placed on the patient's chest and back. The electrodes are connected to the temporary pacemaker generator (Fig. 17-28). Because the impulse must travel through the patient's skin and tissue before reaching the heart, transcutaneous pacing can cause significant discomfort and is intended to be used only in emergencies. If the patient is alert, sedation and analgesia may be administered.

When pacing is initiated, the ECG tracing will display a straight vertical line, called a *pacemaker spike,* with each pacemaker impulse. The appropriate ECG complex should immediately follow the pacing spike; therefore, a P wave should follow an atrial pacing spike and a QRS complex should follow a ventricular pacing spike. Because the impulse starts in a different place than the patient's normal rhythm, the QRS complex or P wave that responds to pacing looks different from the patient's normal ECG complex. *Capture* is a term used to denote that the appropriate complex followed the pacing spike (Fig. 17-29). *Synchronized biventricular pacing*, also called *cardiac resynchronized therapy* (CRT), has been found to modify the intraventricular, interventricular, and atrial-ventricular conduction defects identified with symptomatic moderate to severe (New York Heart Association Functional Class III and IV) left ventricular dysfunction and heart failure. The generator

for biventricular pacing has three leads: one for the right atrium; one for the right ventricle, as with most standard pacemaker generators; and one for the left ventricle, usually placed in the left lateral wall. Studies have shown that this therapy improves cardiac function, resulting in decreased heart failure symptoms and an improved quality of life. The American College of Cardiology Foundation and the AHA developed four stages for HF, and it is at the level of stage B that a pacemaker or, in many cases, an ICD is recommended to prevent sudden cardiac death (Chapter 15 reviews the stages for HF).

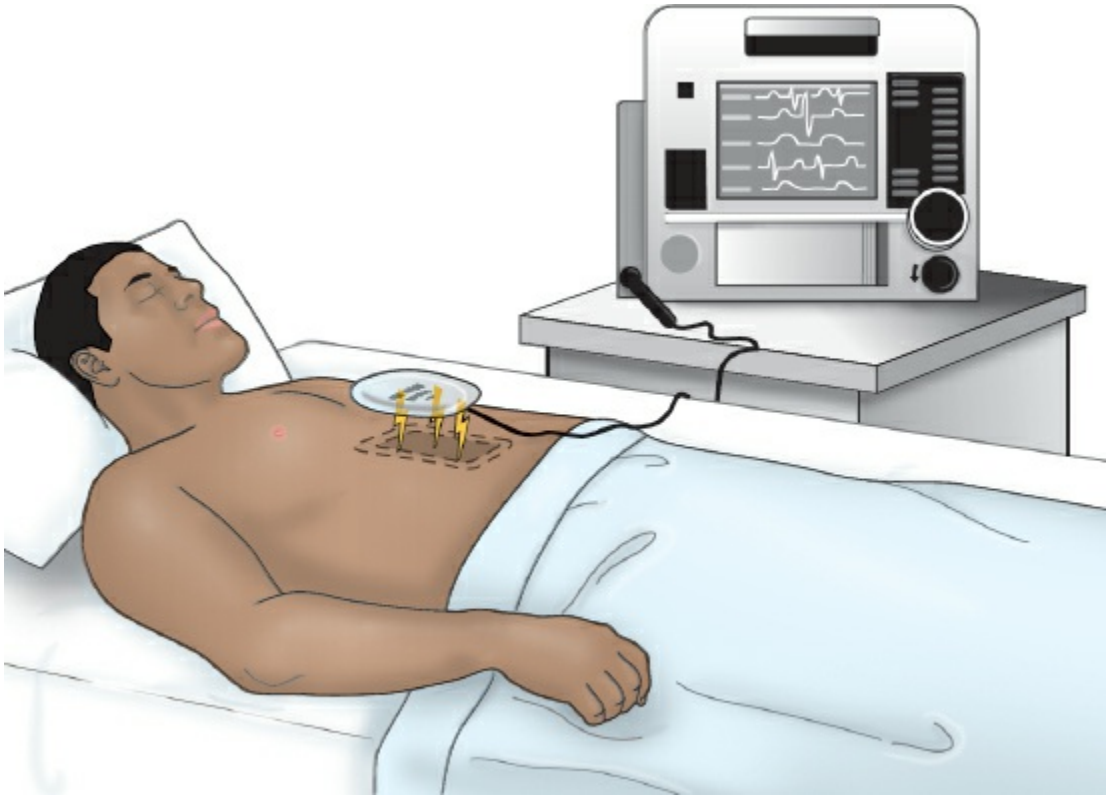

FIGURE 17-28 Transcutaneous pacemaker with electrode pads connected to the anterior and posterior chest walls.

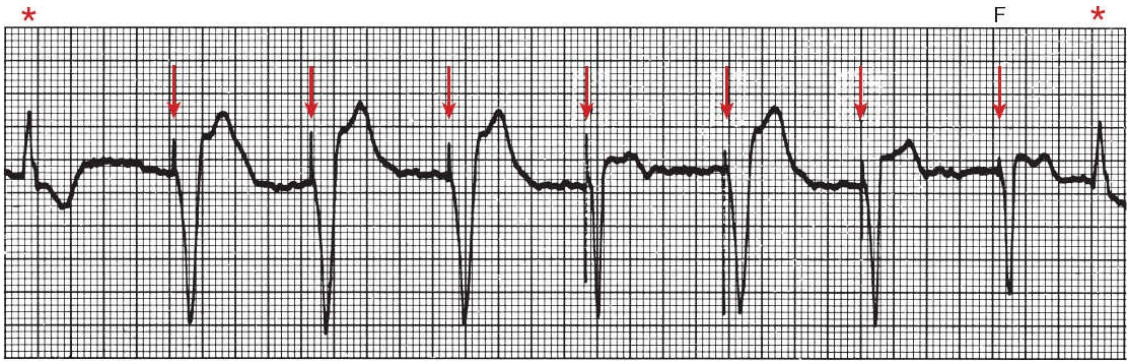

FIGURE 17-29 Pacing with appropriate sensing (on-demand pacing) in lead V_1. *Arrows* denote pacing spike. Asterisk (*) denotes intrinsic (patient's own) beats, therefore no pacing.

Complications of Pacemaker Use

Complications associated with pacemakers relate to their presence within the body and improper functioning. The following complications may arise from a pacemaker:

- Local infection
- Bleeding and hematoma
- Hemothorax
- Ventricular ectopy and tachycardia
- Movement or dislocation of the lead placed
- Phrenic nerve stimulation (hiccuping may be a sign)
- Rarely, cardiac tamponade

In the initial hours after a temporary or permanent pacemaker is inserted, the most common complication is dislodgment of the pacing electrode. Minimizing patient activity can help prevent this complication. If a temporary electrode is in place, the extremity through which the catheter has been advanced is immobilized. With a permanent pacemaker, the patient is instructed initially to restrict activity on the side of the implantation for 2 to 4 weeks (Olshansky & Hayes, 2016).

The ECG is monitored very carefully to detect pacemaker malfunction. Improper pacemaker function, which can arise from failure in one or more components of the pacing system, is outlined in Table 17-4. Pacemaker settings (e.g., rate, energy output [mA], sensitivity [mV], and duration of interval between atrial and ventricular impulses [AV delay]) should be noted in the patient's record.

A patient experiencing pacemaker malfunction may develop bradycardia as well as signs and symptoms of decreased cardiac output. The degree to which these symptoms become apparent depends on the severity of the malfunction, the patient's level of dependency on the pacemaker, and the patient's underlying condition. Pacemaker malfunction is diagnosed by analyzing the ECG and through *interrogation* of the pacemaker's stored bank of activity, performed by trained personnel.

Inhibition of permanent pacemakers or reversion to asynchronous fixed rate pacing can occur with exposure to strong electromagnetic fields (electromagnetic interference [EMI]). However, recent pacemaker technology allows patients to safely use most household electronic appliances and devices (e.g., microwave ovens, electric tools). Objects that contain magnets (e.g., the earpiece of a phone; large stereo speakers; portable media players; magnet therapy products, such as mattresses, jewelry, and wraps) should not be near the generator for longer than a few seconds. Patients are advised to keep digital cellular phones at least 6 to 12 in away from (or on the side opposite of) the pacemaker generator and not to carry them in a shirt pocket.

Pacemaker Surveillance

Pacemaker clinics have been established to monitor patients and to test pulse generators for impending pacemaker battery failure. A computerized device is held over the generator to interrogate it with painless radio signals; it detects the generator's settings, battery status, pacing threshold, sensing function, lead integrity, and other stored information. Several factors, such as lead fracture, muscle inhibition, and insulation disruption, also may be assessed. If indicated, the pacemaker is turned off for a few seconds, using a magnet or a programmer, while the ECG is recorded to assess the patient's underlying cardiac rhythm. Changes may be made in the programming of the pacemaker or ICD prior to surgery or procedures where the device may need to be adjusted. Therefore, it is very important that the perioperative team is made aware of the device that the patient has implanted. In addition, it is important to have a list of manufacturer contacts should there be an emergent need requiring technical support. Transtelephonic transmission of the generator's information is another follow-up method. Special equipment is used to transmit information about the patient's pacemaker over the telephone to a receiving system at a pacemaker clinic. The information is converted into tones; equipment at the clinic converts these tones to an electronic signal and records them on an ECG strip. The pacemaker rate and other data concerning pacemaker function are obtained and evaluated by a cardiologist. This simplifies the diagnosis of a failing generator, reassures the patient, and improves management when the patient is physically remote from pacemaker testing facilities.

TABLE 17-4 Assessing Pacemaker Malfunction/Complications

Problem	Possible Cause	Intervention
Failure to pace; the pacemaker fails to deliver the correct number of electrical stimuli per minute	Output failure—oversensing and undersensing Battery failure Loose connection between lead wire and generator Fracture or displacement of pacing lead wire Pulse generator failure Electromagnetic interference (Potential causes of EMI include use of the TENS unit, electroconvulsive therapy, and monopolar electrocautery) Sensitivity setting too high Lead displacement	Replace the pulse generator battery Tighten the connections between pacing lead and pulse generator Replace the lead wire Replace pulse generator unit Remove the source of electromagnetic interference or moderate it if possible. Check with pacemaker manufacturer. Adjust sensitivity setting Adjust lead May require programming adjustment
Failure to capture; the pacemaker does not depolarize the heart	Battery failure Fracture or displacement of pacing lead wire Perforation of the myocardium by the lead wire Scar tissue or edema formation at lead tip Energy output (mA) too low Increase in stimulation threshold due to medication Electrolyte imbalance Myocardial Infarction	Replace battery Reposition patient; Replace the lead wire Surgical repair Replace pacing lead Increase the output (mA) Increase the output (mA) Correct electrolyte imbalances May require programming adjustment

EMI, electromechanical interference; TENS, transcutaneous electrical nerve stimulation; mA, miliamperage.
Neelankavil et al., 2013.

ELECTROPHYSIOLOGIC STUDIES

An EP study is a minimally invasive procedure used to evaluate and treat significant arrhythmias. It also is indicated for patients with symptoms that suggest an arrhythmia that has gone undetected and undiagnosed by other methods. An EP study is used to do the following:

- Identify the impulse formation and propagation through the cardiac electrical conduction system
- Assess the function or dysfunction of the SA and AV nodal areas
- Identify the location (called *mapping*) and mechanism of dysrhythmogenic foci
- Assess the effectiveness of antiarrhythmic medications and devices for the patient with an arrhythmia
- Treat certain arrhythmias through the destruction of the causative cells (ablation)

An EP procedure is a type of cardiac catheterization that is performed in a specially equipped cardiac catheterization laboratory by an electrophysiologist. One of the main purposes of programmed stimulation is to assess the ability of the area of the myocardium to cause an arrhythmia. If the arrhythmia can be reproduced by programmed stimulation, it is called *inducible.* Once an arrhythmia is induced, a treatment plan is determined and implemented. If, on the follow-up EP study, the tachyarrhythmia cannot be induced, then the treatment is determined to be effective. Different medications may be administered and combined with electrical devices (pacemaker, ICD) to determine the most effective treatment to suppress the arrhythmia.

Patient care, patient teaching, and associated complications of an EP study are the same as those associated with cardiac catheterization (see Chapter 14). The study is usually about 2 hours in length; however, if the electrophysiologist conducts not only a diagnostic procedure but also treatment, the study can take up to 8 hours.

Patients who are to undergo an EP study may be anxious about the procedure and its outcome. Before the procedure, the patient should receive instructions, including its usual duration, the environment where the procedure is performed, and what to expect. Although an EP study is not painful, it does cause discomfort and can be tiring. It may also cause feelings that were experienced when the arrhythmia occurred in the past. In addition, the nurse should prepare the patient for the procedure and what will be expected of him or her (e.g., lying very still during the procedure, reporting symptoms or concerns, etc.).

The patient should also know that the arrhythmia may occur during the procedure. It often stops on its own; if it does not, treatment is given to restore the patient's normal rhythm. The arrhythmia may have to be terminated using cardioversion or defibrillation, but this is performed under more controlled circumstances than if performed in an emergency. Postprocedural care is similar to that for cardiac catheterization.

CARDIAC CONDUCTION SURGERY

Atrial tachycardias and VTs that do not respond to medications and are not suitable for antitachycardia pacing may be treated by methods that include a maze procedure and ablation. The *maze procedure* is an open heart surgical procedure for refractory AF. Sometimes, it is referred to as a Cox procedure or a mini-maze. The surgeon will ablate and/or use small incisions to create nonconducting scar tissue to stop the arrhythmia. This procedure is sometimes done together with an EP procedure or done when a patient is having another surgery such as a CABG or with valve replacement.

Catheter ablation done by radiofrequency destroys specific cells that are the cause or central conduction route of a tachyarrhythmia. It is performed with or after an EP study. Usual indications for ablation are recurrent atrial arrhythmias or VT unresponsive to previous therapy (or for which the therapy produced significant side effects). In addition to the standard catheter radiofrequency ablation, as mentioned earlier in the chapter, cryoablation is a newer type of treatment where the cardiac tissue is frozen, usually in the area of the pulmonary arteries. It often can be done faster since the tissue is frozen in a circle with the end of the catheter all at one time, discontinuing the arrhythmia. This is becoming a safe and effective alternative to radiofrequency ablation.

CHAPTER REVIEW

Critical Thinking Exercises

1. You are caring for a 79-year-old woman who was admitted for control of heart failure 3 days ago. Today, her telemetry monitor alarmed and displayed a new sustained tachycardia with a wide QRS (0.14 second). What are some of the possible causes of this arrhythmia? Identify some of the key factors that would need to be included in your assessment to assist in identification of the arrhythmia. What nursing interventions are needed?

2. You are caring for a 40-year-old man who recently had a pacemaker inserted, with the rate set at 72 bpm. When taking his pulse, you note that his heart rate is 66 bpm. Describe the possible causes of this difference in heart rates and the nursing actions that are needed.

3. The wife of this same patient tells you that her husband has informed her that now he has a pacemaker, they must get rid of their microwave oven and that he can no longer speak on the cell phone. What would you say to the wife? How would you discuss this with the patient? What other education would you provide to this patient and his wife about safety in relation to the pacemaker? What is the evidence base that supports this education? Discuss the strength of the evidence and the criteria used to evaluate the strength of the evidence.

NCLEX-Style Review Questions

1. In interpreting a patient's rhythm strip, the nurse is most concerned with which of the finding?
   a. A PR interval of 0.22 second
   b. Progressively lengthening PR interval
   c. A premature and short PR interval
   d. A PR interval of 0.10 second

2. The nurse is observing the central monitoring station and notes the following rhythm alarms. Which alarm should the nurse respond to first?
   a. Atrial fibrillation rate of 90
   b. First-degree heart block, rate of 80
   c. Ventricular tachycardia (monomorphic)
   d. Torsade des pointes (polymorphic)

3. A patient presents to the emergency room in atrial fibrillation. The nurse understands that the treatment plan for this patient will be determined based on which factor?
   a. Whether or not the patient has a "do not resuscitate" prescription
   b. How long the patient has been in atrial fibrillation
   c. The number of episodes of atrial fibrillation the patient has experienced in the past year
   d. The rate of atrial contractions

4. The nurse notes a new wide complex tachycardia on the telemetry monitor. Upon assessing the patient, the nurse finds the patient cannot be aroused and has gasping respirations. The nurse's next action is to:
   a. Call a code
   b. Notify the provider stat
   c. Document the findings in the telemetry record
   d. Defibrillate the patient at 100 J

5. The nurse notes that a patient has a new second-degree type I block (Wenckebach). The patient denies chest pain or other symptoms, and the patient's blood pressure is 90/60. After paging the provider stat, what intervention would the nurse perform first?
   a. Apply oxygen, assess IV access, bring the portable monitor/external pacemaker to the bedside
   b. Administer nitroglycerin as ordered p.r.n. for chest discomfort and obtain a 12-lead ECG
   c. Call for stat labs to be drawn and prepare the patient for surgical pacemaker implantation
   d. Ask the nurse's aide to stay with the patient and monitor the blood pressure every 5 minutes

CHAPTER 18

Nursing Management: Patients with Vascular Disorders and Problems of Peripheral Circulation

Mary Sieggreen

Learning Objectives

After reading this chapter, you will be able to:

1. Identify factors that affect peripheral blood flow and tissue oxygenation.
2. Identify clinical manifestations, management, and prevention of arterial disorders.
3. Describe prevention and management of deep venous thrombosis.
4. Describe medical and nursing management of venous and arterial ulcers.
5. Describe nursing management of lymphedema.

Conditions of the vascular system include arterial disorders, venous disorders, lymphatic disorders, and cellulitis. Nursing management depends on an understanding of the structure and function of the vascular and lymphatic systems.

Intact, patent, and responsive blood vessels are necessary to deliver adequate amounts of oxygen to tissues and to remove metabolic wastes. Reduced blood flow through blood vessels characterizes all peripheral vascular diseases (PVDs). Perfusion is about supply versus demand. If tissue needs are high, even modestly reduced blood flow may be inadequate to maintain tissue integrity. When arterial blood flow decreases, ischemia follows, and tissues become malnourished and, ultimately, die unless blood flow is restored. Thus, the effect of decreased blood flow depends on the extent to which tissue demands exceed the supply of oxygen.

Nurses are in key positions to help patients with vascular disorders learn about the disease and their personal risk factors. Learning to modify the risk factors and manage their disorders may increase the lifespan of patients with vascular disorders.

ARTERIAL DISORDERS

Arteries become damaged or obstructed as a result of atherosclerotic plaque, thromboemboli, chemical or mechanical trauma, infections or inflammatory processes, vasospastic disorders, and congenital malformations. A sudden arterial occlusion causes profound and often irreversible tissue ischemia and tissue death. When arterial occlusions develop gradually, there is less risk of sudden tissue death because collateral circulation may develop (the rerouting of blood vessels, in which new blood vessels join to take over some

of the circulation of blocked vessels), giving that tissue the opportunity to adapt to gradually decreased blood flow. However, over time, continued decreased perfusion results in ischemia and tissue death (Treat-Jacobson, 2014).

PERIPHERAL ARTERIAL DISEASE

Peripheral artery disease (PAD) refers to any disease process that affects the arteries. Various PADs result in ischemia and produce the signs and symptoms described in Box 18-1. The type and severity of symptoms depend in part on the type, stage, and extent of the disease process and on the speed with which the disorder develops. Arterial insufficiency of the extremities is a common cause of disability. Frequently the legs are affected more than the upper extremities.

Clinical recognition of PAD varies in individuals; it is a slow process that begins in early adulthood and increases with age. PAD is one manifestation of atherosclerosis, thus systemic diseases that affect arteries of the brain, heart, kidneys, mesentery, and limbs should be suspected. Over one third of patients with PAD have significant coronary disease, and up to one quarter have carotid artery disease (White, 2016). Patients with PAD have an increased risk of mortality, myocardial infarction (MI), and cerebrovascular disease. Many patients with PAD are not receiving any treatment for their disease because they do not realize they have the condition (Naito et al., 2016).

BOX 18-1 Focused Assessment

Lower Extremity Peripheral Arterial Disease

Be alert for the following signs and symptoms:

- Structural changes, resulting from chronic lack of oxygen and nutrient delivery to the tissues:
- Hair loss distal to the occlusion
  - Thick, opaque nails; shiny, dry skin
  - Skeletal muscle atrophy
- Skin color changes:
  - Elevational pallor
  - Dependent rubor (red color when limb dependent from dilated damaged vessels)
- Pulse changes:
  - Pulses diminished or absent below area of stenosis/obstruction-pedal, posterior tibial, popliteal, femoral
  - Cool extremity distal to occlusion
- Sensation changes:
  - Paresthesias
  - Numbness
  - Tingling of extremities
- Ulcers or gangrene (traumatic or spontaneous on onset) located at tips of toes,

between toes, over areas of pressure, such as the heel, or areas susceptible to trauma like the shin; defined punched out (circular), necrotic/yellow ulcer base, dry, pale in appearance; usually very painful; poor healing of injuries on the extremities.

- Edema, although frequently absent, may be present and related to dependency

Pathophysiology

As the lumen narrows and blood flow decreases, ischemia occurs, progressing to infarction in the distal tissues. In PAD, obstructive lesions are predominantly confined to segments of the arterial system extending from the aorta below the renal arteries to the popliteal artery. Distal occlusive disease is frequently seen in patients with diabetes mellitus and in the elderly.

Arteriosclerosis, the most common disease of the arteries, is a diffuse process whereby muscle fibers and endothelial linings of the walls of small arteries and arterioles become thickened. Atherosclerosis involves changes of the intima consisting of accumulation of lipids, calcium, blood components, complex carbohydrates, and fibrous tissue, referred to as *atheromas* or *plaques.* Atherosclerosis causes arterial stenosis, obstruction by thrombosis, aneurysm, ulceration, and vessel rupture.

Arterial bifurcations are more vulnerable to atherosclerosis than other areas of the arteries (Fig. 18-1). These include the distal abdominal aorta; the common iliac arteries; the orifice of the superficial femoral and *profunda femoris* arteries; the superficial femoral artery in the adductor canal, which is particularly narrow; and anywhere along the arteries distal to the knee. Gradual narrowing of the arterial lumen stimulates the development of collateral circulation (Fig. 18-2) from pre-existing vessels.

Risk Factors

Risk factors for developing PAD are similar to those for developing coronary artery disease (Eraso et al., 2014) (Box 18-2). The age of onset and disease severity are influenced by the type and number of atherosclerotic risk factors. Risk factors include modifiable (e.g., diet, smoking) and nonmodifiable (e.g., race and age) factors. Evidence indicates modification may slow the disease process. Of those that can be modified, tobacco use is one of the most important in atherosclerotic lesion development. Nicotine decreases blood flow, increases heart rate and blood pressure, and increases the risk for clot formation by increasing platelet aggregation. According to research findings (Lu, Mackay, & Pell, 2013), smokers have a three- to fivefold increased risk of developing PAD compared to nonsmokers.

Hyperhomocysteinemia is considered an independent risk factor for atherosclerosis (Brunelli, Fusco, Iosa, Ricciardi, & Traballesi, 2015). Homocysteine is a protein that promotes coagulation. Elevated homocysteine levels are associated with genetic factors and a diet low in folic acid, vitamin B_6, and vitamin B_{12}. Treatment includes intake of vitamins B_6, B_{12}, and folate, which often lowers homocysteine levels (refer to Chapter 12 for more details on homocysteine levels). In addition, since inflammation plays a fundamental role in the development and progression of atherosclerosis, elevated levels of C-reactive protein (CRP) are strongly associated with the development of PAD (White, 2016).

Hypertension also accelerates the rate at which atherosclerotic lesions form in high-pressure vessels and, therefore, is a major PAD risk factor. Patients with diabetes have about seven to fifteen times the amputation rate of those without diabetes. Therefore, tight control of diabetes is important; the risk of developing PAD increases by 28% for every 1% increase in glycosylated hemoglobin (White, 2016). Obesity, stress, and lack of exercise also have been identified as contributing to the disease process.

Clinical Manifestations and Assessment

Most patients with PAD are initially asymptomatic. Studies have demonstrated that for every patient who has symptomatic disease, approximately three to four patients have no symptoms (Eraso et al., 2014).

Approximately 1% to 5% of patients with PAD have critical limb ischemia (CLI), with chronic ischemic pain at rest (rest pain), nonhealing, ulcers, or gangrene. A small number of patients with PAD have acute limb ischemia (ALI), a sudden decrease in limb perfusion, most commonly caused by either thrombosis or embolism, that produces new or worsening symptoms that may threaten limb viability. Other potential causes of acute arterial occlusion include atherosclerotic stenosis, aneurysm, arterial dissection, arterial embolization, cardiac embolization, trauma (blunt injuries, fractures), tumor compression, graft thrombosis, drug abuse, low cardiac output, phlegmasia cerulea dolens (massive iliofemoral venous thrombosis), and compartment syndrome. Box 18-3 summarizes clinical manifestations of acute arterial occlusion.

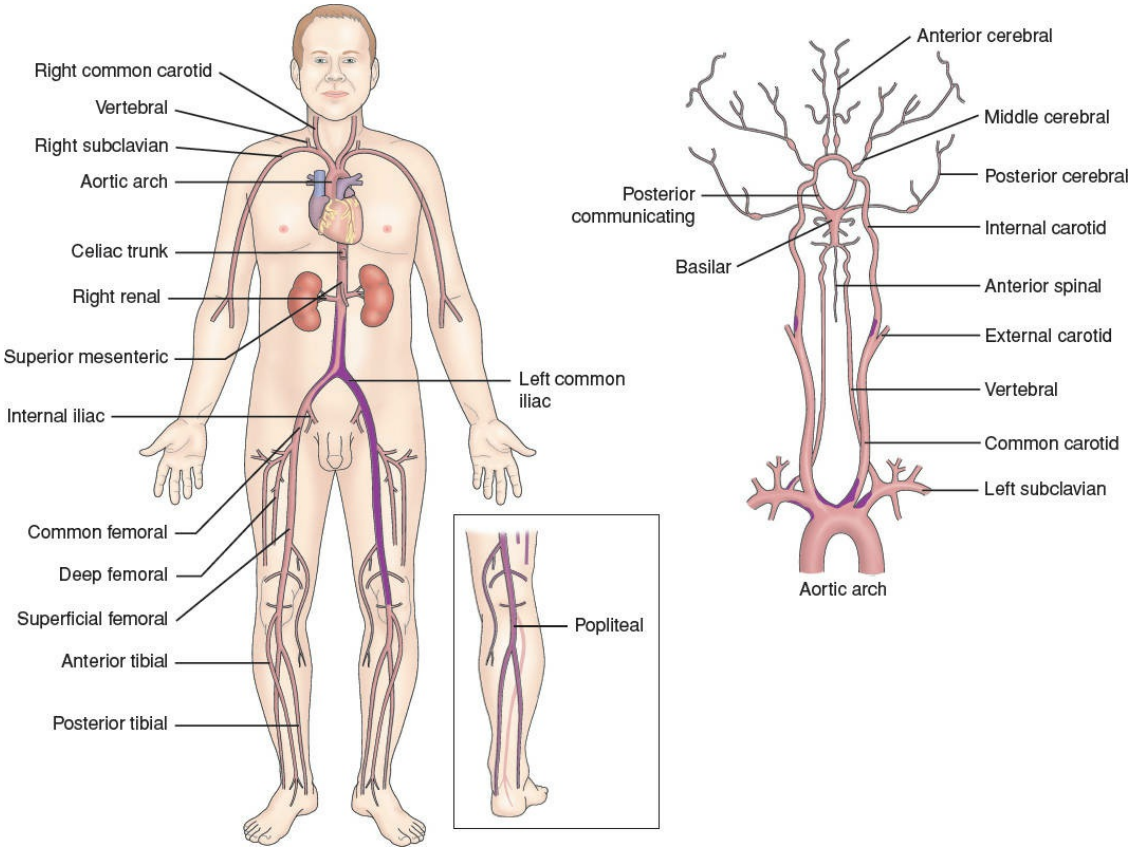

FIGURE 18-1 Common sites of atherosclerotic obstruction in major arteries.

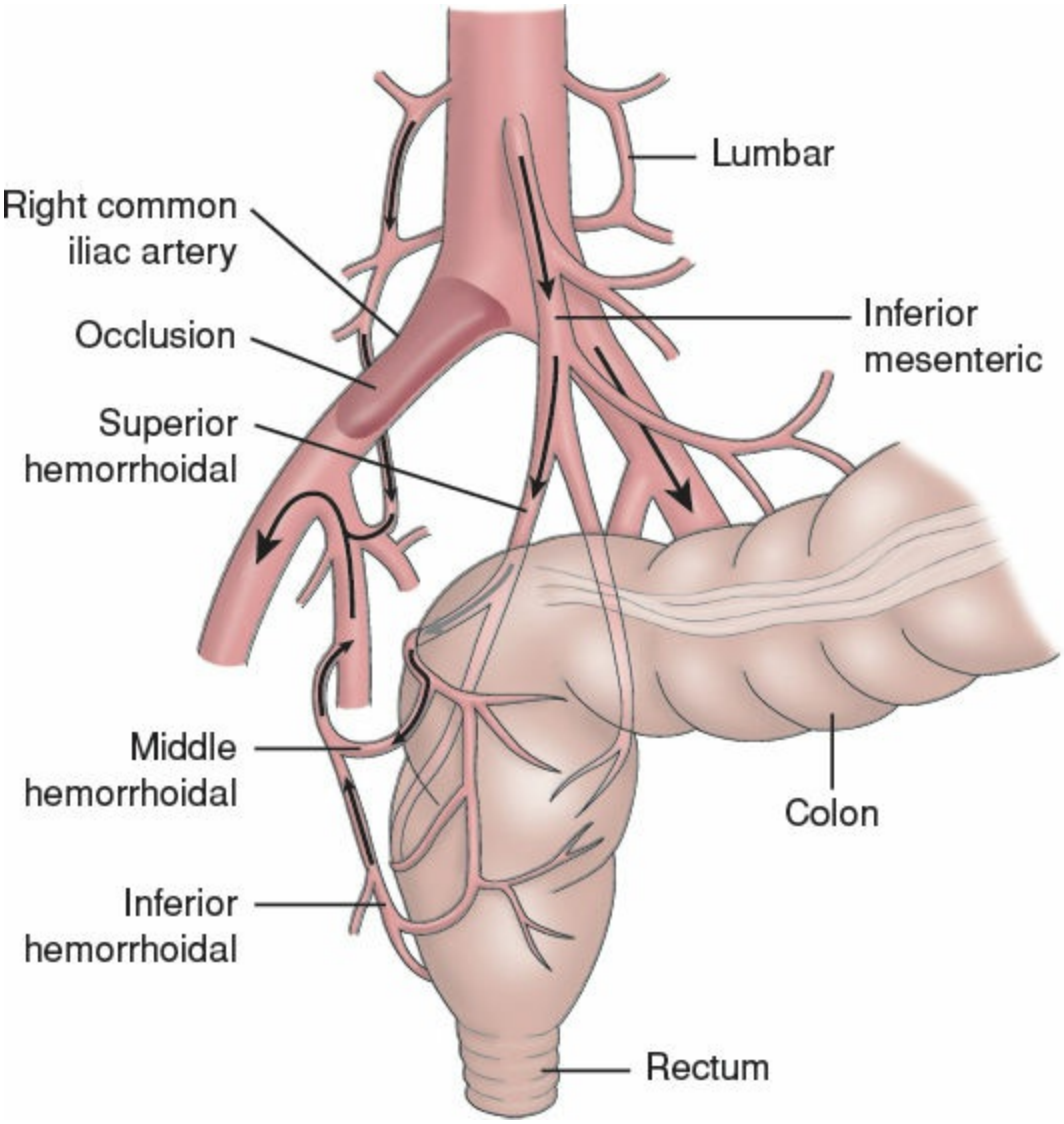

FIGURE 18-2 Development of channels for collateral blood flow in response to occlusion of the right common iliac artery and the terminal aortic bifurcation.

BOX 18-2 Risk Factors for Peripheral Arterial Disease (PAD)

- Family history
- Age (14.5% of adults over 70 years of age have PAD) (White, 2016)
- Obesity
- Smoking
- Pre-existing health conditions:
  - Coronary artery disease
  - Cerebral artery disease
  - Diabetes
  - Hypertension
  - Dyslipidemia
  - Clotting disorders

- Hyperhomocysteinemia

BOX 18-3 Focused Assessment

Acute Arterial Occlusion

Be alert for the following signs and symptoms, known as the "Six Ps":

- Pain (severe, shooting, stabbing, or burning sensation)
- Pallor (lighter color than the rest of the skin)
- Pulselessness (no palpable pulse)
- Poikilothermia (cool temperature to palpation)
- Paresthesia (numbness, tingling, hot/cold sensations)
- Paralysis (immobility [late sign], indicates severe tissue damage)

Nursing Alert
In patients with CLI, minor trauma from poorly fitting shoes or carelessly clipped toenails can cause a nonhealing wound or infection that can progress to amputation.

Clinical signs and symptoms resulting from atherosclerosis are manifested in the end organ supplied by arterial blood flow. Patients complain of pain in the fingers or feet or pain in muscle groups with use (not the joints). Walking causes pain in the leg muscles, and upper extremity physical activity causes pain in the arm muscles. A description of pain and its precipitating factors, assessment of skin color and temperature, and peripheral pulse presence and character are important assessment parameters in the diagnosis of arterial disorders.

Pain

The hallmark symptom for PAD in the lower extremity is intermittent claudication (Box 18-4). This pain may be described as aching or cramping in a muscle that occurs with the same degree of exercise or activity and is relieved with rest. Intermittent claudication is caused by the inability of the arterial system to provide adequate blood flow to the tissues in the face of increased demand for nutrients and oxygen during exercise. As the tissues are forced to complete the energy cycle without adequate nutrients and oxygen, muscle metabolites and lactic acid are produced. Pain is experienced as the metabolites aggravate the nerve endings of the surrounding tissue. When the patient stops muscle activity and thereby decreases the metabolic needs of the muscles, the pain subsides. If the patient must sit to relieve lower extremity pain, the pain may be caused by a nerve injury to the back or another noncirculatory etiology. Progression of arterial disease can be monitored by documenting the ambulatory distance before pain is felt. Because the pain is associated with decreased perfusion, it is important to determine that the pain is reproducible from one day to the next on similar terrain.

BOX 18-4 Intermittent Claudication (IC)

- Cramp-like pain in a muscle
- Consistently reproduced with the same degree of exercise or activity
- Relieved by stopping muscle use
- Caused by inability of the arterial system to provide blood flow that keeps up with increased demand
- Site of arterial disease can be determined by the location of claudication
- Pain occurs in muscle groups distal to the diseased vessel
- 70–80% of patients do not have worsening symptoms
- 10% of claudicants will progress to critical limb ischemia (CLI) (White, 2016)
- Dependent position reduces pain

The location of disease within the arterial system can be determined by the location of claudication symptoms because pain occurs in muscle groups distal to the diseased vessel. Calf pain may accompany reduced blood flow through the superficial femoral or popliteal artery, whereas pain in the hip or buttock may result from reduced blood flow in the abdominal aorta or the common iliac or hypogastric arteries. Persistent pain in the anterior portion of the foot when the patient is resting indicates a severe degree of arterial insufficiency and a critical state of ischemia. Known as rest pain, this discomfort is often worse at night and may interfere with sleep. This pain frequently requires the extremity be lowered to a dependent position to improve perfusion to the distal tissues. The dependent position of the lower extremity may cause edema in the leg and foot, thus edema may be associated with PAD. Rest pain is associated with limb-threatening ischemia. Refer to Table 18-1 for information on how to differentiate claudication from other causes.

Upper extremity atherosclerotic stenosis may cause arm fatigue and pain with exercise (forearm claudication) and inability to hold or grasp objects (e.g., painting, combing hair, placing objects on shelves above the head).

Changes in Skin Appearance and Temperature

Inadequate blood flow results in cool and pale extremities. Further reduction of blood flow to the tissues, which occurs when the extremity is elevated, for example, results in an even whiter or more blanched appearance to the skin compared to the contralateral limb. When the extremity is placed in a dependent position after elevation, it becomes a reddish-blue color called rubor. This color change suggests severe peripheral arterial damage, in which vessels that cannot constrict remain dilated. *Cyanosis*, a bluish tint of the skin, is manifested when the amount of oxygenated hemoglobin contained in the blood is reduced. Skin color changes may be more subtle in darkly pigmented individuals. Comparing the contralateral limb is the best way to discern color changes. Capillary refill time (CRT) is frequently used as an assessment of peripheral perfusion. The nurse depresses the nail bed of the finger or toe between his or her fingers until it blanches. After releasing the pressure, the skin color in normal tissue is expected to return in fewer than 2 seconds. However, recent research

findings call into question the efficacy of this test in assessing circulatory volume because of poor agreement among observers. The nurse considers this test not as a definitive marker for impaired perfusion but rather as an adjunctive tool to consider when clustering other manifestations of peripheral perfusion.

TABLE 18-1 Differentiation of Claudication from Other Disorders in the Lower Extremities

	Intermittent Claudication	Spinal Stenosis	Arthritis	Venous Congestion	Compartment Syndrome
Character	Aching, cramping	Same as claudication or tingling, weakness, clumsiness	Aching	Tightness	Tightness, tense
Location	Dependent on area of obstruction: buttock, hip, thigh, calf, foot	Buttock, hip, thigh	Hip, thigh, knee	Groin, thigh	Dependent on area of high pressure; frequently the tibia, however can occur in foot, thigh, gluteal region
Response to exercise	Yes	Variable	Variable	After walking	Can occur because of inordinate stress or exercise
Response to walking	Reproducible	Variable	Variable	Variable	Excessive exercise
Relief of discomfort	Relief with cessation of muscle activity	Relief with sitting or changing position	Slow relief with avoidance of weight bearing	Slow relief with leg elevation	Unrelieved
Other	Associated with atherosclerosis and decreased pulses	History of back problems	Discomfort at the joints	History of deep vein thrombosis, signs of venous congestion; edema	Seen in athletes May occur with trauma

Adapted from White, C. J. (2016). Atherosclerotic peripheral arterial disease. In L. Goldman, A. I., Schafer AI (Eds.), *Goldman-Cecil Medicine* (25th ed.). Philadelphia, PA: Elsevier, Saunders.

Additional changes resulting from a chronically reduced nutrient supply include loss of hair; brittle nails; dry, shiny, or scaling skin; atrophy; and ulcerations. Skin and nail changes, ulcers, gangrene, and muscle atrophy may be evident in chronic arterial disease but cannot be relied on for diagnosis of acute arterial insufficiency.

Pulses

Unequal pulses between extremities or the absence of a normally palpable pulse is a sign of PAD. Palpation of pulses (Fig. 18-3) is subjective. Box 18-5 provides tips for palpating pulses. The presence of foot pulses does not exclude the possibility of PAD, and further investigation is required in the presence of leg pain. After exercise, the pulses may not be palpable. This is known as "disappearing pulses," and it is caused by the increased need for blood flow in the working muscle, which the arteries cannot provide. This change in pulses is reproducible and is consistent with the distance the patient walks before experiencing claudication. Bruits may be auscultated with a stethoscope just distal to an arterial stenosis, indicating turbulent blood flow that occurs with vessel stenosis (Sieggreen & Walsh, 2014).

Ankle-brachial Index

The presence of PAD is defined as an ankle-brachial index (ABI) of less than 0.90. ABI is calculated as the ratio of the systolic blood pressure in the ankle divided by the higher of the two brachial systolic blood pressures (see Chapter 12).

Sensory changes

Numbness, paresthesias, and motor deficits indicate tissue anoxia. Motor deficits typically progress from distal to proximal; therefore, the nurse assesses initially for weakness of the foot muscles. In contrast, paresthesia denotes ischemia that threatens limb survival.

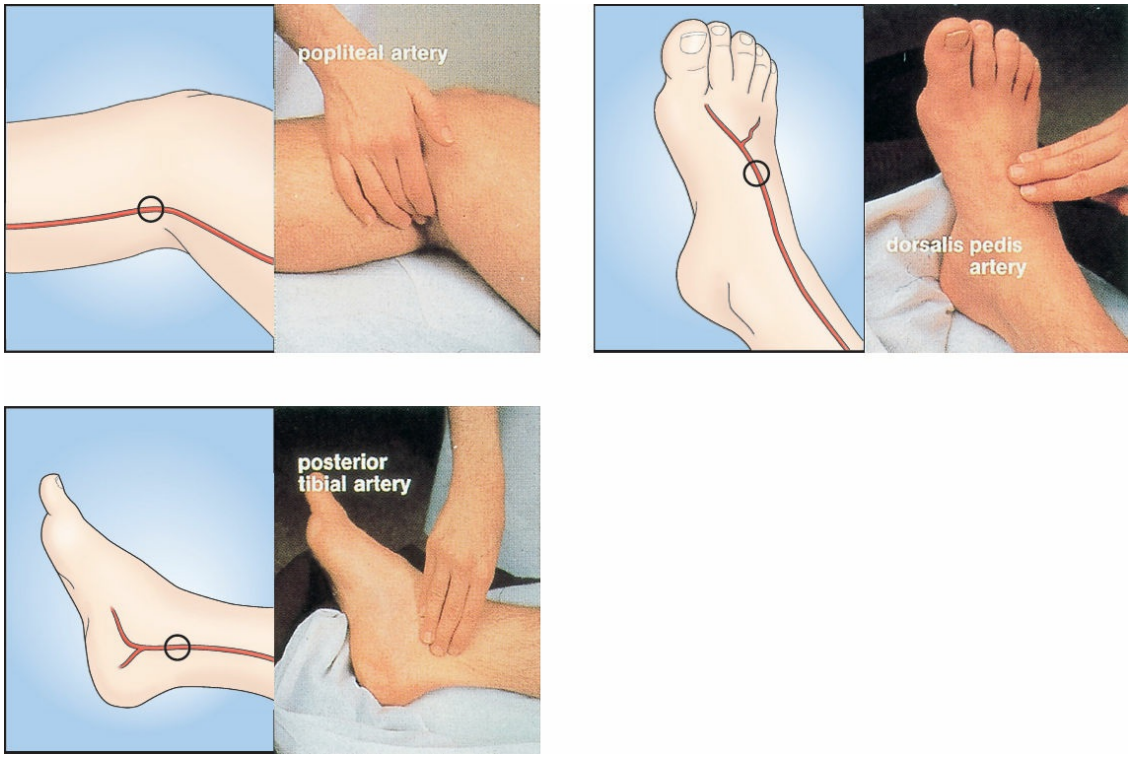

FIGURE 18-3 Assessing peripheral pulses. (*Left*) Popliteal pulse. (*Right*) Dorsalis pedis pulse. (*Bottom*) Posterior tibial pulse.

Nursing Alert
The nurse is aware that in the event of acute occlusion of arterial circulation, symptoms will include pain, pallor, poikilothermia (coldness), paresthesias, delayed capillary refill, cyanosis, and decreased or absent pulses. With chronic arterial disease, the nurse expects to see hair loss, thickened nails, and smooth and shiny skin.

BOX 18-5 Tips for Palpating Peripheral Pulses

- Use tips of fingers to palpate. To avoid mistaking your own pulse for that of the patient, use light touch and avoid using only the index finger for palpation because this finger has the strongest arterial pulsation of all the fingers. The thumb should not be used for the same reason.
- Palpate bilaterally and simultaneously.

- Compare both sides for symmetry in rate, rhythm, and quality (the nurse should grade according to the institution's/facility's scale).
- Document as present, absent, or bounding (Ex. aneurysm).

Diagnostic Tests

Various noninvasive and invasive tests are performed to diagnose abnormalities that affect the arteries. When pulses cannot be palpated reliably, a handheld continuous wave (CW) Doppler ultrasound device may be used to hear (*insonate*) signals in the vessels (Fig. 18-4). The Doppler emits a signal through the tissues, which is reflected off the moving blood cells and returned to the device. Then the filtered output Doppler signal is transmitted to a loudspeaker or headphones, where it can be heard for interpretation. Doppler studies are more useful when combined with the ankle-brachial index (ABI). (Chapter 12 provides detailed discussion of Doppler, ultrasound, and ABI.) The "gold standard" for diagnosis and evaluation of PAD is the invasive digital angiography (White, 2016). Additional diagnostic tools are discussed in Table 18-2.

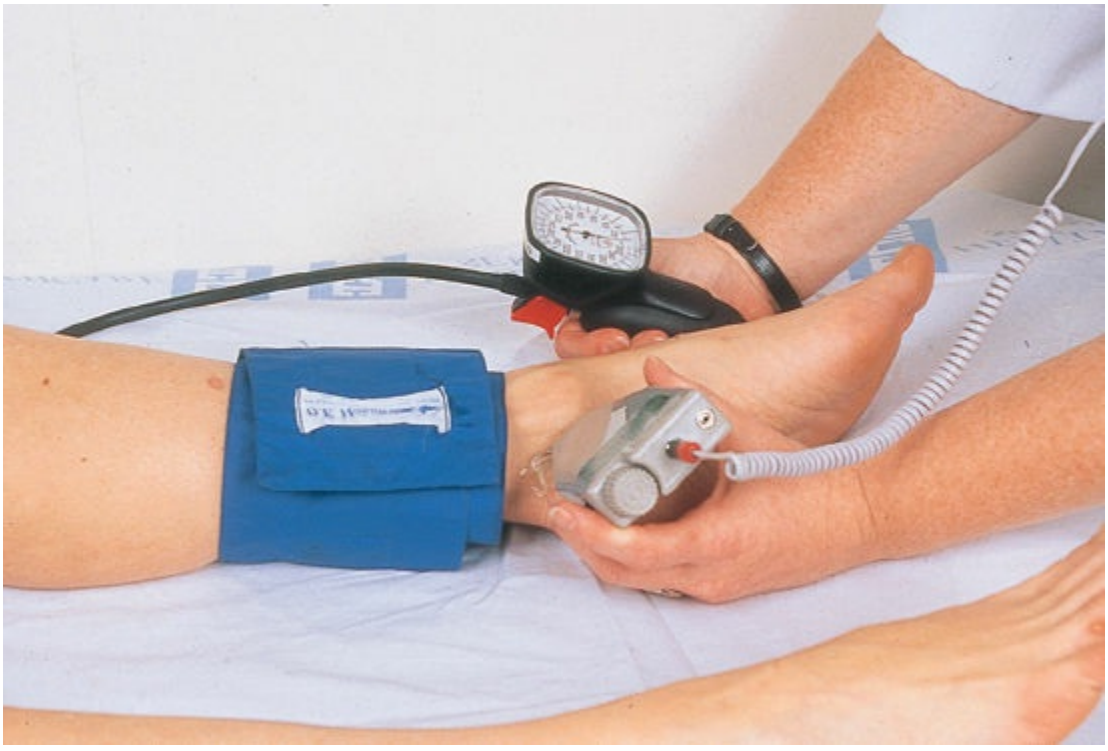

FIGURE 18-4 Continuous-wave (CW) Doppler ultrasound detects blood flow in peripheral vessels (demonstrated in obtaining ABI).

TABLE 18-2 Noninvasive and Invasive Vascular Tests

Test	Purpose
Doppler Ultrasound Flow Studies	Evaluation of arterial signals Blood pressure measurement in the limbs Assessment of vessel size and compressibility Assessment for presence of thrombus Assessment of valve function
Exercise Testing	Assessment of ankle systolic blood pressure in response to walking on treadmill (normal response is little or no drop in ankle systolic pressure after exercise) Assessment for claudication (a drop in ankle pressure correlates with claudication distance reported by the patient)
Duplex Ultrasonography	Localization of vascular obstruction Evaluation of stenosis Assessment for vascular reflux Provides both image and audible signal
Computed Tomography Angiography (CTA) (spiral or helical CT that provides a series of images in continuous spiral)	Demonstration of cross-sectional images of soft tissue Diagnoses of abdominal aneurysms, graft infections or occlusions, hemorrhage
Magnetic Resonance Angiography (MRA) (standard magnetic resonance imaging [MRI] scanner with software programmed to isolate blood vessels and reassemble images in three dimensions)	Detection of changes, aneurysms, DVT Useful in poor kidney function or contrast agent allergy
Air Plethysmography	Measurement of volume, ejection fraction, and residual volume Quantification of venous reflux and calf muscle pump ejection
Venous Duplex	Assessment of venous reflux Manual compression of the veins
Angiography	Confirmation of occlusive arterial disease when considering interventions Patient may report sensation of warmth during injection and may have immediate or delayed allergic reaction to the iodine in the contrast agent Digital subtraction angiography (DSA) has bony structures removed from the image
Venography	Radiopaque contrast agent injected into the venous system produces an image showing unfilled segment of vein Used to outline vein for thrombolytic therapy Infrequently used (duplex ultrasound is standard for diagnosing venous thrombosis)
Vascular Endoscopy (Angioscopy)	Use of fiber optics to visualize the vessel lumen Used to identify plaque, thrombus, hemorrhage, ulcers Used to remove debris or remove venous valves

Medical Management

Medical management is aimed at reducing the patient's risk for life-threatening complications of atherosclerosis; improving walking distance; and salvaging the limb, which includes the use of exercise, pharmacologic treatment, risk factor modification (control of hypertension, hypercholesterolemia, and diabetes, and cessation of smoking), and invasive options. Revascularization is recommended if there is a reasonable likelihood of symptomatic improvement and there has been an inadequate response to pharmacologic or exercise therapy. Invasive methods include surgery and percutaneous endoscopic procedures.

Management of Intermittent Claudication

Treatment goals for patients with intermittent claudication are to relieve symptoms, improve exercise performance, and improve functional abilities. In general, patients with intermittent claudication feel better when on an exercise program. Initial treatment should be focused on a structured exercise program and pharmacotherapy. Patients are advised to "walk into the pain" of claudication, pause until the pain subsides, and continue walking. If this program is combined with weight reduction and tobacco cessation, patients may improve their activity tolerance and experience pain relief without further intervention.

Pharmacologic Therapy

Cilostazol is a phosphodiesterase III inhibitor that is a vasodilator and interferes with platelet aggregation. It is prescribed in combination with an exercise program to improve walking distance (U.S. National Library of Medicine, 2015). Guidelines recommend a 3- to 6-month course of Cilostazol as first-line pharmacotherapy treatment for patients with intermittent claudication (Schirmer & Mosier, 2014).

Antiplatelet agents, such as aspirin or clopidogrel, help prevent the formation of thromboemboli, which can lead to MI and stroke. Aspirin (usually 75 to 325 mg/day) has been shown to reduce the risk of MI, stroke, and death in patients with vascular disease. Clopidogrel is indicated for the prevention of cardiovascular ischemic events in patients with PAD but not for treatment of claudication (Schirmer & Mosier, 2014).

Thrombolysis

A thrombotic stenosis or occlusion may be treated by thrombolysis. After catheter insertion into the affected vessel, the thrombolytic agent is injected directly into the thrombus. It will lyse the thrombus (clot). The patient is admitted to a special or critical care unit for continuous monitoring. Vital signs are taken frequently, according to the facility's protocol. The patient is monitored closely for any signs of bleeding, as this is the most common side effect of thrombolytic therapy. The nurse minimizes the number of punctures for IV lines and obtaining blood samples, avoids intramuscular injections, prevents tissue trauma, and applies pressure at least twice as long as usual after any puncture is performed. Patients will have follow-up images to determine treatment effectiveness. Refer to Table 18-2 for discussion of thrombolytic agents.

Nursing Alert
In order to monitor patients post intervention, it is essential that a baseline assessment of the extremity is documented so that the nurse can determine changes in perfusion of the extremity post instrumentation.

Surgical Management

Disabling claudication or risk for amputation is an indication for surgical or percutaneous intervention. Percutaneous, catheter-based endovascular treatments with or without stenting are seen increasingly over open surgical approaches because of the relative safety, success, and durability of stenting (White, 2016). The initial treatment goals for ALI are to prevent worsening ischemia and thrombus propagation, to manage pain, and to preserve tissue. Anticoagulation is started immediately upon recognizing the acute ischemia. Revascularization or arterial bypass is the first-line intervention used in ALI treatment. Vascular surgical procedures are divided into two groups: inflow procedures, which improve blood supply from the aorta into the femoral artery, and outflow procedures, which provide blood supply to vessels below the femoral artery. The type of procedure performed depends on the degree and location of the stenosis or occlusion. When diffuse disease is present, an inflow procedure is performed first. The restoration of arterial flow may be sufficient after this procedure so that other procedures may not be needed. The overall health of the patient and the ability to tolerate a procedure factors into the decision as to what approach is best for each patient. For some patients who are at high risk or in a life-threatening situation, a primary amputation may be the best choice.

Bypass grafts are placed to reroute blood flow around the stenosis or occlusion. Grafts below the knee require the use of native vein (i.e., autologous; the patient's own vein) to ensure patency; however, synthetic grafts may be used for bypass procedures on larger vessels above the knee. Several synthetic materials are available for use as a peripheral bypass graft. Cryopreserved saphenous veins and umbilical veins are also available but usually do not last as long as native veins or synthetic grafts. Graft patency is determined by the graft size, graft type, and location. Great care is taken to prevent graft infection as the graft must be removed if infected. Vein grafts are reversed before creating the graft conduit to prevent the valves from causing an occlusion, or they are left in place (in situ) and the valves are removed with a special instrument (valvulotome).

Doppler evaluation of the graft and the proximal vessels beyond the graft is usually performed for postprocedure vascular patients. Patients may have arterial studies, ABI, and arterial wave form analysis performed in the vascular laboratory after arterial reconstructive procedures and prior to discharge. Disappearance of a pulse or a Doppler signal that was previously present may indicate an occluded graft and requires notification of the surgeon.

Endovascular Intervention

Several percutaneous interventional techniques are available to remove plaque and dilate vessels. Angioplasty, also called percutaneous transluminal balloon angioplasty (PTA), may be performed with or without a stent. Balloons are inserted into the vessels via a catheter and expanded at the stenotic site within the vessel. The expanding balloon cracks the atherosclerotic plaque and opens the vascular lumen. Stents may be inserted to support the vessel wall and maintain patency. Complications from PTA include hematoma,

embolization, dissection of the vessel, bleeding, intimal damage (dissection), and stent migration. The advantage of angioplasty, stents, and stent-grafts compared to open surgical procedures is the decreased length of hospital stay required for the treatment and less physical trauma to the patient than open surgical procedures. Often percutaneous catheter procedures are performed in an outpatient setting (White, 2013).

Nursing Management

Providing Postoperative Care

In the postoperative period, the nurse collaborates with the surgeon about the patient's appropriate activity level based on the patient's condition (Chung, Modrall, Ahn, Lavery, & Valentine, 2015). In general, every effort is made to encourage patients to move the involved extremity and be active. The primary objective in the postprocedure period is to maintain adequate circulation. Anticoagulant therapy may be continued after surgery to prevent thrombosis of the graft. Metabolic abnormalities, kidney failure, and compartment syndrome are potential complications after arterial occlusions or operations (refer to Chapter 42 for details of compartment syndrome). The nurse assesses for evidence of local complications, such as hemorrhage or thrombosis, by performing neurovascular checks of the limb and systemic complications, by monitoring vital signs, intake and output, physical assessment parameters (e.g., pulmonary, cardiac, PV, GI, mental status), and laboratory data. Any evidence of deterioration is reported to the surgical team immediately (cool; dusky; weakened pulses; delayed capillary refill; decreased sensory/motor function; progressive, unrelieved pain).

Providing Pain Relief

Often narcotics are needed to manage rest pain until circulation can be restored. After interventions, pain management is similar to other postoperative patient care, keeping in mind that the patient may have been taking large doses of narcotics preoperatively and may need more pain medication than expected to relieve symptoms.

Maintaining Tissue Integrity

Poorly perfused tissues are susceptible to damage and infection. When lesions develop, healing may be delayed or inhibited because of the poor blood supply to the area. Infected, nonhealing ulcers of the extremities can be debilitating and may require prolonged, often expensive treatments and run the risk of potential limb loss. Measures to prevent tissue loss and amputation are a high priority. Patients are taught to avoid trauma; wear sturdy, well-fitting shoes or slippers; and use neutral soaps and body lotions. Patients with vascular disease are taught the same precautions that patients with diabetes are taught for foot care (see Chapter 30, Box 30-8). Patients who have an open arterial or venous ulcer are given detailed wound care instructions. Risk factor modification is the most effective intervention for preventing progression of vascular disease (e.g., maintain A1c within target range for patients with diabetes).

Patients and their families are educated on environmental and behavioral risk factors associated with ischemia. For example, excess heat may increase the metabolic rate of the extremities and increase the need for oxygen beyond that provided by the reduced arterial flow through the diseased artery. Cold temperature is associated with vasoconstriction, which decreases perfusion to the extremities. Nicotine from tobacco products causes vasospasm and can dramatically reduce circulation to the extremities. Tobacco smoke also impairs transport and cellular use of oxygen and increases blood viscosity. Patients with

arterial insufficiency who use tobacco must be fully informed of the effects of nicotine on circulation and encouraged to stop using tobacco. Secondhand smoke is also harmful to the vascular system.

Emotional upsets cause vasoconstriction by stimulating the sympathetic nervous system. This can be minimized to some degree by avoiding stressful situations or by following a stress-management program. Counseling services or relaxation training may be indicated for people who cannot cope effectively with situational stressors.

Constrictive clothing and accessories are avoided, as are heating pads and hot water bottles. The temperature of bath water should also be evaluated and the overall water temperature in the home decreased to prevent scalding. Tight socks, panty girdles, belts, and shoelaces are discouraged because they may impede arterial circulation to the extremities and promote venous congestion and edema.

Nursing Alert

Lower extremity elevation is associated with decreased arterial flow, which lessens perfusion to the tissues and increases pain. A dependent position improves flow and decreases pain.

UPPER EXTREMITY ARTERIAL OCCLUSIVE DISEASE

Arterial occlusions from atherosclerosis occur less frequently in the upper extremities than in the legs.

Pathophysiology

Upper extremity arterial symptoms and occlusive disease are more likely to be caused by vasospasm, trauma, or arterial constrictive disorders than by atherosclerosis.

Stenosis may occur at the origin of the subclavian artery proximal to the vertebral artery. Arterial blood flows to the brain via the carotid and the vertebral arteries. If there is diminished flow to the arm from the subclavian artery due to the stenosis, there will be preferential reverse flow down the vertebral artery to the arm when the arm is being used. This is called *subclavian steal syndrome* as the arm is "stealing" blood from the brain.

Clinical Manifestations and Assessment

The patient may complain of arm fatigue and pain when using the arm to paint or comb hair and occasionally may report difficulty when driving. Patients also report dizziness, vertigo, ataxia, syncope, or bilateral visual changes when using the arm.

Assessment findings in the ischemic upper extremity may include coolness and pallor of the affected extremity, decreased capillary refill, a decreased amplitude and delay in radial artery pulse on the affected side, and a difference in arm blood pressures of more than 20 mm Hg (affected limb pressure is lower). Noninvasive studies performed to evaluate for upper extremity arterial occlusions include upper and forearm blood pressure determinations and duplex ultrasound to identify the anatomic location of the lesion and to evaluate the hemodynamics of the blood flow.

Medical and Nursing Management

Surgical bypass or a PTA procedure may be indicated. If the stenosis involves the subclavian artery with siphoning of blood from the intracranial circulation to the arm, a carotid-to-subclavian artery bypass or reimplantation of the subclavian to the carotid artery may be performed.

INFLAMMATORY DISORDERS

Various inflammatory diseases affect the arterial system. Examples of these are Takayasu arteritis, Behçet disease, and giant cell arteritis. The inflammatory response creates granuloma formation and causes vessel destruction. Initial treatment for active vascular inflammatory diseases is high-dose corticosteroids. Revascularization, if indicated, is delayed until the inflammatory process in under control.

RAYNAUD DISEASE AND RAYNAUD PHENOMENON

Primary *Raynaud disease* (primary Raynaud phenomenon or idiopathic Raynaud phenomenon) refers to vasospasm that occurs with cold or stress. Patients with scleroderma or systemic lupus erythematosus may have the same signs and symptoms. This is called *Secondary Raynaud phenomenon.*

Pathophysiology

Raynaud disease is of unknown etiology. While its exact cause is unknown, it may be associated with immunologic disorders. Emotional factors or cold may trigger episodes.

It usually occurs in women between 16 and 40 years of age, and it occurs more frequently in cold climates and during the winter. It may cause skin and muscle atrophy.

The prognosis varies; patients may slowly improve, become progressively worse, or show no change.

Clinical Manifestations and Assessment

The patient's skin becomes cyanotic due to vasospasm, and then vasodilation causes redness (rubor). Numbness, tingling, and burning pain occur. Although typically the fingers are involved, the toes are affected in as many as 40% of patients (Mark, 2015). Typically, the radial, ulnar, and pedal pulses are normal; fingers and toes may be cool between attacks and may perspire excessively.

Medical and Nursing Management

With appropriate patient teaching and lifestyle modifications, the disorder is generally benign and self-limiting. The patient is instructed to avoid the stimuli (e.g., cold, tobacco) that provoke vasoconstriction. Patients are encouraged to dress warmly; wear gloves and mittens; and protect the trunk, head, and feet with warm clothing to prevent cold-induced reflex vasoconstriction. Tobacco use is contraindicated. The patient may be prescribed calcium-channel blockers to relieve symptoms. Digital sympathectomy (interrupting the sympathetic nerves) may help some patients.

Nursing Alert

Remember the red, white, and blue of Raynaud's! The intense spasm of the digital arteries produces initial pallor (white), followed over minutes by capillary dilation and filling with deoxygenated venous blood, resulting in cyanosis (blue). On relaxation of the arterial spasm, the circulation improves (warm red digits).

THROMBOANGIITIS OBLITERANS (BUERGER DISEASE)

Buerger disease is characterized by recurring inflammation of the intermediate and small arteries and vein, resulting in thrombus formation and vessel occlusion. It occurs in both upper and lower extremities. It is differentiated from vessel diseases by microscopic appearance.

Buerger disease is an autoimmune disease. While its etiology is unknown, it is believed to be an autoimmune vasculitis (inflammation of a blood vessel). It most often occurs in men between 20 and 35 years of age and is reported in all races. Tobacco use is a causative factor, and continued use interferes with healing. Pain is generally bilateral and symmetric with focal lesions.

Treatment is essentially the same as for atherosclerotic PAD; sympathetic block may dilate vessels and increase blood flow. Tobacco cessation is mandatory for healing to occur.

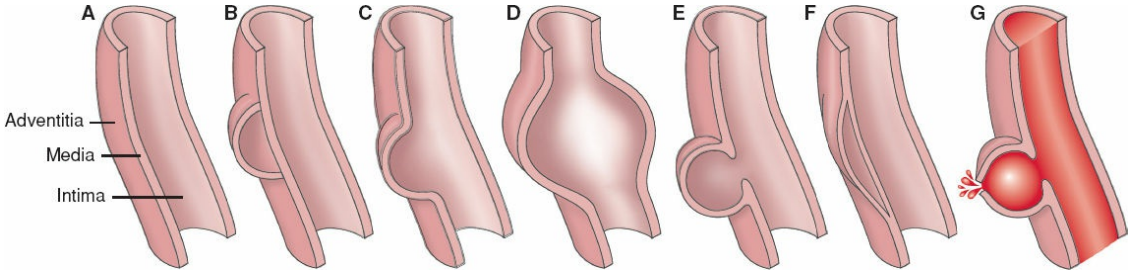

FIGURE 18-5 Characteristics of arterial aneurysm. (A) Normal artery. (B) False aneurysm (pseudoaneurysm); actually a pulsating hematoma. The clot and connective tissue are outside the arterial wall. (C) True aneurysm. One, two, or all three layers of the artery may be involved. (D) Fusiform aneurysm; symmetric, spindle-shaped expansion of entire circumference of involved vessel. (E) Saccular aneurysm; a bulbous protrusion of one side of the arterial wall. (F) Dissecting aneurysm; this usually is a hematoma that splits the layers of the arterial wall. (G) Ruptured aneurysm.

ANEURYSMS

An aneurysm is a localized out-pouching, sac, or dilation formed at a weak point in the artery wall (Fig. 18-5). It may be classified by its shape or form. The most common forms of aneurysms are saccular and fusiform. A *saccular aneurysm* projects from one side of the vessel only. If an entire arterial segment becomes dilated, a *fusiform aneurysm* develops. Very small aneurysms due to localized infection are called *mycotic aneurysms. Aortic aneurysms* occur in the abdominal and thoracic aorta and are characterized by disruption and loss of elastic fibers, resulting in degeneration of the medial vessel wall. It is thought to be an inflammatory process.

ABDOMINAL AORTIC ANEURYSM

The cause of abdominal aortic aneurysm (AAA), the most common type of degenerative aneurysm, has historically been attributed to atherosclerotic changes in the aorta. Recently, the pathogenesis of AAAs has been linked to genetic, environmental, hemodynamic, and immunologic factors, with atherosclerosis contributing to the process (Lederle, 2016). Most AAAs are asymptomatic and are found on routine examinations or during a workup for another condition. The U.S. Preventive Services Task Force recommends one-time ultrasound screening for men 65 to 75 years of age who have ever smoked (Guirguis-Blake, Beil, Senger, & Whitlock, 2014). Aneurysms are serious because they can rupture, leading to hemorrhage and death. If the AAA ruptures, mortality rates as high as 80% are seen (Latessa & Aquila, 2014).

Pathophysiology

All aneurysms involve a damaged media layer of the vessel. This may be caused by congenital weakness, trauma, or disease. The degradation of the medial elastin fibers and collagen (which gives the vessel strength) leads to the weakening and dilation of the aorta and the development of aneurysm. After an aneurysm develops, it tends to enlarge, growing at a rate of 0.3 to 0.4 cm per year on average; however, there is no predictable pattern (Mohler, 2016).

Risk Factors

Risk factors include age (over 50 years of age), male sex, tobacco use, family history, occlusive atherosclerotic disease, and hypertension. Many types of aneurysms have a genetic basis. Patient education includes advising biologic family members to be evaluated for aneurysms.

Clinical Manifestations and Assessment

Not all patients with AAAs have symptoms. Some patients complain that they can feel their heart beating in their abdomen when lying down, or they may say they feel an abdominal mass or abdominal throbbing. If the AAA is associated with thrombus, a major vessel may be occluded, or smaller distal occlusions may result from emboli. Small cholesterol, platelet, or fibrin emboli may lodge in the digital arteries, causing cyanosis and mottling of the toes.

Signs of impending aneurysm rupture include severe back or abdominal pain, which may be persistent or intermittent. Abdominal pain is often localized in the middle or lower abdomen to the left of the midline. Low back pain may be present because of pressure of the aneurysm on the lumbar nerves. This is a significant symptom, usually indicating that the aneurysm is expanding rapidly and is about to rupture. Indications of a rupturing AAA include constant, intense back pain; falling blood pressure; and decreasing hematocrit. Rupture into the peritoneal cavity is rapidly fatal, and surgical repair is the only chance for survival. A retroperitoneal rupture of an aneurysm may result in hematomas in the scrotum, perineum, flank, or penis. Cullen sign (bluish to purplish periumbilical discoloration) and Grey Turner sign (flank discoloration) may be noted with retroperitoneal blood from leaking or ruptured AAA (see Fig. 27-10 on page 843). Symptoms of abdominal distention, constipation, or urinary retention may be caused by a hematoma that compresses the bowel or the urinary tract or by impaired blood supply to these organs (Lederle, 2016).

The most important diagnostic indication of an AAA is a pulsatile mass in the abdomen. These aneurysms can be palpated if the patient is not obese. The aorta is slightly left of midline, measures approximately 2 cm, and is palpated a few centimeters above the umbilicus (level of bifurcation to the iliac arteries). The aortic width is measured using both hands by noting the width of the pulsations, not the intensity. A systolic bruit may be heard over the mass. Duplex ultrasonography or computed tomography (CT) is used to determine the size, length, and location of the aneurysm. An aorta that is 3 cm or greater in width is indicative of an AAA.

Medical Management

Screening intervals are proposed based upon the size of the aneurysm. When the aneurysm is small (3.0 to 3.9 cm), ultrasonography is conducted at 3-year intervals, whereas an AAA greater than 4.5 cm is evaluated annually (Lederle, 2016). Some aneurysms remain stable over many years of observation; however, when the AAA exceeds 5.5 cm, elective repair should be considered.

Pharmacologic Therapy

If an aneurysm is stable in size based on serial duplex ultrasound scans, the blood pressure is closely monitored over time. There is an association between increased diastolic blood pressure, size increase, and rupture. Antihypertensive agents, including diuretics, beta blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor antagonists, and calcium-channel blockers, may be prescribed to maintain the patient's blood pressure within acceptable limits.

Surgical Management

An expanding or enlarging AAA is likely to rupture. Surgery is the treatment of choice for AAAs more than 5.5 cm wide or those that are enlarging (Stone & Cronenwett, 2013). An alternative for treating an infrarenal (below the renal arteries) AAA is endovascular grafting, which involves percutaneous transluminal placement and attachment of an aortic graft prosthesis across the aneurysm (Fig. 18-6). This procedure is performed under local or regional anesthesia. Potential complications are similar to those of other endograft procedures (discussed later). It is important to consider that the overall surgical mortality rate associated with a ruptured aneurysm is 75% to 80%; therefore, early intervention is warranted (Latessa & Aquila, 2014). Nursing management after surgery can be found after the discussion of other types of aneurysms (see Nursing Management After Surgical Interventions, p. 543).

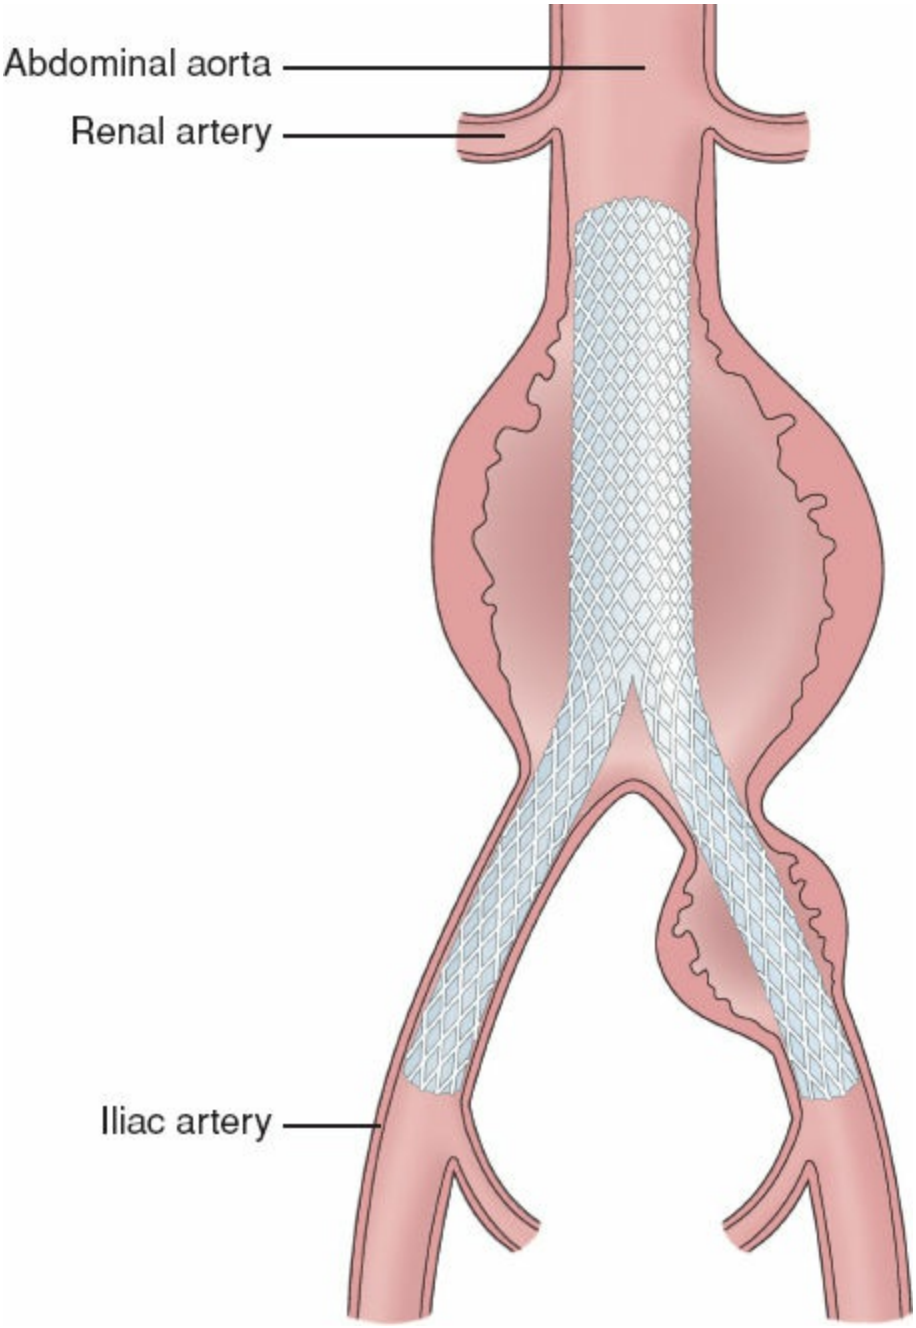

FIGURE 18-6 AneuRx Endograft repair of an abdominal aortic aneurysm (Medtronic).

THORACIC AORTIC ANEURYSM

Approximately 85% of all cases of thoracic aortic aneurysm are caused by atherosclerosis. Ascending thoracic aortic aneurysms are often associated with genetic mutations such as Marfan syndrome (Lederle, 2016). They occur most frequently in men between 40 and 70 years of age. The thoracic area is the most common site for a dissecting aneurysm. About one third of patients with thoracic aneurysms die of rupture of the aneurysm.

Clinical Manifestations and Assessment

Symptoms are variable and depend on how rapidly the aneurysm dilates and how the pulsating mass affects surrounding intrathoracic structures. Some patients are asymptomatic. In most cases, pain is the most prominent symptom. The pain is usually constant and of a boring quality, but it may occur only when the person is supine. Other symptoms are dyspnea, the result of pressure of the aneurysm sac against the trachea, a main bronchus, or the lung itself; cough, frequently paroxysmal and with a brassy quality; hoarseness, stridor, or weakness or complete loss of the voice (aphonia), resulting from pressure against the laryngeal nerve; and dysphagia (difficulty in swallowing) due to impingement on the esophagus by the aneurysm (Latessa & Aquila, 2014).

When large veins in the chest are compressed by the aneurysm, the superficial veins of the chest, neck, or arms become dilated; edematous areas on the chest wall and cyanosis are often evident. Pressure against the cervical sympathetic chain can result in unequal pupils. Diagnosis of a thoracic aortic aneurysm is principally made by chest x-ray, transesophageal echocardiography (TEE), and CT.

Medical Management

Aneurysms are sometimes managed medically with risk factor modification, especially blood pressure control, pain management, and close monitoring of symptoms. However, in most cases, an aneurysm is treated by open surgical method or an endovascular procedure. General measures such as controlling blood pressure and correcting risk factors are important. Systolic pressure is maintained at about 100 to 120 mm Hg with antihypertensive medications or a beta blocker. The goal of surgery is to repair the aneurysm and restore vascular continuity with a vascular graft. Intensive monitoring is usually required after an open surgical procedure, and the patient is cared for in the critical care unit. Endovascular graft repair of unruptured thoracic aneurysms decreases postoperative recovery time and decrease complications compared with traditional surgical techniques; however, it has not improved the adjusted 5-year survival rate (Lederle, 2016). These endovascular grafts are inserted into the thoracic aorta via various vascular access routes, including the femoral or iliac artery (Eagleton & Upchurch, 2013).

Postoperatively the immediate concern is blood pressure control and a device-related complication termed an *endoleak* from the endovascular graft. An endoleak is a persistent leaking of blood out of the graft and into the aneurysm sac. Early leaks have the potential to rupture within the first 30 postoperative days (primary endoleaks), but late endoleaks (secondary endoleaks) can occur as late as 7 years after the procedure. An endoleak is screened by CT scanning and duplex ultrasound. The nurse considers that during the operative procedure, necessary vessel clamping can have profound effect on the mesentery circulation (gut), renal circulation (kidneys), and artery of Adamkiewicz (supplies the lower two thirds of the spinal cord). Postoperatively, regardless of type of procedure performed, the patient is assessed for changes in mentation, vision, speech, or motor strength, as well as pain in the abdomen or flank, vomiting, or bloody diarrhea, which may indicate embolization to cerebral, mesentery circulation, or other organs and should be reported to the surgeon immediately. In addition, depending on length of time the aorta was clamped during the surgery, concerns include spinal cord ischemia with resultant paraplegia and renal insufficiency—thus, both kidney function and sensory/motor function are assessed postoperatively. Patients undergoing open surgical procedures go to the intensive care unit and typically are on mechanical ventilation postoperatively. Endovascular procedures may not require intensive care unit monitoring postprocedure.

PERIPHERAL ANEURYSMS

Aneurysms may also arise in the peripheral vessels, most often as a result of atherosclerosis. These may involve the renal artery, femoral artery, or (most frequently) popliteal artery. Between 50% and 60% of popliteal aneurysms are bilateral and may be associated with AAAs.

The aneurysm produces a pulsating mass and disturbs peripheral circulation distal to it. Pain and swelling develop because of pressure on adjacent nerves and veins. Diagnosis is made by duplex ultrasonography and CT to determine the size, length, and extent of the aneurysm. Arteriography may be performed to evaluate the level of proximal and distal

involvement.

DISSECTING ANEURYSM

Occasionally, in an aorta diseased by arteriosclerosis, a tear develops in the intima or the media degenerates, resulting in a dissection (a false lumen that communicates with the true lumen) (refer to Fig. 18-5). Dissections may be treated medically or surgically.

Pathophysiology

Arterial dissections are commonly associated with poorly controlled hypertension, blunt force chest trauma, and cocaine use. Dissection is caused by rupture in the intimal layer. A rupture may occur through adventitia or into the lumen through the intima, allowing blood to reenter the main channel, resulting in chronic dissection or occlusion of branches of the aorta.

As the separation progresses, the arteries branching from the involved area of the aorta shear and occlude. The tear occurs most commonly in the region of the aortic arch, with the highest mortality rate associated with ascending aortic dissection, which accounts for about 3,000 deaths per year in the United States (Lederle, 2016). The dissection of the aorta may progress toward the heart, obstructing the orifices of the coronary arteries, producing hemopericardium (effusion of blood into the pericardial sac), or aortic insufficiency, or it may extend distally, occluding the arteries supplying the GI tract, kidneys, spinal cord, and legs.

Clinical Manifestations and Assessment

Onset of symptoms is usually sudden. Severe and persistent pain, described as tearing or ripping, may be reported. The pain is in the anterior chest or back and extends to the shoulders, epigastric area, or abdomen. Aortic dissection may be mistaken for an acute MI, which could confuse the clinical picture and initial treatment. Cardiovascular, neurologic, and GI symptoms are responsible for other clinical manifestations, depending on the location and extent of the dissection. For example, if the dissection extends to the renal arteries, patients can present with acute kidney failure (AKF); with mesentery involvement, abdominal pain and bloody diarrhea may be seen; and lower extremity ischemia can be seen with iliac involvement. The patient may appear pale. Diaphoresis and tachycardia may be detected. Blood pressure may be elevated or markedly different from one arm to the other if dissection involves the orifice of the subclavian artery on one side. Because of the variable clinical picture associated with this condition, early diagnosis is difficult.

Nursing Management After Surgical Interventions

Surgical repair of the aorta is performed for dissection, rupture, and aneurysm. General postoperative nursing assessment involves frequent vital signs; recording of intake and output; assessment of oxygen saturation; bilateral comparison of upper arm blood pressures and peripheral pulses; and assessment of motor and sensory function, temperature of extremities, color changes, and capillary refill. The patient who has had an endovascular repair must lie supine according to a protocol. The patient needs to use a bedpan or urinal while on bed rest. The access site (usually the femoral or iliac artery) is assessed when vital signs and pulses are monitored. The nurse assesses for bleeding, pulsation, swelling, pain, and hematoma formation. In addition, the patient is monitored for signs of embolization to the lower extremities; therefore, skin changes of the lumbar area, buttocks, and lower extremity (plantar area of the feet or toes is often affected) are assessed for extremely tender, irregularly shaped, cyanotic areas.

The patient's temperature should be monitored according to a protocol, and any signs of postimplantation syndrome should be reported. Postimplantation syndrome typically begins within 24 hours of stent-graft placement and consists of a spontaneously occurring fever, leukocytosis, and, occasionally, transient thrombocytopenia. The exact etiology is unknown, but the symptoms are thought to be related to the activation of cytokines, which results from thrombosis in the repaired aneurysm that occurs because of the release of coagulation proteins and platelets. These symptoms can be managed with mild analgesics or anti-inflammatory agents, such as acetaminophen or ibuprofen, and usually subside within a week.

Because of the increased risk for hemorrhage, the surgeon is notified of persistent coughing, sneezing, vomiting, or systolic blood pressure greater than 180 mm Hg. Most patients can resume their preprocedure diet and are encouraged to drink fluids. An IV infusion may be continued until the patient can drink normally. Fluids are important to maintain blood flow through the arterial repair site and to assist the kidneys with excreting IV contrast agent and other medications used during the procedure. According to a protocol, after a procedure that involves a catheter in the groin, the patient may be able to roll from side to side and may be able to ambulate with assistance to the bathroom. After the patient can take adequate fluids orally, the IV infusion may be discontinued and the IV access converted to a saline lock. Postoperative care requires intense monitoring of pulmonary, cardiovascular, renal, and neurologic status. Pulmonary complications include the potential development of acute respiratory distress syndrome (ARDS), particularly if large quantities of blood were required intraoperatively (refer to Chapter 10 for discussion of ARDS). MI and arrhythmias are potential cardiac complications and are discussed in Chapters 14 and 17, respectively. GI complications include a risk for ischemic colitis, and symptoms include bloody diarrhea, abdominal distention, leukocytosis, fever, and abdominal pain. Because AKF is a potential complication, urine output is monitored hourly and laboratory parameters are monitored (blood urea nitrogen [BUN] and creatinine values) for significant changes. Potential injury to the spinal cord with resultant paraplegia requires that the nurse assess the patient's sensory motor function postoperatively. In addition, since it is important that perfusion to the spinal cord be maintained, the nurse frequently assesses blood pressure measurements, and the surgeon is

alerted upon evidence of decreasing parameters.

Before discharge, the patient is assisted in developing and implementing a plan to stop using tobacco and to manage pain. The patient may need to be encouraged to make the lifestyle changes necessary to adequately manage a chronic disease, including modifications in diet, activity, and hygiene. The nurse assesses the patient's resources, including family and friends to assist as needed. The nurse ensures that the patient has the knowledge and ability to assess for disease progression and postoperative or postprocedure complications as needed.

VENOUS DISORDERS

Venous blood flow is reduced by a thrombus or embolus obstructing a vein, by incompetent venous valves, or by a reduction of the pumping action effectiveness of surrounding muscles. Decreased venous blood flow causes increased venous pressure, which increases capillary hydrostatic pressure, facilitating filtration of fluid out of the capillaries into the interstitial space, with resultant development of tissue edema. Edematous tissue does not receive adequate nutrition from the blood and is more susceptible to breakdown, injury, and infection. Thus, the nurse is aware that edematous tissue is fragile tissue.

VENOUS THROMBOSIS

The terms *venous thrombosis, deep vein thrombosis* (DVT), *thrombophlebitis, venous thromboembolism*, and *phlebothrombosis* do not necessarily reflect identical disease processes, but they are grouped together for clinical purposes.

BOX 18-6 Virchow Triad

1. *Stasis of blood:* Caused by immobility (bed rest, long plane/car/train rides, obesity, constrictive devices, paralysis, paresis, recent surgery, varicose veins, pregnancy)
2. *Vessel wall injury:* Caused by trauma (fractures, contusions), central venous catheterization, vascular devices (PICC, central lines, pacemaker wires), IV medications, cancer therapy (hormonal, chemotherapy, or radiotherapy)
3. *Altered coagulation:* Caused by estrogen-containing oral contraception or hormone replacement, cancer (secretes procoagulants), smoking, dehydration, hypercoagulable states, late pregnancy, and the postpartum period

Pathophysiology

The exact cause of venous thrombosis remains unclear. Three factors, known as *Virchow triad* (Box 18-6), are believed to play a significant role in the development of venous thrombosis. Some hypercoagulable states are hereditary. Patients with these states should have a hematology consult.

Upper extremity venous thrombosis is not as common as lower extremity thrombosis. However, it may occur in patients with IV catheters (IV lines or wires from pacemaker leads, chemotherapy ports, dialysis catheters, or parenteral nutrition lines) or in patients with an underlying hypercoagulation disorder. Effort thrombosis is caused by repetitive motion (as in competitive swimmers, tennis players, and construction workers) that irritates the vessel wall, causing inflammation and subsequent thrombosis.

Venous thrombi are aggregates of platelets attached to the vein wall that have a tail-like appendage containing fibrin, white blood cells, and many red blood cells. The thrombus can propagate as successive layers of thrombus form. A propagating venous thrombosis is dangerous because it is often the source of a pulmonary embolism (PE). Thrombus fragmentation can occur spontaneously or in association with an elevated venous pressure, as when a person stands suddenly or engages in muscular activity after prolonged inactivity. After an episode of acute DVT, recanalization of the lumen of the vessel occurs. However, the venous valves remain open and are ineffective. Reverse venous flow contributes to chronic venous insufficiency. Over time, postphlebitic syndrome (Box 18-7) occurs, manifested by skin and tissue changes.

Clinical Manifestations and Assessment

A major problem associated with recognizing DVT is that the signs and symptoms are nonspecific. The exception is *phlegmasia cerulea dolens* (massive iliofemoral venous thrombosis), in which the entire extremity becomes massively swollen, tense, and painful, with arterial ischemia (bluish color) and potential loss of distal pulses. Despite this variability, clinical signs should always be investigated.

Deep venous obstruction is associated with edema of the extremity due to inhibition of venous outflow. The nurse should note any differences in leg circumference bilaterally from thigh to ankle; increase in the surface temperature of the leg, particularly the calf or ankle; and areas of tenderness or superficial thrombosis. Swelling can be measured by obtaining the circumference of the affected extremity at specific levels and comparing one extremity with the other at the same level. Asymmetry of extremities (calf swelling at least 3 cm larger than asymptomatic leg), measured 10 cm below the tibial tuberosity, should alert the nurse to a potential DVT. In addition, the nurse should assess for the presence of a low-grade fever.

Tenderness, which usually occurs later, is produced by inflammation of the vein wall, and firmness may be detected along the involved veins by gently palpating the affected extremity (palpated cord). *Homans sign* (pain in the calf after the foot is sharply dorsiflexed) used to be considered a sign of DVT, but it is not reliable and is not used anymore. Dilation and prominence of the superficial veins may be noted. In some cases, signs and symptoms of a PE are the first indication of DVT.

Superficial vein thrombosis produces pain or tenderness, redness, and warmth in the involved area. Many of these thromboses dissolve spontaneously. This condition can be treated at home with bed rest, limb elevation, analgesics, and anti-inflammatory medication. It should be noted that while nonsteroidal anti-inflammatory drugs (NSAIDs) provide analgesia, they are associated with an increase in venous thromboembolism (VTE), caused by an embolism breaking off and lodging in a smaller vein (Ungprasert, Srivali, Wijarnpreecha, Charoenpong, & Knight, 2015).

Careful assessment is the key in detecting early signs of lower extremity venous disorders. Patients with a history of varicose veins, hypercoagulation, neoplastic disease, cardiovascular disease, or recent major surgery or injury are at high risk. Other patients at high risk include those who are obese, immobile, or elderly, as well as women taking oral contraceptives.

BOX 18-7 Focus on Pathophysiology

Postphlebitic Syndrome

Postphlebitic syndrome develops as follows:

1. Venous valve injury results in an incompetent valve and reverse venous flow.
2. Fluid, plasma, and red blood cells leak into the interstitial tissue.
3. Edema forms around ankles and/or lower legs.
4. Staining of skin occurs as red blood cells break down, releasing hemosiderin.

5. Subcutaneous tissue becomes firm and fibrotic.
6. Loss of elasticity in the skin and subcutaneous tissue results.
7. Tissue becomes vulnerable to trauma and ulcer formation.

Nursing Alert

The D*-dimer blood assay is a marker of coagulation activity. When a clot lyses, fibrin degradation occurs and a* D*-dimer is positive. When positive, it is associated with clot breakdown, such as the presence of DVT or PE, but it is also associated with a variety of nonthrombotic disorders, including recent surgery, hemorrhage, trauma, cancer, MI, pneumonia, and sepsis. Thus,* D*-dimers are frequently elevated due to some systemic illness; however, a negative* D*-dimer decreases the likelihood of a DVT or PE.*

Prevention

Preventive measures should be instituted for patients at risk for DVT. These might include physical interventions, such as elastic compression stockings, intermittent pneumatic compression devices, and body positioning and exercise. Medications to prevent thrombosis include anticoagulant therapy, such as subcutaneous unfractionated or low–molecular-weight heparin (LMWH). Studies are ongoing as to which prevention method works best with which patient population. Guidelines for intervention are continuously evolving. It is up to the practitioner to keep up with the research findings and to apply the evidence to clinical practice.

Medical Management

The objectives of treatment for DVT are to prevent the thrombus from growing and fragmenting (risking PE) and to prevent recurrent thromboemboli. Interventions to prevent thrombus formation are indicated in patients with thrombophlebitis, recurrent embolus formation, persistent leg edema from heart failure, and in any patients who may require lengthy immobilization.

Pharmacologic Therapy

Heparin

Anticoagulant therapy is effective prophylaxis; however, anticoagulants do not dissolve a thrombus that has already formed.

Unfractionated Heparin. Unfractionated heparin is administered subcutaneously to prevent development of DVT. In the event of a DVT, although heparin can be administered subcutaneously, common practice is to administer heparin via an IV drip to prevent the extension of a thrombus and the development of new thrombi. IV heparin produces an immediate anticoagulant effect, and, therefore, is used when rapid anticoagulant effects are desired. Unfractionated heparin is administered via an infusion pump to carefully control the rate. Dosage is based on the patient's weight, and any possible bleeding tendencies are detected by a pretreatment clotting profile. If renal insufficiency exists, lower doses of heparin are required. Periodic coagulation tests and hematocrit levels are obtained. Heparin is in the effective, or therapeutic, range when the activated partial thromboplastin time (aPTT) is 1.5 to 2.5 times the baseline control. Normal aPTT level is 21 to 35 seconds (Fischbach & Dunning, 2014). If the PTT is greater than 100 seconds, the risk for hemorrhage is significant! Typically, the PTT level is measured 6 hours after therapy is started. The nurse is aware that heparin has a half-life of about 60 minutes; therefore, in an emergency, the heparin is discontinued for a period of at least 1 hour.

Coumadin, an oral anticoagulant, is administered soon after initiating heparin therapy, since Coumadin may require 3 to 5 days to achieve a therapeutic effect. Until a therapeutic international normalized ratio (INR) is achieved, both medications are administered concurrently. Medication dosage is regulated by monitoring the aPTT for heparin, the INR for Coumadin, and the platelet count, to assess for potential complications of heparin therapy (discussed later in this chapter).

Low–Molecular-Weight Heparin. Subcutaneous LMWH is an effective treatment for some cases of DVT. These agents have longer half-lives than unfractionated heparin so doses can be given in one or two subcutaneous injections each day. Doses are adjusted according to patient weight. LMWH prevents the extension of a thrombus and development of new thrombi, and they are associated with fewer bleeding complications and lower risks of heparin-induced thrombocytopenia (HIT) than is unfractionated

heparin. Because there are several preparations, the dosing schedule must be based on the product used and the protocol at each institution. Because LMWH is cleared almost entirely by the kidneys, clearance can be variable in patients with renal insufficiency, thus a longer half-life may be expected. The cost of LMWH is higher than that of unfractionated heparin; however, another benefit is that LMWH may be used safely in pregnant women.

Direct Thrombin Inhibitor. Thrombin's role in clot formation is to convert soluble fibrinogen to insoluble fibrin, while stimulating platelet activation; thus direct thrombin inhibitors (DTIs) impede this process. In addition, DTIs have a more predictable anticoagulant effect compared with heparin and do not cause an immune-mediated thrombocytopenia. Three parenteral DTIs are approved for use as anticoagulants in the United States: desirudin, bivalirudin, and argatroban. Currently, there is no specific antidote to reverse the effects of parenteral DTIs. Thus, the nurse observes for evidence of bleeding and reports to the provider any concerns. There is one oral DTI that is available: dabigatran. Currently reversal of dabigatran's anticoagulant effects can be achieved in emergency situations with the use of idarucizumab.

In addition to parenterally administered heparins, oral direct factor Xa inhibitors can be utilized although clinical applications differ. Oral direct factor Xa inhibitors include rivaroxaban, apixaban, and edoxaban. They are at least as effective and safe as warfarin, and their ability to be administered in fixed doses without routine coagulation monitoring has led to an increase in their use. However, it has yet to be determined if the reduced need for monitoring overrides the increase in cost and absence of an easy antidote when patients have major bleeding as a current concern.

TABLE 18-3 Arterial and Venous Thrombolysis

Indications (Arterial and Venous)	Drug	Advantages (All Drugs in Arterial and Venous Thrombosis)	Disadvantages (All Drugs in Arterial and Venous Thrombosis)
In situ thrombosis of less than 14 days	Alteplase	Clot lysis between 6 and 72 hours Preferred choice for clot removal if no contraindications Avoidance of invasive surgical operations May be repeated if needed.	Limited in DVT lysis by long infusion times and risks of hemorrhagic complications associated with large doses
Nonlife-threatening limb ischemia (arterial)	Reteplase	Superior thrombus penetration	Risk factors for hemorrhagic complications: older age, lower body weight, elevated pulse pressure, uncontrolled hypertension, recent stroke, recent operation, bleeding disorder, congestive heart failure

Please refer to the latest guidelines from the manufacturer for indications, dosages, general warnings and precautions. Currently complications (among others) associated with thrombolysis include: 1. increased risk of bleeding, 2. orolingual angioedema, 3. cholesterol embolism, 4. Reembolization from the lysis.
Alteplase (Activase) (2016). www. Activase.com. South San Francisco, CA: Genentech Inc.; Reteplase (Reteplase) (2015). Chiesi, Cary, NC; Sobieszcyk, P. S. (2013). Acute arterial occlusion. In M. A. Creager, J. A. Beckman, J. Loscalzo (Eds.), *Vascular medicine: A companion to Braunwald's heart disease*. Philadelphia, PA: Elsevier Saunders.

Thrombolytic Therapy

Unlike heparin, thrombolytic (fibrinolytic) therapy lyses and dissolves thrombi. There is an increase in bleeding complications with thrombolytics compared with heparin. Since thrombolytics have not decreased the incidence of postthrombotic syndrome or pulmonary emboli, this therapy is generally reserved for patients with life-threatening limb ischemia as a result of massive thrombosis. If bleeding occurs, the thrombolytic agent is discontinued. See Table 18-3 for thrombolytic therapy.

Oral Anticoagulants

Warfarin is a vitamin K antagonist (VKA) that is frequently used for extended anticoagulant therapy. Routine coagulation monitoring is essential to ensure that a therapeutic response is obtained and maintained over time. Interactions with a range of other medications and various foods with vitamin K can reduce or enhance the anticoagulant effects of warfarin. Warfarin has a narrow therapeutic window, and there is a slow onset of action. Oral anticoagulants, such as warfarin (Coumadin), are monitored by the INR. Because the full anticoagulant effect of warfarin is delayed for 3 to 5 days, treatment is initially supported with concomitant parenteral anticoagulation with heparin until the warfarin demonstrates anticoagulant effectiveness; then the heparin can be discontinued and the patient maintained on oral Coumadin. A normal INR is

approximately 1. The target INR depends on why the person is being anticoagulated. If, for example, anticoagulation is related to atrial fibrillation or DVT, the INR range will be 2 to 3, with a goal of 2.5. Once INR is stable, levels are checked weekly for 2 to 4 weeks, progressing to monthly thereafter. Refer to Table 18-4 for list of therapeutic goals for INR.

Surgical Management

Surgery is necessary for DVT when anticoagulant or thrombolytic therapy is contraindicated, the danger of PE is likely, or the venous drainage is so severely compromised that permanent damage to the extremity is likely. A thrombectomy (removal of the thrombosis) is the procedure of choice. A vena cava filter may be placed at the time of the thrombectomy; this filter traps large emboli and prevents PE (see Chapter 10, Fig. 10-8). Recent research noted that placement of an inferior vena cava (IVC) filter for 3 months did not reduce recurrent PE, including fatal PE, in anticoagulated patients who had additional risk factors for recurrent VTE (Mismetti et al., 2015). A vena cava filter may be indicated if there is a contraindication to or complication of anticoagulation therapy (DeHart, 2015, p. 212). The filter does not prevent other thrombi from forming. Balloon angioplasty and stent placement are being used in the iliac veins of patients with acute and chronic venous disease.

TABLE 18-4 Therapeutic Context

	INR	Target
Non–hip surgery	1.5–2.5	2.0
Hip surgery	2.0–3.0	2.5
Primary and secondary prevention of deep vein thrombosis	2.0–3.0	2.5
Prevention of systemic embolism in patients with atrial fibrillation	2.0–3.0	2.5
Recurrent systemic embolism	3.0–4.5	3.5
Prevention of recurrent deep vein thrombosis (two or more episodes)	2.5–4.0	3.0
Cardiac stents	3.0–4.5	3.5
Prevention of arterial thrombosis, including patients with mechanical heart valves	2.5–3.5	3.0

Nursing Management

Monitoring Drug Therapy

When the patient is receiving anticoagulant therapy, the nurse frequently monitors the aPTT, prothrombin time (PT), INR, activated coagulation time (ACT), hemoglobin and hematocrit values, platelet count, and fibrinogen level, depending on which medication is being given.

Nurses must watch for potential complications; the principal one is spontaneous bleeding anywhere in the body. Bleeding from the kidneys is detected by microscopic examination of the urine and is often the first sign of excessive dosage. Bruises, nosebleeds, and bleeding gums are also early signs. To promptly reverse the effects of heparin, protamine sulfate may be administered. Risks of protamine administration include bradycardia and hypotension, which can be minimized by slow administration. Protamine sulfate can be used in patients receiving LMWH, but it is less effective with LMWH than with unfractionated heparin. Reversing the anticoagulation effects of warfarin is more difficult, but effective measures may include administration of vitamin K and/or infusion of fresh-frozen plasma or prothrombin concentrate. Oral vitamin K significantly reduces the INR within 24 hours. Low-dose IV vitamin K is also effective.

HIT may be another complication of therapy, which is defined as a sudden decrease in the platelet count by at least 30% of baseline levels in patients receiving heparin.

Nursing Alert

A normal adult platelet count is 140 to 400 × 10^3/mm^3. A platelet count of more than 50 × 10^3/mm^3 is generally not associated with spontaneous bleeding. However, a platelet count of less than 20 × 10^3/mm^3 is associated with bleeding from gums and injection sites; epistaxis (nose bleed), ecchymoses (bruising), and petechiae may be noted. When the platelet count drops to less than 10 × 10^3/mm^3, spontaneous intracranial hemorrhage becomes a significant risk (Fischbach & Dunning, 2014).

Patients at greatest risk for bleeding are those who receive unfractionated heparin for a long period of time (i.e., several days or weeks). Therefore, it is preferable not to anticoagulate patients with unfractionated heparin over the long term. Beginning warfarin concomitantly with heparin can provide a stable INR by day 5 of heparin treatment, at which time the heparin may be discontinued.

The administration of LMWH is less frequently associated with HIT. The thrombocytopenia is thought to result from an autoimmune mechanism that causes destruction of platelets. If the process is not arrested, platelets may aggregate, initiating inappropriate clotting, and thrombosis may occur. This serious complication results in thromboembolic manifestations throughout the body, and the prognosis is extremely guarded.

Prevention of thrombocytopenia depends on regular monitoring of platelet counts. Early signs of complications associated with anticoagulants include a decreasing platelet count, the need for increasing doses of heparin to maintain the therapeutic level, and thromboembolic or hemorrhagic complications, such as skin necrosis at the injection site

and at distal sites of thromboses, and skin discoloration consisting of hemorrhagic areas, hematomas, purpura, and blistering. If thrombocytopenia does occur, platelet aggregation studies are conducted, the heparin is discontinued, and alternate anticoagulant therapy is initiated rapidly because the continued prothrombotic state poses an ongoing threat of continuous clot development.

Lepirudin (Refludan) and argatroban are DTIs approved for treatment of HIT. Lepirudin has a half-life of 1.3 hours, is excreted by the kidneys, and can be monitored using the aPTT. An initial IV bolus infusion followed by a continuous infusion with subsequent adjustments to maintain the aPTT between 1.5 and 2.5 times baseline has been recommended. Strict dosage adjustment in kidney failure is required because the clearance of lepirudin is proportional to the patient's creatinine clearance. Argatroban has a half-life of 30 to 45 minutes, is metabolized by the liver, and is unaffected by kidney function. The anticoagulant effect of argatroban is predictable, with low variability between patients, but it is dose-dependent and requires monitoring with either the aPTT or ACT. There is no safe, rapidly acting antidote if the patient develops bleeding complications from DTIs. Recombinant factor VIIa may reverse the anticoagulant effects, but it may not be available in all hospitals, and it is very expensive. There are new medications being tested for long-term anticoagulation, but the Guidelines (Kearon et al., 2016) have weak recommendations for their use and further research is warranted. The clinician is responsible to keep up with the current research and recommendations for all interventions.

Because oral anticoagulants interact with many other medications and herbal and nutritional supplements, close monitoring of the patient's medication schedule is necessary. Many medications and supplements potentiate or inhibit oral anticoagulants; it is always wise to check to see if any medications or supplements the patient is taking are contraindicated with warfarin. In general, 3 months of therapy is expected (Ginsberg, 2016).

Providing Comfort

Elevation of the affected extremity, elastic compression stockings, and analgesics for pain relief are adjuncts to therapy. They help improve circulation and increase comfort.

Warm, moist packs applied to the affected extremity reduce the discomfort associated with DVT, as do mild analgesics prescribed for pain control. When the patient begins to ambulate, elastic compression stockings are used. Walking is better than standing or sitting for long periods. The patient is advised to elevate the legs when not ambulating.

Nursing Alert

Does research show that bed rest or ambulation is best for a patient with a DVT? Early ambulation has demonstrated the ability to decrease the risk of thrombus extension without increasing the risk of PE (DeHart, 2015). In addition, ventilation/perfusion scanning studies (V/Q scanning) demonstrate no decrease in PE with the use of bed rest, while pain and swelling have been shown to resolve more rapidly with early ambulation (Dehart, 2015, p. 212). However, the use of bed rest versus activity continues as an institutional protocol in many hospitals. The nurse should follow the facility's protocol but be cognizant of the findings described here.

Applying Compression Therapy

Increased venous pressure causes the long-term negative effects of venous disease. Treatment for venous insufficiency is external compression, which counteracts this pressure and protects the tissues from further damage.

Elastic compression stockings are prescribed for patients with chronic venous insufficiency. These stockings exert a sustained, graduated compression over the extremity, compressing the superficial veins, minimizing venous blood pooling, and resulting in increased flow toward the deep veins. They also prevent the sequelae of postphlebitic syndrome (fibrosis, ulceration). Stockings are available in knee-high, thigh-high, or waist-high lengths.

Short stretch elastic wraps may be applied from the toes to the knee in a 50% spiral overlap. These wraps are available in two-, three-, or four-layer systems, which include an inner layer of soft padding. Other types of compression include the Unna boot, which consists of a gauze roll impregnated with glycerin, gelatin, and sometimes zinc oxide or calamine. It is applied without tension in a circular, angular fashion from the base of the toes to the tibial tuberosity with a 50% spiral overlap. This type of compression may remain in place for as long as 1 week. Other manufactured rigid dressings are available to effectively augment the calf muscle pump during ambulation. Patients may find these dressings easier to wear than the Unna boot or a compression stocking.

Intermittent pneumatic compression devices can be used with elastic compression stockings to prevent DVT and to reduce edema. They consist of an electric motor attached to plastic knee-high or thigh-high sleeves, with single-chamber or multiple sequential chamber air bladders. These devices mimic muscle contraction and apply pressure to the veins, increasing blood velocity during bed rest.

Body Positioning and Exercise

When the patient is on bed rest, the feet and lower legs should be elevated periodically above the level of the heart. This position allows the veins to empty rapidly. Active and passive leg exercises, particularly those involving calf muscles, should be performed to increase venous flow. Early ambulation is most effective in preventing venous stasis. Deep-breathing exercises produce increased negative pressure in the thorax, which assists in emptying the large veins. Once ambulatory, the patient is instructed to avoid sitting for more than 2 hours at a time and to perform active and passive leg exercises during long car, train, and plane trips when ambulation is not possible.

VARICOSE VEINS

Varicose veins (varicosities) are abnormally dilated, tortuous, superficial veins caused by incompetent venous valves. They occur more frequently in the lower extremities, the saphenous veins, or the lower trunk, but they can occur elsewhere in the body.

Pathophysiology

Varicose veins may be primary (without involvement of deep veins) or secondary (resulting from obstruction of deep veins). A reflux of venous blood in the veins results in venous stasis. If the superficial veins are affected without deep vein involvement, the patient may be asymptomatic but may be troubled by the appearance of the distended veins.

Risk Factors

Varicose veins are more common in women than men and in people whose occupations require prolonged standing, such as salespeople, hair stylists, teachers, nurses, and ancillary medical personnel, and construction workers. A hereditary weakness of the vein wall may contribute to the development of varicosities, and it commonly occurs in several members of the same family. Varicose veins are rare before puberty. Pregnancy may cause varicosities because of hormonal effects related to venous distensibility, increased pressure by the gravid uterus, and increased blood volume.

Clinical Manifestations and Assessment

Symptoms, if present, may include dull aches, muscle cramps, increased muscle fatigue in the lower legs, ankle edema, and a feeling of heaviness of the legs. Nocturnal cramps are common. When deep venous obstruction results in varicose veins, the patient may develop the signs and symptoms of chronic venous insufficiency: edema, pain, pigmentation changes, and ulcers. Susceptibility to injury and infection is increased.

Diagnostic tests for varicose veins include the duplex scan, which documents the anatomic site of reflux and provides a quantitative measure of the severity of valvular reflux. Air plethysmography measures the changes in venous blood volume. Venography is not routinely performed to evaluate for valvular reflux.

Prevention

The patient should avoid activities that increase venous hypertension, such as wearing constricting clothing, crossing the legs at the thighs, and sitting or standing for long periods. Changing position frequently, elevating the legs when they are tired, and getting up to walk for several minutes of every hour promote circulation. The patient is encouraged to walk 1 or 2 miles each day if there are no contraindications. Walking up the stairs rather than using the elevator or escalator is helpful, and swimming is good exercise. Walking must incorporate the heel–toe step rather than a shuffle to elicit the calf muscle pump effect. Overweight patients should be encouraged to begin a weight-reduction plan.

Surgical Management

Ligation and Stripping

Surgery for varicose veins requires that the deep veins be patent and functional. The saphenous vein is ligated and divided. The vein is ligated high in the groin, where the saphenous vein meets the femoral vein. Pressure and elevation minimize bleeding during surgery. Vein stripping, which used to be a common surgical procedure, has been replaced by the venous ablation techniques.

Ablation Procedures

Thermal ablation is a nonsurgical approach using thermal energy. Radiofrequency ablation uses an electrical contact inside the vein. As the device is withdrawn, the vein is sealed. Laser ablation uses a laser fiber tip that seals the vein (decompresses it). Topical gel may be used first to numb the skin along the course of the saphenous vein. To protect the surrounding tissue, a series of small punctures are made along the vein, and 100 to 200 mL of dilute lidocaine is delivered to the perivenous space using ultrasound guidance. The goal of this tumescent anesthesia (i.e., anesthesia that causes localized swelling) is to provide analgesia, thermal protection (the cuff of fluid surrounds the veins and accompanying nerves), and extrinsic compression of the vein. The saphenous vein is entered percutaneously near the knee using ultrasound guidance. The device is then activated and withdrawn, sealing the vein. Small bandages and compression stockings are applied after the procedure. The patient is asked not to remove the stockings for at least 48 hours and then to rewrap the legs and wear the compression stockings while ambulatory for a period of time according to a protocol. Patients are ambulatory prior to being discharged from the outpatient facility and have no activity restrictions, except that swimming is discouraged for 3 weeks. NSAIDs, such as ibuprofen or acetaminophen, are used as needed for pain. The patient is informed that bruising along the course of the vein, leg cramps (for a few days), and difficulty straightening the knees (for up to 1.5 weeks) may be experienced post procedure.

Sclerotherapy

Sclerotherapy involves injection of an irritating chemical into a vein to produce localized phlebitis and fibrosis, thereby obliterating the lumen of the vein. This treatment may be performed alone for small varicosities or may follow vein ablation or ligation. Sclerosing is palliative rather than curative. Sclerotherapy is typically performed in an examination or procedure room and does not require any sedation. After the sclerosing agent is injected, elastic compression bandages are applied to the leg and are worn according to a protocol, followed by elastic compression stockings. Walking activities are encouraged to maintain blood flow and to dilute the sclerosing agent within the deep venous system.

Post Procedure Nursing Management

After venous ablation procedures, bed rest is discouraged; the nurse encourages the patient to become ambulatory as soon as sedation has worn off. The patient is instructed to walk according to an individual protocol and to increase walking and activity as tolerated. Elastic compression stockings may be worn continuously or just when awake and upright (depending on the individual care provider's protocol) for 1 to 2 weeks after vein procedures. The nurse assists the patient in performing exercises and moving the legs. The foot of the bed should be elevated. Standing and sitting are discouraged. Jogging and hard-impact exercises are avoided according to individual protocols.

Analgesics are prescribed to help the patient move the affected extremities more comfortably. Dressings are inspected for bleeding, particularly at the groin, where the risk of bleeding is greatest. The nurse is alert for reported sensations of "pins and needles," as sensation is regained. Hypersensitivity to touch in the involved extremity may indicate a temporary or permanent nerve injury resulting from the procedure because the saphenous vein and nerve are close to each other in the leg.

Usually, the patient may shower after the first 24 hours. The patient is instructed to dry the incisions well with a clean towel, using a patting technique, rather than rubbing. Application of skin lotion is avoided until the incisions are completely healed to avoid infection. The patient is instructed to apply sunscreen or zinc oxide to the incision area prior to sun exposure for 6 months; otherwise, hyperpigmentation of the incision, scarring, or both may occur. The nurse may encourage the use of a mild analgesic as prescribed and regular short walking to provide relief.

CHRONIC VENOUS INSUFFICIENCY

Venous insufficiency results from obstruction of the venous valves in the legs and a reflux of blood. Both superficial and deep leg veins can be involved. A prolonged increase in venous pressure causes venous hypertension. Because the walls of veins are thinner and more elastic than arterial walls, they distend readily when venous pressure is elevated consistently. In this state, leaflets of the venous valves are stretched and prevented from closing completely, allowing a backflow or reflux of blood in the veins (Fig. 18-7). Duplex ultrasound confirms the obstruction and identifies incompetent venous valves.

Clinical Manifestations and Assessment

Classic signs of venous disease are edema and increased pigmentation of the skin, termed *hemosiderosis.* Because of the poor venous return, there is extravasation of red blood cells, which break down and deposit hemosiderin (a pigment that gives red blood cells their color), staining the skin a gray-brown. Varicosities and telangiectasias are also commonly noted. The extremity is warm, and pulses are present (assuming there is no concomitant arterial disease) but may be difficult to feel due to the extensive edema.

Postthrombotic syndrome is the long-term result of an incompetent venous system and venous hypertension. Venous obstruction or poor calf muscle pumping, in addition to valvular reflux, also contributes to the development of severe postthrombotic syndrome. It is characterized by chronic edema, altered pigmentation, pain, and stasis dermatitis. This is called *dermatosclerosis.* The patient may notice aching and heaviness less in the morning after rest and elevation and more in the evening. The disorder is longstanding, difficult to treat, and often disabling.

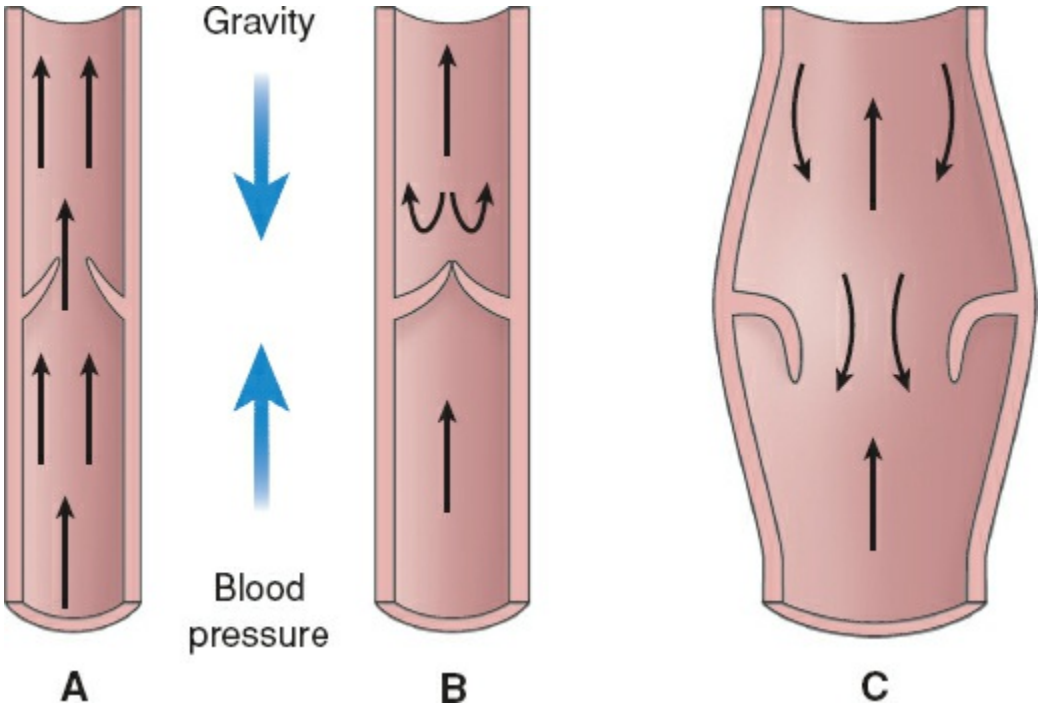

FIGURE 18-7 Competent valves showing blood flow patterns when the valve is open (A) and closed (B), allowing blood to flow against gravity. (C) With faulty or incompetent valves, the blood cannot move toward the heart.

Medical and Nursing Management

Management of the patient with venous insufficiency is directed at reducing venous stasis and preventing ulcers (see additional discussion below). Measures that increase venous blood flow are antigravity activities, such as elevating the leg, and compression of superficial veins with elastic compression stockings.

Elevating the legs decreases edema, promotes venous return, and provides symptomatic relief. The legs should be elevated frequently throughout the day. At night, the patient should sleep with the foot of the bed elevated. Prolonged sitting or standing in one position is detrimental; walking should be encouraged.

VASCULAR ULCERS

Vascular ulcers include arterial ischemic ulcers, venous ulcers, and ulcers on the lymphatic limb (Table 18-5). Treatment is different for each of these ulcers because treatment is based on etiology, which varies for each type of ulcer. Ulcers are not common on lymphatic limbs. When they occur, usually, associated venous disease or trauma to the already compromised tissue is present.

Pathophysiology

Venous ulceration is the most serious complication of chronic venous insufficiency and can be associated with other conditions affecting the circulation of the lower extremities. Cellulitis or dermatitis may complicate the care of chronic venous insufficiency and venous ulcer. Venous ulcers develop as a result of increased venous pressure or external trauma.

TABLE 18-5 Arterial and Venous Ulcer Characteristics

	Arterial	Venous
Location	Distal to arterial stenosis, heels, toes, over bony prominences, metatarsals, malleoli, between toes, trauma points	Around ankle, lower third of leg, more often on medial side
Ulcer base	Dry, pale gray or yellow; may be necrotic	Generally shallow but may be deep. Pink, but may be beefy red with granulation tissue. Ulcer bed usually moist. May have copious drainage
Shape	Border regular and well demarcated	Irregular border
Surrounding tissue	Pale; cooler than other skin areas. In longstanding insufficiency, skin is thin.	Darkened color in gaiter area. Temperature higher than other skin areas. Brawny edema. Skin may be thick and fibrotic (woody). May be oozing and crusted
Edema	Minimal unless leg is dependent often	May be severe
Pain	Claudication. Rest pain; continuous pain worsens with elevation and eases with dependency.	Aching, throbbing, heaviness. Superficial stinging when open to air during dressing changes
Pulses	May be absent or diminished; often disappears with exercise	Usually present with only venous etiology but may be difficult to palpate with edema
ABI	Less than 0.90	Greater than 0.90
Wound treatment	Moist wound healing after revascularization. Monitor for infection. Keep dry gangrene dry.	Compression. Elevation above heart. Absorptive dressings
Operative procedures	Arterial bypass. Angioplasty. Stent placement	Vein ligation/stripping. Valve grafts. Sclerotherapy. Laser or radiofrequency ablation

Atherosclerosis, the most common cause of peripheral arterial occlusive disease, primarily affects the superficial femoral and popliteal vessels, reducing blood flow to the lower extremities. Ulceration will develop as a result of ischemia.

Clinical Manifestations and Assessment

Venous ulcers occur in the lower part of the extremity, in the area of the medial malleolus of the ankle, called the *gaiter area.* They range from small to large in size, are superficial, irregular in shape, highly exudative, and associated with periulcer hemosiderin staining of the skin. The skin becomes dry, cracked, and pruritic; subcutaneous tissues fibrose and atrophy. The risk for injury and infection of the extremities is increased.

Typically, arterial ulcers are small lesions on the tips of toes or in the web spaces between the toes. Ulcers often occur on the medial side of the hallux or lateral fifth toe and may be caused by a combination of ischemia and pressure.

Arterial insufficiency may result in gangrene of the toe (digital gangrene), which may be precipitated by trauma (Box 18-8) (Sieggreen & Kline, 2016a).

Medical and Nursing Management

Patients with ulcers can be effectively managed by advanced practice nurses or wound-ostomy-continence nurses in collaboration with health care providers. The nurse is aware that all ulcers have the potential to become infected.

Pharmacologic Therapy

All ulcers are colonized with superficial bacteria. Most leg ulcers do not need antibiotics. Antibiotic therapy is prescribed when the ulcer is infected; the specific antibiotic agent is based on culture and sensitivity test results. When indicated, oral or intravenous antibiotics usually are prescribed because topical antibiotics have not proven to be effective for leg ulcers.

Wound Cleansing and Débridement

As a general rule, arterial ulcers are kept dry and necrotic tissue is not débrided until revascularization procedures are performed because of the risk of infection and the likelihood of nonhealing associated with poor peripheral perfusion.

Venous ulcers with necrotic tissue should be débrided. To promote healing, the wound is kept clean of drainage. The wound is cleaned with each dressing change using normal saline solution or a non cytotoxic wound-cleansing agent. The cleansing agent should be applied to the wound with enough force to wash the surface debris away. If there is necrotic tissue at the base of the venous wound, debridement, or removal of nonviable tissue, may be necessary. Removing the dead tissue is important to promote wound healing. There are several methods of debridement.

BOX 18-8 Gangrene of the Toe

Gangrene of the toes, resulting from severe arterial ischemia, causes the digits to turn black. Débridement is contraindicated in these instances. Although the toes are gangrenous, this is the dry form of gangrene. Managing dry gangrene is preferable to débriding and creating an open wound that will not heal because of insufficient circulation. A distal amputation requires adequate circulation to heal. Without it, further amputation, such as below the knee or above the knee may be necessary. A higher-level amputation in an elderly person often results in loss of independence and possibly the need for institutional care. Dry gangrene of the toe(s) in an elderly person with poor circulation, who is asymptomatic, is usually left undisturbed. The toes are kept clean and dry until they separate from the viable tissue. Soaking is avoided.

- *Surgical debridement:* This is the fastest method and can be performed by a physician, skilled advanced practice nurse, or wound-ostomy-continence nurse in collaboration with the physician.
- *Wet to dry or nonselective debridement:* This method can be accomplished by applying saline-impregnated gauze to the ulcer. When the dressing dries, it is removed, along with the debris adhering to the gauze. Pain management is usually necessary.
- *Enzymatic debridement:* This method involves application of enzyme ointments prescribed to treat the ulcer. The ointment is applied to the lesion but not to normal surrounding skin. Most enzymatic ointments are covered with saline-soaked gauze that has been thoroughly wrung out. Then a dry gauze dressing and a loose bandage are applied. The enzymatic ointment is discontinued when the necrotic tissue has been débrided, and an appropriate wound dressing is applied.
- *Autolytic debridement:* With this method, an occlusive absorptive dressing, such as a hydrocolloid, is placed over the wound and left in place for a few (3 to 7) days to allow enzymes from the body to liquefy the necrotic tissue and separate it from the viable tissue. The wound is irrigated copiously during dressing changes to cleanse away the necrotic tissue. This type of dressing promotes granulation tissue growth (Sieggreen & Kline, 2016).

Wound Dressings

After the circulatory status has been assessed and determined to be adequate for healing, surgical dressings can be used to promote a moist environment. The simplest method is to use a wound contact material next to the wound bed and cover it with gauze. Other available options that promote the growth of granulation tissue and reepithelialization include the *hydrocolloids.* These materials also provide a barrier for protection because they adhere to the wound bed and surrounding tissue. However, these dressings may not be effective treatment for deep wounds and infected wounds. Patient and family education is necessary before beginning and throughout the wound care program. See Chapter 52 for further information about wound care.

Stimulated Healing

Tissue-engineered human skin equivalent is a skin product cultured from human dermal fibroblasts and keratinocytes used in combination with therapeutic compression. When applied, it seems to react to factors in the wound and may interact with the patient's cells to stimulate the production of growth factors. Application is not difficult, no suturing is involved, and the procedure is painless.

Hyperbaric Oxygenation

Hyperbaric oxygenation (HBO) may be beneficial as an adjunct treatment in patients with diabetes who evidence no signs of wound healing after standard wound treatment. HBO is accomplished by placing the patient into a chamber that increases barometric pressure while the patient is breathing 100% oxygen. The process by which HBO is thought to work involves several factors. The edema in the wound area is decreased because high oxygen tension facilitates vasoconstriction and enhances the ability of leukocytes to phagocytize and kill bacteria. In addition, HBO is thought to increase diffusion of oxygen to the hypoxic wound, thereby enhancing epithelial migration and improving collagen production.

Compression

Leg elevation helps to promote edema reduction. Venous ulcers require external compression. The Unna boot or commercial two- and three-layer compression bandages are available for this treatment. An Unna boot is a gauze dressing impregnated with a paste of glycerin, zinc oxide, and, sometimes, calamine. It is layered on the leg like a cast, from the tips of the toes to just below the knee. Extra padding is used if there is copious wound drainage, and an elastic bandage is placed over the dressing. Once the dressing dries, it becomes rigid. The boot is changed weekly. Its effectiveness depends on healthy calf muscle and the ability to ambulate.

LYMPHATIC DISORDERS

The lymphatic system consists of a set of vessels that start as lymph capillaries, which drain unabsorbed plasma from the interstitial spaces (spaces between the cells). The lymphatic capillaries unite to form the lymph vessels, which pass through the lymph nodes and then empty into progressively larger channels, most of which drain into the thoracic duct that joins the jugular vein on the left side of the neck.

Fluid drained from the interstitial space by the lymphatic system is called *lymph.* Lymph flow depends on the intrinsic contractions of the lymph vessels, the contraction of muscles, respiratory movements, and gravity. The lymphatic vessels of the extremities empty into nodes of the axillae and the groin. Under certain abnormal conditions, the fluid filtered out of the capillaries may greatly exceed the amounts reabsorbed and carried away by the lymphatic vessels. This imbalance can result from a variety of etiologies, including damage to capillary walls and subsequent increased permeability, obstruction of lymphatic drainage, elevation of venous pressure, or decrease in plasma protein osmotic force. Accumulation of excess interstitial fluid that results from these processes is known as lymphedema. In general, the nurse is aware that edema usually represents accumulation of 2.5 to 3 L of interstitial fluid. If the edema is *pitting*—that is, when the nurse presses the thumb into the edematous area for 5 seconds an imprint of the finger is noted—it is estimated that approximately 4.5 kg (10 lb) of fluid has accumulated (Leblond, DeGowin, & Brown, 2015). Refer to Chapter 12 for more details on assessing pitting edema.

Lymphangiography and lymphoscintigraphy are two diagnostic tests to assess lymphatic function. Lymphangiography involves injecting a contrast agent into a lymphatic vessel in each foot (or hand), followed by taking a series of x-rays at the conclusion of the injection, 24 hours later, and periodically thereafter. A diagnosis of lymphedema can be confirmed by the failure to identify subcutaneous lymphatic collection of contrast agent and the persistence of contrast agent in the tissue for days afterward.

Lymphoscintigraphy is a reliable alternative to lymphangiography. A radioactively labeled colloid is injected subcutaneously in the second interdigital space. The extremity is then exercised to facilitate the uptake of the colloid by the lymphatic system, and serial images are obtained at preset intervals.

LYMPHANGITIS AND LYMPHADENITIS

Lymphangitis is an acute inflammation of the lymphatic channels. It arises most commonly from an infection in an extremity. Usually, the infectious organism is a hemolytic streptococcus. The characteristic red streaks that extend up the arm or the leg from an infected wound outline the course of the lymphatic vessels as they drain.

The lymph nodes located along the course of the lymphatic channels also become enlarged, red, and tender (acute lymphadenitis). They can also become necrotic and form an abscess (suppurative lymphadenitis). The nodes involved most often are those in the groin, axilla, or cervical region. Because these infections are nearly always caused by organisms that are sensitive to antibiotics, it is unusual to see abscess formation. Recurrent episodes of lymphangitis are often associated with progressive lymphedema. After acute attacks, and if the edema has subsided, an elastic compression stocking or sleeve should be worn on the affected extremity for several months to prevent long-term edema.

LYMPHEDEMA AND ELEPHANTIASIS

Lymphedema is swelling in the extremities due to an accumulation of lymph from blocked lymphatic vessels.

Pathophysiology

Lymphedemas are classified as primary (congenital malformations) or secondary (acquired obstructions). Tissue swelling occurs in the extremities because of an increased quantity of lymph that results from obstruction of lymphatic vessels. It is especially marked when the extremity is in a dependent position. Initially, the edema is soft and pitting. As the condition progresses, the edema becomes firm, nonpitting, and less responsive to treatment. The most common type is congenital lymphedema (*lymphedema praecox*), which is caused by hypoplasia (underdevelopment) of the lymphatic system of the lower extremity.

The obstruction may be in the lymph nodes and the lymphatic vessels. Sometimes, it is seen in the arm after an axillary node dissection (e.g., for breast cancer) and in the leg in association with varicose veins or chronic thrombophlebitis. In the latter case, the lymphatic obstruction usually is caused by chronic lymphangitis. Lymphatic obstruction caused by a parasite (filaria) is seen frequently in patients in the tropics and is the most common cause of lymphedema worldwide. When chronic swelling is present, there may be frequent bouts of acute infection characterized by high fever and chills and increased residual edema after the inflammation has resolved. These lead to chronic fibrosis, thickening of the subcutaneous tissues, and hypertrophy of the skin. This condition, in which chronic swelling of the extremity recedes only slightly with elevation, is referred to as *elephantiasis.*

Clinical Manifestations and Assessment

The diagnosis of lymphedema is made by clinical evaluation and exclusion of other causes of edema. In the early stages, the tissue is soft and pliable, but in advanced lymphedema, the tissue becomes firm and thick, often with overlapping folds of tissue. Early diagnosis is important to prevent tissue destruction. In the lower extremities the toes are squared, and the skin of the second toe fails to "tent" when pinched (Fife, Sieggreen, & Kline, 2016).

Medical Management

Treatment is focused on reducing the edema and preventing increased edema, infections, and tissue damage. Treatment may consist of comprehensive decongestive therapy provided by a certified lymphedema therapist, use of a pump to reduce the edema, and elastic and nonelastic compression wraps or garments to maintain the edema reduction.

Care must be taken to avoid any break in the skin that would allow bacteria to enter the tissue. Antibiotics are prescribed for infection. Antibiotics used to be prescribed frequently for prophylaxis because chronic infections were common in some individuals. They are very selectively prescribed now because of the increase in antibiotic-resistant infections. Patients need support and must be taught that lymphedema requires lifelong vigilance. The individual needs to learn as much as possible about the condition and how to manage it (Box 18-9). The nurse provides access to resources available, both in the local area and credible references found online. Certified therapists can be located by accessing http://www.lymphnet.org.

Pharmacologic Therapy

As initial therapy, the diuretic furosemide (Lasix) may be prescribed to prevent fluid overload while the extracellular fluid is mobilized. The use of diuretics alone has little benefit because their main action is to limit capillary filtration by decreasing the circulating blood volume. If lymphangitis or cellulitis is present, antibiotic therapy is initiated in addition to the administration of diuretics. Skin care is important to maintain moisture.

BOX 18-9 Patient Education for Lymphedema

- Keep skin clean and dry.
- Wear compression support garments as prescribed.
- Avoid blood pressure cuffs, needle sticks, injections, or procedures on the affected limb.
- Report new swelling, redness, pain, heat, rash, blisters, or fever to the provider/nurse.
- Avoid tight clothing.
- Check feet with a mirror for sores, rashes, or cracks in the skin.
- Avoid trauma: Pet scratches, insect bites, burns, sports injuries, bruising.
- Clean cuts or insect bites with soap and water and apply antibiotic ointment.
- Elevate the affected limb whenever possible.

Exercise and Compression

Active and passive exercises assist in moving lymphatic fluid into the bloodstream. External compression devices move the fluid proximally from the foot to the hip or from the hand to the axilla. When the patient is ambulatory, and the limb is reduced to an acceptable size, custom-fitted elastic compression stockings or sleeves are worn; those with the highest

compression strength, 30–40 mm Hg, may be required. When the leg is affected, continuous bed rest with the leg elevated for a limited time may aid in mobilizing the fluids. Manual lymphatic drainage is a highly specialized massage technique designed to direct or shift the congested lymph through functioning lymphatics that have preserved drainage capacity. Manual lymphatic drainage used in combination with compression bandages, exercises, skin care, pressure gradient sleeves, and, sometimes, pneumatic pumps, depending on the severity and stage of the lymphedema. If the patient is in the hospital and in bed, there may be a reduction of the size of the limb in 24 hours. In this case a compression garment can be placed on to maintain the reduction. If the patient is at home, it is impractical to expect a 24-hour bed rest so the patient may be advised to sit with the legs elevated for 20 minutes three to four times a day. The nurse recognizes there are complications associated with prolonged bed rest, so the plan must be individualized for each person and agreed upon between the patient and the practitioner.

Surgical Management

Surgery is performed if the edema is severe and uncontrolled by medical therapy, if mobility is severely compromised, or if infection persists. One surgical approach involves the excision of the affected subcutaneous tissue and fascia, followed by skin grafting to cover the defect. Copious amounts of lymphatic fluid may make skin grafts nonadherent. Another procedure involves the surgical relocation of superficial lymphatic vessels into the deep lymphatic system by means of a buried dermal flap to provide a conduit for lymphatic drainage. This procedure has had limited success. Surgery is rarely performed in these patients in most hospitals. Patients who would benefit from surgery are referred to specialized centers.

Nursing Management

After surgery, the management of skin grafts and flaps is the same as when these therapies are used for other conditions. Antibiotics are prescribed. Constant elevation of the affected extremity and observation for complications are essential. Complications may include flap necrosis, hematoma or abscess under the flap, and cellulitis. The nurse instructs the patient or caregiver to inspect the dressing daily. Unusual drainage or any inflammation around the wound margin suggests infection and should be reported to the surgeon. The patient is informed that there may be a loss of sensation in the skin graft area. The patient is also instructed to avoid the application of heating pads or exposure to sun to prevent burns or trauma to the area. The patient is taught to inspect the skin for evidence of infection.

CELLULITIS

Cellulitis is the most common infection of the skin and subcutaneous tissue that causes limb swelling. Cellulitis can occur as a single isolated event or a series of recurrent events. It is often misdiagnosed, usually as recurrent thrombophlebitis or chronic venous insufficiency. It occurs when an entry point through normal skin barriers allows bacteria to enter. Cellulitis is a frequent complication in tissues with lymphedema. It is also diagnosed in otherwise healthy tissue.

Pathophysiology

Cellulitis occurs when there is an entry point through the normal skin barrier. This allows bacteria to enter the subcutaneous tissue.

Clinical Manifestations and Assessment

The acute onset of swelling, localized redness, and pain is frequently associated with systemic signs of fever, chills, and sweating. The redness may not be uniform and often skips areas. Dimpling in the skin may be seen when the edema surrounds hair follicles. Regional lymph nodes may also be tender and enlarged.

Medical Management

Mild cases of cellulitis can be treated on an outpatient basis with oral antibiotic therapy. If the cellulitis is severe, the patient is treated with IV antibiotics. The key to preventing recurrent episodes of cellulitis lies in adequate antibiotic therapy for the initial event and in identifying the site of bacterial entry. The most commonly overlooked areas are the cracks and fissures that occur in the skin between the toes. Other possible locations are drug-use injection sites, contusions, abrasions, ulcerations, ingrown toenails, and hangnails.

Nursing Management

The patient is instructed to elevate the affected area above heart level and apply warm, moist packs to the site. Patients with sensory and circulatory deficits, such as those caused by diabetes and paralysis, should use caution when applying warm packs because burns may occur; it is advisable to use a thermometer or have a caregiver ensure that the temperature is not more than lukewarm. Education should focus on preventing a recurrent episode. The patient with PVD or diabetes mellitus should receive education or reinforcement about skin and foot care.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 75-year-old male patient has been diagnosed with a stenosis of his external iliac artery and is scheduled for an angiogram with a possible balloon angioplasty and stent placement. What factors should be considered when planning his post procedure and continuing care? If the patient is taking warfarin for atrial fibrillation and has renal insufficiency (creatinine of 1.8 mg/dL) as a complication of diabetes, how would these factors be addressed in the plan of care?

2. A 96-year-old patient presents with a 2-year history of chronic venous ulceration of the left lower extremity, requiring weekly placement of an Unna boot. The patient lives alone, six blocks from any mass transit or shopping area, and no longer drives a vehicle. The patient wants to continue living at his current location. What options and plan of care should be discussed with the patient?

3. One of your patients has been diagnosed with a recurrent DVT of the femoral vein. The patient has been treated previously with unfractionated heparin and developed HIT. Discuss strategies for DVT prophylaxis that you will include in your teaching plan with this patient.

NCLEX-Style Review Questions

1. The nurse is caring for a patient diagnosed with peripheral arterial disease. Based on assessment, which clinical manifestation would be inconsistent with acute arterial occlusion?
   a. Pallor
   b. Paresthesia
   c. Hyperthermia
   d. Poikilothermia

2. A new postsurgical patient has been prescribed unfractionated heparin to prevent DVT. What is a true statement regarding the use of heparin?

a. Heparin has a half-life of approximately 60 minutes.
b. Therapeutic PT level is three times the baseline control
c. Vitamin K interferes with the action of heparin
d. Heparin is administered by gravity drip

3. The nurse is using a hydrocolloid dressing for a patient who is undergoing autolytic debridement of a necrotic venous ulcer. What is characteristic of this type of debridement?
a. Accomplished by applying enzymatic ointment to the lesion
b. Left in place for 3 to 7 days
c. The fastest method of debridement
d. Accomplished by applying saline impregnated gauze to the ulcer

4. Which of the following is not a reliable indicator of a possible DVT?
a. Calf tenderness
b. Edema of the extremity
c. Homan sign
d. Increased circumference of affected extremity

5. Which characteristic is consistent with an arterial ulcer?
a. Pink or beefy red appearance with granulation tissue
b. May have severe edema
c. Darkened color tissue in gaiter area
d. Pale and cool extremity

Problems Related to Hematologic Function

A 65-year-old woman has been diagnosed with chronic myeloid leukemia (CML). Previously she had been complaining of fatigue. She has lost 10 lb in the last month. She is very apprehensive about starting chemotherapy.

- What is the only curative treatment for CML?

- Discuss the three phases of the disease.
- Discuss important nursing considerations of the patient undergoing treatment for CML (Gleevec).

CHAPTER 19

Nursing Assessment: Hematologic Function

Lisa M. Barbarotta

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the process of hematopoiesis.
2. Describe the processes involved in maintaining hemostasis.
3. Differentiate between normal and abnormal hematologic laboratory values.
4. Describe the pertinent components of nursing assessment based on abnormal hematologic laboratory values.
5. Describe the procedure and patient preparation for a bone marrow biopsy.

Unlike many other body systems, the hematologic system truly encompasses the entire human body. Patients with hematologic disorders often have significant abnormalities in blood tests but few or no symptoms. Therefore, the nurse must have an understanding of the pathophysiology of the patient's condition and the ability to make a thorough assessment that relies heavily on the interpretation of laboratory tests. It is equally important for the nurse to anticipate potential patient needs and to target nursing interventions accordingly. A basic appreciation of blood cells and bone marrow function is critical to the understanding of hematologic diseases.

ANATOMIC AND PHYSIOLOGIC OVERVIEW

The hematologic system consists of the blood and the sites where blood is produced, including the bone marrow and the reticuloendothelial system (RES). Blood is a specialized organ that differs from other organs in that it exists in a fluid state. Blood is composed of plasma and various types of cells. Plasma is the fluid portion of blood; it is thin and colorless and contains various proteins, such as albumin, globulin, fibrinogen, and other factors necessary for clotting, as well as electrolytes, waste products, and nutrients. Approximately 55% of blood volume is plasma, and 45% consists of various cellular components.

Blood

The cellular component of blood consists of three primary cell types (Table 19-1): erythrocytes (red blood cells [RBCs]), leukocytes (white blood cells [WBCs]), and thrombocytes (platelets). As noted above, these cellular components of blood normally make up approximately 45% of the blood volume. Because most blood cells have a short lifespan, the need for the body to replenish its supply of cells is continuous; this process is termed hematopoiesis (the formation and production of blood cells). RBCs generally live for 120 days, WBCs live from days to years depending on the type, and platelets live 7 to 10 days. The primary site for hematopoiesis is the bone marrow. During embryonic development and in other conditions, the liver and spleen may also be involved; production of blood cells outside of the bone marrow is often referred to as extramedullary hematopoiesis (Golub, Vieira, & Cumano, 2014).

Under normal conditions, the adult bone marrow produces approximately 175 billion erythrocytes, 70 billion neutrophils (a mature type of WBC), and 175 billion platelets each day. When the body needs more blood cells, as in infection (when neutrophils are needed to fight the invading pathogen) or in bleeding (when more RBCs and platelets are needed), the marrow increases its production of the cells required. Thus, under normal conditions, the marrow responds to increased demand and releases adequate numbers of cells into the circulation.

Blood makes up approximately 7% to 10% of the normal body weight and amounts to 5 to 6 L of volume. Blood circulates through the vascular system carrying oxygen and nutrients to the various cells throughout the body to promote cell growth and function. Blood also carries proteins such as hormones, antibodies, and other substances to their sites of action or use. In addition, blood carries waste products produced by cellular metabolism to the lungs, skin, liver, and kidneys for elimination.

TABLE 19-1 Blood Cells

Cell Type	Major Function
WBC (Leukocyte)	Fights infection
Neutrophil	Essential in preventing or limiting bacterial infection via phagocytosis
Monocyte	Enters tissue as macrophage; highly phagocytic, especially against fungus
Eosinophil	Involved in allergic reactions (neutralizes histamine); digests foreign proteins
Basophil	Contains histamine; integral part of hypersensitivity reactions
Lymphocyte	Integral component of immune system
T lymphocyte	Responsible for cell-mediated immunity; recognizes material as "foreign"
B lymphocyte	Responsible for humoral immunity; many mature into plasma cells to form antibodies
Plasma cell	Secretes immunoglobulin (Ig, antibody); most mature form of B lymphocyte
RBC (Erythrocyte)	Carries hemoglobin to provide oxygen to tissues; average lifespan is 120 days
Platelet (Thrombocyte)	Fragment of megakaryocyte; provides basis for coagulation to occur; maintains hemostasis; average lifespan is 7 days

To prevent blood loss as a result of trauma or injury, an intricate clotting mechanism is activated to seal any leak in the blood vessels. Excessive clotting is equally as dangerous as excessive blood loss because it can obstruct blood flow to vital tissues. To prevent this, the

body has a fibrinolytic mechanism that eventually dissolves clots (thrombi) formed within blood vessels. The balance between these two systems, clot (thrombus) formation and clot dissolution, or fibrinolysis, is called hemostasis.

Bone Marrow

The bone marrow is the site of hematopoiesis, or blood cell formation (Fig. 19-1). In children, blood formation involves all skeletal bones, but with aging, marrow activity is usually limited to the pelvis, ribs, vertebrae, and sternum.

Marrow, which accounts for up to 4% to 5% of total body weight, consists of islands of cellular components (red marrow) separated by fat (yellow marrow). As the adult ages, the proportion of active marrow is gradually replaced by fat; however, in the healthy person, the fat can again be replaced by active marrow when more blood cell production is required. In adults with disease that causes marrow destruction, fibrosis, or scarring, the liver and spleen can also resume production of blood cells (*extramedullary hematopoiesis*).

The marrow is highly vascular. Within it are primitive cells called stem cells, which have the ability to self-replicate, thereby ensuring a continuous supply of stem cells throughout the lifecycle. When stimulated, stem cells can begin a process of differentiation into either myeloid or lymphoid stem cells. Lymphoid stem cells produce either T or B lymphocytes, whereas myeloid stem cells differentiate into three broad cell types: erythrocytes, leukocytes, and platelets. Thus, with the exception of lymphocytes, all blood cells are derived from myeloid stem cells. A defect in a myeloid stem cell can cause problems with erythrocyte, leukocyte, and platelet production. Many complex mechanisms are involved in hematopoiesis, many at the molecular level.

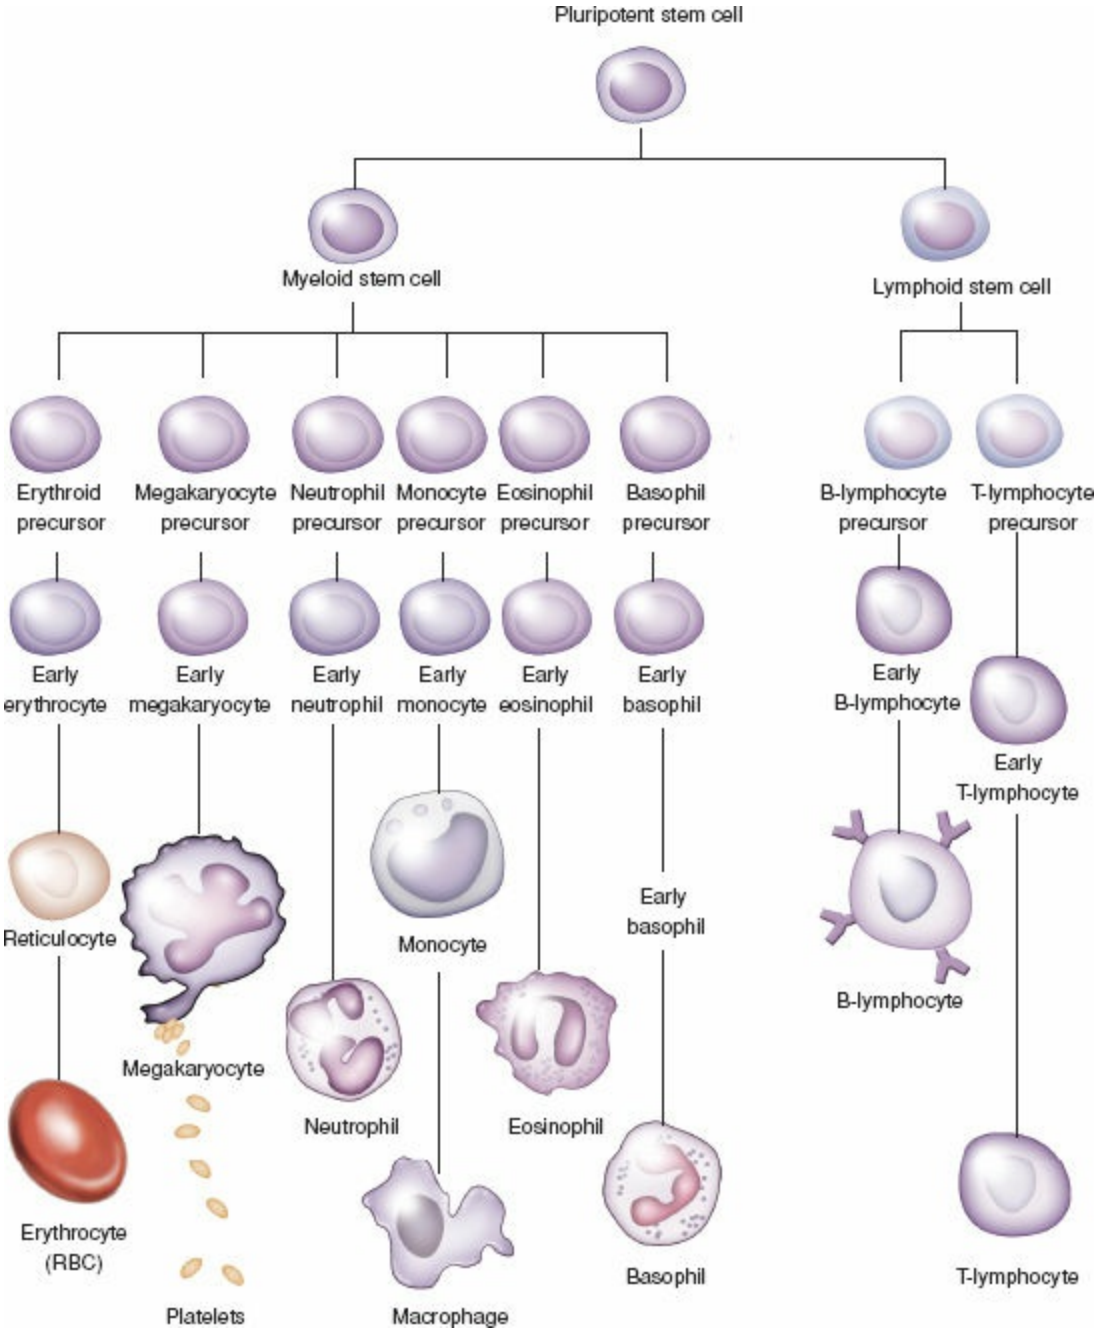

FIGURE 19-1 Hematopoiesis. Uncommitted (pluripotent) stem cells can differentiate into myeloid or lymphoid stem cells. These stem cells then undergo a complex process of differentiation and maturation into normal cells that are released into the circulation. The myeloid stem cell is responsible not only for all nonlymphoid white blood cells (WBCs) but also for the production of red blood cells (RBCs) and platelets. Each step of the differentiation process depends in part on the presence of specific growth factors for each cell type. When the stem cells are dysfunctional, they may respond inadequately to the need for more cells, or they may respond excessively, sometimes uncontrollably, as in leukemia.

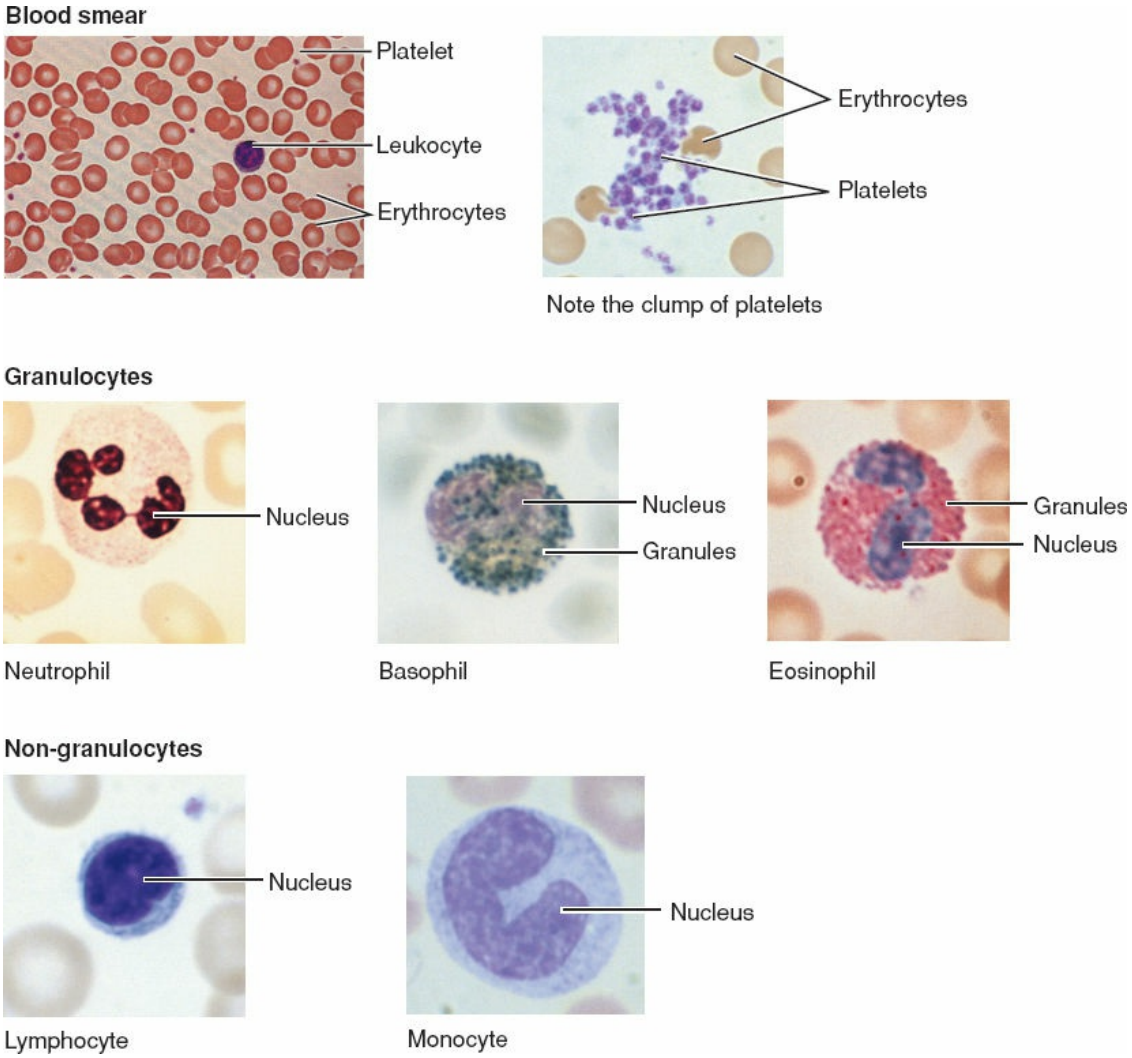

FIGURE 19-2 Normal types of blood cells. (From Cohen, B. J. (2016). *Memmler's the human body in health and disease* (12th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Erythrocytes (Red Blood Cells)

The normal erythrocyte has a biconcave disk shape (Fig. 19-2). It has a diameter of approximately 8 μm and is so flexible that it can pass easily through capillaries that may be as small as 2.8 μm in diameter. The membrane of the red cell is very thin so that gases, such as oxygen and carbon dioxide, can easily diffuse across it; the disk shape provides a large surface area that facilitates the absorption and release of oxygen molecules.

Mature erythrocytes consist primarily of hemoglobin, which contains iron and makes up 95% of the cell mass. Mature erythrocytes have no nuclei, and they have many fewer metabolic enzymes than do most other cells. The presence of a large amount of hemoglobin enables the red cell to perform its principal function of oxygen transport. Occasionally, the marrow releases slightly immature forms of erythrocytes, called reticulocytes, into the circulation. An elevation in the reticulocyte count may occur as a normal response to an increased demand for erythrocytes (as in bleeding) or in some disease states.

The oxygen-carrying hemoglobin molecule is made up of four subunits, each containing a heme portion attached to a globin chain. Iron is present in the heme component of the molecule. An important property of heme is its ability to bind to oxygen loosely and

reversibly. Oxygen readily binds to hemoglobin in the lungs and is carried as oxyhemoglobin in arterial blood. Oxyhemoglobin is a brighter red than hemoglobin that contains lesser amounts of oxygen (reduced hemoglobin), which is why arterial blood is a brighter red than venous blood. The oxygen readily dissociates (detaches) from hemoglobin in the tissues, where the oxygen is needed for cellular metabolism. In venous blood, hemoglobin combines with hydrogen ions produced by cellular metabolism and thus buffers excessive acid. Whole blood normally contains approximately 15 g of hemoglobin per 100 mL of blood.

Erythropoiesis

Erythroblasts arise from the primitive myeloid stem cells in bone marrow. The erythroblast is an immature nucleated cell that accumulates hemoglobin and then gradually loses its nucleus. At this stage, the cell is known as a *reticulocyte*. Further maturation into an erythrocyte entails the loss of the dark-staining material within the cell and slight shrinkage. Then the mature erythrocyte is released into the circulation.

Differentiation of the primitive myeloid stem cell of the marrow into an erythroblast is stimulated by erythropoietin, a hormone produced primarily by the kidney. If the kidney detects low levels of oxygen (as would occur in anemia, in which fewer red cells are available to bind to oxygen, or with people living at high altitudes), the release of erythropoietin is stimulated. The increase in erythropoietin production then stimulates the marrow to increase production of erythrocytes. The entire process typically takes 5 days.

For normal erythrocyte production, the bone marrow also requires iron, vitamin B_{12}, folic acid, pyridoxine (vitamin B_6), protein, and other factors. A deficiency in any one of these factors during erythropoiesis can result in decreased red cell production and anemia.

Iron Stores and Metabolism. The average daily diet in the United States contains 10 to 15 mg of elemental iron, but only 0.5 to 1 mg of ingested iron is normally absorbed from the small intestine daily. The rate of iron absorption is regulated by the amount of iron already stored in the body and by the rate of erythrocyte production. Additional amounts of iron, up to 2 mg daily, must be absorbed by women of childbearing age to replace that lost during menstruation. Total body iron content in the average adult is approximately 3 to 4 g. The majority of iron stores (2 to 3 g) is carried in hemoglobin. The remainder of iron is stored in hepatocytes and macrophages, with a small portion stored in other proteins (ferroproteins) (Ganz & Nemeth, 2012a, 2012b).

The concentration of iron in blood is normally about 75 to 175 μg/dL (13 to 31 μmol/L) for men and 65 to 165 μg/dL (11 to 29 μmol/L) for women. With iron deficiency, bone marrow iron stores are depleted rapidly; hemoglobin synthesis is depressed, and the erythrocytes produced by the marrow are small and low in hemoglobin. This is known as *microcytic anemia* (characterized by small RBCs). Part of a standard complete blood count (CBC) includes the mean corpuscular volume (MCV), which measures the size of the RBCs. In microcytic anemia, a small (less than 82 μm^3) MCV is seen. Causes of microcytic anemia include iron deficiency related to dietary inadequacy, malabsorption, increased iron loss (blood loss), and increased iron requirements (Fischbach & Dunning, 2014, p. 99). In the adult, lack of dietary iron is rarely the sole cause of iron deficiency anemia. Iron deficiency in the adult generally indicates that blood has been lost from the body (e.g., most commonly from bleeding in the GI tract or heavy menstrual

flow). The source of iron deficiency should be investigated promptly because iron deficiency in an adult may be a sign of bleeding in the GI tract or colon cancer.

Vitamin B_{12} and Folic Acid Metabolism. Vitamin B_{12} and folic acid are required for the synthesis of DNA in many tissues. Deficiencies of either of these vitamins have a significant impact on erythropoiesis. Both vitamin B_{12} and folic acid are derived from the diet and depend on a functioning intestinal mucosa for absorption. Vitamin B_{12} combines with intrinsic factor produced in the stomach and is absorbed in the distal ileum.

Nursing Alert
It is important for nurses to recall that patients who have had a partial or total gastrectomy may have limited amounts of intrinsic factor, and, therefore, the absorption of vitamin B_{12} may be diminished, leading to anemia. The effects of either decreased absorption or decreased intake of vitamin B_{12} may not be apparent for 2 to 4 years.

Red Blood Cell Destruction

Aged erythrocytes lose their elasticity and become trapped in small blood vessels and the spleen. They are removed from the blood by the reticuloendothelial cells, particularly in the liver and the spleen. As the erythrocytes are destroyed, most of their hemoglobin is recycled. Some hemoglobin also breaks down to form bilirubin and is secreted in the bile. Most of the iron is recycled to form new hemoglobin molecules within the bone marrow; small amounts are lost daily in the feces and urine and monthly in menstrual flow.

Leukocytes (White Blood Cells)

Leukocytes are divided into two general categories: granulocytes and agranulocytes. In normal blood, the total leukocyte count is 5,000 to 10,000 cells per cubic millimeter. Of these, approximately 60% to 70% are granulocytes, and 30% to 40% are lymphocytes. Both of these types of leukocytes protect the body against infection and tissue injury.

Granulocytes

Granulocytes are defined by the presence of granules in the cytoplasm of the cell. Granulocytes are divided into three main subgroups (see Fig. 19-2): eosinophils, basophils, and neutrophils. Neutrophils are the most numerous cells of this class. Neutrophils are also called *polymorphonuclear neutrophils* (PMNs, or polys) or *segmented neutrophils* (segs).

The nucleus of the mature neutrophil has multiple lobes (usually two to five), or a "segmented" nucleus. The immature granulocyte has a single-lobed, elongated nucleus and is called a band cell. Ordinarily, band cells account for only a small percentage of circulating granulocytes, although their percentage can increase greatly under conditions in which neutrophil demand increases, such as infection. An increased number of band cells is sometimes called bandemia. A patient with bandemia should be evaluated thoroughly for infection.

Fully mature neutrophils result from the gradual differentiation of myeloid stem cells, specifically myeloid blast cells. The process, called myelopoiesis, takes an average of 10

days (see Fig. 19-1). Once the neutrophil is released into the circulation from the marrow, it stays there for only about 6 hours before it migrates into the body tissues to perform its function of phagocytosis (ingestion and digestion of bacteria and particles; Fig. 19-3). Here, neutrophils survive no more than 1 to 2 days before they die.

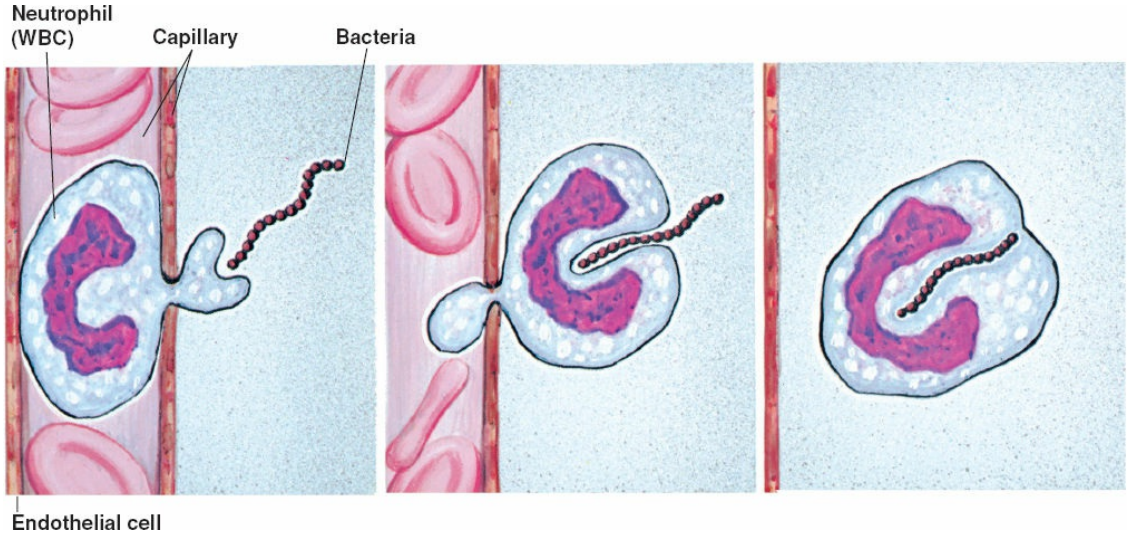

FIGURE 19-3 Phagocytosis. In order for phagocytosis to occur, a foreign body (such as bacteria, parasites, or cellular debris) must adhere to the cell wall of the phagocyte. The phagocyte then extends around the foreign body by projecting out pseudopods, engulfing the foreign body. Once inside the phagocyte, the engulfed material is left in a vacuole, where enzymes within the cell destroy the foreign material.

Eosinophils play a key role in response to parasitic and allergic diseases. The presence of certain microbes (such as parasites) results in the release of the granular contents of the eosinophil, allowing for destruction and phagocytosis of the organism.

Basophils are the least numerous of the circulating leukocytes and have characteristically large, dark-purple granules. The granules contain heparin and histamine and are released in response to exposure to allergens.

The number of circulating granulocytes found in the healthy person is relatively constant. An elevation in the total number of WBCs may indicate infection, trauma, tissue injury, or malignancy (such as leukemia), or it may be a side effect of certain medications, such as corticosteroids. A WBC count that is below normal may be related to viral infections, the result of side effects from medications such as antiviral medications, or may hint of a more serious condition, such as leukemia or myelodysplastic syndrome (MDS).

Agranulocytes

Monocytes and lymphocytes are leukocytes with granule-free cytoplasm—hence the term *agranulocyte* (see Fig. 19-2).

Monocytes

Monocytes (also called *mononuclear leukocytes*) have a single-lobed nucleus. They are the largest of the leukocytes. In normal adult blood, monocytes account for approximately 5% of the total leukocyte count. When released from the marrow, monocytes spend a short time in the circulation (approximately 24 hours) and then enter the body tissues. Within

the tissues, the monocytes continue to differentiate into macrophages, which can survive for months. Macrophages are particularly active in the spleen, liver, peritoneum, and alveoli; they remove debris from these areas and phagocytize bacteria within the tissues (see discussion of the Reticuloendothelial System on page 563).

Lymphocytes

Mature lymphocytes are small cells with scanty cytoplasm (see Fig. 19-2). Immature lymphocytes are produced in the marrow from the lymphoid stem cells. A second major source of production is the cortex of the thymus. Cells derived from the thymus are known as T lymphocytes (or T cells); those derived from the marrow can also be T cells but are more commonly B lymphocytes (or B cells). Lymphocytes complete their differentiation and maturation primarily in the lymph nodes and in the lymphoid tissue of the intestine and spleen after exposure to a specific antigen. Mature lymphocytes are the principal cells of the immune system, producing antibodies and identifying other cells and organisms as foreign.

Function of Leukocytes

Granulocytes protect the body from invasion by bacteria and other foreign entities. Neutrophils arrive at a given site within 1 hour after the onset of an inflammatory reaction and initiate phagocytosis, but they are short lived. An influx of monocytes follows; these cells continue their phagocytic activities for long periods as macrophages. This process constitutes a second line of defense for the body against inflammation and infection. Although neutrophils often can work adequately against bacteria without the help of macrophages, macrophages are particularly effective against fungi and viruses.

The primary function of lymphocytes is to produce substances that aid in attacking foreign material. T lymphocytes kill foreign cells directly or release a variety of *lymphokines*, substances that enhance the activity of phagocytic cells. T lymphocytes are responsible for delayed allergic reactions, rejection of foreign tissue (e.g., transplanted organs), and destruction of tumor cells. This process is known as *cellular immunity.* B lymphocytes are capable of differentiating into plasma cells. Plasma cells, in turn, produce antibodies called immunoglobulin (Ig), which are protein molecules that destroy foreign material. This process is known as *humoral immunity.*

Both eosinophils and basophils are active in allergic reactions. For example, a patient with an allergic rash may have an elevated eosinophil count (Fischbach & Dunning, 2014, p. 76). Eosinophils also have a role in the destruction of parasites.

Platelets (Thrombocytes)

Platelets, or thrombocytes, are not technically cells; rather, they are granular fragments of giant cells in the bone marrow, called *megakaryocytes*. Platelet production in the marrow is regulated in part by the hormone thrombopoietin, which stimulates the production and differentiation of megakaryocytes from the myeloid stem cell.

Platelets play an essential role in the control of bleeding (hemostasis). They circulate freely in the blood in an inactive state, where they nurture the endothelium of the blood vessels, maintaining the integrity of the vessel. When vascular injury occurs, platelets collect at the site and are activated. They adhere to the site of injury and to each other, forming a

platelet plug that temporarily stops bleeding. Substances released from platelet granules activate coagulation factors in the blood plasma and initiate the formation of a stable clot composed of fibrin, a filamentous protein.

Plasma and Plasma Proteins

After cellular elements are removed from blood, the remaining liquid portion is called *plasma*. More than 90% of plasma is water. The remainder consists primarily of plasma proteins, clotting factors (particularly fibrinogen), and small amounts of other substances such as nutrients, enzymes, waste products, and gases. If plasma is allowed to clot, the remaining fluid is called serum. Serum has essentially the same composition as plasma, except that fibrinogen and several clotting factors have been removed in the clotting process.

Plasma proteins consist primarily of albumin and the globulins. The globulins can be separated into three main fractions (alpha, beta, and gamma), each of which consists of distinct proteins that have different functions. Important proteins in the alpha and beta fractions are the transport globulins and the clotting factors that are made in the liver. The transport globulins carry various substances in bound form in the circulation. For example, thyroid-binding globulin carries thyroxin, and transferrin carries iron. The clotting factors, including fibrinogen, remain in an inactive form in the blood plasma until activated by the clotting cascade. The gamma globulin fraction refers to the immunoglobulins, or antibodies. These proteins are produced by the well-differentiated lymphocytes and plasma cells. The actual fractionation of the globulins can be measured on a specific laboratory test (serum protein electrophoresis or SPEP).

Albumin is particularly important for the maintenance of fluid balance within the vascular system. Capillary walls are impermeable to albumin, so its presence in the plasma creates an osmotic force that keeps fluid within the vascular space. Albumin, which is produced by the liver, has the capacity to bind to several substances that are transported in plasma (e.g., certain medications, calcium, bilirubin, and some hormones). People with poor liver function may have low concentrations of albumin with a resultant decrease in osmotic pressure and the development of edema.

Reticuloendothelial System

The reticuloendothelial system (RES) (also called the *mononuclear phagocytic system*, or MPS) is a system of phagocytic cells, including monocytes and macrophages. The RES is divided into primary and secondary lymphoid systems. The primary lymphoid system is the site of RES cell production and includes the bone marrow and thymus. The secondary lymphoid system is the site of RES cell function and includes the liver, spleen, and lymph nodes. In the liver, spleen, lymph nodes, and other areas throughout the body, these cells function to recognize foreign cells and trigger an immune response.

The spleen has a number of additional functions, including recycling of iron, pooling of platelets, and blood volume regulation. It also acts as a filter for bacteria. In addition, the spleen is a major source of fetal hematopoiesis. It can resume hematopoiesis later in adulthood if necessary, particularly when marrow function is compromised (e.g., in bone marrow fibrosis, also known as myelofibrosis).

Hemostasis

Hemostasis refers to prevention of blood loss from intact vessels as well as the termination of bleeding when blood vessels are damaged. The prevention of blood loss from intact vessels requires adequate numbers of functional platelets. Platelets nurture the endothelium and thereby maintain the structural integrity of the vessel wall. Two processes are involved in arresting bleeding: primary hemostasis and secondary hemostasis (Fig. 19-4).

In primary hemostasis, the severed blood vessel constricts. Von Willebrand factor (vWf) binds to the collagen exposed on the damaged vessel and creates a binding site for platelets (DeLoughery, 2015b). Acting as the "glue" between platelets and the damaged vessel (Israels, 2015, p. 23), vWf also carries factor VIII to the vessel to assist in fibrin clot formation.

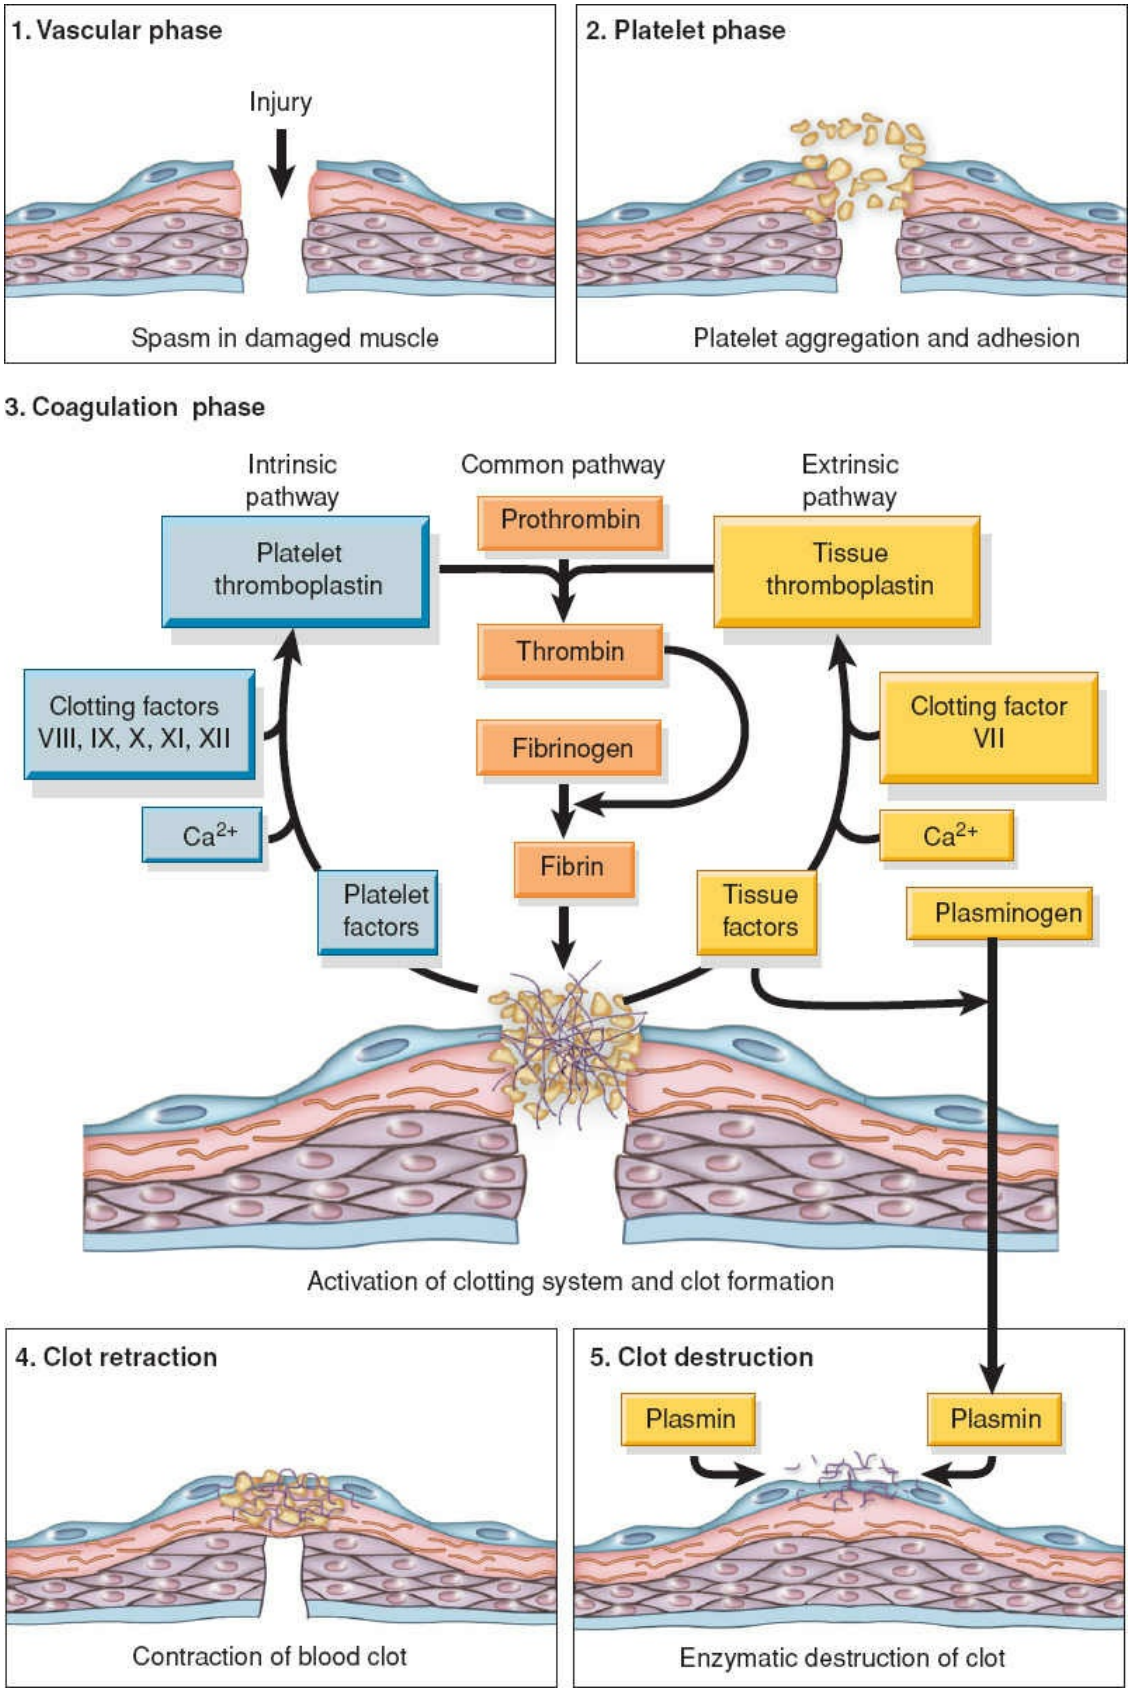

FIGURE 19-4 Hemostasis. When the endothelial surface of a blood vessel is injured, several processes occur. In primary hemostasis, platelets within the circulation are attracted to the exposed layer of collagen at the site of injury. They adhere to the site of injury, releasing factors that stimulate other platelets to aggregate at the site, forming an unstable platelet plug. In secondary hemostasis, based on

the type of stimulus, one of two clotting pathways is initiated—the intrinsic or extrinsic pathway—and the clotting factors within that pathway are activated. The end result from either pathway is the conversion of prothrombin to thrombin. Thrombin is necessary for fibrinogen to be converted into fibrin, the stabilizing protein that anchors the fragile platelet plug to the site of injury to prevent further bleeding and permit the injured vessel or site to heal. (Modified from www.irvingcrowley.com/cls/clotting.gif.)

For the coagulation process to be activated correctly, circulating inactive coagulation factors must be converted to active forms. This process occurs on the surface of the aggregated platelets at the site of vessel injury. The end result is the formation of fibrin, which reinforces the platelet plug and anchors it to the injury site. This process is termed *secondary hemostasis*.

The process of blood coagulation is highly complex. It can be activated by the intrinsic or the extrinsic pathway. Both pathways are needed for maintenance of normal hemostasis.

Many factors are involved in the coagulation cascade that forms fibrin. When tissue is injured, the extrinsic pathway is activated by the release of thromboplastin from the tissue. As the result of a series of reactions, prothrombin is converted to thrombin, which, in turn, catalyzes the conversion of fibrinogen to fibrin.

Clotting by the intrinsic pathway is activated when the collagen that lines blood vessels is exposed. Clotting factors are activated sequentially until, as with the extrinsic pathway, ultimately fibrin is formed.

As the injured vessel is repaired and again covered with endothelial cells, the fibrin clot is no longer needed. The fibrin is digested via two systems: the plasma fibrinolytic system and the cellular fibrinolytic system. The substance plasminogen is required to lyse (break down) the fibrin. Plasminogen, which is present in all body fluids, circulates with fibrinogen and, therefore, is incorporated into the fibrin clot as it forms. When the clot is no longer needed (e.g., after an injured blood vessel has healed), the plasminogen is activated to form plasmin. Plasmin digests the fibrinogen and fibrin. The by-products of clot digestion, called *fibrin degradation products*, are released into the circulation. Through this system, clots are dissolved as tissue is repaired, and the vascular system returns to its normal baseline state.

Gerontologic Considerations

In elderly patients, the bone marrow's ability to respond to the body's need for blood cells (erythrocytes, leukocytes, and platelets) may be decreased. This decreased ability is a result of many factors, including diminished production of the growth factors necessary for hematopoiesis by stromal cells within the marrow or a diminished response to the growth factors (in the case of erythropoietin). In addition, in elderly patients, the bone marrow may be more susceptible to the myelosuppressive effects of medications. As a result of these factors, when an elderly person needs more blood cells (e.g., leukocytes in infection, erythrocytes in anemia), the bone marrow may not be able to increase production of these cells adequately. Leukopenia (a decreased number of circulating leukocytes), thrombocytopenia (a decrease in the platelet count), and/or anemia can result.

Anemia is the most common hematologic condition affecting elderly patients; with each successive decade of life, the incidence of anemia increases. Anemia frequently results from iron deficiency (in the case of blood loss) or from a nutritional deficiency, particularly folate or vitamin B_{12} deficiency or protein–calorie malnutrition; it may also result from inflammation, chronic disease such as an underlying malignancy, or alcohol abuse. Management of the disorder varies, depending on the etiology. Therefore, it is important to identify the cause of the anemia rather than to consider it an inevitable consequence of aging. Elderly people with concurrent cardiac or pulmonary problems may not tolerate anemia well, and a prompt, thorough evaluation is always warranted.

ASSESSMENT AND DIAGNOSTIC EVALUATION

Most hematologic diseases reflect a defect in the hematopoietic or hemostatic systems, or in the RES. The defect can be quantitative (e.g., increased or decreased production of cells), qualitative (e.g., the cells that are produced are not functioning normally), or both.

Many hematologic conditions lack symptoms initially. Therefore, an extensive history and laboratory tests are used to determine a diagnosis. For many hematologic conditions, continued monitoring of laboratory results over time is essential to establish trends. Trends help to establish the acuity of the condition and also help to assess the response to interventions.

Hematologic Studies

The most common tests used to assess bone marrow function are the CBC and the peripheral blood smear (PBS). Blood for both the CBC and PBS is typically obtained by venipuncture. The CBC identifies the total number of blood cells (leukocytes, erythrocytes, and platelets) as well as the hemoglobin, hematocrit (percentage of blood volume consisting of erythrocytes), and RBC indices (Table 19-2). Because cellular morphology (shape and appearance of the cells) is particularly important in most hematologic disorders, the blood cells involved must be examined. This process is referred to as the *manual examination of the peripheral smear*. In this test, a drop of blood is spread on a glass slide, stained, and examined under a microscope. Visualizing the shape and size of the leukocytes, erythrocytes, and platelets provides useful information in identifying hematologic conditions. Increases or decreases in any one parameter of the CBC may indicate a hematologic disorder and indicate the need for further testing (refer to Chapter 20). However, an abnormal CBC should always be assessed relative to the patient's baseline; up to 5% of the general population may have labs outside of the normal limits in the absence of disease. In addition, people of African descent may have lower Hgb, WBC, neutrophil and platelet counts (Tefferi et al., 2005; Fischbach & Dunning, 2014). Nurses must be familiar with the normal CBC parameters and be aware of potential implications of hematologic alterations.

Nursing Alert

A falsely elevated hematocrit is noted in conditions of fluid volume loss (such as dehydration). Since no single test confirms hemoconcentration, the nurse must assess for signs of fluid deficit, such as weight loss, dry mucous membranes, delayed skin turgor, orthostatic hypotension, decreased pulse pressure (the difference between the systolic and diastolic pressure), decreasing urinary output with elevated urine specific gravity, and vital sign changes (increasing heart rate and decreasing blood pressure as volume is lost). Regardless of the etiology, a hematocrit of greater than 60% is associated with spontaneous clotting (Fischbach & Dunning, 2014, p. 91). Likewise, in times of hemodilution (i.e., fluid gain), a falsely lower hematocrit is noted. The nurse assesses for weight gain, moist mucous membranes, edema, hypertension, crackles in the lung fields, an S_3 gallop over the mitral area, increased urinary output with decreased specific gravity, and distended neck veins. A hematocrit of less than 20% is associated with increased risk of cardiac failure and death (Fischbach & Dunning, 2014, p. 91).

TABLE 19-2 Normal Complete Blood Count with Differential

Example: 42-Year-Old Caucasian Man[a]		
Tests	**Normal Reference Range**	**Case Example**
WBC	5,000–10,000/μL Absolute neutrophil count >1,800/μL	5,300/μL
Segments	38–71% of total WBC	61%
Bands	0–10% of total	5%
Monocytes	2–15% of total	11%
Basophils	0–1% of total	0%
Eosinophils	0–5% of total	1%
Lymphocytes	20–40% of total	22%
Hemoglobin	Male: 14–18 g/dL Female: 12–16 g/dL	17 g/dL
Hematocrit	Male: 40–52% Female: 37–47%	51%
Red blood cells (RBCs)	Male: 4.5–5.5 × 10^6/mm^3 Female: 3.8–5.2 × 10^6/mm^3	5 × 10^6/mm^3
RBC distribution width (%)	Male: 11.8–15.6% Female: 11.9–15.5%	12%
Mean corpuscular volume (MCV)	Male: 81–101.4 (fL) Female: 81.1-99.8 (fL)	90 fL
Mean corpuscular hemoglobin (MCH)	28–34 pg/cell	30 pg/cell
Mean corpuscular hemoglobin concentration (MCHC)	32–36 g/dl	32 g/dL
Platelets	150–400,000/mm^3	200,000/mm^3
Mean Platelet Volume	7.4–10.3 fL	8 fL

[a]People of African ancestry may have lower WBC, neutrophil and platelet counts.
Fischbach and Dunning (2014).

Assessing the Patient with Low Hemoglobin and Hematocrit

Patients with mildly to moderately lowered hemoglobin and hematocrit levels may be asymptomatic due to effective compensatory mechanisms. However, a careful history may uncover the following: progressive fatigue, poor activity tolerance, headaches, dizziness, irritability, difficulty sleeping or concentrating, tinnitus, anorexia, dyspnea, palpitations, chest pain, indigestion, abnormal menstruation in females, impotence in males, and loss of libido. On physical examination, pallor is the most common and obvious sign of anemia. Pallor can be most easily assessed in the oral mucous membranes, nail beds, conjunctiva, and creases of the palms. Other findings may include tachypnea, tachycardia and flow murmurs, and hypotension. Tachypnea and tachycardia may be seen with activity. Patients with hemolytic anemia may exhibit jaundice and splenomegaly.

Assessing the Patient with a Low White Blood Cell Count

When assessing a patient with low WBC count, the nurse must examine the WBC differential to see which type of WBC is low. The myeloid and/or lymphoid lines may be low. However, the most critical factors influencing an individual's risk for infection are the severity and duration of neutropenia. Nurses caring for a patient with a low WBC count should calculate the absolute neutrophil count (ANC; Box 19-1). Neutropenia severity is classified using the following guidelines:

- ANC 1,500 to 1,000/mm^3 indicates mild neutropenia;
- ANC 999 to 500/mm^3 indicates moderate neutropenia;
- ANC of less than 500/mm^3 indicates severe neutropenia.

BOX 19-1 Calculating the Absolute Neutrophil Count (ANC)

Normally, the neutrophil count is greater than 2,000/mm^3. The actual (or absolute) neutrophil count (ANC) is calculated using this formula:

$$\text{Total WBC} \times [\%\text{segs} + \%\text{bands}] = \text{ANC}$$

For example, if the total white blood cell (WBC) count is 3,000/mm^3 with 72% neutrophils and 3% bands, the ANC would be calculated as follows:

$$3{,}000 \times [72\% + 3\%] = 2{,}250/mm^3$$

This result is not indicative of neutropenia because the ANC is greater than 1,000/mm^3 despite the low total WBC count (3,000/mm^3).

Conversely, in the following example, neutropenia is evident despite a normal WBC count (5500/mm^3) with 8% neutrophils and 0% bands:

$$5{,}500 \times [8\% + 0\%] = 440/mm^3$$

Here, the ANC is severely low (440/mm^3) despite the normal total WBC count (5,500/mm^3).

When evaluating neutropenia, it is important to calculate the ANC and not to rely solely on the total WBCs and percentage of neutrophils alone.

Patients with severe neutropenia are at significantly increased risk for developing opportunistic infections and sepsis. The most common sites of infection in neutropenic patients include the respiratory tract, GI and GU tracts, and the skin (Vioral & Wentley, 2015). Patients with neutropenia must be assessed carefully for the following:

- *Skin*: Check for tenderness, erythema, edema, breaks in skin integrity, moisture, drainage, lesions (especially under breasts, axillae, groin, skin folds, bony prominences, perineum, and perirectum); check all puncture sites (e.g., IV sites) and central venous access device sites for erythema, tenderness, induration, and drainage.
- *Oral mucosa*: Check for moisture, lesions, color (check palate, tongue, buccal mucosa, gums, lips, oropharynx); assess level of pain and taste changes, which may precede objective signs of mucosal damage by 3 to 5 days.
- *Respiratory*: Check for presence of cough, sore throat, tachypnea, pain on inspiration; auscultate breath sounds. Note color, amount, and consistency of sputum.
- *Gastrointestinal*: Check for abdominal discomfort and distention by palpating the abdomen, assess for nausea, change in bowel pattern; auscultate bowel sounds.
- *Genitourinary*: Check for dysuria, urgency, frequency; check urine for color, clarity, and odor.
- *Neurologic*: Ask about headache, neck stiffness, visual disturbances; assess level of consciousness, orientation, and behavior.
- *Temperature*: Check for elevation (greater than 38°C [greater than 100.4°F]).

Often patients with neutropenia are not able to manifest the classic signs of infection, such as pus, because pus is comprised of WBCs. Signs of infection may be subtle; therefore, the presence of fever may be the only sign that the patient has an infection and should be addressed immediately.

Nursing Alert

Agranulocytosis or marked neutropenia and leukopenia place the patient at significant risk for infection. The nurse is aware that handwashing is critical to prevent infection (Bossaer & Cluck, 2013). Strict reverse isolation procedures, such as the use of mask, gown, and gloves to prevent infection, have not been demonstrated to decrease infection rates and are no longer routinely implemented (Vioral & Wentley, 2015). Patients should be cautioned to avoid large crowds and sick contacts. See Chapter 6 for further discussion.

Assessing the Patient at Risk for Bleeding

Assessment of bleeding risk should include a thorough examination of bleeding history, family history, laboratory tests, and a thorough physical examination (Stasi, 2012; Israels,

2015). The strongest predictor of bleeding risk is a history of bleeding (DeLoughery, 2015c). Assessment of bleeding history should include questions about frequency and severity of nosebleeds; bleeding with dental work, both immediate and delayed; bleeding with surgery and need for blood transfusions; bruising; length of menstrual periods, need for iron replacement due to heavy menses, excessive bleeding with childbirth necessitating blood transfusion; blood in stool or urine; and gum bleeding (DeLoughery, 2015c). History of mucocutaneous bleeding may signal inherited or acquired defects in platelet number or function, or von Willebrand disease (vWd) (Israels, 2015). The patient may report easy bruising, bleeding gums, and frequent nosebleeds (DeLoughery, 2015c). In comparison, patients with coagulation factor defects, such as hemophilia, are more likely to experience muscle and joint bleeding (DeLoughery, 2015c). Coagulation problems result in bleeding that is excessive (DeLoughery, 2015c). For example, patients with hemophilia may bleed for several hours after a minor procedure (DeLoughery, 2015).

Family history of bleeding is also important. Hemophilias A (factor VIII deficiency) and B (factor IX deficiency) are inherited and sex linked; family history should include questioning of bleeding in brothers, male cousins, and uncles (DeLoughery, 2015c).

Laboratory Tests to Assess Type of Bleeding Defect

Patients with a bleeding history should have a CBC, peripheral blood smear (PBS), prothrombin time and International Normalized Ratio (PT/INR), partial thromboplastin time (PTT), and assessment of platelet function assay-100 (PFA-100) (DeLoughery, 2015b). Testing for vWd should also be considered if the patient has a low platelet count (Israels, 2015).

A CBC and PBS are performed to assess platelet count, size, and shape. The presence of schistocytes on PBS suggests disseminated intravascular coagulation (DIC) or thrombotic thrombocytopenia purpura (TTP); these must be ruled out as they require prompt intervention. See Chapter 20 for further discussion (Stasi, 2012).

Pseudothrombocytopenia may occur as a result of platelet clumping when collected in Ethylenediaminetetraacetic acid (EDTA); recollecting a sample in a citrate-based anticoagulant will provide an accurate platelet count (Stasi, 2012; Israels, 2015).

Bleeding may be due to a decrease in platelet number or function (Stasi, 2012). A decrease in platelet number does not exclude the possibility of platelet dysfunction. Some of the inherited platelet disorders are marked by both a decrease in platelet number and abnormal function (Israels, 2015). The Platelet Function Assay (PFA)-100 test is a screening tool for primary hemostasis and assesses platelet function (Francis et al., 1999; Fischbach & Dunning, 2014). An abnormal result suggests a problem with platelet function.

Thrombocytopenia severity can be described as follows: excess bleeding that may occur as a result of injury, trauma, or surgery, with a platelet count of 50,000 to 100,000/mm^3; platelet counts of 20,000/mm^3 or less increase the risk for spontaneous bleeding; and platelet counts of 10,000/mm^3 or less are associated with serious episodes of spontaneous bleeding, including intracranial hemorrhage. Bleeding precautions are recommended for patients with a platelet count of less than 50,000/mm^3. The nursing care and patient education required to safely care for patients with thrombocytopenia are outlined in Box 19-2.

BOX 19-2 Nursing Interventions for Patients with Thrombocytopenia (Platelet Co 50,000/mm^3)

Prevent Complications: Implement Bleeding Precautions

- Avoid giving aspirin and aspirin-containing medications or other medications known to inhibit platelet function (NSAIDs), if possible.
- Assess for use of herbal medications, such as *Ginkgo biloba*, which can predispose the patient to bleeding.
- Do not give intramuscular injections.
- Do not insert indwelling catheters.
- Do not use the rectal route for taking temperatures or administering medications.
- Use stool softeners and oral laxatives to prevent constipation.
- Use the smallest possible needles when performing venipuncture.
- Apply pressure to venipuncture sites for 5 minutes or until bleeding has stopped.
- Use only soft-bristled toothbrush for mouth care.
- Do not permit wearing of restrictive clothing; avoid tourniquets or overinflation of blood pressure cuffs.
- Lubricate lips with water-soluble lubricant every 2 hours while patient is awake.
- Avoid suctioning if at all possible; if unavoidable, use only gentle suctioning.
- Discourage vigorous coughing or blowing of the nose.
- Use only electric razor for shaving.
- Pad side rails as needed.
- Prevent falls by ambulating with patient as necessary and keeping the environment safe.
- Teach patient to avoid contact sports and sports with risk for falling or injury (such as biking or roller-blading).
- Teach patient to avoid sexual intercourse (both vaginal and anal) until platelet count is over 50,000/mm^3.
- Hematest secretions and excretions for occult blood for early identification of internal bleeding.

Control Bleeding

- Apply direct pressure.
- Use manual pressure with gauze over the source of bleeding.
- For epistaxis, position patient in high Fowler position with body tilted forward and the mouth open so that the blood can be spit out instead of swallowed; apply ice pack to the bridge of the nose and direct pressure to nose.
- Hemostatic agents such as thromboplastin, absorbable gelatin, fibrin sealants,

collagen, and alginate can be used for hemostasis at wound sites and central venous access device sites that are bleeding.

- Notify health care provider for prolonged bleeding (e.g., unable to stop within 10 minutes).
- Administer platelets, fresh-frozen plasma, and/or packed red blood cells as prescribed.

Adapted from Doenges (2016).

PT measures the time needed for factor VIIa to form a complex with tissue factor and form a clot (DeLoughery, 2015b). Prolongation/elevation of the PT alone often indicates a factor VII deficiency. In the past, PT was used to monitor response to warfarin therapy; however, due to laboratory variations, a more consistent way to monitor response to warfarin is the INR. The INR is a method of standardizing PT times obtained from different labs (DeLoughery, 2015b). INR is calculated by dividing the PT by the control and then applying the International Sensitivity Index, which adjusts the PT for the differing sensitivities of reagents by laboratory (DeLoughery, 2015b). Use of INR has resulted in more accurate monitoring of warfarin use.

Elevation of the PTT may indicate a deficiency in Factor VIII, IX, or XI. Prolongation of both the PT and PTT may indicate a deficiency in factor X, II, or V, or a combination of deficits in these factors (DeLoughery, 2015).

A thorough physical examination can be very useful in determining the source of the hemostatic defect. Abnormalities of the vascular system give rise to local bleeding, usually into the skin. Because platelets are primarily responsible for hemostasis in small vessels, patients with platelet defects develop petechiae (see Fig. 19-5), often in clusters; these are most often seen first on the extremities and then the mucous membranes. With prolonged thrombocytopenia, petechiae may also be seen on the trunk.

Other pertinent assessment findings include ecchymoses or hematomas, conjunctival hemorrhages, bleeding gums, bleeding at puncture sites (venipuncture); hypotension, tachycardia, dizziness, epistaxis (nosebleed); respiratory distress, tachypnea, hemoptysis (coughing of blood); abdominal or back pain, hematemesis (vomiting blood), abdominal distention, rectal bleeding; vaginal or urethral bleeding; and headache, blurred vision, and mental status changes.

Nursing Alert

Because of the risk of spontaneous intracranial bleeding, patients with very severe thrombocytopenia (platelet count below 10,000/mm³) must be monitored closely for subtle changes in mental status, including irritability and restlessness, and educated to report even mild headaches immediately.

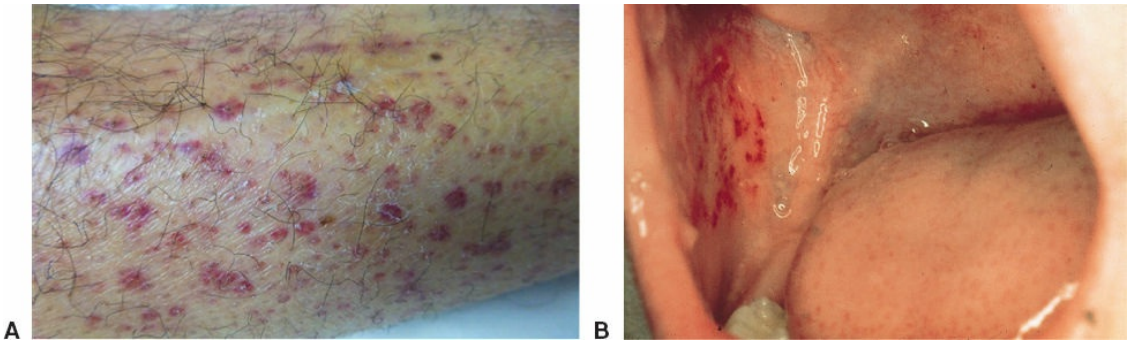

FIGURE 19-5 Petechiae of limb and oral cavity. (Laurin Council, M., Sheinbein, D. M., Cornelius, L. A. *The Washington Manual of Dermatology Diagnostics*. Sharon Jensen, Nursing Health Assessment.)

In contrast to platelet defects, coagulation factor defects do not tend to cause superficial bleeding because the primary hemostatic mechanisms are still intact. Instead, bleeding occurs deeper within the body (e.g., subcutaneous or intramuscular hematomas, hemorrhage into joint spaces). Because of this bleeding, the patient may report joint pain.

External bleeding diminishes very slowly when local pressure is applied; it often recurs several hours after pressure is removed. For example, severe bleeding may start several hours after a tooth extraction.

Bone Marrow Aspiration and Biopsy

The bone marrow aspiration and biopsy are indicated to further assess the underlying cause of an abnormal CBC, when additional information is needed to assess the quantity and quality of each type of cell produced within the marrow. Bone marrow aspiration and biopsy are used in the diagnosis and classification of malignancies, benign hematologic disorders, infections, and storage disorders, as well as for assessment of response to treatment (Jackson, Guinigundo, & Waterhouse, 2012; Fischbach & Dunning, 2014; Malempati, Joshi, Lai, Braner, & Tegtmeyer, 2009 [The later reference is a video of a Bone Marrow Aspiration and Biopsy video]).

For example, a patient with an abnormal CBC undergoes a bone marrow biopsy and aspirate with results revealing acute myeloid leukemia. After receiving chemotherapy to treat the leukemia, another bone marrow aspirate and biopsy are done to assess response to treatment; if the treatment was effective, no leukemia cells should be seen in the biopsy or aspirate specimens.

Normal bone marrow is in a semifluid state and can be aspirated through a special hollow core, large-bore needle. In adults, bone marrow is usually aspirated from the posterior iliac crest. The aspirate provides a sample of cells. Aspirate alone may be adequate for evaluating certain conditions, such as anemia. However, in most cases, a biopsy is also performed. Biopsy samples are taken from the posterior iliac crest; occasionally, an anterior iliac approach is required. The sternum can be used to obtain an aspirate but should not be used to obtain a biopsy because of its proximity to vital organs. A bone marrow biopsy shows the architecture of the bone marrow as well as its degree of cellularity.

The first step in the procedure is obtaining informed consent. Informed consent is obtained by the physician, nurse practitioner, or physician's assistant performing the procedure and includes the reason the procedure is being performed, alternatives, and risks of the procedure. Risks include infection, bleeding, and pain. The risk for bleeding is somewhat increased if the patient's platelet count is low (less than 20/mm^3) or if the patient has been taking a medication (e.g., aspirin) that alters platelet function. Rare, serious complications include trauma to nearby structures, such as the gluteal artery, retroperitoneal hematomas, and fractures of the underlying bone. Fortunately these complications are very rare (incidence less than 1% [0.05 to 0.07% in two studies]) (Malempati et al., 2009; Zehnder, 2015).

Most adult patients need no more preparation than a careful explanation of the procedure and the sensations that will be experienced, but for some very anxious patients, administration of an antianxiety agent, such as lorazepam, may be useful. Pediatric patients usually require deeper sedation. Though this procedure is potentially painful, generous local anesthesia and a skilled operator minimize the risk for discomfort.

After informed consent is obtained, the patient is assisted to either a prone or lateral decubitus position. The skin is cleansed using aseptic technique and either a chlorhexidine-based solution or povidone-iodine. A sterile drape is applied; then the skin is numbed using local anesthesia. The periosteum, which contains many nerve endings, is numbed next. The bone itself cannot be numbed. An aspirate needle is inserted with a stylet in place through the numbed skin into the cortical bone through to the marrow; when the needle is felt to go through the outer cortex of bone and into the marrow cavity, the stylet is removed, a

syringe is attached, and a small volume (10 to 20 mL) of marrow is aspirated (this is often referred to as the aspirate sample). Patients typically feel a sensation of pressure as the needle is advanced into position. The aspiration of fluid causes a sudden and sharp but brief pain, resulting from the suction exerted as the marrow is aspirated into the syringe; the patient should be warned about this. Taking deep breaths or using relaxation techniques often helps ease the discomfort.

Once the aspirate sample is obtained, the aspirate needle is removed and then a longer hollow core needle with stylet is inserted through the same hole in the skin. A drilling motion is used to advance the needle through the cortical bone; once the needle is anchored into the cortical bone, the stylet is removed and the hollow needle is advanced into the marrow to a depth of 2 to 3 cm (Fischbach & Dunning, 2014; Malempati et al., 2009). Next the needle is turned clockwise and then counterclockwise several times to help loosen the specimen; the needle is carefully removed revealing a solid core specimen of bone and bone marrow inside the hollow needle. A probe is used to gently push the specimen out of the needle and into a specimen container. During the biopsy, the patient may feel pressure but should not feel pain; if the patient experiences pain radiating down the leg, repositioning of the needle may be necessary.

After the marrow sample is obtained, pressure is applied to the site for several minutes. Then the site is covered with a sterile dressing. Most patients have no discomfort after a bone marrow aspiration, but the site of a biopsy may ache for 1 or 2 days. Patients should be instructed not to submerge in a bath for 24 hours, until the site heals. A mild analgesic (e.g., acetaminophen) may be useful. Aspirin-containing analgesics should be avoided because of the increased risk of bleeding.

The nurses' role is to reinforce patient education pre- and postprocedure, provide emotional support during the procedure, assist the operator, and assess for pain and anxiety. The nurse also reviews postprocedure care with the patient, including keeping the site clean and dry for 24 hours and instructing the patient and family to call if any signs or symptoms of bleeding or infection develop (Fischbach & Dunning, 2014; Malempati et al., 2009).

The bone marrow aspirate and biopsy samples are evaluated by a pathologist who ultimately provides a summary of findings. The aspirate provides information on the cell type, size, shape, and number present in the marrow and also allows for specialized tests, including flow cytometry, cytogenetic studies, and molecular studies to be conducted, all of which help classify the bone marrow disorder. The bone marrow biopsy provides information on the cellularity of the marrow as well as the severity of disease or dysfunction; normal cellularity can be estimated based on the patient's age and subtracting the age from 100. For example, a 30-year-old woman should have a cellularity of 70%. Fewer cells than expected is referred to as hypocellular; more cells than expected is called hypercellular.

Unfolding Patient Stories: Lloyd Bennett • Part 1

Lloyd Bennett is a 76-year-old male who fell while working outdoors. He presents to the emergency department with a hip fracture. What physical assessment and laboratory data can assist the nurse in evaluation for possible internal blood loss from the fracture or indications that the patient is at higher risk of bleeding? (Lloyd Bennett's story continues in Chapter 26.)

Care for Lloyd and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in (thepoint.lww.com/DocuCareEHR).

CHAPTER REVIEW

Critical Thinking Exercises

1. You are caring for a patient with acute leukemia and sepsis who has a declining platelet count of 10,000/mm^3. On assessment, you observe oozing blood from the Hickman catheter site, petechiae to the upper and lower extremities, and epistaxis. What are the potential causes of this patient's bleeding? What other laboratory results would you assess? What further assessments would you perform? What nursing interventions would you implement? What medical interventions would you anticipate?

2. You are working in a hematology–oncology clinic. The laboratory reports a critical laboratory result for one of your patients presenting with possible acute leukemia: the leukocyte count is 1,200/mm^3 with 10% neutrophils. What other laboratory results would be important to review or consider? The patient is also anemic (hemoglobin 8.2 mg/dL), and platelets are 110,000/mm^3. What observations will you include in your assessment of this patient? Determine the extent to which this patient is neutropenic. What medical treatments would you anticipate? How would you educate the patient about neutropenia precautions? What information do you need to obtain about the patient's home setting that will assist you in determining the patient's risk of developing an infection at home? How will you modify this education if the patient has mild dementia? Lives alone? Does not understand or speak English well?

NCLEX-Style Review Questions

1. A nurse is caring for a patient who is 73 years old with a platelet count of 5,000/mm^3

resulting from myelodysplastic syndrome. At 10 PM, the patient complains of a headache. What should be the nurse's immediate action to take?

a. Administer aspirin per p.r.n. order.
b. Administer acetaminophen per p.r.n. order.
c. Notify the health care provider.
d. Administer a nonpharmacologic intervention, such as a cool compress.

2. A patient presents to her primary care provider with a complaint of a "cold that just won't go away." She has a CBC drawn, revealing the following: WBC 4.5: segs 5, bands 0, lymphs 45, eosinophils 5, basophils 5, monocytes 5, blasts 35. What is the patient's absolute neutrophil count?

a. 500
b. 250
c. 225
d. 2,250

3. What is the priority nursing diagnosis for a client experiencing anemia?

a. Risk for injury related to poor blood clotting
b. Fatigue related to decreased cellular oxygenation
c. Risk of infection related to decreased leukocytes
d. Imbalanced nutrition; less than body requirements related to anorexia

4. A patient with thrombocytopenia due to chemotherapy develops a nose bleed (epistaxis). What is the nurse's expected response?

a. Apply ice to the anterior surface of the nose and place the patient in a supine position
b. Apply pressure to the nares and position the patient in a high Fowler position, leaning slightly forward
c. Squeeze the nares together firmly and position the patient in prone position with mouth open
d. Ask the patient to blow the nose vigorously as the nurse applies firm pressure to the nares

5. The nurse recognizes this as the most common hematologic condition associated with aging.

a. Thrombocytopenia
b. Leukopenia
c. Agranulocytosis
d. Anemia

CHAPTER 20

Nursing Management: Patients with Hematologic Disorders

Lisa M. Barbarotta

Learning Objectives

After reading this chapter, you will be able to:

1. Differentiate between the different types of anemias and compare and contrast the physiologic mechanisms, clinical manifestations, medical management, and nursing interventions for each.
2. Compare the leukemia types in terms of incidence, physiologic alterations, clinical manifestations, management, and prognosis.
3. Discuss physiologic mechanisms, clinical manifestations, medical management and nursing interventions for myelodysplastic syndromes.
4. Discuss nursing management of patients with lymphoma and multiple myeloma.
5. Discuss nursing management of patients with bleeding or thrombotic disorders.
6. Identify therapies for blood disorders, including the nursing implications for the administration of blood components.

Hematologic disorders include both benign and malignant conditions. These disorders can impact every system in the body. Nursing care of these patients requires an understanding of the anatomy and physiology of hematopoiesis and immunology, as well as astute assessment skills.

RED BLOOD CELL DISORDERS

Anemia

Anemia, a condition in which the hemoglobin concentration is lower than normal, reflects the presence of fewer than normal erythrocytes (red blood cells; RBCs) within the circulation. As a result, the amount of oxygen delivered to body tissues is also diminished. Anemia is not a specific disease state per se but a sign of an underlying disorder. It is by far the most common hematologic condition, affecting one fourth of the world population (Jiminez, Kulnigg-Dabsch, & Gasche, 2015). Anemia is a common occurrence among all age groups, with prevalence increasing with age (Jiminez et al., 2015).

Overview

Anemia, a decrease in the number of red blood cells (RBCs), has a number of different etiologies. The treatment varies based on the cause. The different classifications of anemia, as well as the nursing management of each, will be discussed here.

Classification of Anemias

Anemia can be classified by cellular morphology (shape) or by physiologic process. Morphologic classification is the most common approach and includes the cell size, color, and shape. Changes in the size of the RBC are described as normocytic (normal or average size), macrocytic (larger than normal), or microcytic (smaller than normal). Changes in the color of the RBC are described as normochromic (normal in color), hyperchromic (darker cellular contents), or hypochromic (pale or lighter cellular contents) (see Table 20-1). A physiologic approach (see Table 20-2) classifies anemia according to whether the deficiency in erythrocytes is caused by a defect in their production (hypoproliferative anemia), by their destruction (hemolytic anemia), or by their loss (e.g., bleeding) (Fig. 20-1).

In hypoproliferative anemias, the marrow cannot produce adequate numbers of erythrocytes. The reticulocyte count reflects bone marrow production of RBCs. In anemia due to blood loss, a healthy bone marrow compensates for losses and increases RBC production, reflected as an increased reticulocyte count. In hypoproliferative anemias, the bone marrow cannot mount an adequate response to anemia, and this lack of RBC production is reflected as a low reticulocyte count.

Inadequate production of erythrocytes may result from marrow damage due to medications (e.g., chloramphenicol) or chemicals (e.g., benzene) or from a lack of essential factors (e.g., iron, vitamin B_{12}, folic acid, erythropoietin) necessary for erythrocyte formation.

TABLE 20-1 Classification of Anemia by Morphology

Type of Anemia	Morphology	Examples	Laboratory Values Expected
Normocytic (MCV 80–100 fL), normochromic	Cells of normal size with normal Hgb content	Aplastic anemia Acute blood loss Hemolytic anemia Anemia of chronic disease Sickle cell anemia	Normal MCV Normal MCHC ↓ Hgb ↓ Hct
Microcytic (MCV less than 80 fL), hypochromic	Small, reduced amount of Hgb	Iron deficiency anemia Sideroblastic anemia Thalassemia	↓ MCV ↓ MCHC ↓ Hgb ↓ Hct
Macrocytic (MCV greater than 100 fL), normochromic	Large in size, thickness, and volume	Folic acid deficiency Vitamin B_{12} deficiency Alcohol abuse Medications (e.g., hydroxyurea)	↑ MCV Normal MCHC ↓ Hgb ↓ Hct

MCV, mean corpuscular volume; MCHC, mean corpuscular hemoglobin concentration; Hgb, hemoglobin; Hct, hematocrit.

In hemolytic anemias, premature destruction of erythrocytes results in the liberation of hemoglobin from the erythrocytes into the plasma. The increased erythrocyte destruction leads to tissue hypoxia, which, in turn, stimulates erythropoietin production. This increased production is reflected in an increased reticulocyte count as the bone marrow responds to the destruction of erythrocytes. The released hemoglobin is converted in large part to bilirubin; therefore, the bilirubin concentration rises. Hemolysis can result from an abnormality within the erythrocyte itself (e.g., sickle cell anemia, glucose-6-phosphate dehydrogenase [G-6-PD] deficiency) or within the plasma (e.g., immune hemolytic

anemias), or from direct injury to the erythrocyte within the circulation (e.g., hemolysis caused by mechanical heart valve).

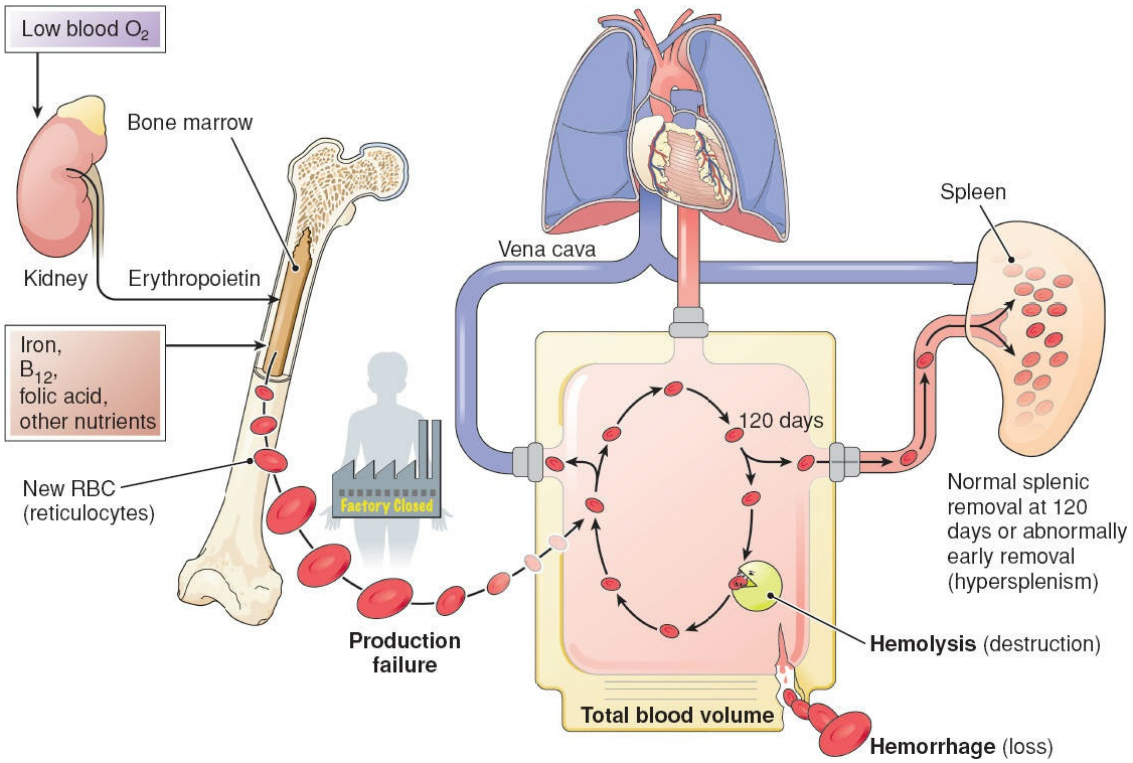

FIGURE 20-1 Production, circulation, and death of red blood cells. Every anemia is caused by at least one of three problems: (1) decreased red cell production, (2) loss of red cells by hemorrhage, or (3) early death (destruction) of RBCs. (From McConnell, T. H. (2007). *The nature of disease pathology for the health professions*. Philadelphia, PA: Lippincott Williams & Wilkins.)

TABLE 20-2 Anemia Classification by Etiology

Type of Anemia	Pathophysiology	Laboratory Findings	Treatment
Hypoproliferative (Decreased Production)			
Pernicious, megaloblastic	Vitamin B_{12} deficiency; lack of intrinsic factor required for B_{12} absorption	Decreased vitamin B_{12} level; increased MCV Elevated methylmalonic acid and homocysteine levels Low reticulocyte count	B_{12} replacement Cyanocobalamin 1,000 μg IM monthly
Folate deficiency	Decreased folic acid intake; impaired absorption; alcohol impairs folate metabolism in the liver, causing a significant depletion in folate reserves Decreases in folate impair DNA synthesis and increase erythroblast cell deaths	Decreased folate levels Increased MCV	Oral folic acid 1–5 mg/day PO
Iron deficiency	Chronic blood loss, failure to recapture iron from recycled RBCs Demands for iron exceed iron intake. Decreased iron intake results in use and depletion of iron stores, resulting in decreased Hgb production	Decreased reticulocytes, iron, ferritin, iron saturation, MCV Increased TIBC	Iron replacement therapy: ferrous sulfate 325 mg PO t.i.d. Parenteral iron therapy reserved for those who cannot take oral replacement due to intolerance, poor enteral absorption, or continued blood loss IV iron therapy requires careful monitoring for signs of hypersensitivity
Decreased erythropoietin production	Kidney disease can impair erythropoietin production (due to renal disease, malignancy), which, in turn, decreases RBC production	Decreased erythropoietin level; normal MCV and MCH; increased creatinine level	Erythropoietin replacement
Anemia of chronic disease (seen in AIDS, malignancy, SLE, chronic kidney disease, chronic liver disease, rheumatoid arthritis)	Marked by three defects: Decreased erythrocyte lifespan, ineffective bone marrow response to erythropoietin, altered iron metabolism	Normal MCV and MCHC Low serum iron Low or normal TIBC Normal or high ferritin	Primary treatment is to treat the underlying cause
Aplastic anemia	An immune response mediated by cytotoxic T cells; targets the cells in the bone marrow, causing cell death and bone marrow failure Hereditary or acquired (exposure to benzene, pesticides)	Decreased reticulocyte count Decreased white blood cells, Hgb, Hct, and platelets	Immunosuppressive therapy (e.g., cyclosporine, corticosteroids, antithymocyte globulin) Stem cell transplant
Blood Loss			
Bleeding	Bleeding from gastrointestinal tract, menorrhagia (excessive menstrual flow), epistaxis (nosebleed), trauma results in decrease in circulating blood volume and decreased Hgb and Hct	Increased reticulocyte level Normal Hgb and Hct if measured soon after bleeding starts, but levels decrease thereafter Normal MCV initially but later decreases Decreased ferritin and iron levels (later)	Packed RBC transfusions Identify and control source of blood loss

Hemolysis (Destruction of RBCs)			
Autoimmune hemolytic anemia Acquired; caused by extrinsic insults such as infection, medications, venom, trauma	Both inherited and acquired forms result in hemolysis within blood vessels and/or lymphoid tissue	Presence of schistocytes Increased spherocyte level Increased reticulocytes	Immunosuppressive therapy (i.e., corticosteroids) Acquired: remove insult, treat underlying disorder
Thalassemias A group of inherited forms of autoimmune hemolytic anemia	Caused by cellular abnormalities of the Hgb structure, marked by an imbalance between the beta chain and alpha chain of Hgb, resulting in RBC membrane damage, ineffective RBC production, and hemolysis	Decreased MCV; fragmented RBCs Increased reticulocyte level	Transfusion therapy with PRBCs Monitor ferritin regularly to assess for iron overload
Sickle cell disease	Inherited disorder in which abnormal hemoglobin (HbS) polymerizes when deoxygenated, creating a semisolid gel that makes an RBC rigid with a distorted shape (sickle cell) that leads to hemolytic anemia, pain (stasis of RBCs in capillaries) and organ failure	Anemia (resulting from chronic hemolysis), reticulocytosis, leukocytosis, and thrombocytosis are common. Elevations of bilirubin and lactate dehydrogenase are also common. Peripheral blood smear may reveal sickle cells	Transfusion therapy with PRBCs Monitor ferritin regularly to assess for iron overload Hydroxyurea

MCV, mean corpuscular volume; MCHC, mean corpuscular hemoglobin concentration; TIBC, total iron binding capacity; Hgb, hemoglobin; Hct, hematocrit; AIDS, acquired immune deficiency syndrome; SLE, systemic lupus erythematosus; RBCs, red blood cells; PRBCs, packed RBCs.

To determine whether the presence of anemia in a given patient is caused by destruction or by inadequate production of erythrocytes, consider the following factors:

- The marrow's ability to respond to decreased erythrocytes (as evidenced by an increased reticulocyte count in the circulating blood)
- The degree to which young erythrocytes (nucleated RBCs) proliferate in the bone marrow and the manner in which they mature (as observed on bone marrow biopsy)
- The presence or absence of end products of erythrocyte destruction within the circulation (e.g., increased bilirubin level, decreased haptoglobin [a protein produced by the liver] level)

Clinical Manifestations and Assessment

Aside from the severity of the anemia itself, several factors influence the development of anemia-associated symptoms:

- The rapidity with which the anemia has developed
- The duration of the anemia (i.e., chronicity)
- The metabolic requirements of the patient
- Other concurrent disorders or disabilities (e.g., cardiopulmonary disease)

In general, the more rapidly an anemia develops, the more severe its symptoms. An otherwise healthy person can often tolerate as much as a 50% gradual reduction in hemoglobin without pronounced symptoms or significant incapacity, whereas the rapid loss of as little as 30% may precipitate profound vascular collapse in the same person. A person who has become gradually anemic, with hemoglobin levels between 9 and 11 g/dL, may have few or no symptoms other than mild tachycardia on exertion and fatigue.

People who usually are very active or who have significant demands on their lives (e.g., a single, working mother of small children) are more likely to experience symptoms. Patients with hypothyroidism with decreased oxygen needs may be completely asymptomatic, without tachycardia or increased cardiac output, at a hemoglobin level of 10 g/dL. Similarly, patients with coexistent cardiac, vascular, or pulmonary disease may develop more pronounced symptoms of anemia (e.g., dyspnea, chest pain, muscle pain or cramping) at a higher hemoglobin level than those without these concurrent health problems.

BOX 20-1 Focused Assessment

Anemia

Be alert for the following signs and symptoms:

- General:
  - Weakness, fatigue
  - Dizziness
  - Pica (craving unusual items including: ice, starch, or dirt)
- Neurologic:
  - Numbness and tingling (paresthesias), irritability
  - Weakness
  - Headache
  - Poor coordination, confusion
  - Gait disturbances
  - Reflex abnormalities
  - Loss of position (proprioception) and vibration sense
  - Spasticity

- Roaring, rushing, ringing, or pounding sensation in the ears
- Integumentary:
  - Pallor of the skin and mucous membranes
  - Jaundice (hemolytic anemia)
  - Brittle, ridged, concave nails
  - Impaired wound healing
  - Loss of elasticity
  - Early thinning and graying of hair
  - Dry skin
  - Painful mouth sores
  - Beefy red, sore tongue (megaloblastic anemia)
  - Smooth and red tongue (iron deficiency anemia)
  - Ulcerated corners of the mouth (angular cheilitis)
- Cardiovascular:
  - Palpitations
  - Chest pain
  - Tachycardia
  - Hypotension
  - Peripheral edema
  - Murmurs
- Respiratory:
  - Dyspnea
  - Orthopnea
  - Tachypnea
- Gastrointestinal:
  - Anorexia, nausea, vomiting
  - Dysphagia
  - Abdominal pain
  - Flatulence
  - Diarrhea
  - Hepatomegaly
  - Splenomegaly
- Musculoskeletal:
  - Muscle pain (claudication)

[a]Neurologic signs and symptoms are most commonly seen in pernicious anemia.

The most common signs and symptoms of anemia are discussed in Box 20-1. A careful and thorough assessment is essential in identifying potential complications and targeting nursing interventions.

A variety of hematologic studies are performed to determine the type and cause of the anemia (see Chapter 19 for a detailed overview). In an initial evaluation, the hemoglobin,

hematocrit, reticulocyte count, and RBC indices, particularly the mean corpuscular volume (MCV) and red cell distribution width (RDW), are particularly useful. Iron studies (serum iron level, total iron-binding capacity [TIBC], % saturation, and ferritin), as well as serum vitamin B_{12} and folate levels are also frequently obtained. Other tests include haptoglobin (if hemolysis is suspected) and erythropoietin levels. The remaining complete blood count (CBC) values are useful in determining whether the anemia is an isolated problem or part of another hematologic condition, such as leukemia or myelodysplastic syndrome (MDS) (a group of disorders where the bone marrow does not produce enough healthy blood cells). Bone marrow aspiration and biopsy may be performed. In addition, other diagnostic studies, including endoscopy and colonoscopy, may be performed to determine the presence of underlying chronic illness, such as malignancy, or the source of any blood loss, such as polyps or ulcers within the gastrointestinal (GI) tract.

Medical Management

Management of anemia is directed toward correcting or controlling the cause of the anemia; if the anemia is severe, the erythrocytes that are lost or destroyed may be replaced with a transfusion of packed RBCs (PRBCs). The management of the various types of anemia is covered in the discussions that follow.

Nursing Management

Managing Fatigue

The most common symptom and complication of anemia is fatigue. This distressing symptom is too often minimized by health care providers. Fatigue is often the symptom that has the greatest negative impact on a patient's level of functioning and consequent quality of life. Patients often describe the fatigue from anemia as oppressive. Fatigue can interfere with a person's ability to work, both inside and outside the home. It can disrupt relationships with family and friends. Patients often lose interest in hobbies and activities, including sexual activity. The severity of distress from fatigue is often related to a person's responsibilities and life demands as well as the amount of assistance and support received from others.

Other factors that may be contributing to fatigue should also be assessed and managed including pain, emotional distress, sleep disturbances, comorbidities, physical deconditioning, and nutritional deficiencies (NCCN, 2016a).

Nursing interventions can focus on assisting the patient to prioritize activities and to establish a balance between activity and rest that is realistic and feasible from the patient's perspective. Patients with chronic anemia need to maintain some physical activity and exercise to prevent the deconditioning that results from inactivity. Short periods of daily exercise can also decrease the severity of fatigue (Tomlinson, Diorio, Beyene, & Sung, 2014).

Maintaining Adequate Nutrition

Inadequate intake of essential nutrients, such as iron, vitamin B_{12}, and folic acid can cause anemia. The symptoms associated with anemia (e.g., fatigue, anorexia) can, in turn, interfere with maintaining adequate nutrition. A healthy diet should be encouraged. The nurse should inform the patient that alcohol interferes with the utilization of essential nutrients and should advise the patient to avoid alcoholic beverages or to limit intake. Dietary teaching sessions should be individualized and culturally sensitive to food preferences and food preparation. The involvement of family members enhances compliance with dietary recommendations. Dietary supplements (e.g., vitamins, iron, folate, protein) may be prescribed as well depending on the results of testing.

Equally important, the patient and family must understand the underlying cause of the anemia because many forms of anemia are not the result of a nutritional deficiency. In such cases, even an excessive intake of nutritional supplements will not improve the anemia. A potential problem in patients with chronic transfusion requirements occurs with the indiscriminate use of iron supplements. These individuals are at risk for iron overload from their transfusions. The addition of an iron supplement will only increase their iron burden, contributing to risk for end-organ damage.

Maintaining Adequate Perfusion

Patients with acute blood loss or severe hemolysis may have decreased tissue perfusion from decreased blood volume or reduced circulating erythrocytes (decreased hematocrit). Lost

volume is replaced with transfusions or IV fluids, based on the symptoms and the laboratory test results. Supplemental oxygen may be necessary, but it is rarely needed on a long-term basis unless there is underlying severe cardiac or pulmonary disease. The nurse monitors the patient's vital signs and pulse oximetry readings closely; other medications, such as antihypertensive agents, may need to be adjusted or withheld.

Complications

General complications of severe anemia include heart failure, paresthesias (abnormal sensation of pricking, tingling, numbness, burning, etc.), and confusion. At any given level of anemia, patients with underlying heart disease are far more likely to have angina or symptoms of heart failure than those without heart disease.

HYPOPROLIFERATIVE ANEMIAS

IRON DEFICIENCY ANEMIA

The development of iron deficiency anemia occurs when the body's iron stores are depleted and there is no iron available for hemoglobin synthesis. The volume of individual iron stores is dependent upon sex, age, rate of growth, and the balance between dietary iron absorption and losses. Iron is stored primarily in the liver, spleen, and bone marrow. The remainder of iron exists as hemoglobin and proteins. Iron deficiency anemia is diagnosed based on the presence of a microcytic anemia, transferrin saturation below 20%, and ferritin below 30 ng/mL (Jiminez et al., 2015).

Iron deficiency anemia is the most common type of anemia in all age groups, and it is the most common anemia in the world. It is particularly prevalent in developing countries, where inadequate iron stores can result from inadequate intake of iron (seen with vegetarian diets) or from blood loss (e.g., from intestinal hookworm). Iron deficiency is also common in the United States. In children, adolescents, and pregnant women, the cause is typically inadequate iron in the diet to keep up with increased growth. However, for most adults with iron deficiency anemia, the cause is blood loss. In fact, in adults, the cause of iron deficiency anemia should be considered to be bleeding until proven otherwise.

The most common cause of iron deficiency anemia in men and postmenopausal women is bleeding (from ulcers, gastritis, inflammatory bowel disease, or GI tumors). The most common cause of iron deficiency anemia in premenopausal women is menorrhagia (excessive menstrual bleeding) and pregnancy with inadequate iron supplementation. Patients with chronic alcoholism often have chronic blood loss from the GI tract, which causes iron loss and eventual anemia. Other causes include iron malabsorption, as is seen after gastrectomy or with celiac disease.

Medical Management

Except in the case of pregnancy, the cause of iron deficiency should be investigated. Anemia may be a sign of a curable GI cancer or of uterine fibroid tumors. Stool specimens should be tested for occult blood and *H. pylori* infection. Blood samples should be sent for celiac serology and antiparietal cell antibodies (to rule out pernicious anemia). In the presence of iron deficiency, patients over 50 years of age, those with a family history of GI disorders, those with GI symptoms, men with Hgb below 13 g/dL or women with Hgb below 10 g/dL should undergo endoscopy and colonoscopy to rule out GI blood loss (Jiminez et al., 2015).

Several oral iron preparations—ferrous sulfate, ferrous succinate, ferrous gluconate, and ferrous fumarate—are available for treating iron deficiency anemia. The oral route of administration is preferred over IV. The recommended daily dose for treatment of iron deficiency is 100 mg/day of elemental iron. Oral preparations are inexpensive and readily available. Ferrous sulfate, fumarate, and gluconate each contain 50 to 65 mg of elemental iron per tablet with recommended dosing of one tab three times/day (Auerbach & Adamson, 2016). Despite the development of a number of orally effective iron-containing compounds, the original salt, ferrous sulfate (325 mg three times daily), remains the most useful. However, some newer oral iron preparations, such as ferrous gluconate (300 mg two or three times daily) or ferrous fumarate (325 mg two or three times daily), may induce fewer GI side effects.

Food can decrease iron absorption by as much as 50% although vitamin C facilitates the absorption of iron. Therefore, oral iron should be taken with a glass of orange juice or a vitamin C tablet on an empty stomach to maximize absorption. However, taking iron on an empty stomach and taking iron with vitamin C can increase GI side effects. GI side effects, including nausea and epigastric discomfort, occur in up to 70% of patients taking oral iron and are dose dependent (Auerbach & Adamson, 2016). Taking iron with meals may decrease nausea and epigastric discomfort but may result in decreased absorption. In addition, calcium supplements can decrease iron absorption; therefore, administration of these two medications should be staggered (Ferri, 2016a).

The hemoglobin level should begin to rise after 1 week of replacement and should increase by 1 to 2 g/dL within 4 to 8 weeks. If hemoglobin levels fail to improve within this time frame, adherence to the regimen should be assessed and IV iron replacement should be considered. If the patient has been adherent to the prescribed regimen, then assess for absorption problems, continued blood loss, concomitant deficiencies (folate, B_{12}, copper), and drug interactions. Diet has been implicated when large quantities of phytates from cereals or tannate from teas inhibit iron absorption (Ginder, 2016). In addition, iron absorption is impaired by conditions that affect the duodenum's ability to absorb iron, as in extensive gastric surgery, generalized intestinal malabsorption, and atrophic gastritis; whereas proton pump inhibitors (PPIs) or histamine 2 receptor blockers (H2) do not appear to cause iron deficiency (Ginder, 2016). Iron store repletion takes much longer (goal ferritin greater than 100 ng/mL), so it is important that the patient continue taking the iron for as long as 6 to 12 months (Auerbach & Adamson, 2016).

In some cases, oral iron is poorly absorbed or poorly tolerated, or iron supplementation is needed in large amounts. In these situations, IV administration of iron may be needed.

There are currently six available intravenous iron preparations:

- INFeD® (low–molecular-weight [LMWH] iron dextran),
- Ferrlecit® (ferric gluconate),
- Venofer® (iron sucrose),
- Feraheme® (ferumoxytol),
- Monofer® (iron isomaltoside 1,000), and
- Injectafer® (ferric carboxymaltose).

All IV iron preparations carry some risk for hypersensitivity. INFeD® is the only formulation that requires a test dose due to the risk of hypersensitivity. INFed® also allows the delivery of higher doses of iron (1,000 mg) over 1 hour. Ferrlecit® and Venofer® must be given in smaller doses. Feraheme®, Monofer®, and Injectafer® allow higher doses to be given over shorter periods of time (15 minutes). Feraheme® and Injectafer® are available in the United States and Europe; Monofer® is available only in Europe (Auerbach & Macdougall, 2014). In most cases, multiple doses of IV iron replacement are required to replace the patient's iron stores.

Nursing Management

Preventive education is important, because iron deficiency anemia is common in menstruating and pregnant women. Food sources high in iron include organ meats (beef or calf's liver, chicken liver), other red meats, beans (black, pinto, and garbanzo), leafy green vegetables, raisins, and molasses. Taking iron-rich foods with a source of vitamin C (e.g., orange juice) enhances the absorption of iron.

The nurse helps the patient select a healthy diet and refers the patient to a registered dietitian as appropriate. Nutritional counseling can be provided for those whose usual diet is inadequate. Patients with a history of eating fad diets or strict vegetarian diets are counseled that such diets often contain inadequate amounts of absorbable iron. The nurse encourages the patient to continue iron therapy as long as it is prescribed, even if the symptoms of anemia resolve. The nurse helps to assess and manage side effects of oral iron replacement.

Because iron is best absorbed on an empty stomach, the patient is instructed to take the supplement an hour before meals. Iron supplements are usually given in the oral form, typically as ferrous sulfate. Most patients can use the less expensive, more standard forms of ferrous sulfate. Tablets with enteric coating may be absorbed poorly and should be avoided. Many patients have difficulty tolerating iron supplements because of GI side effects (diarrhea, constipation, epigastric discomfort, nausea, and vomiting). Some iron formulations are designed to limit GI side effects by the addition of a stool softener or use of sustained-release formulations to limit nausea or gastritis. Specific patient teaching aids (Box 20-2) can assist patients with the use of iron supplements.

IV supplementation may be used when the patient's iron stores are completely depleted, if the patient has impaired iron absorption, or the patient cannot tolerate oral forms of iron supplementation (see Medical Management). The IV route is preferred for administration of iron dextran. Due to the risk for hypersensitivity reactions with parenteral iron formulations, the patient should be monitored closely during and shortly after the infusion; vital signs should be monitored carefully per institution guidelines.

BOX 20-2 Patient Education

Taking Oral Iron Supplements

- Take iron on an empty stomach (1 hour before or 2 hours after a meal). Because iron absorption is reduced with food, especially dairy products and antacids, avoid taking iron with these items.
- To prevent gastrointestinal distress, the following schedule may work better if more than one tablet a day is prescribed: Start with only one tablet per day for a few days, then increase to two tablets per day, and then three tablets per day. This method permits the body to adjust gradually to the iron.
- Increase the intake of vitamin C (citrus fruits and juices, strawberries, tomatoes, broccoli), to enhance iron absorption.
- Eat foods high in fiber to minimize problems with constipation.

- Remember that stools will become dark in color.
- To prevent staining the teeth with a liquid preparation, use a straw or place a spoon at the back of the mouth to take the supplement. Rinse the mouth thoroughly afterward.

ANEMIA IN KIDNEY DISEASE

The degree of anemia in patients with end-stage kidney disease (ESKD) varies greatly, but in general patients do not become significantly anemic until the serum creatinine level exceeds 3 mg/dL.

Pathophysiology

This anemia is caused by both a mild shortening of erythrocyte lifespan and a deficiency of erythropoietin (necessary for erythropoiesis). As kidney function decreases, erythropoietin, which is produced by the kidney, also decreases. Because erythropoietin is also produced outside the kidney, some erythropoiesis continues, even in patients whose kidneys have been removed. However, the number of RBCs produced is small and the degree of erythropoiesis is inadequate.

Patients undergoing long-term hemodialysis lose blood into the dialyzer and, therefore, may become iron deficient. Folic acid deficiency develops because this vitamin passes into the dialysate. Therefore, patients who receive hemodialysis and who have anemia should be evaluated for iron and folate deficiency and treated appropriately.

Clinical Manifestations and Assessment

For patients with ESKD, the symptoms of anemia, including fatigue and decreased activity tolerance, are often the most disturbing. If untreated, the hematocrit may fall to between 20% and 30%, although in rare cases it may fall to less than 15%. The erythrocytes appear normal in shape, size, and color on the peripheral smear.

Medical and Nursing Management

The availability of recombinant erythropoietin (also referred to as erythropoiesis stimulating agents or ESAs) (epoetin alfa [Epogen, Procrit]; darbepoetin alfa [Aranesp]) has dramatically altered the management of anemia in ESKD by decreasing the need for RBC transfusion, with its associated risks. Iron stores, including transferrin saturation and ferritin, must be measured prior to starting ESAs, and iron replacement should be initiated in patients with a ferritin of less than 100 ng/mL; adequate iron stores are essential for optimal response to erythropoietin. Erythropoietin, in combination with oral iron supplements, can raise and maintain hematocrit levels to between 33% and 38%. This treatment has been successful with dialysis patients. ESAs carry an increased risk of death and cardiovascular events, including stroke, venous thromboembolism (VTE), and myocardial infarction (MI) when hemoglobin targets exceed 11 g/dL; therefore, the lowest dose required to reduce transfusion requirements is recommended (Aranesp® package insert, Amgen 2015).

Hypertension is also seen in this patient population when the hematocrit rapidly increases to a high level. Therefore, the hemoglobin and blood pressure should be checked frequently when a patient with kidney disease begins erythropoietin therapy. The dose of erythropoietin should be titrated to the goal hemoglobin based on available guidelines (Aranesp® package insert, Amgen 2015). Some patients may require initiation of antihypertensive therapy.

ANEMIA OF CHRONIC DISEASE

The term "anemia of chronic disease" is a misnomer in that only the chronic diseases of inflammation, infection, and malignancy cause this type of anemia. Many chronic inflammatory diseases are associated with a normochromic, normocytic anemia (i.e., the erythrocytes are normal in color and size). These disorders include rheumatoid arthritis; severe, chronic infections; and many cancers. It is, therefore, imperative that the "chronic disease" be diagnosed when this form of anemia is identified so that it can be managed appropriately.

The anemia is usually mild to moderate and nonprogressive. It develops gradually over 6 to 8 weeks and then stabilizes at a hematocrit seldom less than 25%. The hemoglobin level rarely falls below 9 g/dL, and the bone marrow has normal cellularity with increased stores of iron as the iron is diverted from the serum.

Most of these patients have few symptoms and do not require treatment for the anemia. With successful treatment of the underlying disorder, the bone marrow iron is used to make erythrocytes and the hemoglobin level rises.

MEGALOBLASTIC ANEMIAS

In the anemias caused by deficiencies of either vitamin B_{12} or folic acid, identical bone marrow and peripheral blood changes occur because both vitamins are essential for normal DNA synthesis. In either anemia, the erythrocytes that are produced are abnormally large

and are called *megaloblastic red cells*; therefore, the MCV is elevated. Other cells derived from the myeloid stem cell (nonlymphoid leukocytes, platelets) are also abnormal, resulting in low leukocyte and platelet counts in advanced stages of disease. A bone marrow analysis reveals hyperplasia (abnormal increase in the number of cells), and the precursor erythroid and myeloid cells are large and bizarre in appearance.

Pathophysiology

Folic Acid Deficiency

Folic acid is stored as compounds referred to as *folates*. The folate stores in the body are much smaller than those of vitamin B_{12}, and they are quickly depleted when the dietary intake of folate is deficient (within 4 months). Folate is found in green leafy vegetables, legumes, egg yolks, fortified foods like cereal, and liver (Lolin, 2014). Folate deficiency occurs in people who rarely eat uncooked vegetables. Alcohol increases folic acid requirements; patients with alcoholism usually have a diet that is deficient in the vitamin. Folic acid requirements are also increased in patients with chronic hemolytic anemias and in women who are pregnant because the need for erythrocyte production is increased in these conditions. Folate is absorbed in the upper small intestine; therefore, some patients with malabsorptive diseases of the small bowel, such as celiac sprue, may not absorb folic acid normally (Lolin, 2014).

Vitamin B_{12} Deficiency

A deficiency of vitamin B_{12} can occur in several ways. Inadequate dietary intake is rare but can develop in strict vegans (who consume no meat or dairy products). Faulty absorption from the GI tract is a more common cause. This occurs in conditions such as Crohn disease, or after ileal resection, bariatric gastric bypass surgery, or gastrectomy. Even if adequate vitamin B_{12} and intrinsic factor are present, a deficiency may occur if disease involving the ileum or pancreas impairs absorption. Another cause is the absence of intrinsic factor, as in pernicious anemia. Intrinsic factor is normally secreted by cells within the gastric mucosa; normally, it binds with the dietary vitamin B_{12} and travels with it to the ileum, where the vitamin is absorbed. Without intrinsic factor, orally consumed vitamin B_{12} cannot be absorbed, and eventually erythrocyte production is diminished. Pernicious anemia, which tends to run in families, is primarily a disorder of adults, particularly the elderly. Pernicious anemia is an autoimmune disorder involving autoantibodies to intrinsic factor and parietal cells resulting in poor absorption of B_{12} (Rojas Hernandez & Oo, 2015). For unknown reasons, patients with pernicious anemia have a higher incidence of gastric cancer, adenocarcinomas, and other cancers compared to the general population (Murphy et al., 2015). Though routine screening for this population has not yet been recommended, these patients should understand their risks and be educated on reporting any new symptoms promptly to health care providers. It is recommended that patients with newly diagnosed pernicious anemia or any patient with pernicious anemia and GI symptoms undergo screening endoscopy (Evans et al., 2015). The body normally has large stores of vitamin B_{12} so years may pass before the deficiency results in anemia. Because the body compensates so well, the anemia can be severe before the patient becomes symptomatic.

Clinical Manifestations and Assessment

People with vitamin B and/or folic acid deficiency may present with nonspecific symptoms including fatigue, mood changes, memory difficulty, and weakness (Lolin, 2014). Assessment of patients who have or are at risk of megaloblastic anemia includes inspection of the skin and mucous membranes. Mild jaundice may be apparent and is best seen in the sclera without using fluorescent lights. Vitiligo (patchy loss of skin pigmentation) and premature graying of the hair are often seen in patients with pernicious anemia. The tongue is smooth, red, and sore (referred to as glossitis).

Symptoms of folic acid and vitamin B_{12} deficiencies are similar, and the two anemias may coexist. However, the neurologic manifestations of vitamin B_{12} deficiency do not occur with folic acid deficiency, and they persist if vitamin B_{12} is not replaced. Therefore, careful distinction between the two anemias must be made. Serum levels of both vitamins can be measured. In the case of folic acid deficiency, even small amounts of folate increase the serum folate level. Therefore, measuring the amount of folate within the red cell itself (red cell folate) is a more sensitive test in determining true folate deficiency (Lolin, 2014).

Neurologic symptoms are seen in severe vitamin B_{12} deficiency and pernicious anemia and include psychiatric symptoms and peripheral neuropathy (Lolin, 2014). This presentation happens infrequently due to earlier diagnosis.

After the body's stores of vitamin B_{12} are depleted, the patient may begin to show signs and symptoms of the anemia. However, because the onset and progression of the anemia are so gradual, the body can compensate very well until the anemia is severe so that the typical manifestations of anemia (weakness, listlessness, fatigue) may not be apparent initially. The hematologic effects of deficiency are accompanied by effects on other organ systems, particularly the GI tract and nervous system (see Box 20-1). These symptoms are progressive, although the course of illness may be marked by spontaneous partial remissions and exacerbations. Without treatment, patients can die after several years, usually from heart failure secondary to anemia.

Medical Management

Underlying causes for vitamin B_{12} and folate deficiency should be investigated and treated.

Dietary counseling should include discussion on increasing dietary sources of folic acid. Supplemental oral folic acid should be administered at a dosage of 1 to 5 mg daily until recovery (Lolin, 2014). Patients with malabsorption will need to continue folic acid supplements over the long term. Pregnant patients should take folic acid (0.4 to 0.8 mg daily) when planning for pregnancy as well as throughout the course of pregnancy (Antony, 2016).

Vitamin B_{12} deficiency is treated by vitamin B_{12} replacement. Vegetarians can prevent or treat deficiency with oral supplements, vitamins, or fortified soy milk. When the deficiency is due to the more common defect in absorption or the absence of intrinsic factor, replacement by IM injections of vitamin B_{12} is necessary. The replacement schedule includes daily or every other day administration of 1 mg (1,000 μg) of cyanocobalamin IM for 1 week, followed by weekly administration for 1 to 2 months and then monthly through the remainder of the patient's life (Rojas Hernandez & Oo, 2015; Stabler, 2013).

As vitamin B_{12} is replaced, the reticulocyte count rises within 1 week, and in several weeks all the blood counts should improve to normal. The characteristic beefy red, sore tongue feels better and appears less red in several days. However, the neurologic manifestations require more time for recovery; if there is severe neuropathy, the patient may never recover fully. To prevent recurrence of pernicious anemia, vitamin B_{12} therapy must be continued for life.

Nursing Alert

Even when the megaloblastic anemia is severe, RBC transfusions may not be used because the patient's body has compensated over time by expanding the total blood volume. Administration of blood transfusions to such patients, particularly those who are elderly or who have cardiac dysfunction, can precipitate pulmonary edema. If transfusions are required, the RBCs should be transfused slowly, with careful attention to signs and symptoms of fluid overload.

Nursing Management

In the setting of peripheral neuropathy, the nurse needs to pay particular attention to ambulation and should assess the patient's gait and stability as well as the need for assistive devices (e.g., canes, walkers) and for assistance in managing daily activities. Of particular concern is ensuring safety when position sense, coordination, and gait are affected. Physical and occupational therapy referrals may be needed. If sensation is altered, the patient needs to be instructed to avoid excessive heat and cold.

Because mouth and tongue soreness may restrict nutritional intake, the nurse advises the patient to eat small amounts of bland, soft foods frequently and educates the patient on routine mouth care. The nurse also may explain that other nutritional deficiencies, such as alcohol-induced anemia, can induce neurologic problems.

HEMOLYTIC ANEMIAS

In hemolytic anemias, the erythrocytes have a shortened lifespan; thus, their number in the circulation is reduced. Fewer erythrocytes result in decreased available oxygen, causing hypoxia, which, in turn, stimulates an increase in erythropoietin release from the kidney. The erythropoietin stimulates the bone marrow to compensate by producing new erythrocytes and releasing some of them into the circulation somewhat prematurely as reticulocytes. If the red cell destruction persists, the hemoglobin is broken down excessively; about 80% of the heme is converted to bilirubin, conjugated in the liver, and excreted in the bile.

The mechanism of erythrocyte destruction varies, but all types of hemolytic anemia share certain laboratory features: the reticulocyte count is elevated, the fraction of indirect (unconjugated) bilirubin is increased, and the supply of haptoglobin (a binding protein for free hemoglobin) is depleted as more hemoglobin is released. As a result, the plasma haptoglobin level is low. The severity of anemia will increase if the marrow does not compensate by replacing the hemolyzed erythrocytes (poor response indicated by a decreased reticulocyte count). Causes of hemolytic anemia are discussed in Box 20-3.

THALASSEMIA

The thalassemias are a group of hereditary anemias characterized by hypochromia (an abnormal decrease in the hemoglobin content of erythrocytes), extreme microcytosis (smaller-than-normal erythrocytes), destruction of blood elements (hemolysis), and variable degrees of anemia due to impaired hemoglobin production and ineffective RBC production (Tubman et al., 2015). The thalassemias occur worldwide, but the highest prevalence is found in people of Mediterranean, African, and Southeast Asian ancestry.

Thalassemias are classified into two major groups according to which hemoglobin chain is diminished: alpha or beta. The alpha thalassemias occur mainly in people from Asia and the Middle East, and the beta thalassemias are most prevalent in people from Mediterranean regions but also occur in those from the Middle East or Asia. The alpha thalassemias are milder than the beta forms and often occur without symptoms; the erythrocytes are extremely microcytic, but the anemia, if present, is mild.

The severity of beta thalassemia varies depending on the extent to which the hemoglobin chains are affected. Patients with mild forms have a microcytosis and mild anemia. If left untreated, severe beta thalassemia (*thalassemia major*, or *Cooley anemia*) can be fatal within the first few years of life. Peripheral blood stem cell transplant (PBSCT) offers a chance of cure, but when this is not possible, the disease is usually treated with transfusion of PRBCs. Complications related to lifelong transfusions include the development of anti-RBC antibodies, transfusion-associated infections, and iron overload. Transfusional iron overload is the primary cause of death in patients with thalassemia (90% of deaths). In the 1980s, life expectancy was not expected to exceed the third decade of life. However, with improvements in methods to measure iron overload as well as treatments for iron overload, life expectancy has improved (Tubman et al., 2015).

BOX 20-3 Causes of Hemolytic Anemias

Inherited Hemolytic Anemia

- Abnormal hemoglobin:
  - Sickle cell anemia
  - Thalassemia
- RBC membrane abnormality:
  - Hereditary spherocytosis
  - Hereditary elliptocytosis
  - Acanthocytosis
  - Stomatocytosis
- Enzyme deficiencies:
  - Glucose-6-phosphate dehydrogenase (G-6-PD) deficiency

Acquired Hemolytic Anemia

- Antibody-related:
  - Iso-antibody/transfusion reaction
  - Autoimmune hemolytic anemia (AIHA)
  - Cold agglutinin disease
- Not antibody-related:
  - RBC membrane defects
  - Paroxysmal nocturnal hemoglobinuria (PNH)
  - Liver disease
  - Uremia
  - Trauma
  - Mechanical heart valve
  - Microangiopathic hemolytic anemia
  - Infection
  - Bacterial
  - Parasitic
  - Disseminated intravascular coagulation (DIC)
  - Toxins
  - Hypersplenism

Patient teaching during the reproductive years should include preconception counseling about the risk of thalassemia major.

Treatment of iron overload involves the use of chelating agents. Deferoxamine (given IV or SQ), deferasirox (oral), and deferiprone (oral) are used alone or in combination to treat iron overload. Each medication requires monitoring for toxicity, including bone marrow suppression (deferiprone), liver function abnormalities (deferasirox), annual eye and

hearing examinations (due to risk for ocular toxicity and ototoxicity) (all) (Tubman et al., 2015). Side effects of the oral agents include nausea, vomiting, diarrhea, and abdominal pain and may contribute to interruptions in therapy. Adherence with these agents is essential to response; therefore, nursing education should focus on necessary monitoring parameters and the importance of taking agents as directed.

AUTOIMMUNE HEMOLYTIC ANEMIA

Autoimmune hemolytic anemia (AIHA) results when the patient's own immune system hemolyzes RBCs (Hill, 2015). Hemolysis results from exposure of the erythrocyte to antibodies, which coat the RBCs, resulting in early destruction. In half of the cases, no identifiable cause for AIHA can be found. In the other half, other disorders, including chronic lymphocytic leukemia (CLL), lupus, or some infections, trigger the AIHA (Hill, 2015). Medications can also trigger immune hemolysis.

Pathophysiology

Autoantibodies may develop for many reasons. In many instances, the person's immune system is dysfunctional so that it falsely recognizes its own erythrocytes as foreign and produces antibodies against them. This mechanism is seen in people with CLL. Another mechanism is a deficiency in suppressor lymphocytes, which normally prevent antibody formation against a person's own antigens. Autoantibodies tend to be of the IgG type. The erythrocytes are sequestered in the spleen and destroyed by the macrophages outside the blood vessel (extravascular hemolysis).

AIHAs can be classified based on the body temperature involved when the antibodies react with the RBC antigen. Warm-body antibodies bind to erythrocytes most actively in warm conditions (37°C); cold-body antibodies react in cold conditions (0°C). Most AIHAs are the warm-body type. AIHA is associated with other disorders in most cases (e.g., medication exposure, lymphoma, CLL, other malignancy, collagen vascular disease, autoimmune disease, infection). In idiopathic autoimmune hemolytic states, the etiology of autoantibody production is not known. All ages and both genders are equally vulnerable to this form, whereas the incidence of secondary forms is greater in people older than 45 years of age and in females.

Medical Management

Treatment depends on the severity of the anemia, the type of AIHA, and the presence or absence of an underlying disorder. Treatment of the underlying disorder may improve the AIHA (Hill, 2015). Mild, asymptomatic AIHA may not require intervention other than close monitoring over time. Since medications can also trigger immune hemolysis, any possible offending medication should be discontinued immediately.

In warm AIHA, the treatment includes high doses of corticosteroids until hemolysis decreases. Corticosteroids decrease the macrophage's ability to clear the antibody-coated erythrocytes. If the hemoglobin level returns to normal, usually after several weeks, the corticosteroid dose can be lowered or, in some cases, tapered and discontinued. However, corticosteroids rarely produce a lasting remission. In severe cases, blood transfusions may be required. Because the antibodies may react with all possible donor cells, careful blood typing is necessary, and the transfusion should be administered slowly and cautiously.

In the setting of steroid failure, other immunosuppressive medications may be attempted to decrease antibody production. The immunosuppressive agents most frequently used are cyclophosphamide (Cytoxan), which has a more rapid effect but more toxicity, and azathioprine (Imuran), which has a less rapid effect but less toxicity. The monoclonal antibody, Rituximab, has been used with success in 45% to 60% of patients with AIHA, and studies are ongoing to determine the duration of remission following Rituximab therapy (Hill, 2015). The synthetic androgen, danazol, can be useful in some patients, particularly in combination with corticosteroids. The mechanism for this success is unclear. If corticosteroids or immunosuppressive agents are used, the taper must be very gradual to prevent a rebound "hyperimmune" response and exacerbation of the hemolysis.

Immunoglobulin administration is effective in about one third of patients, but the effect is transient and the medication is expensive. Transfusions may be necessary if the anemia is severe; it may be extremely difficult to cross-match samples of available units of PRBCs with that of the patient.

Splenectomy (removal of the spleen) removes the major site of erythrocyte destruction; therefore, splenectomy may be performed if medications do not produce a remission.

For patients with cold-antibody hemolytic anemia, no treatment may be required other than to advise the patient to keep warm; relocation to a warm climate may be necessary. Intravenous solutions and blood products that have been refrigerated must have their temperature raised before infusion. Treatment with Rituximab may be considered for severe symptoms or anemia requiring transfusion (Hill, 2015).

Nursing Management

Patients may have great difficulty understanding the pathologic mechanisms underlying the disease and may need repeated explanations in terms they can understand. Patients who have had a splenectomy should be vaccinated against pneumococcal and encapsulated bacteria infections (e.g., Pneumovax) and informed that they are permanently at greater risk for infection. Patients receiving long-term corticosteroid therapy, particularly those with concurrent diabetes or hypertension, need careful monitoring of blood sugar and blood pressure. They must understand the need for adherence to the medication and the importance of never abruptly discontinuing it. A written explanation and a tapering schedule should be provided, and needed adjustments based on hemoglobin levels should be emphasized. Similar teaching should be provided when immunosuppressive agents are used. Corticosteroid therapy is not without significant risk, and patients need to be monitored closely for complications.

Polycythemia, literally meaning "too many cells in the blood," refers to an increased number of erythrocytes. It is a term used when the hematocrit is elevated (to greater than 55% in males, greater than 50% in females). Polycythemia is classified as either primary or secondary (Porth, 2015). Primary polycythemia, also known as polycythemia Vera (PV) is a malignant condition that will be described later in the chapter; secondary polycythemia is a benign condition, discussed below.

Long-term complications of corticosteroid therapy are presented in Chapter 31 (Table 31-7).

SECONDARY POLYCYTHEMIA

Pathophysiology

Secondary polycythemia is caused by excessive production of erythropoietin. This may occur in response to a reduced amount of oxygen, which acts as a hypoxic stimulus, as in cigarette smoking, obstructive sleep apnea, chronic obstructive pulmonary disease (COPD), or cyanotic heart disease, or in nonpathologic conditions, such as living at a high altitude. It can also result from certain hemoglobinopathies (e.g., hemoglobin Chesapeake), in which the hemoglobin has an abnormally high affinity for oxygen. Secondary polycythemia can also occur from neoplasms (e.g., renal cell carcinoma) that stimulate erythropoietin production.

Medical and Nursing Management

Management of secondary polycythemia may not be necessary; when management is necessary, the goal is to treat the underlying primary conditions. If the cause cannot be corrected (e.g., by treating the renal cell carcinoma or improving pulmonary function), therapeutic phlebotomy may be necessary in symptomatic patients to reduce blood viscosity and volume.

PLATELET DISORDERS

Thrombocythemia

Thrombocythemia is the overproduction of platelets. There are two types with very different etiologies and treatment approaches: primary or essential (a malignant condition described later in the chapter) and secondary (a benign condition discussed here). Refer to Chapter 19 for discussion of bleeding disorders.

SECONDARY THROMBOCYTOSIS

Increased platelet production is the primary mechanism of secondary, or reactive, thrombocytosis. The platelet count is above normal, but, in contrast to primary thrombocythemia, an increase to more than 1 million/mm^3 is rare. Platelet function is normal; the platelet survival time is normal or decreased. Consequently, symptoms associated with hemorrhage or thrombosis are rare. Many disorders or conditions can cause a reactive increase in platelets, including infection, chronic inflammatory disorders, iron deficiency, malignant disease, acute hemorrhage, and splenectomy (see later discussion of primary thrombocythemia). Treatment is aimed at the underlying disorder. With successful management, the platelet count usually returns to normal.

THROMBOCYTOPENIA

Thrombocytopenia (low platelet level) can result from various factors: decreased production of platelets within the bone marrow, increased destruction of platelets, or increased consumption of platelets. There are numerous causes of thrombocytopenia, including malignancy, infection, medications, autoimmunity (ITP), and DIC. The primary strategy for managing thrombocytopenia is correction or treatment of the underlying cause or removal of the offending agent.

Clinical Manifestations and Assessment

Bleeding and petechiae usually do not occur with platelet counts greater than 50,000/mm^3, although excessive bleeding can follow surgery or trauma. When the platelet count drops to less than 20,000/mm^3, petechiae can appear, along with spontaneous nasal and gingival bleeding, excessive menstrual bleeding, and excessive bleeding after surgery or dental extractions. When the platelet count is less than 10,000/mm^3, spontaneous, potentially fatal CNS or GI hemorrhage can occur. If the platelets are dysfunctional due to disease (e.g., MDS) or medications (e.g., aspirin), the risk for bleeding may be much greater even when the actual platelet count is not significantly reduced.

A platelet deficiency that results from decreased production (e.g., leukemia, MDS) is diagnosed by examining the bone marrow via aspiration and biopsy. Infections, either viral or bacterial, as well as alcoholism can suppress platelet production. Therefore, laboratory tests should include testing for HIV and hepatitis B and C.

When platelet destruction is the cause of thrombocytopenia, the marrow shows increased megakaryocytes (the cells from which the platelets originate) and normal or even increased platelet production as the body attempts to compensate for the decreased platelets in circulation. Another cause of thrombocytopenia is sequestration. Approximately one third of the circulating platelets are within the spleen, and a greatly enlarged spleen results in increased sequestration of platelets.

Many medications (e.g., sulfa drugs, methotrexate) can either decrease platelet production or shorten their lifespan. Numerous genetic causes of thrombocytopenia have been discovered, including autosomal dominant, autosomal recessive, and X-linked mutations (Abrams, 2016).

An important cause to exclude is *pseudothrombocytopenia*. Here, platelets aggregate and clump in the presence of ethylenediamine tetra-acetic acid (EDTA), the anticoagulant present in the tube used for CBC collection. This clumping accounts for 15% to 30% of instances of isolated thrombocytopenia (Diz-Küçükkaya & López, 2016; Greenberg & Kaled, 2013). A manual examination of the peripheral smear can easily determine platelet clumping as the cause of thrombocytopenia; newer cell counter machines can also detect this.

Medical Management

The management of thrombocytopenia is usually treatment of the underlying cause. If the platelet count is low due to medications, removal of the offending agent may improve the platelet count. Medications strongly associated with thrombocytopenia include antibiotics (quinine, quinidine, penicillin, cephalosporin, vancomycin, trimethoprim-sulfamethoxazole, sulfonamides, and sulfonylureas), cardiovascular medications (digoxin, salicylates, and abciximab), and some miscellaneous agents (Cimetidine, Famotidine, Ranitidine, Valproate, and Interferon) (Abrams, 2016). When the platelet count is predictably lowered as a result of chemotherapy treatment, platelet transfusions may be needed to support the patient and prevent bleeding.

In hospitalized patients with chemotherapy-induced thrombocytopenia, platelets should be transfused to maintain a platelet count of more than 10,000/mm^3 to reduce the risk for spontaneous bleeding (Kaufman et al., 2015). Outpatients may be transfused more liberally (e.g., a platelet count less than 20,000/mm^3) because they may not be able to get daily transfusions due to logistical constraints (e.g., transportation availability). See Table 20-6 for further information on platelet transfusion parameters.

If excessive platelet destruction occurs, transfused platelets are also destroyed, and the platelet count does not increase. The most common cause of excessive platelet destruction is immune thrombocytopenia purpura (ITP) (see the following discussion). In some instances, splenectomy can be a useful therapeutic intervention, but often it is not an option; for example, in patients in whom the spleen is enlarged due to portal hypertension related to cirrhosis, splenectomy may cause more bleeding disorders.

Nursing Management

Nursing interventions for patients with thrombocytopenia are listed in Chapter 19, Box 19-3.

IMMUNE THROMBOCYTOPENIA PURPURA (ITP)

ITP is the most common autoimmune blood disorder, affecting people of all ages, although it is more common among children and young women. Historically, this disorder was referred to as "idiopathic" thrombocytopenia purpura because in many cases the underlying causes were unknown. In recent years, scientists have uncovered a number of etiologies leading to our current understanding of ITP as an autoimmune process, thus leading to the change in terminology from *idiopathic* to *immune* (Abrams, 2016). There are two forms of ITP: acute and chronic. Acute ITP, which occurs predominantly in children, often appears 1 to 6 weeks after a viral illness. This form is self-limited; remission often occurs spontaneously within 6 months. Chronic ITP is often diagnosed by exclusion of other causes of thrombocytopenia.

Pathophysiology

Although the precise cause of ITP remains unknown, the platelet count is decreased by a combination of antibody-mediated platelet destruction and impaired platelet production secondary to antiplatelet antibodies produced by B cells (Neunert, 2013). In addition, there is an inappropriately low rise in serum thrombopoietin, a hormone that stimulates platelet production (Abrams, 2016). Normally, in the presence of a low platelet count, the serum thrombopoietin rises to stimulate platelet production. In ITP, there is a low platelet count and an inappropriately low thrombopoietin level. While antiplatelet antibodies that bind to the platelets can be found in the blood of patients with ITP, testing for these antibodies is not currently recommended due to poor test sensitivity (Neunert, 2013). When the platelets are bound by the antibodies, the RES or tissue macrophage system ingests the platelets, destroying them. The production of autoantibodies may be triggered by medications or infections. Viral infections sometimes precede the disease in children. Occasionally medications, such as sulfa drugs, can induce ITP. Other conditions, such as systemic lupus erythematosus or pregnancy, can also induce ITP.

Clinical Manifestations and Assessment

Many patients have no symptoms, and the low platelet count (often below 20,000/mm^3; below 5,000/mm^3 is not uncommon) is an incidental finding. Common physical manifestations are easy bruising, heavy menses, and petechiae on the extremities or trunk. Patients with simple bruising or petechiae, termed "dry purpura," tend to have fewer complications from bleeding than do those with bleeding from mucosal surfaces, such as the GI tract (including the mouth) and pulmonary system (e.g., hemoptysis), termed "wet purpura." Patients with wet purpura have a greater risk of intracranial bleeding than do those with dry purpura.

Severe bleeding is rare in patients with platelet counts exceeding 30,000/mm^3 (Neunert, 2013). Despite low platelet quantity, the platelets are young and very functional. They adhere to endothelial surfaces and to one another so that spontaneous bleeding does not always occur. Thus, treatment may not be initiated unless bleeding becomes severe or life-threatening, the platelet count is extremely low (less than 10,000/mm^3), or in those with risk factors for bleeding, such as uncontrolled hypertension or peptic ulcer disease (Diz-Küçükkaya & López, 2016; Abrams, 2016).

Medical Management

The primary goal of treatment is a "safe" platelet count. Because the risk for bleeding typically does not increase until the platelet count is less than 10,000/mm^3, a patient whose count exceeds 30,000/mm^3 to 50,000/mm^3 may be carefully observed without additional intervention. However, if the count is less than 30,000/mm^3 or if bleeding occurs, treatment with steroids (prednisone) should be initiated (Abrams, 2016). The goal is to improve the patient's platelet count rather than to cure the disease. The decision to treat should not be made merely on the basis of the patient's platelet count but also on his or her lifestyle and activity level. A person with a sedentary lifestyle can tolerate a low platelet count more safely than one with a more active lifestyle.

ITP patients with severe thrombocytopenia (less than 5,000/μL) and/or those who have internal bleeding should be treated promptly with high doses of pulse corticosteroids and intravenous immunoglobulin IVIG (Abrams, 2016).

Treatment for ITP first focuses on removing any possible inciting agents. If the patient is taking a medication known to cause ITP (e.g., quinine, sulfa-containing medications), then the medication must be stopped immediately.

Traditional first-line therapies often include corticosteroids or corticosteroids in combination with IVIG (Neunert, 2013). A substantial number of adults with newly diagnosed ITP (40% to 60%) achieve and maintain a response to first-line therapy that can last up to 6 months; however, very few maintain this response at 1 year (Cuker, Luning Prak, & Cines, 2015).

Because of the associated side effects, patients cannot take high doses of corticosteroids indefinitely. It is not unusual for the platelet count to drop once the corticosteroid dose is tapered. Some patients can be maintained successfully on low doses of prednisone.

IVIG is also commonly used to treat ITP. The timing of IVIG in the treatment of ITP is controversial as other treatments offer comparable efficacy at a lower cost with less toxicity (Kessler, 2015). IVIG works by binding receptors on the macrophages; the effects are more rapid than daily oral prednisone, and response rates are approximately 80% with effects that are transient, lasting 2 to 4 weeks (Abrams, 2016).

Second-line therapies for patients whose platelet count drops after cessation of steroids include splenectomy, rituximab, and thrombopoietin receptor antagonists (TPO-RAs) (Neunert, 2013; Abrams, 2016).

The spleen is the primary site of platelet destruction and antiplatelet antibody production; removal of the spleen removes the mechanism for platelet destruction (Neunert, 2013). Splenectomy is the only curative therapy for ITP, with studies demonstrating a durable response in 66% to 72% of patients (Mikhael et al., 2009; Neunert, 2013; Abrams, 2016). Approximately half of the remaining patients who do not have normal platelet counts following splenectomy do achieve a partial response that is clinically meaningful (i.e., no bleeding events) (Abrams, 2016). However, even those who do respond initially to splenectomy may have recurrences of severe thrombocytopenia months or years later. Unfortunately, 10% to 15% of patients derive no benefit from splenectomy, and there is no test to predict whether a particular patient will respond to this treatment (Abrams, 2016).

Despite promising rates of success with splenectomy, the availability of newer

medications (such as TPO-RAs) has resulted in reluctance from patients and providers to recommend invasive surgery for splenectomy (Neunert, 2013).

Patients who have undergone splenectomy are permanently at risk for sepsis, most commonly caused by pneumococcus or encapsulated bacteria. Though the incidence of sepsis in asplenia is relatively rare, when sepsis does develop in asplenic patients, there is a mortality rate of up to 50% (Rubin & Schaffner, 2014). Prevention of fatal infection depends on comprehensive patient education, vaccination, and early antibiotic initiation in the onset of fever (Rubin & Schaffner, 2014). Prior to splenectomy, these patients should receive pneumococci (Pneumovax), *Haemophilus influenzae* B, influenza virus, and meningococcal vaccines. PCV13 followed by PPSV23 8 weeks later is recommended for the prevention of pneumococcal infection; the series should be completed at least 2 weeks before splenectomy. A second dose of PPSV23 should be repeated in 5 years. Boosters of the meningococcal vaccine must be given every 5 years, and influenza vaccines should be given every year (Rubin & Schaffner, 2014). If an asplenic patient has a fever, antibiotics should be administered immediately. For this reason, asplenic patients are often given prescriptions for antibiotics such as amoxicillin or levofloxacin so that they always have antibiotics on hand.

Rituximab, a monoclonal antibody that targets the CD 20 marker on B cells, has been used successfully to treat ITP following treatment with steroids. Rituxan depletes the B cells that produce platelet-destroying autoantibodies, effectively increasing the platelet count. Although rituximab has not been approved by the U.S. Food and Drug Administration (FDA) for the treatment of ITP, it is widely used in clinical practice. It is well tolerated and has few side effects. Studies have demonstrated a response rate between 28% and 44%; however, when used in combination with dexamethasone, higher response rates have been seen (Abrams, 2016).

The treatment of ITP has changed dramatically with the discovery of drugs that target the point of platelet production. Romiplostim (Nplate®) and Eltrombopag (Promacta®) are thrombopoietin receptor agonists that stimulate platelet production by stimulating proliferation and differentiation of platelet precursors (Cuker, Luning Prak, & Cines, 2015). Romiplostim is administered weekly via subcutaneous injection, and Eltrombopag is a pill given once daily. Both medications have demonstrated efficacy in increasing the platelet count by 70% (Abrams, 2016). These drugs are not currently considered curative, and most patients require continuation of therapy to maintain response (Cuker et al., 2015; Neunert, 2013).

Despite the extremely low platelet count, platelet transfusions are usually avoided. Transfusions tend to be ineffective because the patient's antiplatelet antibodies bind with the transfused platelets, causing them to be destroyed. Platelet counts can actually drop after platelet transfusion. Occasionally, transfusion of platelets may protect against catastrophic bleeding in patients with severe wet purpura.

Nursing Management

Nursing care includes an assessment of the patient's lifestyle to determine the risk of bleeding from activity. Also a careful medication history is obtained, including use of over-the-counter medications, herbs, and nutritional supplements. The nurse must be alert for sulfa-containing medications and others that alter platelet function (e.g., aspirin-based or other nonsteroidal anti-inflammatory drugs [NSAIDs]) (see Box 20-4). The nurse assesses for any history of recent viral illness and for risk factors for hepatitis and HIV. Reports of headache or visual disturbances should be reported to the licensed provider immediately as these symptoms can signal intracranial bleeding. Patients who are admitted to the hospital with wet purpura and low platelet counts should have a neurologic assessment incorporated into their routine vital sign measurements. All intramuscular injections and rectal medications should be avoided, and rectal temperature measurements should not be performed because they can stimulate bleeding.

Patient teaching addresses signs of exacerbation of disease (petechiae, ecchymoses, wet purpura), how to contact appropriate health care personnel, the name and type of medication inducing ITP (if appropriate), current medical treatment (medications, tapering schedule if relevant, side effects), and the frequency of monitoring the platelet count. The patient is instructed to avoid all agents that interfere with platelet function (see Box 20-4). The patient should avoid constipation, as well as the Valsalva maneuver (straining to have a bowel movement). Electric razors should be used for shaving, and soft-bristled toothbrushes should replace stiff-bristled ones. The patient is also counseled to refrain from sexual intercourse when the platelet count is less than 50,000/mm^3. Patients who are receiving corticosteroids long term are at risk for complications, including osteoporosis, proximal muscle wasting, cataract formation, and dental caries. Bone mineral density should be monitored, and these patients may benefit from calcium and vitamin D supplementation and bisphosphonate therapy to prevent significant bone disease.

BOX 20-4 Medications and Substances that Impair Platelet Function

- Anesthetic agents:
  - Local anesthetics
  - Halothane
- Antibiotics:
  - Beta-lactam antibiotics
  - Penicillins
  - Cephalosporins
  - Nitrofurantoin
  - Sulfonamides
- Anticoagulation agents:
  - Heparin
  - Fibrinolytic agents

- Anti-inflammatory agents (Nonsteroidal):
  - Aspirin
  - Ibuprofen
  - Naproxen
- Antineoplastic agents:
  - Carmustine
  - Daunorubicin
  - Mithramycin
- Cardiovascular drugs:
  - Beta blockers
  - Calcium-channel blockers
  - Isosorbide
  - Nitroglycerine
  - Nitroprusside
  - Quinidine
- Medications that increase platelet cAMP:
  - Dipyridamole
  - Prostacyclin
  - Theophylline
- Food and food additives:
  - Caffeine
  - Chinese black tree fungus
  - Clove
  - Cumin
  - Ethanol
  - Fish oils
  - Garlic
  - Onion extract
  - Turmeric
- Plasma expanders:
  - Dextrans
  - Hydroxyethyl starch
- Psychotropic agents:
  - Tricyclic antidepressants
  - Phenothiazines
- Miscellaneous:
  - Antihistamines
  - Clofibrate
  - Furosemide
  - Heroin
  - Contrast agents

- Ticlopidine
- Vitamin E

- Herbal supplements:
  - Feverfew
  - Ginger
  - Gingko
  - Ginseng
  - Kava kava

PLATELET DEFECTS

Quantitative platelet defects are relatively common (thrombocytopenia), but qualitative defects can occur also. With qualitative defects, the number of platelets may be normal, but the platelets do not function normally. See Chapter 19 for an outline of testing for platelet defects.

An important functional platelet disorder is that induced by aspirin. Even small amounts of aspirin reduce normal platelet aggregation, and the prolonged bleeding time lasts for several days after aspirin ingestion. Although this does not cause bleeding in most people, patients with a coagulation disorder (e.g., hemophilia) or thrombocytopenia can have significant bleeding after taking aspirin, particularly if invasive procedures or trauma has occurred.

NSAIDs can also inhibit platelet function, but the effect is not as prolonged as with aspirin (about 5 days vs. 7 to 10 days). Other causes of platelet dysfunction include, possibly metabolic products affecting platelet function, MDS, multiple myeloma (MM) (due to abnormal proteins interfering with platelet function), cardiopulmonary bypass, and other medications (see Box 20-4).

Clinical Manifestations and Assessment

Bleeding may be mild or severe. The extent is not necessarily correlated with the platelet count or with tests that measure coagulation (prothrombin time [PT], partial thromboplastin time [PTT]). Ecchymoses are common, particularly on the extremities. Patients with platelet dysfunction may be at risk for significant bleeding after trauma or invasive procedures (e.g., biopsy, dental extraction).

Medical Management

If the platelet dysfunction is caused by medication, use of the offending medication should be stopped, if possible, particularly when bleeding occurs or prior to an invasive procedure. If platelet dysfunction is marked, bleeding often can be prevented by transfusion of normal platelets before or during invasive procedures. Aminocaproic acid (EACA, Amicar), an antifibrinolytic agent, may be required to prevent significant bleeding after such procedures.

Nursing Management

Patients with significant platelet dysfunction need to be instructed to avoid substances that can diminish platelet function, such as certain over-the-counter medications, herbs, nutritional supplements, and alcohol. They also need to serve as their own advocates and inform their health care providers (including dentists) of the underlying condition before any invasive procedure is performed so that appropriate steps can be initiated to diminish the risk of bleeding. Bleeding precautions should be initiated as appropriate (see Chapter 19, Box 19-2).

BLEEDING DISORDERS

Von Willebrand Disease

Von Willebrand disease (vWD) is the most common inherited bleeding disorder in humans (Taylor, 2015). The disease affects males and females equally. The prevalence of this disease is estimated to be 1% to 2%; thus, it is the most common inherited bleeding disorder (Ferri, 2016b). The disease is a result of deficiency, dysfunction, or absence of von Willebrand Factor (vWF) (Ferri, 2016b). vWF is necessary for factor VIII activity and is essential for platelet adhesion at the site of vascular injury. Although synthesis of factor VIII is normal in vWD, its half-life is shortened; therefore, factor VIII levels are mildly low (15% to 50% of normal).

There are three types of vWD. Type 1, the most common (accounting for 60% to 80% of cases), is a quantitative defect in vWF and is inherited in an autosomal dominant pattern (Taylor, 2015). Type 2 shows variable qualitative defects based on the specific vWF subtype involved (with subtypes 2A, 2B, 2M, and 2N). Type 3 is very rare and is characterized by a severe vWF deficiency as well as by a significant deficiency of factor VIII.

Clinical Manifestations and Assessment

The history should include questions related to bleeding following a procedure, such as a dental procedure; need for blood transfusions following surgery or childbirth; history of heavy menses; and easy bruising (Ferri, 2016b). Patients commonly have mucocutaneous bleeding, including nosebleeds and large bruises (Taylor, 2015). Women may report heavy menses. Bleeding with minor surgery may also be seen. Joint bleeding is uncommon (Taylor, 2015).

Laboratory test results show a normal platelet count but a prolonged bleeding time and a normal or slightly prolonged PTT. These defects are not static, and laboratory test results can vary widely within the same patient over time. As the laboratory values can vary over time so can the history and extent of bleeding. For example, a careful history of prior bleeding may show little problem with postoperative bleeding on one occasion but significant bleeding from a dental extraction at another time. Laboratory tests required to diagnose vWD include the vWF ristocetin cofactor activity, vWF antigen, factor VIII activity, and, for patients with suspected type 2 defects, vWF multimers (Taylor, 2015).

Medical Management

The goal of treatment is to replace the deficient protein (e.g., vWF or factor VIII) at the time of spontaneous bleeding or prior to an invasive procedure to minimize postprocedural bleeding. There are two general strategies to meet this goal. For types 1 and 1A, the first line of treatment is administration of a synthetic form of the hormone vasopressin, called desmopressin (DDAVP). Desmopressin causes the release of vWF stored within the endothelium, resulting in a temporary increase in circulating vWF and factor VIII (Taylor, 2015). Desmopressin can be administered intranasally or intravenously. With major surgery or invasive procedures, IV administration is preferable. DDAVP is contraindicated in patients with unstable coronary artery disease because it can induce platelet aggregation and cause an MI. Side effects include headache, facial flushing, tachycardia, hyponatremia from free water retention, and, rarely, seizures. It is contraindicated in type 2B vWD because of risk of thrombocytopenia and has no efficacy for type 3 vWD (Nichols, 2016).

The second strategy is the administration of replacement products, such as Alphanate SD/HT (Grifols), Humate-P (CSL Behring), and Wilate (Octapharma), which are commercial concentrates of vWF and factor VIII (Nichols, 2016). Administration of these agents shortens bleeding time through normalization of multimer patterns (Taylor, 2015). Replacement continues for several days to ensure correction of the factor VIII deficiency. Treatment should continue for 4 days following minor surgery, and up to 14 days of treatment may be necessary after major surgery. The dosage and frequency of administration depend on factor VIII levels; doses may need regular adjustment based on trough levels. Antibody (inhibitor) formation is usually seen only in patients with type 3 vWD when large amounts of replacement products have been administered.

Other agents may be effective in reducing the bleeding. Aminocaproic acid (EACA, Amicar) is useful in managing mild forms of mucosal bleeding, for example, prior to dental work (Taylor, 2015). Hormonal contraceptives, such as the levonorgestrel-releasing intrauterine device, have demonstrated efficacy in reducing menorrhagia in women with bleeding disorders (Nichols, 2016). Platelet transfusions may be useful when significant bleeding is present.

Nursing Alert
Avoidance of aspirin and other NSAIDs is important nursing education to share with patients who have vWD.

ACQUIRED COAGULATION DISORDERS

The most common causes of acquired coagulation disorders include liver disease, vitamin K deficiency, and disseminated intravascular coagulation (DIC), all of which can result in abnormal bleeding.

LIVER DISEASE

With the exception of factor VIII, most blood coagulation factors are synthesized in the liver. Therefore, liver dysfunction (due to cirrhosis, tumor, or hepatitis; see Chapter 25) can result in diminished amounts of the factors needed to maintain coagulation and hemostasis. Prolongation of the PT, unless it is caused by vitamin K deficiency, may indicate severe liver dysfunction. Although minor bleeding is common (e.g., ecchymoses), these patients are also at risk for significant bleeding, related especially to trauma or surgery. Transfusion of fresh-frozen plasma may be required to replace clotting factors and to prevent or stop bleeding. Patients may also have life-threatening hemorrhage from peptic ulcers or esophageal varices. In these cases, replacement with fresh-frozen plasma, PRBCs, and platelets is usually required.

VITAMIN K DEFICIENCY

The synthesis of many coagulation factors depends on vitamin K. Vitamin K deficiency is common in malnourished patients, and some antibiotics decrease the intestinal flora that produce vitamin K, depleting vitamin K stores. Administration of vitamin K (phytonadione [Mephyton]), either orally or as a subcutaneous injection, can correct the deficiency quickly; adequate synthesis of coagulation factors is reflected by normalization of the PT.

COMPLICATIONS OF ANTICOAGULANT THERAPY

Anticoagulants are used in the treatment or prevention of thrombosis. These agents, particularly warfarin or heparin, can cause bleeding. If the PT or PTT is longer than desired, and bleeding has not occurred, the medication can be stopped or the dose decreased. Vitamin K is administered as an antidote for warfarin toxicity. Protamine sulfate is rarely needed for heparin toxicity because the half-life of heparin is very short. With significant bleeding, fresh-frozen plasma is needed to replace the vitamin K–dependent coagulation factors.

DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

DIC is not a disease but a sign of an underlying condition. DIC may be triggered by sepsis, trauma, cancer, shock, abruptio placentae, toxins, or allergic reactions. The severity of DIC is variable, but it is potentially life-threatening. The mortality rate can exceed 80% of patients who develop severe DIC with ischemic thrombosis and frank hemorrhage.

Identification of patients who are at risk for DIC and recognition of the early clinical manifestations of this syndrome can result in earlier medical intervention, which may improve the prognosis. However, the primary prognostic factor is the ability to treat the underlying condition that precipitated DIC.

Pathophysiology

Normal hemostatic mechanisms are altered in DIC so that a massive amount of tiny clots forms in the microcirculation. Initially, the coagulation time is normal. However, as the platelets and clotting factors are consumed to form the microthrombi, coagulation fails. Thus, the paradoxical result of excessive clotting is bleeding. The clinical manifestations of DIC are reflected in the organs, which are affected either by excessive clot formation (with resultant ischemia to all or part of the organ) or by bleeding. The excessive clotting triggers the fibrinolytic system to release fibrin degradation products, which are potent anticoagulants, furthering the bleeding. The bleeding is characterized by consumption of platelets and clotting factors, thus precipitating low platelet and fibrinogen levels (due to the consumption of fibrinogen); prolonged PT, PTT, and thrombin time; and elevated fibrin degradation products (D-dimers) (see Table 20-3 for an overview of laboratory values commonly found in DIC).

Clinical Manifestations and Assessment

Patients with frank DIC may bleed from mucous membranes, venipuncture sites, and the GI and urinary tracts. The bleeding can range from minimal occult internal bleeding to profuse hemorrhage from all orifices. The patient may also develop organ dysfunction, such as kidney failure and pulmonary and multifocal CNS infarctions, as a result of microthromboses, macrothromboses, or hemorrhages.

During the initial process of DIC, the patient may have no new symptoms, the only manifestation being a progressive decrease in the platelet count. As the thrombosis becomes more extensive, the patient exhibits signs and symptoms of thrombosis in the organs involved. Then, as the clotting factors and platelets are consumed to form these thrombi, bleeding occurs. Initially, the bleeding is subtle, but it can develop into frank hemorrhage. Signs and symptoms, which depend on the organs involved, are listed in Table 20-4.

Medical Management

The most important management factors in DIC are early recognition and treatment of the underlying cause; until the cause is controlled, the DIC will persist (Toh & Alhamdi, 2013). Correcting the secondary effects of tissue ischemia by improving oxygenation, replacing fluids, correcting electrolyte imbalances, and administering vasopressor medications is also important.

TABLE 20-3 Laboratory Values Commonly Found in Disseminated Intravascular Coagulation (DIC)[a]

Test	Function Evaluated	Normal Range	Changes in DIC
Platelet count	Platelet number	150,000–450,000/mm^3	↓
Prothrombin time (PT)	Extrinsic pathway	11–12.5 seconds	↑
Partial thromboplastin time (PTT)	Intrinsic pathway	23–35 seconds	↑
Thrombin time (TT)	Clot formation	8–11 seconds	↑
Fibrinogen	Amount available for coagulation	170–340 mg/dL	↓
D-dimer	Local fibrinolysis	0–250 ng/mL	↑
Fibrin degradation products (FDPs) or fibrin split products (FSPs)	Fibrinolysis	0–5 µg/mL	↑
Euglobulin clot lysis	Fibrinolytic activity	2 or more hours	1 hour or less

[a]Because DIC is a dynamic condition, the laboratory values measured will change over time. Therefore, a progressive increase or decrease in a given laboratory value is likely to be more important than the actual value of a test at a single point in time.

Blood product support includes platelets, fresh-frozen plasma, and cryoprecipitate (to replace fibrinogen). The decision to transfuse should be based on laboratory trends and the patient's condition. FFP should be given in the presence of bleeding and prolonged PT/PTT; platelets are transfused if the platelet count is less than 50,000/mm^3; cryoprecipitate is considered in patients with a fibrinogen below 1.5 g/L (less than 150 mg/dL) (Toh & Alhamdi, 2013).

TABLE 20-4 Assessing for Thrombosis and Bleeding in Disseminated Intravascular Coagulation (DIC)[a]

System	Signs and Symptoms of Microvascular Thrombosis	Signs and Symptoms of Microvascular and Frank Bleeding
Integumentary system (skin)	↓ Temperature and sensation; ↑ pain; cyanosis in extremities, nose, earlobes; focal ischemia, superficial gangrene	Petechiae, including oral mucosa; bleeding: gums, oozing from wounds, previous injection sites, around catheters (IV or foley); tracheostomies; epistaxis; diffuse ecchymoses; subcutaneous hemorrhage; joint pain
Circulatory system	↓ Pulses; capillary filling time greater than 3 sec	Tachycardia
Respiratory system	Hypoxia (secondary to clot in lung); dyspnea; chest pain with deep inspiration; ↓ breath sounds over areas of large embolism	High-pitched bronchial breath sounds; tachypnea; ↑ consolidation; signs and symptoms of acute respiratory distress syndrome
Gastrointestinal system	Gastric pain; "heartburn"	Hematemesis (heme⊕ NG output) melena (heme⊕ stools → tarry stools → bright-red blood from rectum) retroperitoneal bleeding (abdomen firm and tender to palpation; distended; ↑ abdominal girth; back pain)
Kidney system	↓ Urine output; ↑ creatinine, ↑ blood urea nitrogen	Hematuria
Neurologic system	↓ Alertness and orientation; ↓ pupillary reaction; ↓ response to commands; ↓ strength and movement ability	Anxiety; restlessness; ↓ mentation, altered level of consciousness; headache; visual disturbances; conjunctival hemorrhage

heme⊕, positive for hemoglobin.
[a]Signs of microvascular thrombosis are the result of an inappropriate activation of the coagulation system, causing thrombotic occlusion of small vessels within all body organs. As the clotting factors and platelets are consumed, signs of microvascular bleeding appear. This bleeding can quickly extend into frank hemorrhage. Treatment must be aimed at the disorder underlying the DIC; otherwise, the stimulus for the syndrome will persist.

A controversial treatment strategy is to interrupt thrombosis through the use of heparin infusion. Heparin may inhibit the activation of the coagulation pathway in sepsis, inhibiting microthrombi formation and thereby correcting perfusion of the organs. However, a beneficial effect of heparin on outcomes in patients with DIC has never been demonstrated in controlled trials and may increase the incidence and risk for bleeding in patients with DIC. Heparin is indicated only in patients with clinically evident thromboembolism in a large blood vessel or with evidence of tissue damage secondary to thromboemboli; extreme caution must be used due to the high risk for bleeding (Schafer, 2016). There is a recent trend toward using LMWH due to decreased bleeding risks and predictable half-life (Toh & Alhamdi, 2013).

Another therapy in the treatment of DIC includes recombinant activated protein C (APC; drotrecogin alfa [Xigris®]), which is effective in diminishing inflammatory responses on the surface of the vessels and has anticoagulant properties. APC has been used in the setting of DIC secondary to sepsis; however, the overall survival benefit with these agents in patients with DIC has not been demonstrated (Schafer, 2016). APC is contraindicated in patients with bleeding and increases the risk for bleeding in patients with low platelet counts (less than 30,000/mm^3) or an international normalized ratio (INR) of more than 3.0. Bleeding is common, can occur at any site, and can be significant. Antithrombin (AT) infusions can also be used for their anticoagulant and anti-inflammatory properties. Bleeding can be significant, particularly when administered in association with heparin. Use of AT has yet to demonstrate a survival advantage and needs further study (Toh & Alhamdi, 2013).

Nursing Management

Nurses need to be aware of which patients are at risk of DIC. Sepsis and acute promyelocytic leukemia (APML) are the most common causes of DIC. Patients need to be assessed thoroughly and frequently for signs and symptoms of thrombi and bleeding and monitored for any progression of these signs. Timely recognition of symptoms and prompt reporting to the medical team can help facilitate early intervention and improve outcomes (see Table 20-4).

In addition, the nurse monitors and manages potential complications. Assessment and interventions should target potential sites of end-organ damage (see Table 20-4). As organs are inadequately perfused because of occlusion by microthrombi, organ function diminishes; the kidneys, lungs, brain, and skin are particularly vulnerable, and kidney dysfunction is common. Lack of renal perfusion may result in acute tubular necrosis and kidney failure, sometimes requiring dialysis. Placement of a large-bore dialysis catheter is extremely hazardous for this patient population and should be accompanied by adequate platelet and plasma transfusions. Liver dysfunction is also relatively common, reflected in altered liver function tests, depleted albumin stores, and diminished synthesis of clotting factors. Respiratory function warrants careful monitoring and aggressive measures to diminish alveolar compromise, such as incentive spirometry. Suctioning (if required) should be performed as gently as possible to diminish the risk for additional bleeding. CNS involvement can be manifested as headache, visual changes, and alteration in level of consciousness. A plan of nursing care for the patient with DIC is available online at http://thepoint.lww.com/Honan2e.

THROMBOTIC DISORDERS

Several conditions can alter the balance within the normal hemostatic process and cause excessive thrombosis. Abnormalities that predispose a person to thrombotic events include decreased clotting inhibitors within the circulation (which enhances coagulation), altered liver function (which may decrease production of clotting factors or clearance of activated coagulation factors), lack of fibrinolytic enzymes, and tortuous vessels (which promote platelet aggregation). Thrombosis can be caused by more than one predisposing factor. Several conditions can result from thrombosis, such as myocardial infarction (MI) (see Chapter 14), Cerebral Vascular Accident (CVA) (brain attack or stroke; see Chapter 47), and peripheral arterial occlusion (see Chapter 18). Several inherited or acquired deficiency conditions, including hyperhomocysteinemia, AT III deficiency, protein C deficiency, APC resistance, factor V Leiden, and protein S deficiency, can predispose a patient to repeated episodes of thrombosis; these are referred to as hypercoagulable states or thrombophilia. Table 20-5 lists these disorders, their abnormal laboratory values, and the need for family testing.

Thrombosis requires anticoagulation therapy. The duration of therapy varies with the location and extent of the thrombosis, precipitating events (e.g., trauma, immobilization), and concurrent risk factors (e.g., use of oral contraceptives, tortuous blood vessels, history of thrombotic events). With some conditions, lifelong anticoagulant therapy is necessary. Refer to Chapter 18 for details on anticoagulation.

MALIGNANT HEMATOLOGIC CONDITIONS

Myeloproliferative Neoplasms

Myeloproliferative neoplasms (MPNs) are a group of myeloid malignancies with varying clinical presentation, disease course, treatment, and prognosis. In 2014, the World Health Organization (WHO) convened to revise the classification of MPNs to include: PV, essential thrombocythemia (ET), primary myelofibrosis, chronic myelogenous leukemia (CML), chronic neutrophilic leukemia (CNL), systemic mastocytosis, chronic eosinophilic leukemia, and MPN-unclassifiable (Tefferi & Pardanani, 2015). Here we will focus on the most common MPNs: PV, ET, and CML.

TABLE 20-5 Hypercoagulable States

Disorder	Abnormal Laboratory Value[a]
Inherited Disorders (Family Testing Necessary)	
Hyperhomocysteinemia	Homocysteine ↑ after methionine load
Antithrombin III (AT III) deficiency	AT III ↓
Protein C deficiency	Protein C activity ↓ (must be measured off warfarin [Coumadin])
Activated protein C (APC) resistance	Must be measured off anticoagulant; less than 2× prolongation of PTT when APC added. Patients with APC resistance have a smaller increase in clotting time than normal (i.e., the prolongation of clotting time is less than normal).
Factor V Leiden	Positive
Protein S deficiency	Protein S activity ↓; must be measured off warfarin (Coumadin)
Dysfibrinogenemia	↑ thrombin time; ↑ reptilase time; ↓ functional fibrinogen; often requires special fibrinogen assays
Acquired Disorders (Family Testing Unnecessary)	
Anticardiolipin antibody	Positive
Cancer	Varied, depending on disorder
Lupus anticoagulant	Positive
Hyperhomocysteinemia	Homocysteine ↑ after methionine load
AT III deficiency	AT III ↓
Paroxysmal nocturnal hemoglobinuria	+ Hamm test; acid hemolysis
Myeloproliferative disorders	Varied, depending on disorder
Nephrotic syndrome	Varied, depending on disorder
Cancer chemotherapy	Varied, depending on specific agent

[a]Protein C and protein S are vitamin K–dependent proteins. Warfarin (Coumadin) interferes with the hepatic synthesis of vitamin K–dependent factors, which may decrease levels of protein C or protein S; therefore, protein C and protein S should be measured while the patient is off warfarin.

POLYCYTHEMIA VERA

Polycythemia vera (PV), or primary polycythemia, is a clonal myeloproliferative disorder in which the myeloid stem cells have escaped normal control mechanisms. In most cases, PV is the result of a mutation in the JAK-STAT pathway, which stimulates cell growth (Ferri, 2016c). The bone marrow is hypercellular, and the erythrocyte, leukocyte, and platelet counts in the peripheral blood are elevated. The erythrocyte elevation is predominant; the hematocrit can exceed 60%. This phase can last for an extended period (10 years or longer). Over time, the spleen resumes its embryonic function of hematopoiesis and enlarges. Splenomegaly (enlarged spleen) is a hallmark of PV, present in 75% of patients (Ferri, 2016c). Eventually, the bone marrow may become fibrotic, with a resultant inability to produce as many cells ("burnt out" or spent phase). The disease evolves into myeloid metaplasia with myelofibrosis, MDS, or acute myeloid leukemia (AML) in approximately 10% of patients at 20 years from diagnosis; this form of AML is usually refractory to standard treatments (Tefferi, 2015). The incidence of polycythemia has been estimated at 1 per 100,000 people. The median age at onset is 60 years, occurring most commonly in patients 50 to 75 years of age; men are affected more than women (Ferri, 2016c). Median survival duration is 14 years (Tefferi, 2015).

Pathophysiology

PV is a clonal myeloid disorder driven by mutations in JAK2. According to criteria from WHO proposed in 2015, a diagnosis of PV requires the presence of an elevated Hgb (greater than 16.5 g/dL in men and greater than 16.0 g/dL in women) or evidence of increased RBC mass (over 49% in men; over 48% in women) and the presence of a JAK2 genetic mutation; additional criteria include a hypercellular bone marrow and low serum erythropoietin levels (Tefferi & Barbui, 2015; Passamonti, 2012). More than 95% of patients with PV have mutations in JAK2V617F, and patients with suspected PV should be screened for these mutations. A test that is positive for the mutation supports the diagnosis of PV.

Clinical Manifestations and Assessment

Patients may present with a ruddy complexion (referred to as plethora) and complaints related splenomegaly, including left upper quadrant pain and early satiety. Symptoms result from increased blood volume (headache, dizziness, tinnitus, fatigue, paresthesias, and blurred vision) or from increased blood viscosity (angina, claudication, dyspnea, and thrombophlebitis), particularly if the patient has atherosclerotic blood vessels. For this reason, blood pressure is often elevated. Uric acid may be elevated, resulting in gout and kidney stone formation. Another common and bothersome problem is generalized pruritus, which may be caused by histamine release due to the increased number of basophils. A hallmark feature of PV is severe and painful itching that is triggered by exposure to water (referred to as aquagenic pruritus) (Ferri, 2016c). Erythromelalgia a syndrome of painful burning, warmth, and redness in a localized distal area of the extremities; it most commonly occurs in the fingers and toes and is only partially relieved by cooling.

Patients who present with elevated hemoglobin and hematocrit should be assessed for the presence of PV. Causes of secondary erythrocytosis should not be present (see earlier discussion). Patients typically have a normal oxygen saturation level and splenomegaly on physical examination.

Complications

Patients with PV are at increased risk for thromboses, including: cerebrovascular accident (CVA or stroke), MI, and deep vein thrombosis (DVT); thrombotic complications are the most common cause of death. Risk factors for thrombosis in PV include age over 60 years, a history of vascular events, and smoking (Passamonti, 2012; Ferri, 2016c). Nearly 20% of patients experience arterial or venous thrombosis as their initial symptom (Ferri, 2016c). Bleeding is also a complication in the setting of extremely high platelet counts (exceeding 1.5 million) and associated acquired vWD (Passamonti, 2012; Tefferi, 2015). The bleeding can be significant and can occur in the form of nosebleeds, ulcers, frank GI bleeding, hematuria, and intracranial hemorrhage.

Medical Management

The goals of therapy include preventing thrombosis, palliating disease-associated symptoms, and delaying progression of disease to myelofibrosis or AML (Ferri, 2016c). Treatment strategies to achieve these goals include phlebotomy to reduce the hematocrit, antiplatelet therapy to reduce thrombosis risk, cytoreduction to control the blood counts, and modification of cardiovascular risk factors (Passamonti, 2012).

Phlebotomy is a critical part of therapy to lower the hematocrit and is the only treatment that has demonstrated improved survival; phlebotomy extends the average survival time to 12 years and is recommended in all PV patients (Ferri, 2016c; Tefferi, 2016a). It involves removing enough blood (initially 500 mL once or twice weekly) to diminish the blood viscosity and then intermittently to maintain the hematocrit below 45% in men and 42% in women. Many patients are managed by routine phlebotomy on an intermittent basis.

Additional therapy may be indicated based on the individual risk for thrombosis (high risk vs. low risk). Risk factors include a history of venous or arterial thrombosis, the presence of a JAK2 mutation, and age over 60 years (Tefferi, 2016a; Tefferi, 2016b). Risk factors for high-risk disease include a history of thrombosis or age over 60 years with a JAK2 mutation. Patients with high-risk disease with a history of venous thrombosis are treated with hydroxyurea and systemic anticoagulation; patients with high-risk disease and a history of arterial thrombosis are treated with hydroxyurea and once-daily aspirin (Tefferi, 2016b). High-risk patients with additional cardiovascular risk factors and a history of arterial thrombosis should be advised to take aspirin twice a day; if they are high risk with additional CV risk factors and a history of venous thrombosis, once-daily aspirin may be added to systemic anticoagulation (Tefferi, 2016b). Patients with very low risk (no history of thrombosis, age under 60 years, and no JAK2 mutation) and low-risk disease (no risk of thrombosis, age under 60 years, JAK2 mutation present) may be managed with aspirin alone (Tefferi, 2016b).

Randomized studies have demonstrated the value of low-dose aspirin (40 to 100 mg/day) and should be administered in the absence of contraindications (i.e., history of GI bleeding, hemorrhagic stroke). Aspirin is also effective in alleviating vasomotor symptoms, including painful erythromelalgia (a symptom that affects the extremities causing redness, warmth, and burning pain), headaches, pruritus, lightheadedness, tinnitus, paresthesias, and chest pain (Tefferi, 2015). Aspirin must be used with caution in patients with platelet counts exceeding 1 million/mm^3 given the risks for acquired vWD and associated bleeding risk.

Patients receiving hydroxyurea (Hydrea) appear to have a lower incidence of thrombotic complications than do those treated by phlebotomy alone; this may result from a more effectively controlled platelet count. Patients on hydrea must be counseled on avoiding pregnancy. Other side effects include mouth sores, skin (leg) ulcers, and nail changes (Passamonti, 2012). There is no conclusive data showing that hydrea increases the risk for leukemic transformation (Tefferi, 2014).

For patients unable to tolerate or who are resistant to hydroxyurea, interferon alpha-2b (Intron-A) is also an effective treatment for cytoreduction (Tefferi, 2016b). Interferon alpha is also effective in alleviating the pruritus associated with PV (Passamonti, 2012;

Tefferi, 2015) but may be difficult for patients to tolerate because of its frequent side effects (e.g., flu-like syndrome, depression).

Ruxolitinib, an oral JAK1-2 inhibitor that targets the JAK mutation, was recently approved for use in hydroxyurea-resistant or hydroxyurea-intolerant patients (Tefferi, 2016b). Studies have demonstrated that ruxolitinib lowers hematocrit to target goals, reduces spleen size, controls white blood cell (WBC) and platelet counts, and improves patient reported symptoms; however ruxolitinib has yet to demonstrate improvements in survival (Passamonti, 2012; Ferri, 2016c; Tefferi, 2016b).

Aquagenic pruritus is seen in 31% to 69% of patients with PV and can have a negative impact on quality of life (Lelonek & Szepietowski, 2016). It is a challenging symptom to manage. Improvement in pruritus often correlates with improvement in blood counts. Interferon alpha is often most effective in alleviating pruritus when used as treatment for PV. Antihistamines have demonstrated inconsistent efficacy and should not be recommended routinely. Selective serotonin receptor inhibitors have demonstrated efficacy (80%) in a small study of patients with PV (Tefferi et al., 2002; Lelonek & Szepietowski, 2016). Allopurinol (Zyloprim) is used to prevent gout in patients with elevated uric acid concentrations.

Patients with PV who smoke must be counseled on smoking cessation. Other modifiable cardiovascular risk factors, including obesity, hypertension, and diabetes, should also be addressed (Passamonti, 2012).

Nursing Management

The nurse's role is primarily that of educator. Risk factors for thrombotic complications, particularly smoking, obesity, and poorly controlled hypertension, should be assessed, and the patient should be instructed about risk reduction as well as the signs and symptoms of thrombosis. To reduce the likelihood of DVT, activity should be promoted, and crossing the legs and use of restrictive clothing should be avoided. The nurse instructs patients to walk around frequently on long flights. Patients with a history of bleeding are usually advised to avoid aspirin and aspirin-containing medications because these medications alter platelet function. The nurse encourages minimizing alcohol intake to further diminish the risk of bleeding. The patient needs to be instructed to avoid iron supplements, including those within multivitamin supplements, because the iron can further stimulate RBC production. For pruritus, the nurse may recommend bathing in tepid or cool water (hot water can exacerbate the symptom), limiting bathing time to 30 minutes or extending to every other day, and avoiding vigorous toweling-off after bathing. Use of mild soaps, application of emollient lotions, adding colloidal oatmeal treatment to bath water, use of cotton blankets and clothing, and washing sheets, clothing, and undergarments with baby detergent may also decrease pruritus.

ESSENTIAL THROMBOCYTHEMIA

ET (primary thrombocythemia) is a chronic, clonal, MPN. It most commonly occurs in women over 50 years of age and is marked by an overproduction of platelets. Women are 1.5 times more likely to have ET than men. Twenty percent of ET patients are under 40 years of age. Median survival is 20 years (Tefferi & Barbui, 2015).

Pathophysiology

Similar to PV, most cases of ET are driven by acquired mutations in *JAK2* (60% of ET cases); the remainder of patients will have mutations in either *CALR* or *MPL* genes (Tefferi & Barbui, 2015). The criteria proposed in 2015 by WHO for diagnosis of ET include: a platelet count of 450/mm^3 or higher; a bone marrow biopsy with increased numbers of large, mature megakaryocytes and no significant increase in neutrophil granulopoiesis or erythropoiesis; not meeting WHO criteria for CML, PV, primary myelofibrosis, MDS or other myeloid neoplasm; and/or presence of a clonal marker (such as *JAK2, MPL*, or *CALR* mutation) (Tefferi & Barbui, 2015).

Clinical Manifestations and Assessment

The diagnosis of ET is made by ruling out secondary causes of thrombocytosis (see earlier discussion). Iron deficiency should be excluded because a reactive increase in the platelet count often accompanies this deficiency. Occult malignancy should be excluded. The CBC shows markedly large and abnormal platelets. CBC, bone marrow aspiration and biopsy, and mutational testing for *JAK2, MPL*, and *CALR* are the cornerstones of diagnostic evaluation for ET (Tefferi & Barbui, 2015).

Many patients with ET are asymptomatic; the illness is diagnosed as the result of finding an elevated platelet count on a CBC. Symptoms, when they do occur, result primarily from hemorrhage or vaso-occlusion in the microvasculature. Symptoms occur most often when the platelet count exceeds 1 million/mm^3. However, symptoms do not always correlate with the extent to which the platelet count is elevated. Thrombosis is common and can be either arterial or venous; the life-threatening complications include large-vessel thrombosis (both arterial and venous), and hemorrhage (Tefferi, 2016b). Common sites of large vessel arterial occlusion include the arteries of the legs, the coronary arteries, and the renal arteries. Vasomotor symptoms are not infrequent complaints and can include visual disturbances, lightheadedness, headaches, palpitations, atypical chest pain, and distal paresthesias (Tefferi, 2016b). Headache is the most common neurologic complication, followed by transient ischemic attacks, dizziness, syncope, and seizures. More common forms of venous thrombosis include DVT and pulmonary embolism; less commonly, stroke and MI occur. Small vessel vaso-occlusive manifestations cause symptoms of erythromelalgia (described earlier).

Because these platelets can be dysfunctional, minor or major hemorrhage can also occur. The GI tract is the most common site of bleeding, followed by the skin, eyes, urinary tract, tooth socket and gums, joints, or brain. Bleeding typically does not occur unless the platelet count exceeds 1 million/mm^3. The spleen may be enlarged but usually not to a clinically significant extent.

No data reliably predict the development of complications. Risk factors for the development of thrombotic complications are age older than 60 years, gender (men are at greater risk than women), smoking, prior thrombotic or bleeding events, and pre-existing cardiac risk factors (obesity, hypertension, hypercholesterolemia, and smoking) (Lai, 2015).

Medical Management

The approach to therapy in ET is similar to PV; the goals are to reduce thrombotic risk and alleviate symptoms (Tefferi & Pardanani, 2015). The risk for significant thrombotic or hemorrhagic complications may not be increased until the platelet count exceeds 1.5 million/mm^3. A careful assessment of other risk factors, such as history of peripheral vascular disease, history of tobacco use, atherosclerosis, and prior thrombotic events, should be used in making the decision regarding when to initiate therapy.

As in PV, a risk-adapted strategy for ET is recommended with high risk defined as a history of thrombosis or age greater than 60 years with a JAK2 mutation (Tefferi, 2016a). High-risk patients are treated with hydroxyurea and either systemic anticoagulation (history of venous thrombosis) or aspirin (history of arterial thrombosis) (Tefferi, 2016a). Low-risk patients may be treated with aspirin alone.

Aspirin (81 mg/day) is recommended for patients with *JAK2*-mutated ET and also can be used to relieve the neurologic symptoms (e.g., headache), erythromelalgia, and visual symptoms of ET (Tefferi & Pardanani, 2015). As in PV, in the setting of very high platelet counts, acquired vWD can occur; use of aspirin should be avoided unless the Ristocetin Cofactor Activity test is greater than 30% (Lai, 2015; Tefferi & Barbui, 2015).

For patients unable to tolerate or resistant to hydroxyurea, interferon alpha is an option for second-line therapy (Tefferi, 2016). Interferon alpha has been associated with hematologic response rates up to 80% for ET, but its use is limited by side effects, including cytopenias, flu-like symptoms, and fatigue, contributing to discontinuation in up to 20% of patients (Kaplan et al., 2016).

Rarely, the occlusive symptoms of ET are so great that the platelet count must be reduced immediately. When necessary, plateletpheresis (see later discussion) can reduce the amount of circulating platelets but only transiently. The extent to which symptoms and complications (e.g., thromboses) are reduced by pheresis remains unclear.

Nursing Management

Patients with ET need to be instructed about the accompanying risks of hemorrhage and thrombosis. The patient is informed about signs and symptoms of thrombosis, particularly the neurologic manifestations, such as visual changes, numbness, tingling, and weakness as well as chest pain, and extremity swelling, redness, or pain. Risk factors for thrombosis are assessed, and measures to diminish risk factors (particularly cessation of tobacco use and weight management) are encouraged.

Patients receiving aspirin therapy should be informed about the increased risk of bleeding. Patients who are at risk for bleeding should be instructed about medications (e.g., aspirin, NSAIDs) and other substances (e.g., alcohol) that can alter platelet function and, therefore, should be avoided. Patients receiving interferon therapy are taught to self-administer the medication and manage any side effects promptly (primarily fatigue, flu-like symptoms, and depression).

CHRONIC MYELOID LEUKEMIA (CML)

There were an estimated 5,900 new cases of CML in 2013 (ACS, 2013). The incidence of CML increases with age; the median age at diagnosis is 67 years. Thus, the prevalence of CML is predicted to increase because of demographics (aging population), and the acknowledgment that because of highly effective therapies for CML, there will be an increased number of those living with the disease. Prevalence is expected to reach 250,000 in the next 20 years. CML may be seen at any age, but is uncommon in children and adolescents (NCCN, 2016b). CML is slightly more common in men and accounts for 15% to 20% of adult leukemias (Rathore, 2017a).

Pathophysiology

CML is a clonal myeloid MPN marked by the presence of the Philadelphia chromosome; a balanced mutation of chromosomes 9 and 22 (t9;22) resulting in the production of the bcr/abl kinase protein, which is responsible for aberrant cell growth.

CML involves an overproduction of myeloid WBCs. The platelet count may also be elevated. Because there is an uncontrolled proliferation of cells, the marrow expands into the cavities of long bones (e.g., the femur), resulting in bone pain, and myeloid cells may also be produced in the liver and spleen (extramedullary hematopoiesis), resulting in enlargement of these organs that is sometimes painful.

There are three phases of the disease: the chronic phase, where most of the leukocytes produced are mature and retain some ability to function normally; the accelerated phase, in which the numbers of abnormal cells are being produced at a faster rate; and blast crisis, in which the predominant cell type is immature. Most patients are diagnosed in the chronic phase. Untreated CML will progress to advanced phases in 3 to 5 years (NCCN, 2016b). Once the disease transforms to the acute phase (blast crisis), the overall survival rarely exceeds several months.

Clinical Manifestations and Assessment

The clinical picture of CML varies based on the phase of the disease. During the chronic phase, 40% to 50% of patients are asymptomatic, and so the diagnosis may be detected based on abnormal blood work. The most common symptoms include fatigue, night sweats, abdominal pain, early satiety, and weight loss (O'Brien & Jabbour, 2016).

Patients with extremely high leukocyte counts (over 100,000/mm^3) may exhibit signs of leukostasis (the excessive volume of leukocytes slows and inhibits blood flow through the capillaries via increased viscosity) including confusion, vision changes, shortness of breath, or chest pain due to decreased capillary perfusion to the brain, eyes, and lungs. The patient may have an enlarged, tender spleen. The liver may also be enlarged.

Medical Management

Advances in understanding of the pathology of CML at a molecular level have led to dramatic changes in its treatment. The development of drugs that target and inhibit the bcr/abl tyrosine kinase protein (called tyrosine kinase inhibitors or TKIs) have significantly extended survival for patients with CML and have shifted the paradigm of CML management to that of a chronic disease. The 5-year survival rate for patients diagnosed in the chronic phase and treated with TKIs is as high as 90% (Cortes et al., 2016).

Therapy depends on the stage of disease. In the chronic phase, the expected outcome is correction of the chromosomal abnormality (i.e., conversion of the malignant stem cell population back to normal), and the standard therapy is a TKI. TKIs approved for the front-line setting include imatinib, nilotinib, and dasatinib. TKIs approved in the second-line setting include dasatinib, nilotinib, and bosutinib (Bauer, Buchanan, & Ryan, 2016). Initial response to therapy is through monitoring of the CBC with expected normalization of blood counts within the first 4 to 6 weeks of therapy, called a complete hematologic response. Subsequent response to TKI therapy using blood measurement of bcr/abl quantity (molecular testing) is done every 3 months with the goal of reaching major molecular response. Achievement and maintenance of early major molecular response is predictive of longer survival (Cortes, Goldman, & Hughes, 2012). There are established goals for molecular response at set time points, including 3 months, 6 months, 12 months, etc. (NCCN, 2016b). If patients do not meet established milestones, assessment of adherence must be performed as well as resistance testing. There is a blood test to assess for the development of mutational resistance to TKIs. The test will alert the provider if the patient has developed resistance to a particular TKI and will direct the provider to TKIs to which the disease remains sensitive. Adherence to prescribed therapy is essential to response; when adherence falls below 90%, response to therapy declines.

During the initial phase of treatment, if there is significant leukocytosis, the WBC needs to be reduced quickly to minimize complications from leukostasis. This goal can be achieved by using drugs like hydroxyurea in conjunction with initiation of TKI therapy. In the case of an extreme leukocytosis at diagnosis (e.g., leukocyte count greater than 300,000/mm^3), a more emergent treatment may be required. In this instance, *leukapheresis* (in which the patient's blood is removed and separated, with the leukocytes withdrawn, and the remaining blood returned to the patient) can reduce the number of leukocytes temporarily.

The treatment of CML in the accelerated and blast phases is more challenging, as many patients in advanced stages of disease have developed resistance to TKIs. There is no consensus on optimal treatment of patients with advanced CML (Mukherjee & Kalycio, 2016). Options for treatment include second-line TKIs based upon mutation analysis or allogeneic hematopoietic stem cell transplantation (AHSCT) (discussed in Chapter 6) (O'Brien & Jabbour, 2016). Prognosis at time to progression is 7 to 11 months (Mukherjee & Kalycio, 2016).

The accelerated or transformation phase can be insidious or rapid. In the accelerated phase, the patient may complain of bone pain and may report fevers (without any obvious sign of infection), night sweats, and weight loss. Even with treatment, the spleen may continue to enlarge. The patient may become more anemic and thrombocytopenic.

In the acute form of CML (blast crisis), the disease progresses to either Acute lymphocytic leukemia (ALL) or Acute Myeloid Leukemia (AML) blast phase, and treatment is targeted to the specific type. Patients whose disease evolves into a "lymphoid" blast crisis are more likely to reenter a chronic phase after ALL induction therapy. For those whose disease evolves into AML, therapy is largely ineffective in achieving a second chronic phase. Life-threatening infections and bleeding occur frequently in this phase.

Allogeneic stem cell transplantation remains the only curative treatment for CML. However, the efficacy of imatinib in first-line treatment and the treatment-related mortality of stem cell transplant limit the use of transplant to patients with high-risk or relapsed disease or in those patients who are resistant to TKI therapy (Jabbour, 2016). Human leukocyte antigen (HLA)-matched, related donor stem cell transplants result in long-term survival in 45% to 70% of recipients. Patients over 50 years of age have a slightly lower survival rate (30% to 40%) compared with those younger than 30 to 40 years of age (60% to 80%) (O'Brien & Jabbour, 2016).

Nursing Management

The nurse must educate the patient on proper administration of TKI therapy. Some TKIs require timing around meals (nilotinib), and patients may need assistance with optimal scheduling. Antacids, PPIs, and grapefruit juice may interfere with drug absorption, and patients must be counseled to avoid these while on TKI therapy. There are a number of other drug interactions with TKIs, and nurses should collaborate with the pharmacist to review the patient's drug list for potential interactions. Most patients will require lifetime therapy with TKIs. Each TKI has a specific side-effect profile that may interfere with adherence and tolerance. For example, GI side effects and fluid retention are common with some of the TKIs. Patients must be counseled on the individual side-effect profile of the drug and be instructed to notify their health care team promptly with any new symptoms. The nurse's role in side-effect anticipation and management is critical. The nurse also plays an active role in the assessment and promotion of adherence to TKI therapy.

BONE MARROW FAILURE SYNDROMES

Bone marrow failure syndrome is the term for a classification that includes aplastic anemia (AA), paroxysmal nocturnal hemoglobinuria (PNH), and MDS.

APLASTIC ANEMIA (AA)

AA is a rare disease caused by a decrease in or damage to bone marrow stem cells, damage to the microenvironment within the marrow, and replacement of the marrow with fat, resulting in cytopenias (reduction in number of blood cells). Immune effects on marrow function (e.g., viral infection, idiosyncratic drug reactions, direct stem cell toxicity [radiation, chemotherapy]) have been implicated as an underlying etiology (Bagby, 2016). Inherited bone marrow failure has been implicated in 10% to 15% of patients with AA (Bagby, 2016).

Pathophysiology

AA can be congenital or acquired, but most cases are idiopathic (i.e., without apparent cause). Infections and pregnancy can trigger it, or it may be caused by certain medications, chemicals, or radiation damage. Agents that regularly produce marrow aplasia include benzene and benzene derivatives (e.g., airplane glue). Certain toxic materials, such as inorganic arsenic and several pesticides (including dichlorodiphenyltrichloroethane [DDT], which is no longer used or available in the United States), have also been implicated as potential causes. Other possible origins include cytotoxic agents used in cancer chemotherapy: alkylating agents (busulfan, cyclophosphamide) antimetabolites (antifolic compounds), antimitotics (vincristine, vinblastine, colchicine), and some antibiotics (daunorubicin, doxorubicin [Adriamycin]) (Ferri, 2016d). Pregnancy has also been associated with AA, and while the causal relationship is unknown, it may reflect a high level of immunologic activation during pregnancy; the prognosis is poor and associated with bleeding complications (Bagby, 2016).

Clinical Manifestations and Assessment

The manifestations of AA are often insidious. Patients may present with symptoms of anemia or bleeding. Symptoms of anemia, including fatigue, shortness of breath, and decreased activity tolerance, are usually present at the time of diagnosis. Infection at presentation is uncommon even in the setting of severe neutropenia (Ferri, 2016d). CBC may reveal neutropenia, anemia, and/or thrombocytopenia. The MCV is usually elevated. A bone marrow aspirate and biopsy provides the most sensitive evidence for AA. There is an absence of dysplasia, which helps to distinguish between AA and MDS (which is marked by dysplasia) (Bagby, 2016).

Patients with AA should also be tested for PNH because there is an overlap in 40% to 50% of cases. PNH is diagnosed via flow cytometry of the peripheral blood (Bagby, 2016).

Medical Management

Severe AA, defined by the degree of cytopenias, must be treated quickly. Symptomatic anemia and thrombocytopenia can be supported with transfusions of irradiated blood and platelets, respectively. In patients with an absolute neutrophil count (ANC) below 500/μL, prophylactic antibiotics should be considered, and in the presence of fever, empiric antibiotics must be started promptly (Ferri, 2016d).

In patients under 40 years of age who have a matched sibling donor, stem cell transplant is the definitive treatment and is considered curative (Ferri, 2016d). In patients over 40 years of age or those with no matched sibling, immunosuppressive therapy (IST) is the primary treatment. A combination of antithymocyte globulin (ATG) and cyclosporine is employed. ATG, a purified gamma globulin solution, is obtained from horses or rabbits immunized with human T lymphocytes. Infusion reactions are common and may include fever and chills. The sudden onset of a rash or bronchospasm may herald anaphylaxis and requires prompt management (see Chapter 38). Serum sickness, a delayed immune response, evidenced by fever, rash, arthralgias, and pruritus, may develop in some patients; it may take weeks to resolve. Side effects of cyclosporine include hypertension, hirsutism, and gingival hyperplasia. Many patients on cyclosporine require initiation of antihypertensive therapy (Malat & Culkin, 2016). Steroids are used to decrease the risk of serum sickness associated with ATG (Killick et al., 2016). Complete response to IST (development of normal blood counts) can occur, and relapses are uncommon (10% relapse rate), whereas partial responders (blood counts do not normalize, but transfusions are not required) relapse in 40% to 60% of cases within 5 years (Bagby, 2016). If relapse occurs following treatment with IST (i.e., the patient becomes pancytopenic [reduction of RBCs, WBCs, and platelets] again), reinstitution of the same immunologic agents may induce another remission. Corticosteroids are useful as immunosuppressive agents; however, they have significant side effects, including bone complications (i.e., avascular necrosis) and life-threatening infections. For this reason, long-term use of steroids is not recommended.

In patients who do not respond to IST, matched unrelated stem cell transplant should be considered; however, the mortality rate is higher (Ferri, 2016d). Frail elderly patients or those with significant comorbidities may be poor candidates for IST, and alternative therapies, such as androgens or supportive care, should be considered.

Supportive therapy plays a major role in the management of AA. Blood-product support with irradiated products is recommended (Killick et al., 2016). Aspirin is avoided in patients with thrombocytopenia because of its antiplatelet effect, and oral or injectable contraceptives are used to suppress menstruation to prevent menorrhagia (Bagby, 2016). There are no randomized, controlled trials to provide guidance on optimal antimicrobial prophylaxis in patients with AA and no consensus on standards of care (Hochsmann et al., 2013). In patients with a low neutrophil count (below 500) and receiving IST, prolonged neutropenia increases the risk for mold infections; these types of infections are associated with high mortality rates. Therefore, antifungal prophylaxis with agents such as voriconazole or posaconazole is recommended for patients with severe AA and should continue as long as the patient is neutropenic. There remains some controversy related to antibacterial prophylaxis due to concerns for antimicrobial resistance. Patients at highest

risk for bacterial sepsis are patients with severe AA, and antibiotic prophylaxis with quinolones can be considered (Hochsmann et al., 2013). Prophylaxis with an antipneumocystis agent (such as aerosolized pentamidine) is essential. Antiviral prophylaxis is routinely recommended for transplant recipients and, in many centers, also considered for those treated with IST (Bagby, 2016).

Death in this population is most commonly caused by hemorrhage or infection.

Nursing Management

Patients with AA are vulnerable to problems related to erythrocyte (RBC), leukocyte (WBC), and platelet deficiencies. They should be assessed carefully for signs of infection and bleeding. Specific nursing interventions are outlined in the sections on neutropenia and thrombocytopenia.

Patients receiving ATG must be educated to promptly report signs and symptoms of hypersensitivity reactions and should be reassured that nurses who administer ATG are properly trained to respond to these reactions. Nurses should educate patients taking cyclosporine regarding the importance of taking the medication as directed and monitoring drug levels and blood pressure as well as reporting signs and symptoms of high blood pressure. The nurse provides anticipatory guidance regarding hirsutism and gingival hyperplasia as these side effects may significantly impact body image and coping.

MYELODYSPLASTIC SYNDROMES (MDSs)

MDS represents a group of heterogeneous diseases with highly variable disease courses, prognosis, treatment strategies, and risk for leukemic transformation. Accurate diagnosis is essential for guiding discussion regarding treatment options and prognosis.

Median age at diagnosis is 71 years; peak incidence is in the seventh and eighth decades of life (Steensma & Stone, 2016). MDS is rare in children, and incidence increases with age. From 2009 through 2013, incidence of MDS was 21,338 with higher incidence in men (U.S. National Cancer Institute's Survey, Epidemiology, and End Results [SEER]).

Pathophysiology

MDS is a group of diseases characterized by ineffective hematopoiesis, dysplasia in at least one cell line (RBC, platelet, or WBC), progressive bone marrow failure, and variable risk for progression to leukemia (Rathore, 2017b).

Clinical Manifestations and Assessment

The majority of symptoms and clinical complications in this population result from cytopenias and the risk for leukemic progression (NCCN, 2016c). Thirty percent of patients with MDS will progress to AML. The risk for leukemia progression varies with the percentage of blasts in the bone marrow, the number and depth of cytopenias, and the presence of high-risk cytogenetic abnormalities and other genetic mutations such as tp53 (Rathore, 2017b; Ousseine et al., 2016). Patients may present with fatigue, dyspnea, activity intolerance, unexplained bruising or bleeding, or recurrent infections. However, many patients are asymptomatic at the time of diagnosis, and in these cases, the diagnosis is suspected based on routine bloodwork alone (Steensma & Stone, 2016).

Diagnosis includes a review of the CBC as well as bone marrow biopsy and aspirate. CBC is evaluated for cytopenias, peripheral blasts, and morphologic abnormalities. The reticulocyte count helps assess the bone marrow response to anemia. Other causes of anemia are ruled out. Serum EPO (erythropoietin) levels are checked to determine the potential role of ESAs in the management of MDS. Aspirate is sent for flow cytometry, cytogenetics, and assessment of genetic mutations. Aspirate is evaluated for evidence of dysplasia, blast count, number of monocytes, ringed sideroblasts, and megakaryocytes, which helps to classify the MDS subtype. The biopsy is evaluated for cellularity and the presence of blasts. Cytogenetics are critical to the prognostic classification of MDS. Favorable cytogenetic abnormalities include deletion of 11q, loss of chromosome Y, or deletion of 5q. Poor cytogenetic abnormalities include a complex karyotype (3 or more cytogenetic abnormalities) (Ridgeway, Fechter, Murray, & Borras, 2012).

Testing for mutations in specific genes has also become important in predicting prognosis in MDS. For example, mutation in TP53 is an independent predictor of poor prognosis in MDS (Rathore, 2017b).

The WHO provides diagnostic categorization of MDS based on morphology and blast percentage. The International Prognostic Scoring System (IPSS) helps to provide prognostic data using number of cytopenias, cytogenetics, and blast percentage, which helped to predict overall survival and risk for transformation to leukemia (Steensma & Stone, 2016). Prognosis can vary greatly; for example, a patient with low-risk MDS has a median overall survival of 5.7 years without therapy compared to a patient with high-risk disease, who has an overall survival of 0.4 months (Ridgeway et al., 2012; NCCN, 2016c).

Medical Management

Treatment strategies depend on the risk category (low risk vs. high risk), performance status, quality of life, and presence of comorbidities (Steensma & Stone, 2016). Strategies for treatment of low-risk MDS focus on minimizing the symptoms associated with cytopenias and minimizing transfusion requirements whereas in high-risk disease, immediate treatment is indicated to improve overall survival since the life expectancy is less than 2 years (Steensma & Stone, 2016). The initial approach to treatment may be to treat symptomatically and monitor the counts over time to assess how quickly the cytopenias progress (NCCN, 2016c).

For symptomatic anemia, transfusions of PRBCs are the mainstay of treatment (Ridgeway et al., 2012; NCCN, 2016c). Long-term transfusion dependence is associated with iron overload so attempts to decrease transfusion requirements with use of other therapies may be considered. Platelet transfusions may be considered in the setting of bleeding (NCCN, 2016c). Granulocyte-colony stimulating factor (GCSF) may be considered in neutropenic patients with recurrent infections. ESAs may be considered in transfusion-dependent patients with a serum EPO less than 500 mU/mL (NCCN, 2016c).

Lenalidomide is also indicated in patients with transfusion-dependent MDS who have low-risk disease and a deletion 5q cytogenetic abnormality with or without other cytogenetic abnormalities. In a phase III study, 57% of patients who took lenalidomide achieved RBC transfusion independence compared to 2% of patients who received a placebo (Giagounidis et al., 2014). Lenalidomide is a pill taken daily; common side effects in MDS include myelosuppression, rash, and diarrhea (Steensma & Stone, 2016). For further discussion of lenalidomide, refer to section on myeloma.

Patients with high-risk disease are at higher risk for transformation to leukemia; decision to treat must consider the patient's performance status and presence of comorbidities in order to predict treatment tolerance. The only cure for MDS is allogeneic stem cell transplant. Many patients may not be eligible due to advanced age, comorbidities, and lack of a suitable donor (Steensma & Stone, 2016).

Azacitidine is a hypomethylating agent approved in the United States for the treatment of MDS with studies demonstrating improved blood counts, prolonged overall survival, prolonged time to progression to AML, and improved quality of life (Steensma & Stone, 2016). Hypomethylating agents are considered low-intensity therapy that are generally well tolerated and can be given in the outpatient setting (NCCN, 2016c).

Response to treatment can take 4 to 6 months of therapy; providing patients anticipatory guidance and setting realistic expectations around this is critical (Kurtin, Demakos, Hayden, & Boglione, 2012; Nazha et al., 2016).

High-intensity therapy includes chemotherapy similar to that used in the treatment of AML, and stem cell transplant. High-intensity therapy is generally reserved for younger patients with no comorbidities. The morbidity and mortality of high-intensity therapies is high with lack of strong supporting evidence; these therapies are recommended in the context of clinical trials (NCCN, 2016c).

Myelosuppression is the most common complication of both MDS and its treatment and cytopenias often get worse with treatment before they improve (Kurtin et al., 2012).

Nursing Management

It is critical that the nurse provides patient education about the disease and management of symptoms, including reportable signs and symptoms of anemia, thrombocytopenia, and infection. The nurse helps the patient to track and trend blood counts and monitor transfusion requirements. The nurse helps the patient understand treatment options and have realistic expectations about timing of response. The majority of care for MDS is provided in the outpatient setting with the patient and family having primary responsibility for care at home. The nurse helps the patient and family with self-care needs and identifies needs for visiting nurse services.

ACUTE LEUKEMIA

Acute leukemia is the result of a series of genetic mutations that occur during hematopoiesis and ultimately reflect the type, quality, and quantity of cells produced (Rose-Inman & Kuehl, 2014). Hematopoiesis is characterized by a rapid, continuous turnover of cells. Normally, production of specific blood cells from their stem cell precursors is regulated carefully according to the body's needs. If the mechanisms that control the production of these cells are disrupted as a result of mutations, the cells proliferate excessively and mature abnormally.

Often hematopoietic malignancies are classified by the cells involved. Leukemia, literally "white blood," is a term used to describe neoplastic proliferation of one particular hematopoietic cell type (granulocytes, monocytes, lymphocytes, or, infrequently, erythrocytes or megakaryocytes). The defect originates in the hematopoietic stem cell, in either the myeloid or the lymphoid stem cell. Preferential proliferation of leukemia cells leads to decreased production of normal hematopoietic cells (Rose-Inman & Kuehl, 2014).

Thus the common feature of acute leukemias is an unregulated proliferation of leukocytes in the bone marrow and a suppression of other blood cells, including RBCs and platelets. The bone marrow becomes packed with abnormal cells and ultimately begins to release these cells into the circulation prematurely. The increase in the number of leukocytes in the circulation is referred to as *leukocytosis*. Typically, only one specific type of leukocyte is increased, most commonly either the neutrophils (myeloblast) or the lymphocytes (lymphoblast). Extramedullary hematopoiesis is also seen with resultant splenomegaly. With acute leukemias, there can be infiltration of other organs, such as the meninges, lymph nodes, gums, and skin (leukemia cutis).

The cause of leukemia is not fully known, but there is some evidence that genetic influences and viral pathogenesis may be involved. Bone marrow damage from radiation exposure or from chemicals benzene, topoisomerase II inhibitors (such as etoposide) and alkylating agents (e.g., cyclophosphamide [Cytoxan], melphalan [Alkeran]) can cause leukemia.

The leukemias are commonly classified according to the stem cell line involved, either lymphoid (relating to lymphatic tissue) or myeloid (relating to bone marrow myeloid elements). They are also classified as either acute or chronic based on the phase of cell development that is halted, with few leukocytes differentiating beyond that phase.

In acute leukemia, the onset of symptoms is abrupt, often occurring within a few weeks. Leukocyte development is halted at the blast phase so that most leukocytes are undifferentiated, immature cells (blasts). Acute leukemia progresses very rapidly; death can occur within weeks to months without aggressive treatment.

In chronic leukemia, symptoms evolve over a period of months to years. Most of the leukocytes produced are mature and retain some ability to function normally. Chronic leukemia progresses more slowly; the disease trajectory can extend for years.

In 2013, the American Cancer Society estimated close to 6,000 cases of ALL and 14,500 cases of AML (ACS, 2013).

ACUTE MYELOID LEUKEMIA

AML results from a defect in the hematopoietic stem cell that differentiates into all myeloid cells: monocytes, granulocytes (neutrophils, basophils, eosinophils), erythrocytes, and platelets. All age groups are affected; the incidence rises with age, with a peak incidence at age 60 years. Median age of diagnosis is 65 years (Rose-Inman & Kuehl, 2014). AML accounts for 80% of acute leukemias in adults and less than 10% of leukemias in children (Schiffer & Anastasi, 2016).

AML represents a heterogeneous group of clonal myeloid malignancies marked by an excess of myeloid blast cells (greater than 20%). Classification of AML has evolved from a morphologic classification to one based on cytogenetic and molecular abnormalities. The French American British system classifies AML based primarily on morphology and stage of maturation arrest, with eight subtypes. The more recent classification system is that of the WHO, which incorporates cytogenetic and molecular abnormalities, allowing for improved prognostication (Schiffer & Anastasi, 2016). There are cytogenetic abnormalities that may be considered favorable (translocation 15;17, translocation 8;21, and inversion 16), whereas survival is poor in instances of unfavorable cytogenetic abnormalities (deletions of chromosome 5 or 7 and patients with more than three abnormalities [referred to as a complex karyotype]) (Ferri, 2016e). The identification of molecular mutations has further complicated the classification of AML. Mutations in NPM1, FLT3, and CEBPA genes have resulted in the identification of four groups with very different prognoses, with mutations in NPM1 or CEBPA being favorable while mutations in FLT3-ITD are unfavorable (Estey, 2014).

The prognosis of AML is highly variable and related to patient age, performance status, and cytogenetic and molecular characteristics of their disease (Schiffer & Anastasi, 2016). The strongest risk factors for resistant disease, early relapse, and decreased survival include advanced age, poor functional status, and complex cytogenetic abnormalities. Patients over 65 years of age have a poorer response to treatment and a worse prognosis than younger patients. Complete remission rates range from 20% to 90% depending on patient- and disease-specific risk factors (Chen et al., 2015). Those who have leukemia stemming from pre-existing MDS or who previously received alkylating agents or topoisomerase II inhibitors for cancer (secondary AML) have a much worse prognosis; the leukemia tends to be more resistant to treatment, resulting in a much shorter duration of remission. With treatment, patients with secondary AML survive an average of less than 1 year, with death usually a result of infection or hemorrhage. Patients receiving supportive care also usually survive less than 1 year, dying of infection or bleeding.

Clinical Manifestations and Assessment

Most signs and symptoms of AML result from insufficient production of normal blood cells. Fever and infection result from neutropenia, weakness and fatigue from anemia, and bleeding tendencies from thrombocytopenia. The proliferation of leukemic cells within organs leads to a variety of additional symptoms: pain from an enlarged liver or spleen, hyperplasia of the gums, and bone pain from expansion of the bone marrow.

AML develops without warning, with symptoms occurring over a period of weeks to months. The CBC may show a decrease in both erythrocytes and platelets. Although the total leukocyte count can be low, normal, or high, usually the percentage of normal cells is vastly decreased. The differential may reveal the presence of circulating blasts and a decreased neutrophil count.

Diagnosis is established with bone marrow aspirate and biopsy with biopsy revealing more than 20% myeloblasts. Aspirate samples are sent for flow cytometry, analysis of cytogenetic abnormalities, and genetic mutations.

Complications

Complications of AML include bleeding and infection, the major causes of death. The risk of bleeding correlates with the severity of thrombocytopenia. The low platelet count can result in ecchymoses (bruises) and petechiae (pinpoint red or purple hemorrhagic spots on the skin) (Fig. 20-2). Major spontaneous hemorrhages also may develop when the platelet count drops to less than 10,000/mm^3. The most common sites of bleeding are GI, pulmonary, and intracranial. Fever increases platelet consumption and, therefore, may increase the likelihood of bleeding.

Because of the lack of mature and normal granulocytes, infection is the most common cause of death in patients with acute leukemia. The likelihood of infection increases with the degree and duration of neutropenia; neutrophil counts that persist at less than 100/mm^3 for prolonged periods make the likelihood of systemic infection extremely high. As the duration of severe neutropenia increases, the patient's risk of developing fungal infection also increases.

Medical Management

When considering approaches to therapy for AML, the first determination is if the patient would be a candidate for allogeneic stem cell transplant. In general, patients who are considered transplant candidates will be treated with an aggressive approach. Patients who are not transplant candidates due to poor performance status, advanced age, or significant comorbidity would be treated with a less aggressive approach focused on optimizing quality of life.

The initial objective of treatment is to achieve complete remission, in which there is no evidence of residual leukemia in the bone marrow. For patients with a good performance status and absence of comorbidities, attempts are made to achieve remission by the aggressive administration of chemotherapy, called *induction therapy*, which usually requires hospitalization for several weeks. Induction therapy typically involves IV administration of cytarabine (Cytosar, Ara-C) and an anthracycline, such as idarubicin (Idamycin) or daunorubicin. The choice of agents is based on the patient's performance status and history of prior antineoplastic treatment. For older patients or patients with poor performance status and comorbidities, less aggressive approaches may be used. Enrollment in clinical trials is always encouraged.

The aim of induction therapy is to eradicate the leukemic cells, but this is often accompanied by the eradication of normal types of myeloid cells. Thus, the patient becomes severely neutropenic (an absolute neutrophil count [ANC] of 0 is not uncommon), anemic, and thrombocytopenic (a platelet count of less than 10,000/mm^3 is common). (Refer to Chapter 19 for calculation of the ANC.) During this time, the patient is hospitalized due to high risk for life-threatening complications. Common complications include bacterial, fungal, and, occasionally, viral infections; bleeding; and severe mucositis, which can cause mouth pain and diarrhea as well as a marked decline in the ability to eat and meet nutritional demands.

Supportive care consists of administering blood products (PRBCs and platelets) and promptly treating infections. Prophylactic use of granulocytic growth factors (GCSF or Filgrastim) to minimize the risk of neutropenic fever and infection have not demonstrated the same effects on survival in patients with AML compared to patients with nonhematologic malignancies; therefore, widespread use of GCSF in patients with AML is not recommended (Larson, 2016).

Response to treatment is assessed using bone marrow aspirate and biopsy after induction when blood counts are recovering. The expected result is an absence of leukemic blasts and recovery of normal marrow function. When the patient has recovered from the induction therapy (i.e., the neutrophil and platelet counts have returned to normal and any infection has resolved) and response to induction has been assessed, he or she typically receives *consolidation therapy* (additional postremission chemotherapy) to eliminate any residual leukemia cells that are not clinically detectable and to reduce the chance for recurrence. Multiple treatment cycles of various agents are used, with most regimens using high-dose cytarabine (e.g., Cytosar, Ara-C).

Following consolidation therapy, the next step is determined based on the patient's risk for recurrence. Patients with low- or intermediate-risk leukemia may not require further treatment after they complete consolidation therapy. Patients with high-risk leukemia, or

patients who have been treated for a relapse, may be candidates for PBSCT. When a suitable donor is identified (either a sibling or unrelated donor identified in the national registry), the patient embarks on an even more aggressive regimen of chemotherapy (sometimes in combination with total body radiation therapy), with the treatment goal of destroying the hematopoietic function of the patient's bone marrow. The patient is then "rescued" with the infusion of the donor stem cells to reinitiate hematopoiesis. In addition to providing a "rescue" and a healthy source of hematopoiesis, infusion of donor cells also provides protection against disease recurrence. The healthy immune system of the donor kills residual cancer cells and prevents cancer recurrence; this is known as the *graft versus leukemia* effect. Patients who undergo PBSCT have a significant risk for infection, graft-versus-host disease (GVHD, in which the donor's lymphocytes [graft] recognize the patient's body as "foreign" and attack the "foreign" host), and other complications. Refer to Chapter 6 for a detailed discussion of PBSCT.

For patients who are not candidates for transplant, less aggressive approaches to therapy with drugs like hypomethylating agents (decitabine or azacitidine) may be considered (Vasu & Blum, 2013). Both agents have demonstrated response in AML, though further study is required to identify patients most likely to respond. Patients over 65 years of age tend to have poorer prognosis related to treatment-resistant disease (Appelbaum, 2016).

Another important option for the patient to consider is supportive care alone. In fact, supportive care may be the only option if the patient has significant comorbidity, such as extremely poor cardiac, pulmonary, kidney, or liver function; advanced age; or poor performance status. In such cases, aggressive antileukemia therapy is not used; occasionally, hydroxyurea (Hydrea) may be used to control the WBC count and prevent the potential sequelae of leukocytosis. Patients are supported with antimicrobial therapy and transfusions as needed. This treatment approach provides the patient with some additional time at home; however, death frequently occurs within months, typically from infection or bleeding. (Refer to Chapter 3 for a discussion of end-of-life care.)

Treatment of relapsed AML may involve different combinations of chemotherapy if the patient is in good physical condition, or less aggressive therapies or supportive care alone may be used. Clinical trials may also be considered. Relapsed AML is often difficult to treat and overall survival rate is low.

Nursing Management

The priority nursing interventions for the patient with AML include infection prevention, bleeding prevention, promoting comfort, and patient education. Nursing care to prevent infection and bleeding are discussed in detail in Chapters 6 and 19. Patients with a new diagnosis of AML are experiencing a crisis and require an overwhelming amount of education about their disease, self-care, and treatment strategies. The role of the nurse is critical in alleviating anxiety by providing information tailored to the patient's readiness and educational level.

The nurse also assesses for complications of treatment. Massive leukemic cell destruction from chemotherapy results in the release of intracellular electrolytes and fluids into the systemic circulation. Increases in uric acid levels, potassium, and phosphate are seen; this process is referred to as tumor lysis syndrome (see Chapter 6). Patients require a high fluid intake and prophylaxis with allopurinol to prevent crystallization of uric acid and subsequent stone formation. Anorexia, nausea, vomiting, diarrhea, and severe mucositis are common.

ACUTE PROMYELOCYTIC LEUKEMIA (APML)

APML is a subtype of AML that is characterized by the cytogenetic abnormality of translocation 15;17, which results in the PML-RARα protein. APML, unlike most other types of AML, is highly curable. APML is often associated with life-threatening DIC, and once the diagnosis is presumed, treatment must start emergently. Diagnosis is established through the detection of the PML-RARα protein, which can be detected in the blood. A bone marrow aspirate and biopsy is also done to establish the diagnosis though detection of PML-RARα protein justifies initiation of treatment. Treatment includes all-trans-retinoic acid (ATRA), an oral agent that stimulates differentiation of the promyelocytes into mature neutrophils. Aggressive supportive care to manage DIC in the initial stages of the disease is critical. Platelets and cryoprecipitate are used to minimize bleeding risk. ATRA has also been shown to decrease the risk of coagulopathy, which is the leading cause of death in APML (Mantha, Tallman, & Soff, 2016). One fourth of patients treated with ATRA will experience differentiation syndrome in the first 21 days of induction treatment with ATRA. The symptoms include weight gain, shortness of breath, fever, hypotension, effusions, and liver and kidney dysfunction. Risk for differentiation syndrome is increased when the WBC count is over 30. Often steroids are used to prevent and treat this syndrome. Diuretics also may be used to manage volume overload. ATRA may be used in combination with chemotherapy or arsenic trioxide, which is also a differentiating agent (Ferri, 2016f).

Response to treatment is assessed through measurement of PML-RARα protein levels in the blood and bone marrow.

The nursing role in APML is critical; astute assessment skills should be focused on identifying early signs and symptoms of DIC and differentiation syndrome. Daily weights and strict I/Os are important data points in assessing for differentiation syndrome. The nurse also counsels the patient on the importance of adherence to ATRA therapy. For patients on arsenic therapy, monitoring of EKG for prolongation of the QT interval is essential. Other drugs that prolong the QT interval should be minimized (refer to Chapter 17 for drugs associated with prolonged QT).

ACUTE LYMPHOCYTIC LEUKEMIA

Acute lymphocytic leukemia (ALL) results from an uncontrolled proliferation of immature lymphoid cells (lymphoblasts) derived from the lymphoid stem cell. The cell of origin is the precursor to the B lymphocyte in approximately 75% of ALL cases; T-lymphocyte ALL occurs in approximately 25% of ALL cases. The *BCR-ABL* translocation or Philadelphia chromosome (see earlier CML discussion) is found in 20% of ALL blast cells. ALL is most common in young children, with boys affected more often than girls. ALL accounts for 75% of pediatric leukemias and 25% of adult leukemias (NCCN, 2016d). The peak incidence is 4 years of age. After 15 years of age, ALL incidence decreases with a second peak occurring after age 50 (Rose-Inman & Kuehl, 2014). Increasing age appears to be associated with diminished survival; the 5-year event-free survival rate is almost 90% for childhood ALL, but decreases to approximately 60% in adolescents; in young adults (15 to 24 years) survival is nearly 55%, for those 25 years of age to 39, the rate is 42%, 24% for ages 40 to 59 years, and 17.7% for ages 60 to 69 years (Pulte et al., 2014).

Clinical Manifestations and Assessment

Immature lymphocytes proliferate in the marrow and impede the development of normal myeloid cells. As a result, normal hematopoiesis is inhibited, resulting in reduced numbers of leukocytes, erythrocytes, and platelets. Leukocyte counts may be either low or high, but there is always a high proportion of immature cells. Manifestations of leukemic cell infiltration into other organs are more common with ALL than with other forms of leukemia and include pain from an enlarged liver or spleen and bone pain. The testes and central nervous system (CNS) are sanctuary sites where leukemic cells may infiltrate. The patient may exhibit testicular swelling or discomfort, or headache, visual changes, vomiting, and neurologic deficits from CNS invasion. Children are more likely to report musculoskeletal symptoms, including bone and joint pain (Rose-Inman & Kuehl, 2014; NCCN, 2016d).

Diagnosis is established with bone marrow aspirate and biopsy, with bone marrow biopsy demonstrating lymphoblasts at 20% or higher. Aspirate samples are evaluated for flow cytometry as well as cytogenetic and molecular abnormalities. Due to the high incidence of CNS involvement, diagnostic lumbar puncture is also performed. Typically chemotherapy is given into the intrathecal space at the time of initial lumbar puncture to treat or provide prophylaxis for ALL in the CNS (NCCN, 2016d).

Men should have a testicular examination, and abnormalities on examination warrant evaluation with ultrasound as the testes are a sanctuary site for ALL.

Medical and Nursing Management

The expected outcome of treatment is complete remission. Lymphoid blast cells are typically very sensitive to corticosteroids and to vinca alkaloids; therefore, these medications are an integral part of the initial induction therapy. Because ALL frequently invades the CNS, prophylaxis with cranial irradiation or intrathecal (injection of medications into the subarachnoid space [cerebral spinal fluid]) chemotherapy (e.g., methotrexate), or both is also a key part of the treatment plan (Ferri, 2016g).

Treatment protocols for ALL tend to be complex, using a wide variety of chemotherapeutic agents given over a protracted period of time. Treatment includes an induction phase, followed by a consolidation phase, followed by a maintenance phase, when lower doses of medications are given for up to 3 years. Despite the complexity, treatment can often be provided in the outpatient setting.

Imatinib is highly effective in those with Philadelphia chromosome–positive ALL and can be used alone or in combination with chemotherapy, with remission rates exceeding 90%; however, the impact of the addition of imatinib on the duration of remission is not yet known (Appelbaum, 2016). Monoclonal antibodies, in which the antibody specific for the antigens expressed on the ALL blast cell—including CD20, CD22, CD33, and CD52—are a type of targeted therapy used to treat ALL. For example, the CD52 antigen is expressed on approximately 70% of ALL cells; thus, alemtuzumab (Campath), a monoclonal antibody with specific affinity for the CD52 antigen, is effective therapy for this subset of patients.

Infections, especially viral infections, are common. The use of corticosteroids to treat ALL increases the patient's susceptibility to infection. Patients with ALL often require prophylactic antimicrobials to decrease the risk of certain types of infection. Patients with ALL tend to have a better response to treatment than do patients with AML. PBSCT offers a chance for prolonged remission, or even cure, if the illness recurs after therapy.

Nursing Management for Acute Myeloid Leukemia and Acute Lymphocytic Leukemia

Nursing management of the patient with ALL is similar to the care of patients with AML. The nursing priorities include the prevention of infection and bleeding as well as management of symptoms, such as nausea and pain, often resulting from mucositis. As ALL is a disease that most commonly affects children and young adults, fertility preservation should be discussed prior to the initiation of treatment.

Although the clinical picture varies with the type of leukemia as well as the treatment implemented, the health history may reveal a range of subtle symptoms reported by the patient before the problem is detectable on physical examination. Weakness and fatigue are common manifestations, not only of the leukemia but also of the resulting complications of anemia and infection. If the patient is hospitalized, the assessments should be performed daily or more frequently as warranted. Because the physical findings may be subtle initially, a thorough, systematic assessment incorporating all body systems is essential. For example, a dry cough, mild dyspnea, and diminished breath sounds may indicate a pulmonary infection. However, the infection may not be seen initially on the chest x-ray; the absence of neutrophils delays the inflammatory response against the pulmonary infection, and it is the inflammatory response that produces the x-ray changes. The platelet count can become dangerously low, leaving the patient at risk for significant bleeding. The specific body system assessments are delineated in the neutropenic precautions and bleeding precautions found in Chapters 6 and 19, respectively. When serial assessments are performed, current findings are compared with previous findings to evaluate the patient's condition for improvement or worsening.

The nurse also must monitor the results of laboratory studies closely. Flow sheets are particularly useful in tracking the leukocyte count, ANC, hematocrit, platelet, creatinine and electrolyte levels, and liver function tests. During initial treatment for acute leukemia, the ANC often drops below 100/mm^3, placing the patient at very high risk for infection (Andersen et al., 2016; Applebaum, 2016). Empiric antibiotics are used to treat infection preemptively when the patient has a fever of 100.4°F or greater. Culture results need to be reported immediately so that antimicrobial therapy can be modified appropriately based on microbial sensitivity.

LYMPHOMA

The lymphomas are neoplasms (abnormal growth of tissue) of lymphoid tissue, usually derived from B lymphocytes. These tumors usually start in lymph nodes but can involve lymphoid tissue in the spleen, the GI tract (e.g., the wall of the stomach), the liver, or the bone marrow. Often they are classified according to the degree of cell differentiation and the origin of the predominant malignant cell. Lymphomas can be classified into two broad categories: Hodgkin lymphoma and non-Hodgkin lymphoma (NHL). NHLs can be furthered characterized into low grade and high grade.

HODGKIN LYMPHOMA

Hodgkin lymphoma is a relatively rare malignancy that has an impressive cure rate. In 2013, there were 9,290 cases of Hodgkin lymphoma, with more cases in men than women (ACS, 2013).

Pathophysiology

Unlike other lymphomas, Hodgkin lymphoma is unicentric in origin in that it initiates in a single node. The disease spreads by contiguous extension along the lymphatic system. The malignant cell of Hodgkin lymphoma is the Reed–Sternberg cell, a large tumor cell that is morphologically unique and is thought to be of immature lymphoid origin. It is the pathologic hallmark and essential diagnostic criterion for Hodgkin disease. However, the tumor is very heterogeneous and actually may contain few Reed–Sternberg cells. Repeated biopsies may be required to establish the diagnosis.

The cause of Hodgkin lymphoma is unknown, but a viral etiology is suspected. In fact, fragments of the Epstein–Barr virus (EBV) have been found in some Reed–Sternberg cells; however, evidence implicating EBV remains controversial (Ferri, 2016h).

The WHO classifies Hodgkin lymphoma into two groups: classic Hodgkin lymphoma (92% to 97% of cases), which has four main histologic subtypes based on the number of lymphocytes, Reed–Sternberg cells, and the presence of fibrous tissue; and nodular lymphocyte-predominant Hodgkin lymphoma (3% to 8% of cases) (Ferri, 2016h).

Risk Factors

Hodgkin lymphoma is somewhat more common in men than women and has two peaks of incidence: one in the early 20s and the other after 50 years of age. Disease occurrence has a familial pattern: first-degree relatives have a higher-than-normal frequency of disease, but the actual incidence of this pattern is low. Hodgkin lymphoma is seen more commonly in patients receiving chronic IST (e.g., for kidney transplant) and in woodworkers. Also it is seen in veterans of the military who were exposed to the herbicide Agent Orange.

Clinical Manifestations and Assessment

Hodgkin lymphoma usually begins as a painless enlargement of one or more lymph nodes above the diaphragm (most commonly in the cervical or supraclavicular region) (Bartlett & Foyil, 2014). The individual nodes are painless and rubbery or firm but not hard. A mediastinal mass may be seen on chest x-ray; occasionally, the mass is large enough to compress the trachea and cause dyspnea and cough. Pruritus is common; it can be extremely distressing, and the cause is unknown. Rarely patients experience brief but severe pain after drinking alcohol, usually at the site of the tumor (Ferri, 2016h). Again, the cause of this is unknown.

All organs are vulnerable to invasion by Hodgkin lymphoma. The symptoms result from compression of organs by the tumor, such as cough and pulmonary effusion (from pulmonary infiltrates), jaundice (from hepatic involvement or bile duct obstruction), abdominal pain (from splenomegaly or retroperitoneal adenopathy), or bone pain (from skeletal involvement). Herpes zoster infections are common. A cluster of constitutional symptoms has important prognostic implications. Referred to as "B symptoms," they include fever (without chills), drenching sweats (particularly at night), and unintentional weight loss of more than 10%. B symptoms are found in 40% of patients and are more common in advanced disease. An elevated erythrocyte sedimentation rate (ESR) represents a poor prognostic indicator (Bartlett & Foyil, 2014).

A mild anemia is the most common hematologic finding. The leukocyte count may be elevated or decreased. The platelet count is typically normal unless the tumor has invaded the bone marrow, suppressing hematopoiesis. Patients with Hodgkin lymphoma have impaired cellular immunity as evidenced by an absent or decreased reaction to skin sensitivity tests (e.g., *Candida,* mumps).

Because many manifestations are similar to those occurring with infection, diagnostic studies are performed to rule out an infectious origin for the disease. The diagnosis is made by means of an excisional lymph node biopsy and the finding of the Reed–Sternberg cell. Once the diagnosis is confirmed and the histologic type is established, it is necessary to assess the extent of the disease, a process referred to as *staging*. See Chapter 6 for discussion of staging.

In addition to a careful physical examination, a chest x-ray; computed tomography (CT) scan of the chest, abdomen, and pelvis; and a positron emission tomography (PET) scan are all obtained to assist with staging. The PET scan may be the most sensitive imaging test in identifying residual disease. Laboratory tests include CBC, platelet count, ESR, lactate dehydrogenase (LDH), and liver and kidney function studies. A bone marrow biopsy is performed if there are signs of marrow involvement, and some physicians routinely perform bilateral biopsies. Bone scans may be performed to identify any involvement in these areas.

Medical Management

The general goal in treatment of Hodgkin lymphoma, regardless of stage, is cure. Data reveal that 90% of patients with early-stage Hodgkin lymphoma and 80% of advanced-stage patients will be cured (Bartlett & Foyil, 2014). Treatment is determined primarily by the stage of the disease, not the histologic type; however, extensive research is ongoing to target treatment regimens to histologic subtypes or prognostic features. Traditionally, early Hodgkin disease was treated by a staging laparotomy followed by radiation therapy. This treatment method has been replaced by a short course (2 to 4 months) of chemotherapy followed by radiation therapy in early-stage disease (I and II). Advanced-stage disease is often treated with chemotherapy alone; the role of radiation in advanced disease remains under investigation (Hutchings, Piris, Baiocchi, & Hertzberg, 2015). When chemotherapy is used alone or with combination radiation therapy for early-stage classical Hodgkin lymphoma, 3- to 5-year progression-free survival rates of 82% to 94.6% have been reported. For advanced-stage classical Hodgkin lymphoma, front-line treatment with combination chemotherapy, such as ABVD [doxorubicin (also known as Adriamycin), bleomycin, vinblastine, and dacarbazine], BEACOPP [bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine (also known as Oncovin), procarbazine, and prednisone] or the Stanford V regimen (doxorubicin, vinblastine, mechlorethamine, vincristine, bleomycin, etoposide, and prednisone), produces reports of 5-year progression-free survival rates as high as 86.4% (Alinari & Blum, 2016).

Even when Hodgkin lymphoma does recur, the use of high doses of chemotherapeutic agents, followed by autologous PBSCT, can be effective in controlling the disease and extending survival time with progression-free survival rates of up to 60% reported (Alinari & Blum, 2016).

Newer therapies for Hodgkin lymphoma have emerged, including monoclonal antibodies, antibody-drug conjugates (Brentuximab vedotin), and checkpoint inhibitors (nivolumab and pembrolizumab). These new agents offer promising potential alternatives to classical chemotherapy but are currently limited to the relapsed/refractory setting (Rashidi & Bartlett, 2015).

Nursing management is similar to that of NHL and is discussed in that section.

Long-Term Complications of Therapy

Much is now known about the long-term effects of chemotherapy and radiation therapy, primarily from the large numbers of people who were cured of Hodgkin lymphoma by these treatments. Long-term complications include hypothyroidism, immune dysfunction, dental caries, cardiomyopathy, infertility, and secondary malignancies. The incidence of late effects increases over time (NCCN, 2016e). Patients should be followed carefully for late effects, including surveillance for and assessment of risk factors for secondary cancers. Lung cancer and breast cancer are the most common type of secondary malignancy in patients with Hodgkin disease, particularly following combination chemotherapy and radiation (NCCN, 2016e).

Secondary cancers, including lung, breast, lymphoma, and leukemia, as well as cardiovascular disease, including heart failure, valvular disease, coronary artery disease, and MI, are late effects of treatment for Hodgkin lymphoma (van Nimwegen et al., 2015; Hodgson & von Leeuwen, 2015). Secondary cancers are the leading cause of death in survivors of Hodgkin lymphoma. Among female survivors of childhood Hodgkin lymphoma, breast cancer is the most common secondary cancer. There are many contributing risk factors for secondary breast cancer, with age at time of chest radiation being the most important risk factor (Koo, Henderson, Dwyer, & Skandarajah, 2015). For survivors of Hodgkin lymphoma who were treated with radiation to the chest, screening for breast cancer using mammography is recommended beginning 8 years from the time of radiation to the chest or beginning at age 40, whichever comes first (Hodgson & von Leeuwen, 2015). Breast MRI in addition to mammogram is recommended for women treated with radiation to the chest between 10 and 30 years of age (NCCN, 2016e). It is critical that survivors of Hodgkin lymphoma are counseled on their risk for secondary cancers and cardiovascular risk and that the recommended screening tests are adhered to throughout the patient's lifetime (Ferri, 2016h).

Patients should be encouraged to reduce other factors that increase the risk of developing secondary cancers and cardiovascular disease, such as use of tobacco and alcohol and exposure to environmental carcinogens, as well as maintaining an exercise regimen and healthy weight. Revised treatment approaches are under investigation with the goal of minimizing the risk for complications (secondary malignancy and cardiovascular disease) without sacrificing the potential for cure.

NON-HODGKIN LYMPHOMAS

The NHLs are a heterogeneous group of cancers that originate from the neoplastic growth of lymphoid tissue. As in CLL, the neoplastic cells are thought to arise from a single clone of lymphocytes; however, in NHL, the cells may vary morphologically. Most NHLs involve malignant B lymphocytes; only 5% involve T lymphocytes. In contrast to Hodgkin lymphoma, the lymphoid tissues involved in NHL are largely infiltrated with malignant cells. The spread of these malignant lymphoid cells occurs unpredictably, and true localized disease is uncommon. Lymph nodes from multiple sites may be infiltrated as may sites outside the lymphoid system (extranodal tissue).

While the incidence of NHL continues to rise in the United States, it now accounts for approximately 4% of new cancers in the United States and 3% of cancer deaths (Bierman & Armitage, 2016). In 2013, there were 69,740 cases of NHL in the United States with more cases in men (ACS, 2013). The incidence increases with each decade of life, is higher in whites than other ethnic groups, and is diagnosed in patients with an average age of 50 to 60 years. Although no common etiologic factor has been identified, the incidence of NHL has increased in people with immunodeficiencies or autoimmune disorders; treatment with immunosuppressive medications; prior treatment for cancer; prior organ transplant; viral infections (including EBV and HIV); and exposure to pesticides, solvents, dyes, or defoliating agents, including Agent Orange. In addition, some cases may be explained by improved pathology techniques (Bierman & Armitage, 2016). Prognosis varies greatly among the various types of NHL. NHL can be further characterized as low grade or high grade. The most common types of low-grade lymphomas include CLL and follicular lymphoma. High-grade lymphomas include diffuse large B-cell lymphoma, peripheral T-cell lymphomas, and Burkitt lymphoma.

Long-term survival (over 10 years) is commonly achieved in low-grade, localized lymphomas. Even with aggressive disease forms, cure is possible in at least one third of patients who receive aggressive treatment.

Clinical Manifestations and Assessment

Symptoms are highly variable, reflecting the diverse nature of the NHLs. Lymphadenopathy is most common (66%); however, in more indolent (less aggressive) types of lymphomas, the lymphadenopathy can wax and wane. With early-stage disease or with the types that are considered more indolent, there may be no symptoms, and the illness typically is not diagnosed until it progresses to a later stage, when the patient becomes symptomatic. At these stages (III or IV), lymphadenopathy is prominent. One third of patients with NHLs have "B symptoms" (recurrent fever, drenching night sweats, and unintentional weight loss of 10% or more). Lymphomatous masses can compromise organ function. For example, a mass in the mediastinum can cause respiratory distress; abdominal masses can compromise the ureters, leading to kidney dysfunction; and splenomegaly can cause abdominal discomfort, nausea, early satiety, anorexia, and weight loss. Less than 10% of patients will experience CNS involvement at some point in their disease. Certain populations have higher rates of CNS involvement, including patients with HIV or those with testicular, breast, epidural, or sinus involvement.

The actual diagnosis of NHL is categorized into a highly complex classification system based on histopathology, immunophenotyping, and cytogenetic analyses of the malignant cells. The specific histopathologic type of the disease has important prognostic implications. Treatment also varies and is based on these features. Staging, also an important factor, is typically based on data obtained from CT and PET scans, bone marrow biopsy, and, occasionally, cerebrospinal fluid analysis. The stage is based on the site of disease and its spread to other sites. For example, in stage I disease, only one area of involvement is detected; thus, stage I disease is highly localized and may respond well to localized therapy (e.g., radiation therapy). In contrast, in stage IV disease, at least one extranodal site is detected.

Medical Management

Treatment is based on the classification of disease, the stage of disease, prior treatment (if any), and the patient's ability to tolerate therapy. If the disease is not an aggressive form and is truly localized, radiation alone may be the treatment of choice.

Low-grade lymphomas may not require treatment until the disease progresses to a later stage, but historically they have been relatively unresponsive to treatment, and, in most cases, use of therapeutic modalities did not improve overall survival. More aggressive types of NHL (e.g., lymphoblastic lymphoma, Burkitt lymphoma) require prompt initiation of combination chemotherapy; however, these types tend to be more responsive to treatment.

With aggressive types of NHL, aggressive combinations of chemotherapeutic agents are given even in early stages. More intermediate forms are commonly treated with combination chemotherapy and radiation therapy for stage I and II diseases. The advent of the monoclonal antibody, Rituximab, which targets the CD20 antigen on the surface of B cells, has improved survival in patients with NHL significantly. The combination of rituximab with conventional chemotherapy (Cytoxan, doxorubicin, vincristine, and prednisone [CHOP]) is now considered standard treatment for common, aggressive B-cell lymphomas (Bierman & Armitage, 2016). Unfortunately, more than 30% of patients with diffuse large B-cell NHL will experience a relapse. Treatment for relapsed disease includes Rituximab and combination chemotherapy followed by high-dose chemotherapy with stem cell support, which offers the best chance for response. For patients who are not eligible for transplant, chemotherapy may be used alone (Sehn & Gascoyne, 2015). A number of novel therapies are under investigation in an attempt to enhance the efficacy of front-line therapy and improve outcomes in patients with relapsed or refractory disease (Sehn & Gascoyne, 2015). CNS involvement may occur with some aggressive forms of NHL; in this situation, intrathecal chemotherapy is used in addition to systemic chemotherapy. Radiation may be used for palliation of symptoms.

Nursing Management

Lymphoma is a highly complex constellation of diseases. When caring for patients with lymphoma, it is extremely important to know the specific disease type, stage of disease, treatment history, and current treatment plan. Most of the care for patients with Hodgkin lymphoma or NHL takes place in the outpatient setting, unless complications occur (e.g., infection, respiratory compromise due to mediastinal mass). The most commonly used treatment methods are chemotherapy and radiation therapy. Chemotherapy causes systemic side effects (e.g., myelosuppression, nausea, hair loss, risk of infection), whereas radiation therapy causes specific effects that are limited to the area being irradiated. For example, patients receiving abdominal radiation therapy may experience nausea and diarrhea but not hair loss. Regardless of the type of treatment, all patients experience fatigue.

The risk for infection is significant for these patients, not only from treatment-related myelosuppression but also from the defective immune response that results from the disease itself. Patients need to be taught to minimize the risks of infection, to recognize signs of possible infection, and to contact the health care professional should such signs develop (see Chapters 6 and 19). Additional complications depend on the location of the lymphoma. Therefore, it is important for the nurse to know the tumor location so that assessments can be targeted appropriately. For example, patients with lymphomatous masses in the upper chest should be assessed for superior vena cava obstruction or airway obstruction if the mass is near the bronchus or trachea.

Many lymphomas can be cured with current treatments. However, as survival rates increase, the incidence of secondary malignancies, particularly AML or MDS, also increases. Therefore, survivors should be screened regularly for the development of second malignancies.

CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

CLL is classified as a type of low-grade lymphoma as it is a disease that encompasses both CLL and small lymphocytic lymphoma (SLL). It is the most frequent form of leukemia in Western countries, affecting more than 15,680 people in the Unites States (ACS, 2013). It is a common malignancy of older adults (70% of diagnoses are made in patients over 65 years of age), and the mean age at diagnosis is 65 years (Ferri, 2016i). In general, prognosis is related to the clinical stage (e.g., the average survival in patients with early stage is 10 years, whereas for stage 4 [or Binet stage C] survival is approximately 2½ years). That said, the overall 5-year survival rate has increased to 66% from 60% in the past 10 years largely related to the addition of immunotherapy to combination chemotherapy (Ferri, 2016i).

Pathophysiology

CLL is typically derived from a malignant clone of B lymphocytes (T-lymphocyte CLL is rare). In contrast to the acute forms of leukemia, most of the leukemia cells in CLL are fully mature. It appears that these cells can escape apoptosis (programmed cell death), resulting in an excessive accumulation of the cells in the marrow and circulation. The antigen CD52 is prevalent on the surface of many of these leukemic B cells.

Two classification systems are in regular use to stage CLL; the disease is classified into three (Binet system; stage A, B, C) or five stages (Rai system; stage 0–IV). Both staging systems help to estimate prognosis and assist with treatment stratification (Ferri, 2016i). In the early stage, an elevated lymphocyte count is seen; it can exceed 100,000/mm^3. Because the lymphocytes are small, they can travel easily through the small capillaries within the circulation, and the pulmonary and cerebral complications of leukocytosis (as seen with myeloid leukemias) typically are not found in CLL.

Lymphadenopathy occurs as the lymphocytes are trapped within the lymph nodes. The nodes can become very large and are sometimes painful. Hepatomegaly and splenomegaly then develop.

In later stages, anemia and thrombocytopenia may develop. Typically treatment is initiated in the later stages; earlier treatment does not appear to increase survival so treatment for limited-stage disease is employed only if the patient is symptomatic (Rai & Stilgenbauer, 2014). Autoimmune complications also can occur at any stage as either AIHA or ITP. ITP is characterized by the destruction of blood platelets due to the presence of antiplatelet autoantibodies, in which antibodies are directed against the patient's own platelets. As the term implies, the platelet level decreases (thrombocytopenia), resulting in visible bruising (purpura) in the skin and mucous membranes. Simply put, in the autoimmune process, the reticuloendothelial system (RES) destroys the body's own erythrocytes (hemolytic anemia) or platelets (ITP).

Clinical Manifestations and Assessment

Many patients are asymptomatic and are diagnosed incidentally during routine physical examinations or during treatment for another disease. At the time of diagnosis, lymphadenopathy is seen in 50% to 90% of patients and splenomegaly in 25% to 55% of patients (Rai & Stilgenbauer, 2014). An increased lymphocyte count (lymphocytosis) is always present. The erythrocyte and platelet counts may be normal or, in later stages of the illness, decreased.

Approximately 5% to 10% of patients with CLL present with "B symptoms," a constellation of symptoms including fevers, fatigue, drenching sweats (especially at night), and unintentional weight loss (Rai & Stilgenbauer, 2014). Patients with CLL have defects in their humoral and cell-mediated immune systems; therefore, infections are common. The defect in cellular immunity is evidenced by an absent or decreased reaction to skin sensitivity tests (e.g., *Candida*, mumps), which is known as anergy. Life-threatening infections are common. Viral infections, such as herpes zoster, can become widely disseminated.

Medical Management

In early stages, CLL may require no treatment. The decision to treat is triggered by symptom progression, including drenching night sweats, fatigue, weight loss, painful lymphadenopathy or progressive cytopenias, or the development of an associated autoimmune disorder (such as AIHI or ITP) (Wierda, 2015). The period of observation can be as long as several years. Treatment options are selected based on the patient's age, performance status, comorbidities, and risk factors (deletion of chromosome 17 predicts poor response to therapy) (Wierda, 2015; NCCN, 2016f). Five to 10% of patients will experience a transformation from CLL to a more aggressive form of lymphoma. The median survival in this population is 5 months, and often aggressive therapy is employed.

The combination of FCR (fludarabine, cyclophosphamide, and rituxan) remains the standard of care for young patients who have a good performance status (Wierda, 2015; NCCN, 2016f). The major side effect of fludarabine is prolonged bone marrow suppression manifested by prolonged periods of neutropenia, lymphopenia, and thrombocytopenia. Patients are then at risk for infections, such as *Pneumocystis jiroveci, Listeria*, mycobacteria, herpes viruses, and cytomegalovirus (CMV). Most patients receive prophylactic antimicrobials to minimize risk for these infections.

For older or more frail patients, newer agents such as the CD20 monoclonal antibodies, obinutuzumab or ofatumumab, or the oral agent, ibrutinib, may be considered (Wierda, 2015; NCCN, 2016f). Ibrutinib targets a tyrosine kinase called Bruton tyrosine kinase, which is responsible for CLL cell growth. It was approved for relapsed or refractory CLL and in patients with CLL who have a deletion of 17p. It has a favorable risk–benefit profile, is taken orally, and shown efficacy even in the refractory setting. Common side effects include diarrhea, fatigue, fever, nausea, and cytopenias (McNally, Long, Brophy, & Badillo, 2015).

Bacterial infections are common in patients with CLL, and treatment with IV immunoglobulin (IVIG) may be given to selected patients with low immunoglobulin levels to decrease the risk for infection.

MULTIPLE MYELOMA (MM)

MM is malignant disease of the plasma cell; it accounts for 10% of all hematologic cancers (Ferri, 2016j). Plasma cells are mature B cells that secrete immunoglobulins, proteins necessary for antibody production (IgG, IgA, IgM, IgD, IgE) to fight infection. Myeloma results in the production of monoclonal antibody proteins (M protein). Incidence in 2013 was 22,350 cases of MM (ACS, 2013). Prevalence is 70,000 in the United States, and the higher prevalence rates are related to more effective therapies, resulting in extended survival (Faiman & Richards, 2014). Median age at diagnosis is 60 years with the majority of patients over 70 years of age (NCCN, 2016g). The incidence rate is more than twice as high in the black population as compared to white populations. Most patients develop resistance to treatment over time (Faiman & Richards, 2014). The overall survival of MM has improved significantly in the last 15 years from a 2.5-year median survival before 2001 to 4.6 years from 2001 to 2005 and 6.1 years in patients diagnosed between 2006 and 2010 (Rajkumar, 2016). Infection is the leading cause of death.

Pathophysiology

Clonal plasma cells develop as a result of a series of acquired genetic mutations and alterations in the bone marrow microenvironment that create an environment favorable to myeloma cell growth (Falco, Smith, & Sullivan, 2011; Faiman & Richards, 2014). Myeloma cells grow and accumulate in the bone marrow, resulting in bone lesions and bone marrow failure (NCCN, 2016g). In MM, the malignant plasma cells produce an increased amount of a specific immunoglobulin that is nonfunctional. Functional types of immunoglobulin are still produced by nonmalignant plasma cells but in lower-than-normal quantity. The nonfunctional, specific immunoglobulin secreted by the myeloma cells is detectable in the blood and/or urine and is referred to as the *monoclonal protein*, or *M protein*. This protein serves as a useful marker to monitor the extent of disease and the patient's response to therapy. In addition, the presence of light chains (antibodies are made up of light chains and heavy chains) in the urine (sometimes referred to as *Bence–Jones protein*) is considered to be a major criterion in the diagnosis of MM. The monoclonal protein is commonly measured by serum or urine protein electrophoresis. Moreover, the patient's total protein level is typically elevated, again due to the production of M protein.

To establish a diagnosis of myeloma, there must be a measurable M protein in the serum and/or urine; in the absence of measurable M protein, an abnormal serum free light chain ratio may substitute for this criteria. Bone marrow aspirate and biopsy are performed; the presence of more than 10% plasma cells in the bone marrow is another hallmark diagnostic criterion. The diagnosis of myeloma also requires evidence of end-organ damage, including: anemia, hypercalcemia, kidney dysfunction, or bone destruction (Ferri, 2016j). Testing for end-organ damage includes serum creatinine, hemoglobin/hematocrit, calcium, and x-rays of the axial skeleton to detect lytic lesions.

Malignant plasma cells also secrete certain substances to stimulate the creation of new blood vessels to enhance the growth of these clusters of plasma cells; this process is referred to as angiogenesis. Occasionally, the plasma cells infiltrate other tissue, in which case they are referred to as *plasmacytomas*. Plasmacytomas can occur in the sinuses, spinal cord, and soft tissues.

Clinical Manifestations and Assessment

As many as 90% of patients with MM develop bone lesions. Although patients can have asymptomatic bone involvement, the most common presenting symptom of MM is bone pain, usually in the back or ribs. Unlike arthritic pain, the bone pain associated with myeloma increases with movement and decreases with rest; patients may report that they have less pain on awakening, but the pain intensity increases during the day. In myeloma, a substance secreted by the plasma cells, osteoclast-activating factor, and other substances (e.g., interleukin-6 [IL-6]) are involved in stimulating osteoclasts. Both mechanisms appear to be involved in the process of bone breakdown. Thus, lytic lesions as well as osteoporosis may be seen on bone x-rays (they are not well visualized on bone scans). The bone destruction can be severe enough to cause vertebral collapse and fractures, including spinal fractures, which can impinge on the spinal cord and result in spinal cord compression. It is this bone destruction that causes significant pain.

If the bone destruction is fairly extensive, excessive ionized calcium is lost from the bone and enters the serum; therefore, hypercalcemia may develop (frequently manifested by excessive thirst, dehydration, constipation, altered mental status, confusion, and, rarely, coma). Kidney failure may also occur; the configuration of the circulating immunoglobulin molecule (particularly the shape of lambda light chains) can damage the renal tubules.

As more and more malignant plasma cells are produced, the marrow has less space for erythrocyte production, and anemia may develop. This anemia is also caused to a great extent by a diminished production of erythropoietin by the kidney. The patient may complain of fatigue and weakness due to the anemia. In the late stage of the disease, a reduced number of leukocytes and platelets may also be seen because the bone marrow is infiltrated by malignant plasma cells.

Nursing Alert

Any elderly patient whose chief complaint is back pain and who has an elevated total protein level should be evaluated for possible myeloma. Elderly patients with anemia should also have myeloma on the list of differential diagnoses.

Medical Management

There is no cure for MM. Even autologous PBSCT is considered to extend remission rather than provide a cure. However, for many patients, it is possible to control the illness and maintain their level of functioning quite well for several years. Initial treatment is dictated by risk level and transplant eligibility. Patients who are transplant eligible are treated with combination therapy, including a proteasome inhibitor (bortezomib in low- and intermediate-risk patients and carfilzomib in high-risk patients), lenalidomide, and dexamethasone for four cycles followed by autologous transplant and maintenance therapy with either lenalidomide (low-risk patients) or a proteasome inhibitor (high-risk patients) (Rajkumar, 2016). Patients who are not eligible for transplant are treated with bortezomib, lenalidomide, and dexamethasone for several cycles followed by maintenance therapy with a proteasome inhibitor for intermediate- and high-risk patients. Frail elderly patients may be treated with lenalidomide and dexamethasone (Rajkumar, 2016).

Recent advances in the understanding of the process of angiogenesis have resulted in new therapeutic options. The sedative thalidomide (Thalomid), initially used as an antiemetic, and the newer agents, Lenalidomide, and Pomalidomide, have significant antimyeloma effects. These agents inhibit the cytokines necessary for new vascular generation, such as vascular endothelial growth factor, and for myeloma cell growth and survival, such as IL-6 and tumor necrosis factor, by boosting the body's immune response against the tumor and by creating favorable conditions for apoptosis (programmed cell death) of the myeloma cells. Thalidomide is effective in refractory myeloma and in "smoldering" disease states and may prevent progression to a more active state. Thalidomide, lenalidomide, and pomalidomide are not typical chemotherapeutic agents and have unique side-effect profiles. Thalidomide commonly causes fatigue, dizziness, constipation, rash, and peripheral neuropathy. Lenalidomide and pomalidomide side-effect profiles are quite different from that of thalidomide: myelosuppression and infections such as pneumonia are more common, whereas sedation, neuropathy, and constipation are not (NCCN, 2016g). Patients who have progressed on thalidomide still can be treated with lenalidomide; lenalidomide is thought to exhibit more antimyeloma activity than thalidomide. Often lenalidomide is used in combination with bortezomib; together, the two drugs are synergistic and may improve outcomes.

Thalidomide, lenalidomide, and pomalidomide are contraindicated in pregnancy because of associated severe birth defects. In addition, due to the risks for birth defects, use of either agent requires registry into a monitoring program that ensures routine pregnancy testing, contraception, and control of drug distribution. Patients must be counseled monthly and agree to use approved methods of birth control prior to taking these drugs.

Newer agents recently approved for the treatment of myeloma include the monoclonal antibodies (MoAb), elotuzumab and daratumumab (Darzalex™). Elotuzumab is a humanized MoAb that targets the CS-1 antigen that is expressed in 97% of cases of myeloma. CS-1 stimulates tumor growth and cell adhesion through interaction with the bone marrow microenvironment; elotuzumab interferes with the activity of CS-1. In the relapsed/refractory setting, elotuzumab, in combination with lenalidomide and dexamethasone, had a response rate of 92% at 18 months (Lonial et al., 2013). Daratumumab is a CD38-targeted MoAb approved in the relapsed/refractory setting in

patients treated with at least three prior therapies; overall response rate was 29.2% (Darzalex package insert, 2015).

Radiation therapy is very useful in strengthening the bone at a specific lesion, particularly one at risk for bone fracture or spinal cord compression. It is also useful in relieving bone pain and reducing the size of plasma cell tumors that occur outside the skeletal system. However, because it is a nonsystemic form of treatment, it does not diminish the source of the bone conditions (i.e., the production of malignant plasma cells). Therefore, typically radiation therapy is used in combination with systemic treatment such as chemotherapy.

When lytic lesions result in vertebral compression fractures, vertebroplasty is often performed. This procedure is performed under fluoroscopy. A hollow needle is positioned within the fractured vertebra, and when the precise location is confirmed, an orthopedic cement is injected into the vertebra to stabilize the fracture and strengthen the vertebra. For most patients, relief from pain is almost immediate. This procedure has been enhanced by concomitant kyphoplasty, the use of a special inflatable balloon inserted into the vertebra to increase the height of the vertebra prior to injecting the cement.

All patients with myeloma are at risk for skeletal-related events (SREs), including pathologic fractures and spinal cord compression. Bisphosphonate therapy has been shown to decrease the risk of SREs in patients with and without bone involvement (Munchi & Anderson, 2015). As a result of this data, all patients with symptomatic myeloma should receive bisphosphonate therapy with either pamidronate or zoledronic acid, as an adjunct to their antimyeloma therapy (Terpos, Roodman, Dimopoulos, 2013; NCCN, 2016g). Pamidronate (Aredia) and zoledronic acid (Zometa) have been shown to strengthen bone in MM by diminishing the secretion of osteoclast-activating factor, thus controlling bone pain and potentially preventing bone fracture. These agents are also effective in managing and preventing hypercalcemia. A recent study evaluated survival outcomes and found a survival advantage in patients with myeloma who received bisphosphonate treatment (Morgan et al., 2013). However, a complication associated with IV bisphosphonates is osteonecrosis of the jaw, which can result in intractable pain, swallowing difficulty, sinusitis, soft-tissue abscesses, and extraoral fistulas (a permanent abnormal passageway between the mouth and exterior of the body). Estimates of incidence are from 1% to 12% of patients receiving IV bisphosphonates. Patients should receive a comprehensive dental examination and appropriate dental interventions as needed prior to initiation of bisphosphonate therapy. Throughout the duration of treatment, careful assessment for this complication should be performed.

Hyperviscosity may result from elevations in the M protein levels. When patients have signs and symptoms of hyperviscosity, such as mental status changes or blurred vision, plasmapheresis may be used to lower the immunoglobulin level. Symptoms may be more useful than serum viscosity levels in determining the need for this intervention.

MM increases the risk for the development of VTE. Drugs such as thalidomide, lenalidomide, and pomalidomide are also thrombogenic; the risk for VTE increases when these agents are used in combination with dexamethasone. To minimize the risk for VTE, patients are educated to maintain an active lifestyle including daily exercise. In addition, prophylaxis with aspirin is recommended unless contraindicated.

Nursing Management

Pain management is very important in patients with MM. NSAIDs can be very useful for mild pain or can be administered in combination with opioid analgesics. Because NSAIDs can cause gastritis and kidney dysfunction, kidney function must be monitored carefully. The patient needs to be educated about activity restrictions (e.g., lifting no more than 10 lb, use of proper body mechanics). Braces are needed occasionally to support the spinal column. Patients must understand the importance of reporting any new pain promptly as there is risk for spontaneous pathologic fractures that require prompt intervention to minimize morbidity.

Peripheral neuropathy is a common side effect of the immunomodulatory agents used to treat MM, occurring in as many as 80% of patients. Peripheral neuropathy can significantly impact the patient's quality of life and ability to perform activities of daily living (ADLs). The physical examination should include an assessment of neuropathy using a neurotoxicity assessment tool as well as a subjective assessment of the patient's discomfort. Management of peripheral neuropathy may include decreasing drug doses, holding therapy, treating discomfort with medications such as gabapentin, and involving other disciplines such as occupational and physical therapy to maximize and restore function.

The patient also needs to be instructed about the signs and symptoms of hypercalcemia. Maintaining mobility and hydration is important to minimize risk of exacerbations of this complication; however, the primary cause is the disease itself. Also kidney function should be monitored closely. Kidney failure can become severe, and dialysis may be needed. Maintaining high urine output with aggressive hydration (3 L/day) can be very useful in preventing or limiting this complication.

Because antibody production is impaired, infections, particularly bacterial infections, are common and can be life-threatening. The patient needs to be instructed in appropriate infection-prevention measures, such as hand hygiene and avoiding sick individuals, and should be advised to contact the health care provider immediately if he or she has a fever or other signs and symptoms of infection. The patient should receive vaccines for pneumonia (Pneumovax) and influenza. Sometimes prophylactic antibiotics are used. IVIG can be useful for patients with recurrent infections and low levels of immunoglobulins.

Many patients with MM are treated with high doses of corticosteroids for protracted periods of time. Patients must be monitored for potential short- and long-term effects of steroids, including hyperglycemia and insomnia (short term), and osteopenia, osteoporosis, cataracts, and diabetes (long term).

Gerontologic Considerations 

The incidence of MM increases with age; the disease is less common in patients younger than 40 years of age. Due in part to the aging population, incidence is rising. Back pain, which is often a presenting symptom in this disease, should be investigated closely in older patients. In addition, any patient over 40 years of age presenting with anemia should undergo a workup for myeloma, primarily through an evaluation of the serum protein electrophoresis (SPEP). Autologous PBSCT is an option that can prolong remission and potentially cure some patients, but it is unavailable to many older people because of age limitations, poor performance status, and comorbidities.

THERAPIES FOR BLOOD DISORDERS

Splenectomy

Each year 25,000 splenectomies are performed in the United States with the estimated prevalence of asplenic patients reaching 1 million (Rubin & Schaffner, 2014). Removal may be an emergency, in the case of trauma or rupture, or elective in the case of treating selected hematologic disorders. Because the spleen is very vascular, severe hemorrhage can result if the spleen is ruptured. Under such circumstances, splenectomy becomes an emergency procedure.

Splenectomy is also a possible treatment for other hematologic disorders. For example, an enlarged spleen may be the site of excessive destruction of blood cells. If the destruction is life-threatening, surgery may be life-saving. This is the case in AIHA and ITP when these disorders do not respond to more conservative measures, such as corticosteroid therapy. Some patients with grossly enlarged spleens develop severe thrombocytopenia due to the platelets being sequestered in the spleen; splenectomy removes the "trap," and platelet counts may normalize over time.

In general, the mortality rate after splenectomy is low. Laparoscopic splenectomy can be performed in selected patients, with a resultant decrease in postoperative morbidity. The most common complications in patients following splenectomy include infection, thrombosis, bleeding, and wound dehiscence (Matharoo, Afthinos, & Gibbs, 2014; Terreri, 2016). Although young children are at the highest risk after splenectomy, all age groups are vulnerable to overwhelming, lethal infections and should receive recommended vaccinations and be treated promptly for fever or signs of infection (see earlier detailed discussion about splenectomy care in ITP section).

Often, patients with high platelet counts have even higher counts after splenectomy (over 1 million/mm^3), which can predispose them to serious thrombotic or hemorrhagic problems. However, this increase is transient and usually does not warrant additional treatment.

THERAPEUTIC APHERESIS

Apheresis is a Greek word meaning separation. In therapeutic apheresis (or pheresis), blood is taken from the patient and passed through a centrifuge, in which a specific component is separated from the blood and removed. Then the remaining blood is returned to the patient.

The most common apheresis modalities used include therapeutic plasma exchange (e.g., used to treat hyperviscosity in plasma cell disorders), leukocytopheresis (used to treat symptomatic leukocytosis in patients with leukemia), extracorporeal photopheresis (ECP) (used to treat cutaneous T-cell lymphoma, Sezary syndrome, and GVHD), thombocytopheresis (used to treat symptomatic thrombocytosis with MPNs), and erythrocytapheresis (used in selected cases of PV or ET) (Connelly-Smith & Linenberger, 2015).

The entire system is closed so the risk of bacterial contamination is extremely low. When platelets or leukocytes are removed, the decrease in these cells within the circulation is temporary. However, the temporary decrease provides a window of time until suppressive medications (e.g., chemotherapy) can have therapeutic effects. Sometimes plasma is removed rather than blood cells—typically so that specific, abnormal proteins within the plasma are lowered transiently until a long-term therapy can be initiated.

Also apheresis is used to obtain larger amounts of platelets from a donor than can be provided from a single unit of whole blood. A unit of platelets obtained in this way is equivalent to six to eight units of platelets obtained from six to eight separate donors via standard blood donation methods. Platelet donors can have their platelets apheresed as often as every 14 days.

Leukocytes can be obtained similarly, typically after the donor has received growth factors (G-CSF, GM-CSF) to stimulate the formation of additional leukocytes and thereby increase the leukocyte count. The use of these growth factors also stimulates the release of stem cells within the circulation. Apheresis is used to harvest these stem cells (typically over a period of several days) for use in PBSCT.

THERAPEUTIC PHLEBOTOMY

Therapeutic phlebotomy is the removal of a certain amount of blood under controlled conditions. Usually patients with elevated hematocrits (e.g., those with PV) or excessive iron absorption (e.g., hemochromatosis) can be managed by periodically removing 1 unit (about 500 mL) of whole blood; however, the elderly, those with small body mass, comorbidities, or women may be able to tolerate only 250 mL (Bacon, 2016; Zubair, 2014). Eventually, this process can produce iron deficiency, leaving the patient unable to produce as many erythrocytes. The actual procedure for therapeutic phlebotomy is similar to that for blood donation (see later discussion).

BLOOD COMPONENT THERAPY

A single unit of whole blood contains 450 mL of blood and 50 mL of an anticoagulant. A unit of whole blood can be processed and dispensed for administration. However, it is more appropriate, economical, and practical to separate that unit of whole blood into its primary components: erythrocytes, platelets, and plasma (leukocytes are rarely used; see later discussion). Because the plasma is removed, a unit of PRBCs is very concentrated (hematocrit approximately 70%). Each component must be processed and stored differently to maximize the longevity of the viable cells and factors within it; each individual blood component has a different storage life. PRBCs are stored at 4°C. With special preservatives, they can be stored safely for up to 42 days before they must be discarded. In contrast, platelets must be stored at room temperature because they cannot withstand cold temperatures, and they last for only 5 days before they must be discarded. To prevent clumping, platelets are agitated gently while stored. Plasma is frozen immediately to maintain the activity of the clotting factors within; it lasts for 1 year if it remains frozen. Alternatively, plasma can be further pooled and processed into blood derivatives, such as albumin, immune globulin, factor VIII, and factor IX. Table 20-6 describes each blood component and how each is commonly used.

Blood transfusion is discussed in detail on page 617.

Special Preparations

Factor VIII concentrate (antihemophilic factor) is a lyophilized (to dry by freezing in a high vacuum) or freeze-dried concentrate of pooled fractionated human plasma. It is used in treating hemophilia A. Factor IX concentrate (prothrombin complex) is prepared similarly and contains factors II, VII, IX, and X. It is used primarily for treatment of factor IX deficiency (hemophilia B). Factor IX concentrate is also useful in treating congenital factor VII and factor X deficiencies. Recombinant forms of factor VIII, such as Humate-P or Alphanate, are also useful. Because they contain vWF, these agents are used in vWD as well as in hemophilia A, particularly when patients develop acquired factor VIII inhibitors (e.g., antibodies).

TABLE 20-6 Blood and Blood Components Commonly Used in Transfusion Therapy[a]

	Composition	Indications and Considerations
Whole blood	Cells and plasma, hematocrit about 40%	Volume replacement and oxygen-carrying capacity; usually used only in significant bleeding (more than 25% blood volume lost)
Packed red blood cells (PRBCs)	RBCs with little plasma (hematocrit about 70%); some platelets and WBCs remain. Platelets in the unit are not functional; WBCs in the unit may cause reaction and are not functional.	Hemoglobin less than 7–8 g/dL; symptomatic anemia
Platelets—random	Platelets (5.5×10^{10} platelets/unit) Plasma; some RBCs, WBCs survival ↓ in presence of fever, chills, infection Repeated treatment leads to ↓ transfused platelet survival due to alloimmunization	To prevent bleeding in patients with a platelet count below 10,000/mm^3 To prevent bleeding in patients with fever or sepsis and platelet count below 20,000/mm^3 Prior to major surgery or invasive procedure when platelet count *is less than or equal to* 50,000/mm^3 Prior to ocular surgery or neurosurgery when platelet count is *less than or equal to* 100,000/mm^3
Platelets—single donor	Platelets (3×10^{11} platelets/unit) 1 unit is equivalent to 6–8 units of random platelets	Used to decrease alloimmunization risk by limiting exposure to multiple donors Preferred for patients who will require repeated transfusions over time
Plasma or fresh-frozen plasma (FFP)	Plasma; all coagulation factors Complement	Bleeding in patients with coagulation factor deficiencies To reverse the effects of warfarin in presence of major bleeding
Granulocytes	Neutrophils (greater than 1×10^{10}/unit); lymphocytes; some RBCs and platelets	Severe neutropenia in selected patients; controversial, rarely used
Donor lymphocytes (white blood cells [WBCs])	Lymphocytes (number varies) taken from a donor and infused into a recipient	Stimulate graft-versus-disease effect in a patient who has undergone prior allogeneic stem cell transplant

	Composition	Indications and Considerations
Cryoprecipitate	Fibrinogen 150 or greater mg/bag, Contains high concentrations of factor VIII and fibrinogen; AHF (VIII:C) 80–110 units/bag	von Willebrand disease Hypofibrinogenemia Hemophilia A
Antihemophilic factor (AHF)	Factor VIII	Hemophilia A
Factor IX concentrate	Factor IX	Hemophilia B (Christmas disease)
Factor IX complex	Factors II, VII, IX, X	Hereditary factors VII, IX, X deficiency Hemophilia A with factor VII inhibitors
Albumin	Albumin 5%, 25%	Hypoproteinemia Burns Volume expansion by 5% to ↑ intravascular volume; 25% → ↑ intravascular volume which ↓'s hematocrit due to hemodilution
IV gamma globulin (IVIG)	IgG antibodies	Hypogammaglobulinemia (in CLL, recurrent infections) ITP Primary immunodeficiency states
Antithrombin III concentrate (AT III)	AT III (trace amounts of other plasma proteins)	AT III deficiency with or at risk for thrombosis

AHF, antihemophilic factor; CLL, chronic lymphocytic leukemia; ITP, immune thrombocytopenic purpura.
[a]The composition of each type of blood component is described, as well as the most common indications for using a given blood component. RBCs, platelets, and fresh-frozen plasma are the blood products most commonly used. When transfusing these blood products, it is important to realize that the individual product is always "contaminated" with very small amounts of other blood products (e.g., WBCs mixed in a unit of platelets). This contamination can cause some difficulties, particularly isosensitization, in certain patients.
Shah (2015).

Plasma albumin is a large protein molecule that usually stays within vessels and is a major contributor to plasma oncotic pressure. This protein is used to expand the blood volume of patients in hypovolemic shock and, rarely, to increase the concentration of circulating albumin in patients with hypoalbuminemia.

Immunoglobulin is a concentrated solution of the antibody IgG; it contains very little IgA or IgM. It is prepared from large pools of plasma. The IV form (IVIG) is used in various clinical situations to replace inadequate amounts of IgG in patients who have experienced recurrent bacterial infection (e.g., those with CLL, BMT or PBSCT recipients) to reduce the risk for future infection. It is also used in certain autoimmune disorders, such as ITP. IVIG, in contrast to all other fractions of human blood, cells, or plasma, can survive being subjected to heating at 60°C (140°F) for 10 hours to free it of the viral contaminants that may be present.

PHARMACOLOGIC ALTERNATIVES TO BLOOD TRANSFUSIONS

Pharmacologic agents that stimulate production of one or more types of blood cells by the marrow are commonly used (Box 20-5).

Researchers continue to seek a blood substitute that is practical and safe (Paul & Nesbitt, 2016). Manufacturing artificial blood is problematic, given the myriad functions of blood components. Research has focused on the role of blood in oxygen transport or its role as an oxygen carrier and the manufacturing of a suitable RBC substitute. The substitutes can be classified as perfluorocarbon emulsions that have a high gas-dissolving capacity for oxygen and hemoglobin-based oxygen carriers (Duke, 2016). Current artificial RBC products have distinct advantages and disadvantages compared with human RBCs. These products can be rendered essentially sterile, resulting in fewer immune-related transfusion problems. They require no refrigeration, have possible unlimited availability, long storage life, and require no cross-matching (Duke, 2016). Potential problems associated with these products include low concentrations of 2,3-DPG, the shifting of the oxyhemoglobin dissociation curve to the left, and a decrease in the off-loading of oxygen at the tissue level. Because the substitutes are also nitric oxide scavengers, vasoconstriction may occur, risking pulmonary hypertension and myocardial ischemia (Duke, 2016). Finally, the solutions may also result in platelet activation (Duke, 2016). Thus, further study is needed to establish safety and efficacy.

BOX 20-5 Pharmacologic Alternatives to Blood Transfusions

Growth Factors

Recombinant technology has provided a means to produce hematopoietic growth factors necessary for the production of blood cells within the bone marrow. By increasing the body's production of blood cells, transfusions and complications resulting from diminished blood cells (e.g., infection from neutropenia or transfusions) may be avoided. However, the successful use of growth factors requires functional bone marrow.

Erythropoietin

Erythropoietin (epoetin alpha/EPO [e.g., Epogen, Procrit]) is an effective alternative treatment for patients with chronic anemia secondary to diminished levels of erythropoietin, as in chronic kidney disease. This medication stimulates erythropoiesis. It also has been used for patients who are anemic from chemotherapy or zidovudine (AZT) therapy and for those who have diseases involving bone marrow suppression, such as myelodysplastic syndrome (MDS). Recent studies have shown that exceeding the recommended Hgb goal of 11 g/dL results in increased risk for cardiovascular events, including stroke and MI. In addition, use of erythropoietin has been associated with decreased survival in certain types of cancer. EPO has been used safely in the

preoperative setting to decrease the need for allogeneic blood transfusions. In this setting, erythropoietin also can enable a patient to donate several units of blood for future use (e.g., preoperative autologous donation). The medication can be administered intravenously or subcutaneously, although plasma levels are better sustained with the subcutaneous route. Side effects are rare, but erythropoietin can cause or exacerbate hypertension. If the anemia is corrected too quickly or is overcorrected, the elevated hematocrit can cause headache, hypertension, and, potentially, seizures. These adverse effects are rare except for in patients with kidney failure. Serial CBCs should be performed to evaluate the response to the medication. The dose and frequency of administration are titrated to the hematocrit.

Granulocyte-Colony Stimulating Factor (G-CSF)

G-CSF (filgrastim [Neupogen]) is a cytokine that stimulates the proliferation and differentiation of myeloid stem cells; a rapid increase in neutrophils is seen within the circulation. G-CSF is effective in improving transient but severe neutropenia after chemotherapy or in some MDS subtypes. It is particularly useful in preventing bacterial infections that would be likely to occur with neutropenia. G-CSF is administered subcutaneously on a daily basis. The primary side effect is bone pain; this probably reflects the increase in hematopoiesis within the marrow. Serial CBCs should be performed to evaluate the response to the medication and to ensure that the rise in white blood cells is not excessive. The effect of G-CSF on myelopoiesis is short; the neutrophil count drops once the medication is stopped. There is a long-active formulation, Pegfilgrastim (Neulasta) that is given once per chemotherapy cycle to decrease the risk for infection.

Granulocyte-Macrophage Colony Stimulating Factor (GM-CSF)

GM-CSF (sargramostim [Leukine]) is a cytokine that is naturally produced by a variety of cells, including monocytes and endothelial cells. It works either directly or synergistically with other growth factors to stimulate myelopoiesis. GM-CSF is not as specific to neutrophils as is G-CSF; thus, an increase in erythroid (RBC) and megakaryocytic (platelet) production also may be seen. GM-CSF serves the same purpose as G-CSF. However, it may have a greater effect on macrophage function and, therefore, may be more useful against fungal infections, whereas G-CSF may be better used to fight bacterial infections. GM-CSF is also administered subcutaneously. Side effects include bone pain, fevers, and myalgias.

PROCURING BLOOD, BLOOD PRODUCTS, AND BLOOD TRANSFUSIONS

Blood Donation

To protect both the donor and the recipients, all prospective donors are examined and interviewed before they are allowed to donate their blood. The intent of the interview is to assess the general health status of the donor and to identify risk factors that might harm a recipient of the donor's blood. Donors should be in good health and meet a number of specific criteria (Box 20-6).

Potential donors should be asked whether they have consumed any aspirin or aspirin-containing medications within the past 3 days. Although aspirin use does not render the donor ineligible, the platelets obtained would be dysfunctional and therefore not useful; aspirin usage within 48 to 72 hours contraindicates platelet donation. Aspirin does not affect the erythrocytes or plasma obtained from the donor.

Directed Donation

At times, friends and family of a patient wish to donate blood specifically for that person. These blood donations are termed *directed donations*. These donations are not any safer than those provided by random donors because directed donors may not be as willing to identify themselves as having a history of any of the risk factors that disqualify a person from donating blood.

BOX 20-6 Eligibility Requirements for Blood Donation

All donors are expected to meet the following minimum requirements:

- Be healthy and feeling well
- Be at least 17 years old in most states
- Body weight should exceed 50 kg (110 lb) for a standard 450-mL donation.
- Men must be at least 5′1″ tall; women must be at least 5′5″
- No fever or signs/symptoms of infection.
- Blood pressure less than 180/100.
- The hemoglobin level should be at least 12.5 g/dL.

Contraindications to Blood Donation

- A history of viral hepatitis at any time in the past. If the donor lives with or has had sexual contact with a person who has hepatitis, the donor must wait 12 months after the last contact to donate.
- A history of receiving a blood transfusion or an infusion of any blood derivative (other than serum albumin) within 12 months
- A history of untreated malaria because malaria can be transmitted by transfusion even years later
- A history of syphilis or gonorrhea; acceptable if it has been more than 12 months since donor completed treatment for syphilis or gonorrhea
- A history or evidence of IV drug abuse
- A history of possible exposure to HIV
- A recent tattoo within the last 12 months because of the risk of blood-borne infections (e.g., hepatitis, HIV)
- A recent history of asthma, urticaria, or allergy to medications because hypersensitivity can be transferred passively to the recipient
- Recent immunizations (exception: influenza, tetanus, or meningitis, provided that the donor is symptom free and afebrile)
- Pregnancy, because of the nutritional demands of pregnancy on the mother
- A diagnosis of cancer, hemochromatosis, sickle cell disease, or active skin infections

at the venipuncture site

- A history of whole blood donation within the past 56 days

For a detailed list of eligibility criteria by topic, visit the American Red Cross website: http://www.redcrossblood.org/donating-blood/eligibility-requirements American Red Cross (2017).

Standard Donation

Phlebotomy consists of venipuncture and blood withdrawal. Standard precautions are used. Donors are placed in a semi-recumbent position, and venipuncture with a large bore IV is performed. Withdrawal of 450 mL of blood usually takes less than 15 minutes. After the needle is removed, donors are asked to hold the involved arm straight up, and firm pressure is applied with sterile gauze for 2 to 3 minutes or until bleeding stops. Then a firm bandage is applied. The donor remains recumbent until he or she feels able to sit up, usually within a few minutes.

The donor is instructed to:

- leave the dressing on for a few hours
- avoid heavy lifting or vigorous exercise for the rest of the day
- increase fluid intake by drinking an extra four 8-oz glasses of fluid and avoid alcoholic beverages over the next 24 hours

Specimens from this donated blood are tested to detect infections and to identify the specific blood type (see later discussion).

Autologous Donation

A patient's own blood may be collected for future transfusion; this method is useful for many elective surgeries in which the potential need for transfusion is high (e.g., orthopedic surgery). Preoperative donations are ideally collected 4 to 6 weeks before surgery. Iron supplements are prescribed during this period to prevent depletion of iron stores. Occasionally, erythropoietin (epoetin-alfa [Epogen, Procrit]) is given to stimulate erythropoiesis, so that the donor's hematocrit remains high enough to be eligible for donation. Typically, one unit of blood is drawn each week; the number of units obtained varies with the type of surgical procedure to be performed (i.e., the amount of blood anticipated to be transfused). Phlebotomies are not performed within 72 hours of surgery.

The primary advantage of autologous transfusions is the prevention of viral infections from another person's blood. It is the policy of the American Red Cross that autologous blood be transfused only to the donor. If the blood is not required, it can be frozen until the donor needs it in the future (for up to 10 years). Wastage rates of autologous transfusions can be up to 40% to 56% (Greenky et al., 2014). The blood is never returned to the general donor supply of blood products to be used by another person.

The disadvantage of autologous donation is that it may be performed even when the likelihood is small that the anticipated procedure will necessitate a transfusion. Needless autologous donation is expensive, takes time, and uses resources inappropriately. Furthermore, although autologous transfusion can eliminate the risk of viral contamination, the risk for bacterial contamination is the same as that in transfusion from random donors.

Contraindications to donation of blood for autologous transfusion are acute infection, severely debilitating chronic disease, hemoglobin level of less than 12.5 g/dL, hematocrit less than 38%, unstable angina, and acute cardiovascular or cerebrovascular disease.

Intraoperative Blood Salvage

This transfusion method provides replacement for patients who cannot donate before surgery and for those undergoing vascular, orthopedic, or thoracic surgery. During a surgical procedure, blood lost into a sterile cavity (e.g., hip joint) is suctioned into a cell-saver machine. The whole blood or PRBCs are washed, often with saline solution, filtered, and then returned to the patient as an IV infusion. The goal of intraoperative salvage is to reduce the need for allogeneic blood transfusions. Studies have demonstrated that intraoperative blood salvage safely and effectively decreases the need for transfusions of donated blood without causing adverse outcomes (Greenky et al., 2014). Devices that collect blood for reinfusion allow for either washing or not washing prior to transfusion. If the blood is washed (with normal saline) to remove lysed RBC debris and contaminants, it can be stored up to 4 hours at room temperature after processing. However, unwashed products must be filtered to remove clots and tissue debris and must be infused within 6 hours from the start of collection due to the risk from other contaminants (Shi, 2013).

Hemodilution

This transfusion method may be initiated before or after induction of anesthesia. About one to two units of blood are removed from the patient through a venous or arterial line and simultaneously replaced with a colloid or crystalloid solution. Then the blood that is obtained is reinfused after surgery. The advantage of this method is that the patient loses fewer erythrocytes during surgery because the added IV solutions dilute the concentration of erythrocytes and lower the hematocrit. However, patients who are at risk of myocardial injury should not be further stressed by hemodilution.

Complications of Blood Donation

The overall incidence of complications secondary to blood donation is very low (2% to 5%) (Greco & Shaz, 2013). The most common complications include bleeding secondary to needle injury (such as hematoma formation) and vasovagal reactions. Excessive bleeding at the donor's venipuncture site is sometimes caused by a bleeding disorder in the donor but more often results from a technique error: laceration of the vein, excessive tourniquet pressure, or failure to apply enough pressure after the needle is withdrawn. A donor who appears pale or complains of faintness should immediately lie down or sit with the head lowered below the knees. He or she should be observed for another 30 minutes.

BLOOD PROCESSING

Samples of the unit of blood are always taken immediately after donation so that the blood can be typed and tested. Each donation is tested for antibodies to HIV 1 and 2, hepatitis B core antibody (anti-HBc), hepatitis C virus (HCV), West Nile virus, and human T-cell lymphotropic virus type I (anti-HTLV-I/II). The blood is also tested for hepatitis B, hepatitis C virus, and Pallidum (Syphilis) (Klineman, 2016). Negative reactions are required for the blood to be used, and each unit of blood is labeled to certify the results. Blood is also screened for Cytomegalovirus (CMV); if it tests positive for CMV, it still can be used except in recipients who are negative for CMV and who are immunocompromised (e.g., BMT or PBSCT recipients).

Equally important to viral testing is accurate determination of the blood type. More than 200 antigens have been identified on the surface of RBC membranes. Of these, the most important for safe transfusion are the ABO and Rh systems. The ABO system identifies which antigens are present on the membrane of a person's erythrocytes: A, B, both A and B, or neither A nor B (type O). Individuals have antibodies in their plasma that are directed against blood group antigens that their RBCs do not express. For example, a person with Type A blood expresses the A antigen on the RBC membrane and has anti-B antibodies. To prevent a significant reaction, the same type of PRBCs should be transfused. In an emergency situation in which the patient's blood type is not known, type O blood may be transfused safely.

The Rh antigen (also called D) is present on the surface of erythrocytes in 85% of the population (Rh-positive). Those who lack the D antigen are called Rh-negative. PRBCs are routinely tested for the D antigen as well as ABO. Patients with Rh positive blood can receive Rh negative blood; however, patients who are Rh negative should only receive Rh negative blood.

The majority of transfusion reactions (other than those due to procedural error) are due to the presence of donor leukocytes within the blood component unit (PRBCs or platelets); the recipient may form antibodies to the antigens present on these leukocytes. PRBC components typically have 1 to 3×10^9 leukocytes remaining in each unit. Leukocytes from the blood product are frequently filtered to diminish the likelihood of developing reactions and refractoriness to transfusions, particularly in patients who have chronic transfusion needs. Filtration can occur at the time the unit is collected from the donor and processed, which achieves better results but is more expensive, or at the time the blood component is transfused by attaching a leukocyte filter to the blood administration tubing. Many centers advocate routinely using leuko-poor filtered blood components for people who have or are likely to develop chronic transfusion requirements.

When a patient is extremely immunocompromised, as in the case of bone marrow or stem cell transplant, any donor lymphocytes must be removed from the blood components. In this situation, the blood component is exposed to low amounts of radiation (25 Gy) that kill any lymphocytes within the blood component. Irradiated blood products are highly effective in preventing transfusion-associated GVHD, which is fatal in most cases. Irradiated blood products have a shorter shelf life.

TRANSFUSION

Administration of blood and blood components requires knowledge of correct administration techniques and possible complications. It is very important to be familiar with the facility's policies and procedures for transfusion therapy.

Setting

Although most blood transfusions are performed in the acute care setting, patients with chronic transfusion requirements often can receive transfusions in other settings, including free-standing infusion centers, ambulatory care clinics, physicians' offices, and, occasionally, even patients' homes. Typically, patients who need chronic transfusions but are otherwise stable physically are appropriate candidates for outpatient therapy. Verification and administration of the blood product are performed as in a hospital setting.

Method

Transfusing blood components are presented in Box 20-7.

Nursing Management

Nursing responsibilities include pretransfusion and posttransfusion assessment.

Pretransfusion Assessment

Patient history is an important component of the pretransfusion assessment to determine the history of previous transfusions as well as previous reactions to transfusion. The history should include the type of reaction, its manifestations, the interventions required, and whether any preventive interventions were used in subsequent transfusions. It is important to assess the number of pregnancies a woman has had because a high number can increase her risk for reaction due to antibodies developed from exposure to fetal circulation. Patients with blood disorders, such as sickle cell anemia or CLL, and patients who have received a stem cell transplant also may be at increased risk for transfusion reactions based on the number of previous transfusions. Other concurrent health problems should be noted, with careful attention to cardiac (particularly congestive heart failure with a decreased left ventricular ejection fraction), pulmonary, and vascular disease.

A systematic physical assessment and measurement of baseline vital signs are important before transfusing any blood product. The respiratory system should be assessed, including careful auscultation of the lungs and the patient's use of accessory muscles. Cardiac system assessment should include careful inspection for any edema as well as other signs of cardiac failure (e.g., jugular venous distention). The skin should be observed for rashes, petechiae, and ecchymoses. The sclera should be examined for icterus. In the event of a transfusion reaction, a comparison of findings can help differentiate between types of reactions.

Nursing Alert
To evaluate a patient's response to therapy, the nurse is aware that when administering PRBCs it is expected that one unit of PRBCs will raise the hemoglobin by 1 g and HCT by 3%, if the patient is not bleeding or hemolyzing. If administering platelets (which generally consists of six units of pooled platelets from random donors [random donor platelets or RDP]), the count should increase by approximately 30,000 mm^3 in an adult of average size (Yuan & Goldfinger, 2016).

Providing Patient Teaching

Reviewing the signs and symptoms of a transfusion reaction is crucial for patients who have not received a transfusion before. Even for patients who have received prior transfusions, a brief review of the signs and symptoms of transfusion reactions is essential. Signs and symptoms of a reaction include fever, chills, itching, hives, respiratory distress, low back pain, nausea, pain at the IV site, or anything "unusual." Although a thorough review is very important, it is also important to reassure the patient that the blood is tested carefully against the patient's own blood (cross-matched) to diminish the likelihood of any adverse reaction. Such assurance can be extremely beneficial in allaying anxiety.

Monitoring and Managing Potential Complications

Any patient who receives a blood transfusion may develop complications from that transfusion. When explaining the reasons for the transfusion, it is important to include the risks and benefits and what to expect during and after the transfusion. Patients must be informed that the supply of blood is not completely risk-free, although it has been tested carefully (Box 20-8). Nursing management is directed toward preventing complications, promptly recognizing complications if they develop, and promptly initiating measures to control complications. The following sections describe the most common or potentially severe transfusion-related complications. Table 20-7 summarizes potential long-term complications.

BOX 20-7 Transfusion of Packed Red Blood Cells (PRBCs)

Preprocedure

- Confirm that the transfusion has been prescribed.
- Confirm that a current type and screen of the patient's blood is on file per institution policy.
- Check that patient's blood has been typed and cross-matched.
- Verify that patient has been provided informed consent per institution or agency policy.
- Explain the procedure to the patient. Instruct the patient in signs and symptoms of transfusion reaction (itching, hives, swelling, shortness of breath, fever, chills).
- Take the patient's temperature, pulse, respiration, oxygen saturation, and blood pressure to establish a baseline for comparing vital signs during transfusion.
- Perform hand hygiene and wear gloves in accordance with Standard Precautions.
- Use a 20-gauge or larger needle for insertion in a large vein. Use special tubing that contains a blood filter to screen out fibrin clots and other particulate matter. Do not vent the blood container.

Procedure

- Obtain the PRBCs from the blood bank *after* the IV line is started and vital signs are assessed. (Institution policy may limit release to only one unit at a time.)
- Double-check the labels with another licensed provider (nurse, advanced practice provider, or physician) to make sure that the ABO group and Rh type agree with the compatibility record. Check to see that the number and type on the donor blood label and on the patient's chart are correct. Check the patient's identification by using two forms of identification (can include the patient's name, date of birth, and medical record number) comparing the blood product label to the patient identification bracelet. Also ask the patient to confirm his or her name and date of birth.
- Check the blood for gas bubbles and any unusual color or cloudiness. (Gas bubbles may indicate bacterial growth. Abnormal color or cloudiness may be a sign of

hemolysis.)

- Make sure PRBC transfusion is initiated within 30 minutes after removal of the PRBCs from the blood bank refrigerator.
- For the first 15 minutes, run the transfusion slowly—no faster than 5 mL/min. Observe the patient carefully for adverse effects. If no adverse effects occur during the first 15 minutes, then increase the flow rate unless the patient is at high risk for circulatory overload.
- Monitor the patient closely for 15–30 minutes to detect signs of reaction. Monitor vital signs at regular intervals per institution or agency policy; compare the results with baseline measurements. Increase frequency of measurements based on the patient's condition. Observe the patient frequently throughout the transfusion for any signs of adverse reaction, including restlessness, hives, nausea, vomiting, torso or back pain, shortness of breath, flushing, hematuria, fever, or chills. Should any adverse reaction occur, stop infusion immediately, notify the health care provider, and follow the agency's transfusion reaction policy.
- Note that administration time does not exceed 4 hours because of the increased risk for bacterial growth.
- Be alert for signs of adverse reactions: circulatory overload, sepsis, febrile reaction, allergic reaction, and acute hemolytic reaction.
- Change blood tubing after every 2 units transfused to decrease the chance of bacterial contamination.

Postprocedure

- Obtain vital signs and compare them with baseline measurements.
- Dispose of used materials properly.
- Document the procedure in the patient's medical record, including patient assessment findings and tolerance to procedure.
- Monitor the patient for response to and effectiveness of the procedure.

Note: Never add medications to blood or blood products; if blood is too thick to run freely, normal saline may be added to the unit. If blood must be warmed, use an in-line blood warmer with a temperature monitoring system.

Note: Fresh-frozen platelets (FFP) require ABO but not Rh compatibility. Typically platelets are not cross-matched for ABO compatibility. Never add medications to blood or blood products. Both platelets and FFPs can be infused as rapidly as the patient can tolerate, based on fluid status and cardiac function.

Febrile Nonhemolytic Transfusion Reaction (FNHTR)

A febrile nonhemolytic transfusion reaction is defined by a temperature of 100.4°F or a 1°C

(1.8°F) increase in temperature with or without chills during or within 4 hours following completion of a transfusion (Dasararaju & Marques, 2015). An FNHTR is caused by antibodies to donor leukocytes that remain in the unit of blood or blood component; it is the most common type of transfusion reaction, accounting for more than 90% of reactions. It occurs more frequently in patients who have had previous transfusions (exposure to multiple antigens from previous blood products) and in Rh-negative women who have borne Rh-positive children (exposure to an Rh-positive fetus raises antibody levels in the mother). These reactions occur in 1% of PRBC transfusions and 20% of platelet transfusions. Rates have declined since the standardization of leukocyte reduction, which significantly decreases the number of leukocytes in a transfused product, thus decreasing the risk of an antibody-antigen reaction (Silvergleid, 2016a, 2016b). More than 10% of patients with chronic transfusion requirements develop this type of reaction.

The diagnosis of a febrile nonhemolytic reaction is made by excluding other potential causes, such as a hemolytic reaction, sepsis, or bacterial contamination of the blood product. The signs and symptoms of a febrile nonhemolytic transfusion reaction are chills (minimal to severe) followed by fever. The fever typically begins within 2 hours after the transfusion is begun. Although the reaction is not life-threatening, the fever, and particularly the chills and muscle stiffness, can be frightening to the patient.

BOX 20-8 Diseases Transmitted by Blood Transfusion

Hepatitis (Viral Hepatitis B, C)

- Greater risk from pooled blood products and blood of paid donors than from volunteer donors
- Screening test detects most hepatitis B and C
- Transmittal risk estimated at 1:1 million for hep B and 1: 1.93 million for hep C (Leparc, 2015)

HIV and HTLV

- Donated blood screened for antibodies to HIV
- Transmittal risk estimated at 1:2.135 million (Leparc, 2015)
- People with high-risk behaviors (multiple sex partners, anal sex, IV/injection drug use) and people with signs and symptoms that suggest AIDS should not donate blood

Cytomegalovirus (CMV)

- Transmittal risk greater for premature newborns with CMV antibody-negative mothers and for immunocompromised recipients who are CMV-negative (e.g., those with acute leukemia, organ or tissue transplant recipients)
- Blood products rendered "leukocyte-reduced" help reduce the transmission of virus

Graft-Versus-Host Disease (GVHD)

- Occurs only in severely immunocompromised recipients (e.g., leukemia, bone

marrow, and stem cell transplantation)

- Transfused lymphocytes engraft in the recipient and attack host lymphocytes or body tissues; signs and symptoms are fever, diffuse reddened skin rash, nausea, vomiting, diarrhea
- Preventive measures include irradiating blood products to inactivate donor lymphocytes (no known radiation risks to transfusion recipient) and processing donor blood with leukocyte-reduction filters

Creutzfeldt–Jakob Disease (CJD)

- Rare, fatal disease causing irreversible brain damage
- No evidence of transmittal by transfusion, but hemophiliacs and others are concerned that transmittal is possible
- All blood donors must be screened for positive family history of CJD. Those with a blood relative with CJD are not eligible to donate blood.
- Potential donors who spent 6 months or more in the United Kingdom (or Europe) from 1980 to 1996 cannot donate blood; blood products from a donor who develops CJD are recalled.

For more detailed guidelines regarding travel, CJD, and blood donations, please visit the American Red Cross website: http://www.redcrossblood.org/donating-blood/eligibility-requirements

This reaction can be diminished, even prevented, by further depleting the blood component of donor leukocyte through filtration. Antipyretics can be given to prevent fever, but routine premedication is not advised because it can mask the beginning of a more serious transfusion reaction. For recurrent FNHTRs despite leukoreduction, washed PRBCs may be indicated (Dasararaju & Marques, 2015).

TABLE 20-7 Common Complications Resulting from Long-Term Packed Red Blood Cell (PRBC) Transfusion Therapy[a]

	Manifestation	Management
Infection	Hepatitis (B, C) Cytomegalovirus (CMV)	May immunize against hepatitis B; give alpha-interferon for hepatitis C; monitor liver function Use WBC filters to protect against CMV
Iron overload	Heart failure Endocrine failure (diabetes, hypothyroidism, hypoparathyroidism, hypogonadism)	Prevent or treat using iron chelation therapy
Transfusion reaction	Sensitization Febrile reactions	Diminish by RBC phenotyping, using WBC-filtered, leukocyte-reduced, or irradiated products

PRBC, packed RBCs; WBC, white blood cell; RBC, red blood cell.
[a]Patients with long-term transfusion therapy requirements are at risk not only for the transfusion reactions discussed in the text but also for the complications noted above. In many cases, the use of WBC-filtered (e.g., leukocyte-poor) blood products is standard for patients who receive long-term PRBC transfusion therapy. Blood product irradiation, which more effectively reduces the leukocytes in the product, is reserved for patients at highest risk for infection, alloimmunization, and GVHD. Iron chelation may be used in select populations to reduce iron burden.

Acute Hemolytic Reaction

The most dangerous, and potentially life-threatening, type of transfusion reaction occurs

when the donor blood is incompatible with that of the recipient. Antibodies already present in the recipient's plasma rapidly combine with antigens on donor erythrocytes, and the erythrocytes are hemolyzed (destroyed) in the circulation (intravascular hemolysis). The most rapid hemolysis occurs in ABO incompatibility. This reaction can occur after transfusion of as little as 10 mL of PRBCs. Rh incompatibility often causes a less severe reaction. The most common causes of acute hemolytic reaction are errors in blood component labeling and patient misidentification that result in the administration of an ABO-incompatible transfusion (Dasararaju & Marques, 2015).

Symptoms consist of fever, chills, nausea, vomiting, chest tightness, dyspnea, hypotension, flank pain, hematuria, oliguria, bleeding, and anxiety (Dasararaju & Marques, 2015). As the erythrocytes are destroyed, the hemoglobin is released from the cells and excreted by the kidneys; therefore, hemoglobin appears in the urine (hemoglobinuria). Hypotension, bronchospasm, and vascular collapse may result. Diminished renal perfusion results in acute kidney failure, and DIC also may occur.

The reaction must be recognized promptly and the transfusion discontinued immediately. Blood and urine specimens must be obtained and analyzed for evidence of hemolysis, including DAT testing, haptoglobin, LDH, bilirubin, creatinine, PT/PTT, and fibrinogen. Treatment goals include maintaining blood volume and renal perfusion and preventing and managing DIC if needed. Acute hemolytic transfusion reactions are preventable. Meticulous attention to detail in labeling blood samples and blood components and accurately identifying the recipient cannot be overemphasized.

Delayed Hemolytic Reaction

Delayed hemolytic reactions usually occur within 14 days after transfusion, when the level of antibody has been increased to the extent that a reaction can occur. The hemolysis of the erythrocytes is extravascular via the RES and occurs gradually.

Signs and symptoms of a delayed hemolytic reaction are fever, anemia, increased bilirubin level, decreased or absent haptoglobin, and possibly jaundice. Rarely is there hemoglobinuria. In general, these reactions are not dangerous, but it is useful to recognize them because subsequent transfusions with blood products containing these antibodies may cause a more severe hemolytic reaction. However, recognition is also difficult because the patient may not be in a health care setting to be tested for this reaction, and even if the patient is hospitalized, the reaction may be too mild to be recognized clinically. Because the amount of antibody present can be too low to detect, it is difficult to prevent delayed hemolytic reactions. Fortunately, the reaction is usually mild and requires no intervention.

Allergic Reaction

Allergic reactions occur in 1% to 3% of transfusions. An allergic reaction is marked by the development of urticaria (hives) or generalized itching, rash, or wheezing during a transfusion (Dasararaju & Marques, 2015). The cause of these reactions is thought to be a sensitivity reaction to a plasma protein within the blood component being transfused. The reactions are usually mild and respond to antihistamines. If the symptoms resolve after administration of an antihistamine (e.g., diphenhydramine [Benadryl]), the transfusion may be resumed. Rarely, the allergic reaction is severe, with bronchospasm, laryngeal edema, and shock. These reactions are managed with epinephrine, corticosteroids, and

pressor support, if necessary.

Giving the patient antihistamines before the transfusion may prevent future reactions. For severe reactions, future blood components are washed to remove any remaining plasma proteins. Leukocyte filters are not useful to prevent such reactions because the offending plasma proteins can pass through the filter.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI) is defined as new-onset lung injury within 6 hours of transfusion with an oxygen saturation of at least 90% on room air and bilateral infiltrates on chest x-ray (Dasararaju & Marques, 2015). TRALI is caused by antibodies to human leukocyte antigens (HLAs) in the transfused blood product. Signs of TRALI include an onset of symptoms within 6 hours of transfusion; symptoms include dyspnea, cyanosis, hypotension, fever, chills, hypoxia, and/or pulmonary artery pressure below 18 mm Hg (and/or no evidence of circulatory overload/left atrial hypertension) (Dasararaju & Marques, 2015). TRALI is often a diagnosis of exclusion because symptoms overlap with other transfusion reaction types (e.g., transfusion-associated circulatory overload [TACO] and FNHTR). Workup should include exclusion of hemolysis, CBC (neutropenia may be seen with TRALI), and chest x-ray, which may reveal bilateral infiltrates. Treatment consists of respiratory support and pressors. Treatment with steroids has not been shown to provide benefits to the patient. Mortality rates are as high as 25%, but with aggressive support, 80% of patients recover within 96 hours (Dasararaju & Marques, 2015).

Transfusion-Associated Circulatory Overload

TACO is the second leading cause of transfusion-related death in the United States (Dasararaju & Marques, 2015). If too much blood is infused too quickly, hypervolemia can occur. Risk factors include older age, the number of units infused, history of CHF, COPD, anemia, or transfusion of plasma products (Dasararaju & Marques, 2015). PRBCs are safer to use than whole blood. If the administration rate is sufficiently slow, circulatory overload may be prevented. Patients receiving fresh-frozen plasma or even platelets may also develop circulatory overload. The infusion rate of these blood components must also be titrated to the patient's tolerance, and concurrent fluid administration should be avoided. Patients at risk must be monitored carefully. For patients who are at risk of, or already in, circulatory overload, diuretics are administered after the transfusion or between units of products (Dasararaju & Marques, 2015).

Nursing Alert
When administering blood products in patients at risk for TACO, the nurse considers all infusing IV solutions and informs the provider so that IV rates can be altered to lower rates while blood is infusing.

Signs of circulatory overload include dyspnea, orthopnea, tachycardia, and sudden anxiety. Jugular vein distention, crackles at the base of the lungs, and an increase in blood pressure can also occur. If the transfusion is continued, pulmonary edema can develop, as manifested by severe dyspnea and coughing up of pink, frothy sputum. These signs and symptoms usually present within 2 hours of initiation of transfusion but may take as long

as 6 hours to manifest (Dasararaju & Marques, 2015).

If fluid overload is mild, often the transfusion can be continued after slowing the rate of infusion and administering diuretics. However, if the overload is severe, the patient is placed in an upright position with the feet in a dependent position, the transfusion is discontinued, and the provider is notified. The IV line is kept patent with a very slow infusion of normal saline solution or a saline or heparin lock device to maintain access to the vein in case IV medications are necessary. Oxygen and morphine may be needed to treat severe dyspnea.

Bacterial Contamination

The incidence of bacterial contamination of blood components is very low; however, administration of contaminated products puts the patient at great risk. Gram-negative bacteria, including *Pseudomonas*, *Yersinia*, and *Enterobacter*, are the most common organism found in contaminated RBC products, but *Serratia* can be present also (Spelman & MacLaren, 2016). Contamination can occur at any point during procurement or processing but is usually due to organisms on the donor's skin (Spelman & MacLaren, 2016). Many bacteria cannot survive in the cold temperatures used to store PRBCs, although some organisms can survive cold temperatures. Parasites that infect RBCs, such as *Babesia* or other species of malaria, are more likely to cause infection from RBCs (Dasararaju & Marques, 2015). Platelets are at greater risk of contamination because they are stored at room temperature. Since 2004, blood centers have developed rapid methods of culturing the platelet unit to decrease the risk of using a contaminated platelet unit for transfusion. Despite bacterial testing, this complication has not been eradicated, thus mandating that nurses remain vigilant for this complication.

Preventive measures include meticulous care in the procurement and processing of blood components. When PRBCs or whole blood is transfused, it should be administered within a 4-hour period because warm room temperatures promote bacterial growth. A contaminated unit of blood product may appear normal, or it may have an abnormal color.

The signs of bacterial contamination are fever, chills, and hypotension, which most commonly occur during the transfusion. Occasionally, the signs of a reaction may occur hours after the transfusion is complete. If the condition is not recognized and treated immediately with fluids and broad-spectrum antibiotics, shock can occur. While these reactions are rare, they can be fatal (Spelman & MacLaren, 2016). The median interval between completion of transfusion and appearance of symptoms is 30 minutes (range 0 to 5 hours) (Spelman & MacLaren, 2016). Patient education must include prompt reporting of any signs of transfusion reaction at home and need for emergent evaluation.

The following steps are taken to determine the type and severity of the reaction:

- Stop the transfusion. Maintain the IV line with normal saline solution through new IV tubing, administered at a slow rate.
- Assess the patient carefully. Compare the vital signs with baseline. Assess the patient's respiratory status carefully. Note the presence of adventitious breath sounds, use of accessory muscles, extent of dyspnea, changes in mental status including anxiety and confusion, and changes in oxygen saturation. Note any chills, diaphoresis, jugular vein distention, and reports of back pain or urticaria.

- Notify the health care provider of the assessment findings, and implement any treatments prescribed. Continue to monitor the patient's vital signs and respiratory, cardiovascular, and renal status.
- Notify the blood bank that a suspected transfusion reaction has occurred.
- Send the blood container and tubing to the blood bank for repeat typing and culture. The identifying tags and numbers are verified.

If a hemolytic transfusion reaction or bacterial infection is suspected, the nurse does the following:

- Obtain appropriate blood specimens from the patient (this usually includes blood cultures, a CBC and a type and screen, LDH, DAT, haptoglobin).
- Collect a urine sample as soon as possible for a hemoglobin determination.
- Document the reaction according to the institution's policy.

CHAPTER REVIEW

Critical Thinking Exercises

1. You are working in a hematology-oncology clinic. The laboratory reports a critical laboratory result for one of your patients with possible acute leukemia: the leukocyte count is 1,200/mm^3 with 10% neutrophils. What other laboratory results would be important to review or consider? The patient is also anemic (hemoglobin 8.2 mg/dL), and platelets are 30,000/mm^3. What observations will you include in your assessment of this patient? Determine the extent to which this patient is neutropenic. What medical treatments would you anticipate? How would you educate the patient about neutropenia and bleeding precautions? What information do you need to obtain about the patient's home setting that will assist you in determining the patient's risk of developing an infection at home?

2. You are caring for a man with a chronic transfusion requirement (typically two to three units of PRBCs each month). He asks you how he should modify his diet so that "I don't need so much blood." How would you respond? What role do iron supplements play in patients with chronic transfusion needs? How would you assess this patient for iron overload?

3. You are caring for a patient who is septic and is now receiving a transfusion of two units of PRBCs. The patient's temperature spikes to 101.3°F (38.5°C) after half of the second unit has been transfused. What are the possible causes of the fever? What are the appropriate nursing interventions?

4. You are caring for a patient with acute leukemia and sepsis who has a declining platelet count of 10,000/mm^3. On assessment, you observe oozing blood from the Hickman catheter site, petechiae to the upper and lower extremities, and epistaxis. What are the potential causes of this patient's bleeding? What other laboratory results would you

assess? What further assessments would you perform? What nursing interventions would you implement? What medical interventions would you anticipate?

NCLEX-Style Review Questions

1. A patient's 18-year-old son would like to donate blood. The nurse educates him regarding eligibility requirements for blood donation. Which statement demonstrates that he does not understand the education provided?
   a. "I am so glad that I am old enough to donate."
   b. "Because I just got a tattoo a week ago, I am unable to donate."
   c. "Because I live with a friend with HIV, I cannot donate."
   d. "Because my girlfriend has hepatitis, and we are sexually active, I cannot donate."

2. The nurse is explaining the potential signs and symptoms of a transfusion reaction to a patient who is receiving a first blood transfusion for the first time. How will the nurse ensure safe blood product administration? *Select all that apply*.
   a. Check ABO compatibility by comparing the blood product label to the patient's medical record.
   b. Use two patient identifiers, such as the patient's date of birth and name, to verify the blood product.
   c. Administer the blood product slowly for the first 15 minutes.
   d. Administer acetaminophen and diphenhydramine, which are standard premedications used in all transfused patients.
   e. Obtain baseline vital signs before the transfusion is administered.

3. A patient is being treated for sepsis. On the second day of receiving care, the patient experiences epistaxis and persistent bleeding from a venipuncture site. The nurse suspects DIC. Which laboratory result supports the nurse's suspicion?
   a. Increased fibrinogen, decreased PTT, decreased platelets
   b. Decreased fibrinogen, increased PTT, increased platelets
   c. Decreased fibrinogen, increased PTT, decreased platelets
   d. Increased fibrinogen, increased PTT, increased platelets

4. The nurse provides patient education related to the management of iron deficiency anemia. Which statement made by the patient signifies understanding of the education provided?
   a. "I should take my iron pills with a glass of orange juice."
   b. "I should take my iron pills with breakfast to decrease stomach upset."
   c. "Iron pills often cause constipation so I should decrease my fluid and fiber intake."
   d. "I will need to take these pills for only a few days, and then my problem will be fixed."

5. The nurse is caring for a patient diagnosed with ALL who is receiving initial treatment. The patient has been complaining of a dry cough. The patient also has diminished

breath sounds upon auscultation. What should the nurse monitor as priority with regard to potential complications in this patient?

a. Hemoglobin
b. Absolute neutrophil count (ANC)
c. Hematocrit
d. Urine

Problems Related to Digestive, Gastrointestinal, and Metabolic Function

A 55-year-old patient is undergoing bariatric surgery to treat morbid obesity. She is 120 lb over her ideal body weight. The patient also has comorbidities of diabetes and hypertension.

- Discuss patient selection for bariatric surgery.
- What lifestyles changes might the patient expect?
- What complications should the patient be aware of regarding the surgical procedure?

CHAPTER 21

Nursing Assessment: Digestive, Gastrointestinal, and Metabolic Function

Deborah Bains Fahs

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the anatomy and physiology of the gastrointestinal (GI) tract.
2. Identify the metabolic functions of the liver.
3. Discuss important physical assessment findings of the GI tract.
4. Identify the assessment parameters used to determine the status of the upper and lower GI tract.

The gastrointestinal (GI) system performs the functions of ingestion, digestion, and elimination. Its major organs include the esophagus, stomach, small intestines, large intestines, pancreas, gallbladder, spleen, and liver (a most complex organ) (Drake, 2015). An understanding of the structure and function of the biliary tract and pancreas is essential to providing clinical care. Interruption of any of these functions can quickly affect the patient nutritionally and cause myriad fluid, electrolyte, and acid–base imbalances. When performing the GI assessment, the nurse must remember that the majority of people have pre-existing problems and that these problems can be exacerbated or new conditions can develop when illness in other systems occurs.

ANATOMIC AND PHYSIOLOGIC OVERVIEW OF THE DIGESTIVE SYSTEM

Anatomy of the Gastrointestinal Tract

The GI tract is a 23- to 26-foot-long (7 to 7.9 m) pathway that extends from the mouth to the esophagus, stomach, small and large intestines, and rectum, to the terminal structure, the anus (Fig. 21-1). The esophagus is located in the mediastinum, anterior to the spine and posterior to the trachea and heart. This hollow muscular tube, which is approximately 10 in (25 cm) long, passes through the diaphragm at an opening called the *diaphragmatic hiatus* (Reinus & Simon, 2014).

The remaining portion of the GI tract is located within the peritoneal cavity. The stomach is situated in the left upper portion of the abdomen under the left lobe of the liver and the diaphragm, overlaying most of the pancreas (see Fig. 21-1). A hollow muscular organ with a capacity of approximately 1,500 mL, the stomach stores food during eating, secretes digestive fluids, and propels the partially digested food into the small intestine. The gastroesophageal junction is the inlet to the stomach. The stomach has four anatomic regions: the cardia (entrance), fundus, body, and pylorus (outlet). Circular smooth muscle in the wall of the pylorus forms the pyloric sphincter and controls the opening between the stomach and the small intestine, allowing for both stomach emptying and prevention of regurgitation of intestinal contents back into the stomach (Porth, 2015).

The small intestine is the longest segment of the GI tract, accounting for about two thirds of the total length. It folds back and forth on itself, providing approximately 7,000 cm of surface area for secretion and absorption, the process by which nutrients enter the bloodstream through the intestinal walls. It has three sections: the most proximal section is the duodenum, where the common bile duct and pancreatic duct enter at the ampulla of Vater, allowing for the passage of both bile and pancreatic secretions. The middle section of the small intestine is the jejunum, and the distal section is the ileum. They terminate at the ileocecal valve. This valve, or sphincter, controls the flow of digested material from the ileum into the cecal portion of the large intestine, preventing reflux of bacteria into the small intestine. Attached to the cecum is the vermiform appendix, an appendage that has little or no physiologic function.

The large intestine consists of an ascending segment on the right side of the abdomen, a transverse segment that extends from right to left in the upper abdomen, and a descending segment on the left side of the abdomen. Completing the terminal portion of the large intestine are the sigmoid colon, the rectum, and the anus. Regulating the anal outlet is a network of striated muscle, which forms both the internal and the external anal sphincters.

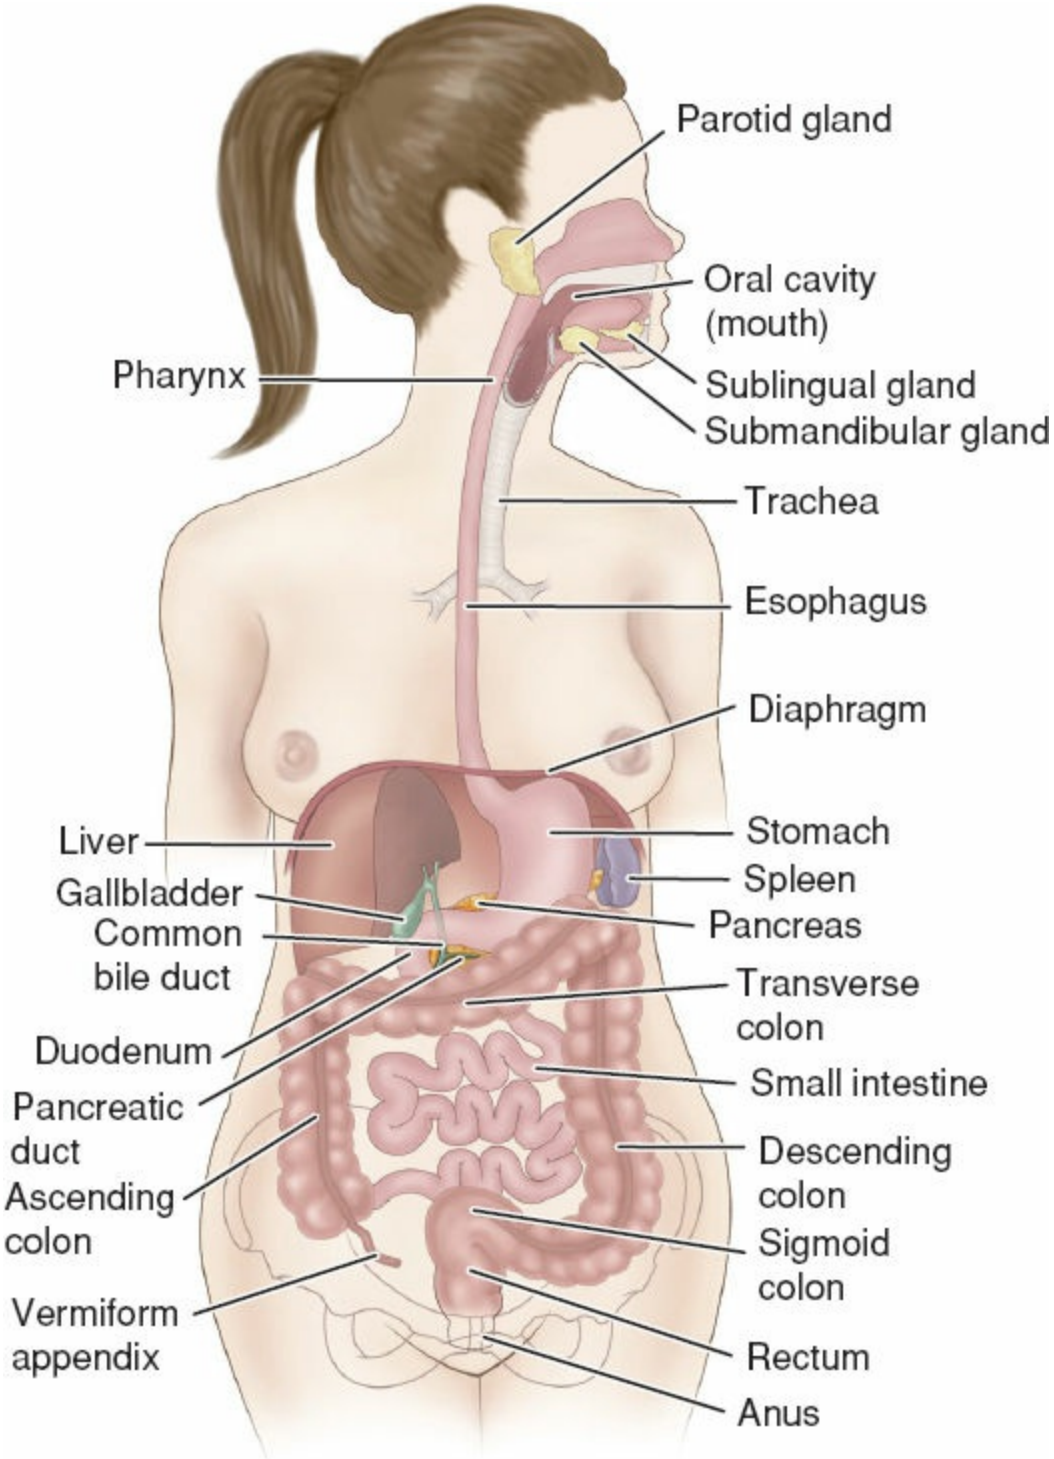

FIGURE 21-1 Organs of the digestive system and associated structures.

Nursing Alert
Since the sigmoid colon lies on the left side of the lower abdomen, the nurse understands that the best position for administration of an enema is left lateral position.

The GI tract receives blood from arteries that originate along the entire length of the thoracic and abdominal aorta and veins that return blood from the digestive organs and the

spleen. This portal venous system is composed of five large veins: the superior mesenteric, inferior mesenteric, gastric, splenic, and cystic veins, which eventually form the vena portae that enters the liver. Once in the liver, the blood is distributed throughout and collected into the hepatic veins that then terminate in the inferior vena cava. Of particular importance are the gastric artery and the superior and inferior mesenteric arteries. Oxygen and nutrients are supplied to the stomach by the gastric artery and to the intestine by the mesenteric arteries (Fig. 21-2). Venous blood is returned from the small intestine, cecum, and the ascending and transverse portions of the colon by the superior mesenteric vein, which corresponds with the distribution of the branches of the superior mesenteric artery. Blood flow to the GI tract is approximately 20% of the total cardiac output and increases significantly after eating.

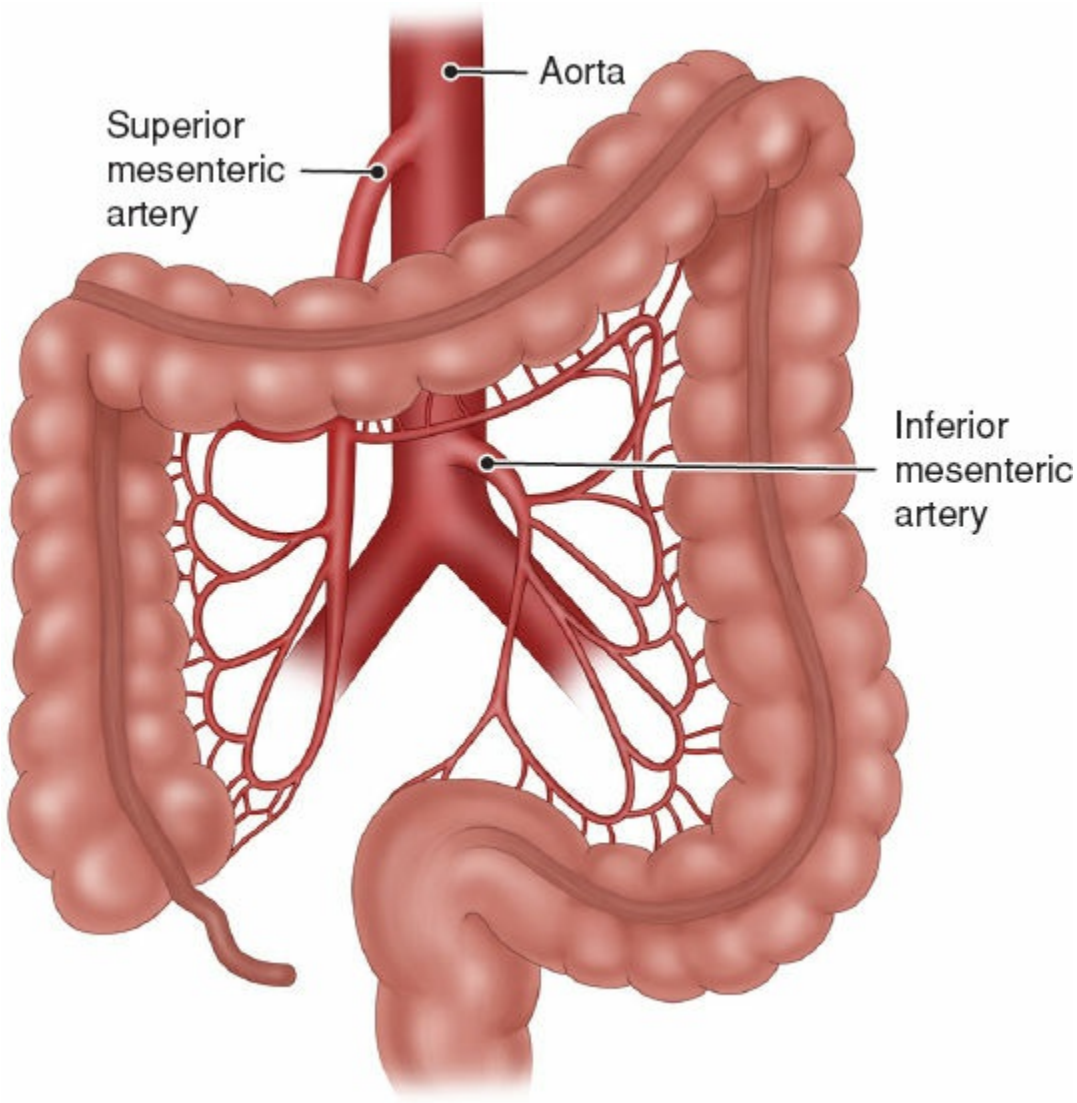

FIGURE 21-2 Anatomy and blood supply of the large intestine.

The internal abdominal cavity is lined with peritoneum, which is the largest serous membrane in the body and which has a surface area similar to that of skin. The peritoneum is a single sheet that has visceral and parietal components. The visceral peritoneum covers the abdominal organs, and the parietal peritoneum lines the walls of the abdominal pelvic

cavity. Between these two layers is a potential space containing fluid secreted by the serous membranes (Grossman & Porth, 2014). This space is sometimes accessed for diagnostic procedures, such as peritoneal tap to assess for internal injuries or catheter insertion for peritoneal dialysis. Organs that lie within the peritoneal cavity are called intraperitoneal organs, and include the liver, spleen, and appendix, among others. Structures that lie behind the parietal peritoneum are said to be *retroperitoneal*. A useful mnemonic for retroperitoneal organs is SAD PUCKER which stands for the suprarenal (adrenal) gland, aorta, duodenum, pancreas (except tail), ureters, colon (ascending and descending), kidneys, esophagus, and rectum.

A *mesentery* is a double layer of peritoneum that encircles internal organs such as the intestines and contains blood vessels, nerves, and lymphatic vessels. An *omentum* is a fold of mesentery that passes from the stomach to the organs in the abdominal cavity. It is a sheet that has mobility, cushions the abdominal organs against injury, and provides insulation against loss of body heat.

Both the sympathetic and parasympathetic portions of the autonomic nervous system innervate the GI tract. In general, sympathetic nerves exert an inhibitory effect on the GI tract, decreasing gastric secretion and motility and causing the sphincters and blood vessels to constrict. Parasympathetic nerve stimulation causes peristalsis and increases secretory activities. The sphincters relax under the influence of parasympathetic stimulation except for the sphincter of the upper esophagus and the external anal sphincter, which are under voluntary control.

Nursing Alert

The nurse is aware that the vagus nerve (cranial nerve [CN] X) surrounds the anus and can be stimulated with rectal temperatures or bearing down forcefully, which causes a parasympathetic response of decreased heart rate and blood pressure. Thus, contraindications to rectal temperatures include cardiac conditions, such as myocardial infarction (MI), because of the risk of bradycardia and arrhythmias. In addition, recent rectal, anal, vaginal, and prostate surgeries would prohibit rectal temperatures because of proximity to the surgical site.

Function of the Digestive System

All cells of the body require nutrients. These nutrients are derived from the diet and need the GI system for digestion, absorption via blood or lymphatic channels, and elimination. Primary functions of the GI tract are the following:

- The breakdown of food particles into the molecular form for digestion
- The absorption into the bloodstream of small nutrient molecules produced by digestion
- The elimination of undigested unabsorbed foodstuffs and other waste products

After food is ingested, it is propelled through the GI tract, coming into contact with a wide variety of secretions that aid in its digestion, absorption, or elimination.

Chewing and Swallowing

The process of digestion begins with the act of chewing, in which food is broken down into small particles that can be swallowed and mixed with digestive enzymes. Eating—or even the sight, smell, or taste of food—can cause reflex salivation. Approximately 1.5 L of saliva is secreted daily from the parotid, submaxillary, and sublingual glands. Ptyalin, or salivary amylase, is an enzyme that begins the digestion of starches. Water and mucus, also contained in saliva, help lubricate the food as it is chewed, thereby facilitating swallowing.

Swallowing begins as a voluntary act that is regulated by the swallowing center in the medulla oblongata of the central nervous system (CNS). The act of swallowing requires the innervations of five CNs, specifically CN V (trigeminal nerve), VII (facial), IX (glossopharyngeal), X (vagus), and XII (hypoglossal). Diseases that disrupt the brain centers or CNs predispose the patient to aspiration. As a bolus of food is swallowed, the epiglottis moves to cover the tracheal opening and prevent aspiration of food into the lungs. Swallowing, which propels the bolus of food into the upper esophagus, thus ends as a reflex action. The smooth muscle in the wall of the esophagus contracts in a rhythmic sequence from the upper esophagus toward the stomach to propel the bolus of food along the tract. During this process of esophageal peristalsis, the lower esophageal sphincter relaxes and permits the bolus of food to enter the stomach. Subsequently, the lower esophageal sphincter closes tightly, preventing reflux of stomach contents into the esophagus.

Gastric Function

The stomach, which stores and mixes food with secretions, secretes a highly acidic fluid in response to the presence or anticipated ingestion of food. This fluid, which can total 2.4 L/day, can have a pH as low as 1 and derives its acidity from hydrochloric acid (HCl) secreted by the glands of the stomach. The function of this gastric secretion is twofold: to break down food into more absorbable components and to aid in the destruction of most ingested bacteria. Pepsin, an important enzyme for protein digestion, is the end product of the conversion of pepsinogen from the chief cells (Table 21-1). Intrinsic factor, also secreted by the gastric mucosa, combines with dietary vitamin B_{12} so that the vitamin can

be absorbed in the ileum. In the absence of intrinsic factor, vitamin B_{12} cannot be absorbed and pernicious anemia results.

Nursing Alert
The nurse is aware that critically ill patients may develop bleeding caused by stress ulceration. Thus it is common prophylactic practice to prescribe medications to suppress acid production of the stomach for patients at risk of stress ulcer bleeding (see Chapter 53 for Curling ulcer).

Peristaltic contractions in the stomach propel the stomach's contents toward the pylorus. Because large food particles cannot pass through the pyloric sphincter, they are churned back into the body of the stomach. In this way, food in the stomach is agitated mechanically and broken down into smaller particles. Food remains in the stomach for a variable length of time, from 30 minutes to several hours, depending on the volume, osmotic pressure, and chemical composition of the gastric contents. Peristalsis in the stomach and contractions of the pyloric sphincter allow the partially digested food to enter the small intestine at a rate that permits efficient absorption of nutrients. This partially digested food mixed with gastric secretions is called chyme. Hormones, neuroregulators, and local regulators found in the gastric secretions control the rate of gastric secretions and influence gastric motility (Table 21-2).

TABLE 21-1 The Major Digestive Enzymes and Secretions

Enzyme/Secretion	Enzyme Source	Digestive Action
Action of Enzymes That Digest Carbohydrates		
Ptyalin (salivary amylase)	Salivary glands	Starch → dextrin, maltose, glucose
Amylase	Pancreas and intestinal mucosa	Starch → dextrin, maltose, glucose Dextrin → maltose, glucose
Maltase	Intestinal mucosa	Maltose → glucose
Sucrase	Intestinal mucosa	Sucrose → glucose, fructose
Lactase	Intestinal mucosa	Lactose → glucose, galactose
Action of Enzymes/Secretions That Digest Protein		
Pepsin	Gastric mucosa	Protein → polypeptides
Trypsin	Pancreas	Proteins and polypeptides → polypeptides, dipeptides, amino acids
Aminopeptidase	Intestinal mucosa	Polypeptides → dipeptides, amino acids
Dipeptidase	Intestinal mucosa	Dipeptides → amino acids
Hydrochloric acid	Gastric mucosa	Protein → polypeptides, amino acids
Action of Enzymes Secretions That Digest Fat (Triglyceride)		
Pharyngeal lipase	Pharynx mucosa	Triglycerides → fatty acids, diglycerides, monoglycerides
Steapsin	Gastric mucosa	Triglycerides → fatty acids, diglycerides, monoglycerides
Pancreatic lipase	Pancreas	Triglycerides → fatty acids, diglycerides, monoglycerides
Bile	Liver and gallbladder	Fat emulsification

Small Intestine Function

The digestive process continues in the duodenum. Duodenal secretions come from the accessory digestive organs—the pancreas, liver, and gallbladder—and the glands in the wall of the intestine itself. These secretions contain digestive enzymes: amylase, lipase, and bile. Pancreatic secretions have an alkaline pH due to their high concentration of bicarbonate. This alkalinity neutralizes the acid entering the duodenum from the stomach. Digestive enzymes secreted by the pancreas include trypsin, which aids in digesting protein; amylase, which aids in digesting starch; and lipase, which aids in digesting fats. These secretions drain into the pancreatic duct, which empties into the duodenum along with the common bile duct at a short dilated tube called the *hepatopancreatic ampulla*, or ampulla of Vater. Bile, secreted by the liver and stored in the gallbladder, aids in emulsifying ingested fats, making them easier to digest and absorb. The sphincter of Oddi (muscle tissue at the confluence of the common bile duct and the duodenum) controls the flow of bile. When this sphincter is closed, bile will move back into the common bile duct and gallbladder. Hormones, neuroregulators, and local regulators found in these intestinal secretions control the rate of intestinal secretions and also influence GI motility. Intestinal secretions total approximately 1 L/day of pancreatic juice, 0.5 L/day of bile, and 3 L/day of secretions from the glands of the small intestine. Tables 21-1 and 21-2 give further information about the actions of digestive enzymes and GI regulatory substances.

Two types of contractions occur regularly in the small intestine: segmentation contractions and intestinal peristalsis. *Segmentation contractions* produce mixing waves that move the intestinal contents back and forth in a churning motion. *Intestinal peristalsis* propels the contents of the small intestine toward the colon. Both movements are stimulated by the presence of chyme.

Food, initially ingested in the form of fats, proteins, and carbohydrates, is broken down into absorbable particles (constituent nutrients) by the process of digestion. Carbohydrates are broken down into disaccharides (e.g., sucrose, maltose, and galactose) and monosaccharides (e.g., glucose, fructose). Glucose is the major carbohydrate that tissue cells use as fuel. Proteins are a source of energy after they are broken down into amino acids and peptides. Ingested fats become monoglycerides and fatty acid by the process of emulsification, which makes them smaller and, therefore, easier to absorb. Chyme stays in the small intestine for 3 to 6 hours, allowing for continued breakdown and absorption of nutrients.

TABLE 21-2 The Major Gastrointestinal Regulatory Substances

Substance	Stimulus for Production	Target Tissue	Effect on Secretions	Effect on Motility
Neuroregulators				
Acetylcholine	Sight, smell, chewing food, stomach distention	Gastric glands, other secretory glands, gastric and intestinal muscle	Increased gastric acid	Generally increased; decreased sphincter tone
Norepinephrine	Stress, other various stimuli	Secretory glands, gastric and intestinal muscle	Generally inhibitory	Generally decreased; increased sphincter tone
Hormonal Regulators				
Gastrin	Stomach distention with food	Gastric glands	Increased secretion of gastric juice, which is rich in HCl	Increased motility of stomach, decreased time required for gastric emptying Relaxation of ileocecal sphincter Excitation of colon Constriction of gastroesophageal sphincter
Cholecystokinin	Fat in duodenum	Gallbladder Pancreas Stomach	Release of bile into duodenum Increased production of enzyme-rich pancreatic secretions Inhibits gastric secretion somewhat	Delays gastric emptying
Secretin	pH of chyme in duodenum below 4–5	Stomach Pancreas	Inhibits gastric secretion somewhat Increased production of bicarbonate-rich pancreatic juice	Inhibits stomach contractions
Local Regulator				
Histamine	Unclear; substances in food	Gastric glands	Increased gastric acid production	Increased bowel peristalsis

Small, finger-like projections called villi are present throughout the entire intestine and function to produce digestive enzymes as well as to absorb nutrients. Absorption is the primary function of the small intestine. Vitamins and minerals are not digested but rather absorbed essentially unchanged. The process of absorption begins in the jejunum and is accomplished by both active transport and diffusion across the intestinal wall into circulation. Nutrients are absorbed at specific locations throughout the small intestine and duodenum, whereas fats, proteins, carbohydrates, sodium, and chloride are absorbed in the jejunum. Vitamin B_{12} and bile salts are absorbed in the ileum. Magnesium, phosphate, and potassium are absorbed throughout the small intestine.

Colon Function

Within 4 hours after eating, residual waste material passes into the terminal ileum and slowly into the proximal portion of the right colon through the ileocecal valve. With each peristaltic wave of the small intestine, the valve opens briefly and permits some of the contents to pass into the colon.

It is estimated that there are 300 to 500 different species of intestinal bacteria in the large intestine (Grossman & Porth, 2014), which maintain intestinal homeostasis and are critical to human health (Friedman & Sitaraman, 2012). Bacteria have many favorable benefits, such as modulating the immune system, producing some vitamins as well as fatty

acids (Jensen-Jarolin, 2014). This intestinal flora also provides a critical resistance to potential invading pathogens. The nurse is aware that broad-spectrum antibiotics have the potential to disrupt this normal intestinal flora and place the patient at risk for overgrowth of pathogens, such as *Clostridium difficile*. Probiotics, such as lactobacilli, are live organisms considered healthy for the host organisms and often are administered to restore the microbial balance in the intestines.

Two types of colonic secretions are added to the residual material: an electrolyte solution and mucus. The electrolyte solution is chiefly a bicarbonate solution that acts to neutralize the end products formed by the colonic bacterial action, whereas the mucus protects the colonic mucosa from the interluminal contents.

Slow, weak peristaltic activity moves the colonic contents along the tract. This slow transport allows for efficient reabsorption of water and electrolytes, which is the primary purpose of the colon. The waste materials from a meal eventually reach and distend the rectum, usually in about 12 hours. As much as 25% of the waste materials from a meal may still be in the rectum 3 days after the meal was ingested.

Nursing Alert

Approximately 9 L of fluid are sent through the GI tract daily, and all but 100 mL are reabsorbed; thus the nurse is aware that any process or pathology that increases peristalsis will result in decreased fluid, nutrient, and electrolyte reabsorption, resulting in malnutrition, profound dehydration, and electrolyte depletion.

Waste Products of Digestion

Feces consist of undigested food, inorganic materials, water, and bacteria. Fecal matter is approximately 75% fluid and 25% solid material. The composition is relatively unaffected by alterations in diet because a large portion of the fecal mass is of nondietary origin, derived from the secretions of the GI tract. The brown color of the feces results from the breakdown of bile by the intestinal bacteria. Chemicals formed by intestinal bacteria are responsible in large part for the fecal odor. Gases formed contain methane, hydrogen sulfide, and ammonia, among others. The GI tract normally contains approximately 150 mL of these gases, which are either absorbed into the portal circulation and detoxified by the liver or expelled from the rectum as flatus.

Elimination of stool begins with distention of the rectum, which reflexively initiates contractions of the rectal musculature and relaxes the normally closed internal anal sphincter. The internal sphincter is controlled by the autonomic nervous system; the external sphincter is under the conscious control of the cerebral cortex. During defecation, the external anal sphincter voluntarily relaxes to allow colonic contents to be expelled. Normally, the external anal sphincter is maintained in a state of tonic contraction. Thus, defecation is seen to be a spinal reflex (involving the parasympathetic nerve fibers) that can be inhibited voluntarily by keeping the external anal sphincter closed. Contracting the abdominal muscles (straining) facilitates emptying of the colon. The average frequency of defecation in humans is once daily, but this varies among people.

ACCESSORY DIGESTIVE ORGANS

Liver

The liver, the largest gland of the body, can be considered a chemical factory that manufactures, stores, alters, and excretes a large number of substances involved in metabolism. The location of the liver is essential in this function because it receives nutrient-rich blood directly from the GI tract and then either stores or transforms these nutrients into chemicals that are used elsewhere in the body for metabolic needs. The liver is especially important in the synthesis of glucose, protein, and blood-clotting factors.

An important and unique characteristic of the liver is its ability to regenerate. The normal liver maintains a constant mass regulated by the metabolic needs and size of the person. After removal or injury of liver tissue, hepatocytes proliferate to replace the mass of the liver to its original size (Harvard Stem Cell Institute, 2014). This physiologic feature is important in the event of liver transplant (Cotler, Brown, & Travis, 2015). Thus, the liver displays an extraordinary ability to regenerate cells through matrix remodeling; however, chronic damage results in depletion of this cell pool and subsequent liver failure (Karkampouna, Goumans, Ten Dijke, Dooley, & Kruithof-de Julio, 2014).

The major functions of the liver include glucose metabolism, conversion of ammonia to urea, protein metabolism, fat metabolism, vitamin and iron storage, drug metabolism, bile formation, and bilirubin excretion.

Bile, which is manufactured by the liver and plays a major role in the digestion and absorption of fats in the GI tract, is stored temporarily in the gallbladder until it is needed for digestion, at which time the gallbladder empties and bile enters the intestine (Fig. 21-3). Waste products removed by the liver are secreted into bile. The smallest bile ducts, called *canaliculi*, are located between the lobules of the liver. The canaliculi receive secretions from the hepatocytes and carry them to larger bile ducts, which eventually form the hepatic duct. The hepatic duct from the liver and the cystic duct from the gallbladder join to form the common bile duct, which empties into the small intestine. The sphincter of Oddi, located at the junction where the common bile duct enters the duodenum, controls the flow of bile into the intestine.

The liver is located behind the ribs in the upper right portion of the abdominal cavity and, under normal conditions, cannot be palpated as it lies within the rib cage. It weighs approximately 1,800 g in men and 1,400 g in women and is divided into two large lobes and two smaller lobes. A thin layer of connective tissue surrounds each lobe, extending into the lobe itself and dividing the liver mass into small, functional units called *lobules* (Tortora & Derrickson, 2014).

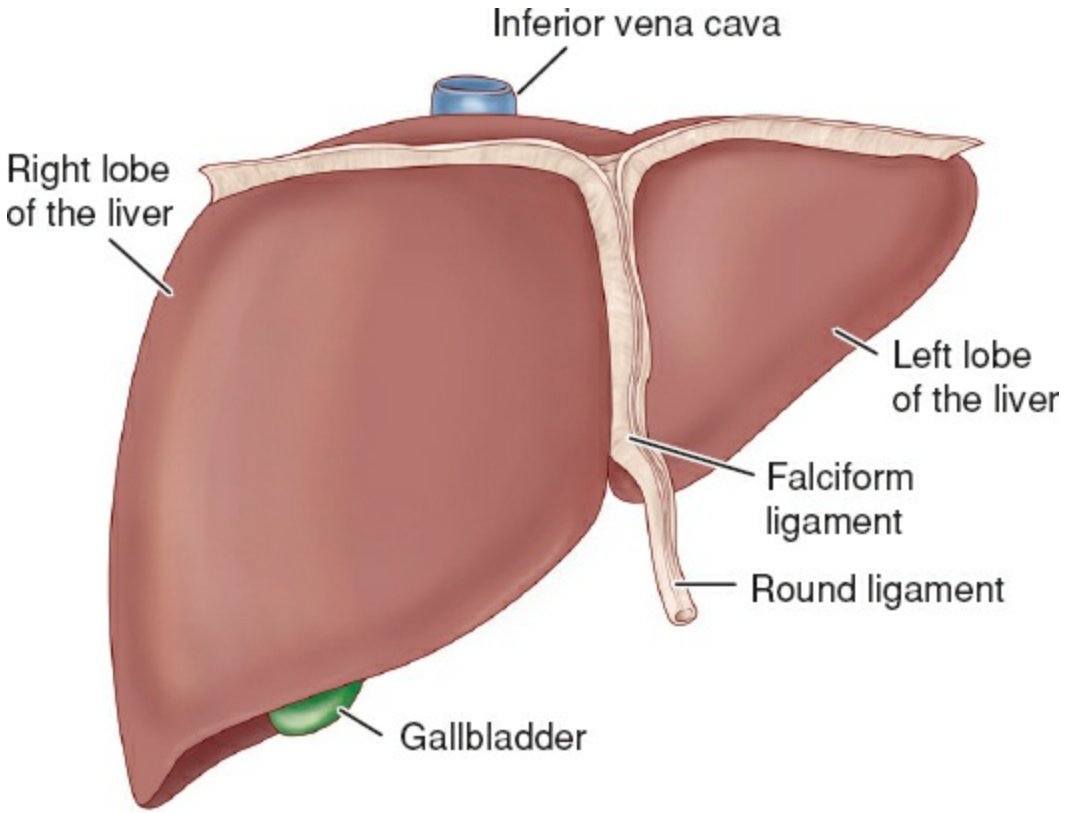

FIGURE 21-3 The liver and biliary system.

The circulation of the blood into and out of the liver is of major importance to liver function. The blood that perfuses the liver comes from two sources. Approximately 75% of the blood supply comes from the portal vein, which drains the GI tract and is rich in nutrients. The remainder of the blood supply enters by way of the hepatic artery and is rich in oxygen. Terminal branches of these two blood vessels join to form common capillary beds, which constitute the sinusoids of the liver (Fig. 21-4). Thus, a mixture of venous and arterial blood bathes the liver cells (hepatocytes). The sinusoids empty into venules that occupy the center of each liver lobule and are called the *central veins*. The central veins join to form the hepatic vein, which constitutes the venous drainage from the liver and empties into the inferior vena cava, close to the diaphragm. Thus, there are two sources of blood flowing into the liver and only one exit pathway. Because of the pressure differences between the hepatic and portal veins, the liver normally stores approximately 500 to 1,000 mL of blood (Grossman & Porth, 2014), which can be available in times of hypovolemia. However, in conditions such as right heart failure, in which blood flows back up in the vena cava, additional blood accumulates in the liver.

In addition to hepatocytes, phagocytic cells belonging to the reticuloendothelial system (RES) are present in the liver. Other organs that contain reticuloendothelial cells are the spleen, bone marrow, lymph nodes, and lungs. In the liver, these cells are called *Kupffer cells*. As the most common phagocyte in the human body, their main function is to engulf particulate matter (e.g., bacteria) that enters the liver through the portal blood.

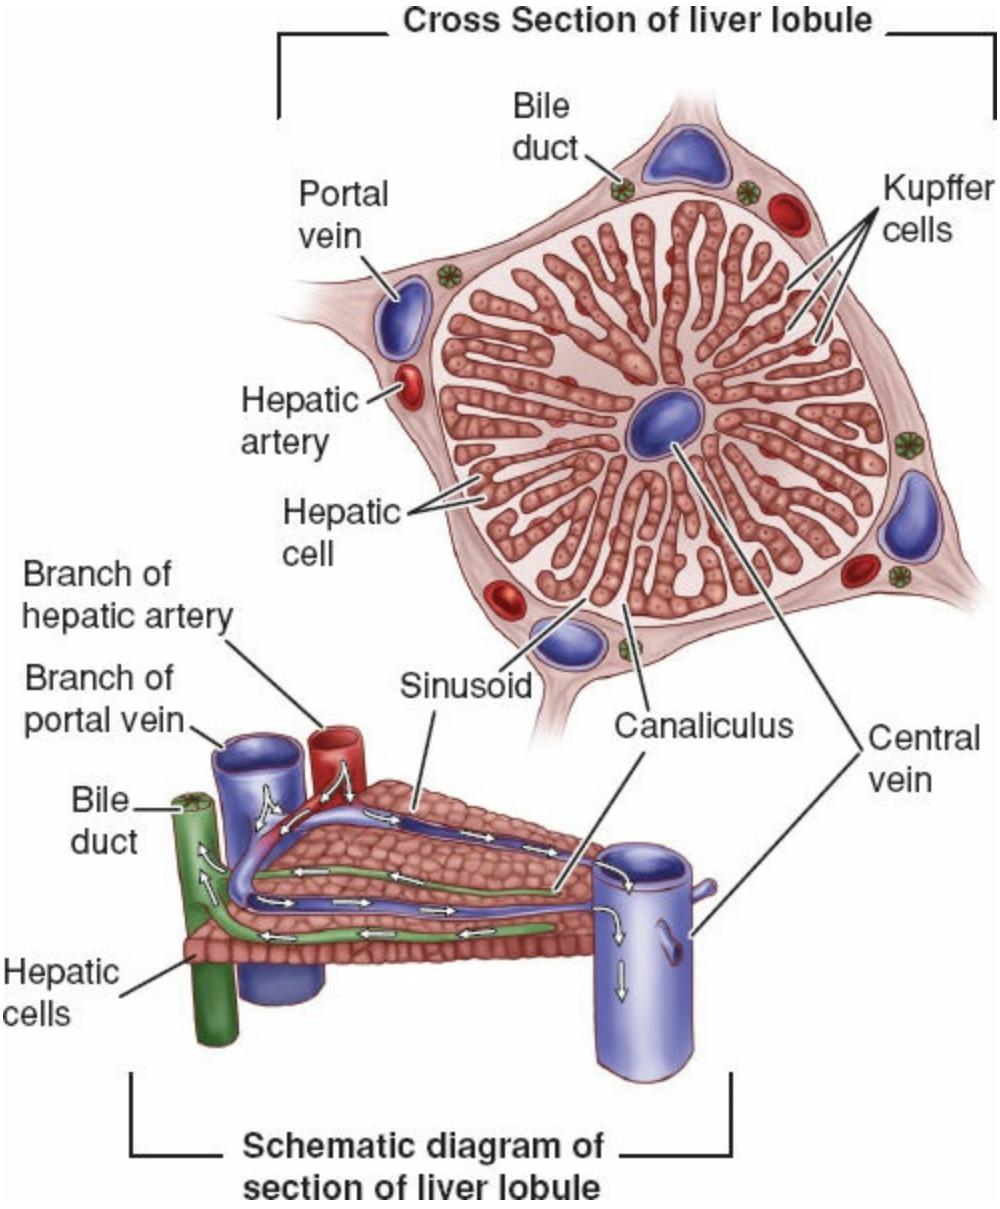

FIGURE 21-4 A section of liver lobule showing the location of hepatic veins, hepatic cells, liver sinusoids, and branches of the portal vein and hepatic artery.

The Gallbladder

The gallbladder, a pear-shaped, hollow, saclike organ, 7.5 to 10 cm (3 to 4 in) long, lies in a shallow depression on the inferior surface of the liver, to which it is attached by loose connective tissue. The capacity of the gallbladder is 30 to 50 mL of bile. Its wall is composed largely of smooth muscle. The gallbladder is connected to the common bile duct by the cystic duct (Fig. 21-5).

The gallbladder functions as a storage area for bile. Between meals, when the sphincter of Oddi is closed, bile produced by the hepatocytes enters the gallbladder. During storage, a large portion of the water in bile is absorbed through the walls of the gallbladder so that gallbladder bile is five to ten times more concentrated than that originally secreted by the liver. When food enters the duodenum, the gallbladder contracts and the sphincter of Oddi relaxes, which allows the bile to enter the intestine. This response is mediated by secretion of the hormone cholecystokinin-pancreozymin (CCK-PZ) from the intestinal wall.

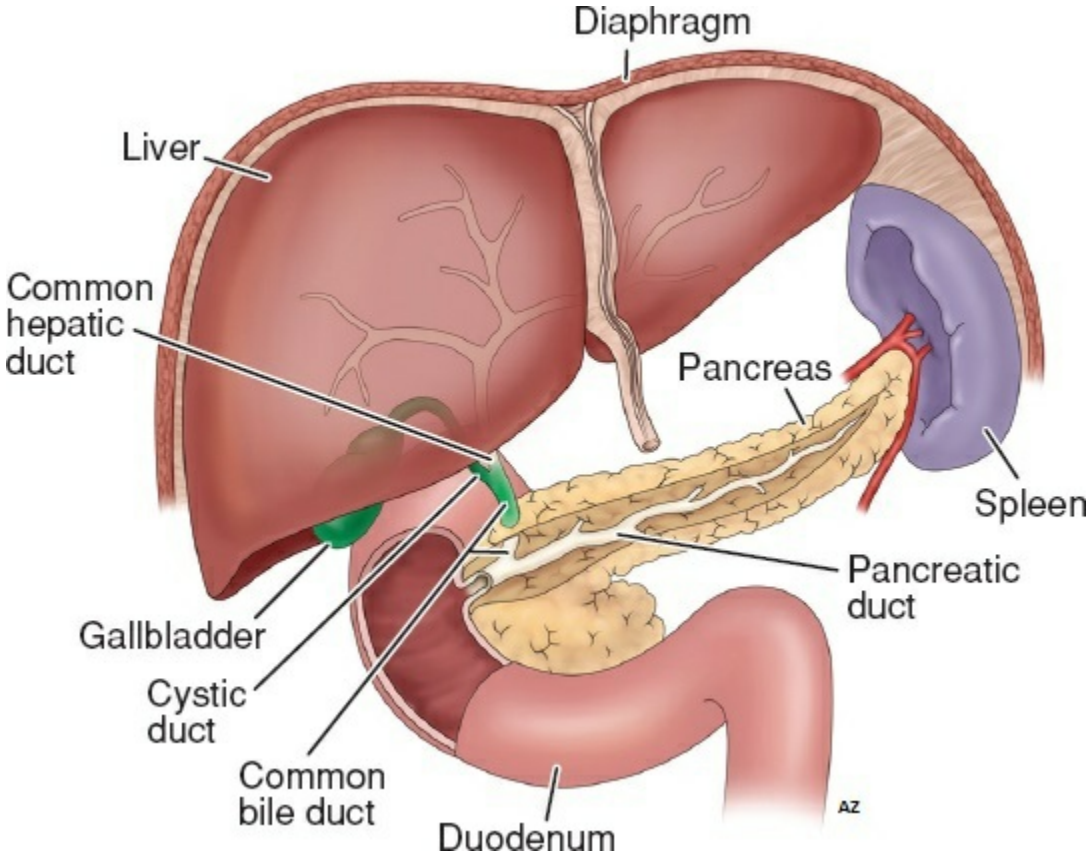

FIGURE 21-5 The liver, biliary system, and pancreas.

Bile is composed of water and electrolytes (sodium, potassium, calcium, chloride, and bicarbonate) along with significant amounts of lecithin, fatty acids, cholesterol, bilirubin, and bile salts. The bile salts, together with cholesterol, assist in emulsification of fats in the distal ileum. Then they are reabsorbed into the portal blood for return to the liver, after which they are excreted into the bile once again. This pathway from hepatocytes to bile to intestine and back to the hepatocytes is called the *enterohepatic circulation*. Because of the

enterohepatic circulation, only a small fraction of the bile salts that enters the intestine are excreted in the feces. This decreases the need for active synthesis of bile salts by the liver cells.

Approximately half of the bilirubin, a pigment derived from the breakdown of red blood cells, is converted by the intestinal flora into urobilinogen, a highly soluble substance. Urobilinogen is either excreted in the feces or returned to the portal circulation, where it is re-excreted into the bile.

If the flow of bile is impeded (e.g., by gallstones in the bile ducts), bilirubin does not enter the intestine. As a result, blood levels of bilirubin increase and cause a characteristic yellow hue to the skin, termed *jaundice*, and yellowing of the sclera, termed *icterus*. Increased levels of bilirubin cause increased renal excretion of urobilinogen, resulting in dark-colored urine, which, since bile is a soap, will be frothy when agitated. If the bile is prevented from entering the small intestine, clay-colored stool will be noted. Bile salts are also irritating to the skin, thus the nurse is alert for complaints of itchy skin or pruritus. These changes produce many of the signs and symptoms seen in gallbladder disorders.

The Pancreas

The pancreas, located in the upper abdomen, has endocrine as well as exocrine functions (see Fig. 21-5). The exocrine functions include secretion of pancreatic enzymes into the GI tract through the pancreatic duct. The endocrine functions include secretion of insulin, glucagon, and somatostatin directly into the bloodstream.

The Exocrine Pancreas

The secretions of the exocrine portion of the pancreas are collected in the pancreatic duct, which joins the common bile duct and enters the duodenum at the ampulla of Vater. Surrounding the ampulla is the sphincter of Oddi, which partially controls the rate at which secretions from the pancreas and the gallbladder enter the duodenum.

The secretions of the exocrine pancreas are digestive enzymes high in protein content and an electrolyte-rich fluid; they include amylase, trypsin, and lipase. The secretions, which are very alkaline because of their high concentration of sodium bicarbonate, are capable of neutralizing the highly acidic gastric juice that enters the duodenum. Hormones originating in the GI tract stimulate the secretion of these exocrine pancreatic juices. The hormone secretin is the major stimulus for increased bicarbonate secretion from the pancreas, and the major stimulus for digestive enzyme secretion is the hormone CCK-PZ. The vagus nerve also influences exocrine pancreatic secretion.

The Endocrine Pancreas

The islets of Langerhans, the endocrine part of the pancreas, are collections of cells embedded in the pancreatic tissue. They are composed of alpha, beta, and delta cells. The hormone produced by the beta cells is called *insulin*. The alpha cells secrete glucagon, and the delta cells secrete somatostatin. Refer to Chapter 30 for details on insulin and glucagon secretion.

Somatostatin is a hormone secreted in the pancreas, the stomach, and the small intestine. It decreases GI activity after ingestion of food and also acts in the islets of Langerhans to inhibit the release of insulin and glucagon (Grossman & Porth, 2014). By decreasing the transit time and inhibiting insulin and glucagon, it is proposed that absorption of foodstuffs and nutrients is enhanced.

Spleen

The spleen is a large lymphoid organ located high in the left upper abdominal cavity near ribs 9 and 11 (posterior to the midaxillary line), and rib fractures in this region should alert the nurse to potential splenic laceration. The spleen is highly vascular and is frequently injured in cases of blunt trauma. The spleen filters antigens from the blood, removes old or abnormal RBCs, and is responsible for immune response to infection because it is rich with B- and T-cell lymphocytes. The spleen in a healthy adult is approximately 9 to 13 cm (3.5 to 5.1 in) in length. It cannot be palpated unless significantly enlarged.

Gerontologic Considerations

Although an increased prevalence of several common GI disorders occurs in the elderly population, normal digestion and absorption occurs in the elderly. Thus, aging per se appears to have minimal direct effect on most GI functions, in large part because of the functional reserve of the GI tract (Table 21-3). However, since the rate of cell growth declines and tissues atrophy with aging, there is an increased susceptibility to age-related GI disorders. Common problems in the elderly range from constipation or acid reflux to life-threatening occurrences of infectious colitis or bowel ischemia. In addition to the increased prevalence of diseases such as diverticulitis and colon cancer in older patients, the role of polypharmacy needs to be considered. The use of nonsteroidal anti-inflammatory drugs (NSAIDs), aspirin, or anticoagulants is a risk factor for ulceration or bleeding. Since symptoms may be subtle, the nurse needs to be alert for a variety of potential GI diseases in the elderly (Hall, 2014).

TABLE 21-3 GERONTOLOGIC CONSIDERATIONS / Age-Related Changes of the Gastrointestinal System

Component	Structural Changes	Implications
Oral Cavity and Pharynx	• Injury/loss or decay of teeth • Atrophy of taste buds • Decreased saliva production • Reduced ptyalin and amylase in saliva • Atrophy of gingival tissue	Difficulty chewing and swallowing
Esophagus	• Decreased motility and emptying • Weakened gag reflex • Decreased resting pressure of lower esophageal sphincter • Decreased muscle tone and weakness in lower esophageal sphincter	Reflux and heartburn Dysphagia (difficulty swallowing) Dyspepsia (indigestion)
Stomach	• Degeneration and atrophy of gastric mucosal surfaces with decreased production of HCl • Decreased secretion of gastric acids and most digestive enzymes • Decreased motility and emptying	Delayed gastric emptying Food intolerances Malabsorption Decrease in absorption of iron and vitamin B_{12} Anorexia Anemia
Small Intestine	• Atrophy of muscle and mucosal surfaces • Thinning of villi and epithelial cells	Decreased motility and transit time, which lead to complaints of indigestion and constipation
Large Intestine	• Decrease in mucus secretion • Decrease in elasticity of rectal wall • Decreased tone of internal anal sphincter • Slower and duller nerve impulses in rectal area	Decreased absorption of nutrients (dextrose, fats, calcium, and iron), leading to decreased sensation to defecate and increased constipation Fecal incontinence from decrease or loss of sphincter control
Liver	• Decrease in size and weight • Decrease in total hepatic blood flow • Decreased phagocytosis by the Kupffer cells • Decreased drug metabolism	Decreases in size proportional to decreases in body size and weight Increased incidence of hepatitis B Increased incidence of liver abscesses Increased incidence of drug toxicity

ASSESSMENT

Health History

A focused GI assessment begins with a complete history. Information about abdominal pain, appetite changes, dyspepsia, gas, nausea and vomiting, diarrhea, constipation, fecal incontinence, and previous GI disease is investigated. Past and current medication use and any previous diagnostic studies, treatments, and surgery are noted.

The initial presentation of a patient with liver disease varies greatly and can range from elevated liver enzymes on routine screening with no clinical signs or symptoms of disease to the patient who presents in liver failure with jaundice, hepatic coma, or esophageal bleeding. A comprehensive and complete health history is critical to determine exposure to hepatotoxic substances (including alcohol) or infectious agents causing liver dysfunction and to distinguish between acute and chronic liver dysfunction.

Current History

Current nutritional status is ascertained. The nurse and patient discuss changes in appetite or eating patterns and any unexplained weight gain or loss over the past year. A complete metabolic panel, including liver function studies, triglyceride levels, iron studies, and complete blood count (CBC) are obtained.

Questions are raised about the use of tobacco and alcohol and include the need for detailed answers about type, amount, length of use, and the date of discontinuation, if any. It is also important to include questions about psychosocial, spiritual, or cultural factors that may be affecting the patient.

If liver disease is suspected because of clinical manifestations or abnormal liver function tests, the health history focuses on previous exposure of the patient to hepatotoxic substances or infectious agents. Lifestyle behaviors that increase the risk for exposure to infectious agents are identified. The patient's history of alcohol and drug use, including but not limited to the use of IV injection drugs, provides additional information about exposure to toxins and infectious agents. The patient's occupational, recreational, and travel history may assist in identifying exposure to hepatotoxins (e.g., industrial chemicals, other toxins). Travel to endemic areas such as Asia, Africa, the Middle East, and Central America may indicate a risk for hepatitis E (Friedman, Chopra, & Travis, 2015). Sexual practices may be a potential risk factor for liver disease (Grossman & Porth, 2014). The amount and type of alcohol consumption are identified using screening questionnaires that have been developed for this purpose. Men who consume 210 g of alcohol per week and women who consume 140 g per week are estimated to be at high risk for alcoholic cirrhosis; an alcoholic drink generally contains about 14 g of alcohol (Chalasani et al., 2012). The nurse is aware that the impact of alcohol-induced liver injury or disease is increased in the presence of other risk factors, such as hepatitis C (Kasper et al., 2015).

Many medications (including acetaminophen, ketoconazole, and valproic acid) are responsible for liver dysfunction and disease. Acetaminophen overdose can result in fulminant hepatic failure, while chronic liver disease is commonly caused by alcohol and viruses, such as hepatitis B or C. A prior history of inflammatory bowel disease or ulcerative

colitis may lead to the diagnosis of primary sclerosing cholangitis. Patients with nonalcoholic fatty liver disease (NAFLD) may frequently have a medical history of diabetes, hyperlipidemia, and obesity.

A thorough medication history to assess liver dysfunction should address all current and past prescription medications, over-the-counter medications, herbal remedies, and dietary supplements.

Past History

The history also includes an evaluation of the client's medical history to identify risk factors for liver disease. Current and past medical conditions, including those of a psychological or psychiatric nature, are identified. The family history includes questions about familial liver disorders that may have their origin in alcohol abuse or gallstone disease as well as other familial or genetic diseases, such as hemochromatosis, Wilson disease, or alpha$_1$-antitrypsin disease (Friedman et al., 2014; Kasper et al., 2015). A positive family history of hepatitis B may indicate vertical transmission (infection transmitted from mother to child [embryo, fetus, or baby] during pregnancy or childbirth) (Kubo et al., 2014).

Common Complaints

Pain

Pain can be a major symptom of GI disease. Pain may be described as visceral; that is, nociceptors in the abdominal organs are stimulated and the pain is often described by patients as cramping, aching, squeezing, or colicky and difficult to pinpoint. Parietal pain occurs when the parietal peritoneum is inflamed, as occurs with appendicitis. It is a steady, severe pain that may be localized. Referred pain is pain that travels to a more distant site, where it localizes or presents. The character, duration, pattern, frequency, location, and distribution of referred pain (Fig. 21-6) vary greatly depending on the underlying cause. Other factors such as meals, rest, activity, and defecation patterns may directly affect this pain.

Nursing Alert
The pain of appendicitis initially presents as vague discomfort in the periumbilical area. As the inflammatory process progresses to involve the parietal peritoneum, the pain localizes to the right lower quadrant. The nurse maintains a high degree of suspicion of appendicitis for patients complaining of abdominal pain, nausea, anorexia, and "migratory" pain.

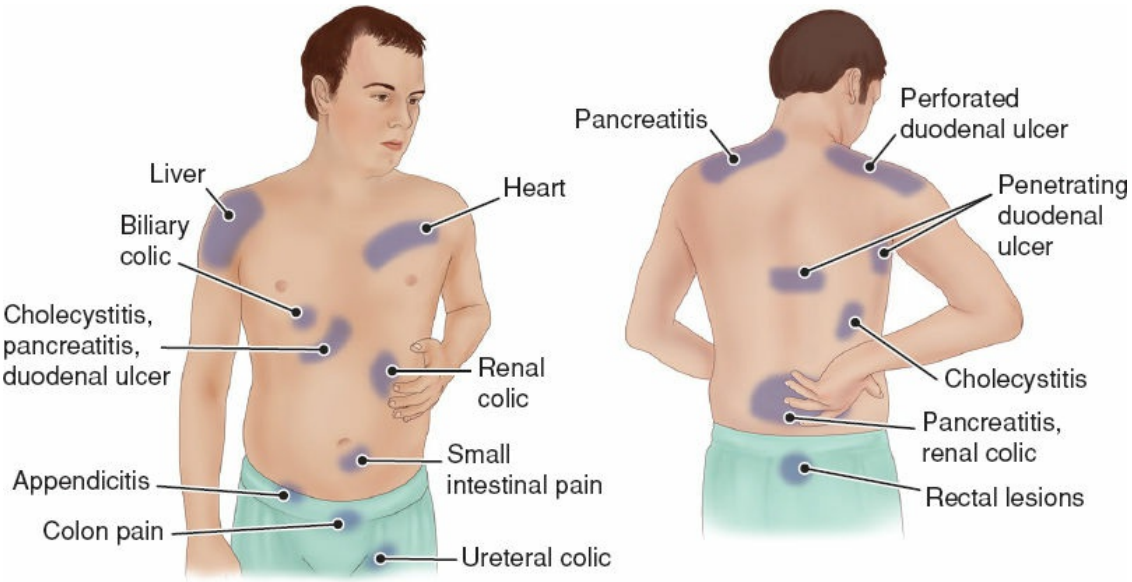

FIGURE 21-6 Common sites of referred abdominal pain.

Dyspepsia

Dyspepsia, which is upper abdominal discomfort or distress associated with eating (commonly called *indigestion*) is the most common symptom of clients with GI dysfunction. Indigestion is an imprecise term that refers to a host of upper abdominal or epigastric symptoms, such as pain, discomfort, fullness, bloating, early satiety, belching, heartburn, and regurgitation; it occurs in approximately 25% of the adult population. Typically, fatty foods cause the most discomfort because they remain in the stomach for digestion longer than proteins or carbohydrates. Salads and coarse vegetables, as well as highly seasoned foods, may also cause considerable GI distress.

Intestinal Gas

The accumulation of gas in the GI tract may result in belching (expulsion of gas from the stomach through the mouth) or flatulence (expulsion of gas from the rectum). Usually, gases in the small intestine pass into the colon and are released as flatus. Patients often complain of bloating, distention, or feeling "full of gas," with excessive flatulence as a symptom of food intolerance or gallbladder disease.

Nausea and Vomiting

Nausea is a vague, intensely unsettling sensation of sickness or "queasiness" that may or may not be followed by vomiting. It can be triggered by odors, activity, medications, or food intake. The emesis, or vomitus, may vary in color and content and may contain undigested food particles, blood (hematemesis), or bilious material mixed with gastric juices. The causes of nausea and vomiting are many. Nausea and vomiting may result from visceral afferent stimulation (i.e., dysmotility, peritoneal irritation, infections, hepatobiliary or pancreatic disorders, mechanical obstruction); CNS disorders (i.e., vestibular disorders, increased intracranial pressure, infections, psychogenic conditions); and irritation of the chemoreceptor trigger zone from radiation therapy, systemic disorders, and antitumor chemotherapy medications.

Change in Bowel Habits and Stool Characteristics

Changes in bowel habits may signal colonic dysfunction or disease. Diarrhea, an abnormal increase in the frequency of bowel movements and liquidity of the stool or in daily stool weight or volume, commonly occurs when the contents move so rapidly through the intestine and colon that there is inadequate time for the GI secretions and oral contents to be absorbed. Typically this physiologic function is associated with abdominal pain or cramping and nausea or vomiting. Constipation, a decrease in the frequency of bowel movements, or stools that are hard, dry, and of smaller volume than normal, may be associated with anal discomfort and rectal bleeding.

TABLE 21-4 Foods and Medications That Alter Stool Color

Altering Substance	Color
Meat protein	Dark brown
Spinach	Green
Carrots and beets	Red
Cocoa	Dark red or brown
Senna	Yellow
Bismuth, iron, licorice, and charcoal	Black
Barium	Milky white

The characteristics of the stool can vary greatly. Stool is normally light to dark brown; however, specific disease processes and ingestion of certain foods and medications may change the appearance of stool (Table 21-4). Blood in the stool can present in various ways and must be investigated. If blood is shed in sufficient quantities into the upper GI tract, it produces a tarry-black color (melena), whereas blood entering the lower portion of the GI tract or passing rapidly through will cause the stool to appear bright or dark red. Lower rectal or anal bleeding is suspected if there is streaking of blood on the surface of the stool or if blood is noted on toilet tissue. Other common abnormalities in stool characteristics described by the patient may include:

- Bulky, greasy, foamy stools that are foul in odor and may or may not float
- Light-gray or clay-colored stool, caused by a decrease or absence of conjugated bilirubin
- Stool with mucus threads or pus that may be visible on gross inspection of the stool
- Small, dry, rock-hard masses occasionally streaked with blood
- Loose, watery stool that may or may not be streaked with blood

Nursing Alert

Melena, or black "tarry" stools, occurs in association with upper GI bleeding from the esophagus, stomach, duodenum, or small intestine. Melena can result after blood loss in an amount as small as 60 mL and is caused by stomach acid (hydrochloric acid) or intestinal bacterial conversion of hemoglobin to the black pigment hematin. Pseudomelena, or false melena, is associated with ingestion of iron. The term hematochezia refers to stools that are maroon or bright red in color, signifying a bleeding below the ligament of Treitz (duodenum level) but may be associated with a rapid upper GI bleed.

Jaundice

When the bilirubin concentration in the blood is elevated abnormally, all the body tissues, including the sclerae and the skin, become tinged yellow or greenish yellow, a condition called jaundice. Jaundice becomes clinically evident when the serum bilirubin level exceeds 2.5 mg/dL (43 μmol/L). The elevated bilirubin stains tissues and fluid, but jaundice is seen most frequently in the sclera (icteris) (Grossman & Porth, 2014). Increased serum bilirubin levels and jaundice may result from impairment of hepatic uptake, conjugation of bilirubin, or excretion of bilirubin into the biliary system. There are several types of jaundice: hemolytic, hepatocellular, and obstructive jaundice, and jaundice due to hereditary hyperbilirubinemia. Hepatocellular and obstructive jaundice are the two types commonly associated with liver disease (refer to Chapter 25).

Pathophysiology Alert

A normal direct bilirubin is 0.0 to 0.3 mg/dL (Hall, 2014). Bilirubin, which gives bile its color, may be reported as direct (conjugated or combined in a molecule similar to glucose) or indirect (termed free or unconjugated). The direct bilirubin reflects bilirubin excreted by the GI tract, whereas indirect bilirubin reflects what normally circulates in the bloodstream (Daniels, 2014). Both are elevated in a variety of disorders since bilirubin is produced in the liver, spleen, and bone marrow.

Ascites

Ascites is an increased accumulation of peritoneal fluid in the abdomen caused by a variety of disorders associated with the liver. One factor associated with development of ascites is portal hypertension and the resulting increase in capillary pressure and obstruction of venous blood flow through the damaged liver. Portal hypertension causes an increased pressure gradient (a difference in pressure between the portal vein and the hepatic veins), facilitating fluid accumulation in the peritoneal cavity. Another factor is the decreased synthesis of albumin in liver disease. The hypoalbuminemia results in decreased plasma oncotic pressure, which facilitates fluid accumulation in the abdominal cavity. An obstruction of the normal lymphatic drainage can cause fluid accumulation in the peritoneum, as can cancers or inflammatory processes that stimulate increased production of peritoneal fluid. Ascites also can be associated with nonhepatic etiologies, such as kidney failure and heart failure.

Engorged Veins

Under normal conditions, the veins in the abdominal wall are barely noted unless the skin and subcutaneous fat are thin. When venous pressure increases as a result of obstruction, as in portal hypertension, vessels distal to the inferior vena cava engorge, and distended veins can be seen on the abdomen, chest, and extremities.

Physical Examination

For the purposes of examination and documentation, the abdomen can be divided into either four quadrants or nine regions (Fig. 21-7). The nurse must know the physical proximity of the organs and blood vessels to these quadrants or regions. Choosing one of these mapping methods and using it consistently will ensure a thorough evaluation of the abdomen and appropriate corresponding documentation.

The physical examination includes assessment of the mouth, abdomen, and rectum. Good lighting is necessary, as is full exposure of the abdomen. The patient should be comfortable and relaxed, with an empty bladder. The nurse's hands should be warm and the fingernails short.

The patient lies supine with knees flexed slightly for inspection, auscultation, palpation, and percussion of the abdomen. Arms should not be raised over the head because the abdominal muscles tense in this position. A small pillow may be placed behind the patient's head for comfort. The patient's breasts are covered with a gown, and sheets are rolled down to above the symphysis pubis. Examination of the abdomen is performed with the nurse standing on the patient's right side.

Inspection

The mouth, tongue, buccal mucosa, teeth, and gums are inspected, noting any ulcers, nodules, swelling, discoloration, or inflammation. Dentures should be removed to allow good visualization of the entire oral cavity.

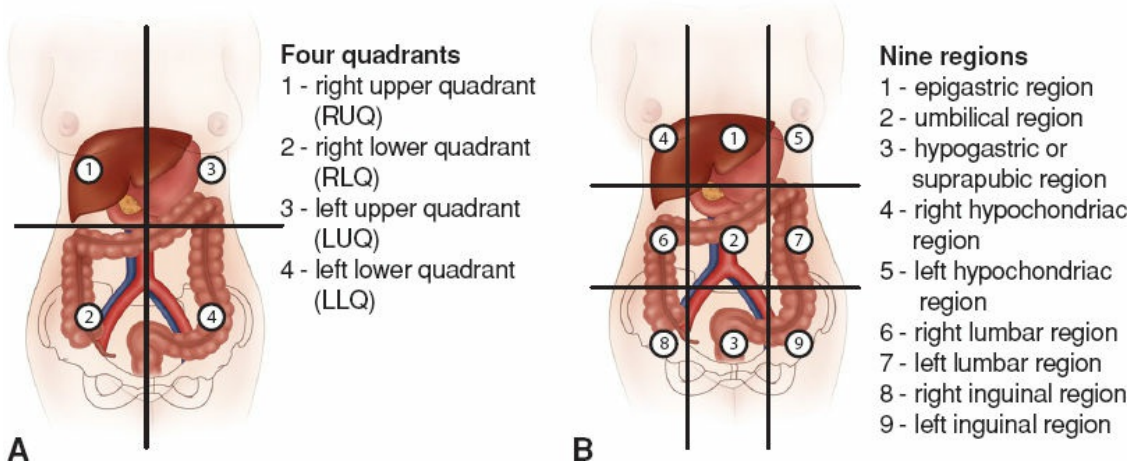

FIGURE 21-7 Division of the abdomen into (A) four quadrants or (B) nine regions.

The nurse inspects the abdominal skin for nodules, lesions, masses, scarring, discolorations, inflammation, bruising, increased vascularity of the abdominal skin, and striae (stretch marks). In the presence of liver disease, the nurse inspects the skin, mucosa, and sclera for jaundice. The extremities are assessed for muscle atrophy, edema, and skin excoriation secondary to scratching. The nurse observes the skin for petechiae or ecchymotic areas (bruises), spider angiomas, and palmar erythema (a diffuse reddening of

the palm, particularly near the base of the thumb (thenar eminence) and base of the little finger (hypothenar eminence) that is associated with chronic liver disease. In addition, a male patient is assessed for unilateral or bilateral gynecomastia and testicular atrophy due to hormonal changes associated with liver disease. The patient's cognitive status (recall, memory, abstract thinking) and neurologic status are assessed. The nurse observes for general tremor, asterixis (flapping of the hands when wrists dorsiflexed), weakness, and slurred speech related to elevated ammonia levels secondary to liver failure; the nurse notes the patient's breath for hepatic fetor, a sweet, mildly fecal breath odor associated with encephalopathy. The contour and symmetry of the abdomen are noted, and any localized bulging, distention, or peristaltic waves are identified. Under normal circumstances, peristalsis is not noted on the abdominal wall and, if present, usually is associated with early intestinal obstruction. Expected contours of the anterior abdominal wall can be described as flat, rounded, or scaphoid (hollowed or shaped like a boat). The umbilicus is assessed for color, position, and shape. The umbilicus may be everted with increased intra-abdominal pressure. Ecchymoses around the umbilical area is termed *Cullen sign* and is associated with a retroperitoneal bleed due to any cause. Ecchymoses noted on either flank, the groin, or the abdomen, termed *Grey–Turner sign*, is also associated with a retroperitoneal bleed (see Chapter 27, Fig. 27-10). A hernia is a protrusion on the abdominal wall and may be noted anywhere in the abdomen. If ascites is suspected, the nurse notes bulging flanks when the patient is in the supine position as the weight of the fluid flows dependently to the sides.

Nursing Alert
If abdominal distention is noted, the nurse assesses for common causes described as the 6 F's: fetus (pregnancy), feces (constipation), flatulence, fat (obesity), fluid (ascites), and fibroids or full-size tumor.

Auscultation

Auscultation always precedes percussion and palpation since manipulation of the abdomen may alter the frequency and intensity of bowel sounds. The nurse listens to determine the character, location, and frequency of bowel sounds and to identify vascular sounds. Bowel sounds are assessed in all four quadrants using the diaphragm of the stethoscope, which affords greatest auscultation of high-pitched and gurgling sounds. The frequency and character of the sounds are usually heard as clicks and gurgles that occur irregularly and range from 5 to 35 per minute. Frequently the terms *normoactive* (sounds heard about every 2 to 12 seconds), *hypoactive* (fewer than 5 clicks or gurgles per minute), *hyperactive* (more than 35 per minute), or *absent* (no sounds in 3 to 5 minutes) are used in documentation, but these assessments are highly subjective. Hypoactive bowel sounds are associated with decreased bowel function, as occurs in postoperative patients, patients with myxedema, peritonitis, hypokalemia, or mesentery ischemia, and in patients on medications, such as opioid and anticholinergic agents. The nurse must listen for 5 minutes before documenting the absence of bowel sounds, which is suggestive of ileus and can be due to a variety of causes. Hyperactive bowel sounds are associated with diarrhea or gastroenteritis. High-pitched, high-frequency bowel sounds and abdominal cramping are suggestive of a partial intestinal obstruction.

Bruits in the aortic, renal, iliac, and femoral arteries are noted using the bell of the

stethoscope. Bruits are associated with turbulent blood flow in an artery. Friction rubs are high-pitched grating sounds heard over the liver or spleen during respiration. These are rare findings but are associated with pathology. Borborygmi, or "stomach growling," is heard as a loud, prolonged gurgle.

Percussion

Percussion is used to assess the size and density of the abdominal organs and to detect the presence of air-filled, fluid-filled, or solid masses. Percussion is used either independently or concurrently with palpation because it can validate palpation findings. All quadrants are percussed for a sense of overall tympany and dullness. Tympany is the predominant sound that results from the presence of air in the stomach and small intestines; dullness is heard over organs and solid masses (Jarvis, 2016).

If ascites is suspected, the nurse can test for shifting dullness, which may help confirm the presence of ascites. This is performed through percussion with the patient in supine position. In this position, the nurse percusses the top of the abdomen and notes tympany, however when the abdomen in percussed laterally, the sound of dullness is noted. The nurse then rolls the patient on their side and will percuss again. Shifting dullness is noted as the fluid flows to the dependent regions when the patient moves to a lateral position (Bickley, 2017).

The nurse estimates the size of the liver by percussing its upper border beginning at lung resonance and changing to liver dullness; then the nurse percusses the lower border by noting the change in sound from abdominal tympany to liver dullness usually at the right costal margin (Jarvis, 2016). The normal liver span is 6 to 12 cm in the midclavicular line (MCL). A hollow tympanic note over the stomach in the left upper quadrant (LUQ) should be expected. A full bladder elicits dullness above the suprapubic area, whereas abdominal distention increases the area of tympany. If the spleen is enlarged, dullness may be percussed in the LUQ at the area in proximity to the ninth through eleventh ribs (Bickley & Szilagyi, 2013).

Palpation

If a patient complains of abdominal pain, it is important to assess the area of tenderness last. Use of light palpation is appropriate for identifying areas of tenderness or muscular resistance, and deep palpation is used to identify masses. If a mass is noted, the nurse assesses its size, shape, location, consistency, pulsatility, mobility, and tenderness.

A palpable liver has a firm, sharp ridge and a smooth surface (Fig. 21-8). If the liver is palpable, the examiner notes and records its size, its consistency, any tenderness, and whether its outline is regular or irregular. If the liver is enlarged, the degree to which it descends below the right costal margin is recorded to provide some indication of its size. The nurse determines whether the liver's edge is sharp and smooth or blunt and whether the enlarged liver is nodular or smooth. The liver of a patient with cirrhosis is small and hard with a palpable edge, whereas the liver of a patient with acute hepatitis is enlarged and smooth (Jarvis, 2016).

Tenderness of the liver indicates recent acute enlargement with consequent stretching of the liver capsule. The absence of tenderness may imply that the enlargement is of longstanding duration. The liver of a patient with viral hepatitis is tender, whereas that of a

patient with alcoholic hepatitis is not. Enlargement of the liver is an abnormal finding that requires evaluation (Bickley & Szilagyi, 2013).

FIGURE 21-8 Technique for palpating the liver. The examiner places one hand under the right lower rib cage and presses downward with light pressure with the other hand.

The fluid wave test can be conducted if ascites is suspected. A fluid wave can be demonstrated by tapping the patient's flank sharply with one hand while the other hand receives the impulse against the opposite flank. There is a perceptible time lag between the tap and reception of the impulse. Since mesentery fat may produce a similar wave, the patient or an assistant presses the ulnar surface of his or her hand into the midline of the abdomen. A wave passing this hand barrier is usually caused by free fluid. This finding may be negative until ascites is visibly obvious. If both the fluid wave test and the test for shifting dullness are positive and accompanied by peripheral edema, it is three to six times more probable that ascites is present (Bickley, 2017).

Cholecystitis, acute inflammation of the gallbladder, causes pain and tenderness and makes it difficult for the nurse to palpate and percuss the abdomen. The nurse should observe for Murphy sign (the patient's inability to take a deep breath when the examiner's fingers are pressed below the right costal margin).

Testing for rebound tenderness is not performed by many examiners because it can cause severe pain; light percussion is used instead to produce a mild, localized response when peritoneal irritation is present. If testing for rebound tenderness is undertaken, it is

done at the end of the examination since the patient's pain will interfere with the remaining examination. Using palpation, the nurse's places his or her hand in the painful quadrant and then releases it quickly. Pain upon releasing is termed *Blumberg sign* and is associated with peritonitis, such as appendicitis.

Nursing Alert
Guarding, rigidity, and rebound tenderness (Blumberg sign) are reliable indicators of peritonitis, which is inflammation of the peritoneum. Peritonitis can be caused by bacterial invasion (i.e., ruptured appendix, perforated diverticulum), chemical irritation (i.e., perforated ulcer), abdominal trauma, and wounds.

Rectal Examination

The final part of the physical examination is evaluation of the terminal portions of the GI tract, the rectum, perianal region, and anus. The anal canal is approximately 2.5 to 4 cm in length and opens into the perineum. Concentric rings of muscle, the internal and external sphincters, normally keep the anal canal closed securely. Gloves, water-soluble lubrication, a penlight, and drapes are necessary tools for the evaluation. Although the rectal examination is generally uncomfortable and often embarrassing for the patient, it is a mandatory part of every thorough examination. For women, the rectal examination may be part of the gynecologic examination. Positions for the rectal examination include knee–chest, left lateral with hips and knees flexed, and standing with hips flexed and upper body supported by the examination table. External examination includes inspection for lumps, rashes, inflammation, excoriation, tears, scars, pilonidal dimpling, and tufts of hair at the pilonidal area. The discovery of tenderness, inflammation, or both should alert the examiner to the possibility of a pilonidal cyst, perianal abscess, or anorectal fistula or fissure. The patient's buttocks are carefully spread and visually inspected until the patient has relaxed the external sphincter control. The patient is asked to bear down, thus allowing the ready appearance of fistulas, fissures, rectal prolapse, polyps, and internal hemorrhoids. Internal examination is performed with a lubricated index finger inserted into the anal canal while the patient bears down. The tone of the sphincter is noted, as are any nodules or irregularities of the anal ring. Because this is an uncomfortable part of the examination for most people, the patient is encouraged to focus on deep breathing during the brief examination.

Diagnostic Evaluation

Initial diagnostic tests begin with serum laboratory studies, including but not limited to CBC, a complete metabolic panel, prothrombin time/partial thromboplastin time (PT/PTT), triglycerides, liver function tests, amylase, and lipase, with the possibility of more specific studies, such as carcinoembryonic antigen (CEA), cancer antigen (CA) 19-9, and alpha-fetoprotein, indicating sensitivity and specificity for colorectal and hepatocellular carcinomas, respectively. CEA is a protein that normally is not detected in the blood of a healthy person; therefore, when detected, it indicates that cancer is present but not what type of cancer is present. Practitioners can use CEA results to determine the stage and extent of the disease and the prognosis for patients with cancer, especially colorectal, pancreatic, lung, and stomach cancer (Grossman & Porth, 2014). CA 19-9 is also a protein that exists on the surface of certain cells and is shed by tumor cells, making it useful as a tumor marker to follow the course of the cancer. CA 19-9 levels are elevated in most patients with advanced pancreatic cancer, but it also may be elevated in other conditions, such as colorectal, lung, and gallbladder cancers; gallstones; pancreatitis; cystic fibrosis; and liver disease.

Many other modalities are available for diagnostic assessment of the GI tract. Table 21-5 identifies various procedures and their diagnostic uses.

The majority of these tests and procedures are performed on an outpatient basis in special settings designed for this purpose (e.g., endoscopy suite or GI laboratory). In the past, frequently patients who required such tests were elderly; however, within the past 5 years, in part due to heightened media exposure on the subject of early diagnosis of colorectal cancer, the median age of patients evaluated for colorectal cancer has decreased significantly. Preparation for many of these studies includes clear liquid diets, fasting, ingestion of a liquid bowel preparation, the use of laxatives or enemas, and ingestion or injection of a contrast agent or a radiopaque dye. These measures are poorly tolerated by some patients and are especially problematic in the elderly population or in patients with comorbidities because bowel preparations significantly alter the internal fluid and electrolyte balance. If further assessment or treatment is needed after any outpatient procedure, the patient may be admitted to the hospital. Specific interventions for each diagnostic test are listed in Table 21-6.

General nursing interventions for the patient who is undergoing a GI diagnostic evaluation include:

- Establishing the possible nursing diagnosis
- Providing needed information about the test and the activities required of the patient
- Providing instructions about postprocedure care and activity restrictions
- Providing health information and procedural teaching to patients and significant others
- Helping the patient cope with discomfort and alleviating anxiety
- Informing the physician or nurse practitioner of known medical conditions or abnormal laboratory values that may affect the procedure
- Assessing for adequate hydration before, during, and immediately after the procedure, and providing education about maintenance of hydration

Stool Tests

Basic examination of the stool includes inspecting the specimen for consistency, color, and occult (not visible) blood. Additional studies, including fecal urobilinogen, fecal fat, nitrogen, *Clostridium difficile,* fecal leukocytes, calculation of stool osmolar gap, parasites, pathogens, food residues, and other substances, require laboratory evaluation.

Usually stool samples are collected on a random basis unless a quantitative study (e.g., fecal fat, urobilinogen) is to be performed. Random specimens should be sent promptly to the laboratory for analysis; however, the quantitative 24- to 72-hour collections must be kept refrigerated until transported to the laboratory. Some stool collections require the patient to follow a specific diet or refrain from taking certain medications before the collection. Thorough and accurate patient education regarding a specific stool study prior to collection greatly increases the accuracy of study results.

The stool antigen test is a noninvasive, simple procedure for determining the presence of monoclonal antibodies specific to *Helicobacter pylori*, which places the patient at risk for peptic ulcer disease (Kasper et al., 2015). This test may be performed in the laboratory or, most recently, in the office during a clinic visit (Crowe, Feldman, & Grover, 2015).

Fecal occult blood testing (FOBT) is one of the most commonly performed stool tests. It can be useful in initial screening for several disorders, although it is used most frequently in early cancer detection programs. FOBT can be performed at the bedside, in the laboratory, or at home. Probably the most widely used in-office or at-home occult blood test is the Hemoccult II. It is inexpensive, noninvasive, and carries minimal risk to the patient.

TABLE 21-5 Additional Laboratory Studies for Digestive, Gastrointestinal, and Metabolic Function

Study	Clinical Functions
Abdominal x-ray	To determine gross liver size, assess for intestinal obstruction and/or fecal impaction
Angiography	To visualize liver circulation and detect presence and nature of liver masses
Barium study of esophagus	To identify varices, which indicate increased portal blood pressure
Celiac axis arteriography	To visualize liver and pancreas
Cholecystogram and cholangiogram	To visualize gallbladder and bile duct
Cholesterol levels	Elevated in biliary obstruction; decreased in parenchymal liver disease
Computed tomography (CT) scan	To detect hepatic neoplasms; diagnose cysts, abscesses, and hematomas; and distinguish between obstructive and nonobstructive jaundice. Detects cerebral atrophy in hepatic encephalopathy
Electroencephalogram	To detect abnormalities that occur with hepatic coma
Endoscopic retrograde cholangiopancreatography (ERCP)	To visualize biliary structures and pancreas via endoscopy
Esophagoscopy/endoscopy	To search for esophageal varices and other abnormalities
Gamma-glutamyl transferase (GGT), gamma-glutamyl transpeptidase (GGTP), lactate dehydrogenase (LDH)	Markers for biliary stasis; also elevated in alcohol abuse
Laparoscopy	To directly visualize the anterior surface of liver, gallbladder, and mesentery through a trocar
Liver biopsy (percutaneous or transjugular)	To determine anatomic changes in liver tissue
Liver scan with radio-tagged iodinated rose bengal, gold, technetium, or gallium	To show size and shape of liver; to show replacement of liver tissue with scars, cysts, or tumor
Magnetic resonance imaging (MRI)	To detect hepatic neoplasms; diagnose cysts, abscesses, and hematomas. Detects cerebral atrophy in encephalopathy
Measurement of portal pressure	To detect increased portal pressure, which occurs with cirrhosis of the liver
Serum alkaline phosphatase	In absence of bone disease, to measure biliary tract obstruction
Splenoportogram (splenic portal venography)	To determine adequacy of portal blood flow
Ultrasonography	To show size of abdominal organs and presence of masses

Breath Tests

H. pylori is a bacteria that can live in the mucosal lining of the stomach, causing peptic ulcer disease (Grossman & Porth, 2014). The urea breath test is a noninvasive procedure used to detect *H. pylori* based upon the separation of urea by *H. pylori* and creating CO_2 and ammonia. A carbon isotope is administered to the patient by mouth, and the *H. pylori* joins with CO_2 and can be identified via the breath sample (Crowe, Feldman, & Grover, 2015).

Abdominal Ultrasonography

Ultrasonography is a noninvasive diagnostic technique in which high-frequency sound waves are passed into internal body structures and the ultrasonic echoes are recorded on an oscilloscope as they strike tissues of different densities. A clear, water-based conducting gel is applied to the skin over the abdomen, which helps with the transmission of the sound waves. Then a handheld probe, called a transducer, is moved over the abdomen.

Ultrasonography is particularly useful in the detection of an enlarged gallbladder or pancreas, the presence of gallstones, an enlarged ovary, an ectopic pregnancy, or appendicitis. Most recently this technique has proved useful in diagnosing acute colonic diverticulitis.

TABLE 21-6 Gastrointestinal Laboratory Tests

Test	Nursing Implications
Abdominal ultrasonography	• The patient is instructed to fast for 8–12 hours before the test to decrease the amount of gas in the bowel. • If gallbladder studies are to be performed, the patient should eat a fat-free meal the evening before the test. • If barium studies are to be performed, they should be scheduled after ultrasonography; otherwise, the barium could interfere with the transmission of the sound waves.
Anoscopy, proctoscopy, and sigmoidoscopy	• Preparation varies according to providers. Patients may receive an enema until the returns are clear. • During the procedure, the nurse monitors vital signs, skin color and temperature, pain tolerance, and vagal response. • After the procedure, the nurse monitors the patient for rectal bleeding and signs of intestinal perforation (i.e., fever, rectal drainage, abdominal distention, and pain). On completion of the examination, the patient can resume regular activities and diet.
Breath tests	• The patient ingests a capsule of carbon-labeled urea, and a breath sample is obtained 10–20 minutes later. Because *Helicobacter pylori* metabolizes urea rapidly, the labeled carbon is absorbed quickly; then it can be measured as carbon dioxide in the expired breath to determine whether *H. pylori* is present. • The patient is instructed to avoid antibiotics and loperamide (Pepto-Bismol) for 1 month before the test; sucralfate (Carafate) and omeprazole (Prilosec) for 1 week before the test; and cimetidine (Tagamet), famotidine (Pepcid), and ranitidine (Zantac) for 24 hours before the test. • *H. pylori* also can be detected by assessing serum antibody levels.
Blood chemistry	• Many electrolytes are altered in GI dysfunction. Calcium is absorbed in the GI tract and may be measured to detect malabsorption. Excessive vomiting or diarrhea causes electrolyte depletion, thus requiring replacement. • Assays of serum enzymes are important in the evaluation of liver damage. AST and ALT are two enzymes found in most patients' livers and other organs. These enzymes are elevated in most liver disorders, but they are highest in conditions that cause necrosis (viral hepatitis). • Conjugated (direct) and unconjugated (indirect) bilirubin are important measurements in the diagnosis of jaundice. • Serum ammonia level is measured to evaluate liver function. • CA 19-9 and CEA are evaluated to diagnose, monitor the success of cancer therapy, and assess for the recurrence of cancer in the GI tract (Daniels, 2014).
Cholecystography	• The patient is asked about allergies to iodine or seafood. If no allergy is identified, the patient receives the oral form of the contrast agent the evening before (10–12 hours) the x-rays are obtained. • After the contrast agent is administered, the patient is permitted nothing by mouth, to prevent contraction and emptying of the gallbladder. • An x-ray of the right upper abdomen is obtained. If the gallbladder is found to fill and empty normally and to contain no stones, gallbladder disease is ruled out. • If gallbladder disease is present, the gallbladder may not be visualized because of obstruction by gallstones. If the gallbladder is not visualized on the first attempt, a repeat of the oral cholecystography with a second dose of the contrast agent may be necessary.
CT	• CT may be performed with or without an oral or IV contrast agent, but the study is far superior with the administration of a contrast agent. • Any allergies to contrast agents, iodine, or shellfish; the patient's current serum creatinine level; and urine levels of human chorionic gonadotropin must be determined before administration of a contrast agent. Patients allergic to the contrast agent may be premedicated with steroids and antihistamines before the scan. • In addition, renal protective measures include the administration of IV sodium bicarbonate 1 hour before and 6 hours after IV contrast and oral acetylcysteine (Mucomyst) before or after the study. Both sodium bicarbonate and Mucomyst are free radical scavengers that sequester the contrast byproducts that are destructive to kidney cells. • The patient is informed that during injection of the contrast medium, a burning sensation may be felt for a few seconds behind the eyes or in the jaw, teeth, tongue, or lips (Daniels, 2014).

Endoscopy through ostomy stoma	• Nursing interventions are similar to those for other endoscopic procedures.
ERCP	• Before the procedure, the patient is given an explanation of the procedure and their role in it. • The patient is NPO for several hours before the procedure. • Moderate sedation is used, and the sedated patient must be monitored closely. • It may be necessary to administer medications, such as glucagon or anticholinergics, to make cannulation easier by decreasing duodenal peristalsis. • The nurse observes closely for signs of respiratory and CNS depression, hypotension, oversedation, and vomiting (if glucagon is administered). • During the procedure, the nurse monitors IV fluids, administers medications, and positions the patient. • After the procedure, the nurse monitors the patient's condition, observing vital signs and monitoring for signs of perforation or infection. • The nurse monitors the patient for side effects of any medications received during the procedure and for return of the gag and cough reflexes after the use of local anesthetics.
Fiberoptic colonoscopy	• Adequate colon cleansing provides optimal visualization and decreases the time needed for the procedure. The physician may prescribe a laxative for two nights before the examination and a Fleet's or saline enema until the return is clear the morning of the test. More commonly, polyethylene glycol electrolyte lavage solutions (Go-LYTELY, CoLyte, and Nu-Lytely) are used as intestinal lavages for effective cleansing of the bowel. • The patient maintains a clear liquid diet starting at noon the day before the procedure. Then the patient ingests the lavage solution orally at intervals over 3–4 hours. If necessary, the nurse can give the solution through a feeding tube if the patient cannot swallow. • Patients with a colostomy receive this same bowel preparation. • The use of lavage solutions is contraindicated in patients with intestinal obstruction or inflammatory bowel disease. • Side effects of the electrolyte solutions include nausea, bloating, cramping or abdominal fullness, fluid and electrolyte imbalance, and hypothermia.
	• The side effects are especially problematic for elderly patients, and sometimes they have difficulty ingesting the required volume of solution. Monitoring elderly patients after a bowel prep is especially important because their physiologic ability to compensate for fluid loss is diminished. • Many elderly people take multiple medications each day; therefore, the nurse's knowledge of their daily medication regimen can prompt assessment for and prevention of potential problems and early detection of physiologic changes.
Gastric analysis, gastric acid stimulation test	• The patient is NPO for 8–12 hours before the procedure. • Any medications that affect gastric secretions are withheld for 24–48 hours before the test. • Smoking is not allowed on the morning of the test because it increases gastric secretions.
Laparoscopy (peritoneoscopy)	• The patient is NPO 12 hours prior to the procedure. An empty stomach lowers the chance of vomiting during or after the procedure. • An enema may be prescribed the day before or several hours prior to the procedure to empty the colon. • The patient should ask the primary care provider if daily medicines should be taken the day of the laparoscopy.
Lower GI series (Barium enema)	• Preparation includes emptying and cleansing the lower bowel. This often necessitates a low-residue diet 1–2 days before the test, a clear liquid diet and a laxative the evening before, NPO after midnight, and cleansing enemas until returns are clear the following morning. • The nurse makes sure that barium enemas are scheduled before any upper GI studies. • If the patient has active inflammatory disease of the colon, enemas are contraindicated. Barium enemas also are contraindicated in patients with signs of perforation or obstruction; instead, a water-soluble contrast study may be performed. • Active GI bleeding may prohibit the use of laxatives and enemas. • Postprocedural patient education includes information about increasing fluid intake, evaluating bowel movements for evacuation of barium, and noting increased number of bowel movements, because barium, due to its high osmolarity, may draw fluid into the bowel, thus increasing the intraluminal contents and resulting in greater output.

MRI	• The patient should be NPO 6–8 hours before the study. • Any ferromagnetic objects (metals that contain iron) can be attracted to the magnet and cause injury. Items that can be problematic or dangerous include jewelry, pacemakers, dental implants, paperclips, pens, keys, IV poles, clips on patient gowns, and oxygen tanks. • The patient and family are informed that the study may take 60–90 minutes; during this time, the technician will instruct the patient to take deep breaths at specific intervals. • The close-fitting scanners used in many MRI facilities may induce feelings of claustrophobia, and the machine will make a knocking sound during the procedure. Patients may choose to wear a headset and listen to music or to wear a blindfold during the procedure. Open MRIs that are less close-fitting eliminate the claustrophobia that many patients experience. • MRI is contraindicated for patients with permanent pacemakers, artificial heart valves and defibrillators, implanted insulin pumps, or implanted transcutaneous electrical nerve stimulation devices because the magnetic field could cause malfunction of the device. • MRI is also contraindicated for patients with internal metal devices (e.g., aneurysm clips) or intraocular metallic fragments. Foil-backed skin patches (e.g., NicoDerm, nitroglycerine [Transderm-Nitro], scopolamine [Transderm-Scop], clonidine [Catapres-TTS]) should be removed before an MRI because of the risk of burns; however, the patient's physician should be consulted before the patch is removed to determine whether an alternate form of the medication should be provided.
PET	• The patient should be NPO for 4 hours on the day of the test. • The patient should refrain from alcohol, caffeine, and tobacco for 24 hours. • Diabetic patients should take their pretest dose of insulin with a meal 3–4 hours before the test. • The patient should be informed that an IV line may be inserted. • After the PET, the patient should change position slowly from lying to standing to avoid postural hypotension. • The patient should be encouraged to drink fluids and urinate frequently to aid in the removal of the radioisotope from the bladder.
pH monitoring	• The patient is NPO for 6 hours before the test. • All medications affecting gastric secretions are withheld for 24–36 hours before the test.
Small-bowel enteroscopy with capsule endoscope (CE)	• The patient must be NPO for 8–10 hours before the test and be NPO for the first 2 hours of the testing. • At the time of the procedure, the patient's abdomen is marked for the location of the sensors, and the 8-lead sensors are applied. The patient wears an abdominal belt that houses a recorder to capture the transmitted images. • After the capsule is taken with a glass of water, the patient may return to normal activity for the remainder of the study. The patient can resume a normal diet 4 hours after the ingestion of the capsule. • During the procedure, the patient may receive a mild sedative and pain medication for comfort. At the end of the procedure, the patient returns to the facility with the receiver for downloading to a central computer. • The procedure lasts approximately 8 hours. • The capsule endoscopy is a single-use device that is propelled through the GI tract by peristalsis and excreted naturally. The patient should be informed that the capsule will be excreted in the stool. • If the patient is concerned about nonevacuation of the capsule, an abdominal x-ray can establish if it has been retained.
Stool tests	• Should not be performed if there is hemorrhoidal bleeding. • Careful assessment of the patient's diet and medication regimen is essential to avoid incorrect interpretation of results. Red meats, fish, turnips, horseradish, and NSAIDs should be avoided for 72 hours prior to the study because they may cause a false-positive result. Ingestion of vitamin C from supplements or foods can cause a false-negative result. • A small amount of the specimen is applied to the guaiac-impregnated paper slide. If the test is performed at home, then the patient mails the slide to the health care provider or laboratory in an envelope provided for that purpose. • Other occult blood tests that may yield more specific and more sensitive readings include Hematest II SENSA and HemoQuant.

Ultrasonography	• No fasting is required for ultrasonography of the abdominal aorta, kidney, liver, spleen, or pancreas, but fasting is preferred before ultrasonography of the gallbladder and biliary tree. • During the procedure, the patient is lying down. The patient may be asked to change position so that the health care provider can examine different areas. • The patient also may be asked to hold his or her breath for short periods of time during the examination.
Upper GI fibroscopy/ esophagogastroduodenoscopy	• The patient should be NPO for 8 hours prior to the examination. • A sedative that provides moderate sedation and relieves anxiety during the procedure may be administered at the initiation of the study. • Before the introduction of the endoscope, the patient is given a local anesthetic gargle or spray. • The patient is placed in the left lateral position to facilitate clearance of pulmonary secretions and provide smooth entry of the scope. • After gastroscopy, assessment includes level of consciousness, vital signs, oxygen saturation, pain level, and monitoring for signs of perforation (i.e., pain, bleeding, unusual difficulty swallowing, and rapidly elevated temperature). • After the patient's gag reflex has returned, lozenges, saline gargle, and oral analgesics may be offered to relieve minor throat discomfort. • Patients who were sedated for the procedure must remain in bed until fully alert.
Upper GI series (Barium swallow)	• The patient is instructed to fast after midnight the day before the test. • Smoking, chewing gum, and using mints can stimulate gastric motility; therefore, the nurse advises against these practices. • Typically, oral medications are withheld on the morning of the study and resumed that evening, but each patient's medication regimen should be evaluated on an individual basis. • Follow-up care is provided after the upper GI procedure to ensure that the patient has eliminated most of the ingested barium. Fluids may be increased to facilitate evacuation of stool and barium.
Urine tests	• Amylase can be detected in the urine. There is an increased renal clearance of amylase in patients with acute pancreatitis. Amylase levels in the urine remain high even after serum levels return to normal. • Urine urobilinogen is a form of bilirubin that is converted by the intestinal flora and excreted in the urine. Its measurement is useful in the evaluation of liver and biliary obstruction. The presence of bilirubin in urine often precedes the development of jaundice. For the urine urobilinogen test, some laboratories require keeping the patient NPO after midnight the day of the test, except for water.

ALT, alanine aminotransferase; AST, aspartate aminotransferase; CA 19-9, carbohydrate antigen 19-9; CEA, carcinoembryonic antigen; CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; GI, gastrointestinal tract; IV, intravenous; MRI, magnetic resonance imaging; NSAIDs, nonsteroidal anti-inflammatory drugs; NPO (*nil per os*), nothing by mouth; PET, positron emission tomography.

Ultrasonography is the diagnostic procedure of choice for gallbladder disease because it is rapid and accurate and can be used in patients with liver dysfunction and jaundice. It does not expose patients to ionizing radiation. The procedure is most accurate if the patient fasts for 4 to 6 hours prior to the procedure so that the gallbladder is distended (Schiff, Maddrey, & Sorrell, 2012). Ultrasound studies are based on analysis of reflected sound waves. Ultrasound findings include gallbladder sludge, gallbladder wall thickening, and pericholecystic fluid, which are diagnostic for acute cholecystitis. Ultrasonography is diagnostic of calculi in 90% to 95% of cases as it detects thickening of the gallbladder wall, pericholecystic fluid and dilation of the bile duct which are all signs of gallbladder inflammation (Kasper et al., 2015).

Cholescintigraphy (a nuclear medicine test also known as HIDA [hepatobiliary iminodiacetic acid]) or gallbladder scan helps determine if obstruction of the cystic duct is the underlying cause of cholecystitis. The patient is injected with TC-99m HIDA; if the gallbladder is not filled within 60 minutes in response to the injection, it is considered abnormal but not completely diagnostic of acute cholecystitis (Ziessman, O'Malley, & Thrall, 2014). Cholescintigraphy is 90% to 97% sensitive in diagnosing acute cholecystitis but the presence of a stone or tumor-causing cystic duct obstruction without acute cholecystitis may result in a false-positive result (Zakko & Afdhal, 2015).

Endoscopic ultrasonography (EUS) is a specialized enteroscopic procedure that aids in the diagnosis of GI disorders by providing direct imaging of a target area. A small, high-frequency ultrasonic transducer is mounted at the tip of the fiberoptic scope, which displays an image that enables tumor staging and visualization of marginal structures. This procedure delivers results with higher-quality resolution and definition in comparison with regular ultrasonic imaging. EUS may be used for evaluating submucosal lesions, specifically determining their location and depth of penetration. In addition, EUS may aid in the evaluation of Barrett esophagus, portal hypertension, chronic pancreatitis, suspected pancreatic neoplasm, biliary tract disease, and changes in the bowel wall that occur in ulcerative colitis. Intestinal gas, bone, and thick layers of adipose tissue (all of which hamper conventional ultrasonography) are not problematic when EUS is used.

DNA Testing

Researchers have refined methods for genetics risk assessment, preclinical diagnosis, and prenatal diagnosis to identify people who are at risk for certain GI disorders (e.g., gastric cancer, lactose deficiency, inflammatory bowel disease, or colon cancer). In some cases, DNA testing allows providers to prevent (or minimize) disease by intervening before its onset and to improve therapy; however, it is imperative to seek advice from genetics counselors routinely, given the exponential growth of genetics information. People who are identified as at risk of certain GI disorders may choose to undergo genetic counseling to learn about the disease, to understand options for preventing and treating the disease, and to receive support in coping with the situation. Ethical and legal issues are involved in genetic testing, and there are legal protections for clients against discrimination. For instance, false-positive results can create unnecessary worry, alarm, and further testing, typically at the expense of the patient and the family, with potential effects on health-related quality of life (Hidayatallah et al., 2014).

Imaging Studies

Many minimally invasive and noninvasive imaging studies, including x-ray and contrast studies, computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET), and virtual endoscopy, are available today to aid in the accurate assessment of the many possible causes of GI abnormalities.

Upper Gastrointestinal Tract Study

An upper GI study delineates the entire GI tract after the introduction of a contrast agent. A radiopaque liquid (e.g., barium sulfate) is commonly used; however, thin barium, Hypaque, and, at times, water are used due to their low associated risks. The GI series enables the examiner to detect or exclude anatomic or functional derangement of the upper GI organs or sphincters. It also aids in the diagnosis of ulcers, varices, tumors, regional enteritis, and malabsorption syndromes. The procedure may be extended to examine the duodenum and small bowel (small bowel follow-through). As the barium descends into the stomach, the position, patency, and caliber of the esophagus are visualized, enabling the examiner to detect or exclude any anatomic or functional derangement of that organ. Fluoroscopic examination next extends to the stomach as its lumen fills with barium, allowing observation of stomach motility, thickness of the gastric wall, the mucosal pattern,

patency of the pyloric valve, and the anatomy of the duodenum. Multiple x-ray films are obtained during the procedure, and additional images may be taken at intervals for up to 24 hours to evaluate the rate of gastric emptying. Small-bowel x-rays taken while the barium is passing through that area allow for observation of the motility of the small bowel. Obstructions, ileitis, and diverticula can be detected if present.

Variations of the upper GI study include double-contrast studies and enteroclysis (defined below). The double-contrast method of examining the upper GI tract involves administration of a thick barium suspension to outline the stomach and esophageal wall, after which tablets that release carbon dioxide in the presence of water are administered. This technique has the advantage of showing the esophagus and stomach in finer detail, permitting signs of early superficial neoplasms to be noted.

Enteroclysis is a very detailed, double-contrast study of the entire small intestine that involves the continuous infusion, through a duodenal tube, of 500 to 1,000 mL of a thin barium sulfate suspension; after this, methylcellulose is infused through the tube. The barium and methylcellulose fill the intestinal loops and are observed continuously by fluoroscopy and viewed at frequent intervals as they progress through the jejunum and the ileum. This process (even with normal motility) can take up to 6 hours and can be quite uncomfortable for the patient. The procedure aids in the diagnosis of partial small-bowel obstructions or diverticula.

Lower Gastrointestinal Tract Study

Visualization of the lower GI tract is obtained after rectal installation of barium. The barium enema can be used to detect the presence of polyps, tumors, or other lesions of the large intestine and demonstrate any anatomic abnormalities or malfunctioning of the bowel. After proper preparation and evacuation of the entire colon, each portion of the colon may be readily observed. The procedure usually takes about 15 to 30 minutes, during which time x-ray images are obtained.

Other means for visualizing the colon include double-contrast studies and a water-soluble contrast study. A double-contrast, or air-contrast, barium enema involves the instillation of a thicker barium solution, followed by the instillation of air. The patient may feel some cramping or discomfort during this process. This test provides a contrast between the air-filled lumen and the barium-coated mucosa, allowing easier detection of smaller lesions.

If active inflammatory disease, fistulas, or perforation of the colon is suspected, a water-soluble iodinated contrast agent (e.g., Gastrografin) can be used. The procedure is the same as for a barium enema, but the patient must be assessed for allergy to iodine or contrast agent. The contrast agent is eliminated readily after the procedure so there is no need for postprocedure laxatives. Some diarrhea may occur in a few patients until the contrast agent has been totally eliminated.

Computed Tomography

CT provides cross-sectional images of abdominal organs and structures. Multiple x-ray images are taken from numerous angles, digitized in a computer, reconstructed, and then viewed on a computer monitor. The procedure is completely painless, but radiation doses are considerable. New continuous-motion (helical or spiral), three-dimensional CT, which

provides very detailed pictures of the GI organs and vasculature, has been developed.

Magnetic Resonance Imaging

MRI is used in gastroenterology to supplement ultrasonography and CT. This noninvasive technique uses magnetic fields and radio waves to produce an image of the area being studied. The use of oral contrast agents to enhance the image has increased the application of this technique for the diagnosis of GI diseases. It is useful in evaluating abdominal soft tissues as well as blood vessels, abscesses, fistulas, neoplasms, and other sources of bleeding.

Positron Emission Tomography

PET produces images of the body by detecting the radiation emitted from radioactive substances. The radioactive substances are injected into the body intravenously and usually are tagged with a radioactive atom, such as carbon-11, fluorine-18, oxygen-15, or nitrogen-13. The atoms decay quickly, do not harm the body, have lower radiation levels than a typical x-ray or CT scan, and are eliminated in the urine or feces. The scanner essentially "captures" where the radioactive substances are in the body, transmits information to a scanner, and produces a scan with "hot spots" for evaluation by the radiologist or oncologist.

Endoscopy Procedures

Endoscopy procedures are performed for a variety of reasons and are associated with a variety of psychological reactions from the patients. Many patients avoid the recommended endoscopies out of fear of the procedure or what the procedure may find. In recent years, propofol has been used increasingly during endoscopy procedures instead of sedation with the combination of an opiate and benzodiazepine. Box 21-1 details nursing responsibilities associated with the use of propofol during a GI endoscopy procedure.

Upper Gastrointestinal Fibroscopy/Esophagogastroduodenoscopy

Fibroscopy of the upper GI tract allows direct visualization of the esophageal, gastric, and duodenal mucosa through a lighted endoscope (Fig. 21-9). Esophagogastroduodenoscopy (EGD) is especially valuable when esophageal, gastric, or duodenal abnormalities or inflammatory, neoplastic, or infectious processes are suspected. This procedure also can be used to evaluate esophageal and gastric motility and to collect secretions and tissue specimens for further analysis.

BOX 21-1 Sedation and Anesthesia in Gastrointestinal Endoscopy

Endoscopy is direct visualization of the GI tract using a flexible fiberoptic endoscope. Visualization of the esophagus, stomach, biliary system, and bowel is possible with an endoscope. Sedation is given to reduce anxiety and diminish the patient's memory of this uncomfortable event. The level of sedation required to perform an endoscopy ranges from minimal sedation to general anesthesia.

In recent years, studies have identified advantages of using propofol during endoscopy procedures over sedation with the combination of an opiate (pethidine and

fentanyl are the most popular) and benzodiazepines (midazolam is the benzodiazepine of choice because of its shorter duration of action and better pharmacokinetic profile compared with diazepam). Propofol during GI endoscopy procedures can lead to patient and physician satisfaction, improved patient cooperation, faster recovery, and mild antiemetic properties. Propofol is currently preferred for the endoscopic sedation of patients with advanced liver disease due to its short biologic half-life and lower risk of inducing hepatic encephalopathy. However, there are some disadvantages, including the potential to induce hypotension as it is a cardiovascular depressant and respiratory depression and the fact that there is no pharmacologic antagonist.

The patient should be monitored to detect any changes in pulse, blood pressure, ventilator status (RR, and O_2 saturation), cardiac electrical activity, and neurologic status. An individual with skill sets including certification in basic and advanced cardiac life support should be present to monitor and interpret the patient's status throughout the procedure. The use of an anesthesiologist is recommended in the following situations: endoscopic procedures requiring deep sedation, anticipated intolerance to standard sedatives, multiple comorbidities (obesity; pregnancy; elderly individuals; as well as patients with chronic lung, kidney, or liver disease), and increased risk for airway obstruction because of anatomical variation.

Adapted from American Society for Gastrointestinal Endoscopy, 2008; Triantafillidis et al., 2013.

FIGURE 21-9 Patient undergoing gastroscopy (fibroscopy of the upper GI tract).

In EGD, the gastroenterologist views the GI tract through a viewing lens and can take still or video photographs through the scope to document findings. Electronic video endoscopes also are available that attach directly to a video processor, converting the electronic signals into pictures on a television screen. This allows larger and continuous viewing capabilities, as well as the simultaneous recording of the procedure.

PillCam ESO2, a pill-sized instrument equipped with two cameras, is available. Each camera takes photographs, and it is used to detect the presence of varices or diseases of the esophageal mucosa. A disadvantage is that it does not allow for obtaining biopsies and cannot be used to perform therapeutic procedures, such as esophageal banding to treat esophageal varices (Cave, Saltzman, & Travis, 2015).

Two additional drawbacks to this method of endoscopy are that it evaluates only the esophagus and that it may become lodged in a previously anastomosed section of bowel and require further endoscopic or surgical intervention for removal.

Side-viewing flexible scopes are used to visualize the common bile duct and the pancreatic and hepatic ducts through the ampulla of Vater in the duodenum. This procedure, called endoscopic retrograde cholangiopancreatography (ERCP), uses the endoscope in combination with x-ray techniques to view the ductal structures of the biliary tract. ERCP is helpful in detecting and treating bile duct stones, bile duct strictures, pancreatic duct disruption, and sphincter of Oddi dysfunction. It should be used carefully in patients diagnosed with acute pancreatitis as it may worsen the severity of the condition (Daniels, 2014). The examination of the hepatobiliary system is carried out via a side-viewing flexible fiberoptic endoscope inserted through the esophagus to the descending duodenum (Fig. 21-10). Multiple position changes are required to pass the endoscope during the procedure, beginning in the left semiprone position. Careful insertion of a catheter through the endoscope into the common bile duct is the most important step in sphincterotomy (division of the muscles of the biliary sphincter) for gallstone extraction via this technique. Although ERCP has been considered the procedure of choice in evaluating biliary disorders, it is now used less frequently as it has been replaced by other imaging methods such as transabdominal and endoscopic ultrasonography, multislice helical CT, and MRI/MRCP (magnetic resonance imaging/cholangiopancreatography) (Hawkey, Bosche, Richter, Garcia-Tsao, & Chan, 2012).

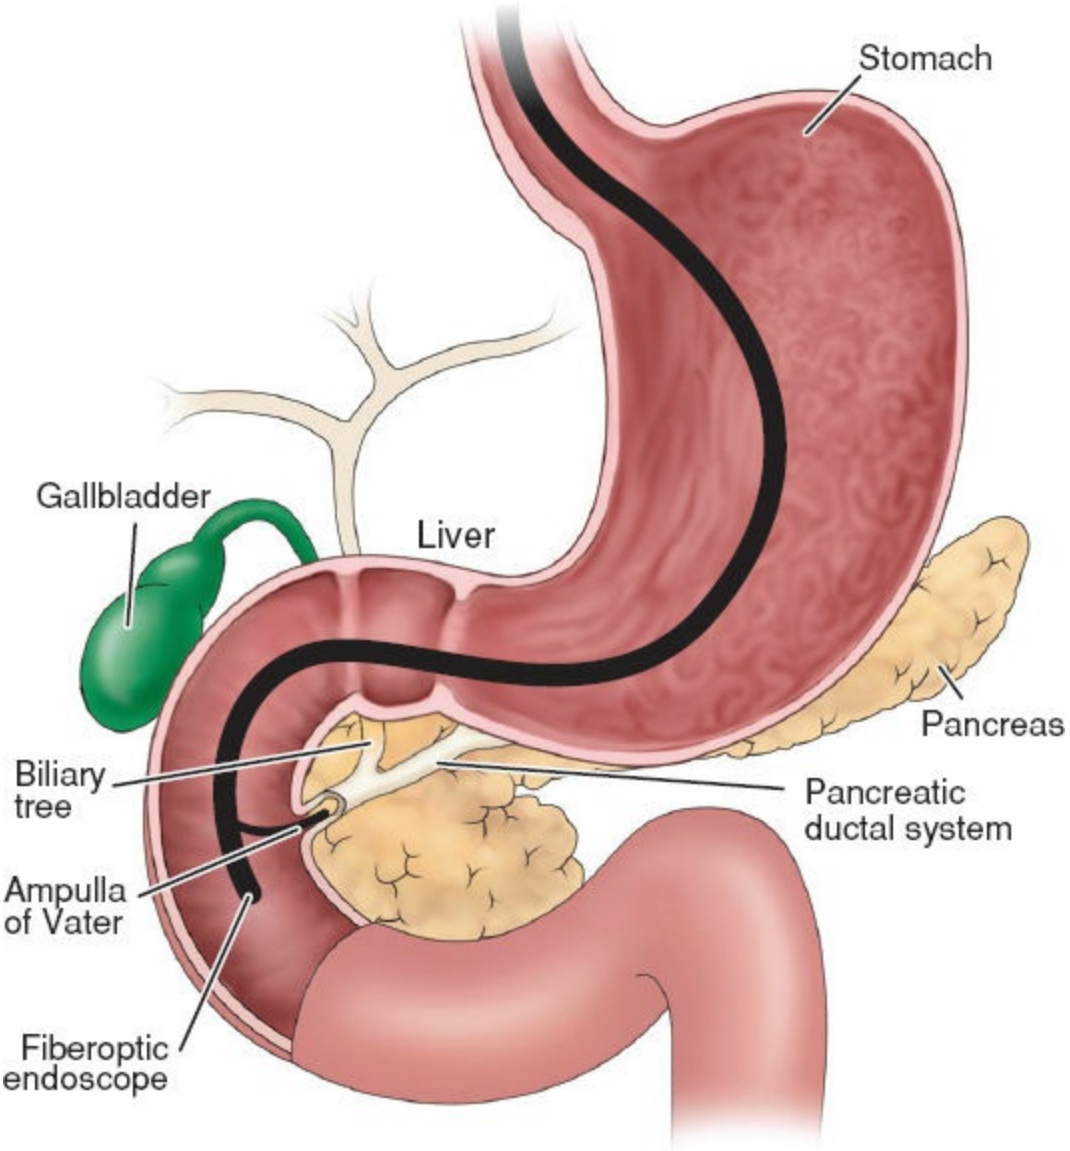

FIGURE 21-10 Endoscopic retrograde cholangiopancreatography (ERCP). A fiberoptic duodenoscope, with side-viewing apparatus, is inserted into the duodenum. The ampulla of Vater is catheterized, and the biliary tree is injected with contrast agent. The pancreatic ductal system is also assessed, if indicated. This procedure is of special value in visualizing neoplasms of the ampulla area and extracting a biopsy specimen.

Upper GI fibroscopy also can be a therapeutic procedure when it is combined with other procedures. Therapeutic endoscopy can be used to remove common bile duct stones, dilate strictures, and treat gastric bleeding and esophageal varices. Laser-compatible scopes can be used to provide laser therapy for upper GI neoplasms. Sclerosing solutions can be injected through the scope in an attempt to control upper GI bleeding in cases such as bleeding ulcers and varices.

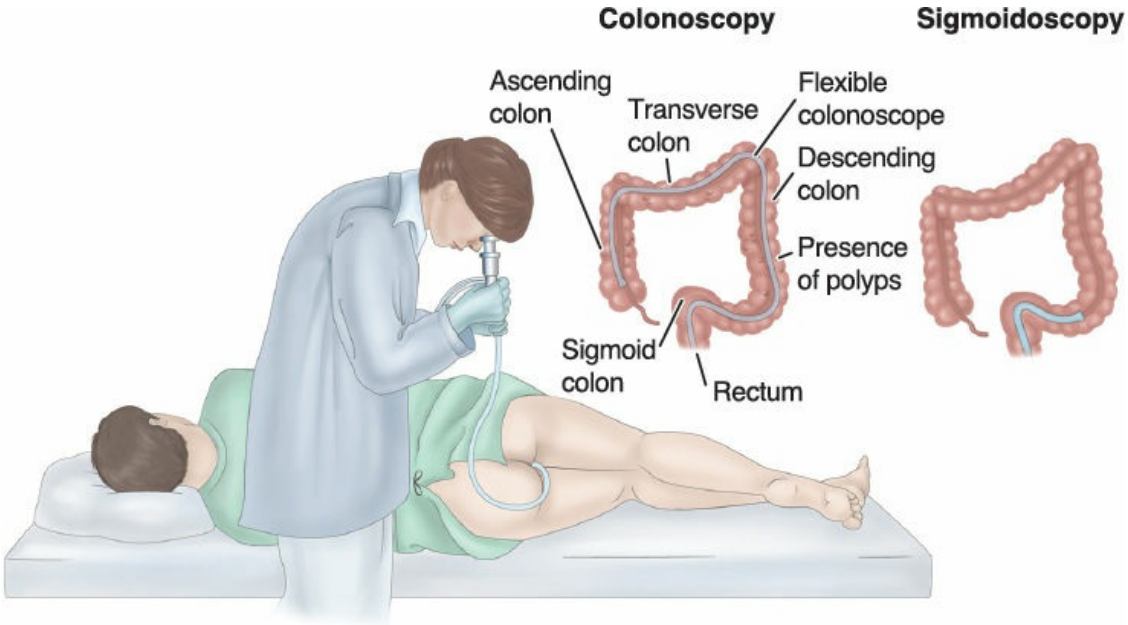

FIGURE 21-11 Colonoscopy. The flexible scope is passed through the rectum and sigmoid colon into the descending, transverse, and ascending colon.

Fiberoptic Colonoscopy

Historically, direct visualization of the bowel was the only means to evaluate the colon, but virtual colonoscopy (also known as CT colonography) has brought a more patient-friendly approach to this study. First described by Vining in 1994, virtual colonoscopy provides a computer-simulated endoluminal perspective of the air-filled distended colon using conventional spiral or helical CT scanning (Johnson, 2009). Because it can accurately identify tumor location, nodal, staging, and extent, it may become the diagnostic tool of choice in evaluating colorectal cancers preoperatively (Stagnitti et al., 2015).

Direct visual inspection of the large intestine (anus, rectum, sigmoid, transcending and ascending colon) is possible by means of a flexible fiberoptic colonoscope (Fig. 21-11). These scopes have the same capabilities as those used for EGD but are larger in diameter and longer. Still and video recordings can be used to document the procedure and findings.

This procedure is used commonly as a diagnostic aid and screening device. It is most frequently used for cancer screening (Box 21-2) and for surveillance in patients with previous colon cancer or polyps. In addition, tissue biopsies can be obtained as needed, and polyps can be removed and evaluated. Other uses of colonoscopy include the evaluation of patients with diarrhea of unknown cause, occult bleeding, or anemia; further study of abnormalities detected on barium enema; and diagnosis, clarification, and determination of the extent of inflammatory or other bowel disease.

Therapeutically, the procedure can be used to remove all visible polyps with a special snare and cautery through the colonoscope. Many colon cancers begin with adenomatous polyps of the colon; therefore, one goal of colonoscopic polypectomy is early detection and prevention of colorectal cancer. This procedure also can be used to treat areas of bleeding or stricture. Use of bipolar and unipolar coagulators, use of heater probes, and injections of sclerosing agents or vasoconstrictors are all possible during this procedure. Laser-compatible scopes provide laser therapy for bleeding lesions or colonic neoplasms. Bowel decompression (removal of intestinal contents to prevent gas and fluid from distending the

coils of the intestine) also can be completed during the procedure.

BOX 21-2 Health Promotion

Guidelines for Colon and Rectal Cancer Screening

- Colorectal screening is currently divided into one of two groups: those tests that primarily detect cancer, including fecal occult blood test (FOBT), fecal immunochemical test (FIT) or stool tests for exfoliated DNA (sDNA), or those that detect cancer and advanced lesions, such as endoscopic and radiologic testing, flexible sigmoidoscopy, colonoscopy, double barium enema, CT colonography, or virtual colonoscopy. Beginning at 50 years of age, both men and women should follow one of these testing schedules:
  - Annual high-sensitivity FOBT
  - sDNA test every 3 years
  - Flexible sigmoidoscopy every 5 years
  - Colonoscopy every 10 years
  - Double-contrast barium enema every 5 years
  - CT colonoscopy every 5 years

  All tests with positive results should be followed up with colonoscopy.

  Individuals should talk to their providers about starting colorectal cancer screening earlier and/or undergoing screening more often if they have any of the following risk factors for colorectal cancer:
- A personal history of colorectal cancer or adenomatous polyps
- A strong family history of colorectal cancer or colorectal adenomas found in first-degree relatives (guidelines are based upon relatives' age at diagnosis)
- A personal history of chronic inflammatory bowel disease
- A family history of a hereditary colorectal cancer syndrome (familial adenomatous polyposis or hereditary nonpolyposis colon cancer)
- Patients who have had curative-intent resection of colorectal cancer

Smith et al., 2015.

Colonoscopy is performed while the patient is lying on the left side with the legs drawn up toward the chest. The patient's position may be changed during the test to facilitate advancement of the scope. Biopsy forceps or a cytology brush may be passed through the scope to obtain specimens for histology and cytology examinations. Complications during and after the procedure can include cardiac arrhythmias and respiratory depression resulting from the medications administered, vasovagal reactions, bowel perforation, bleeding from biopsy sites, and circulatory overload or hypotension resulting from overhydration or underhydration during bowel preparation. Therefore, it is important to monitor the patient's cardiac and respiratory function and oxygen saturation continuously,

providing supplemental oxygen used as necessary. Typically, the procedure takes about 1 hour, and postprocedure discomfort results from instillation of air to expand the colon and insertion and movement of the scope during the procedure.

Anoscopy, Proctoscopy, and Sigmoidoscopy

Endoscopic examination of the anus, rectum, and sigmoid and descending colon is used to evaluate chronic diarrhea, fecal incontinence, ischemic colitis, and lower GI hemorrhage and to observe for ulceration, fissures, abscesses, tumors, polyps, and other pathologic processes.

Flexible scopes have largely replaced the rigid scopes used in the past for routine examinations. The flexible fiberoptic sigmoidoscope (see Fig. 21-11) permits the colon to be examined up to 40 to 50 cm (16 to 20 in) from the anus, much more than the 25 cm (10 in) that can be visualized with the rigid sigmoidoscope. It has many of the same capabilities as the scopes used for the upper GI study, including the use of still or video images to document findings.

For flexible scope procedures, the patient assumes a comfortable position on the left side with the right leg bent and placed anteriorly. It is important to keep the patient informed throughout the examination and to explain the sensations associated with the examination. Biopsies and polypectomies can be performed during this procedure. Biopsy is performed with small biting forceps introduced through the endoscope; one or more small piece of tissue may be removed. If rectal or sigmoid polyps are present, they may be removed with a wire snare, which is used to grasp the pedicle or stalk. Then an electrocoagulating current is used to sever the polyp and prevent bleeding. It is extremely important that all excised tissue be placed immediately in moist gauze or in an appropriate receptacle, labeled correctly, and delivered without delay to the pathology laboratory for examination. Monitoring the patient for early signs of cardiac arrhythmias, perforation, and hemorrhage are important considerations.

Endoscopy for Esophageal Varices

Esophageal varices are varicosities that develop from elevated pressure in the veins that drain into the portal system. Varices are associated with cirrhosis of the liver. They are prone to rupture and often are the source of massive hemorrhages from the upper GI tract. Immediate endoscopy is indicated to identify the cause and the site of bleeding; at least 30% of patients with suspected bleeding from esophageal varices are actually bleeding from another source (gastritis, ulcer). Nursing support can be effective in relieving anxiety during this often stressful experience. Careful monitoring can detect early signs of cardiac arrhythmias, perforation, and hemorrhage.

After the examination, fluids are not given until the gag reflex returns. Lozenges and gargles may be used to relieve throat discomfort if the patient's physical condition and mental status permit. If the patient is actively bleeding, oral intake will not be permitted, and the patient will be prepared for further diagnostic and therapeutic procedures.

Laparoscopy (Peritoneoscopy)

With the tremendous advances in minimally invasive surgery, diagnostic laparoscopy is efficient, cost-effective, and useful in the diagnosis of GI disease. After creating a

pneumoperitoneum (gas, usually carbon dioxide, is insufflated into the peritoneal cavity to separate the intestines from the pelvic organs, creating a working space for visualization), a small incision is made lateral to the umbilicus, allowing for the insertion of the fiberoptic laparoscope. This allows direct access to the organs and structures within the abdomen, permitting visualization and identification of any growths, anomalies, and inflammatory processes. In addition, biopsy samples can be taken from the structures and organs as necessary. This procedure can be used to evaluate peritoneal disease, chronic abdominal pain, abdominal masses, and gallbladder and liver disease. However, laparoscopy has not become an important diagnostic modality in patients with acute abdominal pain because less invasive tools (i.e., CT and MRI) are readily available. Laparoscopy usually requires general anesthesia and sometimes requires that the stomach and bowel be decompressed. One of the benefits of this procedure is that after visualization of a problem, then excision (e.g., removal of the gallbladder) can be performed at the same time, if appropriate. Patient complaints of shoulder and abdominal pain are associated with residual carbon dioxide effects. Postprocedure standard protocol for postoperative care is followed (see Chapter 5).

Small-Bowel Enteroscopy

Capsule endoscopy is a noninvasive enteroscopy that visualizes the entire small bowel, including the distal ileum. It is used to evaluate the source of GI bleeding. Prior to the development of the capsule endoscopy, visualization of the small intestine was inadequate and physicians relied primarily on barium x-rays for diagnosing disorders of the small intestine. Because the procedure is noninvasive, it has the capability to improve colorectal cancer screening and is useful in those patients where colonoscopy is incomplete (ranges between 10% and 40%) or where colonoscopy is contraindicated (Eliakim & Adler, 2015). The technique consists of the patient swallowing a capsule approximately the size of a vitamin pill that has embedded within it wireless miniature cameras at both ends, a light source, and an image transmission system that takes photographs as it passes through the GI tract (Eliakim & Adler, 2015). The capsule is propelled through the intestines by peristalsis and is excreted naturally in the stool in 1 to 2 days. During the procedure, images are transmitted from the capsule to a data recorder housed in an abdominal belt worn by the patient. In order to achieve accurate results, the bowel-cleansing procedure prior to ingesting the capsule is more rigorous than that of the standard colonoscopy (Sieg, 2011). In addition, the capsule may be retained requiring surgical intervention (Matsui, Matsumoto, Aoyagi, 2014). Colonoscopy remains the preferred method of screening for colorectal cancer as it allows for the removal of polyps and biopsy samples; the nurse must be cognizant that successful screening is dependent upon the quality of the colonoscopy (Sieg, 2011).

Another procedure used to visualize the entire mucosa of the small bowel, as well as to enable diagnostic and therapeutic interventions, is double-balloon enteroscopy (DBE) used with a push and pull method (Matsui et al., 2014). This endoscope has two balloons, one attached to the distal end of the scope and the other attached to the transparent overtube that slides over the endoscope. The endoscope is advanced using a push-and-pull technique that involves inflating and deflating the balloons alternatively. This process causes the telescoping of the small intestine onto the overtube, which enables the endoscope to visualize much more of the small intestine than the length of the scope itself. The procedure takes 1 to 3 hours and requires moderate sedation. DBE is indicated in patients

with inflammatory bowel disease, obstruction, neoplastic diseases, hemorrhagic disorders, bile/pancreatic diseases, and for the removal of foreign bodies. It is contraindicated in patients with perforations or severe inflammations (Matsui et al., 2014).

Endoscopy Through Ostomy

Endoscopy using a flexible endoscope through an ostomy stoma is useful for visualizing a segment of the small or large intestine and may be indicated to evaluate the anastomosis for recurrent disease or to visualize and treat bleeding in a segment of the bowel.

Gastric Analysis, Gastric Acid Stimulation Test, and pH Monitoring

Analysis of the gastric juice yields information about the secretory activity of the gastric mucosa and the presence or degree of gastric retention in patients thought to have pyloric or duodenal obstruction. It is also useful for diagnosing Zollinger-Ellison syndrome, or atrophic gastritis.

A small nasogastric tube with a catheter tip marked at various points is inserted through the nose. When the tube is at a point slightly less than 50 cm (21 in), it should be within the stomach, lying along the greater curvature. Once in place, the tube is secured to the patient's cheek, and the patient is placed in a semi-reclining position. The entire stomach contents are aspirated by gentle suction into a syringe.

The gastric acid stimulation test usually is performed in conjunction with gastric analysis. Histamine or pentagastrin is administered subcutaneously to stimulate gastric secretions. It is important to inform the patient that this injection may produce a flushed feeling. The nurse monitors the patient's blood pressure and pulse frequently to detect hypotension. Gastric specimens are collected after the injection every 15 minutes for 1 hour and are labeled to indicate the time of specimen collection after histamine injection. The volume and pH of the specimen are measured; in certain instances, cytologic study by the Papanicolaou technique may be used to determine the presence or absence of malignant cells.

Because gastroesophageal reflux with esophageal inflammation may predispose patients to adenocarcinomas of the esophagus, diagnosis of gastroesophageal reflux is important (Fisichella, Allaix, Morino, & Patti, 2014). One method of diagnosing reflux is through ambulatory pH monitoring, considered a valuable method for diagnosing gastroesophageal disease (Fisichella et al., 2014). This may be accomplished by attaching a transmitter sensitive to pH measurement to the esophagus or by inserting a catheter containing a probe through the nose and ending in the distal part of the esophagus to measure pH (Kasper et al., 2015). These measurements are taken while the patient is ambulatory and are measured over 24 to 48 hours (Kasper et al., 2015).

A Bernstein test, developed in the 1950s (Bashashati, Hejazi, Andrews, & Storr, 2014), may be performed to evaluate complaints of acid-related chest or epigastric pain. HCl is instilled through a small feeding tube positioned in the esophagus to try to elicit the reported chest pain. Resultant signs and symptoms are compared with the patient's usual symptoms. To date, the advantage in using this examination to diagnose GERD or functional esophageal disorder is unclear (Bashashati et al., 2014).

Esophageal Manometry

Esophageal manometry is the placement of a catheter via the esophagus that detects pressure and measures esophageal contractility while the patient swallows. It is used to detect motility abnormalities, such as achalasia or esophageal spasms, and to evaluate peristaltic activity of the esophagus prior to surgery (Kasper et al., 2015).

The Bravo pH monitoring system is a newer procedure that offers the advantage of pH monitoring of the esophagus without the transnasal catheter. The Bravo system involves a pH capsule about the size of a gel cap, which is temporarily attached to the wall of the esophagus. The Bravo pH capsule measures pH levels in the esophagus and transmits readings via radio telemetry to the pager-sized receiver worn on the patient's belt or waistband. The patient is instructed to push a button at the onset of symptoms, which then are associated with the presence or absence of acid reflux. If possible, the patient should discontinue using proton pump inhibitors for 5 to 7 days prior to the study. Data are collected for up to 48 hours and then downloaded and analyzed (Bashashati et al., 2014).

Liver Function Tests

Early recognition and assessment of liver dysfunction is critical to provide timely and appropriate care for the patient with acute or chronic liver disease. More than 70% of the parenchyma of the liver may be damaged before liver function test results become abnormal. Function is generally measured in terms of serum enzyme activity (i.e., serum aminotransferases, alkaline phosphatase [ALP], lactic dehydrogenase) and serum concentrations of proteins (albumin and globulins), bilirubin, ammonia, clotting factors, and lipids. Several of these tests may be helpful for assessing patients with liver disease. However, the nature and extent of liver dysfunction cannot be determined by these tests alone because other disorders can affect test results.

Serum aminotransferases (also called transaminases) are enzymes that reflect varying degrees of hepatocellular injury or inflammation of the liver and are useful in detecting acute liver disease, such as hepatitis. Alanine aminotransferase (ALT), aspartate aminotransferase (AST), and gamma-glutamyl transferase (GGT; also called G-glutamyl transpeptidase) are the most frequently used tests for liver damage. ALT levels increase primarily in liver disorders and may be used to monitor the course of hepatitis or cirrhosis or the effects of treatments that may be toxic to the liver. AST is present in tissues that have high metabolic activity; therefore, the level may be increased if there is damage to or death of tissues of organs such as the heart, liver, skeletal muscle, and kidney. Although not specific to liver disease, levels of AST may be increased in cirrhosis, hepatitis, and liver cancer. Abnormal aminotransferases may occur in the absence of any clinical indication of liver disease, and this finding requires further investigation to determine if it is incidental or if hepatic injury is present. The normal ratio of AST to ALT is 0.8. In most cases of hepatocellular damage, the AST is lower than the ALT and the AST/ALT ratio of 2:1 suggests liver injury caused by excessive alcohol ingestion (Friedman et al., 2015).

Increased GGT levels are associated with cholestasis but also can be due to alcoholic liver disease. Although the kidney has the highest level of the enzyme, the liver is considered the source of normal serum activity. Alkaline phosphatase (ALP) elevations may indicate injury to the biliary tree (i.e., biliary obstruction), presence of tumors, primary biliary cirrhosis, and primary sclerosing cholangitis. Elevations of both ALP and GGT indicate disease of the liver or biliary system. Elevation of ALP with normal GGT levels should

initiate evaluation for possible bone disease, as this enzyme is also present in bone tissue.

Other important tests to determine the extent of liver dysfunction are serum bilirubin, serum albumin, and prothrombin time as measured by the international normalized ratio (INR). These tests represent the synthetic function of the liver and are used as a prognostic tool to determine the severity of liver disease (Friedman et al., 2015). Common liver function tests are summarized in Table 21-7.

Liver Biopsy

Liver biopsy is considered the gold standard for the diagnosis of liver disease. A small sample of liver tissue is obtained, usually through needle aspiration, for microscopic evaluation of liver cells and architecture. The most common indication is to evaluate diffuse disorders of the parenchyma and to diagnose space-occupying lesions. Liver biopsy is especially useful when clinical findings and laboratory tests are not diagnostic. Bleeding and bile peritonitis after liver biopsy are the major complications; therefore, coagulation studies are obtained, their values are noted, and abnormal results are treated before liver biopsy is performed. Other techniques for liver biopsy are preferred if ascites or coagulation abnormalities exist. A liver biopsy can be performed percutaneously with ultrasound guidance or transvenously through the right internal jugular vein to the right hepatic vein under fluoroscopic control. Liver biopsy also can be performed laparoscopically. Guidelines for assisting with a liver biopsy are found in Box 21-3.

Paracentesis

Paracentesis is the removal of fluid (ascites) from the peritoneal cavity through a puncture or a small surgical incision through the abdominal wall under sterile conditions. Ultrasound guidance may be indicated in some patients who are at high risk for bleeding because of an abnormal coagulation profile and in those who have had previous abdominal surgery and may have adhesions. Also ultrasound guidance is recommended for patients in whom percussion cannot locate the ascites or in whom a first paracentesis attempt does not yield fluid (Garcia-Tsao, 2016). Paracentesis may be used for therapeutic reasons (removal of more than 5 L of fluid) to decrease intra-abdominal pressure resulting in dyspnea, abdominal pain, and abdominal fullness. In addition, paracentesis is appropriate for diagnostic purposes (Runyon, Chopra, & Travis, 2015) in evaluating new-onset ascites, diagnosing spontaneous versus secondary bacterial peritonitis, or detecting the presence of cancer. It is contraindicated in cases of acute abdomen and is generally not used in patients with lower volume ascites (less than 5 L), uncorrected hypovolemia, and those with a platelet count of less than 20,000/uL (Kasper et al., 2015). Paracentesis is used to evaluate patients whose clinical condition has deteriorated or to measure ascitic fluid for cell count, albumin total protein levels, culture, Gram stain, and neutrophilic count (Vincent, Abraham, Moore, Kochanek, & Fink, 2011).

TABLE 21-7 Common Laboratory Tests to Assess Liver Function

Test	Normal	Clinical Functions
Pigment Studies		
Serum bilirubin, direct Serum bilirubin, total Urine bilirubin Urine urobilinogen Fecal urobilinogen (infrequently used)	0–0.3 mg/dL (0–5.1 μmol/L) 0–0.9 mg/dL (1.7–20.5 μmol/L) 0(0) 0.05–2.5 mg/24 hr (0.09–4. Ehrlich U/24 hr) 50–300 mg/24 hr (100–400 Ehrlich U/100 g)	These studies measure the ability of the liver to conjugate and excrete bilirubin. Results are abnormal in liver and biliary tract diseases and are associated with jaundice clinically.
Protein Studies		
Total serum protein Serum albumin Serum globulin Serum protein electrophoresis Albumin Alpha$_1$-Globulin Alpha$_2$-Globulin Beta-Globulin Gamma-Globulin Albumin/globulin (A/G) ratio	7.0–7.5 g/dL (70–75 g/L) 4.0–5.5 g/dL (40–55 g/L) 1.7–3.3 g/dL (17–33 g/L) 4.0–5.5 g/dL (40–55 g/L) 0.15–0.25 g/dL (1.5–2.5 g/L) 0.43–0.75 g/dL (4.3–7.5 g/L) 0.5–1.0 g/dL (5–10 g/L) 0.6–1.3 g/dL (6–13 g/L) A > G or 1.5:1–2.5:1	Proteins are manufactured by the liver. Their levels may be affected in a variety of liver impairments: albumin is affected in cirrhosis, chronic hepatitis, edema, and ascites; globulins are affected in cirrhosis, liver disease, chronic obstructive jaundice, and viral hepatitis. A/G ratio is reversed in chronic liver disease (decreased albumin and increased globulin).
Prothrombin Time	100% or 12–16 seconds	Prothrombin time may be prolonged in liver disease. It will not return to normal with vitamin K in severe liver cell damage.
Serum Alkaline Phosphatase	Varies with method: 2–5 Bodansky units 30–50 U/L at 34°C (17–142 U/L at 30°C) (20–90 U/L at 30°C)	Serum alkaline phosphatase is manufactured in bones, liver, kidneys, and intestine and excreted through biliary tract. In the absence of bone disease, it is a sensitive measure of biliary tract obstruction.
Serum Aminotransferase Studies AST ALT	 10–40 units (4.8–19 U/L) 5–35 units (2.4–17 U/L)	The studies are based on release of enzymes from damaged liver cells. These enzymes are elevated in liver cell damage.
GGT, GGTP **LDH**	10–48 IU/L Adults: 140–280 U/L or 2.34–4.68 μkat/L	Elevated in alcohol abuse. Marker for biliary cholestasis.
Ammonia (plasma)	15–45 μg/dL (11–32 μmol/L)	Liver converts ammonia to urea. Ammonia level rises in liver failure.
Cholesterol		
Ester HDL (high-density lipoprotein) LDL (low-density lipoprotein)	60% of total (fraction of total cholesterol: 0.60) HDL Male: 35–70 mg/dL, Female: 35–85 mg/dL LDL <130 μg/dL	Cholesterol levels are elevated in biliary obstruction and decreased in parenchymal liver disease.

Large-volume (5 to 6 L) paracentesis has been shown to be a safe method for treating patients with severe ascites in those patients with diuretic-resistant ascites or those patients who have been unresponsive to medication or dietary restrictions. This technique may be used in combination with an isotonic albumin solution and sodium (sodium concentrations are dependent upon a hypervolemic or hypovolemic state) (Such, Runyon, Lindor, & Travis, 2015). Therapeutic paracentesis provides only temporary removal of fluid; ascites rapidly recur, necessitating repeated fluid removal. Guidelines for assisting with paracentesis are found in Box 21-4.

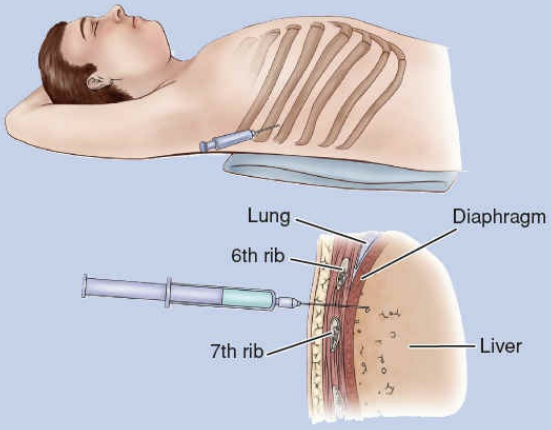
BOX 21-3 GUIDELINES FOR NURSING CARE

Assisting with Percutaneous Liver Biopsy

Equipment

- Liver biopsy tray (contains needles, scalpel, specimen tubes, etc.)
- Sterile gloves
- Antiseptic solution
- Local anesthetic
- Sterile dressing
- Sphygmomanometer to monitor BP

Implementation

NURSING ACTION	RATIONALE
Preprocedure	
1. Ascertain that results of coagulation tests (prothrombin time, partial thromboplastin time, and platelet count) are available and that compatible donor blood is available.	1. Many patients with liver disease have clotting defects and are at risk for bleeding.
2. Check for signed consent; confirm that informed consent has been provided.	2. Ensure that the patient consents to this invasive procedure.
3. Measure and record the patient's pulse, respirations, and blood pressure immediately before biopsy.	3. Prebiopsy values provide a basis on which to compare the patient's vital signs and evaluate status after the procedure.
4. Describe to the patient in advance: steps of the procedure, sensations expected, after-effects anticipated, restrictions of activity, and monitoring procedures to follow.	4. Explanations allay fears and ensure cooperation.
During Procedure	
1. Support the patient during the procedure.	1. Encouragement and support of the nurse enhance comfort and promote a sense of security.
2. Expose the right side of the patient's upper abdomen (right hypochondriac).	2. The skin at the site of penetration will be cleansed and a local anesthetic will be infiltrated.
3. Instruct the patient to inhale and exhale deeply several times, finally to exhale, and to hold breath at the end of expiration. The physician promptly introduces the biopsy needle by way of the transthoracic (intercostal) or transabdominal (subcostal) route, penetrates the liver, aspirates, and withdraws.	3. Holding the breath immobilizes the chest wall and the diaphragm; penetration of the diaphragm thereby is avoided, and the risk of lacerating the liver is minimized.
4. Instruct the patient to resume breathing.	4. The patient often continues holding his or her breath because of anxiety.
	


Postprocedure	
1. Immediately after the biopsy, some providers may suggest the patient turn onto the right side with a small pillow under the costal margin (provides extra pressure), and caution the patient to remain in this position, recumbent and immobile, for 2 hours. Instruct the patient to avoid coughing or straining.	1. In this position, the liver capsule at the site of penetration is compressed against the chest wall, and the escape of blood or bile through the perforation is prevented.
2. Measure and record the patient's pulse, respiratory rate, and blood pressure at 10- to 15-minute intervals for the first hour, then every 30 minutes for the next 1–2 hours or until the patient's condition stabilizes.	2. Changes in vital signs may indicate bleeding, severe hemorrhage, or bile peritonitis, rare but serious complications of liver biopsy.
3. If the patient is discharged after the procedure, instruct the patient to avoid heavy lifting and strenuous activity for 1 week.	3. Activity restriction reduces the risk of bleeding at the biopsy puncture site.

BOX 21-4 GUIDELINES FOR NURSING CARE

Assisting with a Paracentesis

Equipment

- Paracentesis tray (contains trocar, syringe, needles, drainage tube)
- Sterile gloves
- Antiseptic solution
- Local anesthetic
- Sterile dressing
- Drainage collection bottles, receptacles
- Sphygmomanometer to monitor BP

Implementation

NURSING ACTION	RATIONALE
Preprocedure	
1. Check for signed consent form.	1. Ensure that patient has agreed to procedure.
2. Prepare the patient by providing the necessary information and instructions and by offering reassurance.	2. Having information increases the patient's understanding of the procedure and the reason for it.
3. Instruct the patient to void.	3. An empty bladder minimizes the risk of inadvertent puncture of the bladder and minimizes discomfort from a full bladder.
4. Gather appropriate sterile equipment and collection receptacles.	4. Sterility of equipment is essential to minimize risk of infection; having equipment available enables the procedure to be performed smoothly.
5. Place the patient in an upright position on the edge of the bed or in a chair with feet supported on a stool. Fowler position should be used by the patient confined to bed.	5. An upright position results in movement of the peritoneal fluid close to the abdominal wall and promotes easier puncture and removal of fluid.
6. Place the sphygmomanometer cuff around the patient's arm.	6. This allows the nurse to monitor the patient's blood pressure during procedure.
During Procedure	
1. The physician, using aseptic technique, inserts the trocar through a puncture below the umbilicus. The trocar, or needle, is connected to a drainage tube, the end of which is inserted into a collecting receptacle. (see the figure next page)	1. Sterile technique minimizes the risk of infection. Bleeding at the puncture site is minimal at this location. The fluid drains by gravity or mild siphon into the container.
2. Help the patient maintain position throughout the procedure.	2. The patient who is fatigued or weak may have difficulty maintaining an optimal position for drainage of fluid.

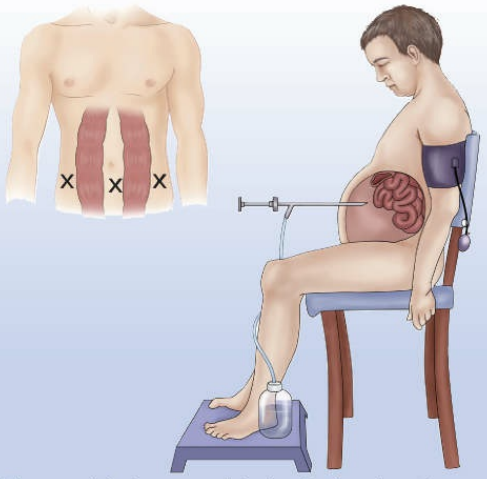


Figure on left shows possible sites for insertion of trocar.

3. Measure and record blood pressure at frequent intervals throughout the procedure.	3. Decreased blood pressure may occur with vascular collapse, which can result from removal of the fluid from the peritoneal cavity and fluid shifts.
4. Monitor the patient closely for signs of vascular collapse: pallor, increased pulse rate, or decreased blood pressure.	4. Vascular collapse (hypovolemia) may occur as fluid moves from the vascular system to replace fluid drained from peritoneal cavity.
Postprocedure	
1. Return the patient to bed or to a comfortable sitting position.	1. The weak or fatigued patient may have difficulty resuming a comfortable position without assistance.
2. Measure, describe, and record the fluid collected.	2. The volume of fluid removed may range from small to very large, and its removal may affect fluid and vascular status; volume should be included in input and output records. The characteristics of the fluid (clear vs. cloudy, red vs. colorless) may be helpful in diagnostic evaluation.
3. Label samples of fluid and send to laboratory.	3. Peritoneal fluid is analyzed as part of the diagnostic workup.
4. Monitor vital signs every 15 minutes for 1 hour, every 30 minutes for 2 hours, every hour for 2 hours, and then every 4 hours.	4. Vital signs (blood pressure, pulse rate) may change as fluid shifts occur after removal of fluid, especially if a large volume of fluid was removed.
5. Measure the patient's temperature.	5. An elevated temperature is a sign of infection and should be reported to the patient's provider.
6. Assess for hypovolemia, electrolyte shifts, changes in mental status, and encephalopathy.	6. Changes in fluid and electrolyte states and mental and cognitive status may occur with removal of fluid and fluid shifts and should be reported.
7. When taking vital signs, check puncture site for leakage or bleeding.	7. Leakage of fluid may occur because of changes in abdominal pressure and may contribute to further loss of fluid if undetected. Leakage suggests a possible site for infection, and bleeding may occur in patients with altered clotting secondary to liver disease.
8. Provide patient teaching regarding the need to monitor for bleeding or excessive drainage from the puncture site, the importance of avoiding heavy lifting or straining, the need to change position slowly, and frequency of monitoring for fever.	8. The patient (or family members) needs to monitor the patient overall and especially the puncture site for bleeding and excessive drainage if the patient is discharged home after the procedure. Heavy lifting or straining is avoided to enable the puncture site to close. Slow changes in position are recommended because of the risk of hypovolemia related to fluid removal. Monitoring for fever is needed to detect infection.

Transjugular Intrahepatic Portosystemic Shunt

Another option to treat patients with ascites who are diuretic resistant or to prevent reoccurrence of hemorrhage is by placement of a transjugular intrahepatic portosystemic shunt (TIPS). This shunt is surgically inserted under radiologic guidance (Kasper et al., 2015), through the internal jugular vein, creating a shunt or opening between the portal and hepatic veins in order to decrease portal pressure (Grossman & Porth, 2014). The nurse should monitor the patient for hepatic encephalopathy, a complication associated

with the TIPS. This complication is likely caused by the inability of ammonia and other toxic substances in the gut to pass through the liver (Grossman & Porth, 2014).

Cholecystography

Although cholecystography has been replaced by ultrasonography as the test of choice for gallstones, it is still used if ultrasound equipment is not available or if the ultrasound results are inconclusive. Oral cholecystography may be performed to detect gallstones and to assess the ability of the gallbladder to fill, concentrate its contents, contract, and empty. An iodide-containing contrast agent that is excreted by the liver and concentrated in the gallbladder is administered to the patient. The normal gallbladder fills with this radiopaque substance. If gallstones are present, they appear as shadows on the x-ray film.

The patient is asked about allergies to iodine or seafood. If no allergy is identified, the patient receives the oral form of the contrast agent the evening before the x-rays are obtained. Cholecystography in the obviously jaundiced patient is not useful because the liver cannot excrete the radiopaque dye into the gallbladder in the presence of jaundice.

CHAPTER REVIEW

Critical Thinking Exercises

1. While having blood pressure measurements taken at the adult day care center, one of the patients tells the nurse that this morning after he had a bowel movement, he noticed bright red blood on the toilet tissue. What further data would the nurse need to gather?

2. A 50-year-old female patient is seen in the emergency department complaining of right upper quadrant (RUQ) abdominal pain and cramping for the last 2 days. The symptoms usually began 1 to 2 hours after eating a dinner of fried or spicy foods. As a marketing specialist, she travels extensively and her usual dietary pattern consists of eating at restaurants several times weekly.
   a. For what aspect of the patient's history should the nurse seek additional information or clarification?
   b. What physical assessment findings would the nurse be most likely to find during the abdominal assessment?

NCLEX Style Review Questions

1. Which assessment finding does the nurse expect as a normal consequence of aging?
   a. Increased salivation and drooling
   b. Hyperactive bowel sounds and loose stools
   c. Increased gastric production and heartburn
   d. Decreased sensation to defecate and constipation

2. Which of the following foods could give a false-positive result on the fecal occult blood test (FOBT)? *Select all that apply.*

a. Red meats
b. Pasta
c. Turnips
d. Fish
e. Whole-grain bread

3. Which question will best assist the nurse in the assessment of a patient with acute diarrhea?
   a. "Have you had a colonoscopy in the last 3 months?"
   b. "Have you traveled outside the country recently?"
   c. "Do you have any trouble swallowing?"
   d. "Do you have any allergies?"

4. The nurse recognizes that most nutrients and electrolytes are absorbed by which organ?
   a. Esophagus
   b. Stomach
   c. Colon
   d. Small intestine

5. When performing an abdominal assessment on a patient with suspected cholecystitis, how does the nurse palpate the patient's abdomen?
   a. Palpate the right lower quadrant only
   b. Palpate the upper quadrants only
   c. Defer palpation and use percussion only
   d. Palpate the right upper quadrant last

CHAPTER 22

Nursing Management: Patients with Oral and Esophageal Disorders and Patients Receiving Gastrointestinal Intubation, Enteral, and Parenteral Nutrition

Zachary R. Krom

Learning Objectives

After reading this chapter, you will be able to:

1. Describe nursing management of patients with conditions of the oral cavity.
2. Use the nursing process as a framework for care of patients undergoing neck dissection.
3. Describe the various conditions of the esophagus and their clinical manifestations and management.
4. Describe the purposes and types of gastrointestinal intubation.
5. Discuss nursing management of the patient who has a nasogastric or nasoenteric tube.
6. Identify the purposes and uses of parenteral nutrition.

Digestion begins in the mouth; adequate nutrition is closely related to good dental health and the general condition of the mouth. Any discomfort or adverse condition in the oral cavity can affect a person's nutritional status, influencing the type and amount of food ingested as well as the degree to which food particles are exposed to salivary enzymes. Given the close relationship between adequate nutritional intake and the structures of the upper gastrointestinal (GI) tract (lips, mouth, teeth, pharynx, esophagus), nursing assessment and health teaching related to food and fluid intake, general nutritional health, speech, and self-image is warranted. In some patients, certain pathologies impede the function of the GI system, and artificial devices must be placed to support nutritional intake. It is important for the nurse to be familiar with the placement procedures, function, and associated complications when caring for patients receiving supplemental enteral (involving or passing through the intestine, e.g., tube feeding) or parenteral (not involving the GI tract, typically intravenous, e.g., partial parenteral nutrition [PPN]) nutrition.

ORAL DISORDERS

ORAL CARE

The nurse understands that oral health is a very important component of a person's physical and psychological well-being; common oral problems include dental plaque and caries. Healthy teeth must be cleaned conscientiously and effectively on a daily basis. Brushing and flossing are particularly effective in mechanically breaking up the bacterial plaque that collects around teeth. The level of mouth care performed on or by patients is dependent upon patient condition and tolerance of the procedure, with the ideal situation being when patients are able to brush and floss their teeth as they normally would at home. The American Dental Society recommends brushing twice a day and flossing once a day (2014). The primary focus of mouth care is to lessen the amount of bacterial film that accumulates on teeth, around gums, and in saliva (Box 22-1). Normal mastication (chewing) and the normal flow of saliva also aid greatly in keeping the teeth clean. Because many ill patients do not eat adequate amounts of food, they produce less saliva, which, in turn, reduces this natural tooth-cleaning process. The nurse may need to assume the responsibility for brushing the patient's teeth. A soft-bristled toothbrush is more effective than a sponge or foam stick. If brushing is not possible, the nurse should wipe the teeth with a gauze pad, and then have the patient swish an antiseptic mouthwash several times before expectorating into an emesis basin. To prevent drying, the nurse can coat the patient's lips with a water-based gel.

BOX 22-1 Health Promotion

Preventive Oral Hygiene

Instruct patients to:

- Brush teeth using a soft toothbrush at least twice daily. Hold toothbrush at a 45-degree angle against the gums and teeth. A small brush is better than a large brush. In addition to the teeth, the gums and tongue surface should be brushed.
- Floss at least once daily.
- Use an antiplaque mouth rinse.
- Visit a dentist at least every 6 months or when you have a chipped tooth, a lost filling, an oral sore that persists longer than 2 weeks, or a toothache.
- Avoid alcohol and tobacco products, including smokeless tobacco.
- Maintain adequate nutrition and avoid sweets.
- Replace your toothbrush at the first sign of wear, usually every 2 months.

Not only is the bacterial film detrimental to the tooth surface and gums, it also can potentially create problems in the respiratory system. This film can translocate to the lungs and cause an infection. A recent systematic review of 35 randomized controlled studies

involving medical, surgical, and trauma ICU patients and oral care practices in ventilated patients (Shi et al., 2013) found that the use of chlorhexidine mouthwash or gel had no bearing on morbidity, length of stay, or number of days on a ventilator. Chlorhexidine did decrease the odds of a patient developing ventilator-associated pneumonia (VAP) by 40%. The study also found that toothbrushing in patients who were ventilated had no effect on the reduction of VAP. Despite recent literature that does not directly support the benefit of individual interventions in oral care programs across critical care nursing practice, many hospitals continue to follow the guidelines to prevent VAP as established by the American Association of Critical Care Nurses (2010) (Munroe & Ruggiero, 2014). The guidelines include: oral moisturizing 6 to 12 times a day; brushing teeth, gums, and tongue twice a day; and using oral chlorhexidine gluconate (0.12%) twice a day in patients having cardiac surgery. For more information on VAP, refer to Chapter 10.

TEMPOROMANDIBULAR JOINT DISORDERS

Disorders of the temporomandibular joint (TMJ) can originate within the joint capsule itself or involve the muscle tissue that surrounds and supports the joint. Osteoarthritis, rheumatoid arthritis, and disruption of the joint structures, such as dislocation or disc displacement, occur within the joint.

Clinical Manifestations and Assessment

Pain with mastication and/or pain in the joint itself are the two most common manifestations of a TMJ disorder. Patients have pain ranging from a dull ache to throbbing, debilitating pain that can radiate to the ears, teeth, neck muscles, and facial sinuses. They often have restricted jaw motion and locking of the jaw. There also may be a sudden change in the way the upper and lower teeth fit together. The patient may hear clicking and grating noises, and chewing and swallowing may be difficult (National Institute of Dental and Craniofacial Research, 2014).

Diagnosis is based on the patient's report of pain, limitations in range of motion (ROM), dysphagia, difficulty chewing, difficulty with speech, or hearing difficulties. Magnetic resonance imaging (MRI), x-ray studies, and an arthrogram may be performed.

Medical Management

Conservative and reversible treatment is recommended. If irreversible surgical options are recommended, the patient is encouraged to seek a second opinion.

Nonsurgical Management

Although some practitioners think the role of stress in TMJ disorders is overrated, patient education in stress management may be helpful (to reduce grinding and clenching of teeth). Often occlusal guards are used in conjunction with stress management to prevent further deterioration of the tooth surface and irritation of the joint. Also the patient may benefit from ROM exercises without overextension of the joint. Pain management measures may include nonsteroidal anti-inflammatory drugs (NSAIDs) with the possible addition of opioids, muscle relaxants, or mild antidepressants. Occasionally, intraoral orthotics (a plastic guard worn over the upper and lower teeth) may be worn to reposition the condyle head in the joint space to a more normal position, which, in turn, relieves the stress and pressure of the joint on the tissues. This allows the tissues to heal.

Surgical Management

Correction of mandibular structural abnormalities may require surgery involving repositioning or reconstruction of the jaw. Simple fractures of the mandible without displacement, resulting from a blow on the chin, and planned surgical interventions, as in jaw repositioning (orthognathic) surgical correction to remedy cosmetic and functional jaw problems, may require treatment by these means. Jaw reconstruction may also be necessary in the aftermath of trauma from a severe injury or cancer, both of which can cause tissue and bone loss.

Usually mandibular fractures are closed fractures. Rigid plate fixation (insertion of metal plates and screws into the bone to approximate and stabilize the bone) is the current treatment of choice in many cases of mandibular fracture and in some mandibular reconstructive surgery procedures (Wein, Chandra, Leemans, & Weber, 2014). In some instances, the fracture repair involves wiring the patient's jaw shut for a number of weeks. Bone grafting may be performed to replace structural defects using bones from the patient's own ilium, ribs, or cranial sites. Also rib tissue may be harvested from cadaver donors.

Nursing Management

The patient who has had rigid fixation should be instructed not to chew food in the first 1 to 4 weeks after surgery. A liquid diet is recommended, and dietary counseling should be obtained to ensure optimal caloric and protein intake. To prevent aspiration, these patients should have wire cutters (for rigid fixation) or scissors (for rubber band fixation) at the bedside to release the jaw if the patient begins to vomit. The patient and family members should be instructed before discharge by the surgeon on where and how to cut the wires or rubber bands in an emergency before the patient is discharged. Rigid fixation remains for approximately 6 weeks depending upon the age of the patient, condition of bone, and the extent of the mandible injury.

The patient needs specific guidelines for mouth care and feeding. Any irritated areas in the mouth should be reported to the surgeon. Emphasis is placed on the importance of keeping scheduled appointments to assess the stability of the fixation appliance.

Consultation with a dietitian may be indicated so that the patient and family can learn about foods that are high in essential nutrients and ways in which these foods can be prepared so that they can be consumed through a straw or spoon while remaining palatable. Nutritional supplements may also be recommended.

DISORDERS OF THE SALIVARY GLANDS

About 1,200 mL of saliva is produced daily and swallowed. The three main functions of saliva are lubrication, protection against harmful bacteria, and digestion. The glands that can be affected include the parotids, the submandibulars, and the sublinguals.

Sialadenitis refers to the bacterial or viral infection of the salivary glands. Infection may be caused by dehydration, radiation therapy (RT), stress, malnutrition, salivary gland calculi (stones), or improper oral hygiene. Patients with a bacterial infection have significant inflammation, pain, swelling, and purulent discharge. Treatment includes antibiotics, massage, hydration, warm compresses, and corticosteroids. Chronic sialadenitis with uncontrolled pain is treated by surgical drainage of the gland or excision of the gland and its ducts.

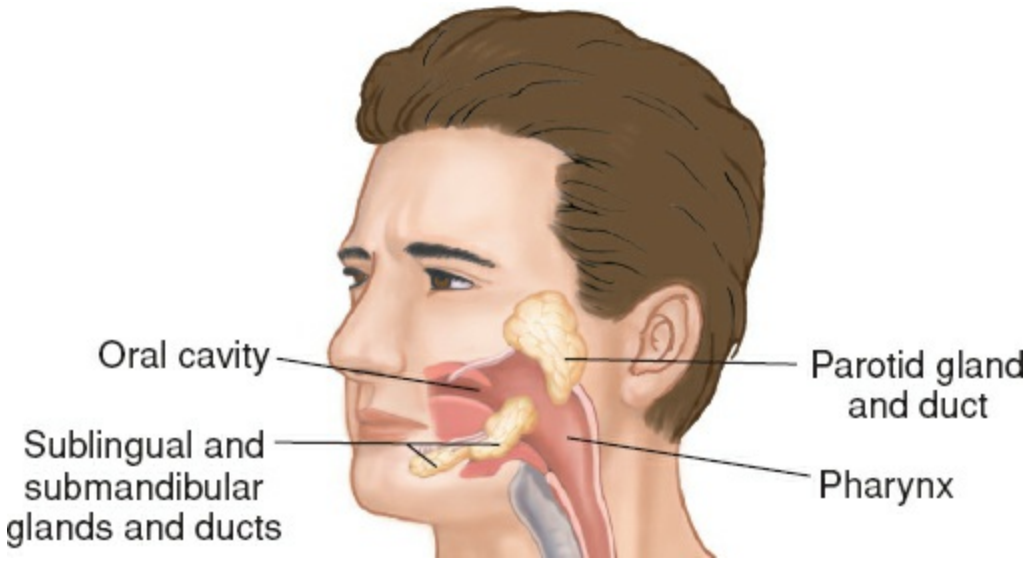

FIGURE 22-1 Parotid gland and duct. (Reprinted from Porth, C. M. (2015). *Essentials of pathophysiology: Concepts of altered states* (4th ed.). Philadelphia, PA: Wolters Kluwer.)

Parotitis (inflammation of the parotid gland) is the most common inflammatory condition of the salivary glands. The parotids are the largest of the salivary glands. Mumps (epidemic parotitis), a communicable disease caused by viral infection and most commonly affecting children, is an inflammation of a salivary gland, usually the parotid.

People who are elderly, acutely ill, or debilitated with decreased salivary flow from general dehydration or medications are at high risk for parotitis. The infecting organisms travel from the mouth through the salivary duct. The organism is usually *Staphylococcus aureus* (except in mumps). The onset of this complication is sudden, with an exacerbation of both the fever and the symptoms of the primary condition. The gland swells and becomes tense and tender (see Fig. 22-1). The patient feels pain in the ear, and swollen glands interfere with swallowing. The swelling increases rapidly, and the overlying skin soon becomes red and shiny. The patient may have purulent drainage from the site as well.

Medical management includes maintaining adequate nutritional and fluid intake, good oral hygiene, and discontinuing medications (e.g., tranquilizers, diuretics) that can diminish salivation. Antibiotic therapy is necessary, and analgesics may be prescribed to control pain. If antibiotic therapy is not effective, the gland may need to be drained by extraoral pressure applied to the area or by surgical removal of the gland via parotidectomy. Also surgery may be necessary to treat chronic parotitis. The patient is advised to have any necessary dental work performed prior to surgery.

ORAL AND OROPHARYNGEAL CANCER

Cancers of the oral cavity, which can occur in any part of the mouth or throat, are curable if discovered early. Almost 40,000 people were diagnosed with oral cancer in 2015, and close to 20% will die from this disease (American Cancer Society, 2017). These types of cancers are equally prevalent in blacks and whites, and men have twice the risk of women of being diagnosed (American Cancer Society, 2017).

Pathophysiology

Malignancies of the oral cavity are usually squamous cell cancers. Any area of the oropharynx can be a site of malignant growths, but the lips, the lateral aspects of the tongue, and the floor of the mouth are most commonly affected.

Risk Factors

Oral cancers are often associated with the use of alcohol and all types of tobacco products, which, if used together, have a synergistic carcinogenic effect. Other factors include dietary deficiency, smoked meat ingestion, and prolonged exposure to sun and wind for cancer of the lip.

Cancer of the oral cavity affects men more often than women; however, the incidence of oral cancer in women is increasing, possibly because of increased use of tobacco and alcohol. Cancers of the oral cavity and oropharynx occur more often in African Americans than in Caucasians.

Clinical Manifestations and Assessment

Many oral cancers produce few or no symptoms in the early stages. Later, the most frequent symptom is a painless sore or mass that will not heal. A typical lesion in oral cancer is a painless indurated (hardened) ulcer with raised edges. Tissue from any ulcer of the oral cavity that does not heal in 2 weeks should be examined through biopsy. As the cancer progresses, the patient may complain of tenderness; difficulty in chewing, swallowing, or speaking; coughing of blood-tinged sputum; or enlarged cervical lymph nodes.

Diagnostic evaluation consists of an oral examination as well as an assessment of the cervical lymph nodes to detect possible metastases. Biopsies are performed on suspicious lesions (those that have not healed in 2 weeks). High-risk areas include the buccal mucosa and gingiva in people who use snuff or smoke cigars or pipes. For those who smoke cigarettes and drink alcohol, high-risk areas include the floor of the mouth, the ventrolateral tongue, and the soft palate complex (soft palate, anterior and posterior tonsillar area, uvula, and the area behind the molar and tongue junction).

Medical Management

Management varies with the nature of the lesion, the preference of the physician, and patient choice. Surgical resection, RT, chemotherapy, or a combination of these therapies may be effective.

In cancer of the lip, usually small lesions are excised liberally. RT may be more appropriate for larger lesions involving more than one-third of the lip because of superior cosmetic results. The choice depends on the extent of the lesion and what is necessary to cure the patient while preserving the best appearance. Tumors larger than 4 cm often recur.

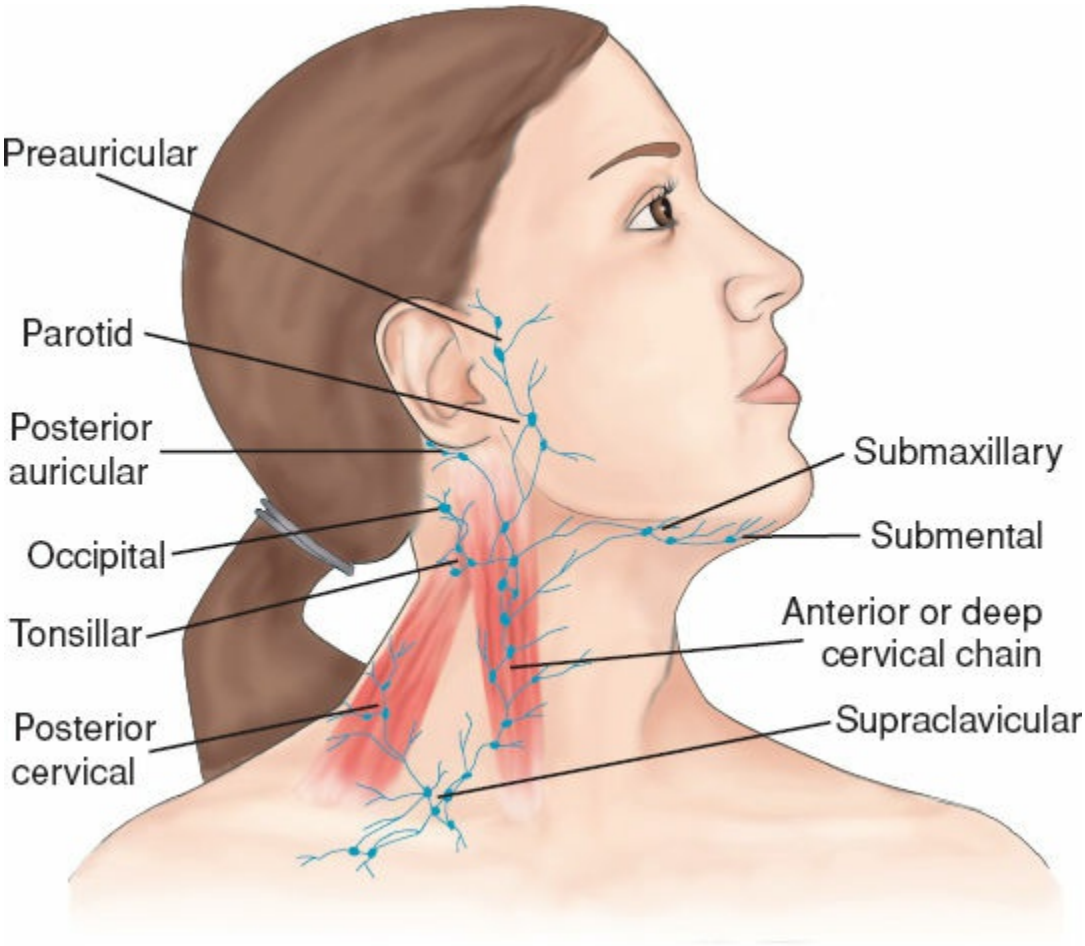

FIGURE 22-2 Lymphatic drainage of the head and neck.

In cancer of the tongue, treatment with RT and chemotherapy may preserve organ function and maintain quality of life. A combination of radioactive interstitial implants (surgical implantation of a radioactive source into the tissue adjacent to or at the tumor site) and external beam radiation may be used. Surgical procedures include hemiglossectomy (surgical removal of half of the tongue) and total glossectomy (removal of the tongue).

Neck Dissection

Often cancer of the oral cavity has metastasized through the extensive lymphatic channel in

the neck region (Fig. 22-2), requiring a neck dissection and reconstructive surgery of the oral cavity. Surgical treatment often is performed shortly after completion of RT or chemoradiation therapy (CRT). Other malignancies of the head and neck that may metastasize into the lymphatic channel include those of the oropharynx, hypopharynx, nasopharynx, nasal cavity, paranasal sinus, and larynx (Fig. 22-3). There are various types of neck dissection: radical, modified radical, and a selective node dissection (Karakousis, 2015). A radical neck dissection involves removal of all cervical lymph nodes from the mandible to the clavicle and removal of the sternocleidomastoid muscle, internal jugular vein, and spinal accessory muscle on one side of the neck. The associated complications include shoulder drop and poor cosmesis (visible neck depression). Modified radical neck dissection, which preserves one or more of the nonlymphatic structures, is used more often. A selective node dissection (in comparison to a radical dissection) preserves one or more of the lymph node groups, the internal jugular vein, the sternocleidomastoid muscle, and the spinal accessory nerve (Fig. 22-4).

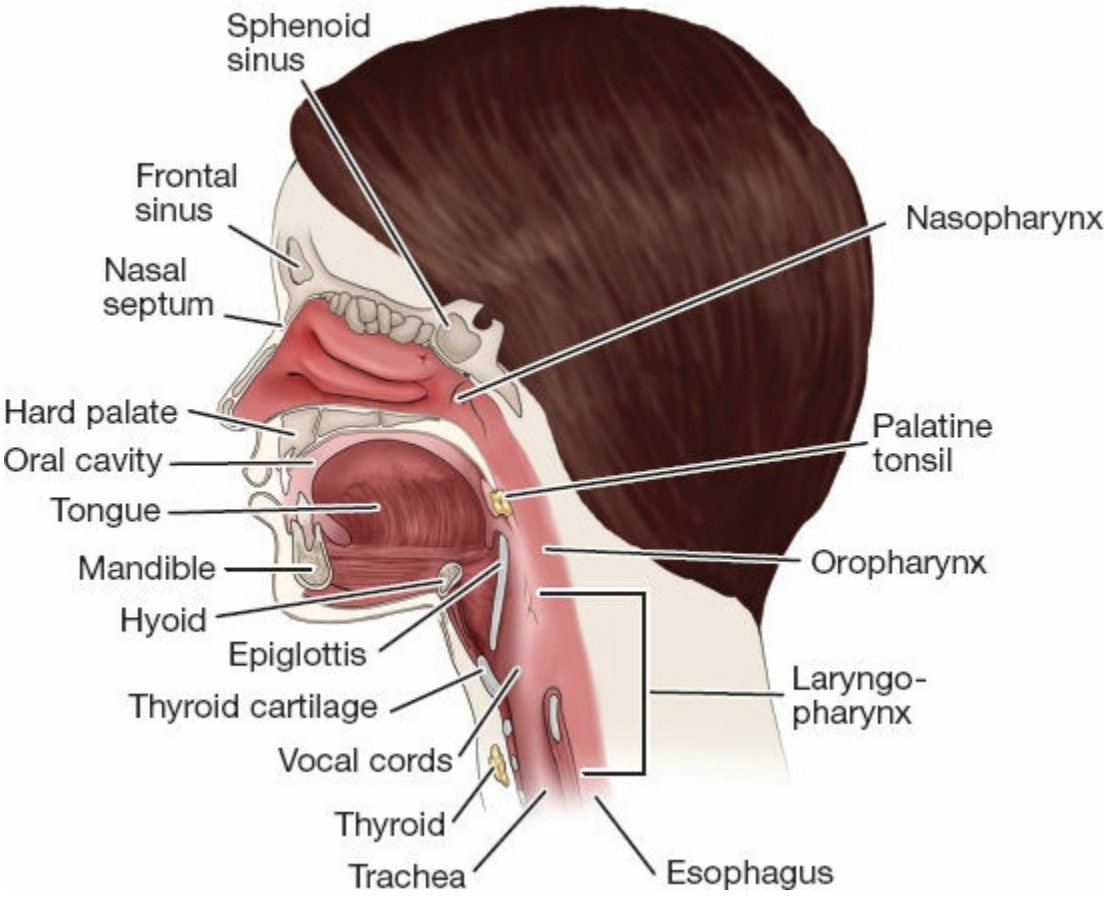

FIGURE 22-3 Anatomy of the head and neck.

Nursing Alert

The nurse recognizes that when a laryngectomy (removal of the larynx) is performed, the patient will have a permanent laryngeal stoma (an artificial opening leading to the trachea) (Fig. 22-5). Nursing issues relate to airway management, communication, nutritional and emotional support.

Reconstructive techniques may be performed with a variety of grafts (Fig. 22-6). A cutaneous flap (skin and subcutaneous tissue), such as the deltopectoral flap, may be used. A myocutaneous flap (subcutaneous tissue, muscle, and skin) is a graft that is used more frequently; the pectoralis major muscle is also used. For large grafts, a microvascular free flap may be used. This involves the transfer of muscle, skin, or bone with an artery and vein to the area of reconstruction, using microinstrumentation. Areas used for a free flap include the scapula, the radial area of the forearm, or the fibula. The fibula, which provides a larger bone area, may be used if mandibular reconstruction is involved. Neck dissection is discussed in more detail in the nursing process section that follows.

Nursing Management

The nurse assesses the patient's nutritional status preoperatively, and a dietary consultation may be necessary. The patient may require enteral or parenteral feedings before and after surgery to maintain adequate nutrition. If a radial graft is to be performed, an Allen test on the donor arm must be performed to ensure that the ulnar artery is patent. Refer to Chapter 12 for details on the Allen test.

Postoperatively, the nurse monitors the patient's ability to protect the airway by assessing the ability to swallow and manage oral secretions. Suctioning of oral secretions may be necessary, and the patient can be instructed on use of a Yankauer suction device (tonsil tip suction) to remove oral secretions if appropriate. If grafting was part of the surgery, suctioning must be performed with care to prevent damage to the graft. The graft is assessed postoperatively for viability. Although color should be assessed (white may indicate arterial occlusion, and blue mottling may indicate venous congestion), it can be difficult to assess the graft by looking into the mouth. An intermittent Doppler ultrasound device or fiberoptic monitoring device (producing a continuous audible pulse of the graft site), may be used to assess the graft perfusion.

Xerostomia, dryness of the mouth, is a frequent sequela of oral cancer, particularly when the salivary glands have been exposed to radiation or major surgery. Also xerostomia is seen in patients receiving psychopharmacologic agents, patients with HIV infection, patients who cannot close the mouth, patients having endotracheal or tracheostomy tubes, and in patients with poor oral food intake.

The patient's mouth appears red, dry, and tender to palpation. Cracks in the dry oral mucosa may occur in which infection could develop. To minimize this problem, the patient is advised to avoid dry, bulky, and irritating foods and fluids, as well as alcohol and tobacco. Also the patient is encouraged to increase intake of fluids (when not contraindicated) and to use a humidifier during sleep. The use of synthetic saliva, a moisturizing antibacterial gel such as Oral Balance, or a saliva-production stimulant, such as Salagen, may be helpful.

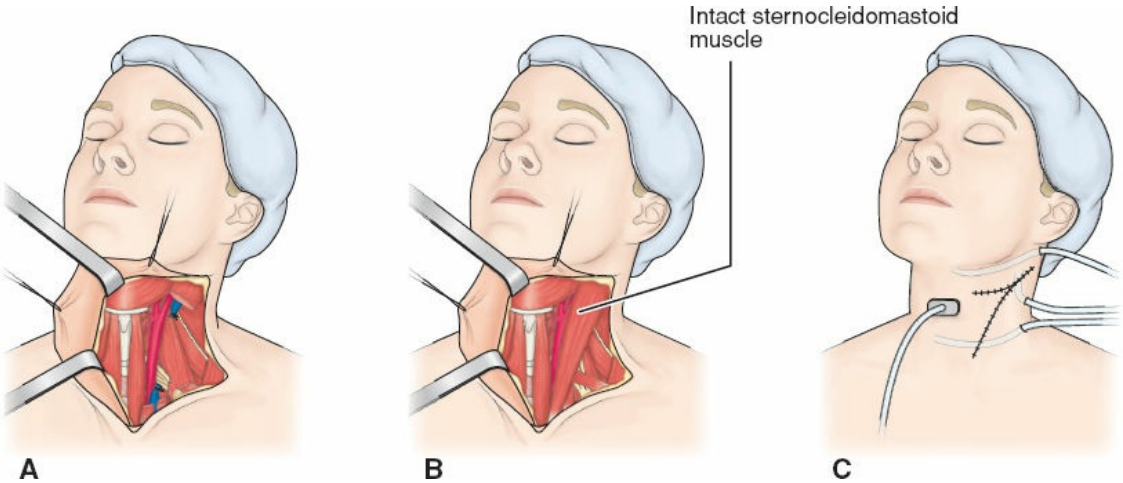

FIGURE 22-4 (A) A classic radical neck dissection in which the sternocleidomastoid and smaller muscles are removed. All tissue is removed, from the ramus of the jaw to the clavicle. The jugular vein has also been removed. (B) The selective neck dissection is similar but preserves the sternocleidomastoid

muscle, internal jugular vein, and spinal accessory nerve. The wound is closed (C), and portable suction drainage tubes are in place.

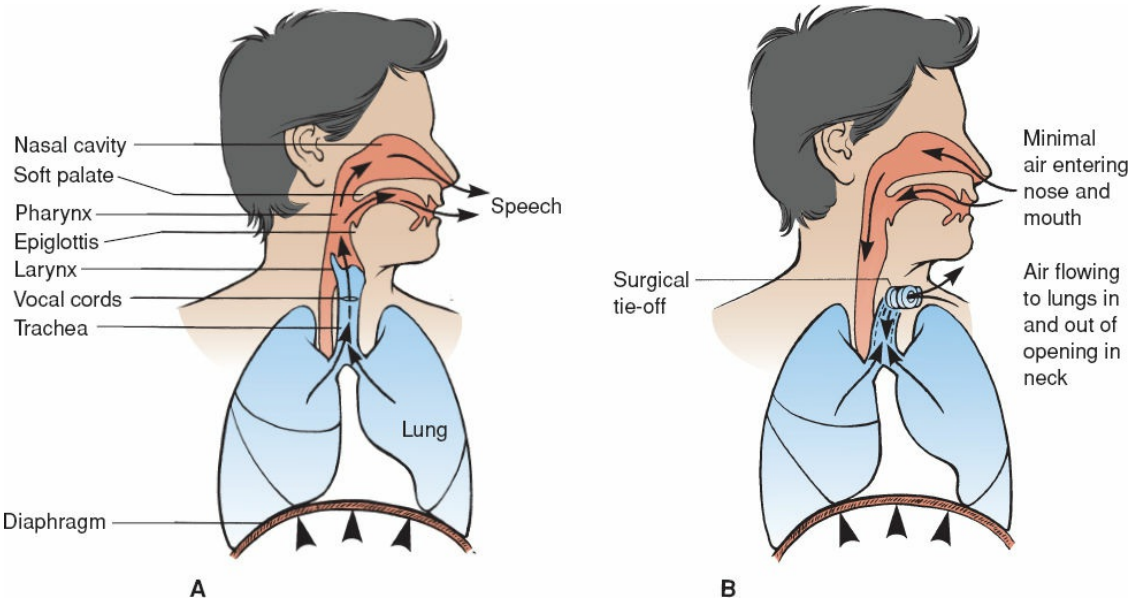

FIGURE 22-5 Airflow after total laryngectomy. After a total laryngectomy the patient breathes through a stoma. A. Normal air flow. B. Airflow after a total laryngectomy.

E

F

G

FIGURE 22-6 (*Continued*) The intent is to orient the proximal soft tissue flap in the direction of the sternocleidomastoid muscle to achieve symmetry with the nonoperated side. The intervening soft tissue helps provide durable improvement in the soft tissue contour as well as added vascularity to the overlying skin when the procedure is being performed in a patient with prior radiation (**G**). The skin monitor, used to assess the vascularity of the deep portion of the flap, is placed into the lower neck (G, *arrow*). In the latter setting, when removal of the sternocleidomastoid muscle is required, the added soft tissue helps protect the carotid artery and the microvascular pedicle.

FIGURE 22-6 The impact of a radical neck dissection on the appearance of the neck is evident in (A) and (B). The underlying structures are located immediately deep to the skin and are readily visible. The hollowed appearance of the contour of the neck serves as a constant reminder of the patient's disease. The effect of adjuvant radiation on the soft tissues of the neck serves to produce further fibrosis and contraction, leading to severe scarring and worsening of the contour deformity. The placement of a soft tissue flap deep to the skin helps to ameliorate the usual concave appearance following a radical neck dissection (C). The photos that follow demonstrate the technique and the postoperative impact of using a radial forearm free flap with a proximal monitor paddle that is located in a window created in the caudal portion of the neck (D, E, F). The intent is to orient the proximal soft tissue flap in the direction of the sternocleidomastoid muscle to achieve symmetry with the nonoperated side. The intervening soft tissue helps provide durable improvement in the soft tissue contour, as well as added vascularity to the overlying skin when the procedure is being performed in a patient with prior radiation (G). The skin monitor, used to assess the vascularity of the deep portion of the flap, is placed into the lower neck (G, *arrow*). In the latter setting, when removal of the sternocleidomastoid muscle is required, the added soft tissue helps protect the carotid artery and the microvascular pedicle.

Stomatitis, or mucositis, which involves inflammation and breakdown of the oral mucosa, is often a side effect of chemotherapy or RT. Mucositis results in decreased oral intake and resultant malnutrition; therefore, the nurse performs routine oral assessments and follows protocols for treatment approaches (see Chapter 6). Prophylactic mouth care is started when the patient begins receiving treatment; however, mucositis may become so severe that a break in treatment is necessary. Often if a patient receiving RT has poor dentition, extraction of the teeth before radiation treatment in the oral cavity is performed to prevent infection. As a result, many RT centers recommend the use of fluoride treatments for patients receiving radiation to the head and neck.

People with cancer of the head and neck frequently have used alcohol or tobacco before surgery; postoperatively, the patient is encouraged to abstain from these substances.

Treatment to decrease the likelihood of alcohol and nicotine withdrawal is recommended. Depression and anxiety are also common in this patient population. A recent study found patients undergoing radiotherapy for head and neck cancers returned to their preoperative levels of anxiety 12 months after ending their treatment course and experienced increasing levels of depression posttreatment due to aforementioned symptoms (Neilson et al., 2013).

NURSING PROCESS

The Patient Undergoing a Neck Dissection

ASSESSMENT

Preoperatively, the patient's physical and psychological preparation for major surgery is assessed along with his or her knowledge of the preoperative and postoperative procedures. Postoperatively, the patient is assessed for complications, such as altered respiratory status, wound infection, and hemorrhage. As healing occurs, neck ROM is assessed to determine whether there has been a decrease in ROM due to nerve or muscle damage. A plan of nursing care for a patient who has undergone a neck dissection is available online at http://thepoint.lww.com/Honan2e.

DIAGNOSIS

Nursing diagnoses may include the following:

- Deficient knowledge about preoperative and postoperative procedures
- Ineffective airway clearance related to obstruction by mucus, hemorrhage, or edema
- Acute pain related to surgical incision
- Risk for infection related to surgical intervention secondary to decreased nutritional status, or immunosuppression from chemotherapy or RT
- Impaired tissue integrity secondary to surgery and grafting
- Imbalanced nutrition, less than body requirements, related to disease process or treatment
- Situational low self-esteem related to diagnosis or prognosis
- Impaired verbal communication secondary to surgical resection
- Impaired physical mobility secondary to nerve injury
- Anxiety related to cancer diagnosis and surgical dissection

Potential postoperative complications that may develop include the following:

- Hemorrhage
- Chyle fistula
- Nerve injury

PLANNING

The major goals for the patient include participation in the treatment plan, maintenance of respiratory status, attainment of comfort, absence of infection, viability of the graft, maintenance of adequate intake of food and fluids, effective coping strategies, effective communication, maintenance of shoulder and neck motion, and absence of complications.

NURSING INTERVENTIONS

Before surgery, the patient should be informed about the nature and extent of the surgery and what the postoperative period will be like (see Chapter 5 for preoperative education).

For the patient who has had extensive neck surgery, specific postoperative interventions include maintenance of a patent airway and continuous assessment of respiratory status, wound care and oral hygiene, maintenance of adequate nutrition, and observation for hemorrhage or nerve injury.

MAINTAINING THE AIRWAY

After the endotracheal tube or airway has been removed and the effects of the anesthesia have worn off, the patient may be placed in Fowler position to facilitate breathing and promote comfort. This position also increases lymphatic and venous drainage, facilitates swallowing, and decreases venous pressure on the skin flaps.

In the immediate postoperative period, the nurse assesses for stridor (coarse, high-pitched sound on inspiration) by listening frequently over the trachea with a stethoscope. This finding must be reported immediately because it indicates partial obstruction of the airway. Signs of respiratory distress, such as dyspnea, cyanosis, changes in mental status, and changes in vital signs, are assessed because they may suggest edema, hemorrhage, inadequate oxygenation, or inadequate drainage.

Pneumonia may occur in the postoperative phase if pulmonary secretions are not removed. To aid in the removal of secretions, coughing and deep breathing are encouraged. The patient should assume a sitting position, with the nurse supporting the neck so that the patient can bring up excessive secretions. If this is ineffective, the patient's respiratory tract may have to be suctioned. Care is taken to protect the suture lines during suctioning.

If the patient has had a laryngectomy performed, "the laryngeal stoma needs vigilant observation, as the suture material, which secures the trachea, acts as a trap for dried mucus and bronchial secretions and may cause the diameter of the stoma to narrow. A laryngectomy tube is placed in the stoma once the patient is fully recovered from the operative procedure" (Davidson, Lester, & Routt, 2014, p. 69). If a laryngectomy tube is

in place, suctioning is performed through the tube. Humidified oxygen or room air decreases the viscosity of secretions and provide moisture to the air (Davidson et al., 2014). Patients and family members are instructed to use a cool mist vaporizer or humidified air compressor to decrease secretion viscosity upon discharge and also should be instructed on care of the stoma and suctioning of the airway. The patient also may be instructed on the use of the Yankauer suction to remove oral secretions. The nurse should not take the patient's temperature orally.

Before a patient takes food or fluid orally, the patient's swallowing function is evaluated to assess for dysphagia; it is important to determine the presence or absence of aspiration, any voice impairment, ease of movement of the larynx, any evidence of gurgling with respiration, pulmonary secretions, lung sounds, and oxygen saturation. Teaching a patient the supraglottic swallowing technique can be effective in reducing the risk of aspiration when surgery impacted the ability of the vocal folds to close (Butler, Pelletier, & Steele, 2013). When the patient is ready to swallow food, the nurse would instruct the patient to inhale deeply, hold their breath, swallow and then finally cough as the swallow was completed. Seeking the guidance of a speech pathologist is recommended when considering aspiration prevention techniques such as this one.

Nursing Alert

Failure to assess for dysphagia in the patient following postoperative neck dissection may result in severe respiratory compromise, prolonged mechanical ventilation, and aspiration pneumonia.

RELIEVING PAIN

Pain and the patient's fear of pain are assessed and managed. Patients with head and neck cancer often report less pain than do patients with other types of cancer; however, the nurse needs to be aware that each person's pain experience is individual. The nurse administers analgesics as prescribed and assesses their effectiveness.

PROVIDING WOUND CARE

Wound drainage tubes usually are inserted during surgery to prevent the subcutaneous collection of fluid. The drainage tubes are connected to a portable suction device (e.g., Jackson-Pratt) (see Box 33-4), and the container is emptied periodically. Between 80 and 120 mL of serosanguineous secretions may drain over the first 24 hours. Excessive drainage may be indicative of a chyle fistula or hemorrhage (see later discussion). If dressings are present, they may need to be reinforced periodically. Dressings are observed for evidence of hemorrhage and constriction, which impairs respiration and perfusion of the graft. A graft, if present, is assessed for color and temperature and for the presence of a pulse if applicable, to determine viability. The graft should be pale pink and warm to the touch. If lymphatic drainage is obstructed, then edema may develop. The surgical incisions are also assessed for infection, which is reported immediately. Prophylactic antibiotics may be prescribed.

MAINTAINING ADEQUATE NUTRITION

Nutritional status is assessed preoperatively; early intervention to correct nutritional imbalances may decrease the risk of postoperative complications. Frequently, nutrition is less than optimal because of inadequate intake, and the patient often requires enteral or parenteral supplements preoperatively and postoperatively to attain and maintain a positive nitrogen balance.

The patient who can chew may take food by mouth; the level of the patient's chewing ability determines whether some diet modification (e.g., soft, puréed, or liquid foods) is necessary. Also food preferences should be discussed with the patient. Oral care before eating may enhance the patient's appetite, and oral care after eating is important to prevent infection and dental caries.

SUPPORTING COPING MEASURES

Preoperatively, information about the planned surgery is given to the patient and family. Postoperatively, psychological nursing interventions are aimed at supporting the patient who has had a change in body image or who has major concerns regarding the prognosis. The patient may have difficulty communicating and may be concerned about his or her ability to breathe and swallow normally. The nurse supports the patient's family and friends in encouraging and reassuring the patient that adjusting to the results of this surgery will take time.

The person who has had extensive neck surgery often is sensitive about his or her appearance. This can occur when the operative area is covered by bulky dressings, when the incision line is visible, or later after healing has occurred and the appearance of the neck, and possibly the lower face, has been altered significantly. If the nurse accepts the patient's appearance and expresses a positive, optimistic attitude, then the patient is more likely to be encouraged. The patient also needs an opportunity to express concerns regarding the success of the surgery and the prognosis. The American Cancer Society may be a resource to provide a volunteer to meet with the patient either preoperatively or postoperatively.

PROMOTING EFFECTIVE COMMUNICATION

If a laryngectomy was performed, the nurse explores other methods of communicating with the patient and obtains a consultation with a speech/language therapist. Alternatives to verbal communication may include use of a pencil and paper or pointing to needed items on a picture pad. Alternative speech techniques, such as an electrolarynx (a mechanical device held against the neck) or esophageal speech, may be taught by a speech/language therapist.

MAINTAINING PHYSICAL MOBILITY

Excision of muscles and nerves results in weakness at the shoulder that can cause *shoulder drop*, a forward curvature of the shoulder. Many problems can be avoided with a

conscientious exercise program. Usually these exercises are begun after the drains have been removed and the neck incision is healed sufficiently. Physical therapists and occupational therapists can assist patients in performing these exercises.

Additionally because lymph node removal can cause nerve damage, and the sternocleidomastoid muscle may have been removed, neck mobility is impaired, thus the neck is supported by the nurse when getting the patient out of bed. Physical therapy can assist with developing a plan for neck and shoulder rehabilitation.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Hemorrhage. Hemorrhage may occur from rupture of the carotid artery as a result of necrosis of the graft or damage to the artery itself from tumor or infection. The following measures are indicated:

- Vital signs are assessed. Tachycardia, tachypnea, and hypotension may indicate hemorrhage and impending hypovolemic shock.
- The patient is instructed to avoid the Valsalva maneuver (bearing-down activities such as having a bowel movement) to prevent stress on the graft and carotid artery.
- Signs of impending rupture, such as high epigastric pain or discomfort, are reported.
- Dressings and wound drainage are observed for excessive bleeding.
- If hemorrhage occurs, assistance is summoned immediately.
- Hemorrhage requires the continuous application of pressure to the bleeding site or major associated vessel.
- Close assessment must occur when changing the patient's position to assist in maintaining blood pressure yet minimizing the risk of aspiration and potentially losing airway patency.
- The nurse should maintain a controlled, calm manner to help allay the patient's anxiety.
- The surgeon is notified immediately because a vascular or ligature tear requires surgical intervention.

Chyle Fistula. A chyle fistula (milk-like lymphatic drainage from the thoracic duct into the thoracic cavity) may develop as a result of damage to the lymphatic thoracic duct during surgery. The nurse notes the color of the drainage from the neck drains and notifies the surgeon if milky, odorless discharge is seen since this is suspicious for a chyle leak. The diagnosis is made if there is excess drainage that has a 3% fat content and a specific gravity of 1.012 or greater. Treatment of a small leak (up to 500 mL or less) includes application of a pressure dressing and a diet of medium-chain fatty acids or parenteral nutrition (PN). Surgical intervention to repair the damaged duct is necessary for larger leaks.

Nerve Injury. Nerve injury can occur during a neck dissection procedure due to the location of multiple nerve pathways in and around muscle, lymphatic, and vascular

structures. Damage to the accessory nerve can result in shoulder pain and potential dysfunction. The facial nerve can also be damaged which would manifest as poor lower lip function. Tongue movement can be effected with injury to the hypoglossal nerve. If a patient has limited mobility of the arm in the postoperative period a brachial plexus injury is suspected. Damage to the phrenic nerve can affect the respiratory system and the patient's voice can be changed due to injury to the vagus nerve. The nurse assesses the functioning of the anatomic structures mentioned with the knowledge of the corresponding nerve pathways to the appropriate health care provider, such as the surgeon, physical therapist or speech pathologist and recommend interventions.

TEACHING PATIENTS SELF-CARE

The patient and caregiver require instructions about management of the wound, the dressing, and any drains that remain in place. Patients who require oral suctioning or who have a tracheostomy may be very anxious about their care at home; the transition to home can be eased if the caregiver is given several opportunities to demonstrate the ability to meet the patient's needs. Also the patient and caregiver are instructed about possible complications, such as bleeding and respiratory distress, and when to notify the health care provider of signs and symptoms of these complications.

If the patient cannot take food by mouth, detailed instructions and demonstration of enteral or parenteral feedings will be required. Education in techniques of effective oral hygiene is also important.

A referral for home care nursing may be necessary in the early period after discharge. The nurse assesses healing, ensures that feedings are being administered properly, and monitors for any complications. The home care nurse assesses the patient's adjustment to changes in physical appearance and status as well as the patient's ability to communicate and to eat normally. Physical and speech therapy also may be continued at home.

The patient is given information regarding local support groups such as "I Can Cope" or "New Voice Club," if indicated. The local chapter of the American Cancer Society may be contacted for information and equipment needed for the patient.

EVALUATION

Expected patient outcomes may include:

1. Discusses expected course of treatment
2. Demonstrates good respiratory exchange:
    a. Lungs are clear to auscultation
    b. Breathes easily with no shortness of breath
    c. Demonstrates ability to use suction effectively
3. Remains free of infection:
    a. Maintains normal laboratory values
    b. Is afebrile
4. Graft is pink and warm to touch

5. Maintains adequate intake of foods and fluids:
    a. Accepts altered route of feeding
    b. Is well hydrated
    c. Maintains or gains weight
6. Demonstrates ability to cope:
    a. Discusses emotional responses to the diagnosis
    b. Attends support group meetings
7. Verbalizes comfort
8. Attains maximal mobility:
    a. Adheres to physical therapy exercises
    b. Attains maximal ROM
9. Exhibits no complications:
    a. Vital signs stable
    b. No excessive bleeding or discharge
    c. Able to move muscles of lower face

DISORDERS OF THE ESOPHAGUS

The esophagus is a mucus-lined, muscular tube that carries food from the mouth to the stomach. It begins at the base of the pharynx and ends about 4 cm below the diaphragm. Its ability to transport food and fluid is facilitated by two sphincters. The upper esophageal sphincter, also called the *hypopharyngeal sphincter*, is located at the junction of the pharynx and the esophagus. The lower esophageal sphincter, also called the *gastroesophageal sphincter* or *cardiac sphincter*, is located at the junction of the esophagus and the stomach. The lower esophageal sphincter prevents reflux (backward flow) of gastric contents. There is no serosal layer of the esophagus; therefore, if surgery is necessary, it is more difficult to perform suturing or anastomosis.

Disorders of the esophagus include motility disorders achalasia (muscles of the lower part of the esophagus fail to relax), hiatal hernias, diverticula, perforation, esophageal obstruction due to swallowed foreign bodies, chemical burns, gastroesophageal reflux disease, Barrett's esophagus, and carcinoma. Dysphagia (difficulty swallowing), the most common symptom of esophageal disease, may vary from an uncomfortable feeling that a bolus of food is caught in the upper esophagus to acute pain on swallowing (odynophagia). Obstruction of food (solid and soft) and even liquids may occur anywhere along the esophagus. Often, the patient indicates that the problem is located in the upper, middle, or lower third of the esophagus.

ACHALASIA

Achalasia is absent or ineffective peristalsis of the distal esophagus, accompanied by failure of the esophageal sphincter to relax in response to swallowing. Narrowing of the esophagus just above the stomach results in a gradually increasing dilation of the esophagus in the upper chest. Achalasia may progress slowly and occurs most often in people 40 years or older.

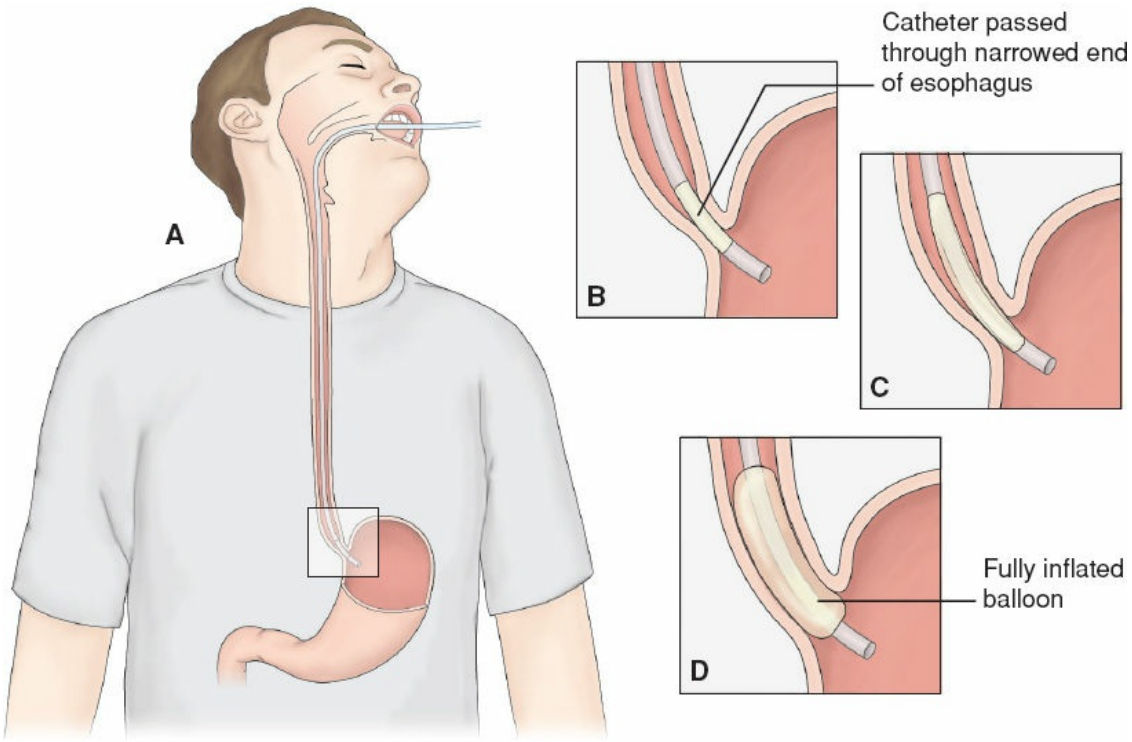

FIGURE 22-7 Treatment of achalasia by pneumatic dilation. A–C. The dilator is passed, guided by a previously inserted guide wire. D. When the balloon is in proper position, it is distended by pressure sufficient to dilate the narrowed area of the esophagus.

Clinical Manifestations and Assessment

The primary symptom is difficulty in swallowing both liquids and solids. The patient has a sensation of food sticking in the lower portion of the esophagus. As the condition progresses, food is regurgitated either spontaneously or intentionally by the patient to relieve the discomfort produced by prolonged distention of the esophagus by food that will not pass into the stomach. The patient may also report chest pain and heartburn (pyrosis) that may or may not be associated with eating. Secondary pulmonary complications may result from aspiration of gastric contents.

X-ray studies show esophageal dilation above the narrowing at the gastroesophageal junction. Barium swallow, computed tomography (CT) of the chest, and endoscopy may be used for diagnosis; however, *manometry*, a process in which the esophageal pressure is measured by a radiologist or gastroenterologist, confirms the diagnosis (McQuaid, 2014).

Medical and Nursing Management

The patient is instructed to eat slowly and to drink fluids with meals. As a temporary measure, calcium channel blockers and nitrates have been used to decrease esophageal pressure and improve swallowing. Injection of botulinum toxin (Botox) to quadrants of the esophagus via endoscopy has been helpful because it inhibits the contraction of smooth muscle. Periodic injections are required to maintain remission.

Achalasia may be treated conservatively by pneumatic dilation to stretch the narrowed area of the esophagus (Fig. 22-7). Pneumatic dilation (forcefully dilating the lower esophagus by a balloon) has a high success rate. Although perforation is a potential complication, its incidence is low. The procedure can be painful; therefore, moderate sedation in the form of an analgesic or tranquilizer, or both, is administered for the treatment. The patient is monitored for perforation. Abdominal tenderness and fever may indicate perforation (see later discussion).

Achalasia may be treated surgically by esophagomyotomy. Usually the procedure is performed laparoscopically, either with a complete lower esophageal sphincter myotomy and an antireflux procedure or without an antireflux procedure. The esophageal muscle fibers are separated to relieve the lower esophageal stricture.

HIATAL HERNIA

In the condition known as hiatus (or hiatal) hernia, the opening in the diaphragm through which the esophagus passes becomes enlarged, and part of the upper stomach tends to move up into the lower portion of the thorax. Hiatal hernia occurs more often in women than in men. There are four types of hiatal hernias: sliding, rolling or paraesophageal, a sliding/rolling or mixed, and simultaneous hiatal hernia with another organ (Jobe, Hunter, & Watson, 2014). Sliding, or type I, hiatal hernia occurs when the upper stomach and the gastroesophageal junction are displaced upward and slide in and out of the thorax (Fig. 22-8A). A sliding hernia is the most commonly diagnosed of the four types. A rolling or paraesophageal hernia occurs when all or part of the stomach pushes through the diaphragm beside the esophagus (see Fig. 22-8B). The mixed hernia, or Type III, is characterized by both the cardia and fundus being displaced upward.

Clinical Manifestations and Assessment

The patient with a sliding hernia may have heartburn, regurgitation, and dysphagia, but at least 50% of patients are asymptomatic. Often sliding hiatal hernia is implicated in reflux. The patient with a paraesophageal hernia usually feels an uncomfortable sense of fullness after eating or chest pain, or there may be no symptoms. Reflux usually does not occur because the gastroesophageal sphincter is intact. Hemorrhage, obstruction, and strangulation can occur with any type of hernia.

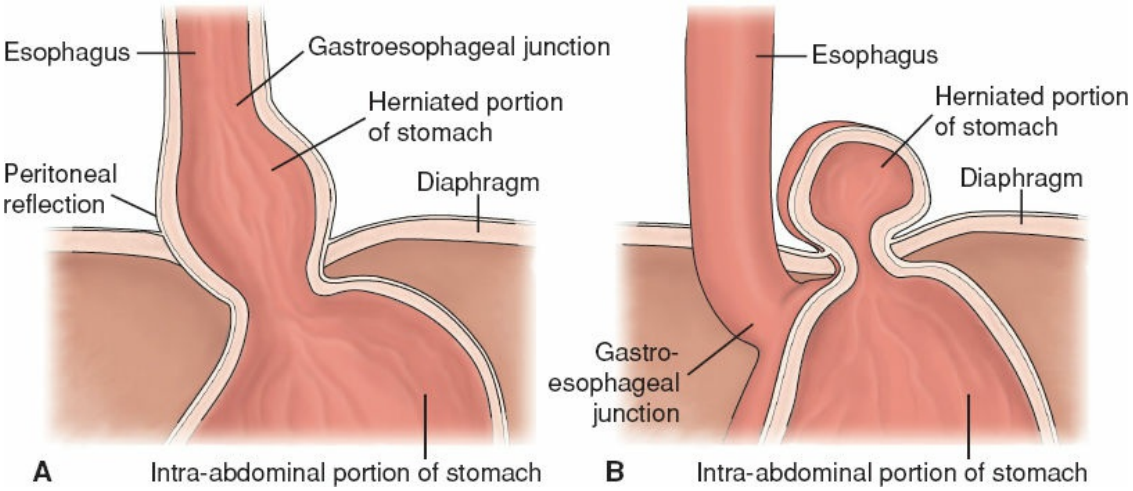

FIGURE 22-8 A. Sliding esophageal hernia. The upper stomach and gastroesophageal junction have moved upward and slide in and out of the thorax. B. Paraesophageal hernia. All or part of the stomach pushes through the diaphragm next to the gastroesophageal junction.

Diagnosis is confirmed by x-ray studies, barium swallow, and fluoroscopy.

Medical and Nursing Management

Management for a sliding hernia includes frequent, small feedings that can pass easily through the esophagus. The patient is advised not to recline for 1 hour after eating, to prevent reflux or movement of the hernia, and to elevate the head of the bed on 4- to 8-in (10- to 20-cm) blocks to prevent the hernia from sliding upward. Surgery is indicated when a patient has significant esophageal injury or when he or she does not respond to medical management. Medical and surgical management of a paraesophageal hernia is similar to that for gastroesophageal reflux; however, people with paraesophageal hernias may require emergency surgery to correct torsion (twisting) of the stomach that can lead to restriction of blood flow to the area.

DIVERTICULUM

A diverticulum is an outpouching of mucosa and submucosa that protrudes through a weak portion of the musculature that can occur at any location in the esophagus.

The most common type of esophageal diverticulum, which is found three times more frequently in men than in women, is *Zenker diverticulum* (also known as pharyngoesophageal pulsion diverticulum or a pharyngeal pouch). It occurs posteriorly through the cricopharyngeal muscle in the midline of the neck. Usually it is seen in people older than 60 years of age. Other types of diverticula include midesophageal (rare), epiphrenic (large), and intramural diverticula (numerous and small; related to stricture).

Clinical Manifestations and Assessment

Symptoms experienced by the patient with a pharyngoesophageal pulsion diverticulum include difficulty swallowing, fullness in the neck, belching, regurgitation of undigested food, and gurgling noises after eating. The diverticulum, or pouch, becomes filled with food or liquid. When the patient assumes a recumbent position, undigested food is regurgitated, and coughing may be caused by irritation of the trachea. Also halitosis and a sour taste in the mouth are common because of the decomposition of food retained in the diverticulum.

Symptoms produced by midesophageal diverticula are less acute. Due to the difficulty these patients have with food passing through their upper GI tract, they often have chest pain and difficulty with swallowing. Some patients experience regurgitation of undigested food, and some do not experience any symptoms at all.

A barium swallow may determine the exact nature and location of a diverticulum. Often pressure studies are performed for patients with epiphrenic diverticula to rule out a motor disorder. Esophagoscopy usually is contraindicated because of the danger of perforation of the diverticulum.

Nursing Alert
Blind insertion of NG tubes should be avoided in patients with esophageal diverticulum, esophageal varices, postgastric bypass, and lap banding procedures due to the potential of causing esophageal rupture or surgical site perforation.

Medical and Nursing Management

Because pharyngoesophageal pulsion diverticulum is progressive, the only means of cure is surgical removal of the diverticulum. During surgery, care is taken to avoid trauma to the common carotid artery and internal jugular veins. The sac is dissected free and amputated flush with the esophageal wall. In addition to a diverticulectomy, often a myotomy of the cricopharyngeal muscle is performed to relieve spasticity of the musculature, which otherwise seems to contribute to a continuation of the previous symptoms. An NG tube may be inserted at the time of surgery. Postoperatively, the surgical incision must be observed for evidence of leakage from the esophagus and a developing fistula. Food and fluids are withheld until radiographic studies indicate that there is no leakage at the surgical site. The diet begins with liquids and is progressively returned to solids as tolerated.

Surgery is indicated for epiphrenic and midesophageal diverticula only if the symptoms are troublesome and becoming worse. Treatment consists of a diverticulectomy and long myotomy. Intramural diverticula usually regress after the esophageal stricture is dilated.

PERFORATION

The esophagus is a common site of injury. Perforation may result from stab or bullet wounds of the neck or chest, trauma from a motor vehicle crash, caustic injury from a chemical burn, inadvertent puncture during a surgical procedure or esophageal dilatation, or from severe retching or vomiting (Boerhaave syndrome).

Clinical Manifestations and Assessment

The patient with a perforated esophagus has persistent pain, followed by dysphagia, fever, leukocytosis (elevated white blood cells), and severe hypotension. In some instances, signs of pneumothorax are observed. X-ray studies and fluoroscopy by either a barium swallow or esophagram are used to identify the site of the injury.

Medical and Nursing Management

Because of the high risk of infection, broad-spectrum antibiotic therapy is initiated. If the perforation is small enough and without symptoms, medical intervention may not be necessary. Nothing is given by mouth; nutritional needs are met by administering nutrition into the intestine, bypassing the stomach, or by the parenteral route. The type of nutritional support depends on the location and the extent of the injury. The enteral or parenteral nutrition lasts for at least 1 month to give the esophagus a chance to heal. A repeat barium swallow study is performed, and the involved area is reevaluated. If there is no evidence of perforation, foods are reintroduced, beginning with liquids and then slowly progressing to solids as tolerated.

Surgery may be necessary to close the wound; in such cases, postoperative nutritional support becomes a primary concern. Depending on the incision site and the nature of surgery, the postoperative nursing management is similar to that for patients who have had thoracic or abdominal surgery.

FOREIGN BODIES

Many swallowed foreign bodies pass through the GI tract without the need for medical intervention. However, some swallowed foreign bodies (e.g., dentures, fish bones, pins, small batteries, items containing mercury or lead) may cause trauma to the esophagus or obstruct its lumen and must be removed. Pain and dysphagia may be present, and dyspnea may occur as a result of pressure on the trachea. The foreign body may be identified by x-ray. Perforation may have occurred (see earlier discussion).

Glucagon, because of its relaxing effect on the esophageal muscle, may be injected intramuscularly. An endoscope (with a covered hood or overtube) may be used to remove the impacted food or object from the esophagus. A mixture consisting of sodium bicarbonate and tartaric acid may be prescribed to increase intraluminal pressure by the formation of a gas, which works to dislodge the foreign body. Caution must be used with this treatment because there is risk of perforation.

CHEMICAL BURNS

The severity of chemical burns to the esophagus is dependent upon the characteristics of the substance: pH, concentration, volume, and duration of contact with mucosa.

Clinical Manifestations and Assessment

Ingestion of the substance can be intentional or unintentional, which is important to consider when assessing the patient or reviewing his or her history. Strongly alkaline substances are more damaging to the esophagus as a result of causing a liquefactive necrosis when they come into contact with the mucosa. Alkalis include lye, chemical strippers, and drain cleaners. In addition, chemical burns of the esophagus also may be caused by undissolved medications in the esophagus. An acute chemical burn of the esophagus may be accompanied by severe burns of the lips, mouth, and pharynx, which can result in airway compromise due to edema or excessive mucus production. Also the patient may experience pain when swallowing.

Medical and Nursing Management

The patient's airway is prioritized, and he or she is treated for pain and possible shock. The patient's injury is evaluated using esophagoscopy. Vomiting and gastric lavage are avoided to prevent further exposure of the esophagus to the caustic agent. The patient is given nothing by mouth (NPO status), and IV fluids are administered. An NG tube may be inserted by the medical team. There is no consensus on the use of corticosteroids to reduce inflammation and minimize scarring and stricture formation at this time.

After the acute phase has subsided, the patient may need nutritional support via enteral or parenteral feedings. The patient may require further treatment to prevent or manage strictures of the esophagus. Strictures are repeatedly dilated with progressively larger cylindrical rubber tubes or bougies. For strictures that do not respond to dilation, surgical management is necessary. Reconstruction may be accomplished by esophagectomy and colon interposition to replace the portion of esophagus removed.

GASTROESOPHAGEAL REFLUX DISEASE

Some degree of gastroesophageal reflux (back-flow of gastric or duodenal contents into the esophagus) is normal in both adults and children. Excessive reflux may occur because of an incompetent lower esophageal sphincter, pyloric stenosis, or a motility disorder. The incidence of reflux seems to increase with aging.

Clinical Manifestations and Assessment

Symptoms of gastroesophageal reflux disease (GERD) may include pyrosis (burning sensation in the esophagus), dyspepsia (indigestion), regurgitation, dysphagia or odynophagia (pain on swallowing), hypersalivation, and esophagitis. The symptoms may mimic those of acute coronary syndrome. The patient's history aids in obtaining an accurate diagnosis.

Diagnostic testing and evaluation of GERD includes differentiation of other disease processes by proton-pump inhibitor (PPI) treatment and response, ambulatory reflux esophageal monitoring, and endoscopy only with severe symptoms (Katz, Gerson, & Vela, 2013). Barium studies and biopsy are not recommended as diagnostic tools.

Medical and Nursing Management

Management begins with teaching the patient to avoid situations that decrease lower esophageal sphincter pressure or cause esophageal irritation. The patient is instructed to eat a low-fat diet; to avoid caffeine, tobacco, beer, milk, foods containing peppermint or spearmint, and carbonated beverages; to avoid eating or drinking 2 hours before bedtime; to maintain normal body weight; to avoid tight-fitting clothes; to elevate the head of the bed on 6- to 8-in (15- to 20-cm) blocks; and to elevate the upper body on pillows. If reflux persists, the patient may be given antacids or H_2 receptor antagonists, such as famotidine (Pepcid), nizatidine (Axid), or ranitidine (Zantac). PPIs (medications that decrease the release of gastric acid, such as lansoprazole [Prevacid], rabeprazole [AcipHex], esomeprazole [Nexium]) may be used; however, these products may increase intragastric bacterial growth and the risk for infection. In addition, the patient may receive prokinetic agents, which accelerate gastric emptying. These agents include bethanechol (Urecholine), domperidone (Motilium), and metoclopramide (Reglan). Metoclopramide can have extrapyramidal side effects that are increased in certain neuromuscular disorders, such as Parkinson disease. These patients should be monitored carefully.

If medical management is unsuccessful, surgical intervention may be necessary (Katz et al., 2013). Transoral incisionless fundoplication, which involves the reconstruction of the valve at the gastroesophageal junction, is another endoscopic option that was found to have positive results in a recent study of 63 patients (Trad et al., 2015).

BARRETT ESOPHAGUS

Barrett esophagus is a condition in which the lining of the esophageal mucosa is altered. The tissue at the gastroesophageal junction changes from squamous epithelium (flat) to columnar epithelium (elongated). Barrett esophagus is sometimes found in patients being evaluated with a history of chronic regurgitation or heartburn. The disease may lead to esophageal cancer in some patients.

Clinical Manifestations and Assessment

The patient with Barrett esophagus complains of symptoms of GERD, notably frequent heartburn. The patient may also complain of symptoms related to peptic ulcers or esophageal stricture, or both.

An esophagogastroduodenoscopy (EGD) is performed. This usually reveals an esophageal lining that is red rather than pink, indicating the cellular change in tissue. With biopsy, cellular changes and goblet cells (mucus producing) are seen.

Medical and Nursing Management

Monitoring for Barrett esophagus varies depending on the extent of cell changes. Some providers recommend a repeat EGD in 6 to 12 months if the cellular changes are minor.

Photodynamic therapy (PDT) may be an alternative for the patient who is considered an operative risk (e.g., at least 70 years of age or older, significant cardiac risk). PDT is a type of laser thermal ablation of the esophageal mucosa that is used to destroy the metaplastic cells once the patient has received a photosensitizing agent, such as sodium porfimer. PDT has been well documented in the literature as a safe and effective treatment.

Ablative techniques including radiofrequency, thermal, and argon plasma coagulation are commonly used with acid suppression treatment. In the past, esophagectomy was the standard of treatment for these patients. Early detection of precancerous changes and the occurrence of high complication rates for surgery have left esophagectomy for treatment of advanced cases.

CANCER OF THE ESOPHAGUS

The American Cancer Society estimates that 16,980 diagnoses of esophageal cancer were made in 2015 as compared with 15,000 estimated diagnoses in 2009 (2015). In the United States, esophageal cancer represents 1% of all cancers diagnosed (American Cancer Society, 2015).

Pathophysiology

Esophageal cancer can be of two cell types: adenocarcinoma and squamous cell carcinoma. The rate of adenocarcinoma is rapidly increasing in the United States as well as in other Western countries. Adenocarcinoma is found in gland cells and is not common to the esophagus except in patients having Barrett esophagus, as described previously. As a result, patients with GERD and Barrett esophagus are at greater risk for developing esophageal cancer.

Tumor cells of adenocarcinoma and of squamous cell carcinoma may spread beneath the esophageal mucosa or directly into, through, and beyond the muscle layers into the lymphatics. In the latter stages, obstruction of the esophagus is noted, with possible perforation into the mediastinum and erosion into the great vessels.

Risk Factors

Esophageal cancer is three to four times more prevalent in men than women (American Cancer Society, 2015).

Chronic irritation is a risk factor for esophageal cancer. In the United States, cancer of the esophagus has been associated with ingestion of alcohol and the use of tobacco. Additional risk factors for squamous cell carcinoma of the esophagus include chronic ingestion of hot liquids or foods, nutritional deficiencies, poor oral hygiene, exposure to nitrosamines in the environment or food, and some esophageal medical conditions, such as caustic injury. Nitrosamines are found in rubber products, cured meats, beer, and pesticides.

Clinical Manifestations and Assessment

Many patients have an advanced ulcerated lesion of the esophagus before symptoms are manifested. Symptoms include dysphagia, initially with solid foods and eventually with liquids; a sensation of a mass in the throat; painful swallowing; substernal pain or fullness; and, later, regurgitation of undigested food with foul breath and hiccups. The patient first becomes aware of intermittent and increasing difficulty in swallowing. As the tumor grows and the obstruction becomes nearly complete, even liquids cannot pass into the stomach. Regurgitation of food and saliva occurs, hemorrhage may take place, and progressive loss of weight and strength occurs from starvation. Later symptoms include substernal pain, persistent hiccup, respiratory difficulty, and foul breath.

The delay between the onset of early symptoms and the time at which the patient seeks medical advice is often 12 to 18 months. Any person having swallowing difficulties should be encouraged to consult a provider immediately.

Currently, diagnosis is confirmed most often by flexible endoscopy with biopsy (Varghese et al., 2013). The biopsy can be used to determine the presence of disease and cell differentiation. At presentation, most patients have moderately differentiated tumors.

Several imaging techniques may provide useful diagnostic information, such as CT, MRI, endoscopic ultrasound, and positron emission tomography (PET). Endoscopic ultrasound is also helpful in determining whether the cancer has spread to the lymph nodes and other mediastinal structures. PET specifically assesses the metabolism of the cells being imaged so that malignant cells can be identified.

Medical Management

If esophageal cancer is detected at an early stage, treatment goals may be directed toward cure; however, it is often detected in late stages, making relief of symptoms the only reasonable goal of therapy. Treatment may include surgery, radiation, chemotherapy, or a combination of these modalities, depending on the type of cell, the extent of the disease, and the patient's condition. A standard treatment plan for a person who is newly diagnosed with esophageal cancer includes the following: preoperative combination chemotherapy/RT for 4 to 6 weeks, followed by a period of no medical intervention for 4 weeks, and, last, surgical resection of the esophagus.

Standard surgical management includes a total resection of the esophagus (esophagectomy) with removal of the tumor plus a wide tumor-free margin of the esophagus and the lymph nodes in the area. The surgical approach may be through the thorax or the abdomen, depending on the location of the tumor. When tumors occur in the cervical or upper thoracic area, esophageal continuity may be maintained by a free jejunal graft transfer, in which the tumor is removed and the area is replaced with a portion of the jejunum (Fig. 22-9). A segment of the colon may be used, or the stomach can be elevated into the chest and the proximal section of the esophagus anastomosed to the stomach.

Tumors of the lower thoracic esophagus are more amenable to surgery than are tumors located higher in the esophagus. GI tract integrity is maintained by anastomosing the lower esophagus to the stomach.

Surgical resection of the esophagus has a relatively high mortality rate because of infection, pulmonary complications, or leakage through the anastomosis. Postoperatively, the patient has an NG tube in place that should not be manipulated. The patient is given nothing by mouth until x-ray studies confirm that the anastomosis is free from an esophageal leak, there is no obstruction, and there is no evidence of pulmonary aspiration.

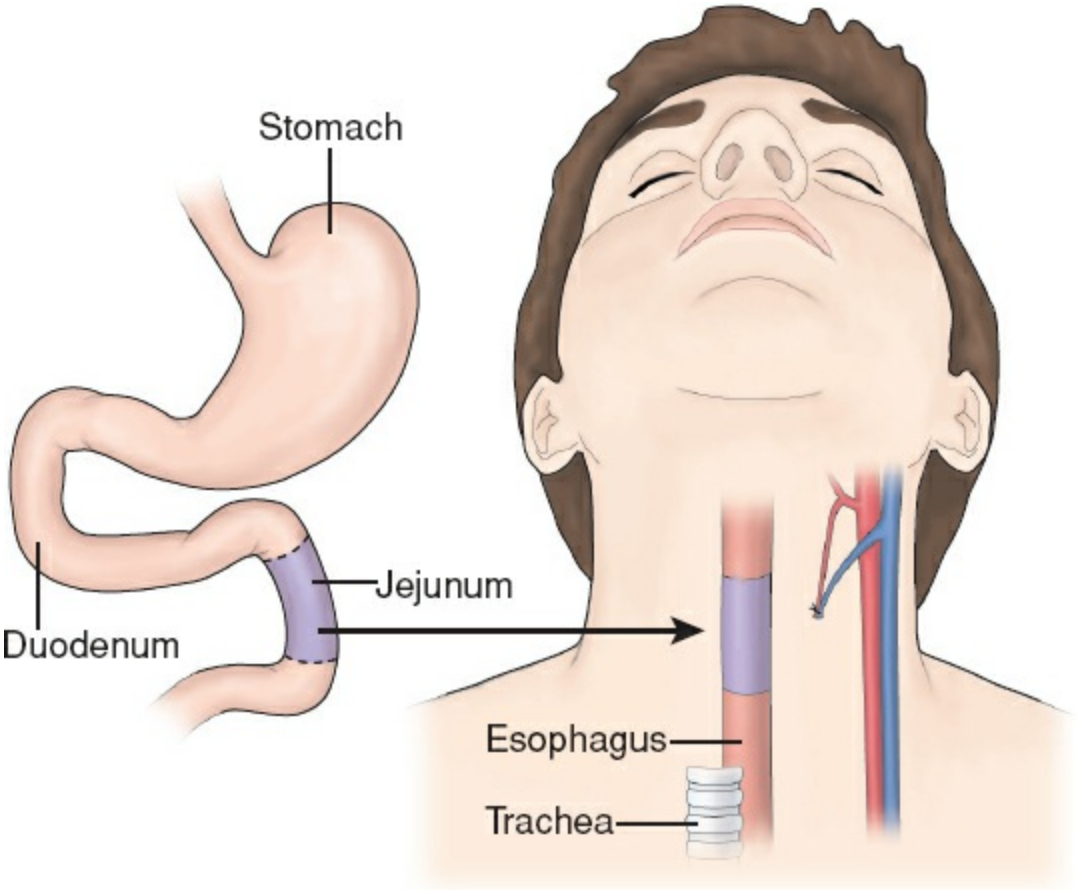

FIGURE 22-9 Esophageal reconstruction with free jejunal transfer. A portion of the jejunum is grafted between the esophagus and pharynx to replace the abnormal portion of the esophagus. The vascular structures are also anastomosed. A portion of the graft may be externalized through the neck wound to evaluate graft viability.

Palliative treatment may be necessary to keep the esophagus open, to assist with nutrition, and to control saliva. Palliation may be accomplished with dilation of the esophagus, laser therapy, placement of an endoprosthesis (stent), radiation, or chemotherapy.

Nursing Management

Intervention is directed toward improving the patient's nutritional and physical status in preparation for surgery, RT, or chemotherapy. A program to promote weight gain based on a high-calorie and high-protein diet, in liquid or soft form, is provided if adequate food can be taken by mouth. If this is not possible, parenteral or enteral nutrition is initiated. Nutritional status is monitored throughout treatment. The patient is informed about the nature of the postoperative equipment that will be used, including that required for closed chest drainage, NG suction, parenteral fluid therapy, and gastric intubation.

Immediate postoperative care is similar to that provided for patients undergoing thoracic surgery. It is not uncommon for patients to be placed in an intensive care unit or step-down unit. After recovering from the effects of anesthesia, the patient is placed in a low Fowler position, and later in a Fowler position, to help prevent reflux of gastric secretions. The patient is observed carefully for regurgitation and dyspnea. A common postoperative complication is aspiration pneumonia. Therefore, the patient is placed on a vigorous pulmonary plan of care that includes incentive spirometry (IS), sitting up in a chair, and, if necessary, nebulizer treatments. Chest physiotherapy is avoided due to the risk for aspiration. The patient's temperature is monitored to detect any elevation that may indicate aspiration or seepage of fluid through the operative site into the mediastinum or pleural cavity (depending on the surgeon's approach), which would indicate an esophageal leak. Drainage from the cervical neck wound, usually saliva, is evidence of an early esophageal leak. Typically, no treatment other than NPO and parenteral or enteral support is warranted.

Cardiac complications include atrial fibrillation, which occurs due to irritation of the vagus nerve at the time of surgery. Typical medical management includes digitalization or beta blockade, depending on the patient's response. Cardioversion may be used in rare occasions.

During surgery, an NG tube is inserted and taped or sutured in place. It is connected to low suction.

Nursing Alert
The NG tube is not manipulated; if displacement occurs, it is not likely to be replaced unless by the surgeon because damage to the anastomosis may occur.

The NG tube is commonly removed 5 to 7 days after surgery. Then a fiberoptic scope is used, often by a speech pathologist, to evaluate the patient's ability to swallow and to rule out possible aspiration before the patient has a Gastrografin study to assess for an anastomotic leak. If a leak into the mediastinum or pleural cavity is visualized, the study is stopped immediately, the patient returns to being NPO, and the provider is notified.

If the patient completes both procedures successfully, he or she is advanced to a regular diet. Small, frequent feedings (6 to 8 per day) are recommended because large quantities of food overload the stomach and promote gastric reflux. When the patient can increase his or her food and fluid intake to an adequate amount, parenteral fluids are discontinued. After each meal, the patient remains upright for at least 2 hours to allow the food to move through the GI tract. It is a challenge to encourage the patient to eat, because the appetite is

usually poor. Family involvement and home-cooked favorite foods may help the patient to eat. Antacids may help patients with gastric distress. Metoclopramide (Reglan) is useful in promoting gastric motility. Daily assessment of weight and nutritional intake is important.

If chemotherapy and radiation are part of the therapy, the patient's appetite will be depressed further, and esophagitis may occur, causing pain when food is eaten. Liquid supplements may be tolerated more easily. However, supplements such as Boost and Ensure should be avoided because they promote *dumping syndrome*, which occurs when large amounts of osmotically active solids and liquids rapidly "dump" into the duodenum. DS involves nausea and diarrhea that can result in symptoms of dehydration effecting the cardiac and respiratory systems. It can occur with each meal or approximately 20 minutes to 2 hours after eating, and although it can be quite disabling, it typically resolves without incident. (Dumping syndrome is discussed in detail later in this chapter.)

When the patient is ready to go home, the family is instructed about how to promote nutrition, what observations to make, what measures to take if complications occur, how to keep the patient comfortable, and how to obtain needed physical and emotional support.

GASTROINTESTINAL INTUBATION

GI intubation involves inserting a tube into the stomach or past the stomach into the duodenum or jejunum. The insertion point can be at the patient's nose, mouth, or the abdominal wall.

Clinical Indications

GI intubation can be done to decompress (remove) stomach fluid or air, lavage the stomach and remove toxins, administer medications and nutrition, treat an obstruction, and to bypass sections of the GI tract to allow them to rest. The size and type of tube used is determined by its purpose.

Tubes

Nasogastric and Orogastric Tubes

Often these types of tubes are used for decompression of a stomach that is distended due to air or fluid. These tubes are of large bore and may be single or double lumen. The Levin tube is a single-lumen tube, ranging from 14 to 18 French (Fr) in size and is made of plastic or rubber with multiple distal openings or "eyes" near its tip (1 Fr equals 1/3 of 1 mm, thus an 18 Fr is 6 mm in diameter). Circular markings at specific points on the tube serve as guides for insertion. The Levin tube is connected to low *intermittent* suction (30 to 40 mm Hg) to avoid erosion of gastric mucosa.

Nursing Alert
If a Levine tube is used, it must be on intermittent low wall suction (30 to 40 mm Hg) to prevent gastric erosion or tearing of the stomach lining (which can result after the stomach contents have been drained from suction, and continuous suction causes invagination of the mucosal lining of the stomach into the "eyes" of the tube).

The smaller the French size, the smaller the lumen of the tube. Contraindications to placement of NG tubes include facial and head trauma, severe coagulopathy, deviated septum, esophageal strictures or diverticula, and a history of alkali ingestion (Roberts & Hedges, 2013). Caution is used when inserting NG tubes in patients with esophageal varices as well as postgastric bypass and lap-banding procedures (Roberts & Hedges, 2013).

A gastric or Salem sump tube (SST) is a double-lumen tube available in 12 to 18 Fr (although typically a 16 to 18 Fr is used for adults); it is marked from the distal end at particular distances indicated by the manufacturer. The larger main lumen tube is intended for suction, and the smaller lumen or *pigtail*, which is typically blue in color, is termed the *venting port.* The venting port ensures that the suction at the distal end of the tube is maintained at a safe level to preserve the mucosa of the stomach by allowing atmospheric air to enter the blue lumen to prevent invagination of stomach into the multiple distal openings. An antireflux valve can be placed in the venting port of the tube if gastric fluid leaks through the air vent. The venting tube (blue pigtail) must be higher than the level of the stomach to prevent the siphoning out of gastric contents via this lumen. In the event that leakage has occurred, the larger lumen is irrigated with 30 mL of normal saline, after which air is injected to reestablish a buffer of air between the lumens, and an antireflux valve is applied to the venting lumen. The antireflux valve is a one-way valve that prevents gastric fluid from exiting the SST via the vent lumen (Fig. 22-10). If an SST is used, it must be on continuous low suction.

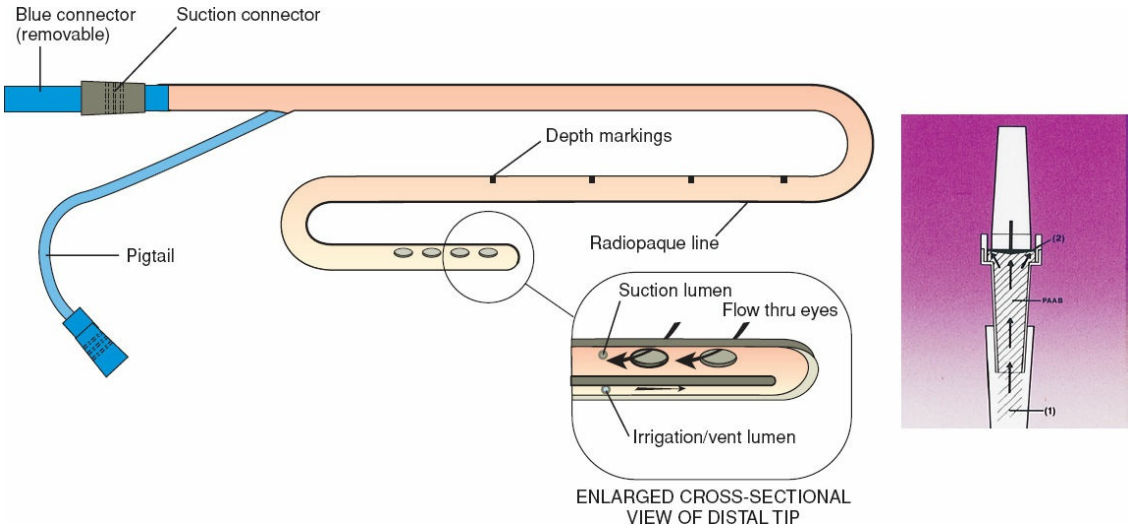

FIGURE 22-10 Gastric sump tube (Salem) equipped with a one-way valve that allows air to enter and can prevent reflux of gastric contents. The antireflux valve is designed with a pressure-activated air buffer (PAAB). The buffer is activated (1) and the valve closes (2) when pressure from gastric contents enters the tubing. (Courtesy of Lippincott's Nursing Procedures and Skills.)

In the event that gastric decompression is no longer needed, an SST can be used to administer intermittent medications, intermittent liquid feedings, or continuous liquid feedings. However, to do so, the venting tube must be plugged to prevent the instillation fluid from leaking out via this lumen. Residual volumes of stomach contents in patients receiving continuous tube feedings can be assessed easily with these large-bore tubes (residual volumes are discussed later in the chapter).

Postpyloric Tubes

Tubes that continue past the stomach and enter the duodenum and jejunum are longer, smaller-bore, single-lumen tubes. Duodenal and jejunal tubes are commonly 8 to 10 Fr and 110 to 140 cm long. Most often postpyloric tubes are inserted into the nares and are designed primarily for continuous feeding into the small intestine when gastric feeding is not desired. Examples of contraindications for gastric feedings include patients with a high risk of aspiration and those undergoing gastric surgery. Patients having pancreatitis or pancreatic surgery may have jejunal tubes placed to rest the pancreas by bypassing the hepatopancreatic ampulla, thereby avoiding the release of digestive enzymes into the duodenum.

Postpyloric tubes can be inserted before or during surgery, by interventional radiologists assisted by fluoroscopy, or at the bedside by a trained nurse or health care provider. At the bedside, the tube is advanced past the stomach actively, using a combination of air bolusing and peristalsis-enhancing medications such as metoclopramide, a gastric motility agent. Another method involves electromagnetic tube placement. In addition, self-advancing systems are available, which use a stylet inside the feeding tube that communicates with a receiver on the outside of the patient's body to indicate the position of the tube tip in the patient's GI tract (see Fig. 22-11). A trained nurse or physician is able to determine where the tube terminates in the small intestine. This method of insertion has been found to decrease time between placement and initiation of feedings, decrease the number of x-rays, and decrease instances of misplacement and pneumothorax (Smithard, Barrett, Hargroves,

& Elliot, 2015).

Passive advancement involves waiting for the peristaltic movement of the stomach and intestine to facilitate the migration of the tube into the small intestine. Placing the patient on his or her right side may be helpful in advancing the tube because gravity may assist the tube in passing through the pyloric sphincter and into the small intestine.

Nursing Management

Assessing the Patient before Tube Placement

When gastric or enteric/postpyloric intubation is ordered for a patient, it is important for the nurse to review the patient's history to check for contraindications for tube placement. Examples of contraindications include oral or nasal surgery, esophageal varices, esophageal diverticula, and esophageal or gastric surgery, such as a gastric pullup or gastric bypass. Such patients would have a greater risk for perforation, and an altered anatomy would make tube placement difficult if the details of the procedure were not known. It is also important to consider the nutritional status of the patient before a tube is inserted into his or her GI tract; serum prealbumin levels should be assessed. Prealbumin is an excellent marker for malnutrition because it has a shorter half-life (2 days) than does albumin (21 days), and it is not influenced by fluid balance. A normal prealbumin level for people aged 7 years and above is 19 to 38 mg/dL (Fischbach & Dunning, 2014). The likelihood of perforation is higher in patients with severe nutritional deficiencies due to poor tissue integrity.

FIGURE 22-11 All-in-one monitor with integrated visual display terminal, touch screen, and embedded computing system. The tip of the stylet contains an electromagnetic transmitter that generates a real-time signal as the feeding tube is inserted and advanced to the desired placement. The signal from the transmitting stylet is tracked throughout the placement procedure via a lightweight

smart receiver unit (SRU) that is placed on the patient's xiphoid process. The real-time tube tip tracking aids confident, safe placement. The all-in-one monitor triangulates the signal from the SRU and displays a real-time representation of the feeding tube tip's passage as it proceeds down the esophagus and into the preferred placement position.

Passage of an NG tube carries risk for patients with known or suspected cervical injuries and may exacerbate hemorrhage in patients with penetrating neck injuries if coughing and gagging occur during insertion (Roberts & Hedges, 2013). Serious complications include pulmonary misplacement of the NG tube and intracranial placement. Patients with head trauma should be evaluated for basilar skull fracture before an NG tube is placed. The tube could be inserted into the cranial vault inadvertently, if the fracture communicates.

Preparing the Patient

Before the patient is intubated, the nurse explains the purpose of the tube; this information may assist the patient in being cooperative and tolerant of what is often an unpleasant procedure. Then the general activities related to inserting the tube are reviewed, including the fact that the patient may have to breathe through the mouth and that the procedure may cause gagging until the tube has passed the area of the gag reflex.

Inserting the Tube

Before inserting the tube, the nurse determines the length of tubing that will be needed to reach the stomach or the small intestine. A mark is made on the tube to indicate the desired length. This length is determined by measuring the distance from the tip of the Nose to the Earlobe and from the earlobe to the Xiphoid process for gastric placement or NEX (Fig. 22-12). A common error in inserting NG tubes is to incorrectly estimate the proper length of the tube that should be inserted, thus NG tubes may be inserted too short (in the lower esophagus) or coiled in the stomach. One additional measurement is noted in the literature: adding 6 in (or 15 cm) to the NEX measurement to prevent high NG tube placement in tall patients (Roberts & Hedges, 2013). The average measurement for adults is 22 to 26 in or 56 to 66 cm (Lippincott Williams & Wilkins, 2013).

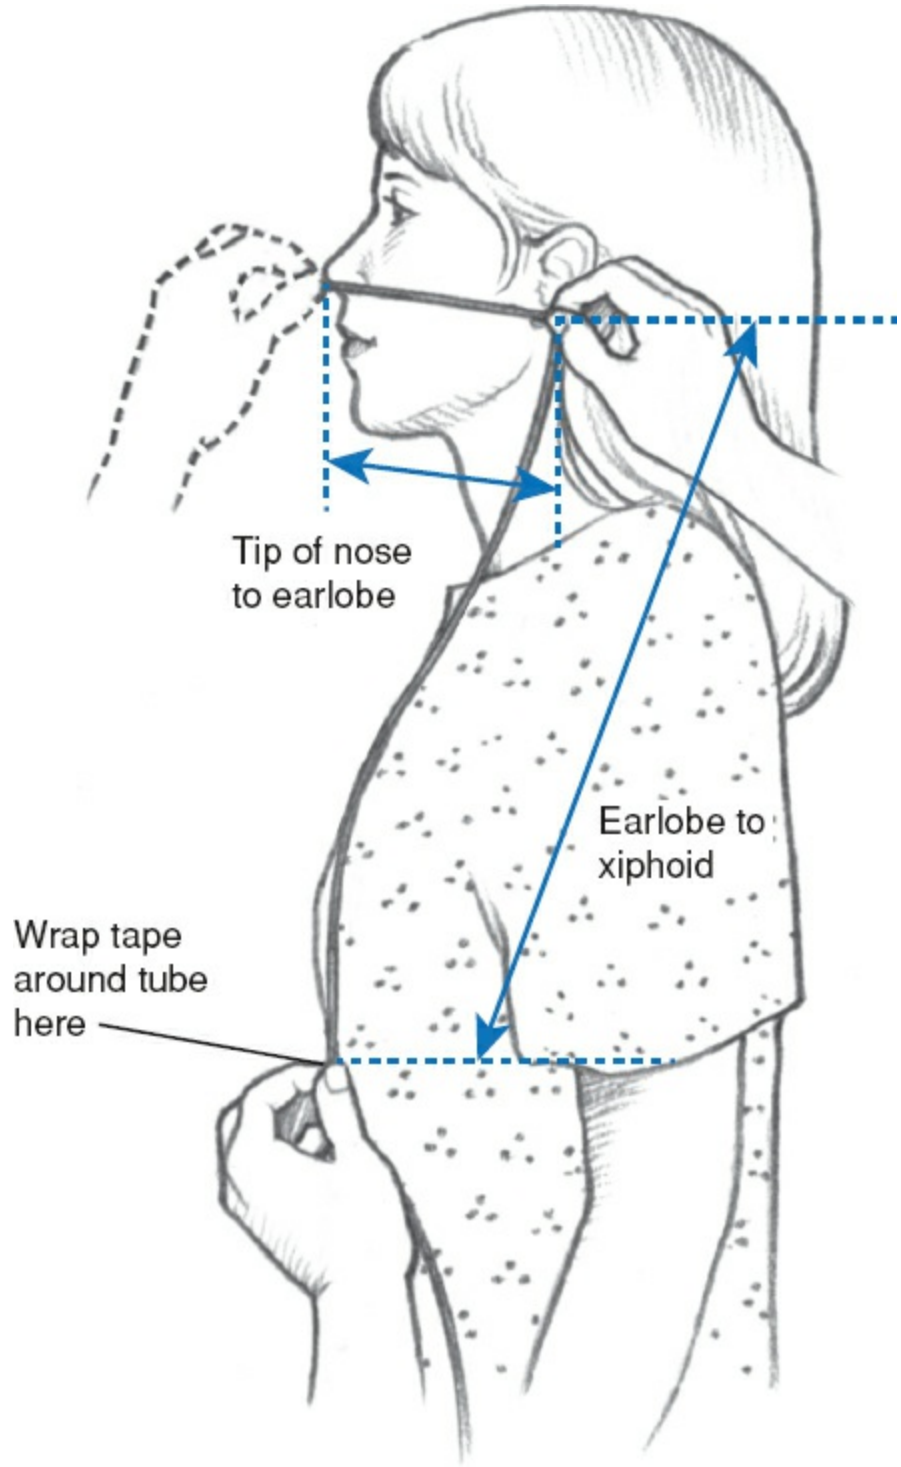

FIGURE 22-12 Measuring length of nasogastric tube for placement into stomach. To determine how long the NG tube must be to reach the stomach, hold the end of the tube at the tip of the patient's nose. Extend the tube to the patient's earlobe and then down to the xiphoid process (as shown above). (Reprinted with permission from *Nursing Procedures* (4th ed.). Ambler: Lippincott Williams & Wilkins, 2004.)

Insertion of the tube is not a sterile procedure; the nurse and other staff involved should follow Universal Precaution procedures as designated by their facility (gloves, gown, and face mask are recommended). While the tube is being inserted, the patient usually sits upright with a towel or some type of protective barrier spread bib-fashion over the chest.

Tissue wipes are made available. Privacy and adequate light are provided. The provider may swab the nostril and spray the oropharynx with tetracaine/benzocaine (Cetacaine) at least 5 minutes before the procedure to numb the nasal passage and suppress the gag reflex. This makes the entire procedure more tolerable. Having the patient gargle with a liquid anesthetic or hold ice chips in the mouth for a few minutes can have a similar effect. Encouraging the patient to breathe through the mouth or to pant often helps, as does swallowing water, if permitted.

A polyurethane tube may need to be warmed to make it more pliable. To make the tube easier to insert, it should be lubricated with a water-soluble lubricant unless it has a dry coating (called *hydromer*), which, when moistened, provides its own lubrication.

The patient is placed in Fowler position, and the nostrils are inspected for any obstruction. The more patent nostril is selected for use. The tip of the patient's nose is tilted, and the tube is aligned to enter the nostril, following the floor of the nose (under the inferior turbinate), not upward toward the nasal bridge. The tube is advanced slowly to avoid pressure on the nasal turbinates until the posterior pharynx is reached. If significant resistance is encountered, the other nostril is tried rather than forcing the tube, which can cause complications of bleeding or dissection into retropharyngeal tissue (Roberts & Hedges, 2013). When the tube reaches the posterior pharynx, the patient is allowed to rest for a few minutes before proceeding. Unless contraindicated, the patient is instructed to flex the neck to facilitate passage into the esophagus and to begin to swallow as the tube is advanced to the predetermined depth. The patient may also sip water through a straw to facilitate advancement of the tube unless drinking is contraindicated. The oropharynx is inspected to ensure that the tube has not coiled in the pharynx or mouth.

Confirming Placement

To ensure patient safety, it is essential to confirm that the tube has been placed correctly: the tube may be inserted in the lungs inadvertently, and this may go undetected in high-risk patients (e.g., those with decreased levels of consciousness, confused mental states, poor or absent cough and gag reflexes, or agitation during insertion). The gold standard for verifying placement of a blindly inserted tube is radiographic or x-ray confirmation (American Association of Critical Care Nurses [AACN, 2016b]). X-ray confirmation is necessary if the patient will be receiving feedings or medications through the tube. When a tube is to be used for removal of air or fluid and not instillation, the nurse can use a combination of visually assessing the aspirate, testing its pH, and using capnographic devices to initially determine placement. Visual assessment of the color of the aspirate may help identify tube placement. The gastric aspirate is most frequently cloudy and green, tan or off-white, or bloody or brown. Intestinal aspirate is primarily clear and yellow to bile-colored. The pleural fluid is usually pale yellow and serous, and tracheobronchial secretions usually consist of mucus that is tan or off-white. The appearance of the aspirate may be helpful in distinguishing between gastric and intestinal placement but is of little value in ruling out respiratory placement.

Determining the pH of the tube aspirate is a more accurate method of confirming tube placement than is maintaining tube length or visually assessing tube aspirate. The pH method also can be used to monitor the advancement of the tube into the small intestine. The pH of gastric aspirate is acidic (1 to 5), typically less than 4. The pH of intestinal

aspirate is approximately 6 or higher, and the pH of respiratory aspirate is more alkaline (greater than 6).

Patients who are receiving histamine 2 (H_2)-receptor antagonists or PPIs may demonstrate pH ranges from 0 to 6.0, and pH can be affected by medications or formulas. This alkaline aspirate could falsely confirm a postpyloric tube position (Damm & Gama de Abreu, 2012). Therefore, testing the pH remains an area where further research is warranted. Capnography involves detecting carbon dioxide at the external end of the NG tubes. In a group of 257 patients in medical ICU with NG tube placements, capnography has been found to have 99.4% sensitivity and 91.3% specificity on identifying tubes that did not terminate in the GI tract on first attempt (Smymios et al., 2015).

Placement also must be ensured at regular intervals once the device is placed. These times include when medications or fluids are given and every 4 hours for patients receiving continuous tube feedings. The traditional method has been to inject air through the tube while auscultating the epigastric area with a stethoscope to detect air insufflation. However, studies indicate that this auscultatory method is not particularly accurate in determining whether the tube has been inserted into the stomach, intestines, or respiratory tract (AACN, 2016b). Instead of the auscultation method, a combination of four methods is recommended: assessment of the patient's tolerance to medication and feeding administration, measurement of tube length, visual assessment of aspirate, and assessing the pH measurement of aspirate.

To determine tolerance of the feeding to ascertain placement, the nurse assesses the patient's respiratory status. Coughing, gagging, and decreased pulse oximetry could indicate that the tube has migrated. The nurse also inspects the oral cavity to visualize the tube in the back of the patient's throat. It is possible for a patient to regurgitate the tube into the mouth with frequent gagging and coughing.

After the tube is inserted, the exposed portion of the tube is measured and the length is documented. The nurse measures the exposed tube length every shift and compares it with the original measurement. An increase in the length of exposed tube may indicate dislodgement.

Securing the Tube

After the correct position of the tip of the tube has been confirmed, the NG tube is secured to the nose (Fig. 22-13). A liquid skin barrier can be applied to the skin where the NG tube will be secured. The prepared area is covered with a strip of hypoallergenic tape or Op-Site, and then the tube is placed over the tape and secured with a second piece of tape. Instead of tape, a number of companies have feeding tube device holders that can be placed. A nasal bridle can be used in patients in multiple levels of care who have a history of tube dislodgment due, for example, to impaired mental status related to dementia or traumatic brain injury. Bridling (Fig. 22-14) involves the insertion of a loop of strong but flexible material through the naris, around the nasal septum, and out the other nare as a "bridle" to which the nasoenteric tube is secured. A meta-analysis involving 6 studies and 594 patients found that the use of bridles was significantly effective in reducing dislodgements compared to using tape; however, one drawback was that the incidence of skin breakdown was higher in patients with bridles (Bechtold et al., 2014). In addition, it is wise to secure the NG tube to the patient's gown or pajamas with an elastic band and safety pin or with adhesive tape

loops so that a tug on the tube will not pull on the naris. It is crucial that the NG tube is secured without putting undue pressure on the medial or lateral nares in order to prevent tissue necrosis. In addition, the tape securing the tube should be changed daily and the nares inspected for complications such as erosion (Lippincott Williams & Wilkins, 2013). The tube must be looped loosely to prevent tension and dislodgement.

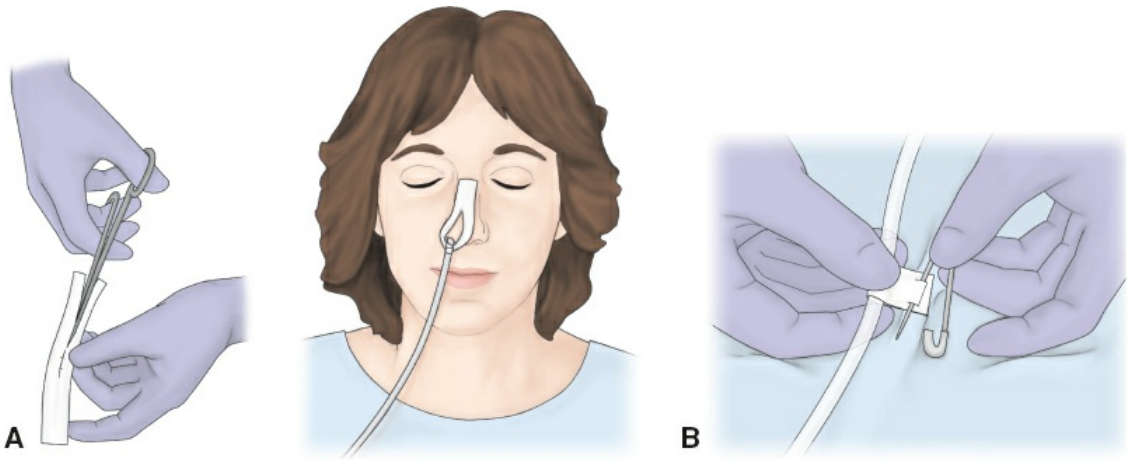

FIGURE 22-13 Securing nasogastric (NG) tubes. A. The NG tube is secured to the nose with tape to prevent injury to the nasopharyngeal passages. B. The tubing is secured to the patient's gown with tape attached to a safety pin to prevent tension on the line.

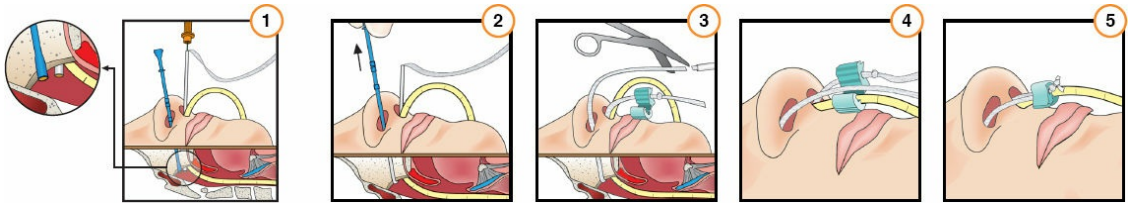

FIGURE 22-14 A bridle nasal tube retaining system. Placement entails: (1) Advance catheter stylet and blue probe in opposite nares until magnets connect. Remove orange stylet from catheter. (2) Slowly remove blue probe, drawing the white catheter around the vomer bone and out the opposite nare. (3) Cut catheter off and discard. (4) Place tube and umbilical tape in clip. (5) Securely close clip 1 cm below nose. Tie two to three knots and cut off excess. (Reprinted with permission from AMT Bridle Nasal Tube Retaining System from Applied Medical Technology, Inc.)

Nursing Alert
If the patient is ambulatory and has an SST, the blue pigtail must be above the level of the stomach to prevent gastric fluid leaking out via this port. The pigtail can be fitted into the larger suction lumen to seal off the NG tube while the patient is ambulating.

Monitoring the Patient and Maintaining Tube Function

It is important to keep an accurate record of all fluid intake, feedings, and irrigation. To maintain patency, the tube is irrigated every 4 to 6 hours with normal saline to avoid electrolyte loss through gastric drainage. Sterile water may be used during medication administration or tube feedings, especially when the access is postpyloric and the acidic environment of the stomach is bypassed (White & Bradnam, 2015). The nurse records the

amount, color, and type of all drainage every 8 hours.

When double- or triple-lumen tubes are used, each lumen is labeled according to its intended use: aspiration, feeding, or balloon inflation (refer to Sengstaken-Blakemore tube in Chapter 25).

When feedings or medications are ordered for administration through a GI tube, it is the nurse's responsibility to maintain the patency of the device as well as to assess the patient's tolerance of the feeding or meds. Liquid nutritional solutions are commonly administered at a continuous rate via programmable electronic pump or by syringe in intermittent boluses. With continuous feedings, it is important for the nurse to assess the volume of feed in the bag to ensure it does not run dry.

Administering Medication

When medications are administered through GI tubes, flushing the tube with 30 to 50 mL of (sterile) water may decrease the risk of tube occlusion (Lippincott Williams & Wilkins, 2013). With NG tubes and small-diameter nasoenteric tubes, thorough crushing of medications in pill form is a necessity. A nurse should collaborate with the medical team and pharmacy to convert medications to liquid forms, if possible. Also the nurse should be aware that administering extended-release tablets that would require crushing through such tubes is prohibited since overdosage can result. However, occasionally, time-released capsules are permitted to be opened (not crushed) and administered, and pharmacy staff should be consulted if any questions or concerns exist related to whether medications can be crushed or opened. The medical team should be notified to have the medications changed to liquid form whenever possible. Table 22-1 discusses administering medications.

TABLE 22-1 Preparing Medication for Delivery by Feeding Tube

Medication Form	Preparation
Liquid	None
Simple compressed tablets	Crush and dissolve in water
Buccal or sublingual tablets	Administer as prescribed
Soft gelatin capsules filled with liquid	Make an opening in the capsule and squeeze the contents out into water to dissolve
Enteric-coated tablets	Do not crush; change in form is required; consult pharmacy department as needed
Timed-release tablets	Do not crush tablets because doing so may release too much drug too quickly (overdose); check with pharmacist for alternative formulation
Timed-release capsules or sustained-release capsules	Some can be opened and contents added to tube-feeding formula; *always* check with pharmacist before doing this

Unclogging Tubes

When a tube becomes clogged with feedings or medications, a number of methods can be used to regain patency of the tube without having to replace it. Smaller-diameter postpyloric tubes can clog if feedings are stopped and the tube is not flushed properly. Warm water can be administered through the tube with caution using varying sizes of syringes; smaller syringes having greater force to dislodge the clog. Cola and cranberry juice have historically been recommended as an effective, noninvasive means of unclogging tubes; however, a more consistently effective method involves instilling a mixture of pancreatic enzymes and sodium bicarbonate into the tube for 20 minutes to digest the clog. The nurse is aware that correct placement of the NG tube must be confirmed before any mixture is injected to unclog the tube.

Nursing Alert

Currently, a small number of research literature evaluates the nursing considerations and interventions relating to the administration of medications via enteral tubes. The nurse should read current literature and access databases such as the Cochrane library for the most current evidence.

Providing Oral and Nasal Hygiene

Regular and conscientious oral and nasal hygiene is a vital part of patient care because the tube causes discomfort and pressure and may be in place for several days. Moistened cotton-tipped swabs can be used to clean the nose, followed by cleansing with a water-soluble lubricant. Frequent mouth care is comforting for the patient. The nasal tape is changed daily, and the nose is inspected for skin irritation. If the nasal and pharyngeal mucosa is excessively dry, steam or cool vapor inhalations may be beneficial. Throat lozenges, an ice collar, chewing gum, or sucking on hard candies (if permitted) as well as limiting talking also assist in relieving patient discomfort. These activities keep the mucous membranes moist and help prevent inflammation of the parotid glands.

Monitoring and Managing Potential Complications

Patients with NG or nasoenteric intubation are susceptible to a variety of problems, including fluid volume deficit (FVD), pulmonary complications, and tube-related irritations. These potential complications require careful ongoing assessment.

Symptoms of FVD include dry skin and mucous membranes, decreased urinary output, lethargy, orthostatic hypotension, and increased heart rate. Also a nurse can calculate the patient's pulse pressure (systolic blood pressure minus diastolic blood pressure) to predict the patient's volume status. A pulse pressure of less than 30 mm Hg is indicative of FVD. Assessment of FVD involves maintaining an accurate record of intake and output. This includes measuring NG or nasointestinal (NI) drainage, fluid instilled by irrigation of the NG/NI tube, water taken by mouth, vomitus, water administered with tube feedings, and IV fluids. Laboratory values, particularly blood urea nitrogen and creatinine, are monitored. The nurse assesses 24-hour fluid balance and reports negative fluid balance, increased NG output, interruption of IV therapy, or any other disturbance in fluid intake or output.

Pulmonary complications from NG intubation occur because coughing and clearing of the pharynx are impaired, because gas buildup can irritate the phrenic nerve, and because tubes may become dislodged, retracting the distal end above the esophagogastric sphincter (which places the patient at risk for aspiration, or breathing fluids or foods into the trachea and lungs). Medications such as metoclopramide (Reglan) can be administered to decrease potential problems. Signs and symptoms of complications include coughing during the administration of foods or medications, difficulty clearing the airway, tachypnea, and fever. Assessment includes regular auscultation of lung sounds and routine assessment of vital signs. It is important to encourage the patient to cough and to take deep breaths regularly. The nurse also carefully confirms the proper placement of the tube by assessing tube length before instilling any fluids or medications.

Irritation of the mucous membranes is a common complication of NG/NI intubation. The nostrils, oral mucosa, esophagus, and trachea are susceptible to irritation and necrosis. Visible areas are inspected frequently, and the adequacy of hydration is assessed. When providing oral hygiene, the nurse carefully inspects the mucous membranes for signs of

irritation or excessive dryness. The nurse palpates the area around the parotid glands to detect any tenderness or enlarged nodes, indicating parotitis, and observes for any irritation or skin breakdown at the insertion site (e.g., naris) or of the mucous membranes. In order to preserve the skin integrity of the naris, the nurse should rotate the position of the tube on the wall of the naris once every 24 hours. In addition, it is important to assess the patient for esophagitis and tracheitis; symptoms include sore throat and hoarseness.

Nursing Alert

The nurse alerts the health provider when new frank bleeding is noted in the NG tube drainage or if "coffee-ground material" is noted because it may indicate bleeding. Gastroccult testing is available to assess the presence of blood in gastric drainage. The nurse is aware that hemoccult test for stool cannot be used for evaluation of gastric drainage.

Removing the Tube

Before removing a tube, the nurse may clamp and unclamp it intermittently for a trial period of several hours to ensure that the patient does not experience nausea, vomiting, or distention. Before the tube is removed, it is flushed with 10 mL of water or normal saline to ensure that it is free of debris and away from the gastric lining. Gloves are worn to remove the tube, and a towel or disposable pad is placed on the patient's chest. The tube is withdrawn gently and slowly for 15 to 20 cm (6 to 8 in) until the tip reaches the esophagus; the remainder is withdrawn rapidly from the nostril. If the tube does not come out easily, force should not be used, and the problem should be reported to the provider. As the tube is withdrawn, it is concealed in the disposable pad or towel to prevent secretions from soiling the patient or nurse. After the tube is removed, the nurse provides oral hygiene.

Administering Tube Feedings with Nasogastric and Nasoenteric Devices

Enteral nutrition feedings are given to meet nutritional requirements when oral intake is inadequate or not possible and the GI tract is functioning normally. Tube feedings have several advantages over PN: they are low in cost, safe, well tolerated by the patient, and easy to use both in extended-care facilities and in the patient's home. Other advantages include:

- Preserving GI integrity by delivery of nutrients and medications intraluminally
- Preserving the normal sequence of intestinal and hepatic metabolism
- Maintaining fat metabolism and lipoprotein synthesis
- Maintaining normal insulin/glucagon ratios

Tube feedings are delivered to the stomach (in the case of NG intubation or gastrostomy) or to the distal duodenum or proximal jejunum (in the case of nasoduodenal or nasojejunal tube feeding). Nasoduodenal or nasojejunal feeding is indicated when the esophagus and stomach need to be bypassed or when the patient is at risk for aspiration. For long-term feedings (longer than 4 weeks), gastrostomy or jejunostomy tubes are

preferred for administration of medications or food. The numerous conditions requiring enteral nutrition are summarized in Table 22-2.

Reducing the Risk of Aspiration

To decrease the risk of aspiration, the head of the bed must remain elevated to 30 to 45 degrees at all times if appropriate for the patient's condition (AACN, 2016a). An elevated head of bed may not be appropriate for some patients, such as those with spinal injuries or mobility restrictions due to interventional procedures involving the vasculature of the groin. In these cases, it may be appropriate to adjust the hospital bed to a reverse Trendelenburg position per health care provider's order to decrease aspiration risk. If the patient is on bedrest, the tube feeding must be shut off when bed making, bathing, or anytime the head of the bed must be lowered to below 30 degrees.

TABLE 22-2 Conditions Requiring Enteral Therapy

Condition or Need	Examples
GI problems	Fistula, short-bowel syndrome, mild pancreatitis, Crohn disease, ulcerative colitis, nonspecific maldigestion or malabsorption
Cancer therapy	Radiation, chemotherapy
Convalescent care	Surgery, injury, severe illness
Coma, semi-consciousness[a]	Stroke, head injury, neurologic disorder, neoplasm
Hypermetabolic conditions	Burns, trauma, multiple fractures, sepsis, AIDS, organ transplantation
Chronic illness, psychiatric or neurologic disorder Alcoholism, chronic depression, anorexia nervosa[a]	Alcoholism, chronic depression, anorexia nervosa[a]
Debilitation[a]	Disease or injury
Maxillofacial or cervical surgery	Disease or injury, wired jaw, spinal cord injury
Oropharyngeal or esophageal paralysis[a]	Disease or injury, neoplasm, inflammation, trauma, respiratory failure

[a]Because some of these patients are at risk for regurgitating or vomiting and aspirating administered formula, each condition must be considered individually.

Residual Assessment

Patient tolerance of liquid enteral nutrition is determined by residual measurement, the presence or absence of nausea and vomiting, and increasing abdominal distention. Residual measurement or volume of aspiration is most easily assessed with large-bore GI tubes. Smaller-diameter nasojejunal tubes and duodenal tubes often collapse when suction is

applied. The volume of aspirate indicates the rate at which the patient is digesting the feedings and how quickly the chyme is passing into the small intestine. The volume of the stomach is approximately 1 L, with an ability to stretch with increased intake depending on the size of the patient.

To assess gastric residuals, a 60-mL syringe is used to measure volumes from feeding tubes every 4 hours. The nurse slowly applies a steady pressure on the plunger and aspirates the residual volume until no more fluid can be withdrawn into the syringe. Policies vary according to institutions, and the nurse should follow unit guidelines. The American Society of Parenteral and Enteral Nutrition and the Society of Critical Care Medicine recommend that if gastric residual volumes are measured in ICU patients that feedings should be held for volumes over 500 mL, although the societies recognize that evidence to support the practice is poor (McClave et al., 2016). Similar guidelines published in Canada in 2013 support the volume range as well (Dhaliwal, Cahill, Lemieux, & Heyland, 2013). Promotility agents are considered with increasing residual volumes (metoclopramide or erythromycin) (McCarthy & Martindale, 2015). Because individual procedures vary widely, and uncertainty exists regarding the assessment and treatment in high residual volumes, it is important to follow institutional procedures closely and hold feedings as indicated.

Osmosis, Osmolality, and Dumping Syndrome

Osmolality is an important consideration for patients receiving tube feedings through the duodenum or jejunum because feeding formulas with a high osmolality may lead to undesirable effects, such as dumping syndrome.

Fluid balance is maintained by osmosis, the process by which water moves through membranes from a dilute solution of lower osmolality (ionic concentration) to a more concentrated solution of higher osmolality until both solutions are of nearly equal osmolality. The osmolality of normal body fluids is approximately 300 mOsm/kg. The body attempts to keep the osmolality of the contents of the stomach and intestines at approximately this level.

Highly concentrated solutions and certain foods can upset the normal fluid balance in the body. Individual amino acids and carbohydrates are small particles that have great osmotic effect. Electrolytes, such as sodium and potassium, are comparatively small particles; they have a great effect on osmolality and, consequently, on the patient's ability to tolerate a given solution.

When a concentrated solution of high osmolality is taken in large amounts, water moves to the stomach and intestines from fluid surrounding the organs and the vascular compartment. The patient has a feeling of fullness, nausea, and diarrhea; this causes dehydration, hypotension, and tachycardia, collectively termed dumping syndrome. Patients vary in the degree to which they tolerate the effects of high osmolality; usually, debilitated patients are less tolerant. The nurse needs to be knowledgeable about the osmolality of the patient's formula and needs to observe for and take steps to prevent undesired effects. Dumping syndrome can be prevented by the following interventions: using room-temperature feedings (gastric emptying will be faster if temperature of the fluid is too hot or too cold), changing from bolus to continuous feedings if appropriate, having the patient remain in a semi-Fowler position for 1 hour after eating to gradually allow the feedings to pass into the intestine, and slowing the rate of feedings to allow more time for

digestion.

In the event that a tube feeding uses a high-osmolality formula, the nurse observes the patient's sodium level and expects that free water may be ordered by diluting the tube feeding or by periodic instillation of water by the health care team if rising sodium levels are seen. Response to the free water (either dilution of tube feeding or tap water instilled via the NG/NI tube) is assessed with subsequent electrolyte levels.

Nursing Alert

The nurse understands that administering medication via an enteral tube is not the same as PO (Per Os or by mouth). For example, liquid antibiotics, laxatives, and vitamin and electrolyte solutions far exceed the osmolality of GI secretions (approximately 300 mOsm/kg). The practice of crushing multiple tablets and mixing powders together before administration is an unsafe habit. Mixing drugs together, whether solid or liquid, creates an unknown substance with an unpredictable mechanism of release and bioavailability. Proper flushing of the tube before, between, and after each drug is recommended. Also, enteral feeding needs to be stopped and the feeding tube needs to be flushed before medication is administered. The pharmacist should be consulted regarding medication administration. Refer to the do not crush list at http://www.ismp.org/tools/donotcrush.pdf for specific information.

Tube Feeding Formulas

The choice of formula to be delivered by tube feeding is influenced by the status of the GI tract and the nutritional needs of the patient. Dietitians collaborate with providers and nurses to determine the best formula for the individual patient. The formula characteristics that are considered prior to selection include the chemical composition of the nutrient source (protein, carbohydrates, fat), caloric density, osmolality, residue, bacteriologic safety, vitamins, minerals, and cost.

Various major formula types for tube feedings are available commercially. Commercially prepared polymeric formulas (formulas with high molecular weight) are composed of protein, carbohydrates, and fats in a high–molecular-weight form (e.g., Boost Plus, TwoCal HN, Isosource). Chemically defined formulas (e.g., Peptamen 1.5 or Vivonex) contain predigested and easy-to-absorb nutrients. Modular products contain only one major nutrient, such as protein (Beneprotein). Disease-specific formulas are available for various conditions. For patients with kidney failure, a formula such as Nepro, which is high in calories and low in electrolytes, is ideal because it is formulated to maintain electrolyte and fluid balance. For patients with severe chronic obstructive pulmonary disease, a formula such as Pulmocare may be selected because it is high in fat and low in carbohydrates, has a high density (1.5 calories/mL) that helps maintain fluid restriction, and reduces carbon dioxide production. Excess carbohydrates may increase production of CO_2, and this negatively impacts respiratory status. Fiber is added to some formulas (e.g., Jevity) to decrease the occurrence of diarrhea in some at-risk patients. Blenderized formulas also can be used. They can be made by the patient's family or obtained in a ready-to-use form that is carefully prepared according to directions. Some feedings are given as supplements, and others are designed to meet the patient's total nutritional needs.

Administration Methods and Frequency

The frequency of tube feeding and administration method depends on the location of the tube in the GI tract, patient tolerance, convenience, and cost. Intermittent bolus feedings are administered into the stomach (usually by gastrostomy tube) in large amounts at designated intervals and may be given four to eight times per day. The intermittent gravity drip, another method for administering tube feedings into the stomach, is commonly used when the patient is at home. In this instance, the tube feeding is administered over 30 minutes at designated intervals. Both of these tube feeding methods are practical and inexpensive. However, the feedings delivered at variable rates may be poorly tolerated and time consuming.

Often the continuous infusion method is used when feedings are administered into the small intestine. This method is preferred for patients who are at risk for aspiration or who tolerate tube feedings poorly (Luttikhold et al., 2016; McClave et al., 2016). The feedings are given continuously at a constant rate by means of a pump. This method decreases abdominal distention, gastric residuals, and the risk of aspiration. However, pumps are expensive, and they allow the patient less flexibility than intermittent feedings.

An alternative to the continuous infusion method is cyclic feeding. The infusion is administered at a higher hourly volume over the course of 8- to 12-hour intervals with the goal of meeting the prescribed calories and/or macronutrient for a 24-hour period. Feedings may be infused at night to avoid interrupting the patient's lifestyle. Cyclic continuous infusions may be appropriate for patients who are being weaned from tube feedings to an oral diet, as supplements for patients who cannot eat enough, and for patients at home who need day time hours free from the pump. Whichever method is chosen, the head of the bed must be maintained at a minimum of 30 degrees to decrease the risk of aspiration. A wide variety of containers, feeding tubes and catheters, delivery systems, and pumps are available for use with tube feedings.

Complications of Tube Feedings

Diarrhea, the most common complication associated with liquid feedings, is commonly due to the hyperosmolality of the feedings and/or the decreased serum osmolality of the patient's serum. Changing the concentration or type of formula often decreases or stops this complication.

Aspiration pneumonia is an important mechanical complication. Aspiration can occur due to improperly placed tubes or when the patient vomits the formula into the airway. When aspiration occurs or is suspected, it is important for the nurse to stop the feeding, suction the pharynx and trachea, and closely assess the patient's respiratory status while contacting the provider. Aspiration prevention involves keeping the patient's head of bed elevated to at least 30 degrees and verifying the tube placement on insertion, before food or medication administration, and periodically throughout a 24-hour shift.

Patients may have increased blood glucose as a metabolic complication of tube feedings. Carbohydrate content varies between the different types of formula used and should be considered if the patient is hyperglycemic. The nurse should assess the patient's blood sugar frequently especially when initiating a tube feeding. Additional complications of enteral therapy can be found in Table 22-3.

GASTROSTOMY

A gastrostomy is a surgical procedure in which an opening is created into the stomach for the purpose of administering foods and fluids via a feeding tube.

Clinical Indications

Gastrostomy is preferred for prolonged enteral nutrition support when the patient's diagnosis makes it difficult to support the nutritional requirements, such as in patients with traumatic brain injury and patients with neurodegenerative diseases (Alzheimer disease). Gastrostomy is also preferred over NG feedings in the patient who is comatose because the gastroesophageal sphincter remains intact. Regurgitation and aspiration are less likely to occur with a gastrostomy than with NG feedings.

Types

Different types of feeding gastrostomies may be used, including the Stamm (temporary and permanent), Janeway (permanent), and percutaneous endoscopic gastrostomy (PEG) tube (temporary) systems. The Stamm and Janeway gastrostomies require either an upper abdominal midline incision or a left upper quadrant transverse incision. The Stamm procedure requires the use of concentric pursestring sutures to secure the tube to the anterior gastric wall. To create the gastrostomy, an exit wound is created in the left upper abdomen. The Janeway procedure necessitates the creation of a tunnel (called a *gastric tube*) that is brought out through the abdomen to form a permanent stoma.

Insertion of a PEG requires the services of two physicians (or a physician and a nurse with specialty skills). After administering a local anesthetic, one health care provider inserts a cannula into the stomach through an abdominal incision and then threads a nonabsorbable suture through the cannula; the second provider inserts an endoscope via the patient's upper GI tract and uses the endoscopic snare to grasp the end of the suture and guide it up through the patient's mouth. The suture is knotted to the dilator tip at the end of the PEG tube. Then the provider who inserted the endoscope advances the dilator tip through the patient's mouth while the first provider pulls the suture through the cannula site. The attached PEG tube is guided down the esophagus, into the stomach, and out through the abdominal incision (Fig. 22-15). The mushroom catheter tip and internal crossbar secure the tube against the stomach wall. An external crossbar or bumper keeps the catheter in place. A tubing adaptor is in place between feedings, and a clamp or plug is used to close or open the tubing.

TABLE 22-3 Complications of Enteral Therapy

Complications	Causes	Selected Nursing Interventions	
		Treatment	Prevention
Gastrointestinal			
Diarrhea (most common)	Hyperosmolar feedings Rapid infusion/bolus feedings Bacteria-contaminated feedings Lactase deficiency Medications/antibiotic therapy Decreased serum osmolality level Food allergies Cold formula	Assess fluid balance and electrolyte levels; report findings Implement changes in tube feeding formula or rate	Assess rate of infusion and temperature of formula Replace formula every 4 hours; change tube feeding container and tubing daily
Nausea/vomiting	Change in formula or rate Hyperosmolar formula Inadequate gastric emptying	Review medications	Check residuals; if >200 mL consider promotility medications, if >500 mL, check with provider. (Because individual procedures vary widely, it is important to follow institutional procedures closely and to hold feedings as indicated)
Gas/bloating/ cramping	Air in tube	Notify provider if persistent	Keep tubing free of air
Dumping syndrome	Bolus feedings/rapid rate Cold formula	Check fiber and water content; report findings Check rate and temperature of formula	Avoid rapid infusion of feeding Administer feeding at or near room temperature
Constipation	High milk (lactose) content Lack of fiber Inadequate fluid intake/ dehydration Opioid use	Check fiber and water content; report findings	Administer adequate amount of hydration as flushes
Mechanical			
Aspiration pneumonia	Improper tube placement Vomiting with aspiration of tube feeding Flat in bed Use of large tube	Assess respiratory status and notify provider	Implement reliable method for checking small-bore enteral tube placement (i.e., measuring length of exposed tube) Keep head of bed elevated 30–45 degrees continuously
Tube displacement	Excessive coughing/vomitus Tension on the tube or unsecured tube Tracheal suctioning Airway intubation	Stop feeding and notify provider	Check tube placement before administering feeding
Tube obstruction	Inadequate flushing/formula rate/inadequate medication crushing	Follow policy for declogging feeding tubes	Obtain liquid medications when possible, flush tube and medications adequately
Residue	Inadequate crushing of medications and flushing after administration		Flush tube and crush medications adequately
Nasopharyngeal irritation	Tube position/improper taping Use of large tubes	Assess nasopharyngeal mucous membranes every 4 hours	Tape tube to prevent pressure on nares

Metabolic			
Hyperglycemia	Glucose intolerance High carbohydrate content of the feeding	Check blood glucose levels periodically Request dietary consult to reevaluate choice of feeding product	Collaborate with dietician for potential solution changes.
Dehydration and azotemia (excessive urea in the blood)	Hyperosmolar feedings with insufficient fluid intake	Report signs and symptoms of dehydration Implement changes in tube feeding formula, rate, or ratio to water	Provide adequate hydration through flushes or dilution of tube feeding

The initial PEG device can be removed and replaced once the tract is well established (10 to 14 days after insertion). Replacement of the PEG device is indicated to provide long-term nutritional support, to replace a clogged or migrated tube, or to enhance patient comfort. The PEG replacement device should be fitted securely to the stoma to prevent leakage of gastric acid and is maintained in place through traction between the internal and anchoring devices.

An alternative to the PEG device is a low-profile gastrostomy device (LPGD) (see Fig. 22-15). The LPGD may be inserted 3 to 6 months after initial gastrostomy tube placement. These devices are inserted flush with the skin; they eliminate the possibility of tube migration and obstruction and have antireflux valves to prevent gastric reflux. Two types of devices may be used—obturated or nonobturated. The obturated devices (G-button) have a dome tip that acts as an internal stabilizer. Only a physician may obturate (insert a tube that is larger than the actual stoma). The nonobturated device (MIC-KEY) has an external skin disk and is inserted into the stoma without force; a balloon is inflated to secure placement. A nurse in the home setting may insert these nonobturated devices. The drawbacks of both types of LPGDs are the inability to assess residual volumes (one-way valve) and the need for a special adaptor to connect the device to the feeding container.

Complications

Reflux from stomach feedings can result in aspiration pneumonia. Therefore, patients at risk for aspiration pneumonia are not ideal candidates for a gastrostomy. A jejunostomy is preferred, or jejunal feeding through a nasojejunal tube may be recommended.

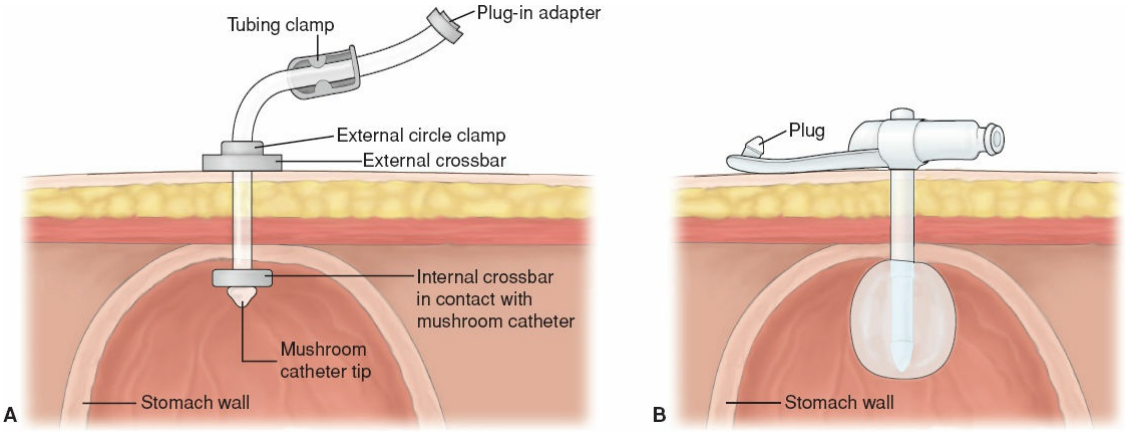

FIGURE 22-15 A. A detail of the abdomen and the percutaneous endoscopic gastrostomy (PEG) tube, showing catheter fixation. B. A detail of the abdomen and the nonobturated low-profile gastrostomy device (LPGD), showing balloon fixation.

Other complications of gastrostomy tube placement include premature removal, infection, and leakage around the insertion site. To prevent premature removal, a loosely taped dressing can be placed over the top of the tube flange. A fenestrated drape (split dressing) often used for tracheotomy care works well. In addition, a tube-securing device can be placed on the patient's abdomen or flank to further decrease the tension on the insertion site. These devices use adhesives and Velcro to fix the gastrostomy tube to the patient's skin temporarily. The nurse should educate the patient on how much mobility he or she has with the gastrostomy tube to aid in preventing tension on the device. If the tube is removed inadvertently, the nurse should clean the site, place a dressing, and notify the provider as soon as possible.

Infection is prevented by assessing and cleansing the site daily. Soap and water can be used around the general area. To remove hardened feedings that may accumulate around the insertion site, the nurse can use normal saline. The area should be dried before a dressing is reapplied. Redness, tenderness, and skin breakdown should be documented and the provider notified.

PARENTERAL NUTRITION

Parenteral nutrition (PN) is a method of providing nutrients to the body by a peripheral or central IV route. The solution is composed of a very complex admixture containing proteins, carbohydrates, fats, electrolytes, vitamins, trace minerals, and sterile water in a single container. The goals of PN are to improve nutritional status, establish a positive nitrogen balance (Box 22-2), maintain muscle mass, promote weight maintenance or gain, and support the healing process.

Clinical Indications

In both the home and hospital settings, PN is indicated in the following situations:

- The patient's intake is insufficient to maintain an anabolic state (e.g., severe burns, malnutrition, short bowel syndrome, AIDS, sepsis, cancer).
- The patient's ability to ingest food orally or by tube is impaired (e.g., paralytic ileus, Crohn disease with obstruction, postradiation enteritis, severe hyperemesis gravidarum in pregnancy).
- The patient is unwilling or unable to ingest adequate nutrients (e.g., anorexia nervosa, postoperative elderly patients).
- The underlying medical condition precludes being fed orally or by tube (e.g., acute pancreatitis, high enterocutaneous fistula).
- Preoperative and postoperative nutritional needs are prolonged (e.g., extensive bowel surgery).

BOX 22-2 Establishing Positive Nitrogen Balance

The balance of nitrogen is determined by how much nitrogen is taken into the body versus how much is excreted. Urine contains 90% of the excreted nitrogen while the remaining 10% exits the body through sweat, hair, and stool (Dominiczak & Logue, 2014). When a patient's intake of protein and nutrients is significantly less than that required by the body to meet energy expenditures, a state of negative nitrogen balance results. In response, the body begins to convert the protein found in muscles into carbohydrates to be used to meet energy needs. The result is muscle wasting, weight loss, fatigue, and, if left uncorrected, death.

The suggested daily amount of protein intake for a normal adult is 1.0–1.2 g of protein/kg of body weight (Dominiczak & Logue, 2014). Traditional IV fluids do not provide sufficient calories or nitrogen to meet the body's daily requirements. PN solutions, which supply nutrients such as dextrose, amino acids, electrolytes, vitamins, minerals, and fat emulsions, provide enough calories and nitrogen to meet the patient's daily nutritional needs. In general, PN usually provides 25–35 kcal/kg of ideal body weight and 1.0–1.5 g of protein/kg of ideal body weight.

The patient with fever, trauma, burns, major surgery, or hypermetabolic disease requires additional daily calories. The volume of fluid necessary to provide these calories would surpass fluid tolerance and lead to pulmonary edema or heart failure. To provide the required calories in a small volume, it is necessary to increase the concentration of nutrients and use a route of administration (i.e., a large, high-flow vein, such as the subclavian) that rapidly dilutes incoming nutrients to the proper levels of body tolerance.

When highly concentrated dextrose is administered, caloric requirements are satisfied

and the body uses amino acids for protein synthesis rather than for energy. Additional potassium is added to the solution to maintain proper electrolyte balance and to transport glucose and amino acids across cell membranes. To prevent deficiencies and fulfill requirements for tissue synthesis, other elements, such as calcium, phosphorus, magnesium, and sodium chloride, are added.

Nursing Alert

Cues to malnutrition in patients include a prealbumin level that is less than 16 mg/dL, albumin that is less than 3.5 mg/dL, unintentional weight loss of 10% in 6 months or 5% in 3 months, or a body mass index (BMI) below 18.5. A BMI greater than 19 or less than 22 places a patient at risk for malnutrition (Stewart, 2014).

Preoperatively malnourished patients who are not candidates for enteral feedings should have PN initiated for nutrient resuscitation a week before surgery if possible. PN therapy lasting less than 7 days has been shown to have no effect on nutritional status or was linked to poor outcomes (McClave et al., 2016).

Parenteral Formulas

A total of 2 to 3 L of solution is administered over a 24-hour period using a filter (1.2-micron particulate filter). Before administration, the PN infusion must be inspected for clarity and any precipitate. The label is compared with the provider's order, noting the expiration date. IV fat emulsions (IVFEs, Intralipids) may be infused simultaneously with PN through a Y-connector close to the infusion site and *should not* be filtered. Before administration, the IVFE is inspected for frothiness, separation, or oily appearance. If any of these are present, the solution is not used. Usually 500 mL of a 10% emulsion or 250 mL of 20% emulsion is administered over 6 to 12 hours, one to three times a week. IVFEs can provide up to 30% of the total daily calorie intake.

IVFEs can be admixed with other components of PN to create a "three-in-one formulation," commonly called a total nutrient admixture (TNA). All the parenteral nutrient components are mixed in one container and administered to the patient over a 24-hour period. A special final filter (1.5-micron filter) is used with this solution. Before administration, the solution is observed for oil droplets that have separated from the solution, forming a noticeable layer ("cracking of lipid emulsion"); such a solution should be discarded.

Initiating Therapy

PN solutions have a higher glucose concentration than do regular IV fluids. As a result, PN is a medium in which bacteria can thrive. It is important for the nurse to use aseptic technique when assessing the catheter port to be used for the PN. The ports should be prepped with an antiseptic wipe. If the PN bag does not come with pre-primed tubing from the pharmacy, the nurse must take great care not to contaminate the bag or tubing. Also the dressing on the catheter should be changed in accordance with the institution's policy to prevent infection at the insertion site. PN solutions are initiated slowly and advanced gradually each day to the desired rate as the patient's fluid and glucose tolerance permits. If the solution is administered too rapidly, the patient could become fluid overloaded. If this occurs, the rate should be decreased, and the patient's respiratory status should be monitored. The patient's laboratory test results and response to PN therapy are monitored on an ongoing basis by the provider and licensed nutrition provider. Standing orders are initiated for weighing the patient; monitoring intake, output, and blood glucose; and baseline and periodic monitoring of complete blood count, platelet count, and chemistry panel, including serum carbon dioxide, magnesium, phosphorus, triglycerides, and prealbumin. A 24-hour urine nitrogen determination may be performed for analysis of nitrogen balance. In most hospitals, the provider prescribes PN solutions on a daily standard PN order form. The formulation of the PN solutions is calculated carefully each day to meet the complete nutritional needs of the individual patient.

Administration Methods

Peripheral Method

A peripheral parenteral nutrition (PPN) formula is prescribed when a patient's oral intake requires supplementation. This type of solution is not as hypertonic as PN or total parenteral nutrition (TPN) so it can be administered peripherally. PPN formulas are not nutritionally complete: there is typically less dextrose content.

Nursing Alert
Any formula with a dextrose concentration of more than 10% should not be administered through peripheral veins because they irritate the intima (innermost walls) of small veins, causing a chemical phlebitis.

Lipids are administered simultaneously to buffer the PPN and to protect the peripheral vein from irritation. For PPN solutions, peripheral access is changed approximately every 3 days to decrease the likelihood of infiltration. These solutions use a *dedicated line*; that is, no other medication or IV solution can be infused other than the PPN solution through this peripheral IV.

Central Method

Because TPN solutions have five or six times the solute concentration of blood (and exert an osmotic pressure of about 2,000 mOsm/L), they are injurious to the intima of peripheral veins. Therefore, to prevent phlebitis and other venous complications, these solutions are administered into the vascular system through a catheter inserted into a high-flow, large blood vessel, such as the subclavian vein. Then concentrated solutions are very rapidly diluted to isotonic levels by the blood in this vessel.

Four types of central venous access devices (CVADs) can be used to administer TPN: nontunneled (or percutaneous) central catheters, peripherally inserted central catheters (PICC), tunneled catheters, and implanted ports. Whenever one of these catheters is inserted, catheter tip placement should be confirmed by x-ray studies before PN therapy is initiated. The optimal position is the midproximal third of the superior vena cava at the junction of the right atrium.

Nontunneled Central Catheters

Nontunneled central catheters are used for short-term IV therapy (less than 6 weeks) in acute-care, long-term care, and home-care settings. The provider inserts these catheters. Examples of nontunneled central catheters are Vas-Cath, percutaneous subclavian Arrow, and Hohn catheters. The subclavian vein is the most common vessel used because the subclavian area provides a stable insertion site to which the catheter can be anchored, allows the patient freedom of movement, and provides easy access to the dressing site. The jugular vein should be avoided and only be considered for cannulation if the patient has no other points of access. Jugular access should be used only temporarily for approximately 1 to 2 days.

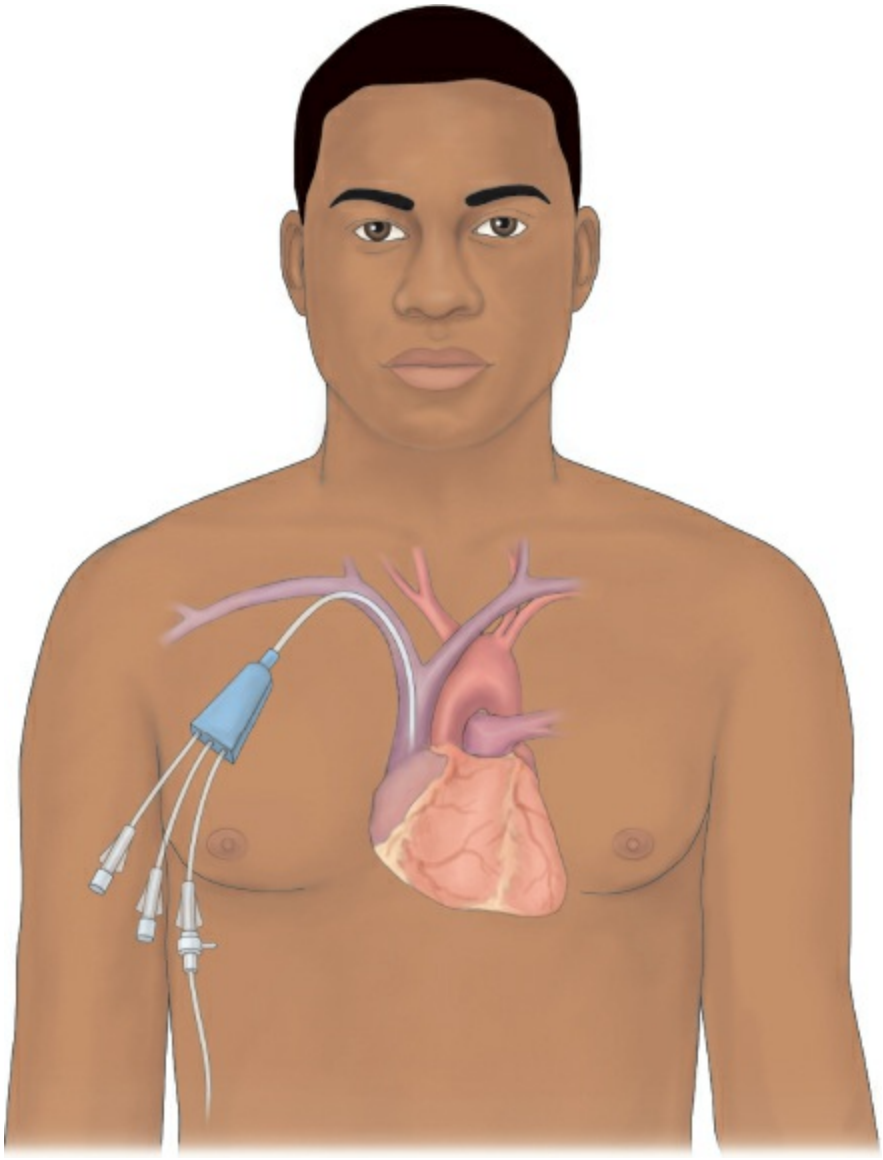

FIGURE 22-16 Subclavian triple-lumen catheter used for parenteral nutrition and other adjunctive therapy. The catheter is threaded through the subclavian vein into the vena cava. Each lumen is an avenue for solution administration. The lumens are secured with threaded needleless adapters or Luer-Lok–type caps when the device is not in use.

To ensure accessibility in a patient with limited IV access, a triple-lumen subclavian catheter can be used because it offers three ports for various uses (Fig. 22-16). Blood sampling and administration is commonly done through the distal port. TPN solutions are administered through the medial port. All three ports can be used for medication administration. The nurse may stop an IV solution or medication drip temporarily (if warranted—some solutions cannot be stopped even for brief periods of time, such as a nitroglycerine drip with an acute MI patient) when drawing blood from another lumen on the triple-lumen catheter. Otherwise, these infusions can contaminate the studies ordered and alter the results. The nurse may also waste 5 to 10 cc of blood from the patient before drawing the actual specimen for analysis as an additional method for getting a clean sample.

If a single-lumen central catheter is used for administering TPN, various restrictions apply:

- Blood cannot be drawn from the catheter, and transfusions of blood products cannot be given through the main line because red blood cells may coat the lumen of the catheter, thereby reducing the flow of the nutritional solution.
- Medications cannot be administered through it because the medication may be incompatible with the components of the nutritional solution (insulin is an exception). If medications must be given, they must be infused through a separate peripheral IV line, not by piggyback into the TPN line.

Once the catheter's position is confirmed, the prescribed TPN solution is started. The initial rate of infusion is usually 50 mL/hr, and the rate is increased gradually to the maintenance rate or predetermined dose (e.g., 100 to 125 mL/hr). An infusion pump is always used for administration of TPN.

Nursing Alert
If, for any reason, there is a delay in the infusion rate, this solution is never increased beyond the hourly ordered rate. There is no "playing catch up" with TPN (Diepenbrock, 2012). If the PN solution is terminated abruptly, a 5% or a 10% dextrose solution is administered for a period of hours to protect against rebound hypoglycemia. Specifically, a 5% solution is administered for PPN, while a 10% solution is administered for TPN at the same rate, owing to the approximate glucose concentration in the two solutions.

An injection site cap is attached to the end of each central catheter lumen, creating a closed system. IV infusion tubing is connected to the insertion site cap of the central catheter with a threaded needleless adapter or Luer-Lok device. Each lumen is labeled by the manufacturer according to location (proximal, middle, and distal). To ensure patency, all lumens are flushed initially, daily when not in use, after each intermittent infusion, after blood drawing, and whenever an infusion is disconnected. A recent systematic review looking at studies comparing the flushing of catheters with saline and heparin found no difference between the two solutions when considering safety and efficacy (Lopez-Briz et al., 2014). Force is never used to flush the catheter. If resistance is met, aspiration may restore lumen patency; if this is not effective, the provider is notified. Low-dose tissue plasminogen activator (alteplase) may be prescribed to dissolve a clot or fibrin sheath. If attempts to clear the lumen are ineffective, the lumen is labeled as "clotted off" and not used again.

Peripherally Inserted Central Catheters

Peripherally inserted central catheters (PICCs) are used for intermediate-term (several days to months) IV therapy in the hospital, long-term care, or home setting. These catheters may be inserted by a specially trained nurse at the bedside or in the outpatient setting. They also can be inserted using fluoroscopy by an interventional radiologist. PICC lines are placed in the arm, specifically the basilic or cephalic vein, via the antecubital space. Then the catheter is threaded to a designated location, depending on the type of solution to be infused (superior vena cava for TPN, which allows dilution of this hypertonic solution).

Blood drawing and blood pressure measurement are avoided in the accessed arm.

Tunneled Central Catheters

Tunneled central catheters are for long-term use and may remain in place for many years. These catheters are cuffed and can have single or double lumens; examples are the Hickman, Groshong, and PermCath. These catheters are inserted surgically. They are threaded under the skin (reducing the risk of ascending infection) to the subclavian vein, and the distal end of the catheter is advanced into the superior vena cava.

Implanted Ports 

Implanted ports also are used for long-term home IV therapy; examples include the Port-A-Cath, Mediport, Hickman Port, and P.A.S. Port. Instead of exiting from the skin, as do the Hickman and Groshong catheters, the end of the catheter is attached to a small chamber that is placed in a subcutaneous pocket, either on the anterior chest wall or on the forearm. The subcutaneous port requires minimal care and allows the patient complete freedom of activity. Implanted ports are more expensive than the external catheters, and access requires passing a special noncoring needle (Huber-tipped) through the skin into the chamber to initiate IV therapy.

Discontinuing Parenteral Nutrition

The PN solution is discontinued gradually to allow the patient to adjust to decreased levels of glucose. A patient's blood sugar must be followed very closely when weaning a patient off PN, while on a continuous insulin infusion, or when increasing enteral feedings concurrently. Providing oral carbohydrates can shorten the tapering time. Specific symptoms of rebound hypoglycemia include weakness, faintness, diaphoresis, shakiness, feeling cold, confusion, and increased heart rate. Once all IV therapy is completed, the nontunneled central venous catheter or PICC can be removed and an occlusive dressing is applied to the exit site. Once a decision is made to discontinue the line, physicians or nurses who have been deemed competent in the removal procedure and are aware of the potential complications may remove central and PICC lines. Tunneled catheters and implanted ports are removed only by the physician.

CHAPTER REVIEW

Critical Thinking Questions

1. You are the night shift nurse in the intensive care unit and have been assigned a new postoperative patient who has undergone a radical neck dissection. Which form of nutritional support would you most likely see being used, and why? What nursing measures would be used to facilitate breathing and promote comfort? Describe the potential complications of radical neck dissection and the assessment parameters that are used to detect the earliest signs and symptoms of these complications.

2. An elderly woman is brought to the emergency department by paramedics. Her daughter found her on the kitchen floor. A bottle of cleaning fluid with a poison label was open next to the kitchen sink. On admission, the patient was in respiratory distress. Burns were observed around her mouth. What emergency care would be provided for this patient to prevent further trauma to the GI and respiratory tracts? Identify the evidence that supports this care, and evaluate the strength of the evidence.

3. You prepare to administer feedings through a patient's newly placed nasojejunal feeding tube. What methods would you consider to confirm the location of the tube before you initiate feedings? What patients would require postpyloric feedings rather than gastric and why? Before administering medications through the tube, how would you prepare them, and which types of medications would you pay particular attention to?

NCLEX-Style Review Questions

1. A confused patient prematurely removes her NG tube. The nurse knows to observe for which complication?
   a. Constipation
   b. Flatulence

c. Abdominal distention
d. Gastric bleeding

2. The nurse is administering liquids to a patient who has recently been changed from NPO to a clear liquid diet. The patient coughs and occasionally gags with sips of water. Which health care team member would the nurse consult?
   a. Physical therapist
   b. Respiratory therapist
   c. Dietician
   d. Speech pathologist

3. A nurse is caring for a patient who is on strict bowel rest and will need IV nutrition. The nurse knows the following devices are appropriate for TPN. Select all that apply.
   a. PICC line
   b. Triple-lumen catheter
   c. Large-bore IV line
   d. Implantable venous assess device (Port-A-Cath)
   e. Arterial line

4. A nurse receives report on a patient experiencing dumping syndrome. The nurse knows that the patient would be displaying which symptom 30 minutes after eating?
   a. Difficulty swallowing
   b. Heartburn
   c. Nausea
   d. Cramping in the abdomen

5. The nurse recognizes which of the following as a cause of xerostomia? Select all that apply.
   a. HIV infection
   b. Oral hypoglycemic medications
   c. Tracheostomy tube
   d. Inability to close the mouth
   e. Kidney failure

CHAPTER 23

Nursing Management: Patients with Gastric and Duodenal Disorders

Jancee Pust-Marcone

Learning Objectives

After reading this chapter, you will be able to:

1. Compare the etiology, clinical manifestations, and management of acute gastritis, chronic gastritis, and peptic ulcer.
2. Describe the management of the patient with gastritis.
3. Describe the dietary, pharmacologic, and surgical treatment of peptic ulcer.
4. Describe the nursing management of patients who undergo surgical procedures to treat obesity.
5. Use the nursing process as a framework for care of patients undergoing gastric surgery.
6. Identify the complications of gastric surgery and their prevention and management.

A person's nutritional status depends not only on the type and amount of intake but also on the functioning of the gastric and intestinal portions of the gastrointestinal (GI) system. This chapter describes disorders of the stomach and duodenum as well as their treatment and related nursing care.

GASTRITIS

Gastritis (inflammation of the gastric or stomach mucosa) is a common GI problem. Gastritis may be acute, lasting several hours to a few days, or chronic, resulting from repeated exposure to irritating agents or recurring episodes of acute gastritis.

Acute gastritis is often caused by dietary indiscretion—the person eats food that is irritating, too highly seasoned, or contaminated with disease-causing microorganisms. Other causes of acute gastritis include overuse of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), excessive alcohol intake, bile reflux, and radiation therapy. A more severe form of acute gastritis is caused by the ingestion of strong acid or alkali, which may cause the mucosa to become gangrenous or to perforate. Scarring can occur, resulting in pyloric stenosis or obstruction. Acute gastritis also may develop in acute illnesses, especially when the patient has had major traumatic injuries; burns; severe infection; liver, kidney, or respiratory failure; or major surgery. Gastritis may be the first sign of an acute systemic infection.

Chronic gastritis and prolonged inflammation of the stomach may be caused either by benign or malignant ulcers of the stomach or by the bacteria *Helicobacter pylori* (*H. pylori*) (Watari et al., 2014; Yamaoka & Graham, 2014; Venerito, Selgrad, & Malfertheiner, 2013). Also chronic gastritis is sometimes associated with autoimmune diseases, such as pernicious anemia (Varbanova et al., 2014); dietary factors, such as caffeine; the use of medications such as NSAIDs, bisphosphonate (e.g., alendronate [Fosamax], risedronate [Actonel]) or ibandronate (Boniva); alcohol; smoking; or chronic reflux of pancreatic secretions and bile into the stomach.

Pathophysiology

In gastritis, the gastric mucous membrane becomes edematous and hyperemic (congested with fluid and blood) and undergoes superficial erosion (Fig. 23-1). It secretes a scanty amount of gastric juice, containing very little acid but much mucus. Superficial ulceration may occur and can lead to hemorrhage.

Clinical Manifestations and Assessment

The patient with acute gastritis may have a rapid onset of symptoms, such as abdominal discomfort, headache, lassitude, nausea, anorexia, vomiting, and hiccupping, which can last from a few hours to a few days. The patient with chronic gastritis may complain of anorexia, heartburn after eating, belching, a sour taste in the mouth, or nausea and vomiting. Some patients may have only mild epigastric discomfort or report intolerance to spicy or fatty foods or slight pain that is relieved by eating. Patients with chronic gastritis from vitamin deficiency usually have evidence of malabsorption of vitamin B_{12} caused by the production of antibodies that interfere with the binding of vitamin B_{12} to intrinsic factor. However, some patients with chronic gastritis have no symptoms.

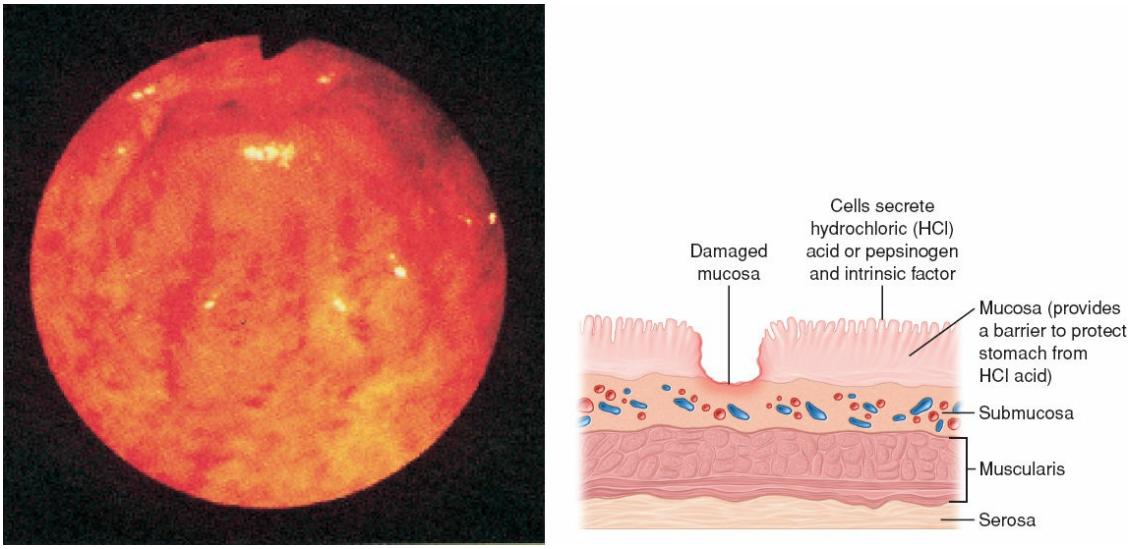

FIGURE 23-1 Endoscopic view of erosive gastritis (*left*). Damage from irritants (*right*) results in increased intracellular pH, impaired enzyme function, disrupted cellular structures, ischemia, vascular stasis, and tissue death. (Grossman, S., & Porth, C. M. (2014). *Porth's pathophysiology: Concepts of altered health states* (9th ed.). Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins.)

Gastritis is sometimes associated with achlorhydria or hypochlorhydria (absence or low levels of hydrochloric acid [HCl]) or with hyperchlorhydria (high levels of HCl). Diagnosis can be determined by an upper GI x-ray series or endoscopy and histologic examination of a tissue specimen obtained by biopsy. Diagnostic measures for detecting *H. pylori* infection may be used and are discussed in the section on peptic ulcers.

Medical and Nursing Management

The gastric mucosa is capable of repairing itself after a bout of gastritis. As a rule, the patient recovers in about 1 day, although the appetite may be diminished for an additional 2 or 3 days. Acute gastritis is also managed by instructing the patient to refrain from alcohol and food until symptoms subside. When the patient can take nourishment by mouth, a nonirritating diet is recommended. If the symptoms persist, IV fluids may need to be administered. If bleeding is present, management is similar to the procedures used to control upper GI tract hemorrhage, discussed later in this chapter.

If gastritis is caused by ingestion of strong acids or alkalis, emergency treatment consists of diluting and neutralizing the offending agent. To neutralize acids, common antacids (e.g., aluminum hydroxide) are used; to neutralize an alkali, diluted lemon juice or diluted vinegar is used. If corrosion is extensive or severe, emetics and lavage are avoided because of the danger of perforation and damage to the esophagus.

Therapy is supportive and may include nasogastric (NG) intubation (see Chapter 22), analgesic agents and sedatives, antacids, and IV fluids. Fiberoptic endoscopy may be necessary. In extreme cases, emergency surgery may be required to remove gangrenous or perforated tissue. A gastric resection or a gastrojejunostomy (anastomosis of jejunum to stomach to detour around the pylorus) may be necessary to treat pyloric obstruction, a narrowing of the pyloric orifice that cannot be relieved by medical management.

Chronic gastritis is managed by modifying the patient's diet, promoting rest, reducing stress, recommending avoidance of alcohol and NSAIDs, and initiating pharmacotherapy. *H. pylori* may be treated with selected drug combinations (Table 23-1).

PEPTIC ULCER DISEASE

A peptic ulcer may be referred to as a gastric, duodenal, or esophageal ulcer, depending on its location. A person who has a peptic ulcer has peptic ulcer disease. A peptic ulcer is an excavation (hollowed-out area) that forms in the mucosal wall of the stomach, in the pylorus (the opening between the stomach and duodenum), in the duodenum (the first part of small intestine), or in the esophagus. Erosion of a circumscribed area of mucous membrane is the cause (Fig. 23-2). This erosion may extend as deeply as the muscle layers or through the muscle to the peritoneum.

TABLE 23-1 Pharmacotherapy for Gastritis and Peptic Ulcer Disease

Pharmacologic Agent	Major Action	Nursing Considerations
Antibiotics		
Amoxicillin (Amoxil)	A bactericidal antibiotic that assists with eradicating *H. pylori* bacteria in the gastric mucosa	• May cause diarrhea • Should not be used in patients allergic to penicillin
Clarithromycin (Biaxin)	Exerts bactericidal effects to eradicate *H. pylori* bacteria in the gastric mucosa	• May cause gastrointestinal (GI) upset, headache, altered taste • Many drug–drug interactions (e.g., cisapride, colchicine, lovastatin, warfarin [Coumadin])
Metronidazole (Flagyl)	A synthetic antibacterial and antiprotozoal agent that assists with eradicating *H. pylori* bacteria in the gastric mucosa when administered with other antibiotics and proton pump inhibitors	• Should be administered with meals to decrease GI upset; may cause anorexia and metallic taste • Patient should avoid alcohol; Flagyl increases blood-thinning effects of warfarin (Coumadin)
Tetracycline	Exerts bacteriostatic effects to eradicate *H. pylori* bacteria in the gastric mucosa	• May cause photosensitivity reaction; warn patient to use sunscreen • May cause GI upset • Must be used with caution in patients with kidney or liver impairment • Milk or dairy products may reduce effectiveness
Antidiarrheal		
Bismuth subsalicylate (Pepto-Bismol)	Suppresses *H. pylori* bacteria in the gastric mucosa and assists with healing of mucosal ulcers	• Given concurrently with antibiotics to eradicate *H. pylori* infection • Should be taken on empty stomach

Histamine-2 (H_2) Receptor Antagonists		
Cimetidine (Tagamet)	Decreases amount of HCl produced by stomach by blocking action of histamine on histamine receptors of parietal cells in the stomach	• Least expensive of H_2 receptor antagonists • May cause confusion, agitation, or coma in the elderly or those with kidney or liver insufficiency • Long-term use may cause diarrhea, dizziness, gynecomastia • Many drug–drug interactions (e.g., amiodarone, amitriptyline, benzodiazepines, metoprolol, nifedipine, phenytoin, warfarin [Coumadin])
Famotidine (Pepcid)	Same as for cimetidine	• Best choice for critically ill patients because it is known to have the least risk of drug–drug interactions; does not alter liver metabolism • Prolonged half-life in patients with kidney insufficiency • Short-term relief for GERD
Nizatidine (Axid)	Same as for cimetidine	• Used for treatment of ulcers and GERD • Prolonged half-life in patients with kidney insufficiency • May cause headache, dizziness, diarrhea, nausea/vomiting, GI upset, as well as urticarial
Ranitidine (Zantac)	Same as for cimetidine	• Prolonged half-life in patients with kidney and liver insufficiency • Causes fewer side effects than cimetidine • May cause headache, dizziness, constipation, nausea and vomiting, or abdominal discomfort
Roxatidine (Roxane)	Same as for cimetidine	• Prolonged half-life in patients with kidney and liver insufficiency • Single bedtime dose in combination with PPI to reduce nocturnal acid reflux • May cause headache, dizziness, constipation, nausea and vomiting, or abdominal discomfort
Proton Pump Inhibitors of Gastric Acid (PPIs)		
Esomeprazole (Nexium)	Decreases gastric acid secretion by slowing the hydrogen–potassium adenosine triphosphatase (H^+, K^+-ATPase) pump on the surface of the parietal cells of the stomach	• Used mainly for treatment of duodenal ulcer disease and *H. pylori* infection • A delayed-release capsule that is to be swallowed whole and taken before meals—the capsule cannot be crushed or chewed • May increase phenytoin (Dilantin), warfarin (Coumadin) levels. Food decreases absorption by up to 35%. • Most common side effects are headache, diarrhea, nausea, gas, abdominal pain constipation or dry mouth
Lansoprazole (Prevacid)	Decreases gastric acid secretion by slowing the H^+, K^+-ATPase pump on the surface of the parietal cells	• A delayed-release capsule that is to be swallowed whole and taken before meals—the capsule cannot be crushed or chewed • May decrease theophylline levels • Side effects include confusion, dizziness, fast or irregular heart rate, jerky muscle movements, muscle cramps or weakness, bloody diarrhea, cough or seizure
Omeprazole (Prilosec)	Decreases gastric acid secretion by slowing the H^+, K^+-ATPase pump on the surface of the parietal cells	• A delayed-release capsule that is to be swallowed whole and taken before meals • May cause diarrhea, nausea and vomiting, constipation, abdominal pain, headache, or dizziness

Pantoprazole (Protonix)	Decreases gastric acid secretion by slowing the H^+, K^+-ATPase pump on the surface of the parietal cells	• A delayed-release capsule that is to be swallowed whole and taken before meals • May cause diarrhea and hyperglycemia, headache, abdominal pain, and abnormal liver function tests
Rabeprazole (AcipHex)	Decreases gastric acid secretion by slowing the H^+, K^+-ATPase pump on the surface of the parietal cells	• A delayed-release tablet to be swallowed whole • May cause abdominal pain, diarrhea, nausea, and headache • Drug–drug interactions with digoxin, iron, and warfarin (Coumadin)
Prostaglandin E_1 Analog		
Misoprostol (Cytotec)	Synthetic prostaglandin; protects the gastric mucosa from agents that cause ulcers; also increases mucus production and bicarbonate levels	• Used to prevent ulceration in patients using NSAIDs • Administer with food • May cause diarrhea and cramping (including uterine cramping)
Sucralfate (Carafate)	Creates a viscous substance in the presence of gastric acid that forms a protective barrier, binding to the surface of the ulcer, and prevents digestion by pepsin	• Used mainly for the treatment of duodenal ulcers • Should be taken without food but with water • Other medications should be taken 2 hours before or after this medication • May cause constipation or nausea

GERD, gastroesophageal reflux disease; NSAID, nonsteroidal anti-inflammatory drug.

Peptic ulcers are more likely to be in the duodenum than in the stomach. As a rule, they occur alone, but they may occur in multiples. Chronic gastric ulcers tend to occur in the lesser curvature of the stomach, near the pylorus. Table 23-2 compares the features of gastric and duodenal ulcers. Esophageal ulcers occur as a result of the backward flow of HCl from the stomach into the esophagus (gastroesophageal reflux disease [GERD]).

Pathophysiology

Peptic ulcers occur mainly in the gastroduodenal mucosa because this tissue cannot withstand the digestive action of gastric acid (HCl) and pepsin. The erosion is caused by the increased concentration or activity of acid–pepsin or by decreased resistance of the mucosa. A damaged mucosa cannot secrete enough mucus to act as a barrier against HCl. The use of NSAIDs inhibits the secretion of mucus that protects the mucosa. Patients with duodenal ulcer disease secrete more acid than normal, whereas patients with gastric ulcer tend to secrete normal or decreased levels of acid. Damage to the gastroduodenal mucosa allows for decreased resistance to bacteria, and, thus, infection from *H. pylori* bacteria may occur.

FIGURE 23-2 Deep peptic ulcer. (Strayer, D., & Rubin, E. (2015). *Rubin's pathology: Clinicopathologic foundations of medicine* (7th ed.). Philadelphia, PA: Wolters Kluwer Health.)

Zollinger-Ellison syndrome (ZES) is suspected when a patient has several peptic ulcers or an ulcer that is resistant to standard medical therapy (Kim, 2015). ZES is identified by the hypersecretion of gastric juice, duodenal ulcers, and gastrinomas (islet cell tumors) in the pancreas. Ninety percent of tumors are found in the "gastric triangle," which encompasses the cystic and common bile ducts, the second and third portions of the duodenum, and the junction of the head and body of the pancreas. Approximately one third of gastrinomas are malignant. Diarrhea and steatorrhea (unabsorbed fat in the stool) may be evident. The patient may have coexisting parathyroid adenomas (benign tumor of glandular origin) or hyperplasia and, therefore, may exhibit signs of hypercalcemia. The most common symptom is epigastric pain. *H. pylori* is not a risk factor for ZES (Kim, 2015).

Stress-related mucosal disease (SRMD) is a term used to describe the phenomenon of injury to the lining of the stomach and the duodenum during conditions of physiologic stress. Other terms commonly used include *stress erosion, stress ulcer, stress gastritis, erosive gastritis,* and *hemorrhagic gastritis*. These terms also have been given to the acute mucosal ulceration of the duodenal or gastric area that occurs after physiologically stressful events, such as burns, shock, severe sepsis, and multiple organ traumas (Bardou, Quenot, & Barkun, 2015). These ulcers, which are clinically different from peptic ulcers, are most common in ventilator-dependent patients after trauma or surgery. Fiberoptic endoscopy within 24 hours of trauma or surgery reveals shallow erosions of the stomach wall; by 72 hours, multiple gastric erosions are observed. The prevalence of SRMD has been reported to be as high as 74% to 100% in critically ill patients (Bardou, Quenot, & Barkun, 2015). As the stressful condition continues, the ulcers spread. When the patient recovers, the lesions are reversed. This pattern is typical of stress ulceration.

Differences of opinion exist as to the actual cause of mucosal ulceration in stress ulcers, but the etiology is thought to be multifactorial. Usually, the ulceration is preceded by a shock state; often involving hypovolemia and hypoperfusion; leading to decreased gastric mucosal blood flow and gastric ischemia. This hypoperfusion triggers the body's protective mechanisms of activation of the sympathetic nervous system, increased catecholamine release causing further vasoconstriction, and reduced gastric blood flow. Gastric hypoperfusion leads to decreased gastric motility, decreased capacity to neutralize hydrogen ions, and the reflux of duodenal contents into the stomach. In addition, large quantities of pepsin are released. The combination of ischemia, acid, and pepsin creates an ideal climate for ulceration (Kim, 2015).

TABLE 23-2 Comparison of Duodenal and Gastric Ulcers

Feature	Duodenal Ulcer	Gastric Ulcer
Incidence	30 to 60 years of age Male: female = 2:1 or 3:1 80% of peptic ulcers are duodenal	Usually 50 years of age or older Male: female = 1:1 15% of peptic ulcers are gastric
Symptoms and Clinical Findings	Hypersecretion of stomach acid (HCl) May have weight gain Pain occurs 2 to 3 hours after a meal; often awakened around 1 or 2 AM; ingestion of food relieves pain Vomiting uncommon Hemorrhage less likely than with gastric ulcer, but if present, melena more common than hematemesis More likely to perforate than gastric ulcers	Normal to hyposecretion of stomach acid (HCl) Weight loss may occur Pain occurs ½ to 1 hour after a meal; rarely occurs at night; may be relieved by vomiting; ingestion of food does not help, sometimes increases pain Vomiting common Hemorrhage more likely to occur than with duodenal ulcer; hematemesis more common than melena
Malignancy Possibility	Rare	Occasionally
Risk Factors	*H. pylori*, alcohol, smoking, cirrhosis, stress	*H. pylori*, gastritis, alcohol, smoking, use of nonsteroidal anti-inflammatory drugs (NSAIDs), stress

Stress ulcers should be distinguished from Cushing ulcers and Curling ulcers, two other types of gastric ulcers. Cushing ulcers are common in patients with head injury and brain trauma. They may occur in the esophagus, stomach, or duodenum and usually are deeper and more penetrating than stress ulcers. Curling ulcer is frequently observed about 72 hours after extensive burns and involves the antrum of the stomach or the duodenum.

Risk Factors

Peptic ulcer disease occurs with the greatest frequency in people between 40 and 60 years of age. It is relatively uncommon in women of childbearing age, but it has been observed in children and even in infants. After menopause, the incidence of peptic ulcers in women is almost equal to that in men. Peptic ulcers in the body of the stomach can occur without excessive acid secretion.

In the past, stress and anxiety were thought to be causes of ulcers, but research has documented that peptic ulcers result from infection with the gram-negative bacteria *H. pylori,* which may be acquired through ingestion of food and water. Person-to-person transmission of the bacteria also occurs through close contact and exposure to emesis. Although *H. pylori* infection is common in the United States, most infected people do not develop ulcers. It is not known why *H. pylori* infection does not cause ulcers in all people, but most likely the predisposition to ulcer formation depends on certain factors, such as the type of *H. pylori* and other as yet unknown factors (Kim 2015; Franceschi et al., 2014; Watari et al., 2014).

In addition, excessive secretion of HCl in the stomach may contribute to the formation of peptic ulcers, and stress may be associated with its increased secretion. The ingestion of milk and caffeinated beverages, smoking, and alcohol also may increase HCl secretion. Stress and eating spicy foods may make peptic ulcers worse.

Familial tendency also may be a significant predisposing factor. People with blood type O are more susceptible to peptic ulcers than are those with blood type A, B, or AB; this is another genetic link. There also is an association between peptic ulcers and chronic pulmonary disease or chronic kidney disease. Other predisposing factors associated with peptic ulcer include chronic use of NSAIDs, alcohol ingestion, and excessive smoking.

Peptic ulcers are found in rare cases in patients with tumors that cause secretion of excessive amounts of the hormone gastrin. ZES consists of severe peptic ulcers, extreme gastric hyperacidity, and gastrin-secreting benign or malignant tumors of the pancreas.

Clinical Manifestations and Assessment

Symptoms of an ulcer may last for a few days, weeks, or months and may disappear only to reappear, often without an identifiable cause. Many people with ulcers have no symptoms, and perforation or hemorrhage may occur in 20% to 30% of patients who had no preceding manifestations.

As a rule, the patient with an ulcer complains of dull, gnawing pain or a burning sensation in the midepigastrium or in the back. It is believed that the pain occurs when the increased acid content of the stomach and duodenum erodes the lesion and stimulates the exposed nerve endings. Another theory suggests that contact of the lesion with acid stimulates a local reflex mechanism that initiates contraction of the adjacent smooth muscle. Pain is usually relieved by eating because food neutralizes the acid or by taking alkali; however, once the stomach has emptied or the alkali's effect has decreased, the pain returns. Sharply localized tenderness can be elicited by applying gentle pressure to the epigastrium at or slightly to the right of the midline.

Other symptoms include pyrosis (heartburn), vomiting, constipation or diarrhea, and bleeding. Pyrosis is a burning sensation in the esophagus and stomach that moves up to the mouth. Often heartburn is accompanied by sour eructation, or burping, which is common when the patient's stomach is empty.

Although vomiting is rare in uncomplicated duodenal ulcer, it may be a symptom of a complication of an ulcer. It results from obstruction of the pyloric orifice caused by either muscular spasm of the pylorus or mechanical obstruction from scarring or acute swelling of the inflamed mucous membrane adjacent to the ulcer. Vomiting may or may not be preceded by nausea; usually, it follows a bout of severe pain and bloating, which is relieved by vomiting the gastric contents. Emesis often contains undigested food eaten many hours earlier. Constipation or diarrhea may occur, probably as a result of diet and medications.

Fifteen percent of patients with peptic ulcer experience bleeding. The two most relevant risk factors for stress-related GI bleeding include prolonged mechanical ventilation and coagulopathy in the critically ill patient (Bardou et al., 2015). Patients may present with GI bleeding as evidenced by the passage of melena (tarry stools). A small portion of patients who bleed from an acute ulcer have only very mild symptoms or none at all (Bardou et al., 2015).

A physical examination may reveal pain, epigastric tenderness, or abdominal distention. A barium study of the upper GI tract may show an ulcer; however, endoscopy is the preferred diagnostic procedure because it allows direct visualization of inflammatory changes, ulcers, and lesions. Through endoscopy, a biopsy of the gastric mucosa and of any suspicious lesions can be obtained. Endoscopy may reveal lesions that, because of their size or location, are not evident on x-ray studies.

Stools may be tested periodically until they are negative for occult blood. Gastric secretory studies are of value in diagnosing achlorhydria and ZES. *H. pylori* infection may be determined by endoscopic and histologic examination of a tissue specimen obtained by biopsy or by a rapid urease test of the biopsy specimen. Other less invasive diagnostic measures for detecting *H. pylori* include serologic testing for antibodies against the *H. pylori* antigen, stool antigen test, and urea breath test (Kim, 2015).

Medical and Nursing Management

Once the diagnosis is established, the patient is informed that the condition can be controlled. Recurrence may develop; however, peptic ulcers treated with antibiotics to eradicate *H. pylori* have a lower recurrence rate than those not treated with antibiotics. The goals are to eradicate *H. pylori* and to manage gastric acidity. Methods used include medications, lifestyle changes, and surgical intervention. The nurse instructs the patient about the factors that will relieve and those that will aggravate the peptic ulcer disease.

Pharmacologic Therapy

Currently, the most commonly used therapy for peptic ulcers is a combination of antibiotics, proton pump inhibitors (PPIs), and bismuth salts that suppress or eradicate *H. pylori* (see Table 23-1). Recommended therapy for 10 to 14 days includes triple therapy with two antibiotics (e.g., metronidazole [Flagyl] or amoxicillin [Amoxil] and clarithromycin [Biaxin]) plus a PPI (e.g., lansoprazole [Prevacid], omeprazole [Prilosec], or rabeprazole [Acephex]), or quadruple therapy with two antibiotics (metronidazole [Flagyl] and tetracycline) plus a PPI and bismuth salts (Pepto-Bismol) (den Hollander, 2012). Quadruple therapy is seen more frequently because of increased prevalence of antimicrobial resistance (Kuipers & Blaser, 2016).

Histamine-2 (H_2) receptor antagonists (H_2 blockers) and PPIs are used to treat NSAID-induced ulcers and other ulcers not associated with *H. pylori* infection (Scheiman, 2013; Tuskey & Peura, 2013). Misoprostol (a mucosal protective drug) has similar effects as H_2 blockers in preventing ulcers when given in full doses, but its usefulness is limited due to gastrointestinal side effects. It is not given to pregnant women because it can cause abortion, premature birth, or birth defects. Table 23-3 provides information about the drug regimens used for peptic ulcer disease.

TABLE 23-3 Drug Regimens for Peptic Ulcer Disease

Indications	Drug Regimen	Comments
Ulcer healing	**H_2 receptor antagonists** Ranitidine 150 mg b.i.d. or 300 mg at bedtime Cimetidine 400 mg b.i.d. or 800 mg at bedtime Famotidine 20 mg b.i.d. or 40 mg at bedtime Nizatidine 150 mg b.i.d. or 300 mg at bedtime **Proton pump inhibitors (PPIs)** Omeprazole—20–40 mg daily Lansoprazole—15–30 mg daily Rabeprazole—20 mg daily Pantoprazole—40–80 mg daily Esomeprazole—20–40 mg daily	Should be used for 6 weeks for duodenal ulcer; 8 weeks for gastric ulcer Should be used for 4 weeks for duodenal ulcer and 6 weeks for gastric ulcer Healing occurs in 90% of patients who are compliant with therapy
Initial *Helicobacter pylori* therapy	**First-line therapy, also referred to as "triple therapy"** PPI b.i.d. plus clarithromycin 500 mg b.i.d. plus amoxicillin 1,000 mg b.i.d. *or* metronidazole 500 mg b.i.d. for 10 to 14 days **Second-line therapy, also referred to as "Quadruple therapy"** Bismuth Salt compound 2 tabs q.i.d. plus tetracycline 250 mg q.i.d. plus metronidazole 250 mg q.i.d. PPI b.i.d. daily for 14 days	Efficacy of therapy is approximately 85% QID dosing may decrease compliance
Therapy for retreatment of *H. pylori* therapy failure	Repeat first-line therapy, substitute metronidazole for amoxicillin (or vice versa) for 14 days; may add Bismuth salt compound q.i.d. Add second-line *H. pylori* therapy.	Efficacy of retreatment not known; success of more than two courses of treatment is very low
Prophylactic therapy for NSAID ulcers	Peptic ulcer healing doses of PPIs (above) Misoprostol 200 µg q.i.d.	Prevents recurrent ulceration in approximately 80%–90% of patients

NSAID, nonsteroidal anti-inflammatory drug.

(2012). Current pharmacotherapy options for gastritis. *Expert Opinion on Pharmacotherapy*, *13*(18), 2625–2636.

Nursing Alert

For patients with peptic ulcer disease who are taking NSAIDs or aspirin, the first step is to ensure the patient understands the need to stop such therapy.

The patient is advised to adhere to and complete the medication regimen to ensure complete healing of the ulcer. Because most patients become symptom-free within a week, it is a nursing responsibility to stress to the patient the importance of following the prescribed regimen so that the healing process can continue uninterrupted and the return of chronic ulcer symptoms can be prevented. Rest, sedatives, and tranquilizers may be added for the patient's comfort and are prescribed as needed. Maintenance dosages of H_2 receptor antagonists are usually recommended for 1 year.

For patients with ZES, hypersecretion of acid may be controlled with high doses of H_2 receptor antagonists. These patients may require twice the normal dose, and dosages usually need to be increased with prolonged use. Octreotide (Sandostatin), a medication that suppresses gastrin levels, also may be prescribed.

Patients at risk for stress ulcers (e.g., patients with head injury or extensive burns) may be treated prophylactically with IV H_2 receptor antagonists and cytoprotective agents (e.g., misoprostol, sucralfate) because of the risk for upper GI tract hemorrhage.

Lifestyle Changes

Lifestyle changes include stress reduction, smoking cessation, and dietary modifications. Reducing environmental stress requires physical and psychological modifications on the

patient's part as well as the aid and cooperation of family members and significant others. The nurse assists the patient to identify situations that are stressful or exhausting. A hectic lifestyle and an irregular schedule may aggravate symptoms and interfere with regular meals taken in relaxed settings along with the regular administration of medications. The patient may benefit from regular rest periods during the day, at least during the acute phase of the disease. Biofeedback, hypnosis, behavior modification, massage, or acupuncture may be helpful.

Studies have shown that smoking decreases the secretion of bicarbonate from the pancreas into the duodenum, resulting in increased acidity of the duodenum. Research indicates that continued smoking may significantly inhibit ulcer repair (DiSaverio, 2014). Therefore, the patient is strongly encouraged to stop smoking. Smoking cessation support groups and other smoking cessation approaches should be offered to patients.

The intent of dietary modification for patients with peptic ulcers is to avoid oversecretion of acid and hypermotility in the GI tract. These can be minimized by avoiding extremes of temperature of food and beverage and overstimulation from consumption of meat extracts, alcohol, coffee (including decaffeinated coffee, which also stimulates acid secretion) and other caffeinated beverages, and diets rich in milk and cream (which stimulate acid secretion). In addition, an effort is made to neutralize acid by eating three regular meals a day. Small, frequent feedings are not necessary as long as an antacid or a histamine blocker is taken. Diet compatibility becomes an individual matter: the patient eats foods that are tolerated and avoids those that produce pain.

Surgical Management

The introduction of antibiotics to eradicate *H. pylori* and of H_2 receptor antagonists as treatment for ulcers has greatly reduced the need for surgical intervention. However, surgery usually is recommended for patients with intractable ulcers (those that fail to heal after 12 to 16 weeks of medical treatment), life-threatening hemorrhage, perforation, or obstruction, and for those with ZES not responding to medications (DiSaverio, 2014). Surgical procedures include vagotomy, with or without pyloroplasty (transecting nerves that stimulate acid secretion and opening the pylorus) and antrectomy, which is removal of the pyloric (antrum) portion of the stomach with anastomosis to either the duodenum (gastroduodenostomy or Billroth I) or jejunum (gastrojejunostomy or Billroth II) procedure (see Table 23-4 and the section on Gastric Surgery, page 699).

Patients who require surgery may have had a long illness. They may be discouraged and have had interruptions in their work role and pressures in their family life that affect their outlook on surgery and resolution of their disease. The nurse provides emotional support regarding the patient and family members altered role and additional responsibilities, and encourages them to express feelings, and ask questions. Referral to support groups or other services may be indicated.

Complications

Several complications may occur for the patient with peptic ulcer disease, including hemorrhage, perforation and penetration, and pyloric obstruction.

Nursing Alert
The nurse reviews with the patient and family the signs and symptoms of complications to be reported. These complications include hemorrhage (cool skin, confusion, increased heart rate, labored breathing, and blood in the stool), penetration and perforation (severe abdominal pain, rigid and tender abdomen, vomiting, elevated temperature, and increased heart rate), and pyloric obstruction (nausea, vomiting, distended abdomen, and abdominal pain).

Hemorrhage

Gastritis and hemorrhage from peptic ulcer are the two most common causes of upper GI tract bleeding (which may also occur with esophageal varices, as discussed in Chapter 22). Hemorrhage, the most common complication, occurs in 28% to 59% of patients with peptic ulcers. Bleeding may be manifested by hematemesis (vomiting blood) or melena (DiSaverio, 2014). The vomited blood can be bright red, or it can have a dark "coffee grounds" appearance from the oxidation of hemoglobin to methemoglobin. When the hemorrhage is large (2,000 to 3,000 mL), most of the blood is vomited. Because large quantities of blood may be lost quickly, immediate correction of blood loss may be required to prevent hemorrhagic shock. When the hemorrhage is small, much or all of the blood is passed in the stools, which appear tarry black because of the digested hemoglobin. Management depends on the amount of blood lost and the rate of bleeding.

The nurse assesses the patient for faintness or dizziness and nausea, which may precede or accompany bleeding. It is important to monitor vital signs frequently and to evaluate the patient for tachycardia, hypotension, and tachypnea. Other nursing interventions include monitoring the hemoglobin and hematocrit, testing the stool for gross or occult blood, and recording hourly urinary output to detect anuria or oliguria (absence of or decreased urine production).

TABLE 23-4 Surgical Procedures for Peptic Ulcer Disease

Operation	Description	Comments
Vagotomy 	Severing of the vagus nerve. Decreases gastric acid by diminishing cholinergic stimulation to the parietal cells, making them less responsive to gastrin. May be performed via open surgical approach, laparoscopy, or thoracoscopy.	May be performed to reduce gastric acid secretion. A drainage type of procedure (see pyloroplasty) is usually performed to assist with gastric emptying (because there is total denervation of the stomach). Some patients experience problems with feeling of fullness, dumping syndrome, diarrhea, and gastritis.
Truncal Vagotomy	Severs the right and left vagus nerves as they enter the stomach at the distal part of the esophagus	This type of vagotomy is most commonly used to decrease acid secretions and reduce gastric and intestinal motility. Recurrence rate of ulcer is 10%–15%.
Selective Vagotomy	Severs vagal innervation to the stomach but maintains innervation to the rest of the abdominal organs	With the availability of excellent acid secretion control with H2-receptor antagonists and proton pump inhibitors, the need for surgical management of PUD has greatly decreased.
Proximal (Parietal Cell) Gastric Vagotomy without Drainage	Denervates acid-secreting parietal cells but preserves vagal innervation to the gastric antrum and pylorus	No dumping syndrome. No need for drainage procedure. Recurrence rate of ulcer is 10%–15%.
Pyloroplasty 	Longitudinal incision is made into the pylorus and transversely sutured closed to enlarge the outlet and relax the muscle	Usually accompanies truncal and selective vagotomies, which produce delayed gastric emptying due to decreased innervation.

Antrectomy		
Billroth I (Gastroduodenostomy) 	Removal of the lower portion of the antrum of the stomach (which contains the cells that secrete gastrin) as well as a small portion of the duodenum and pylorus. The remaining segment is anastomosed to the duodenum.	May be performed in conjunction with a truncal vagotomy. The patient may have problems with feeling of fullness, dumping syndrome, and diarrhea. Recurrence rate of ulcer is 1%.
Billroth Ii (Gastrojejunostomy) 	Removal of lower portion (antrum) of stomach with anastomosis to jejunum. Dotted lines show portion removed (antrectomy). A duodenal stump remains and is oversewn.	Dumping syndrome, anemia, malabsorption, weight loss. Recurrence rate of ulcer is 10%–15%.

Many times, the bleeding from a peptic ulcer stops spontaneously; however, the incidence of recurrent bleeding is high. Because bleeding can be fatal, the cause and severity of the hemorrhage must be identified quickly and the blood loss treated to prevent hemorrhagic shock.

If bleeding cannot be managed by medical therapies (IV infusion of crystalloids and colloids, gastric lavage, and pharmacologic agents), other treatment modalities may be used. Transendoscopic coagulation by laser, heat probe, medication, a sclerosing agent, or a combination of these therapies can halt bleeding and avert surgical intervention. There is debate regarding how soon endoscopy should be performed. Some clinicians believe endoscopy should be performed within the first 24 hours after hemorrhage has been stabilized. Others believe endoscopy may be performed during acute bleeding, as long as the esophageal or gastric area can be visualized (blood may decrease visibility).

For patients who are unable to undergo surgery, selective embolization may be used. This procedure involves forcing emboli of autologous blood clots with or without Gelfoam (absorbable gelatin sponge) through a catheter in the artery to a point above the bleeding lesion. This procedure is performed by an interventional radiologist (DiSaverio, 2014).

Rebleeding may occur and often warrants surgical intervention. The nurse monitors the patient carefully so that bleeding can be detected quickly. Signs of bleeding include tachycardia, tachypnea, hypotension, mental confusion, thirst, and oliguria. If bleeding recurs within 48 hours after medical therapy has been initiated, or more than 6 to 10 units of blood are required within 24 hours to maintain blood volume, the patient may require

surgery. Surgery may be recommended if the patient has three or more bleeding episodes. Other indications for surgery are the patient's age (massive hemorrhage is three times more likely to be fatal in people over 60 years of age), a history of chronic duodenal ulcer, and a coincidental gastric ulcer. The area of the ulcer is removed or the bleeding vessels are ligated. Many patients undergo procedures (e.g., vagotomy and pyloroplasty, gastrectomy) aimed at controlling the underlying cause of the ulcers (see Table 23-4).

Perforation and Penetration

Perforation is the erosion of the ulcer through the gastric serosa into the peritoneal cavity without warning. It is an abdominal catastrophe and requires immediate surgery. Box 23-1 provides signs and symptoms of perforation. Penetration is erosion of the ulcer through the gastric serosa into adjacent structures such as the pancreas, biliary tract, or gastrohepatic omentum. Symptoms of penetration include back and epigastric pain not relieved by medications that had been effective in the past. Like perforation, penetration usually requires surgical intervention.

Because chemical peritonitis develops within a few hours after perforation and is followed by bacterial peritonitis, the perforation must be closed as quickly as possible and the abdominal cavity lavaged of stomach or intestinal contents. In select patients, it may be safe and advisable to perform surgery to treat the ulcer disease in addition to suturing the perforation.

During surgery and postoperatively, the stomach contents are drained by means of an NG tube. The nurse monitors fluid and electrolyte balance and assesses the patient for localized infection or peritonitis (increased temperature, abdominal pain, paralytic ileus, increased or absent bowel sounds, abdominal distention). Antibiotic therapy is administered parenterally as prescribed.

Pyloric Obstruction

Pyloric obstruction, also called gastric outlet obstruction (GOO), occurs when the area distal to the pyloric sphincter becomes scarred and stenosed from spasm or edema or from scar tissue that forms when an ulcer alternately heals and breaks down. More than 95% of benign GOO is associated with peptic ulcer disease (duodenal or pyloric) (Ware-McGee & Wheaton, 2013). The patient may have nausea and vomiting, constipation, epigastric fullness, anorexia, and, later, weight loss. On physical examination, abdominal distension may be noted with tympanic left upper quadrant.

BOX 23-1 Focused Assessment

Perforation

Be alert for the following signs and symptoms:

- Sudden, severe upper abdominal pain (persisting and increasing in intensity); pain may be referred to the shoulders, especially the right shoulder, because of irritation of the phrenic nerve in the diaphragm
- Vomiting

- Collapse (fainting)
- Extremely tender and rigid (boardlike) abdomen
- Hypotension and tachycardia, indicating shock

In treating the patient with pyloric obstruction, the first consideration is to insert an NG tube to decompress the stomach. Usually, an upper GI study or endoscopy is performed to confirm pyloric obstruction. Decompression of the stomach and management of extracellular fluid volume and electrolyte balances may improve the patient's condition and avert the need for surgical intervention. A balloon dilation of the pylorus via endoscopy may be beneficial. If the obstruction is unrelieved by medical management, surgery (in the form of a vagotomy and antrectomy or gastrojejunostomy and vagotomy) may be required. Recently, stent placement has been introduced as an alternative to surgical intervention with initial clinical success but may present problems with recurrent obstruction in patients with malignant gastric outlet obstruction (Goldberg, 2014; Khashab et al., 2013).

MORBID OBESITY

Morbid obesity is a term applied to people who are more than two times their ideal body weight or whose body mass index (BMI) exceeds 30 kg/m^2. Another definition of morbid obesity is body weight that is more than 100 pounds greater than the ideal body weight (Kissler & Setmacher, 2013). In the United States, where morbid obesity is a rapidly growing problem, approximately 65% of the people are overweight (Kissler & Settmacher, 2013), 36.5 percent of adults are obese, and approximately 8 percent are extremely obese (CDC, 2016).

Patients with morbid obesity are at higher risk for health complications, such as diabetes, heart disease, stroke, hypertension, gallbladder disease, osteoarthritis, sleep apnea and other breathing problems, and some forms of cancer (uterine, breast, colorectal, kidney, and gallbladder). They frequently suffer from low self-esteem, impaired body image, and depression. Management for patients with obesity has been outlined in a summary document from the American College of Cardiology and the American Heart Association (2014).

Medical Management

Conservative management of obesity consists of placing the person on a weight loss diet in conjunction with behavioral modification and exercise; however, dietary and behavioral approaches to obesity have had limited success. Depression may be a contributing factor to weight gain, and treatment of the depression with an antidepressant may be helpful (Goritz & Duff, 2014).

Pharmacologic Management

Several medications are approved for treatment of obesity that work as an appetite reduction or inhibition of pancreatic lipase, which results in fat maldigestion. Examples include orlistat (Xenical), Phentermine (Suprenza), and Phentermine and Topiramate extended release (ER) (Qsymia) and Lorcaserin (Belviq). Sibutramine HCL (Meridia) was recently pulled from the European and U.S. markets because of the increased risk of heart attack and stroke associated with this medication. Rimonabant (Acomplia) was pulled from the European markets and has not been approved for use in the U.S. (Hurt, Varayil, & Ebbert, 2014). Orlistat, available by prescription and over the counter as Alli, reduces caloric intake by binding to gastric and pancreatic lipase to prevent digestion of fats. Side effects of orlistat may include increased frequency of bowel movements, increased gas with oily discharge, decreased food absorption, decreased bile flow, and decreased absorption of some vitamins. A multivitamin is usually recommended for patients taking orlistat. These medications are not recommended for pregnant women or those planning to become pregnant as weight loss offers no potential benefit during pregnancy.

Lorcaserin (Belviq) was approved by the FDA in 2012 for weight loss therapy for obesity. Lorcaserin is a selective 5-HT_{2C} agonist with a half-life of about 11 hours. Activation of the serotonin 5-HT_2 has been associated with satiety, hypophagia (decreased food intake), and modulations of the side effects of psychostimulant addiction. Previously, the drugs fenfluramine and dexfenfluramine were used because they activated the 5-HT_{2B} receptor, but they were associated with valvular heart disease (Comerma-Steffenson, Grann, Andersen, Rungby, & Simonsen, 2014). In three large phase III studies, there has been no valvular heart disease associated with Lorcaserin (Hurt et al., 2014). Unfortunately, these medications rarely result in loss of more than 10% of total body weight. Furthermore, studies are needed to evaluate their long-term efficacy and risks (Gadde & Yancy, 2015). Studies are currently being undertaken to evaluate additional medication options for the long term treatment of obesity (Aronne, 2014).

Surgical Management

Bariatric surgery, or surgery for morbid obesity, is performed only after other nonsurgical attempts at weight control have failed. The National Institute of Diabetes and Digestive and Kidney Disease reports that the number of bariatric procedures has increased dramatically with 350,000 worldwide procedures done in 2008 (Kissler & Settmacher, 2013). In the United States, 158,000 procedures were performed in 2011 and 196,000 in 2015 (American Society for Metabolic and Bariatric Surgery [ASMBS], 2016). Bariatric

surgical procedures work by restricting a patient's ability to eat (restrictive procedure), interfering with ingested nutrient absorption (malabsorptive procedures), or both.

Different bariatric surgical procedures entail different lifestyle modifications, and patients must be well informed about the specific lifestyle changes, eating habits, and bowel habits that may result from a particular procedure. Studies have shown that the average weight loss after bariatric surgery in the majority of patients is approximately 61% of previous body weight; comorbid conditions such as diabetes mellitus, hypertension, and sleep apnea resolve; and dyslipidemia improves (Kissler & Setmacher, 2013). Bariatric surgery has been extended to carefully selected adolescents because of its results in adults (Kissler & Settmacher, 2013).

Patient selection is critical, and the preliminary process may necessitate 6 to 12 months of counseling, education, and evaluation by a multidisciplinary team, including social workers, dietitians, a nurse counselor, and a psychologist or psychiatrist, as well as a surgeon (Table 23-5).

TABLE 23-5 Selection Criteria for Bariatric Surgery

Factor	Criteria
Weight (Adults)	• Body mass index (BMI) of at least 40 kg/m^2 with no comorbidities • BMI of at least 35 kg/m^2 with obesity-associated comorbidity (e.g., severe sleep apnea, hypertension, cardiomyopathy related to obesity, severe diabetes mellitus; serious musculoskeletal or neurologic disorders)
Weight loss history	• Failure of previous nonsurgical attempts at weight reduction, including commercial programs (e.g., Weight Watchers, Inc.)
Commitment	• Expectation that patient will adhere to postoperative care • Follow-up visits with provider(s) and team members • Recommended medical management, including the use of dietary supplements • Instructions regarding any recommended procedures or tests
Exclusions	• Reversible endocrine or other disorders that can cause obesity • Current drug or alcohol abuse • Uncontrolled, severe psychiatric illness • Lack of comprehension of risks, benefits, expected outcomes, alternatives, and lifestyle changes required with bariatric surgery

From Mechanick, J, Youdim, A., Jones, D, Timothy Garvey, W., Hurley, D., Molly McMahon, M., . . . Brethauer, S. (2013). AACE/TOS/ASMBS: Clinical practice guidelines for the perioperative nutritional, metabolic, and nonsurgical support of the bariatric surgery patient—2013 update. *Surgery for Obesity & Related Diseases*, *9*(2), 159–191.

Because bariatric surgery involves such a drastic change in the functioning of the

digestive system, body image, and lifestyle adjustments, patients need extensive counseling before and after the surgery (Alegria & Larsen, 2015). Guidelines have been developed to assist physicians and nurses in the care of patients having bariatric surgery (Goritz & Duff, 2014; Kissler & Settmacher, 2013). After bariatric surgery, all patients require lifelong monitoring of weight loss, comorbidities, metabolic and nutritional status, and dietary and activity behaviors because they are at risk for developing malnutrition or weight gain (Goritz & Duff, 2014). Women of childbearing age who have bariatric surgery are advised to use contraceptives for approximately 2 years after surgery to avoid pregnancy until their weight stabilizes.

Procedures

The first surgical procedure used to treat morbid obesity was jejunoileal bypass. This procedure, which resulted in significant complications, has been largely replaced by gastric restriction procedures. Roux-en-Y gastric bypass, gastric banding, vertical banded gastroplasty, laparoscopic sleeve gastrectomy, and biliopancreatic diversion with duodenal switch are the current procedures of choice. These procedures may be performed by laparoscopy or by an open surgical technique. Currently, 90% of all bariatric surgeries are done laparoscopically (Kissler & Settmacher, 2013). Recent studies report long term weight loss success following lapraroscopic sleeve gastrectomy at greater than 50% at 5 years or more (Diamantis et al., 2014).

Gastric restrictive procedures, such as adjustable gastric banding (AGB), vertical banded gastroplasty and sleeve gastrectomy (SG), cause early satiety during meals by decreasing the volume of the stomach. Laparoscopic adjustable gastric banding has replaced the vertical gastric banding (VGB) as the favored restrictive procedure. Malabsorptive procedures, such as biliopancreatic diversion with or without duodenal switch (BPD/DS), rely on bypassing various lengths of the small intestine, reducing nutrient absorption. Mixed procedures such as the Roux-en-Y gastric bypass (RYGB) combine gastric restriction with bypass of a short segment of the small intestine.

The Roux-en-Y gastric bypass is recommended for long-term weight loss. It is a combined restrictive and malabsorptive procedure. Biliopancreatic diversion with duodenal switch combines gastric restriction with intestinal malabsorption. See Figure 23-3A–E for additional details about these procedures. After weight loss, the patient may need surgical intervention for body contouring. This may include lipoplasty to remove fat deposits or a panniculectomy to remove excess abdominal skinfolds.

Complications

Bariatric surgical procedures have their own unique complications in addition to those associated with any major abdominal surgery. The most common complications are bleeding, blood clots, bowel obstruction, incisional or ventral hernias, and infection from a leak at the anastomosis. Prevention of complications is critical. Other postoperative problems that may occur include nausea, usually as a result of overfilling the stomach pouch or improper chewing; dumping syndrome associated with the consumption of simple sugars; and changes in bowel function, including diarrhea and constipation. Long-term complications that are related to nutritional deficiency may occur.

Nursing Management

Nursing management focuses on care of the patient after surgery. General postoperative nursing care is similar to that for a patient recovering from a gastric resection but with great attention given to the risks of complications associated with morbid obesity. Complications that may occur in the immediate postoperative period include peritonitis, stomal obstruction, stomal ulcers, atelectasis and pneumonia, thromboembolism, and metabolic imbalances resulting from prolonged vomiting and diarrhea or altered GI function. After bowel sounds have returned and oral intake is resumed, six small feedings consisting of a total of 600 to 800 calories per day are provided, and fluids are encouraged to prevent dehydration.

The patient is usually discharged in 4 days (23 to 72 hours for patients who have had laparoscopic procedures) with detailed dietary instructions (Box 23-2). The nurse instructs the patient to report excessive thirst or concentrated urine, both of which are indications of dehydration. Psychosocial interventions are also essential for these patients. Efforts are directed at helping them modify their eating behaviors and cope with changes in body image. The nurse explains that noncompliance by eating too much or too fast or eating high-calorie liquids and soft foods results in vomiting and painful esophageal distention. The nurse discusses dietary instructions before discharge and emphasizes the importance of routine follow-up outpatient appointments. Long-term side effects may include increased risk of gallstones, nutritional deficiencies (Table 23-6), and potential to regain weight. Factors integral to postsurgical weight loss success include dietary counseling; medication instruction on the importance of taking supplemental vitamin B_{12}, iron, and calcium as well as a standard multivitamin; cognitive-behavioral therapy; and support groups. Obese patients are at risk for vitamin and nutrient deficiencies (Coupaye et al., 2014; Majumder et al., 2013). Nutritional deficits tend to stabilize by 2 years postprocedure (Aquilera, 2014) and do not seem to be affected by type of gastric bypass procedure (Coupaye et al., 2013).

GASTRIC CANCER

The incidence of gastric or stomach cancer continues to decrease in the United States; however, it still accounts for almost 11,000 deaths annually (American Cancer Society, 2015). The prognosis is generally poor: usually the diagnosis is made late because most patients are asymptomatic during the early stages of the disease. Most cases of gastric cancer are discovered only after local invasion has advanced or metastases are present (Al-Batran & Werner, 2014; Ashraf, Hoffe, & Kim, 2013; Miceli, Tomasello, Bregni, Di Bartolomeo, & Pietrantonio, 2014).

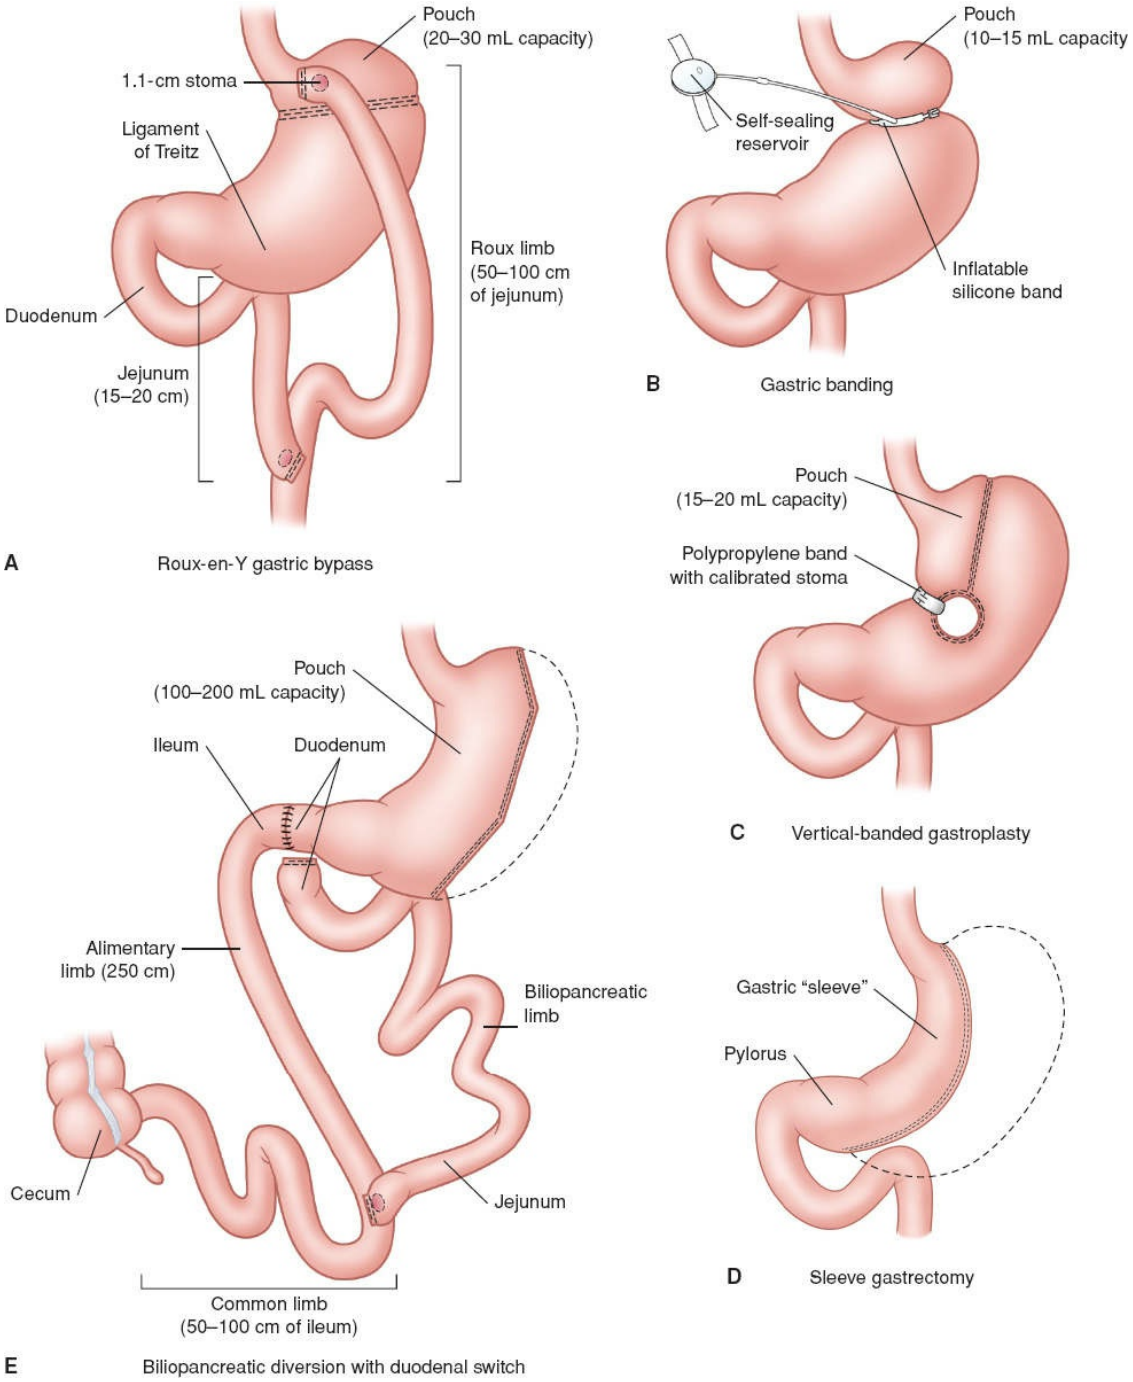

FIGURE 23-3 Surgical procedures for morbid obesity. A. Roux-en-Y gastric bypass. A horizontal row of staples across the fundus of the stomach creates a pouch with a capacity of 20 to 30 mL. The jejunum is divided distal to the ligament of Treitz, and the distal end is anastomosed to the new pouch. The proximal segment is anastomosed to the jejunum. B. Gastric banding. A prosthetic device is used to restrict oral intake by creating a small pouch of 10 to 15 mL that empties through the narrow outlet into the remainder of the stomach. C. Vertical-banded gastroplasty. A vertical row of staples along the lesser curvature of the stomach creates a new, smaller stomach pouch of 10 to 15 mL. D. Sleeve gastrectomy. The stomach is incised vertically and up to 85% of the stomach is surgically removed, leaving a "sleeve"-shaped tube that retains intact nervous innervation and does not obstruct or decrease the size of the gastric outlet. The tubular stomach has a limited gastric volume of 60 to 100 mL. E. Biliopancreatic diversion with duodenal switch. Half of the stomach is removed, leaving a small area that holds about 60 mL. The entire jejunum is excluded from the rest of the gastrointestinal tract. The duodenum is disconnected and sealed off. The ileum is divided above the ileocecal junction, and the

distal end of the jejunum is anastomosed to the first portion of the duodenum. The distal end of the biliopancreatic limb is anastomosed to the ileum. (Reprinted with permission from Hinkle, J. (2013). *Brunner & Suddarth's textbook of medical-surgical nursing* (13th ed.). Philadelphia, PA: Lippincott, Wolters Kluwer Health.)

BOX 23-2 Patient Education

Dietary Guidelines for the Patient Who Has Had Bariatric Surgery

Nutrition:

- Eat six small meals per day (containing protein and fiber), and chew small bites of food thoroughly.
- Consume five daily servings of fresh fruits and vegetables.
- Include two protein snacks per day for a minimum protein intake of 60 g/d.
- Restrict total meal size to less than 1 cup.
- Eat only foods packed with nutrients (e.g., peanut butter, cheese, chicken, fish, beans).
- Do not eat and drink at the same time. Fluids should be consumed slowly.
- Concentrated sweets should be eliminated from the diet to avoid dumping syndrome.

Hydration:

- Fluids should be consumed slowly.
- Drink plenty of water, from 30 minutes after each meal to 15 minutes before the next meal.
- Avoid liquid calories, such as alcoholic beverages, fruit drinks, and regular soda (cola).

Supplements:

- Take 2 chewable multivitamin plus mineral (iron, folic acid, thiamine, copper, zinc) supplements daily.
- Diet/supplements should include 1,200–1,500 mg of elemental calcium.
- Diet/supplements should include:
  - 3,000 IU of vitamin D daily
  - Vitamin B12—1,000 ug/day
- Crushed or liquid rapid-release medications should be used instead of extended-release to maximize absorption.

Exercise:

- Walk for at least 30 minutes per day, minimum of 150 minutes (2½ hours) per week to a goal of 300 minutes (5 hours) per week, supplemented by strength training two

to three times per week.

From Bosnic, G. (2014). Nutritional requirements after bariatric surgery. Critical Care Clinics of North America, 26(2), 255–262; Mechanick, J., Youdim, A., Jones, D., Timothy Garvey, W., Hurley, D., Molly McMahon, M., … Brethauer, S. (2013). AACE/TOS/ASMBS: Clinical practice guidelines for the perioperative nutritional, metabolic, and nonsurgical support of the bariatric surgery patient – 2013 update. Surgery for Obesity & Related Diseases, *9*(2), 159–191.

Pathophysiology

Most gastric cancers are adenocarcinomas; they can occur anywhere in the stomach. The tumor infiltrates the surrounding mucosa, penetrating the wall of the stomach and adjacent organs and structures. Often the liver, pancreas, esophagus, and duodenum are affected at the time of diagnosis. Metastasis through lymph to the peritoneal cavity occurs later in the disease.

TABLE 23-6 Nutritional Deficiencies After Bariatric Surgery

Deficiency	Signs and Symptoms
Decreased hemoglobin	Anemia
Decreased ferritin	Anemia
Decreased iron	Fatigue, anemia, lethargy, pallor, and loss of hair
Decreased vitamin B_{12}	Macrocytic anemia, pernicious anemia, leukopenia, thrombocytopenia, paresthesia, neuropathy, muscular pains, weakness, fatigue, dizziness, and brittle nails
Decreased vitamin D_3	Symptoms may include osteopenia, muscle pain, bone fractures
Decreased β-carotene	Reducing the fat-soluble antioxidant capacity, neuropathy
Decreased calcium	Osteopenia, bone fractures
Decreased magnesium	Muscle cramps, muscle pain, constipation, headaches, insomnia, anxiety, hyperactivity
Decreased zinc	Delayed wound healing, altered immune function, mental lethargy, perhaps association with alopecia

From Gletsu-Miller, N., & Wright, B. (2013). Mineral malnutrition following bariatric surgery. *Advances in Nutrition*, *4*, 506–517.

Gastrointestinal lymphoma represents a second classification, differing in pathogenesis, treatment and prognosis. Gastric MALT (mucosa-associated lymphoid tissue) lymphoma is the most common entity with *H. pylori* as the decisive pathogenic factor (Fischbach & Dunning, 2014). MALT is acquired as a secondary process against *H. pylori*. The bacterium is the cause of chronic gastritis and leads to the formation of intramucosal lymph follicles (Fischbach & Dunning, 2014). Eradication of the bacteria results in regression of the lymphoma in 77.5% of Stage I tumors. Chemotherapy or radiation may be required for patients with Stage II disease (Fischbach & Dunning, 2014).

Risk Factors

The typical patient with gastric cancer is between 40 and 70 years of age, but gastric cancer can occur in people younger than 40 years of age. Men have a higher incidence of gastric cancer than do women. Native Americans, Hispanic Americans, and African Americans are twice as likely as Caucasian Americans to develop gastric cancer. The incidence of gastric cancer is much greater in Japan, which has instituted mass screening programs for earlier diagnosis. Diet appears to be a significant factor: a diet high in smoked, salted, or pickled foods and low in fruits and vegetables may increase the risk of gastric cancer. Other factors related to the incidence of gastric cancer include chronic inflammation of the stomach, *H. pylori* infection, pernicious anemia, smoking, achlorhydria, gastric ulcers, previous subtotal gastrectomy (more than 20 years ago), and genetics.

Clinical Manifestations and Assessment

Symptoms of early disease, such as pain relieved by antacids, resemble those of benign ulcers and are seldom definitive because most gastric tumors begin on the lesser curvature of the stomach, where they cause little disturbance of gastric function. Symptoms of progressive disease include dyspepsia (indigestion), early satiety, weight loss, abdominal pain just above the umbilicus, loss or decrease in appetite, bloating after meals, nausea and vomiting, and symptoms similar to those of peptic ulcer disease.

The physical examination is usually not helpful in detecting the cancer because most early gastric tumors are not palpable. Advanced gastric cancer may be palpable as a mass. Ascites, hepatomegaly (enlarged liver), and jaundice may be apparent if the cancer cells have metastasized to the liver. Palpable nodules around the umbilicus, called Sister Mary Joseph's nodules, are a sign of a GI malignancy, usually a gastric cancer. Patients appear cachectic. Esophagogastroduodenoscopy for biopsy and cytologic washings is the diagnostic study of choice, and a barium x-ray examination of the upper GI tract also may be performed. Endoscopic ultrasound is an important tool to assess tumor depth and any lymph node involvement. Computed tomography (CT) completes the diagnostic studies, particularly to assess for surgical resectability of the tumor before surgery is scheduled. CT of the chest, abdomen, and pelvis is valuable in staging gastric cancer.

Medical and Nursing Management

There is no successful treatment for gastric carcinoma except removal of the tumor. If the tumor can be removed while it is still localized to the stomach, the patient may be cured. If the tumor has spread beyond the area that can be excised, cure is less likely. In many patients, effective palliation to prevent discomfort caused by obstruction or dysphagia may be obtained by resection of the tumor (see Gastric Surgery). A diagnostic laparoscopy may be the initial surgical approach to evaluate the gastric tumor, obtain tissue for pathologic diagnosis, and detect metastasis. The patient with a tumor that is deemed resectable undergoes an open surgical procedure to resect the tumor and appropriate lymph nodes. The patient with an unresectable tumor and advanced disease would undergo chemotherapy.

A total gastrectomy may be performed for a resectable cancer in the midportion or body of the stomach. The entire stomach is removed, along with duodenum, the section of esophagus attached to the stomach, supporting mesentery, and lymph nodes. Reconstruction of the GI tract is performed by anastomosing the end of the jejunum to the end of the esophagus, a procedure called an *esophagojejunostomy*.

A radical subtotal gastrectomy is performed for a resectable tumor in the middle and distal portions of the stomach. A Billroth I or Billroth II operation (see Table 23-4) is performed. The Billroth I involves a limited resection and offers a lower cure rate than the Billroth II. The Billroth II procedure is a wider resection that involves removing approximately 75% of the stomach and decreases the possibility of lymph node spread or metastatic recurrence.

A proximal subtotal gastrectomy may be performed for a resectable tumor located in the proximal portion of the stomach or cardia. A total gastrectomy or an esophagogastrectomy is usually performed in place of this procedure to achieve a more extensive resection. A palliative surgical procedure may be required for patients with gastric cancer to achieve a better quality of life (QOL).

Common problems of advanced gastric cancer that often require surgery include pyloric obstruction, bleeding, and severe pain. Gastric perforation is an emergency situation requiring surgical intervention. A gastric resection may be the most effective palliative procedure for advanced gastric cancer. Palliative procedures, such as gastric or esophageal bypass, gastrostomy, or jejunostomy, may alleviate symptoms such as nausea and vomiting temporarily. Palliative rather than radical surgery may be performed if there is metastasis to other vital organs, such as the liver, or to achieve a better QOL. Patients often report a decrease in QOL when the symptom burden of the cancer is prevalent. Symptoms include fatigue, pain, worry, irritability, lack of energy and difficulty sleeping (Deshields, Potter, Olsen, & Liu, 2014; Koornstra, Peters, Donofrio, van den Borne, & de Jong, 2014).

If surgical treatment does not offer cure, treatment with chemotherapy may offer further control of the disease or palliation (Diaz-Neito, Orti-Rodriguez, & Winslet, 2013). A 10 percent increase in cure rate with adjuvant therapies has been reported (Taketa, Sudo, Wadhawa, Blum, & Ajani, 2013). Commonly used chemotherapeutic agents used unaccompanied or in combination include 5-fluorouracil (5-FU), epirubicin (Ellence), cisplatin (Platinol), irinotecan (Camptosar), capecitabine (Xeloda), docetaxel (Taxotere), oxaliplatin (Eloxatin), doxorubicin (Adriamycin), etoposide (Etopophos), and mitomycin-

C (Mutamycin). For improved response rates, it is more common to administer combination therapy, primarily 5-FU–based therapy, with other agents. Studies are being conducted to assess the use of chemotherapy before surgery. Radiation therapy is used mainly for palliation in patients with obstruction, GI bleeding secondary to tumor, and significant pain. Assessment of tumor markers (blood analysis for antigens indicative of cancer), such as carcinoembryonic antigen (CEA), carbohydrate antigen (CA 19–9), and CA 50, may help determine the effectiveness of treatment. If these values were elevated before treatment, they should decrease if the tumor is responding to the treatment (Miceli et al., 2014). Meticulous attention to nutrition (jejunal enteral feedings or total parenteral nutrition [TPN]) is an essential aspect of patient management. Box 23-3 discusses the relationship between the effect of symptoms and QOL for patients with cancer (Deshields et al., 2014).

BOX 23-3 Nursing Research

Bridging the Gap to Evidence-Based Practice

Assessing Symptoms Experienced by Patients with Cancer

McMillan, S., Tofthagen, C., Choe, R., & Rheingans, J. (2015). Assessing symptoms experienced by patients with cancer: Occurrence, intensity, distress, interference, and frequency. Journal of Hospice & Palliative Nursing, *17*(1), 56–65.

Purpose

Patients with cancer experience multiple symptoms during their disease process. All of these symptoms have the potential to cause significant distress and interfere with the patient's quality of life (QOL). Patients undergoing cancer treatment experience physical, psychosocial, psychological, and economic stressors that may, in turn, affect their QOL. QOL has different meaning for different individuals, reflecting personal values and characteristics. It may be seen as the sum of a whole life or as episodic, a measure of their current state of health and function. Scales to measure QOL reflect this individual diversity, incorporating the physical, psychological, and social dimensions in addition to symptoms of illness and treatment modalities. Many studies have documented the importance of QOL in patients with cancer.

The authors' purpose in conducting this study was to identify the symptom profile of patients being treated for cancer and to validate a new symptom assessment tool for use with persons with cancer, the Cancer Symptom Scale (CSS). In order to manage cancer-related signs and symptoms adequately, nurses caring for patients with cancer need to fully understand each patient's symptom experience. Scales are available for assessing symptoms in patients with cancer, but none of the existing scales include all of the symptoms that patients experience; all four elements that are needed (intensity, distress, interference, and constancy/frequency) can be assessed easily and interpreted on a scale of 0 to 10 using the CSS.

Design

The sample for the study consisted of 234 patients with any cancer diagnosis who were

being treated for cancer or cancer symptoms at one of two facilities in the Southeastern United States: a regional medical center and a National Cancer Institute – designated comprehensive cancer center. Patients had to be adults over 18 years of age and able to read and understand English. Staff nurses referred patients whom they knew to be alert and oriented and able to consent to the study. Patients who were within 3 weeks following surgery were excluded. Consenting patients were accrued during an 18-month period.

Three instruments were used in the study:

1. The CSS was used to assess patient symptoms.
2. The Multidimensional Quality of Life Scale—Cancer (MQOL-C) was used to support the validity of the CSS.
3. Demographic data were also collected.

The CSS assesses the presence, intensity, distress, frequency, and interference of a list of 35 symptoms, each on a scale of 0 to 10 points. The list of symptoms included in the scale was based on the review of literature. Like other scales, the CSS allows the patient to identify whether a symptom has occurred in the past week, and only if the response is "yes" does the patient respond about intensity, distress, frequency, and interference of that symptom. Validity and reliability of this type of scale have been strong. The CSS includes the added assessment of the interference caused by the symptom as well as distress and frequency/constancy. Each dimension is assessed on a scale of 0 to 10 points. Because this is a new study tool, validity and reliability were also studied.

The MQOL-C was used to help assess the construct validity of the new CSS, hypothesizing weak to moderate relationships. QOL is known to be significantly but moderately correlated with symptoms; however, the correlation is not strong because the two instruments are not measuring the same but, rather, related concepts. The MQOL-C has 33 items that measure four dimensions of QOL; physical well-being, psychological well-being, social concerns, and symptoms. Items are scaled from 0 to 10. Validity has been supported by significant correlations with measures of depression as well as social and physical functioning. Cronbach α has been high (0.89–0.91).

Demographic data were collected to describe the sample population, including age, gender, race/ethnicity, and cancer diagnosis. Patients were asked a single item about QOL: "How good has your quality of life been during the past week?" and answered on a scale of 0 (worst) to 10 (best).

Patients were approached in a quiet area within their facilities and asked if they were experiencing any symptoms. If the patient reported any type of symptom, the study was explained, the consent obtained, and questions answered. Consenting patients completed the study questionnaires that were administered to patients by the research assistant who stayed with the patient during the administration. A subset of 15 patients was asked to complete the CSS a second time after a short delay of 1–2 hours. Returning the forms to the research assistant concluded the patient's participation in

the study.

Results

The sample consisted of 234 patients with cancer, 55.6% female, 82.9% white, and 63.2% married. The most common type of cancers was leukemia, breast cancer, lymphoma, and colorectal cancer. The mean age of the sample was 60.4 years with a range of 21–90 years of age. The QOL mean score was slightly above the midrange. The symptoms reported most commonly by this group of patients were fatigue/being tired, feeling drowsy, difficulty sleeping, pain, and dry mouth. Patients reported several signs and symptoms to be in the high range of intensity. Highest were feeling irritable, problem with sex, sweats, and diarrhea. All of these had mean scores higher than 6.0. The signs and symptoms causing the most distress were feeling irritable, diarrhea, worrying, and problems with urination; all had mean distress scores higher than 6.0. The signs and symptoms causing the most interference with patients' lives included diarrhea, feeling irritable, fatigue or feeling tired, problems with urination, difficulty sleeping, and shortness of breath. The signs and symptoms reported as occurring most frequently included problems with urination, problems with sex, difficulty sleeping, rash, poor appetite, numbness and tingling in both the hands and feet, and changes in the skin. All of these had mean scores of 6.4 or higher.

The subscales of the newly developed CSS were correlated with the total scores from the QOL scale and the MQOL-C scale. All correlations were weak to moderate ($r = -0.34$–0.56, $P < 0.001$). Reliability of the CSS was estimated in two ways. First, a small subsample of the patients agreed to complete the CSS twice with a time period between administration of the surveys. Results revealed excellent stability over time in all four of the subscales, with frequency having the highest estimate of reliability. Internal consistency reliability also was estimated using Cronbach α coefficient. All subscale coefficients were greater than 0.70. Reliability of the MQOL-C also was very strong ($\alpha = 0.92$).

Nursing Implications

Cancer outpatients in this study had symptoms of moderate to high intensity that caused distress, caused interference in their lives, and, in some cases, were frequent or long-lasting. Results of this study suggest that nurses need to continue to improve assessment and management of patient symptoms during regular clinic visits. Problems cannot be addressed adequately unless they are thoroughly assessed on an ongoing basis, and this assessment needs to include more than just symptom intensity because distress from symptoms, interference by symptoms, and constancy of symptoms help determine their impact. Patients may not think to tell nurses about all of their symptoms, so nurses must ask. Schools of nursing should emphasize teaching nurses to ask cancer patients about their signs and symptoms at every contact as well as provide teaching on how to manage symptoms. Nurses do assessments for pain frequently, but other symptoms can be neglected. Further research is needed about mechanisms and management of most of the symptoms explored in this study. It should be noted that

multisymptom assessment scales, such as the new CSS, allow clinicians to assess symptoms that patients are experiencing simultaneously, with awareness that treating one symptom may lead to the occurrence of others.

GASTRIC SURGERY

Gastric surgery may be performed on patients with peptic ulcers who have life-threatening hemorrhage, obstruction, perforation, or penetration, or whose condition does not respond to medication. It also may be indicated for patients with gastric cancer or trauma. Surgical procedures include a vagotomy and pyloroplasty (transecting nerves that stimulate acid secretion and opening the pylorus), a partial gastrectomy, or a total gastrectomy (see Table 23-4).

NURSING PROCESS

The Patient Undergoing Gastric Surgery

ASSESSMENT

Before surgery, the nurse assesses the patient's and family's knowledge of pre- and postoperative surgical routines and the rationale for surgery. The nurse also assesses the patient's nutritional status: Has the patient lost weight? How much? Over how much time? The nurse is aware that a 5% weight loss in 30 days, a 7.5% weight loss in 90 days, or a greater than 10% weight loss in 180 days is associated with significant health risks (Bosnic, 2014). Does the patient have nausea and vomiting? Has the patient had hematemesis? The nurse assesses for the presence of bowel sounds and palpates the abdomen to detect masses or tenderness.

After surgery, the nurse assesses the patient for complications secondary to the surgical intervention, such as hemorrhage, infection, abdominal distention, atelectasis, or impaired nutritional status.

DIAGNOSIS

Nursing diagnoses may include the following:

- Anxiety related to surgical intervention
- Acute pain related to surgical incision
- Deficient knowledge about surgical procedure and postoperative course
- Imbalanced nutrition, less than body requirements, related to poor nutrition before surgery and altered GI system after surgery

PLANNING

The major goals for the patient undergoing gastric surgery may include reduced anxiety, increased knowledge and understanding about the surgical procedure and postoperative course, optimal nutrition and management of the complications that can interfere with nutrition, relief of pain, avoidance of hemorrhage and steatorrhea, and enhanced self-care skills at home.

NURSING INTERVENTIONS

REDUCING ANXIETY

An important part of the preoperative nursing care involves allaying the patient's fears and anxieties about the impending surgery and its implications. The nurse encourages the patient to verbalize fears and concerns and answers the patient's and family's questions. If the patient has an acute obstruction, a perforated bowel, or an active GI hemorrhage, adequate psychological preparation may not be possible. In this event, the nurse caring for the patient after surgery should anticipate the concerns, fears, and questions that are likely to surface and should be available for support and further explanations.

RELIEVING PAIN

After surgery, analgesics may be administered as prescribed to relieve pain and discomfort. It is important to provide adequate pain relief so the patient can perform pulmonary care activities (deep breathing and coughing) and leg exercises, turn from side to side, and ambulate. The nurse assesses the effectiveness of analgesic intervention and consults with other members of the health care team if pain is not controlled adequately. Positioning the patient in the Fowler position promotes comfort and allows emptying of the stomach after gastric surgery.

The nurse maintains functioning of the NG tube to prevent distention and secures the tube to prevent dislocation, which may result in increased pain and tension on the suture line. Normally, the amount of NG drainage after a total gastrectomy is minimal as there is no reservoir where secretions can collect.

PROVIDING TEACHING

The nurse explains routine pre- and postoperative procedures to the patient, which include preoperative medications, NG intubation, IV fluids, abdominal dressings, and the possible need for a feeding tube, pain management, and pulmonary care. These explanations need to be reinforced after surgery, especially if the patient had emergency surgery.

RESUMING ENTERAL INTAKE

The patient's nutritional status is evaluated before surgery. If surgery is performed for gastric cancer, often the patient is malnourished and may require preoperative enteral or, more often, parenteral nutrition. After surgery, parenteral nutrition may be continued to

meet caloric needs, to replace fluids lost through drainage and vomiting, and to support the patient metabolically until oral intake is adequate.

After the return of bowel sounds and removal of the NG tube, the nurse may give fluids, followed by food in small portions. Foods are added gradually until the patient is able to eat six small meals a day and drink 120 mL of fluid between meals. The key to increasing the dietary content is to offer food and fluids gradually, as tolerated, and to recognize that each patient's tolerance is different.

RECOGNIZING OBSTACLES TO ADEQUATE NUTRITION

Dysphagia and Gastric Retention. Dysphagia may occur in patients who have had a truncal vagotomy, a surgical procedure that may result in trauma to the lower esophagus. Gastric retention may be evidenced by abdominal distention, nausea, and vomiting. Regurgitation also may occur if the patient has eaten too much or too quickly. It also may indicate that edema along the suture line is preventing fluids and food from moving into the intestinal tract. If gastric retention occurs, it may be necessary to reinstate NPO status and NG suction; pressure must be low in the remaining portion of the stomach to avoid disrupting the sutures.

Bile Reflux. Bile reflux gastritis and esophagitis may occur with the removal of the pylorus, which acts as a barrier to the reflux of duodenal contents. Burning epigastric pain and vomiting of bilious material manifest this condition. Eating or vomiting does not relieve the situation. Agents that bind with bile acid, such as cholestyramine (Questran), may be helpful. Aluminum hydroxide gel (an antacid) and metoclopramide hydrochloride (Reglan) have been used with limited success.

Dumping Syndrome. Dumping syndrome is an unpleasant set of vasomotor and GI symptoms that sometimes occur in patients who have had gastric surgery or a form of vagotomy. It is seen in 10% of all patients having gastric surgery (Ferri, 2016). It may be the mechanical result of surgery in which a small gastric remnant is connected to the jejunum through a large opening. Foods high in carbohydrates and electrolytes must be diluted in the jejunum before absorption can take place, but the passage of food from the stomach remnant into the jejunum is too rapid to allow this to happen. The hypertonic intestinal contents draw extracellular fluid from the circulating blood volume into the jejunum to dilute the high concentration of electrolytes and sugars. The ingestion of fluid at mealtime is another factor that causes the stomach contents to empty rapidly into the jejunum (Bosnic, 2014; Tack & Delosse, 2014).

Early symptoms include a sensation of fullness, weakness, faintness, dizziness, palpitations, diaphoresis, cramping pains, and diarrhea. These symptoms resolve once the intestine has been evacuated. Later, there is a rapid elevation of blood glucose, followed by increased insulin secretion. This results in a reactive hypoglycemia, which also is unpleasant for the patient. Vasomotor symptoms that occur 10 to 90 minutes after eating are pallor, perspiration, palpitations, headache, and feelings of warmth, dizziness, and

even drowsiness. These symptoms are thought to be partially due to hypovolemia caused by rapid shifts of fluid from the intravascular space into the lumen of the bowel (Ferri, 2016). Anorexia also may be a result of the dumping syndrome, as the person may be reluctant to eat. There are no symptoms in fasting state.

Steatorrhea (excess fat in feces) also may occur in the patient with gastric surgery. It is partially the result of rapid gastric emptying, which prevents adequate mixing with pancreatic and biliary secretions. In mild cases, reducing the intake of fat and administering an antimotility medication (e.g., loperamide [Imodium]) may control steatorrhea.

Vitamin and Mineral Deficiencies. Other dietary deficiencies that the nurse should be aware of include malabsorption of organic iron, which may require supplementation with oral or parenteral iron, and a low serum level of vitamin B_{12}, which may require supplementation by the intramuscular route. Total gastrectomy results in lack of intrinsic factor, a gastric secretion required for the absorption of vitamin B_{12} from the GI tract. Unless this vitamin is supplied by parenteral injection after gastrectomy, the patient inevitably will suffer vitamin B_{12} deficiency, which eventually leads to a condition identical to pernicious anemia. All manifestations of pernicious anemia, including macrocytic anemia (few, fragile, and larger than normal red blood cells) and combined system disease (neurologic disorders of the central and peripheral nervous systems), may be expected to develop within a period of 5 years or less; they progress in severity thereafter and, in the absence of therapy, are fatal. This complication is avoided by the regular monthly intramuscular injection of vitamin B_{12}. This regimen should be started without delay after gastrectomy. Weight loss is a common long-term problem because the patient experiences early fullness, which suppresses the appetite (Bosnic, 2014; Tack & Delosse, 2014; Majumder, Soriano, Cruz, & Dasanu, 2013).

BOX 23-4 Patient Education

Dietary Management After Gastric Surgery

- To delay stomach emptying and dumping syndrome, assume a low Fowler position (head of bed [HOB] elevated 30 degrees) during mealtime; after the meal, the patient should lie down for 20–30 minutes.
- Take antispasmodics as prescribed to aid in delaying the emptying of the stomach.
- Do not drink fluids with meals; instead, drink fluids up to 1 hour before or 1 hour after mealtime.
- Create meals containing more dry items than liquid items.
- Eat fat as tolerated, but keep carbohydrate intake low and avoid concentrated sources of carbohydrates (sugared soda, pastries).
- Eat smaller but more frequent meals.
- Take dietary supplements of vitamins and medium-chain triglycerides and injections

of vitamin B_{12} and iron as prescribed.

TEACHING DIETARY SELF-MANAGEMENT

Because the patient may experience any of the described conditions affecting nutrition, nursing intervention includes proper dietary instruction (Box 23-4). The nurse also gives instructions regarding enteral or parenteral supplementation if it is needed.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Occasionally, hemorrhage complicates gastric surgery. The patient has the usual signs of rapid blood loss and shock (see Chapter 54) and may vomit considerable amounts of bright red blood. The nurse assesses NG drainage for type and amount; some bloody drainage for the first 12 hours is expected, but excessive bleeding should be reported. The nurse also assesses the abdominal dressing for bleeding. Because this situation is upsetting to the patient and family, the nurse should remain calm. The nurse performs emergency measures, such as NG lavage and administration of blood and blood products, along with vigilant hemodynamic monitoring.

TEACHING PATIENTS SELF-CARE

Patient teaching is based on the assessment of the patient's physical and psychological readiness to participate in self-care. The nurse provides information about nutrition, enteral or parenteral nutrition if required, nutritional supplements, pain management, and the symptoms of dumping syndrome and measures to prevent or minimize these symptoms.

The patient and caregivers benefit from a team approach to discharge planning. The team members include the patient and caregiver along with the nurse, physician, dietitian, and social worker. Written or video instructions about meals, activities, medications, and follow-up care are helpful. After the patient is discharged from the hospital, the home care nurse helps with the transition to home by supervising the administration of any enteral or parenteral feedings, emphasizing information about detection and prevention of untoward effects or complications related to feedings. Information about community support groups and end-of-life care is provided to the patient, family, or significant other when indicated.

EVALUATION

Expected patient outcomes may include:

1. Reports decreased anxiety; expresses fears and concerns about surgery
2. Demonstrates knowledge regarding postoperative course by discussing the surgical procedure and postoperative course
3. Attains optimal nutrition:
    a. Maintains a reasonable weight
    b. Does not have excessive diarrhea

c. Tolerates six small meals a day
d. Does not experience dysphagia, gastric retention, bile reflux, dumping syndrome, or vitamin and mineral deficiencies

4. Attains optimal level of comfort
5. Exhibits no complications

DUODENAL TUMORS

Tumors of the duodenum are uncommon and, when present, usually are benign and asymptomatic. They are most often discovered at autopsy. Malignant tumors are more likely to cause specific signs and symptoms leading to diagnosis. Unfortunately, malignant tumors often are not discovered until they have metastasized to distant sites. Benign tumors may place patients at an increased risk for malignancy. The relative rarity of tumors of the duodenum and the nonspecific nature of their manifestations complicate their diagnosis and treatment.

Clinical Manifestations and Assessment

Duodenal tumors often present insidiously with vague, nonspecific symptoms. Most benign tumors are discovered incidentally on an x-ray study, during surgery, or at autopsy. When the patient is symptomatic, benign tumors often present with intermittent pain. The next most common presentation is occult bleeding. Malignant tumors often result in symptoms that lead to their diagnosis, although these symptoms may reflect advanced disease. Most patients have sustained weight loss and are malnourished at diagnosis. Bleeding and pain are common. Perforation of the bowel occurs in approximately 10% of patients (di Saverio, 2014).

The traditional approach to diagnosis is an upper GI x-ray series with small bowel follow-through using oral water-insoluble contrast with frequent and detailed x-rays to follow the contrast through the small bowel. A more sensitive examination is an enteroclysis, in which an NG tube is advanced into the small bowel to a position above the area in question; then the area is studied by single-contrast and double-contrast techniques. Abdominal CT is used to determine the extent of disease outside the lumen of the duodenum.

Medical and Nursing Management

Benign tumors of the duodenum include adenomas, lipomas, hemangiomas, and hamartomas (a focal malformation that resembles a neoplasm but, unlike a neoplasm, does not result in compression of adjacent tissue). These tumors may be treated endoscopically by excision/resection or electrocautery if the patient is symptomatic. Routine surveillance may be recommended to assess for malignant transformation.

The most common primary malignant tumor of the duodenum is adenocarcinoma; the second and third portions of the duodenum are most often involved. These tumors may present with bleeding or duodenal obstruction (Kordes, Cats, Meijer, & van Laarhoven, 2014). If the tumor is located at the ampulla of Vater, obstructive jaundice is likely. Other rare malignant tumors of the duodenum include carcinoid tumors, lymphoma, and GI stromal tumors. Specialized abdominal surgery may be required to remove these rare tumors. Chemotherapy and radiation therapy may also be part of the treatment regimen.

Nursing care of the patient with a duodenal tumor is similar to that of the patient with gastric cancer. Each patient requires specialized care, astute assessment for complications, prompt interventions, and individualized teaching for self-care.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 45-year-old woman with a history of rheumatoid arthritis and gastritis related to her medication is admitted with abdominal discomfort, headache, lassitude, and nausea and vomiting. What questions should you ask the patient? What signs should be noted during the physical examination? What diagnostic studies should you anticipate for this patient? Describe your nursing interventions, including teaching. How would you modify teaching for this patient if she does not understand English?

2. A 27-year-old woman who is morbidly obese has tried conservative medical management (weight loss diet, behavior modification, exercise, medications for obesity) of her weight condition. She is scheduled for a vertical-banded gastroplasty. Describe the dietary modifications, along with nutritional needs, for this patient during the immediate postoperative period, after discharge from the hospital, and for long-term maintenance. What is the evidence base that supports the use of specific dietary modifications to meet her nutritional needs after surgical procedures to treat obesity? Describe the strength of this evidence and identify the criteria used to evaluate the strength of the evidence that supports the appropriateness of the dietary modifications.

3. A 54-year-old business executive has been admitted with the diagnosis of peptic ulcer disease. As you enter his room, he is vomiting bright red blood. What are the nursing interventions for managing and monitoring this complication? If the bleeding cannot be controlled, what invasive measures may need to be performed? How would you prepare your patient for these? What other complications may occur with a peptic ulcer, and

how should they be managed? What teaching interventions are warranted for this patient?

NCLEX-Style Review Questions

1. A 47-year-old man with epigastric pain is being admitted to the hospital. During the admission assessment and interview, what specific information should the nurse obtain from the patient, who is suspected of having peptic ulcer disease?
   a. Any allergies to food or medications
   b. Use of nonsteroidal anti-inflammatory drugs (NSAIDs)
   c. Medical history for two previous generations
   d. History of side effects of all medications

2. What assessment finding supports a client's diagnosis of gastric ulcer?
   a. Presence of blood in the client's stool for the past month
   b. Complaints of sharp pain in the abdomen after eating a heavy meal
   c. Periods of pain shortly after eating any food.
   d. Complaints of epigastric burning that moves like a wave

3. Which medication should the nurse question before administering it to a patient with peptic ulcer disease?
   a. E-mycin, an antibiotic
   b. Prilosec, a PPI
   c. Flagyl, an antimicrobial agent
   d. Tylenol, a nonnarcotic analgesic

4. The nurse is planning for the discharge of a client with peptic ulcer disease. Which outcome must be included in the plan of care?
   a. The client's pain is controlled with NSAIDs.
   b. The client understands and maintains lifestyle modifications.
   c. The client takes antacids around the clock.
   d. The client has no episodes of GI bleeding.

5. The client with a peptic ulcer is admitted to the hospital's intensive care unit with obvious gastric bleeding. What is the priority intervention for the nurse?
   a. Keep an accurate record of intake and output.
   b. Provide for quiet environment, restrict visitors.
   c. Prepare the client for an endoscopy.
   d. Monitor vital signs and observe for signs of hypovolemia.

CHAPTER 24

Nursing Management: Patients with Intestinal and Rectal Disorders

Philip R. Martinez, Jr.

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the health care needs of patients with constipation, diarrhea, or fecal incontinence.
2. Compare the conditions of malabsorption with regard to their pathophysiology, clinical manifestations, and management.
3. Describe diverticular disease and the care of patients with diverticulitis.
4. Compare and contrast regional enteritis and ulcerative colitis regarding their pathophysiology and medical, surgical, and nursing management.
5. Identify the care needs of the patient with inflammatory bowel disease.
6. Describe the responsibilities of the nurse in meeting the needs of the patient with an ileostomy.
7. Describe the various types of intestinal obstructions as well as their medical and nursing management.
8. Describe the pathophysiology, assessment, and management in regard to cancer of the colon or rectum.
9. Describe anorectal conditions including fissures, fistulas, hemorrhoids, and sexually transmitted anorectal diseases.

There are approximately 60 to 70 million people in the United States diagnosed with some type of disease of the gastrointestinal (GI) tract (Peery et al., 2015). These diseases account for more than 104.7 million office visits and approximately 13.5 million hospital admissions annually. A recent study focusing on the economic burden of GI diseases reported more than 15 million emergency room visits in 2007 totaling more than $27 billion in cost (Myer et al., 2013). The types of diseases and disorders that affect the lower GI tract are many and varied.

In all age groups, a fast-paced lifestyle, high levels of stress, irregular eating habits, insufficient intake of fiber and water, and lack of daily exercise contribute to GI disorders. There is a growing understanding of the biopsychosocial implications of GI disease. Nurses can have an impact on these GI disorders by identifying behavior patterns that put patients at risk, by educating the public about prevention and management, and by helping those affected to improve their condition and prevent complications.

DISORDERS RELATED TO FECAL ELIMINATION

Constipation

Constipation is considered an abnormal infrequency or irregularity of defecation, an abnormal hardening of stools that makes their passage difficult and sometimes painful, a decrease in actual stool volume, or retention of stool in the rectum for a prolonged period. Any variation from normal habits may be considered a problem. Symptoms of constipation are extremely common in adults and even more common in people aged 60 years and older (Bharucha, Dorn, Lembo, & Pressman, 2013). The most common complaint is the need to strain in order to pass stool.

Nursing Alert
Hemorrhoids and anal fissures can develop as a result of constipation. Hemorrhoids develop as a result of perianal vascular congestion caused by straining. Anal fissures may result from the passage of the hard stool through the anus, tearing the lining of the anal canal.

Perceived constipation also can be a problem. This subjective problem occurs when a person's bowel elimination pattern is not consistent with what he or she perceives as normal. Chronic laxative use may contribute to this problem and is a major health concern in the United States.

Pathophysiology

The pathophysiology of constipation is poorly understood, but it is thought to include interference with one of three major functions of the colon: mucosal transport (i.e., mucosal secretions facilitate the movement of colon contents), myoelectric activity (i.e., mixing of the rectal mass and propulsive actions), or the processes of defecation.

The urge to defecate is stimulated normally by rectal distention, which initiates a series of four actions: stimulation of the inhibitory rectoanal reflex, relaxation of the internal sphincter muscle, relaxation of the external sphincter muscle and muscles in the pelvic region, and increased intra-abdominal pressure. Interference with any of these processes can lead to constipation.

If all organic causes are eliminated, idiopathic constipation is diagnosed. When the urge to defecate is ignored, the rectal mucous membrane and musculature become insensitive to the presence of fecal masses, and, consequently, a stronger stimulus is required to produce the necessary peristaltic rush for defecation. The initial effect of fecal retention is irritability of the colon, which at this stage frequently goes into spasm, especially after meals, giving rise to colicky midabdominal or low abdominal pains. After several years of this process, the colon loses muscular tone and becomes essentially unresponsive to normal stimuli. Atony or decreased muscle tone occurs with aging. This also leads to constipation because the stool is retained for longer periods.

Risk Factors

Constipation can be caused by certain medications (i.e., tranquilizers, anticholinergics, antidepressants, antihypertensives, bile acid sequestrants, opioids, aluminum-based antacids, iron preparations); rectal or anal disorders (e.g., hemorrhoids, fissures); obstruction (e.g., bowel tumors); metabolic, neurologic, and neuromuscular conditions (e.g., Hirschsprung disease, Parkinson disease, multiple sclerosis); endocrine disorders (e.g., diabetes mellitus, hypothyroidism, pheochromocytoma [rare tumor of adrenal medulla]); lead poisoning; and connective tissue disorders (e.g., scleroderma, systemic lupus erythematosus).

Diseases of the colon, such as irritable bowel syndrome (IBS) and diverticular disease, are commonly associated with constipation. Constipation also can occur with any acute disease process in the abdomen (e.g., appendicitis or cholecystitis) or with any abdominal surgery.

Older adults tend to have decreased food intake, reduced mobility, weak abdominal and pelvic muscles, and multiple chronic illnesses requiring medications that can cause constipation. The astute nurse always will check a patient's medication list for those that may exacerbate constipation.

Low-fiber convenience foods are used widely by people who have lost interest in eating. Dentition is important to consider as people with ill-fitting dentures or poor dentition have increased difficulty chewing and frequently will choose softer, processed foods that are lower in fiber. Some older people reduce their fluid intake if they are not eating regular meals. Depression, weakness, or prolonged bed rest also contributes to constipation by decreasing intestinal motility and anal sphincter tone. Nerve impulses are dulled, and there is a decreased urge to defecate. Prolonged bed rest is also a risk factor in constipation; therefore, nursing care for these patients should include ambulation when possible. Many older people overuse laxatives in an attempt to have a daily bowel movement and become dependent on them, which paradoxically can increase the risk of constipation.

Other causes of constipation may include weakness, immobility, debility, fatigue, and an inability to increase intra-abdominal pressure to facilitate the passage of stools, as may occur in patients with emphysema, for instance. Many people develop constipation because they do not take the time to defecate or they ignore the urge to defecate. Additionally, the lack of privacy and interruption of usual bowel regimen are factors associated with constipation in hospitalized patients.

Clinical Manifestations and Assessment

Clinical manifestations of constipation include fewer than three bowel movements per week, abdominal distention, pain and pressure, decreased appetite, headache, fatigue, indigestion, a sensation of incomplete evacuation, straining at stool, and the elimination of small-volume, lumpy, hard, dry stools. Due to the wide range of normal bowel function in people, it is extremely difficult to identify constipation in all patients accurately.

The nurse elicits information about the onset and duration of constipation, current and past elimination patterns, the patient's expectation of normal bowel elimination, and lifestyle information (e.g., exercise and activity level, occupation, food and fluid intake, and stress level) during the health history interview. Medical and surgical history, current medications, and laxative and enema use are important, as is information about the sensation of rectal pressure or fullness, abdominal pain, excessive straining at defecation, and flatulence.

Medical and Nursing Management

Treatment is aimed at the underlying cause of constipation and includes education, bowel habit training, increased fiber and fluid intake, and judicious use of laxatives. Management also may include discontinuing laxative abuse. Routine exercise to strengthen abdominal muscles is encouraged. Inexpensive osmotic agents, such as milk of magnesia or polyethylene glycol, may be prescribed as an early treatment option for patients with chronic constipation prior to the use of stimulant laxatives (Bharucha et al., 2013). Biofeedback has been shown to improve symptoms in many patients with chronic constipation and can be used to help patients learn to relax the sphincter mechanism to expel stool (Woodward, Norton, & Chiarelli, 2014).

Daily dietary intake of 6 to 12 teaspoonfuls of unprocessed bran is recommended, especially for the treatment of the elderly. If laxative use is necessary, one of the following may be prescribed: bulk-forming agents, saline and osmotic agents, lubricants, stimulants, or fecal softeners. The physiologic action and patient education information related to these laxatives are given in Table 24-1. Enemas and rectal suppositories generally are not recommended for treating constipation; they should be reserved for the treatment of impaction. If long-term laxative use is necessary, a bulk-forming agent may be prescribed in combination with an osmotic laxative.

Specific medications may be prescribed to enhance colonic transit by increasing propulsive motor activity. These may include cholinergic agents (e.g., bethanechol [Urecholine]), cholinesterase inhibitors (e.g., neostigmine [Prostigmin]), or prokinetic agents (e.g., metoclopramide [Reglan]).

Patient education and health promotion are important functions of the nurse. Patient education should include establishing a bowel routine, providing dietary information, and reducing patient anxiety. After the health history is obtained, the nurse sets specific goals for teaching. Goals for the patient include restoring or maintaining a regular pattern of elimination by responding to the urge to defecate, ensuring adequate intake of fluids and high-fiber foods, learning methods to avoid constipation, relieving anxiety about bowel elimination patterns, and avoiding complications.

TABLE 24-1 Laxatives: Classification, Agent, Action, and Patient Education

Classification	Sample Agent	Action	Patient Education
Bulk forming	Psyllium hydrophilic mucilloid (Metamucil)	Polysaccharides and cellulose derivatives mix with intestinal fluids, swell, and stimulate peristalsis.	Take with 8-oz water and follow with 8-oz water; do not take dry. Report abdominal distention or unusual amount of flatulence.
Saline agent	Magnesium hydroxide (milk of magnesia)	Nonabsorbable magnesium ions alter stool consistency by drawing water into the intestines by osmosis; peristalsis is stimulated. Action occurs within 2 hours.	The liquid preparation is more effective than the tablet form. Only short-term use is recommended because of toxicity (CNS or neuromuscular depression, electrolyte imbalance). Magnesium laxatives should not be taken by patients with renal insufficiency.
Lubricant	Mineral oil	Nonabsorbable hydrocarbons soften fecal matter by lubricating the intestinal mucosa; the passage of stool is facilitated. Action occurs within 6–8 hours.	Do not take with meals because mineral oils can impair the absorption of fat-soluble vitamins and delay gastric emptying. Swallow carefully, because drops of oil that gain access to the pharynx can produce a lipid pneumonia.
Stimulant	Bisacodyl (Dulcolax)	Irritates the colon epithelium by stimulating sensory nerve endings and increasing mucosal secretions. Action occurs within 6–8 hours.	Catharsis may cause fluid and electrolyte imbalance, especially in the elderly. Tablets should be swallowed, not crushed or chewed. Avoid milk or antacids within 1 hour of taking the medication because the enteric coating may dissolve prematurely.
Fecal softener	Dioctyl sodium sulfosuccinate (Colace)	Hydrates the stool by its surfactant action on the colonic epithelium (increases the wetting efficiency of intestinal water); aqueous and fatty substances are mixed. Does not exert a laxative action.	This can be used safely by patients who should avoid straining (cardiac patients, patients with anorectal disorders).
Osmotic agent	Polyethylene glycol and electrolytes (Colyte)	Cleanses colon rapidly and induces diarrhea	This is a large-volume product. It takes time to consume it safely. It can cause considerable nausea and bloating.

Complications

Complications of constipation include hypertension, fecal impaction, hemorrhoids (dilated portions of anal veins), fissures (tissue folds), and megacolon (abnormal enlargement of the colon). Increased arterial pressure can occur with defecation. Straining at stool, which results in the Valsalva maneuver (i.e., forcibly exhaling with the glottis closed), has a striking effect on arterial blood pressure. During active straining, the flow of venous blood in the chest is impeded temporarily because of increased intrathoracic pressure. This pressure tends to collapse the large veins in the chest. The atria and the ventricles receive less blood, and, consequently, less blood is ejected by the left ventricle. Cardiac output is decreased, and there is a transient drop in arterial pressure. Almost immediately after this period of hypotension, an increase in arterial pressure occurs; the pressure is elevated momentarily to a point far exceeding the original level (i.e., *rebound phenomenon*). Thus bowel regimens to prevent constipation frequently are instituted in patients admitted with cardiac and neurologic problems.

Nursing Alert
In patients with hypertension, the rebound phenomenon reaction may be exaggerated greatly, and the peak pressure attained may be dangerously high—sufficient to rupture a major artery in the brain or elsewhere.

Fecal impaction occurs when an accumulated mass of dry feces cannot be expelled. The mass may be palpable on digital examination, may produce pressure on the colonic mucosa that results in ulcer formation, and frequently causes seepage of liquid stools.

Megacolon is caused by a fecal mass that obstructs the passage of colon contents. Symptoms include constipation, liquid fecal incontinence, and abdominal distention. Megacolon can lead to perforation of the bowel.

Nursing Alert
Care should be taken when performing digital rectal procedures as vagal nerve stimulation may occur, causing a vasovagal response in the patient. Additionally, straining to stool may also cause a vasovagal response. Signs and symptoms of a vasovagal response include: bradycardia, hypotension, light-headedness, nausea, feelings of hot or cold, confusion, or loss of consciousness. Treatment should include reducing the risk of injury during the episode, maneuvers to increase blood flow to the brain (recumbent position with lower extremities elevated), and evaluation of any cardiac and neurologic causes of syncope.

DIARRHEA

Diarrhea is defined as an increased frequency of bowel movements of more than three per day, an increased amount of stool (more than 200 g/day), or abnormally liquid stool. It is usually associated with increased urgency, perianal discomfort, or incontinence. Diarrhea lasting less than 2 weeks is considered acute; conversely, diarrhea lasting more than 4 weeks is considered chronic. Acute diarrhea is associated most often with infection and usually is self-limiting; chronic diarrhea persists for a longer period and may return sporadically. Any condition that causes increased intestinal secretions, decreased mucosal absorption, or altered motility can produce diarrhea. IBS, inflammatory bowel disease (IBD), and lactose intolerance are frequently the underlying disease processes that cause diarrhea.

Pathophysiology

Types of diarrhea include secretory, osmotic, and mixed diarrhea. Secretory diarrhea is usually high-volume diarrhea and is caused by increased production and secretion of water and electrolytes by the intestinal mucosa into the intestinal lumen. Osmotic diarrhea occurs when water is pulled into the intestines by the osmotic pressure of unabsorbed particles, slowing the reabsorption of water. Mixed diarrhea is caused by increased peristalsis (usually from IBD) and a combination of increased secretion and decreased absorption in the bowel.

Risk Factors

Diarrhea can be caused by certain medications (e.g., thyroid hormone replacement, stool softeners and laxatives, antibiotics, chemotherapy, magnesium-based antacids), certain tube-feeding formulas, metabolic and endocrine disorders (e.g., diabetes, Addison disease, thyrotoxicosis), and viral or bacterial infectious processes (e.g., dysentery, shigellosis, food poisoning). Other disease processes associated with diarrhea include nutritional and malabsorptive disorders (e.g., celiac disease), anal sphincter defect, Zollinger–Ellison syndrome, paralytic ileus, intestinal obstruction, and AIDS.

Clinical Manifestations and Assessment

In addition to the increased frequency and fluid content of stools, the patient usually has abdominal cramps, distention, intestinal rumbling (borborygmus), anorexia, and thirst. Painful spasmodic contractions of the anus and ineffective straining (tenesmus) may occur with defecation. Other symptoms depend on the cause and severity of the diarrhea but are related to dehydration and imbalances of fluid and electrolytes.

Watery stools are characteristic of disorders of the small bowel, whereas loose, semisolid stools are associated more often with disorders of the large bowel. Large, greasy stools suggest intestinal malabsorption, and the presence of mucus and pus in the stools suggests inflammatory enteritis or colitis. Oil droplets on the toilet water are almost always diagnostic of pancreatic insufficiency. Nocturnal diarrhea may be a manifestation of diabetic neuropathy.

Typically, when the source of the diarrhea is not clear, the following diagnostic tests may be performed: complete blood cell count (CBC); serum chemistries; urinalysis; routine stool examination; and stool examinations for infectious or parasitic organisms, bacterial toxins, blood, fat, and electrolytes. Endoscopy or barium enema may assist in identifying the cause.

Nursing Alert

Elderly patients can become dehydrated quickly and develop low potassium levels (i.e., hypokalemia) as a result of diarrhea. The nurse observes for clinical manifestations of muscle weakness, arrhythmias, or decreased peristaltic motility that may lead to paralytic ileus. The older patient taking digitalis (e.g., digoxin [Lanoxin]) must be aware of how quickly dehydration and hypokalemia can occur with diarrhea. The nurse teaches the patient to recognize the symptoms of hypokalemia because low levels of potassium intensify the action of digitalis, leading to digitalis toxicity.

Medical and Nursing Management

Primary management is directed at controlling symptoms, preventing complications, and eliminating or treating the underlying disease. Medications, such as antibiotics (reserved for cases of bacterial overgrowth) and anti-inflammatory agents, may be used to reduce the severity of the diarrhea and treat the underlying disease. The mainstay of treatment in most cases of diarrhea is oral, or, if severe or symptomatic, intravenous rehydration.

The nurse's role includes assessing and monitoring the characteristics and pattern of diarrhea. A health history should address the patient's medication therapy, medical and surgical history, and dietary patterns and intake. Reports of recent exposure to an acute illness or recent travel to another geographic area are important as treatment can change depending on the patient's illness and travel history. Assessment includes abdominal inspection, auscultation (for hyperactive bowel sounds), and palpation for abdominal tenderness. Vital signs are assessed for fever and evidence of fluid volume deficit (weak pulse, hypotension, narrow pulse pressure). Inspection of the mucous membranes and skin is important to determine hydration status. Stool samples are obtained for testing.

During an episode of acute diarrhea, the nurse encourages bedrest and intake of liquids and foods low in bulk until the acute attack subsides. When the patient is able to tolerate food intake, the nurse recommends a bland diet of semisolid and solid foods. The patient should avoid caffeine, carbonated beverages, and very hot and very cold foods due to stimulation of intestinal motility. It may be necessary to restrict milk products, fat, whole-grain products, fresh fruits, and vegetables for several days. Antidiarrheal medications, such as diphenoxylate (Lomotil) or loperamide (Imodium), may be administered as prescribed to reduce the frequency and amount of stools. IV fluid therapy may be necessary for rapid rehydration in some patients, especially in elderly patients and in patients with pre-existing GI conditions, such as IBD. It is important to monitor serum electrolyte levels closely as imbalances such as hypokalemia (K^+ less than 3.5 mEq/L) and acute metabolic acidosis due to a direct loss of bicarbonate (HCO_3^- less than 22 mEq/L) can occur. The nurse immediately reports evidence of arrhythmias, muscular weakness, fatigue or flaccid paralysis, and hyporeflexia (associated with a K^+ less than 2.5 mEq/L).

Nursing Alert
Decreased potassium levels cause cardiac arrhythmias (i.e., atrial and ventricular tachycardia, ventricular fibrillation, premature ventricular contractions) that can lead to death.

The perianal area may become excoriated because diarrheal stool contains digestive enzymes that can irritate the skin. Older individuals have decreased skin turgor and reduced subcutaneous fat layers; therefore, care should be taken to follow a structured perianal skin care routine to reduce irritation and excoriation.

FECAL INCONTINENCE

Fecal incontinence describes the involuntary passage of stool from the rectum. It is estimated that over 40% of residents is extended-care facilities and more than 10% of adults in the community have fecal incontinence. A substantial number of residents in extended-care facilities have what is termed "double incontinence," or difficulties with both urine and stool continence (Shahin & Lohrmann, 2015). Factors that influence fecal continence include the ability of the rectum to sense and accommodate stool, the amount and consistency of stool, the integrity of the anal sphincters and musculature, and rectal motility. It is an embarrassing and socially incapacitating problem that requires a many-tiered approach to treatment and much adaptation on the patient's part.

Nursing Alert
Management of double incontinence should include frequent toileting assistance, identifying patients who may most benefit from targeted toileting programs, and treating underlying fecal disorders including chronic constipation.

Pathophysiology

Continence is maintained by tonic contraction of the muscles around the rectum. During defecation, nerves relax the muscles, causing a straightening of the rectoanal angle. Distension of the rectum causes relaxation of the sphincter. Fecal incontinence is a failure of this process and can occur for a variety of reasons.

Risk Factors

Fecal incontinence can result from trauma (e.g., after surgical procedures involving the rectum), neurologic disorders (e.g., stroke, multiple sclerosis, diabetic neuropathy, dementia), inflammation, infection, chemotherapy, radiation treatment, fecal impaction, pelvic floor relaxation, laxative abuse, medications, or advancing age (i.e., weakness or loss of anal or rectal muscle tone).

Clinical Manifestations and Assessment

Patients may have minor soiling, occasional urgency and loss of control, or complete incontinence. Patients also may experience poor control of flatus, diarrhea, or constipation.

The nurse obtains a thorough health history, including information about previous surgical procedures, chronic illnesses, dietary patterns, bowel habits and problems, and current medication regimen. A visual and digital examination of the rectal area is completed, checking for abnormalities (fecal impaction, hemorrhoids, fissures, and fistulas) that may be contributing to the incontinence.

Diagnostic studies are necessary because the treatment of fecal incontinence depends on the cause. A rectal examination and other endoscopic examinations, such as a flexible sigmoidoscopy, are performed to rule out tumors, inflammation, or fissures. X-ray studies, such as barium enema, computed tomography (CT), anorectal manometry, and transit studies, may be helpful in identifying alterations in intestinal mucosa and muscle tone or in detecting other structural or functional problems.

Medical and Nursing Management

Specific management techniques can help the patient achieve a better quality of life. If fecal incontinence is related to diarrhea, the incontinence may disappear when diarrhea is treated successfully. Frequently fecal incontinence is a symptom of a fecal impaction. After the impaction is removed and the rectum is cleansed, normal functioning of the anorectal area can resume. If the fecal incontinence is related to a more permanent condition, other treatments are initiated. Biofeedback therapy can be of assistance if the problem is decreased sensory awareness or sphincter control. Bowel training programs also can be effective. Surgical procedures include surgical reconstruction, sphincter repair, or fecal diversion.

The nurse initiates a bowel training program that involves setting a schedule to establish bowel regularity. The goal is to help the patient achieve fecal continence. If this is not possible, the goal should be to manage the problem so the person can have predictable, planned elimination. Sometimes, it is necessary to use suppositories to stimulate the anal reflex. After the patient has achieved a regular schedule, the suppository can be discontinued.

Complications

Fecal incontinence may cause problems with perineal skin integrity. Maintaining skin integrity is a priority, especially in the debilitated or elderly patient. Incontinence briefs, although helpful in containing the fecal material, allow for increased skin contact with the feces and may cause excoriation of the skin. The nurse encourages and teaches meticulous skin hygiene, and, in the hospital setting, interventions, such as turning the patient every 2 hours and applying barrier creams or sprays to protect the skin, may be warranted.

Continence sometimes cannot be achieved, and the nurse assists the patient and family to accept and cope with this chronic situation. The patient can use fecal incontinence devices, which include external collection devices and internal drainage systems. External devices are special, drainable pouches. They are attached to a synthetic adhesive skin barrier specially designed to conform to the buttocks. Internal drainage systems can be used to eliminate fecal skin contact and are useful especially when there is extensive excoriation or skin breakdown. A rectal catheter is inserted into the rectum and connected to a drainage system, and stool is collected in order to preserve skin integrity. Rectal catheters are contraindicated in patients who are postoperative from rectal or prostate surgery, recent myocardial infarction, rectal mucosal disease, bleeding dyscrasia, and impaired immune status. It is important to consider that at present, long-term consequences of indwelling fecal collectors have not been studied yet, although some research suggests that some commercially available catheters may be safe for upward of 30 days. A provider's order is required to place these devices.

IRRITABLE BOWEL SYNDROME

IBS is one of the most common GI conditions. Approximately 11% of adults globally report classic symptoms of IBS (Canavan, West, & Card, 2014). Roughly 30% of patients with IBS will consult a health care provider for their symptoms, and patients with IBS have a higher likelihood of other functional GI disorders than those in the general population (Canavan et al., 2014). There is no current evidence that patients with IBS have an increased mortality risk, yet this disorder disrupts daily life for millions of people (Grundmann & Yoon, 2014).

Pathophysiology

IBS results from a functional disorder of intestinal motility. The change in motility may be related to neuroendocrine dysregulation, infection or irritation, or a vascular or metabolic disturbance. The peristaltic waves are affected at specific segments of the intestine and in the intensity with which they propel the fecal matter forward. There is no evidence of inflammation or tissue changes in the intestinal mucosa.

Risk Factors

Although no anatomic or biochemical abnormalities have been found that account for the common symptoms, various factors are associated with the syndrome: heredity, a diet high in fat and stimulating or irritating foods, alcohol consumption, smoking, and psychological stress or conditions such as depression and anxiety. As many as 90% of people diagnosed with IBS present with symptoms of major depression, and it is now suggested that psychotherapy and some antidepressant medications may, in fact, help with symptoms of IBS (Ford et al., 2014).

IBS occurs more commonly in women than in men (Grundmann & Yoon, 2014).

Clinical Manifestations and Assessment

There is a wide variability in symptom presentation. Symptoms range in intensity and duration from mild and infrequent to severe and continuous. The primary symptom is an alteration in bowel patterns—constipation, diarrhea, or a combination of both. Pain and abdominal distention often accompany changes in bowel pattern. Sometimes the abdominal pain is precipitated by eating, and frequently it is relieved by defecation.

A definite diagnosis of IBS requires tests that confirm the absence of structural or other disorders. Stool studies, contrast x-ray studies, and proctoscopy may be performed to rule out other colon diseases. Barium enema and colonoscopy may reveal spasm, distention, or mucus accumulation in the intestine (Fig. 24-1). Manometry and electromyography (EMG) are used to study intraluminal pressure changes generated by spasticity.

Medical and Nursing Management

The goals of treatment are relieving abdominal pain, controlling the diarrhea or constipation, and reducing stress. Restriction and then gradual reintroduction of foods that are possibly irritating may help determine what types of food are acting as irritants (e.g., beans, caffeinated products, fried foods, alcohol, and spicy foods). A high-fiber diet is prescribed to help control the diarrhea and constipation. Exercise can assist in reducing anxiety and increasing intestinal motility. Patients often find it helpful to participate in a stress reduction or behavior modification program. Hydrophilic colloids (i.e., bulk) and antidiarrheal agents (e.g., loperamide [Imodium]) may be given to control the diarrhea and fecal urgency. Antidepressants can assist in treating underlying anxiety and depression. Anticholinergics (e.g., propantheline [Pro-Banthine]) may be taken to decrease smooth muscle spasm, thus decreasing cramping and constipation.

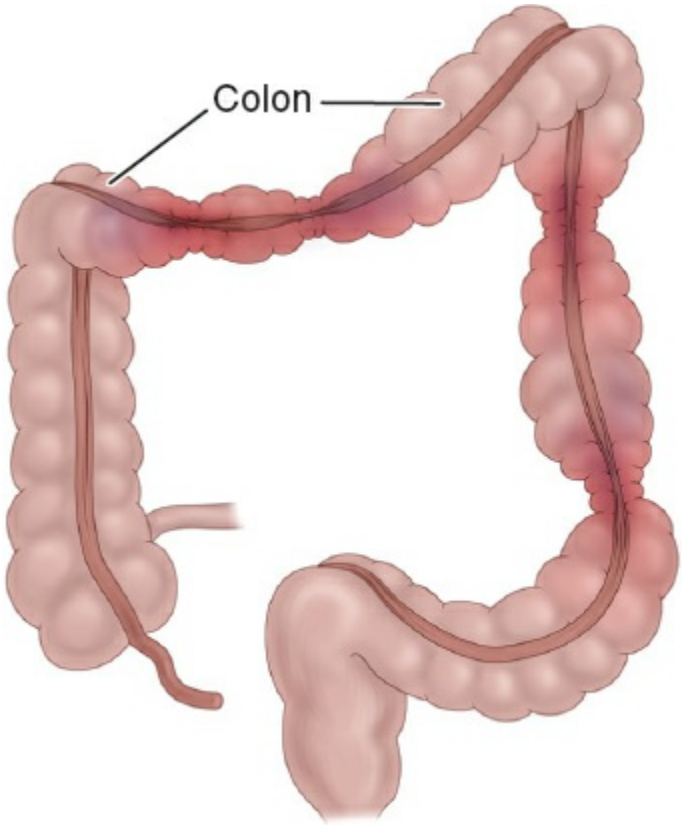

FIGURE 24-1 In irritable bowel syndrome (IBS), the spastic contractions of the bowel can be seen on x-ray contrast studies.

Research is ongoing to continue to identify pharmacologic and psychological therapies, including hypnotherapy and cognitive behavioral therapy to lessen the impact of IBS in patients. Current therapies, including antidepressants, hypnotherapy, and various forms of psychotherapy, all are potential effective treatments for IBS (Ford et al., 2014). The role of alternative and complementary therapies for the treatment of IBS is increasing, and research into alternative therapies, such as acupuncture, is ongoing (Halland & Talley, 2013).

The nurse's role is to provide patient and family education. The nurse emphasizes

teaching and reinforces good dietary habits. Patients are encouraged to eat at regular times and to chew food slowly and thoroughly. They should understand that although adequate fluid intake is necessary, fluid should not be taken with meals because this results in abdominal distention. Alcohol use and cigarettes should be avoided.

Nursing Alert

The key to treating IBS in patients is to treat each patient as an individual. Nursing care plans should include interventions that are based on that patient's unique and individual symptoms blending both pharmacologic and psychological-based interventions specific to that particular patient.

MALABSORPTION

Malabsorption is the inability of the digestive system to absorb one or more of the major vitamins (especially A and B_{12}), minerals (i.e., iron and calcium), and nutrients (i.e., carbohydrates, fats, and proteins). Interruptions in the complex digestive process may occur anywhere in the digestive system and cause decreased absorption.

Pathophysiology

The conditions that cause malabsorption can be grouped into the following categories:

- Mucosal (transport) disorders causing generalized malabsorption (e.g., celiac sprue, regional enteritis, radiation enteritis)
- Infectious diseases causing generalized malabsorption (e.g., small bowel bacterial overgrowth, tropical sprue)
- Luminal disorders causing malabsorption (e.g., bile acid deficiency, Zollinger–Ellison syndrome, pancreatic insufficiency)
- Postoperative malabsorption (e.g., after gastric or intestinal resection)
- Disorders that cause malabsorption of specific nutrients (e.g., disaccharidase deficiency leading to lactose intolerance)

Table 24-2 lists the clinical and pathologic aspects of malabsorptive diseases.

Risk Factors

Risk factors predisposing people to malabsorption include any process that interferes with the body's ability to absorb nutrients. These can include pathologic factors, including abdominal diseases or deformities, surgery, radiation therapy, and certain medications that inhibit bacterial growth within the intestine (antibiotics). Bodily fluid losses, from such things as polyuria, emesis, wound drainage, or diarrhea, can decrease absorption. Finally, use of medications, such as mineral oil or laxatives, can decrease absorption by increasing peristalsis.

Clinical Manifestations and Assessment

The hallmarks of malabsorption syndrome are diarrhea or frequent, loose, bulky, foul-smelling stools that have increased fat content and often are grayish in color. Patients often have associated abdominal distention, pain, increased flatus, weakness, weight loss, and a decreased sense of well-being. The chief result of malabsorption is malnutrition, manifested by weight loss and other signs of vitamin and mineral deficiency (e.g., easy bruising [vitamin K deficiency], osteoporosis [calcium deficiency], anemia [iron, vitamin B_{12} deficiency]).

Patients with a malabsorption syndrome, if untreated, become weak and emaciated because of starvation and dehydration. Failure to absorb the fat-soluble vitamins A, D, and K causes a corresponding avitaminosis (chronic or long-term vitamin deficiency).

Several diagnostic tests may be prescribed, including stool studies for quantitative and qualitative fat analysis, lactose tolerance tests, D-xylose absorption tests (absorption of sugar), and Schilling tests (B_{12} deficiency). The hydrogen breath test that is used to evaluate carbohydrate absorption is performed if carbohydrate malabsorption is suspected. This test requires the patient to be fasting before he or she ingests 25 g of carbohydrate dissolved in water. Exhaled breath is assayed for hydrogen content at baseline and at specific intervals for several hours. Since hydrogen is not a normal product of human metabolism, any increase in breath hydrogen concentration suggests bacterial fermentation and indicates that unabsorbed carbohydrate has reached an area with high concentrations of intraluminal bacteria, typically the colon (Schiller & Sellin, 2016).

Endoscopy with biopsy of the mucosa is the best diagnostic tool. Biopsy of the small intestine is performed to assay enzyme activity or to identify infection or destruction of mucosa. Ultrasound studies, CT scans, and x-ray findings can reveal pancreatic or intestinal tumors that may be the cause. A CBC is used to detect anemia. Pancreatic function tests can assist in the diagnosis of specific disorders.

Medical and Nursing Management

Intervention is aimed at avoiding dietary substances that aggravate malabsorption and at supplementing nutrients that have been lost. Common supplements are water-soluble vitamins (e.g., B_{12}, folic acid), fat-soluble vitamins (e.g., A, D, and K), and minerals (e.g., calcium, iron). Primary disease states may be managed surgically or medically. Dietary therapy is aimed at reducing gluten intake in patients with celiac sprue. Folic acid supplements are prescribed for patients with tropical sprue (see Table 24-2). Sometimes antibiotics (e.g., tetracycline [Tetracap, Tetracyn], ampicillin [Polycillin]) are needed in the treatment of tropical sprue and bacterial overgrowth syndromes. Antidiarrheal agents may be used to decrease intestinal spasms. Parenteral fluids may be necessary to treat dehydration.

The nurse provides patient and family education regarding diet and the use of nutritional supplements. It is important to monitor patients with diarrhea for fluid and electrolyte imbalances. The nurse conducts ongoing assessments to determine whether the clinical manifestations related to the nutritional deficits have abated. Patient education includes information about the risk of osteoporosis related to malabsorption of calcium (refer to Chapter 41 for information on osteoporosis).

Pathophysiology Alert

Patients who are severely malnourished are at a higher risk of developing refeeding syndrome if fed too rapidly. Excessively high dextrose administration (e.g., PPN, TPN) stimulates insulin release, which rapidly lowers phosphorus, magnesium, and potassium in the blood (due to intracellular shift and use in carbohydrate metabolic pathways). The hyperinsulinemia also tends to cause sodium and fluid retention. Thiamine also is consumed with high carbohydrate loads. The combination of fluid and sodium retention, decrease in blood electrolyte levels (which can cause arrhythmias), and hypermetabolism due to increased calories can result in heart failure. Thus, the complications of refeeding syndrome can include a variety of fluid and electrolyte disturbances, which can include hypoglycemia, cardiac arrhythmias, and death. Risk factors for refeeding syndrome include pre-existing malnutrition, electrolyte depletion, or alcoholism, and after prolonged periods of intravenous hydration therapy (e.g., 5% dextrose) without nutrition support (Chiappetta & Stein, 2016).

TABLE 24-2 Characteristics of Diseases of Malabsorption

Diseases/Disorders	Physiologic Pathology	Clinical Features
Gastric resection with gastrojejunostomy	Decreased pancreatic stimulation because of duodenal bypass; poor mixing of food, bile, pancreatic enzymes; decreased intrinsic factor	Weight loss, moderate steatorrhea (presence of fat within the stool), anemia (combination of iron deficiency, vitamin B_{12} malabsorption, folate deficiency)
Pancreatic insufficiency (chronic pancreatitis, pancreatic carcinoma, pancreatic resection, cystic fibrosis)	Reduced intraluminal pancreatic enzyme activity, with maldigestion of lipids and proteins	History of abdominal pain followed by weight loss; marked steatorrhea, azotorrhea (excess of nitrogenous matter in the feces or urine); also frequent glucose intolerance (70% in pancreatic insufficiency)
Ileal dysfunction (resection or disease)	Loss of ileal absorbing surface leads to reduced bile-salt pool size and reduced vitamin B_{12} absorption; bile in colon inhibits fluid absorption	Diarrhea, weight loss with steatorrhea, especially when more than 100 cm resection, decreased vitamin B_{12} absorption
Stasis syndromes (surgical strictures, blind loops, enteric fistulas, multiple jejunal diverticula, scleroderma)	Overgrowth of intraluminal intestinal bacteria, especially anaerobic organisms, to more than 10^6/mL results in deconjugation of bile salts, leading to decreased effective bile-salt pool size, also bacterial utilization of vitamin B_{12}	Weight loss, steatorrhea; low vitamin B_{12} absorption; may have low D-xylose absorption
Zollinger–Ellison syndrome	Hyperacidity in duodenum inactivates pancreatic enzymes	Ulcer; steatorrhea
Lactose intolerance	Deficiency of intestinal lactase results in high concentration of intraluminal lactose with osmotic diarrhea	Varied degrees of diarrhea and cramps after ingestion of lactose-containing foods; positive lactose intolerance test, decreased intestinal lactase
Celiac disease (gluten enteropathy)	Toxic response to a gluten fraction by surface epithelium results in destruction of absorbing surface	Weight loss, diarrhea, bloating, anemia (low iron, folate), osteomalacia, steatorrhea, azotorrhea, low D-xylose absorption; folate and iron malabsorption
Tropical sprue	Unknown toxic factor results in mucosal inflammation, partial villous atrophy	Weight loss, diarrhea, anemia (low folate, vitamin B_{12}); steatorrhea; low D-xylose absorption, low vitamin B_{12} absorption
Whipple disease	Bacterial invasion of intestinal mucosa	Arthritis, hyperpigmentation, lymphadenopathy, serous effusions, fever, weight loss, steatorrhea, azotorrhea
Certain parasitic diseases (giardiasis, strongyloidiasis, coccidiosis, capillariasis)	Damage to or invasion of surface mucosa	Diarrhea, weight loss; steatorrhea; organism may be seen on jejunal biopsy or recovered in stool
Immunoglobulinopathy	Decreased local intestinal defenses, lymphoid hyperplasia, lymphopenia	Frequent association with Giardia: hypogammaglobulinemia or isolated IgA deficiency

TABLE 24-3 Malabsorption of Nutrients, Water, and Electrolytes

Nutrient Malabsorbed	Clinical Manifestation
Protein	Wasting, hypoproteinemic edema
Carbohydrate and fat	Diarrhea, abdominal cramps and bloating, weight loss and growth retardation
Fluid	Kidney stones with volume depletion, weight loss, fluid volume deficit (FVD)
Iron	Anemia
Calcium and vitamin D	Bone pain, fractures, tetany
Magnesium	Paresthesias, tetany
Vitamin B_{12} and folate	Anemia, paresthesias, ataxia (vitamin B_{12} only)
Vitamin E	Paresthesias, ataxia, retinopathy
Vitamin A	Night blindness, diarrhea
Vitamin K	Ecchymoses, bruises easily
Selenium	Cardiomyopathy
Malabsorption of bile salts	Increased colonic fluid secretion and watery diarrhea

Adapted from Semrad, C. (2016). Approach to the patient with diarrhea and malabsorption. In L. Goldman & A. I. Schafer (Eds.), *Goldman-Cecil medicine* (25th ed.). New York: Elsevier/Saunders.

Complications

Complications are related to the underlying disease causing the malabsorption. Depending on the etiology, medical management may include the administration of corticosteroids (for regional enteritis), which may cause a host of adverse effects, such as hypertension, hypokalemia, insomnia, and euphoria. Antibiotics may reduce vitamin K–producing intestinal flora, resulting in a prolonged prothrombin time (PT) and international normalized ratio (INR) if the patient is concurrently taking warfarin (Coumadin). Refer to Table 24-3 for clinical manifestations of malabsorption.

ACUTE INFLAMMATORY CONDITIONS

Appendicitis

The appendix is a small, finger-like appendage about 10 cm (4 in) long that is attached to the cecum just below the ileocecal valve. The appendix fills with food and empties regularly into the cecum. Because it empties inefficiently and its lumen is small, the appendix is prone to obstruction and is particularly vulnerable to infection (i.e., appendicitis).

Appendicitis is the most common reason for emergency abdominal surgery, with an incidence rate in the overall population of 7% to 14% in (Flum, 2015). The disease is most common in patients between 10 and 30 years of age, with a higher incidence in men than women (Flum, 2015).

Pathophysiology

The appendix becomes inflamed and edematous as a result of becoming kinked or occluded by a fecalith (i.e., hardened mass of stool), tumor, or foreign body. The inflammatory process increases intraluminal pressure, initiating a progressively severe, generalized or periumbilical pain that becomes localized to the right lower quadrant of the abdomen within a few hours. Eventually, the inflamed appendix fills with pus.

Risk Factors

Appendicitis is most prevalent in the young, but it can occur at any age. Most cases appear in the winter months although no clear reason as to why has been established. Having a family history of appendicitis may increase a child's risk for the illness, especially in males, and having cystic fibrosis also seems to put a child at higher risk (Lavelle et al., 2015).

Clinical Manifestations and Assessment

Vague epigastric or periumbilical pain progresses to right lower quadrant pain and usually is accompanied by a low-grade fever and nausea and, sometimes, vomiting. Loss of appetite is common. In up to 50% of presenting cases, local tenderness is elicited at McBurney point when pressure is applied (Fig. 24-2). Rebound tenderness (production or intensification of pain when pressure is released) may be present. The extent of tenderness and muscle spasm and the existence of constipation or diarrhea depend not so much on the severity of the appendiceal infection as on the location of the appendix. If the appendix curls around behind the cecum, pain and tenderness may be felt in the lumbar region. If its tip is in the pelvis, these signs may be elicited only on rectal examination. Pain on defecation suggests that the tip of the appendix is resting against the rectum; pain on urination suggests that the tip is near the bladder or impinges on the ureter. Some rigidity of the lower portion of the right rectus muscle may occur. Rovsing sign may be elicited by palpating the left lower quadrant; this paradoxically causes pain to be felt in the right lower quadrant (see Fig. 24-2). If the appendix has ruptured, the pain becomes more diffuse; abdominal distention develops as a result of paralytic ileus, and the patient's condition worsens.

Nursing Alert

Constipation also can occur with an acute process, such as appendicitis. Laxatives administered in this instance may result in perforation of the inflamed appendix. In general, a laxative or cathartic should never be given when a person has fever, nausea, or pain.

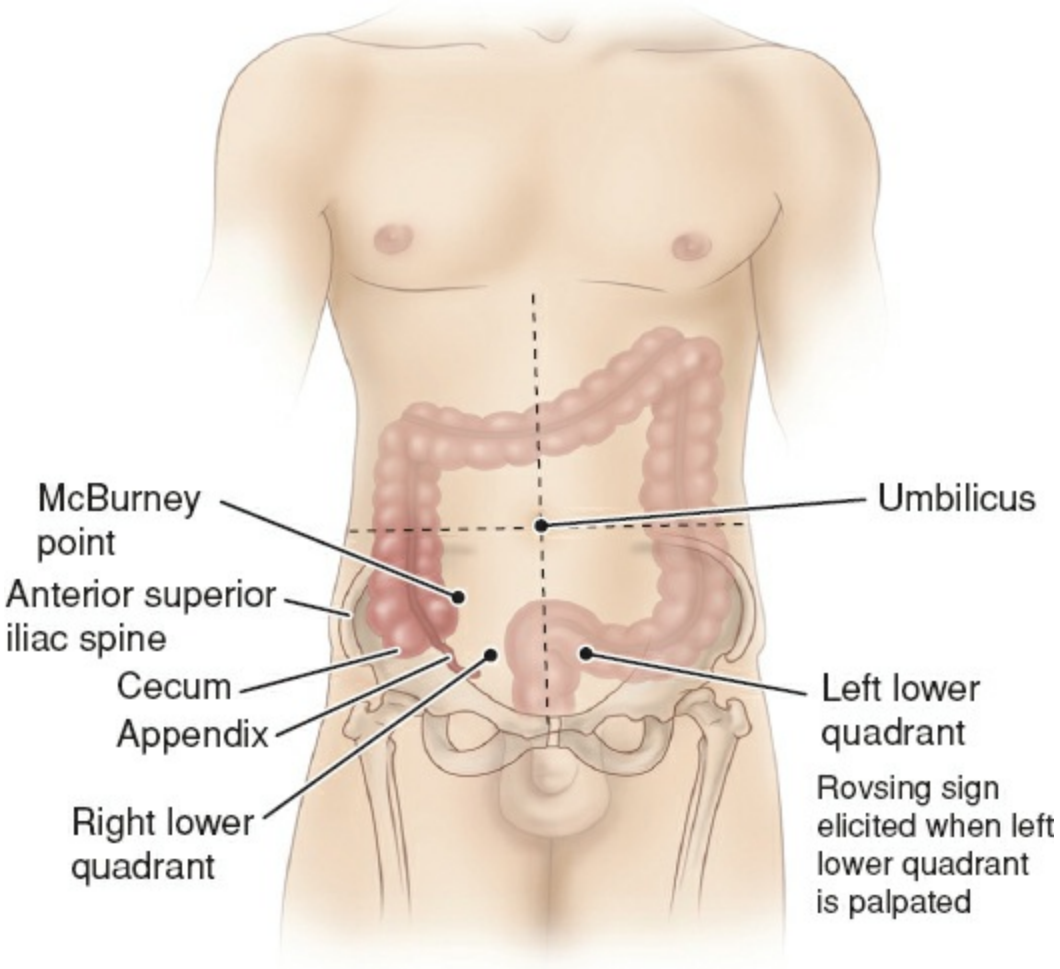

FIGURE 24-2 When the appendix is inflamed, tenderness can be noted in the right lower quadrant at McBurney point, which is between the umbilicus and the anterior superior iliac spine. Rovsing sign is pain felt in the right lower quadrant after the left lower quadrant has been palpated.

Diagnosis is based on results of a complete physical examination and on laboratory findings and imaging studies. The CBC demonstrates an elevated white blood cell (WBC) count with an elevation of the neutrophils. Abdominal x-ray films, ultrasound studies, and CT scans may reveal a right lower quadrant density or localized distention of the bowel. A diagnostic laparoscopy may be used to rule out acute appendicitis in equivocal cases.

Acute appendicitis is uncommon in the elderly population. When it does occur, classic signs and symptoms are altered and may vary greatly. Pain may be absent or minimal. Symptoms may be vague, suggesting bowel obstruction or another process. Fever and leukocytosis may not be present. As a result, diagnosis and prompt treatment may be delayed, causing complications and mortality. The patient may have no symptoms until the appendix ruptures. The incidence of perforated appendix is higher in the elderly population because many of these patients do not seek health care as quickly as younger patients.

Medical and Nursing Management

Typically, immediate surgery is indicated if appendicitis is diagnosed. To correct or prevent fluid and electrolyte imbalance, dehydration, and sepsis, antibiotics and IV fluids are administered until surgery is performed. Appendectomy (i.e., surgical removal of the appendix) is performed as soon as possible to decrease the risk of perforation. It may be performed using general or spinal anesthesia with a low abdominal incision (laparotomy) or by laparoscopy. Both laparotomy and laparoscopy are safe and effective in the treatment of appendicitis with perforation. However, generally recovery after laparoscopic surgery is quicker.

When perforation of the appendix occurs, an abscess may form. If this occurs, the patient may be treated initially with antibiotics, and the surgeon may place a drain in the abscess during the operative procedure to facilitate drainage. Subsequent surgical procedures may be performed to ensure complete drainage of the abscess. The postoperative care of the patient with a perforated appendix is more complex and complicated due to the risk of developing sepsis and organ damage.

The nurse prepares the patient for surgery, which includes an IV infusion to replace fluid loss and promote adequate kidney function, and antibiotic therapy to prevent infection. If there is evidence or likelihood of paralytic ileus, a nasogastric tube is inserted. An enema is not administered because it can lead to perforation.

After surgery, the nurse places the patient in a high Fowler position. This position reduces the tension on the incision and abdominal organs, helping to reduce pain. An opioid, usually morphine sulfate, is prescribed to relieve pain. When tolerated, oral fluids are administered. Any patient who was dehydrated before surgery receives IV fluids. Food is provided as desired and tolerated on the day of surgery, once normal bowel sounds are present.

The patient may be discharged on the day of surgery if the temperature is within normal limits, there is no undue discomfort in the operative area, and the appendectomy was uncomplicated. Discharge teaching for the patient and family is imperative. The nurse instructs the patient to make an appointment to have the surgeon remove the sutures between the fifth and seventh days after surgery. Incision care and activity guidelines are discussed; usually normal activity can be resumed within 2 to 4 weeks.

If there is a possibility of peritonitis, a drain is left in place at the area of the incision. Patients at risk for this complication may be kept in the hospital for several days and are monitored carefully for signs of intestinal obstruction or secondary hemorrhage. Secondary abscesses may form in the pelvis, under the diaphragm, or in the liver, causing elevation of the temperature, pulse rate, and WBC count.

When the patient is ready for discharge, the nurse teaches the patient and family to care for the incision and perform dressing changes and irrigations as prescribed. A home care nurse may be needed to assist with this care and to monitor the patient for complications and wound healing.

Complications

The major complication of appendicitis is perforation of the appendix, which can lead to peritonitis, abscess formation (collection of purulent material), or portal pylephlebitis, which is septic thrombosis of the portal vein caused by vegetative emboli that arise from septic intestines. Perforation generally occurs 24 hours after the onset of pain if no intervention has occurred. Symptoms include a fever of 37.7°C (100°F) or greater, a toxic appearance, and continued abdominal pain or tenderness. Other complications of appendectomy are listed in Table 24-4.

TABLE 24-4 Potential Complications and Nursing Interventions After Appendectomy

Complication	Nursing Interventions
Peritonitis	Observe for abdominal tenderness, fever, vomiting, abdominal rigidity, and tachycardia. Employ nasogastric suction. Correct dehydration as prescribed. Administer antibiotic agents as prescribed.
Pelvic abscess	Evaluate for anorexia, chills, fever, and diaphoresis. Observe for diarrhea, which may indicate pelvic abscess. Prepare patient for rectal examination. Prepare patient for surgical drainage procedure.
Subphrenic abscess (abscess under the diaphragm)	Assess patient for chills, fever, and diaphoresis. Observe for Hiccups because of diaphragmatic irritation. Prepare for x-ray examination. Prepare for surgical drainage of abscess.
Ileus (paralytic and mechanical)	Assess for bowel sounds. Employ nasogastric intubation and suction. Replace fluids and electrolytes by intravenous route as prescribed. Prepare for surgery if diagnosis of mechanical ileus is established.

DIVERTICULAR DISEASE

A diverticulum is a sac-like herniation of the lining of the bowel that extends through a defect in the muscle layer. Diverticula may occur anywhere in the small intestine or colon but occur most commonly in the distal sigmoid colon. The incidence of diverticular disease of the colon is 35% to 50%, and increases with age. For example, the incidence is less than 10% under age 40, but rises to 80% when over 85 (Ferri, 2017). The health care cost of diverticular disease is estimated at more than $2 billion (Perry et al., 2012).

Pathophysiology

Diverticula form when the mucosa and submucosal layers of the colon herniate through the muscular wall because of high intraluminal pressure, low volume in the colon (i.e., fiber-deficient contents), and decreased muscle strength in the colon wall (e.g., muscular hypertrophy from hardened fecal masses). Bowel contents can accumulate in the diverticulum and decompose, causing inflammation and infection. The diverticulum also can become obstructed and then inflamed if the obstruction continues. Inflammation and subsequent infection of the diverticulum (i.e., diverticulitis) can cause the development of abscesses, which may eventually perforate, leading to peritonitis and erosion of the arterial blood vessels, resulting in bleeding. Diverticulitis may occur as an acute attack or may persist as a continuing, smoldering infection. The symptoms manifested generally result from complications: abscess, fistula formation, obstruction, perforation, peritonitis, and hemorrhage.

Diverticulosis (see Fig. 24-3) exists when multiple diverticula are present without inflammation or symptoms. A low intake of dietary fiber is considered a predisposing factor, but the exact cause has not been identified. Most patients with diverticular disease are asymptomatic, so its exact prevalence is unknown.

Risk Factors

It is estimated that 10% to 25% of people with diverticulosis have diverticulitis at some point in their lives (Shahedi et al., 2013). A congenital predisposition is suspected when the disorder occurs in those younger than 40 years of age.

Clinical Manifestations and Assessment

Chronic constipation often precedes the development of diverticulosis, sometimes by many years. Frequently, no problematic symptoms occur with diverticulosis. Signs and symptoms of diverticulosis are relatively mild and include bowel irregularity with intervals of diarrhea, nausea, anorexia, and abdominal distention. Abdominal pain may radiate to the back, flank, or suprapubic region. With repeated local inflammation of the diverticula, the large bowel may narrow with fibrotic strictures, leading to cramps, narrow stools, and increased constipation or, at times, intestinal obstruction. Weakness, fatigue, and anorexia are common symptoms. With diverticulitis, the patient reports an acute onset of mild to severe pain in the lower left quadrant, accompanied by nausea, vomiting, fever, chills, and leukocytosis (elevated WBC). Rebound tenderness is suggestive of perforation. The condition, if untreated, can lead to septicemia (see Chapter 54).

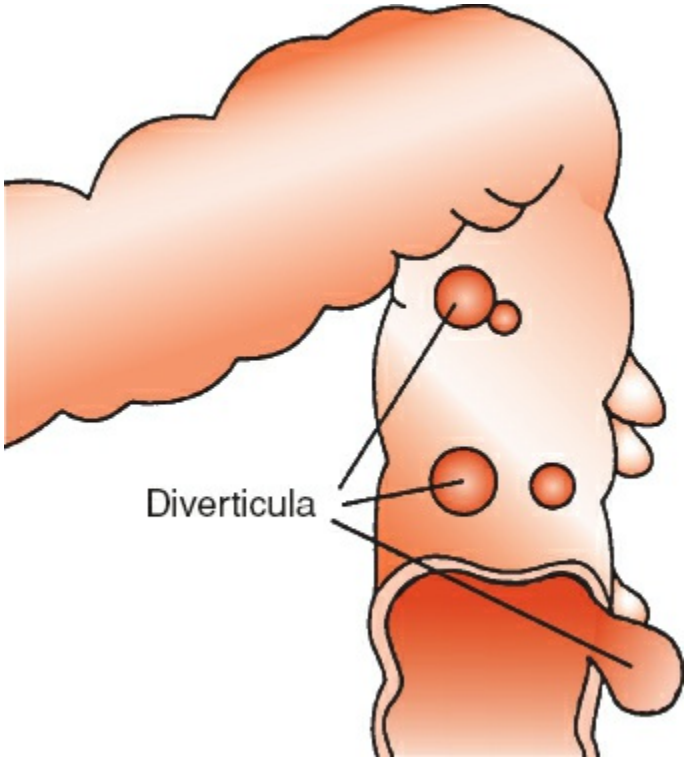

FIGURE 24-3 (Top) Location of diverticula in the sigmoid colon; (Bottom left) Diverticulosis; (Bottom right) Diverticulitis. (Reprinted with permission from Diepenbrock, N. (2011). *Quick reference to critical care* (4th ed.). Philadelphia, PA: Wolters Kluwer.)

Typically diverticulosis is diagnosed by colonoscopy, which permits visualization of the extent of diverticular disease and allows the clinician to biopsy tissue to rule out other diseases as needed. Until recently, barium enema had been the preferred diagnostic test, but now it is used less frequently than colonoscopy. However, if acute diverticulosis is suspected or there are symptoms of peritoneal irritation, a colonoscopy or barium enema is contraindicated because of potential for perforation. CT scan is the diagnostic test of choice if the suspected diagnosis is diverticulitis; it also can reveal one or more abscesses. Abdominal x-rays may demonstrate free air under the diaphragm if a perforation has

occurred from the diverticulitis, which causes peritonitis. Laboratory tests that assist in diagnosis include a CBC, revealing an elevated WBC count, and elevated erythrocyte sedimentation rate (ESR).

Gerontologic Considerations 

The incidence of diverticular disease increases with age because of degeneration and structural changes in the circular muscle layers of the colon and because of cellular hypertrophy. The symptoms are less pronounced in the elderly than in other adults. The elderly may not have abdominal pain until infection occurs. They may delay reporting symptoms because they fear surgery or are afraid that they may have cancer. Frequently blood in the stool is overlooked, especially in the elderly because of a failure to examine the stool or the inability to see changes if vision is impaired.

Medical and Nursing Management

Usually diverticulitis can be treated on an outpatient basis with diet and medication. When symptoms occur, rest, analgesics, and antispasmodics are recommended. Initially, the diet is clear liquid until the inflammation subsides; then a high-fiber, low-fat diet is recommended. This type of diet helps increase stool volume, decrease colonic transit time, and reduce intraluminal pressure. Antibiotics are prescribed for 7 to 10 days. A bulk-forming laxative also is prescribed.

Nursing Alert
High-fiber foods include items such as potatoes, rice, artichoke, and split peas. In addition, patient teaching can include adding foods such as raspberries and pears as snacks to help increase fiber intake. In the past, it was recommended that people with diverticular disease (diverticulosis or diverticulitis) avoid nuts, corn, popcorn, and seeds for fear that these foods would become lodged in the diverticula and lead to inflammation. However, there is no convincing evidence to support any particular foods that should be favored or avoided (Wilkins, Embry, & George, 2013).

In acute cases of diverticulitis hospitalization may be required for patients who cannot tolerate PO fluids and food. Measures taken to rest the bowel include withholding oral intake, administering IV fluids and antibiotics, and instituting nasogastric suctioning if vomiting or abdominal distention are present. An opioid is prescribed for pain relief. Historically, morphine was considered to be contraindicated because of a claim that it could increase intraluminal pressure in the colon, thus exacerbating symptoms; however, no research evidence is available to support this claim. Uncomplicated acute diverticulitis can be managed with oral antibiotics for 7 to 10 days in the outpatient setting. Nonsteroidal anti-inflammatory drugs (NSAIDs) are associated with increased risk of perforation and should be avoided.

More often than not, acute diverticulitis will subside with medical management. Immediate surgical intervention is necessary if complications (e.g., perforation, peritonitis, hemorrhage, obstruction) occur. In cases of abscess formation without peritonitis, hemorrhage, or obstruction, CT-guided percutaneous drainage may be performed to drain the abscess, and IV antibiotics are administered. Stabilization of the patient by drainage of the abscess and resolution of the inflammation is complete after approximately 6 weeks; surgery may be recommended to prevent repeated episodes. Typically two types of surgery are considered either to treat acute complications or to prevent further episodes of inflammation:

- One-stage resection, in which the inflamed area is removed and a primary end-to-end anastomosis is completed
- Multiple-stage procedures for complications such as obstruction or perforation (Fig. 24-4)

The type of surgery performed depends on the extent of complications found during surgery. When possible, the area of diverticulitis is taken out and the remaining bowel is

joined end-to-end (i.e., primary resection and end-to-end anastomosis). This is performed through traditional surgical or laparoscopically assisted colectomy. A two-stage resection may be performed in which the diseased colon is removed (as in a one-stage procedure) but no anastomosis is performed; both ends of the bowel are brought out onto the abdomen as stomas. Then this "double-barrel" temporary colostomy is reanastomosed in a later procedure. Fecal diversion procedures are discussed later in this chapter.

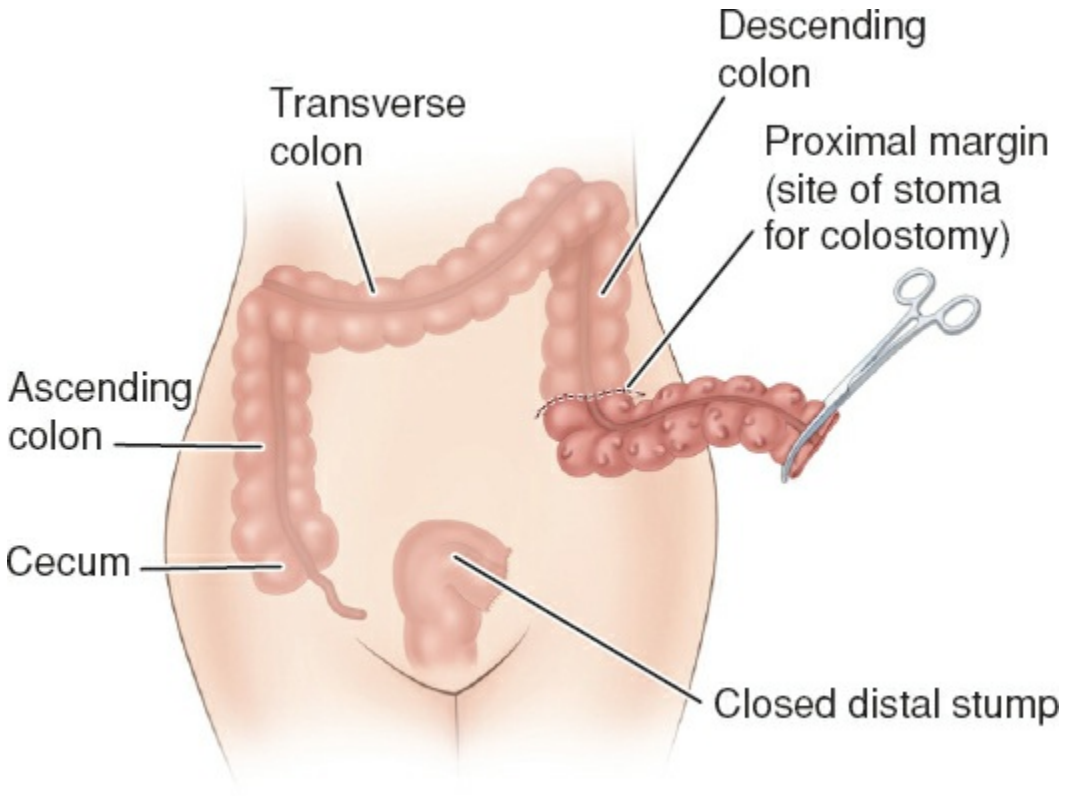

FIGURE 24-4 The Hartmann procedure for diverticulitis: primary resection for diverticulitis of the colon. The affected segment (*clamp attached*) has been divided at its distal end. In a primary anastomosis, the proximal margin (*dotted line*) is transected and the bowel attached end-to-end. In a two-stage procedure, a colostomy is constructed at the proximal margin with the distal stump oversewn (Hartmann procedure, as shown) or brought to the outer surface as a mucous fistula. The second stage consists of colostomy takedown and anastomosis.

Complications

Complications of diverticulitis include peritonitis (see below), abscess formation, and bleeding. If an abscess develops, the associated findings are tenderness, a palpable mass, fever, and leukocytosis. An inflamed diverticulum that perforates results in abdominal pain localized over the involved segment, usually the sigmoid; local abscess or peritonitis follows. Abdominal pain, a rigid board-like abdomen, loss of bowel sounds, and signs and symptoms of shock occur with peritonitis. Noninflamed or slightly inflamed diverticula may erode areas adjacent to arterial branches, causing massive rectal bleeding.

PERITONITIS

Peritonitis is inflammation of the peritoneum, the serous membrane lining the abdominal cavity and covering the viscera. Peritonitis is typically a life-threatening emergency that requires prompt surgical intervention and typically involves postoperative critical care monitoring due to the risk of sepsis, organ failure, and subsequent infections.

Nursing Alert

The development of peritonitis can include a variety of signs and symptoms in patients, including a firm and distended abdomen, rebound tenderness, and guarding by the patient of the abdomen during the examination. These signs and symptoms should cue nurses into suspecting peritonitis in their patients.

Pathophysiology

Peritonitis is caused by leakage of contents from abdominal organs into the abdominal cavity, usually as a result of inflammation, infection, ischemia, trauma, or tumor perforation. Bacterial proliferation occurs. Edema of the tissues ensues, and exudation of fluid develops in a short time. Fluid in the peritoneal cavity becomes turbid with increasing amounts of protein, WBCs, cellular debris, and blood. The immediate response of the intestinal tract is hypermotility, soon followed by paralytic ileus with an accumulation of air and fluid in the bowel.

Risk Factors

Usually, peritonitis is a result of bacterial infection; the organisms come from diseases of the GI tract or, in women, from the internal reproductive organs. Peritonitis also can result from external sources, such as injury or trauma (e.g., gunshot wound, stab wound) or an inflammation that extends from an organ outside the peritoneal area, such as the kidney. The most common bacteria implicated are gram-negative organisms (*Escherichia coli, Klebsiella, Proteus*), gram-positive bacteria (enterococci, streptococci, staphylococci), anaerobic bacteria (*Bacteroides, Clostridium*), and fungi (Ferri, 2016). Inflammation and paralytic ileus are the direct effects of the infection. Other common causes of peritonitis are appendicitis, perforated ulcer, diverticulitis, and bowel perforation (Fig. 24-5). Peritonitis also may be associated with abdominal surgical procedures and peritoneal dialysis.

Clinical Manifestations and Assessment

Symptoms depend on the location and extent of the inflammation. The early clinical manifestations of peritonitis frequently are the symptoms of the disorder causing the condition, aptly nicknamed an "acute abdomen." At first, a diffuse type of pain is felt. The pain tends to become constant, localized, and more intense near the site of the inflammation. Movement usually aggravates it. The affected area of the abdomen becomes extremely tender and distended, and the muscles become rigid. Rebound tenderness and paralytic ileus may be present. Diminished perception of pain in peritonitis can occur in people receiving corticosteroids or analgesics. Patients with diabetes who have symptoms of advanced neuropathy and patients with cirrhosis who have signs of ascites may not experience pain during an acute bacterial episode. Usually, nausea and vomiting occur, and peristalsis is diminished (decreased bowel sounds). A temperature of 100° to 101°F (37.8° to 38.3°C) can be expected, along with an increased pulse rate, tachypnea, dyspnea, and hypotension.

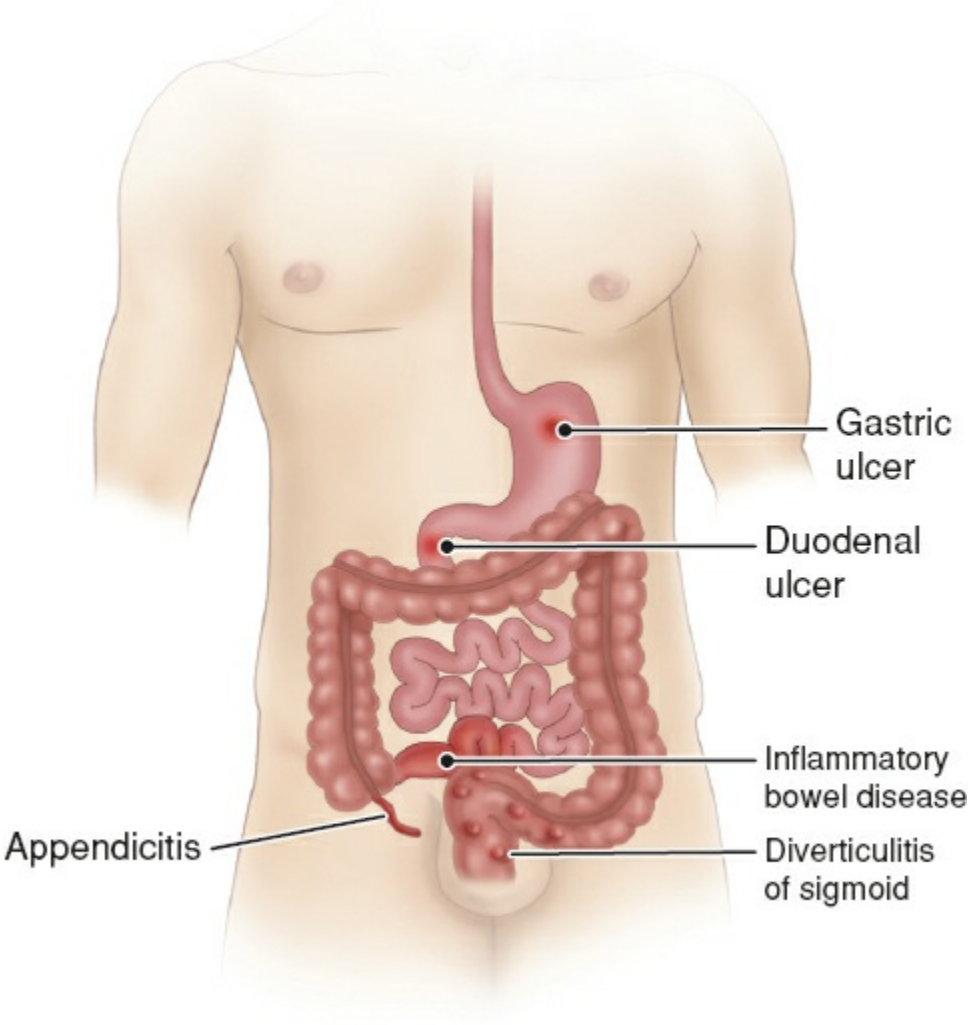

FIGURE 24-5 Common gastrointestinal causes of peritonitis.

The WBC count is almost always elevated. The hemoglobin and hematocrit levels may

be low if blood loss has occurred. Serum electrolyte studies may reveal altered levels of potassium, sodium, and chloride.

An abdominal x-ray study may show air and fluid levels as well as distended bowel loops. A CT scan of the abdomen may show abscess formation, acute inflammation or infection of one of the major abdominal organs, or a perforation of the small or large bowel. Peritoneal aspiration and culture and sensitivity studies of the aspirated fluid may reveal infection and identify the causative organisms.

Medical and Nursing Management

Fluid, colloid, and electrolyte replacement is the major focus of medical management. The administration of several liters of an isotonic solution is emergently prescribed. Hypovolemia occurs because massive amounts of fluid and electrolytes move from the intestinal lumen into the peritoneal cavity and deplete the fluid in the vascular space.

Analgesics are prescribed for pain. Antiemetics are administered as prescribed for nausea and vomiting. Placement of a nasogastric tube is warranted, and suction is maintained to assist in relieving abdominal distention. Fluid in the abdominal cavity can cause pressure that restricts expansion of the lungs and causes respiratory distress. Oxygen therapy by nasal cannula or mask generally promotes adequate oxygenation, but airway intubation and ventilatory assistance occasionally are required due to the patient's inability to compensate for the metabolic acidosis that typically occurs with peritonitis.

Antibiotic therapy is initiated early in the treatment of peritonitis. Large doses of a broad-spectrum antibiotic and antifungicide are administered IV until the specific organism causing the infection is identified and appropriate antibiotic therapy can be initiated.

Surgical objectives include removing the infected material and correcting the cause. Surgical treatment is directed toward excision (i.e., appendix), resection with or without anastomosis (i.e., intestine), repair (i.e., perforation), and/or drainage (i.e., abscess). With sepsis accompanying the peritonitis, a fecal diversion may need to be created.

The two most common postoperative complications are wound evisceration and abscess formation. Any suggestion from the patient that an area of the abdomen is tender or painful or "feels as if something just gave way" must be reported. The sudden occurrence of serosanguineous wound drainage strongly suggests wound dehiscence and is a surgical emergency that must be reported promptly to the on-call provider.

Often intensive care is needed. The blood pressure is monitored by arterial line if shock is present. Accurate recording of all intake and output and central venous pressures and/or pulmonary artery pressures assists in calculating fluid replacement. The nurse administers and closely monitors IV fluids response.

In addition, ongoing assessment of pain, GI function, and fluid and electrolyte balance is important. Bladder pressure also is measured routinely to identify abdominal compartment syndrome (refer to Chapter 53, Fig. 53-4). The nurse reports the nature of the pain, its location in the abdomen, and any changes in location. Administering analgesic medication and positioning the patient for comfort are helpful in decreasing pain. The patient is placed on the side with knees flexed; this position decreases tension on the abdominal organs.

Signs that indicate that peritonitis is subsiding include a decrease in temperature and pulse rate, softening of the abdomen, return of peristaltic sounds, and passing of flatus and bowel movements. The nurse increases fluid and food intake gradually and reduces parenteral fluids as prescribed. A worsening clinical condition may indicate a complication, and the nurse must prepare the patient for emergency surgery.

Frequently drains are inserted during the surgical procedure, and the nurse must observe and record the character of the drainage postoperatively. Care must be taken when moving and turning the patient to prevent the drains from being dislodged. It is prudent to safety-pin the drains to the patient's gown to limit the chance of accidental dislodgement. Also it

is important for the nurse to prepare the patient and family for discharge by teaching the patient to care for the incision and drains if the patient will be sent home with the drains still in place. Referral for home care or rehabilitation may be indicated for further monitoring and patient and family teaching.

Complications

Frequently, the inflammation is not localized, and the entire abdominal cavity shows evidence of widespread infection. Sepsis is the major cause of death from peritonitis. Shock may result from septicemia or hypovolemia. The inflammatory process may cause intestinal obstruction, primarily from the development of bowel adhesions, and care must be made to monitor the patient's nasogastric tube drainage and input and output closely. The patient is also at high risk of developing pulmonary emboli, and compression stockings, sequential-compression boots, and subcutaneous anticoagulation may be prescribed.

INFLAMMATORY BOWEL DISEASE

IBD refers to two chronic inflammatory GI disorders: regional enteritis (i.e., Crohn disease) and ulcerative colitis (UC). Both disorders have striking similarities but also several differences (Table 24-5); medical and nursing management for both types is similar and discussed jointly.

The incidence of IBD in the United States has increased to well over 1 million cases (Kaplan, 2015). Typically IBD presents during childhood or later in life and is attributed to a high morbidity and a decreased quality of life (Kaplan & Jess, 2016). Women and men tend to be affected equally, and family history appears to predispose people to develop IBD, particularly if a first-degree relative has the disease.

Despite extensive research, the cause of IBD is still unknown. Researchers theorize that it is triggered by environmental agents, such as pesticides, food additives, tobacco, and radiation (Kaplan & Jess, 2016). NSAIDs have been found to exacerbate IBD. Allergies and immune disorders also have been suggested as causes. Abnormal response to dietary or bacterial antigens has been studied extensively, and genetic factors also are being examined.

REGIONAL ENTERITIS (CROHN DISEASE)

Usually regional enteritis (Crohn disease) is diagnosed first in adolescents or young adults but can appear at any time in a person's life. The incidence of regional enteritis has risen both nationally and internationally, suggesting that Crohn disease is emerging as a disease of global significance (Conley & Redeker, 2016). The most popular theory is that the body's immune system reacts abnormally in people with Crohn disease, mistaking bacteria, foods, and other substances for dangerous foreign substances (National Institutes of Health [NIH], U.S. Department of Health and Human Services, 2009; Targownik, Coneys, & Dhillon, 2016). Recent research also has suggested that lower levels of vitamin D may play a role in the increasing incidence of regional enteritis and warrants further study (Holmes, Xiang, & Lucas, 2015).

TABLE 24-5 Comparison of Regional Enteritis and Ulcerative Colitis

Factor	Regional Enteritis	Ulcerative Colitis
Course	Prolonged, variable	Exacerbations, remissions
Pathology		
Early	Transmural thickening	Mucosal ulceration
Late	Deep, penetrating granulomas	Minute, mucosal ulcerations
Clinical Manifestations		
Location	Ileum, ascending colon (usually)	Rectum, descending colon
Bleeding	Usually not, but if it occurs, it tends to be mild	Common—severe
Perianal involvement	Common (seen in 30–45% of patients)	Rare—mild
Fistulas	Common	Rare
Rectal involvement	About 20%	Almost 100%
Diarrhea	Less severe	Severe
Diagnostic Study Findings		
Barium series	Regional, discontinuous lesions Narrowing of colon Thickening of bowel wall Mucosal edema Stenosis, fistulas, fissures "String sign" of the terminal ileum, indicating the constriction of a segment of intestine. Ulcerations (the cobblestone appearance)	Diffuse involvement No narrowing of colon No mucosal edema Rare occurrence of stenosis Shortening of colon
Sigmoidoscopy	May be unremarkable unless accompanied by perianal fistulas	Abnormal inflamed mucosa
Colonoscopy	Distinct ulcerations separated by relatively normal mucosa in ascending colon	Friable mucosa with pseudopolyps or ulcers in descending colon
CT scan*	May show bowel-wall thickening and fistula formation in regional enteritis (Crohn disease)	Depicts bowel-wall thickening, abscesses, fistulas, and obstructions
Therapeutic Management	Corticosteroids, sulfonamides (sulfasalazine [Azulfidine]) Antibiotics Parenteral nutrition Partial or complete colectomy with ileostomy or anastomosis Rectum can be preserved in some patients Recurrence common	Corticosteroids, sulfonamides; sulfasalazine useful in preventing recurrence Bulk hydrophilic agents Antibiotics Proctocolectomy, with ileostomy Rectum can be preserved in only a few patients "cured" by colectomy
Systemic Complications	Small bowel obstruction Right-sided hydronephrosis Nephrolithiasis Cholelithiasis Arthritis Retinitis, iritis Erythema nodosum	Toxic megacolon Perforation Hemorrhage Malignant neoplasms Pyelonephritis Nephrolithiasis Cholangiocarcinoma Arthritis Retinitis, iritis Erythema nodosum

*can reveal acute inflammation or infection of one of the major abdominal organs or a perforation of the small or large bowel.

Pathophysiology

Regional enteritis is a subacute and chronic inflammation of the GI tract wall that extends through all layers (i.e., transmural lesion). Although it can occur anywhere in the GI tract, it most commonly occurs in the distal ileum but can be seen in the ascending colon. It is characterized by periods of remission and exacerbation. The disease process begins with edema and thickening of the mucosa. Ulcers begin to appear on the inflamed mucosa. The ulcerations in regional enteritis differ from UC in that they are not continuous or in contact with each other and are separated by normal tissue. Hence, these clusters of ulcers tend to take on a classic "cobblestone" appearance on colonoscopy. Fistulas, fissures, and abscesses form as the inflammation extends down into the peritoneum. Granulomas (localized nodular inflammation) occur in 50% of patients. As the disease advances, the bowel wall thickens and becomes fibrotic, and the intestinal lumen narrows. Diseased bowel loops sometimes stick to other loops surrounding those developing adhesions.

Clinical Manifestations and Assessment

Usually the onset of symptoms is insidious in regional enteritis, with prominent lower right quadrant abdominal pain unrelieved by defecation, fatigue, diarrhea, and weight loss. Scar tissue and the formation of granulomas interfere with the ability of the intestine to transport products of the upper intestinal digestion through the constricted lumen, resulting in crampy abdominal pains. There is abdominal tenderness and spasm. Because eating stimulates intestinal peristalsis, the crampy pain typically occurs after meals. The patient will tend to limit food intake in order to reduce the crampy pain and, in fact, can reduce the amount and type of food to such a degree that normal nutritional requirements often are not met. As a result, weight loss, malnutrition, and secondary anemia occur.

Ulcers in the membranous lining of the intestine and other inflammatory changes result in a weeping, edematous intestine that continually empties a colonic- and skin-irritating discharge. Disrupted absorption causes chronic diarrhea and associated fluid and electrolyte imbalances (hypokalemia, hypomagnesemia, hypocalcemia, and low albumin) as well as nutritional deficits. In some patients, the inflamed intestine may perforate, leading to intra-abdominal and anal abscesses. Fever and leukocytosis may occur. Chronic symptoms of regional enteritis may include steatorrhea (i.e., excessive fat in the feces).

Abscesses, fistulas, and fissures are common. Manifestations may extend beyond the GI tract and commonly include joint disorders (e.g., arthritis), skin lesions (e.g., erythema nodosum), ocular disorders (e.g., conjunctivitis), and oral ulcers. The clinical course and symptoms can vary; in some patients, periods of remission and exacerbation occur, but in others, the disease follows a fulminating course.

Usually a proctosigmoidoscopy is performed initially to determine whether the rectosigmoid area is inflamed. A stool examination also is performed; the result may be positive for occult blood and steatorrhea. Endoscopy, colonoscopy, and intestinal biopsies may be used to confirm the diagnosis. A CT scan may show bowel-wall thickening and fistula formation.

A CBC is performed to assess hematocrit and hemoglobin levels (usually decreased) as well as the WBC count (may be elevated). Usually the ESR is elevated in relation to the inflammation. Albumin (the long-term marker of nutrition) and protein levels may be decreased, indicating malnutrition.

Complications

Complications of regional enteritis include intestinal obstruction or stricture formation, perianal disease, fluid and electrolyte imbalances, malnutrition from malabsorption, and formation of fistulas and abscesses. The most common type of small bowel fistula caused by regional enteritis is the enterocutaneous fistula (i.e., an abnormal opening between the small bowel and the skin). Abscesses can be the result of an internal fistula that results in fluid accumulation and infection. Patients with regional enteritis are also at increased risk of colon cancer.

ULCERATIVE COLITIS

UC is a recurrent ulcerative and inflammatory disease of the mucosal and submucosal layers of the colon and rectum. The prevalence of UC is highest in Caucasians and people of Jewish heritage (Centers for Disease Control [CDC], 2016). It affects men and women equally. It is a serious disease, accompanied by systemic complications and a high mortality rate. Approximately 3% of patients with UC develop colon cancer (Desai et al., 2015; NIH, U.S. Department of Health and Human Services, 2009). Worldwide incidence of UC is more common than incidence of Crohn disease (Ferri, 2016).

Pathophysiology

UC affects the superficial mucosa of the colon and is characterized by multiple ulcerations, diffuse inflammations, and desquamation or shedding of the colonic epithelium. Bleeding occurs as a result of the ulcerations. The mucosa becomes edematous and inflamed. The lesions are contiguous, occurring one after the other. Abscesses form, and infiltrate is seen in the mucosa and submucosa, with clumps of neutrophils found in the lumens of the crypts (i.e., crypt abscesses) that line the intestinal mucosa (Porth, 2015). The disease process usually begins in the rectum and spreads proximally to involve the entire colon. Eventually, the bowel narrows, shortens, and thickens because of muscular hypertrophy and fat deposits.

Clinical Manifestations and Assessment

The clinical course is usually one of intermittent exacerbations and remissions. The predominant symptoms of UC include bloody diarrhea, passage of mucus, urgency, lower left quadrant abdominal pain, intermittent tenesmus, and fever. Symptoms will differ according to the extent of disease. The bleeding may be mild or severe, and pallor, anemia, and fatigue are the result. The patient may have anorexia, weight loss, vomiting, and dehydration, as well as cramping, the feeling of an urgent need to defecate, and the passage of 10 to 20 liquid stools each day. The disease is classified as mild, severe, or fulminant, depending on the severity of the symptoms. Hypocalcemia and anemia frequently develop. Rebound tenderness may occur in the right lower quadrant. Extraintestinal manifestations include skin lesions (e.g., erythema nodosum), eye lesions (e.g., uveitis), joint abnormalities (e.g., arthritis), and liver disease.

The patient should be assessed for tachycardia, hypotension, tachypnea, fever, and pallor (hypovolemic shock) from rectal bleeding. UC bleeding is painless and stops spontaneously in approximately 60% of patients (Ferri, 2016). Treatment is aimed at blood replacement and correction of volume and any clotting abnormalities. Other assessments address level of hydration and nutritional status. The abdomen is examined for bowel sounds, distention, and tenderness. Peripheral edema can occur secondary to hypoalbuminemia. These findings assist in determining the severity of the disease.

The stool can be positive for blood, and laboratory test results reveal low hematocrit and hemoglobin levels in addition to an elevated WBC count, low albumin levels, and an electrolyte imbalance. Iron-deficiency anemia may be present because of chronic blood loss. Hypokalemia, metabolic alkalosis, and elevated serum levels of blood urea nitrogen and creatinine may be present in severe flares of UC, reflecting volume depletion (Osterman & Lichtenstein, 2016). Abdominal x-ray studies are useful for determining the cause of symptoms. Free air in the peritoneum and bowel dilation or obstruction should be excluded as a source of the presenting symptoms, as peritonitis also can occur.

Colonoscopy should be avoided during acute diverticulitis due to the risk of perforation. In general, it can be performed after 6 weeks to rule out the presence of cancer and IBD (Ferri, 2016). Colonoscopy may reveal friable, inflamed mucosa with exudate and ulcerations. This procedure assists in defining the extent and severity of the disease. With the advent of endoscopy, barium studies have been used less often but remain important for certain specific scenarios, such as evaluation of colonic strictures; barium enema provides information on their location, length, and diameter and allows visualization of the entire colon when the presence of strictures precludes advancement of the colonoscope (Osterman & Lichtenstein, 2016). CT scanning can identify acute diverticulitis and diverticulosis, abscesses, and perirectal involvement. Arteriography may be performed with significant rectal bleeding, in which case vasopressin may be infused directly into the arteries supplying the bleeding, as well as selective arterial embolization (Ferri, 2016).

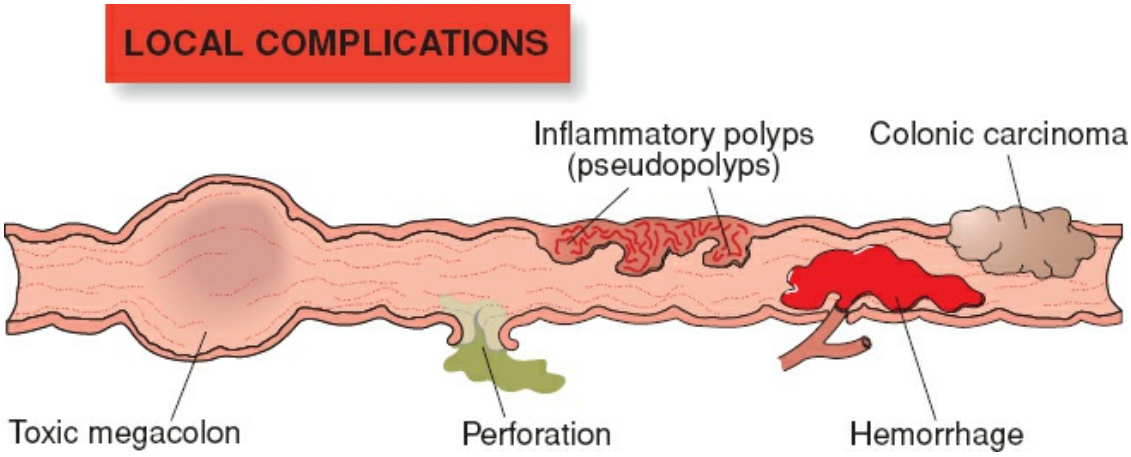

FIGURE 24-6 Ulcerative colitis. A schematic representation of the major features of ulcerative colitis in the colon. (Reprinted with permission from Strayer, D. S., & Rubin, E. (2014). *Rubin's pathology* (7th ed.). Philadelphia, PA: Wolters Kluwer.)

Careful examination of the patient's stool for parasites and other microbes is performed to rule out dysentery caused by common intestinal organisms, especially *Entamoeba histolytica* and *Clostridium difficile*.

Complications

Complications of UC include toxic megacolon, perforation and bleeding as a result of ulceration, vascular engorgement, and highly vascular granulation tissue (Fig. 24-6). In toxic megacolon, the inflammatory process extends into the muscularis, inhibiting its ability to contract and resulting in colonic distention. Symptoms include fever, abdominal pain and distention, vomiting, and fatigue. If the patient with toxic megacolon does not respond within 24 to 72 hours to medical management with nasogastric suction, IV fluids with electrolytes, corticosteroids, and antibiotics, then surgery is required. Then total colectomy is indicated. For many patients, surgery becomes necessary to relieve the effects of the disease and to treat these serious complications; an ileostomy usually is performed. The surgical procedures involved and the care of patients with this type of fecal diversion are discussed later in this chapter. In addition, hypercoagulability is a well-recognized complication of UC, resulting in deep vein thrombosis and pulmonary emboli. The mechanism of increased thrombotic risk is unclear. Standard anticoagulants would be administered. Episcleritis (painless hyperemia of the sclera and conjunctiva without loss of vision) and uveitis (acute or subacute pain in the eye with visual blurring often accompanied by photophobia and headache) occurs in 5% to 8% of patients with UC. Episcleritis parallels the level of bowel disease and generally responds to anti-inflammatory therapy. In contrast, the occurrence of uveitis increases with the dose and duration of glucocorticoid use. Patients with uveitis should receive prompt ophthalmologic examination and treatment with glucocorticoid ocular drops to prevent progression to blindness. Steroid therapy also can lead to cataracts. Thus, patients receiving glucocorticoid therapy should undergo annual ophthalmologic examination (Osterman & Lichtenstein, 2016).

Patients with IBD also have a significantly increased risk of osteoporotic fractures due to decreased bone mineral density. Corticosteroid therapy also may contribute to the diminished bone density.

MEDICAL AND NURSING MANAGEMENT OF INFLAMMATORY BOWEL DISEASE

Medical treatment for regional enteritis and UC is aimed at reducing inflammation, suppressing inappropriate immune responses, providing rest for a diseased bowel so that healing may take place, improving quality of life (Box 24-1), and preventing or minimizing complications. Most patients have long periods of well-being interspersed with short intervals of illness, and management depends on the disease location, severity, and complications.

Oral fluids and a diet that is low residue, high protein, and high calorie with supplemental vitamin therapy and iron replacement are prescribed to meet nutritional needs, reduce inflammation, and control pain and diarrhea. Fluid and electrolyte imbalances from dehydration caused by diarrhea are corrected by IV therapy as necessary if the patient is hospitalized or by oral fluids if the patient is managed at home. Any foods that exacerbate diarrhea are avoided. Milk may contribute to diarrhea in those with lactose

intolerance. Smoking is avoided because of increased intestinal motility. Consultation with a dietitian is highly recommended regarding oral diet or enteral feeding; parenteral nutrition has not yielded clinical benefit in this patient population (see Chapter 22).

Aminosalicylate formulations, such as sulfasalazine (Azulfidine), often are effective for mild or moderate inflammation and are used to prevent or reduce recurrences in long-term maintenance regimens. Sulfa-free aminosalicylates (e.g., mesalamine [Asacol, Pentasa]) are effective in preventing and treating recurrence of inflammation. Antibiotics (e.g., metronidazole [Flagyl]) are used for secondary infections, particularly for purulent complications, such as abscesses, perforation, and peritonitis.

BOX 24-1 Nursing Research

Bridging the Gap to Evidence-Based Practice

The Effect of Abdominal Massage on Constipation and Quality of Life

Does Abdominal Massage have an effect on GI function, quality of life (QOL), and the use of laxatives in patients who have not had a bowel movement in the first 3 days after surgery?

Turan, N., & Atabek Asti, T. (2016). The effect of abdominal massage on constipation and quality of life. Gastroenterology Nursing, *39*(1), 48–59.

Purpose

Constipation is a common problem that has a profound effect on people's health and well-being. There are few existing studies related to nursing interventions regarding abdominal massage. Therefore, the purpose of this study was to identify the effects of abdominal massage in patients with constipation related to their GI function, QOL, and the use of laxatives.

Design

A randomized controlled study was conducted. Sample criteria included patients 18 years of age or older, who had surgery and were hospitalized for treatment, and who had not had a bowel movement for the first 3 days after surgery. A total of 60 patients (30 in the control group and 30 in the experimental group) fit criteria and agreed to be in the study. Abdominal massage was defined for this study as applied daily for 15 minutes in a clockwise fashion using four basic strokes: stroking, effleurage, kneading, and vibration.

Several data collection instruments were used to measure gastrointestinal symptom ratings, constipation severity scores, and the general health of the patient. Analysis of the data showed that patients who had abdominal massage completed defecation more often, had decreased symptoms of constipation, and stated there was improvement in their QOL. The study also showed that abdominal massage decreased the symptoms of constipation more than the use of laxatives, suppositories, or enemas.

Nursing Implications

This study has shown that abdominal massage is an effective tool in decreasing the symptoms of constipation and increasing the QOL for patients who are constipated. The nurse plays an important role in the treatment of constipation in postoperative patients. Implementing abdominal massage, in conjunction with dietary changes and increasing exercise, provide nonpharmacologic treatments for patients that can be implemented by the nurse in the early postoperative period. Future studies should analyze other patient groups to determine the ability of abdominal massage to treat patients with constipation in other clinical settings.

Corticosteroids are used to treat severe and fulminant disease and can be administered orally (e.g., prednisone [Deltasone]) in outpatient treatment or parenterally (e.g., hydrocortisone [Solu-Cortef]) in hospitalized patients. Topical (i.e., rectal administration) corticosteroids (e.g., hydrocortisone enema, budesonide [Entocort]) also are used widely in the treatment of distal colon disease. When the dosage of corticosteroids is reduced or stopped, the symptoms of disease may return. If corticosteroids are continued, adverse sequelae, such as hypertension, fluid retention, cataracts, hirsutism (i.e., abnormal hair growth), adrenal suppression, steroid-induced diabetes mellitus (secondary to the hyperglycemia associated with glucocorticoid therapy), poor wound healing, and loss of bone density, may occur.

Immunomodulators (e.g., azathioprine [AZA], 6-mercapt-opurine [6-MP], methotrexate, and cyclosporine) and antitumor necrosis factor agents have been used to alter the immune response. The exact mechanism of action of these medications in treating IBD is unknown. These medications are useful in maintenance regimens to prevent relapses. Biologic therapies using monoclonal antibodies, such as natalizumab (Tysabri), continue to be used to treat Crohn disease (Scott & Osterman, 2015) and infliximab (Remicade) for treating UC (Bressler et al., 2015). Initial reports from clinical trials appear promising for both these medications (Arias et al., 2015; Scott & Osterman, 2015), although the use of natalizumab is limited currently to patients who have not tolerated or failed treatment with other biologic agents (Scott & Osterman, 2015).

When nonsurgical measures fail to relieve the severe symptoms of IBD, surgery may be necessary. Approximately 75% of all patients with regional enteritis who have had the disease for 20 years required some type of surgery. Fortunately, this number has been decreasing steadily with the increased use of infliximab therapy (Bressler et al., 2015). The most common indications for surgery are medically intractable disease, poor quality of life, or complications from the disease or its treatment. Recurrence of inflammation and disease after surgery in regional enteritis is inevitable.

A common procedure performed for strictures of the small intestines is laparoscope-guided strictureplasty, in which the blocked or narrowed sections of the intestines are widened, leaving the intestines intact. In some cases, a small bowel resection is performed: diseased segments of the small intestines are resected, and the remaining portions of the intestines are anastomosed. Surgical removal of up to 50% of the small bowel usually can be tolerated. In cases of severe regional enteritis of the colon, a total colectomy and ileostomy may be the procedure of choice.

A newer surgical procedure developed for patients with severe regional enteritis is intestinal transplant. Now this technique is available to children and to young and middle-

aged adults who have lost intestinal function from disease. Although this procedure is not a cure, eventually it may provide improvement in quality of life for some patients. The associated technical and immunologic problems remain formidable, and the costs and mortality rates remain high.

Long-term colectomy rates for patients with UC for 3 years ranges from 50% to 62% (Seah & De Cruz, 2016). When the colon is surgically removed, the patient is considered "cured" in that extraintestinal manifestations subside and the disease process is otherwise limited to the colon. Indications for surgery include lack of improvement and continued deterioration, profuse bleeding, perforation, continued stricture formation, and cancer. Surgical excision usually improves quality of life. Proctocolectomy with ileostomy (i.e., complete excision of colon, rectum, and anus) is recommended when the rectum is severely diseased. If the rectum can be preserved, the procedure of choice is restorative proctocolectomy with ileal pouch anal anastomosis (IPAA).

ILEOSTOMY

Procedures

An ileostomy, the surgical creation of an opening into the ileum or small intestine (usually by means of an ileal stoma on the abdominal wall), is commonly performed after a total colectomy (i.e., excision of the entire colon). It allows for drainage of fecal matter (i.e., effluent) from the ileum to the outside of the body. The drainage is typically loose to semiformed and may occur at frequent intervals.

Another procedure involves the creation of a continent ileal reservoir (i.e., Kock pouch) by diverting a portion of the distal ileum to the abdominal wall and creating a stoma (Fig. 24-7). This procedure eliminates the need for an external fecal collection bag. Approximately 30 cm of the distal ileum is reconstructed to form a reservoir with a nipple valve that is created by pulling a portion of the terminal ileal loop back into the ileum. GI effluent can accumulate in the pouch for several hours and then be removed by means of a catheter inserted through the nipple valve. In many patients, a total colectomy also is performed with the Kock pouch. Possible indications for a total colectomy with Kock pouch placement (rather than a restorative proctocolectomy with IPAA) include a badly diseased rectum, lack of rectal sphincter tone, or inability to achieve fecal continence post-IPAA.

The major problem with the Kock pouch is malfunction of the nipple valve. The ileocecal nipple valve is used commonly to create a continent, catheterizable channel. Another surgical option is the appendicovesicostomy, which repurposes the appendix to create a tunneled channel (Levy & Elliott, 2016).

A restorative proctocolectomy with IPAA is the surgical procedure of choice in cases in which the rectum can be preserved in that it eliminates the need for a permanent ileostomy. It establishes an ileal reservoir, and anal sphincter control of elimination is retained. The procedure involves connecting a portion of the ileum to the anus (i.e., ileoanal anastomosis) in conjunction with removal of the colon and the rectal mucosa (i.e., total abdominal colectomy and mucosal proctectomy) (Fig. 24-8). A temporary diverting loop ileostomy is constructed at the time of surgery and closed about 3 months later.

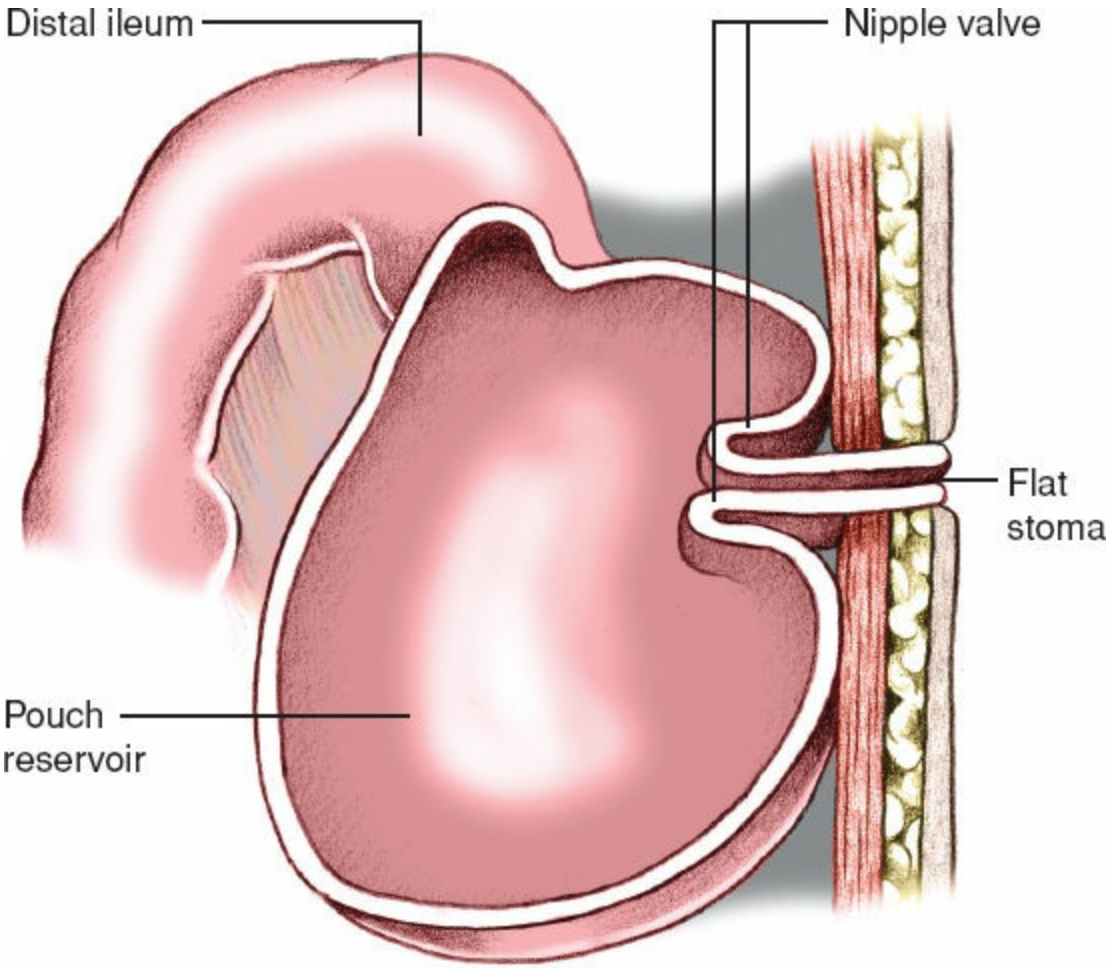

FIGURE 24-7 Anatomy of a Kock pouch. A Kock pouch is formed by surgically looping part of the distal ileum, stapling the loops together, and opening the inner canals to form a reservoir for the soft, watery stool to be held until catheterized for removal. The nipple valve is formed as shown, by pulling part of the pouch tissue back over the terminal end of the ileum and stapling it closed to reduce the size of the opening and form a canal for the catheter. The length and smaller diameter of the nipple valve prevents waste products from escaping, although some mucus drainage may be expected. (Reprinted with permission from Lippincott's Nursing Advisor. (2009), Wolters Kluwer.)

With ileoanal anastomosis, the diseased colon and rectum are removed, voluntary defecation is maintained, and anal continence is preserved. The ileal reservoir decreases the number of bowel movements by 50%, from approximately 14 to 20 per day to seven to 10 per day. Nighttime elimination is reduced gradually to one bowel movement. Complications of ileoanal anastomosis include irritation of the perianal skin from leakage of fecal contents, stricture formation at the anastomosis site, and small bowel obstruction.

Nursing management of patients with IBD may be medical, surgical, or both. Patients in the community setting or those recently diagnosed may require education about diet and medications as well as referral to support groups. Hospitalized patients with longstanding or severe disease also require careful monitoring, parenteral nutrition, fluid replacement, and possibly emergent surgery. The surgical procedures may involve a fecal diversion with attendant needs for physical care, emotional support, and extensive teaching about management of the ostomy.

Nursing Management for Ileostomy

Some patients with IBD eventually require a permanent fecal diversion with creation of an ileostomy to manage symptoms and to treat or prevent complications. Ileostomy education can be started while the patient is still in the hospital, and with a small amount of planning and care, the patient lives a very normal life. A plan of nursing care for a patient undergoing ostomy surgery is available online at http://thepoint.lww.com/Honan2e.

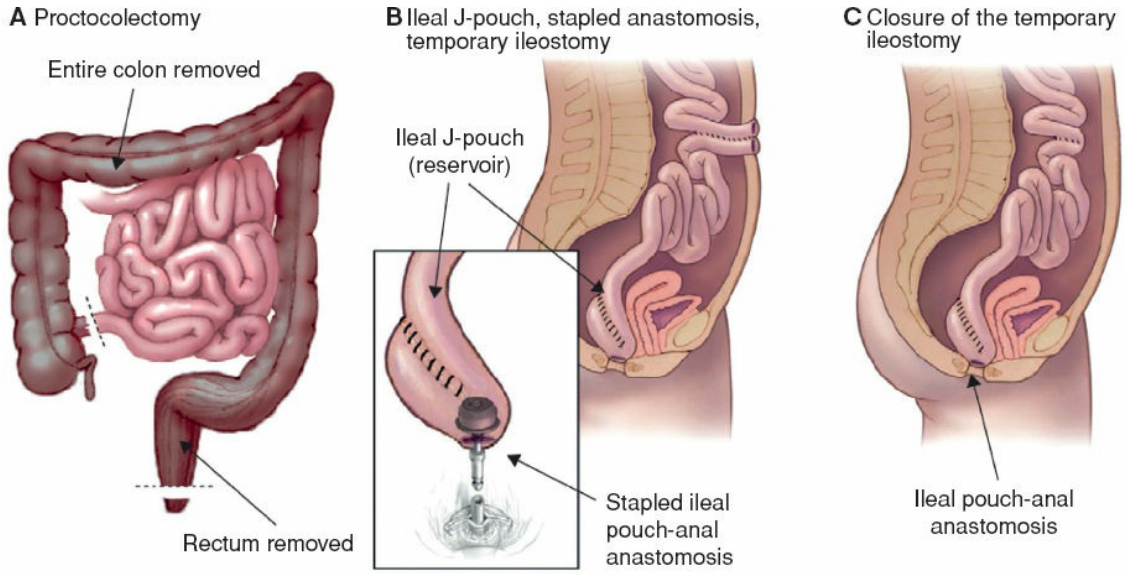

FIGURE 24-8 (A) Proctocolectomy. (B) Ileal J-pouch, stapled anastomosis, and temporary ileostomy. (C) Closure of the temporary ileostomy. The entire surgical procedure is based on four steps: removal of the colon; pelvic dissection and rectum removal sparing the pelvic nerves and the anal sphincter; construction of the ileal pouch, usually with the last 30 to 40 cm of the terminal ileum; and anastomosis of the pouch to the canal anal. (Reprinted with permission from Holzman, R. S., Mancuso, T. J., & Polaner, D. M. (2015). *A practical approach to pediatric anesthesia* (2nd ed.). Philadelphia, PA: Wolters Kluwer.)

Providing Preoperative Care

A period of preparation with intensive replacement of fluid, blood, and protein is necessary before surgery is performed. Antibiotics may be prescribed. If the patient has been taking corticosteroids, they will be continued during the surgical phase to prevent steroid-induced adrenal insufficiency. Usually, the patient is provided with frequent, small feedings. All other preoperative measures are similar to those for general abdominal surgery. The abdomen is marked for the proper placement of the stoma by the surgeon or the enterostomal therapist. Care is taken to ensure that the stoma is placed in a convenient location—usually in the right lower quadrant about 2 in below the waist, in an area away from previous scars, bony prominences, skin folds, or fistulas.

The patient must have a thorough understanding of the surgery to be performed and what to expect after surgery. Information about an ileostomy is presented to the patient by means of written materials, models, and discussion. Preoperative teaching includes management of drainage from the stoma, the nature of drainage, and the need for nasogastric intubation, parenteral fluids, and, possibly, perineal packing.

Providing Postoperative Care

Nursing Alert

A healthy stoma appears pink or red and moist; the nurse alerts the surgeon if the stoma is dusky, white, or dark since circulation may be compromised.

General abdominal surgery wound care is required. The nurse observes the stoma for color and size. It should be pink to bright red and shiny. Typically, a temporary plastic bag with an adhesive facing is placed over the ileostomy in the operating room and firmly pressed onto the surrounding skin. The nurse monitors the ileostomy for fecal drainage, which should begin about 72 hours after surgery. The drainage is a continuous liquid from the small intestine because the stoma does not have a controlling sphincter. The contents drain into the plastic bag and thus are kept from coming into contact with the skin. They are collected and measured when the bag becomes full. If a continent ileal reservoir was created, as described for the Kock pouch, continuous drainage is provided by an indwelling reservoir catheter for 2 to 3 weeks after surgery. This allows the suture lines to heal.

As with other patients undergoing abdominal surgery, the nurse encourages those with an ileostomy to engage in early ambulation. It is important to administer prescribed pain medications as required.

Because these patients lose much fluid in the early postoperative period, an accurate record of fluid intake, urinary output, and fecal discharge is necessary to help gauge the fluid needs of the patient. There may be up to 1 L of fluid lost each day, in addition to expected fluid loss through urine, perspiration, respiration, and other sources. With this loss, sodium and potassium are depleted. The nurse monitors laboratory values and administers electrolyte replacements as prescribed. Fluids are administered IV for 4 to 5 days to replace lost fluids.

Nasogastric suction is also a part of immediate postoperative care, with the tube requiring frequent irrigation as prescribed. The purpose of nasogastric suction is to prevent a buildup of gastric contents. After the tube is removed, the nurse offers sips of clear liquids and gradually progresses the diet. It is important to report nausea and abdominal distention immediately because they may indicate intestinal obstruction.

By the end of the first week, rectal packing is removed. Because this procedure may be uncomfortable, the nurse may administer an analgesic an hour before its removal. After the packing is removed, the perineum is irrigated two or three times daily until full healing takes place.

The patient with a traditional ileostomy cannot establish regular bowel habits because the contents of the ileum are fluid and are discharged continuously. The patient must wear a pouch at all times. Stomal size and pouch size vary initially; the stoma should be rechecked 3 weeks after surgery, when the edema has subsided. The final size and type of appliance is selected in 3 months, after the patient's weight has stabilized and the stoma shrinks to a stable shape.

The location and length of the stoma are significant in the management of the ileostomy by the patient. The surgeon positions the stoma as close to the midline as possible and at a location where even an obese patient with a protruding abdomen can care for it easily. Usually, the ileostomy stoma is about 2.5 cm (1 in) long, which makes it convenient for the attachment of an appliance.

Skin excoriation around the stoma can be a persistent problem. Peristomal skin integrity may be compromised by several factors, such as an allergic reaction to the ostomy appliance, skin barrier, or paste; chemical irritation from the effluent; mechanical injury from the removal of the appliance; and infection. If irritation and yeast growth occur, nystatin powder (Mycostatin) is dusted lightly on the peristomal skin.

Changing an Appliance

A regular schedule for changing the pouch before leakage occurs must be established for those with a traditional ileostomy. The amount of time a person can keep the appliance sealed to the body surface depends on the location of the stoma and on body structure. The usual wearing time is 5 to 7 days. The appliance is emptied every 4 to 6 hours or at the same time the patient empties the bladder. An emptying spout at the bottom of the appliance is closed with a special clip made for this purpose.

Most pouches are disposable and odor-proof. Foods such as spinach and parsley act as deodorizers in the intestinal tract; foods that cause odors include cabbage, onions, and fish. Bismuth subcarbonate tablets, which may be prescribed and taken orally three or four times each day, are effective in reducing odor. Oral diphenoxylate (Lomotil) also can be prescribed to diminish intestinal motility, thereby thickening the stool and assisting in odor control.

Changing an ileostomy appliance also allows for examination of the skin around the stoma, and assists in controlling odor if this becomes a problem. The appliance should be changed at any time that the patient complains of burning or itching under the disk or pain in the area of the stoma; routine changes should be performed early in the morning before breakfast or 2 to 4 hours after a meal, when the bowel is least active. See Box 24-2 for guidelines on changing an ostomy appliance.

Managing Dietary and Fluid Needs

A low-residue diet is followed for the first 6 to 8 weeks. Strained fruits and vegetables are given. These foods are important sources of vitamins A and C. Foods are reintroduced one at a time. The nurse assesses the patient's tolerance for these foods and reminds him or her to chew food thoroughly.

Fluids may be a problem during the summer when fluid lost through perspiration adds to the fluid loss through the ileostomy. Fluids such as Gatorade are helpful in maintaining electrolyte balance.

Preventing Complications

Monitoring for complications is an ongoing activity for the patient with an ileostomy. Peristomal skin irritation, which results from leakage of effluent, is the most common complication of an ileostomy. A drainable pouching system that does not fit well is often the cause. Components of the drainable pouching system include the pouch, a solid skin barrier, and adhesive. The enterostomal therapist typically recommends the appropriate drainable pouching system. The solid skin barrier is the component of this system that is most important in ensuring healthy peristomal skin. Solid skin barriers typically are shaped as rectangular or elliptical wafers and are composed of polymers and hydrocolloids. They protect the skin around the stoma from effluent from the stoma and provide a stable interface between the stoma and the pouch.

Other common complications include fluid volume deficit, stomal stenosis, urinary calculi, and cholelithiasis. Even in the presence of a properly fitted drainable pouching system, loose watery effluent can be problematic, often filling the pouch (every hour or sooner), which can quickly lead to dehydration and electrolyte losses. Supplemental water, sodium, and potassium are administered to prevent hypovolemia and hypokalemia. Antidiarrheal agents or bile salt sequestrants may be administered to decrease the watery effluent.

Stenosis is caused by circular scar tissue that forms at the stoma site. The scar tissue must be released surgically. Urinary calculi may occur in patients with ileostomies and are attributed, at least partly, to dehydration from decreased fluid intake. Intense lower abdominal pain that radiates to the legs, hematuria, and signs of dehydration indicate that the urine should be strained. Fluid intake is encouraged. Sometimes, small stones are passed during urination; otherwise, treatment is necessary to crush or remove the calculi (see Chapter 28).

BOX 24-2 GUIDELINES FOR NURSING CARE

Changing an Ileostomy Appliance

Equipment Needed

- Mild soap
- Clean cloths or towels
- Skin barrier (stoma adhesive, Convatec)
- Cutting guide
- Appliance pouch

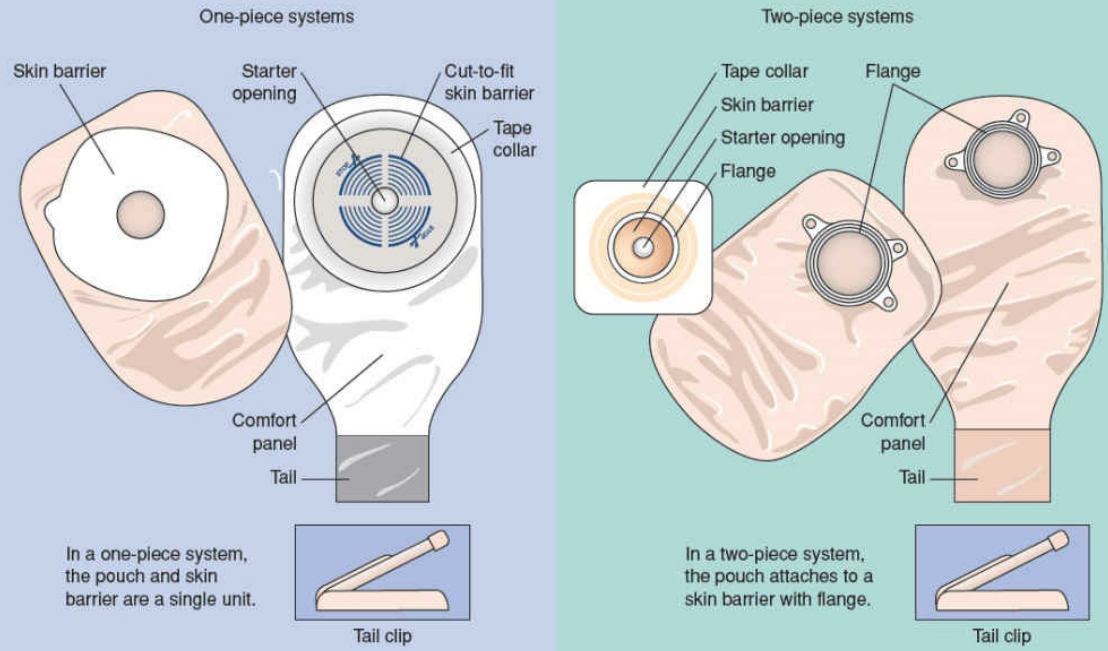
Optional Equipment

- Barrier powder
- Antifungal spray or powder
- Barrier washer

Implementation

NURSING ACTION	RATIONALE
1. Promote patient comfort and involvement in the procedure. a. Have the patient assume a relaxed position. b. Provide privacy. c. Explain details of the procedure. d. Expose the ileostomy area; remove the ileostomy belt (if worn).	1. Providing a relaxed atmosphere and adequate explanations help the patient to become an active participant in the procedure.
2. Remove the appliance. a. Have the patient sit on the toilet or on a chair facing the toilet. A patient who prefers to stand should face the toilet. b. The appliance (pouch) can be removed by gently pushing the skin away from the adhesive.	2. These positions facilitate disposal or drainage.
3. Cleanse the skin: a. Wash the skin gently with a soft cloth moistened with tepid water and mild soap; the patient may prefer to bathe before putting on a clean appliance. b. Rinse the soap and dry the skin thoroughly after cleansing.	3. The patient may shower with or without the pouch. a. Micropore or waterproof tape applied to the sides of the faceplate keeps it secure during bathing. b. Moisture or soap residue interferes with appliance adhesion.

Pouching options



4. Apply appliance: When there is *no* skin irritation: **a.** An appropriate skin barrier is applied to the peristomal skin before the appliance is applied. **b.** Remove cover from adherent surface of disk of disposable plastic appliance and apply directly to the skin. **c.** Press firmly in place for 30 seconds to ensure adherence. When there is skin irritation: **a.** Cleanse the skin thoroughly but gently; pat dry. Apply barrier powder. **b.** If more irritation developed, apply Kenalog spray; blot excess moisture with a cotton pledget, and dust lightly with nystatin (Mycostatin) powder. OR Place the sizing guide directly on the skin around the stoma, leaving as little skin as possible around the stoma uncovered. Then, using the guide, cut the appropriate hole in the disk. At times, the stoma site is irregular; if this is the case, the hole should be cut approximating the stoma site as closely as possible. Apply as an alternative a wafer or barrier (Stomahesive, ConvaTec), which is commercially available. The stomal opening should be the same size as the stoma; use a cutting guide (supplied with appliance as indicated). The wafer is applied directly to the skin. Barrier powder can be used to dry irritated skin before barrier application. **c.** Another alternative is to apply a special barrier washer (e.g., Eakin's Seal). The special barrier adheres well to irritated skin. **d.** Then the pouch is applied to the treated skin. **5.** Check the pouch bottom for closure; use clamp, Velcro closure, or clip provided.	**4.** Many appliances have a built-in skin barrier. The skin should be dried thoroughly before applying the appliance. **a.** Cleansing removes debris and protects irritated skin under the wafer. **b.** The corticosteroid preparation (Kenalog) helps decrease inflammation. The antifungal agent (nystatin) treats those types of infections that are common around stomas. A prescription is required for either medication. A skin barrier is a substance that facilitates healing of excoriated skin. It adheres well even to moist, irritated skin. **c.** A special barrier protects skin from effluent, promotes healing, and helps with adherence. **d.** This allows skin to heal while the appliance is in place. **5.** Proper closure controls leakage.

Cholelithiasis (i.e., gallstones) occurs more commonly in patients with an ileostomy than in the general population because of changes in the absorption of bile acids that occur postoperatively. Spasm of the gallbladder causes severe upper right abdominal pain that can radiate to the back and right shoulder (see Chapter 25).

MASSES IN THE COLON AND RECTUM

A *polyp* is a mass of tissue that protrudes into the lumen of the bowel. Polyps can occur anywhere in the intestinal tract and rectum. They can be classified as neoplastic (i.e., adenomas and carcinomas) or nonneoplastic (i.e., mucosal and hyperplastic).

NONNEOPLASTIC POLYPS

Although most polyps do not develop into invasive neoplasms, they must be identified and followed closely.

Risk Factors

Nonneoplastic polyps, which are benign epithelial growths, are common in the Western world. They occur more commonly in the large intestine than in the small intestine. Adenomatous (benign) polyps are more common in men. The proportion of these polyps arising in the proximal part of the colon increases with age (after 50 years of age). Prevalence rates vary from 25% to 60%, depending on age. Nonneoplastic polyps occur in 80% of the population, and their frequency increases with age.

Clinical Manifestations and Assessment

Clinical manifestations depend on the size of the polyp and the amount of pressure it exerts on intestinal tissue. The most common symptom is rectal bleeding. Lower abdominal pain also may occur. If the polyp is large enough, symptoms of obstruction occur. The diagnosis is based on history and digital rectal examination, barium enema studies, sigmoidoscopy, or colonoscopy.

Medical and Nursing Management

After a polyp is identified, it should be removed. There are several methods: colonoscopy with the use of special equipment (i.e., biopsy forceps and snares), laparoscopy, or colonoscopic excision with laparoscopic visualization. The latter technique enables immediate detection of potential problems and allows laparoscopic resection and repair of the major complications of perforation and bleeding that may occur with polypectomy. Microscopic examination of the polyp then identifies the type of polyp and indicates what further surgery is required, if any.

COLORECTAL CANCER

Tumors of the colon and rectum are relatively common; the colorectal area (the colon and rectum combined) is now the third most common site of new cancer cases and deaths in the United States. Colorectal cancer is the second most common cause of cancer death among men who are 40 to 79 years of age (Siegel, Miller, & Jemal, 2016). Improved screening strategies have helped reduce the number of deaths from colon cancer in recent years. Of the approximately 150,000 people diagnosed each year, fewer than half that number dies annually (American Cancer Society [ACS], 2015).

Early diagnosis and prompt treatment could save almost three of every four people. If the disease is detected and treated at an early stage, the 5-year survival rate is 90%; however, in the more distal stages of disease, the 5-year survival rate is only approximately 13% (ACS, 2015). Most people are asymptomatic for long periods and seek health care only when they notice a change in bowel habits or rectal bleeding. Prevention and early screening are the keys to detection and reduction of mortality rates.

Pathophysiology

Cancer of the colon and rectum is predominantly (95%) adenocarcinoma (i.e., arising from the epithelial lining of the intestine) (ACS, 2015). It may start as a benign polyp but may become malignant, invade and destroy normal tissues, and extend into surrounding structures. Cancer cells may migrate away from the primary tumor and spread to other parts of the body (most often to the liver).

Risk Factors

Colorectal cancer is a disease of Western cultures. The incidence increases with age (the incidence is highest in people over 85 years of age) and is higher in people with a family history of colon cancer and those with IBD or polyps. In men, only the incidence of prostate cancer and lung cancer exceeds that of colorectal cancer. In women, only the incidence of breast and lung cancer exceeds that of colorectal cancer.

Colon cancer in the elderly has been closely associated with dietary carcinogens. High-fiber intake, particularly from fruits and cereals, reduces the risk of colorectal cancer (Kunzmann et al., 2015). Excess dietary fat, high alcohol consumption, and smoking all increase the incidence of colorectal tumors. Physical activity and dietary folate have protective effects (Siegel et al., 2016).

Clinical Manifestations and Assessment

Symptoms are often insidious. Patients with colorectal cancer usually report fatigue, which is caused primarily by iron-deficiency anemia. In early stages, minor changes in bowel patterns and occasional bleeding may occur. The later symptoms reported most commonly by the elderly are abdominal pain, obstruction, tenesmus, and rectal bleeding.

The symptoms are greatly determined by the location of the cancer, the stage of the disease, and the function of the intestinal segment in which it is located. The most common presenting symptom is a change in bowel habits. The passage of blood in the stools is the second most common symptom. Symptoms also may include unexplained anemia, anorexia, weight loss, and fatigue.

The symptoms most commonly associated with right-sided lesions are dull abdominal pain and melena (black, tarry stools). The symptoms most commonly associated with left-sided lesions are those associated with obstruction (abdominal pain and cramping, narrowing stools, constipation, distention), as well as bright red blood in the stool. Symptoms associated with rectal lesions are tenesmus (ineffective, painful straining at stool), rectal pain, the feeling of incomplete evacuation after a bowel movement, alternating constipation and diarrhea, and bloody stool.

Along with an abdominal and rectal examination, the most important diagnostic procedures for cancer of the colon are fecal occult blood testing, barium enema, proctosigmoidoscopy, and colonoscopy (see Chapter 21). The majority of colorectal cancer cases can be identified by colonoscopy with biopsy or cytology smears.

Carcinoembryonic antigen (CEA) studies also may be performed. Although CEA may not be a highly reliable indicator in diagnosing colon cancer because not all lesions secrete CEA, studies show that CEA levels are reliable prognostic predictors. With complete excision of the tumor, the elevated levels of CEA should return to normal within 48 hours. Elevations of CEA at a later date suggest recurrence.

Medical and Nursing Management

The patient with symptoms of intestinal obstruction is treated with IV fluids and nasogastric suction. If there has been significant bleeding, blood component therapy may be required.

Treatment for colorectal cancer depends on the stage of the disease and consists of surgery to remove the tumor, supportive therapy, and adjuvant therapy. Patients who receive some form of adjuvant therapy, which may include chemotherapy, radiation therapy, immunotherapy, or multimodality therapy, typically demonstrate delays in tumor recurrence and increases in survival time.

Radiation therapy is used before, during, and after surgery to shrink the tumor, to achieve better results from surgery, and to reduce the risk of recurrence. For inoperative or unresectable tumors, radiation is used to provide significant relief from symptoms. Intracavitary and implantable devices are used to deliver radiation to the site. The response to adjuvant therapy varies.

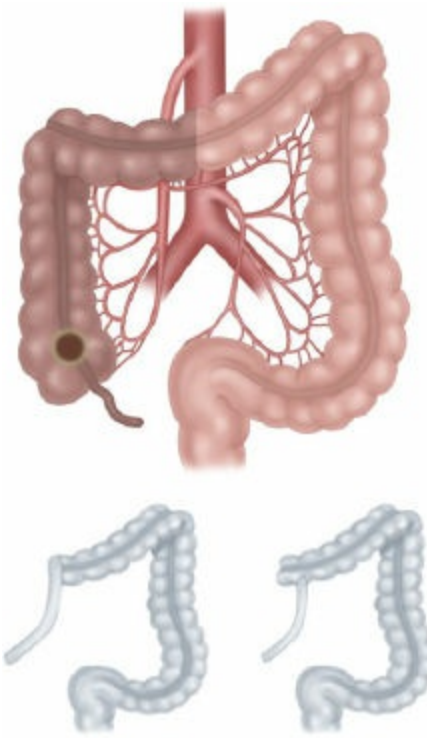
Surgery is the primary treatment for most colon and rectal cancers. It may be curative or palliative. Advances in surgical techniques can enable the patient with cancer to have sphincter-saving devices that restore continuity of the GI tract. The type of surgery recommended depends on the location and size of the tumor. Cancers limited to one site can be removed through the colonoscope. Laparoscopic colotomy with polypectomy minimizes the extent of surgery needed in some cases. A laparoscope is used as a guide in making an incision into the colon; then the tumor mass is excised. Use of the neodymium/yttrium-aluminum-garnet (Nd:YAG) laser has proved effective with some lesions as well.

Surgical procedures include the following:

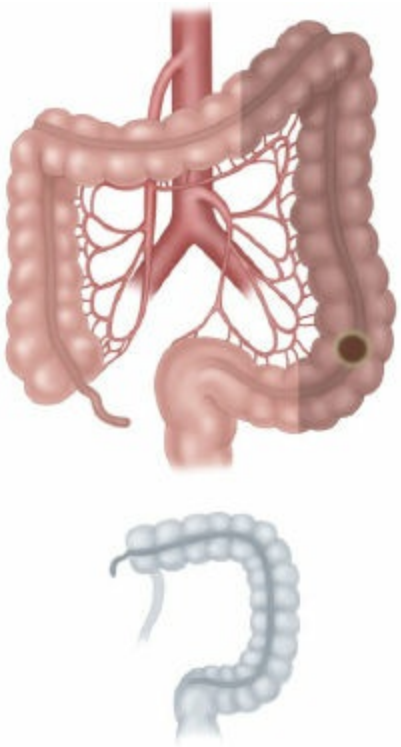
- Segmental resection with anastomosis (i.e., removal of the tumor and portions of the bowel on either side of the growth, as well as the blood vessels and lymphatic nodes) (Fig. 24-9)
- Abdominoperineal resection with permanent sigmoid colostomy (i.e., removal of the tumor and a portion of the sigmoid and all of the rectum and anal sphincter) (Fig. 24-10)
- Temporary colostomy followed by segmental resection and anastomosis and subsequent reanastomosis of the colostomy, allowing initial bowel decompression and bowel preparation before resection
- Permanent colostomy or ileostomy for palliation of unresectable obstructing lesions
- Construction of a coloanal reservoir called a *colonic J pouch*, which is performed in two steps. A temporary loop ileostomy is constructed to divert intestinal flow, and the newly constructed J pouch (made from 6 to 10 cm of colon) is reattached to the anal stump. About 3 months after the initial stage, the ileostomy is reversed and intestinal continuity is restored. The anal sphincter and, therefore, continence are preserved.

A colostomy is the surgical creation of an opening (i.e., stoma) into the colon. It can be created as a temporary or permanent fecal diversion. It allows the drainage or evacuation of

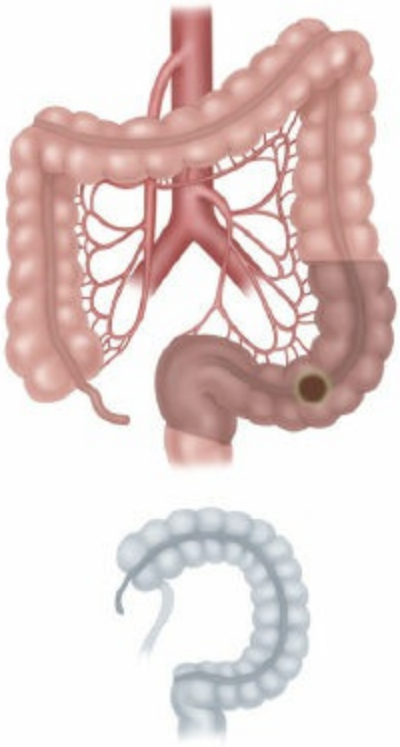
colon contents to the outside of the body. The consistency of the drainage is related to the placement of the colostomy, which is dictated by the location of the tumor and the extent of invasion into surrounding tissues (Fig. 24-11). With improved surgical techniques, colostomies are performed in less than one third of patients with colorectal cancer.



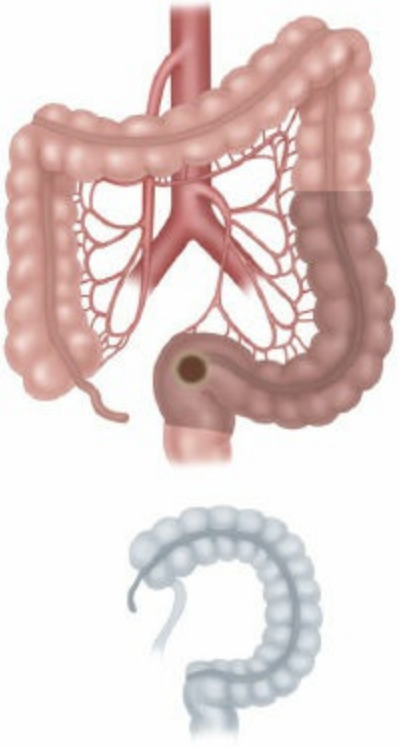
Cecum and lower ascending colon



Descending colon and upper sigmoid



Low sigmoid and upper rectum



Rectal sigmoid resection

FIGURE 24-9 Examples of areas where cancer can occur, the area that is removed, and how the anastomosis is performed (*small diagrams*).

Complications

Tumor growth may cause partial or complete bowel obstruction. Extension of the tumor and ulceration into the surrounding blood vessels result in hemorrhage. Perforation, abscess formation, peritonitis, sepsis, and shock may occur.

The elderly are at increased risk of complications after surgery and may have difficulty managing colostomy care. Some elderly patients may have decreased vision, impaired hearing, and difficulty with fine motor coordination. It may be helpful for patients to handle ostomy equipment and simulate cleaning the peristomal skin and irrigating the stoma before surgery. Skin care is a major concern in older patients with a colostomy because of the skin changes that occur with aging—the epithelial and subcutaneous fatty layers become thin, and the skin is irritated easily. To prevent skin breakdown, special attention is paid to skin cleansing and the proper fit of an appliance. Arteriosclerosis causes decreased blood flow to the wound and stoma site. As a result, transport of nutrients is delayed, and healing time may be prolonged. Some patients have delayed elimination after irrigation because of decreased peristalsis and mucus production. Most patients require 6 months before they feel comfortable with their ostomy care.

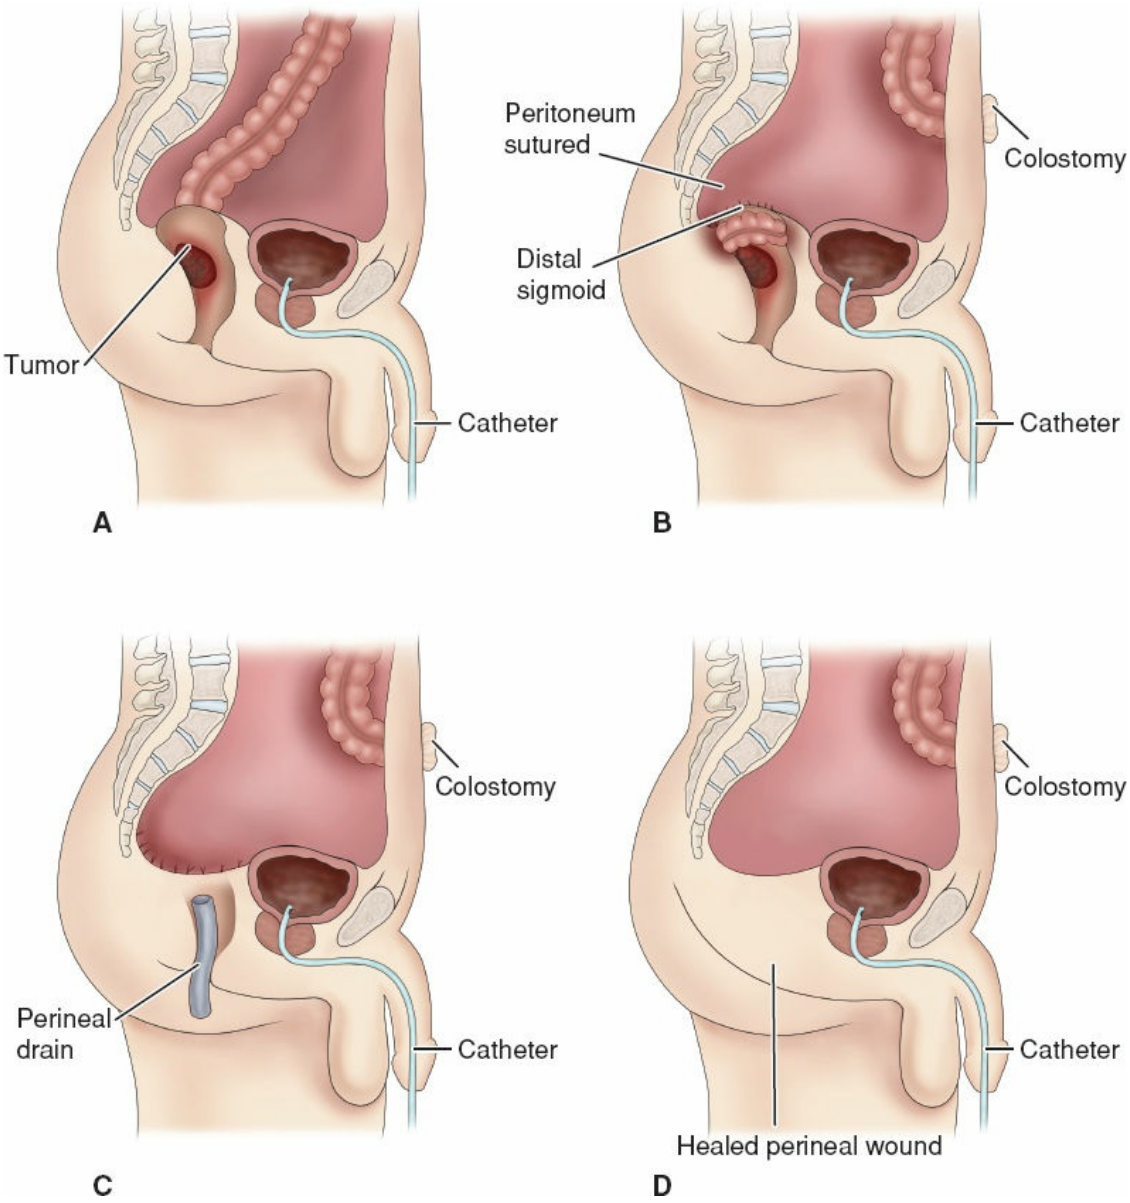


FIGURE 24-10 Abdominoperineal resection for carcinoma of the rectum. A. Prior to surgery. Note tumor in rectum. B. During surgery, the sigmoid is removed and the colostomy is established. The distal bowel is dissected free to a point below the pelvic peritoneum, which is sutured over the closed end of the distal sigmoid and rectum. C. Perineal resection includes removal of the rectum and free portion of the sigmoid from below. A perineal drain is inserted. D. The final result after healing. Note the healed perineal wound and the permanent colostomy.

INTESTINAL OBSTRUCTION

Intestinal obstruction exists when blockage prevents the normal flow of intestinal contents through the intestinal tract. In mechanical obstruction, intraluminal or mural obstructions secondary to pressure on the intestinal wall occur. Examples are intussusception (telescoping of a portion of the intestine within another immediately adjacent portion of intestine), polypoid tumors and neoplasms, stenosis, strictures, adhesions, hernias, and abscesses. Figure 24-12 depicts additional causes of obstruction. In functional obstruction,

intestinal musculature cannot propel the contents along the bowel thereby causing a blockage within the intestine. Examples are amyloidosis, muscular dystrophy, endocrine disorders such as diabetes mellitus, or neurologic disorders such as Parkinson disease. The blockage also can be temporary and the result of the manipulation of the bowel during surgery.

The obstruction can be partial or complete. Its severity depends on the region of bowel affected, the degree to which the lumen is occluded, and especially the degree to which the vascular supply to the bowel wall is disturbed.

Most bowel obstructions occur in the small intestine. Adhesions are the most common cause of small bowel obstruction, followed by hernias and neoplasms. Other causes include intussusception, volvulus (i.e., twisting of the bowel), and paralytic ileus. Most obstructions in the large bowel occur in the sigmoid colon. The most common causes are carcinoma, diverticulitis, inflammatory bowel disorders, and benign tumors. Table 24-6 and Figure 24-12 list mechanical causes of obstruction and describe how they occur.

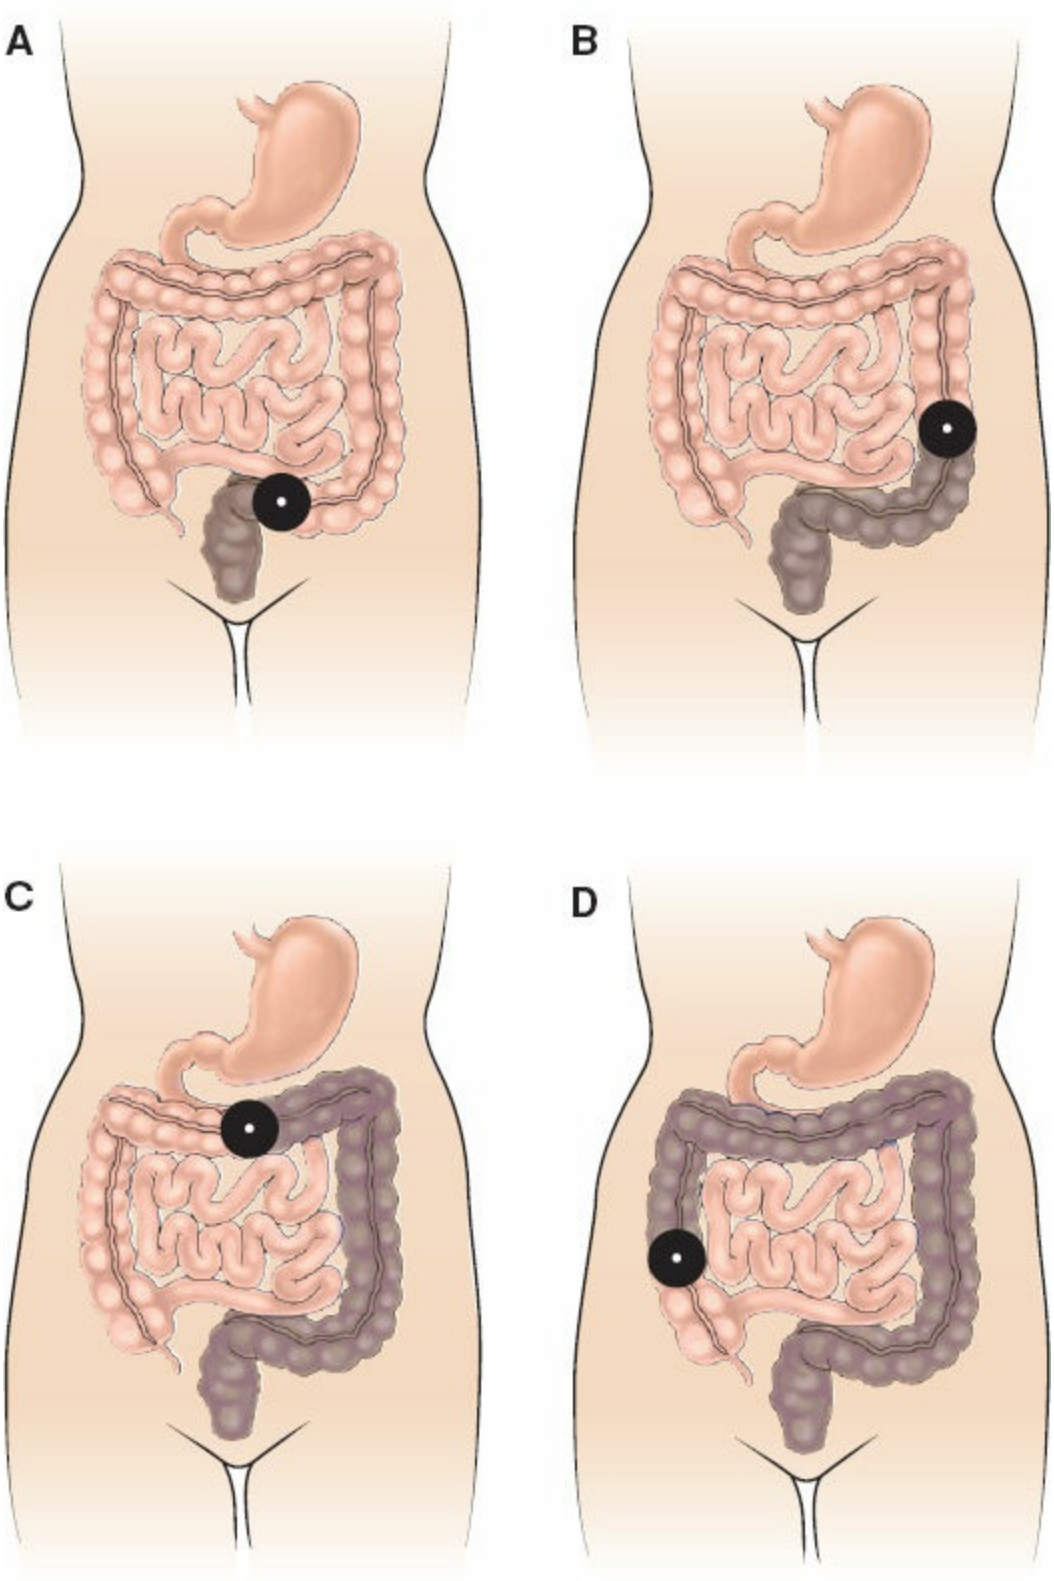

FIGURE 24-11 Placement of permanent colostomies. The nature of the discharge varies with the site. Shaded areas show sections of bowel removed. With a sigmoid colostomy (A), the feces are solid. With a descending colostomy (B), the feces are semiformed. With a transverse colostomy (C), the feces are unformed. With an ascending colostomy (D), the feces are fluid.

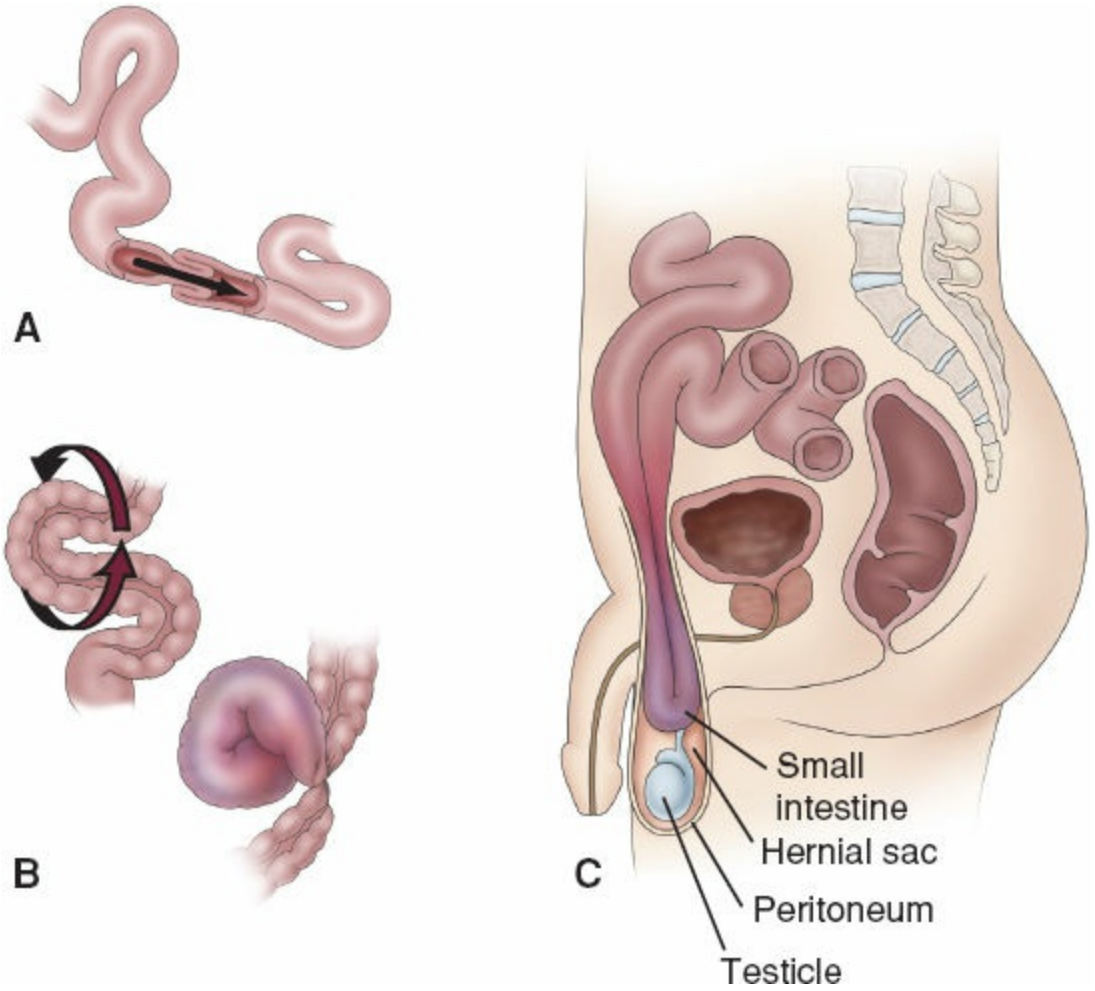

FIGURE 24-12 Three causes of intestinal obstruction. A. Intussusception invagination or shortening of the colon caused by the movement of one segment of bowel into another. B. Volvulus of the sigmoid colon; the twist is counterclockwise in most cases. Note the edematous bowel. C. Hernia (inguinal). The sac of the hernia is a continuation of the peritoneum of the abdomen. The hernial contents are intestine, omentum, or other abdominal contents that pass through the hernial opening into the hernial sac.

SMALL BOWEL OBSTRUCTION

Pathophysiology

Intestinal contents, fluid, and gas accumulate above the intestinal obstruction. The abdominal distention and retention of fluid reduce the absorption of fluids and stimulate more gastric secretion. Increases in intestinal lumen pressure causes occlusion of capillary blood flow and compromise of venous return and arterial flow. This causes edema, congestion, necrosis, and eventual rupture or perforation of the intestinal wall, with resultant peritonitis.

TABLE 24-6 Mechanical Causes of Intestinal Obstruction

Cause	Course of Events	Result
Adhesions	Loops of intestine become adherent to areas that heal slowly or scar after abdominal surgery.	After surgery, adhesions produce a kinking of an intestinal loop.
Intussusception	One part of the intestine slips into another part located below it (like a telescope shortening).	The intestinal lumen becomes narrowed.
Volvulus	Bowel twists and turns on itself.	Intestinal lumen becomes obstructed. Gas and fluid accumulate in the trapped bowel.
Hernia	Protrusion of intestine through a weakened area in the abdominal muscle or wall.	Intestinal flow may be obstructed completely. Blood flow to the area may be obstructed as well.
Tumor	A tumor that exists within the wall of the intestine extends into the intestinal lumen, or a tumor outside the intestine causes pressure on the wall of the intestine.	Intestinal lumen becomes partially obstructed; if the tumor is not removed, complete obstruction results.

Reflux vomiting may be caused by abdominal distention. Vomiting results in loss of hydrochloric acid (HCl) and potassium from the stomach, leading to reduction of chlorides and potassium in the blood and to metabolic alkalosis. Dehydration develops from loss of water and sodium. With acute fluid losses, hypovolemic shock may occur.

Clinical Manifestations and Assessment

The initial symptom is usually crampy pain that is wavelike and colicky. The patient may pass blood and mucus but no fecal matter and no flatus. Vomiting occurs. If the obstruction is complete, the peristaltic waves initially become extremely vigorous and eventually assume a reverse direction, with the intestinal contents propelled toward the mouth instead of toward the rectum. If the obstruction is in the ileum, fecal vomiting takes place. First, the patient vomits the stomach contents, then the bile-stained contents of the duodenum and the jejunum, and finally, with each paroxysm of pain, the darker, fecal-like contents of the ileum. The signs of dehydration become evident: intense thirst, drowsiness, generalized malaise, aching, and a parched tongue and mucous membranes. The abdomen becomes distended. The lower the obstruction is in the GI tract, the more marked the abdominal distention. If the obstruction continues uncorrected, hypovolemic shock occurs from dehydration and loss of plasma volume.

Diagnosis is based on the symptoms described previously and on imaging studies. Abdominal x-ray and CT findings include abnormal quantities of gas, fluid, or both in the intestines. Laboratory studies (i.e., electrolyte studies and a CBC) reveal a picture of dehydration, loss of plasma volume, and possible infection.

Medical and Nursing Management

Decompression of the bowel through a nasogastric tube (see Chapter 22) is successful in most cases. When the bowel is obstructed completely, the possibility of strangulation warrants surgical intervention. Before surgery, IV therapy is necessary to replace the depleted water, sodium, chloride, and potassium.

The surgical treatment of intestinal obstruction depends largely on the cause of the obstruction. In the most common causes of obstruction, such as hernia and adhesions, the surgical procedure involves repairing the hernia or dividing the adhesion to which the intestine is attached. In some instances, the portion of affected bowel may be removed and an anastomosis performed. The complexity of the surgical procedure for intestinal obstruction depends on the duration of the obstruction and the condition of the intestine.

Nursing management of the nonsurgical patient with a small bowel obstruction includes maintaining the function of the nasogastric tube, assessing and measuring the nasogastric output, assessing for fluid and electrolyte imbalance, monitoring nutritional status, and assessing improvement (e.g., return of normal bowel sounds, decreased abdominal distention, subjective improvement in abdominal pain and tenderness, passage of flatus or stool). The nurse reports discrepancies in intake and output, worsening of pain or abdominal distention, and increased nasogastric output. If the patient's condition does not improve, the nurse prepares him or her for surgery. The exact nature of the surgery depends on the cause of the obstruction. Nursing care of the patient after surgical repair of a small bowel obstruction is similar to that for other abdominal surgeries (see Chapter 23).

Unfolding Patient Stories: Stan Checketts • Part 2

Recall from Chapter 7 Stan Checketts, who arrived in the emergency department with severe abdominal pain. He is diagnosed with a small bowel obstruction. He is NPO and has a nasogastric (NG) tube placed to low intermittent suction. Describe the steps of a focused GI assessment performed by the nurse. How would the nurse explain the rationale for an NG tube and NPO status? What are specific assessments and nursing care responsibilities for an NG tube?

Care for Stan and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

LARGE BOWEL OBSTRUCTION

Pathophysiology

As in small bowel obstruction, large bowel obstruction results in an accumulation of intestinal contents, fluid, and gas proximal to the obstruction. Obstruction in the large bowel can lead to severe distention and perforation unless some gas and fluid can flow back through the ileal valve. Large bowel obstruction, even if complete, may be without catastrophic issue if the blood supply to the colon is not disturbed. However, if the blood supply is cut off, intestinal strangulation and necrosis (i.e., tissue death) occur; this condition is life threatening. In the large intestine, dehydration occurs more slowly than in the small intestine because the colon can absorb its fluid contents and can distend to a size considerably beyond its normal full capacity.

Adenocarcinoid tumors account for the majority of large bowel obstructions. Most tumors occur beyond the splenic flexure, making them accessible with a flexible sigmoidoscope.

Clinical Manifestations and Assessment

Large bowel obstruction differs clinically from small bowel obstruction in that the symptoms develop and progress relatively slowly. In patients with obstruction in the sigmoid colon or the rectum, constipation may be the only symptom for months. The shape of the stool is altered as it passes the obstruction that is gradually increasing in size. Blood in the stool may result in iron-deficiency anemia. The patient may experience weakness, weight loss, and anorexia. Eventually, the abdomen becomes markedly distended, loops of large bowel become visibly outlined through the abdominal wall, and the patient has crampy lower abdominal pain. Finally, fecal vomiting develops. Symptoms of shock may occur.

Diagnosis is based on symptoms and on imaging studies. Abdominal x-ray and abdominal CT or MRI findings reveal a distended colon and pinpoint the site of the obstruction. Barium studies are contraindicated because of risk of perforation.

Medical and Nursing Management

Restoration of intravascular volume, correction of electrolyte abnormalities, and nasogastric aspiration and decompression are instituted immediately. A colonoscopy may be performed to untwist and decompress the bowel. A cecostomy, in which a surgical opening is made into the cecum, may be performed in patients who are poor surgical risks and urgently need relief from the obstruction. The procedure provides an outlet for releasing gas and a small amount of drainage. A rectal tube may be used to decompress an area that is lower in the bowel. However, the usual treatment is surgical resection to remove the obstructing lesion. A temporary or permanent colostomy may be necessary. An ileoanal anastomosis may be performed if it is necessary to remove the entire large bowel.

The nurse's role is to monitor the patient for symptoms that indicate that the intestinal obstruction is worsening and to provide emotional support and comfort. The nurse administers IV fluids and electrolytes as prescribed. If the patient's condition does not respond to nonsurgical treatment, the nurse prepares the patient for surgery. This preparation includes preoperative teaching as the patient's condition indicates. After surgery, general abdominal wound care and routine postoperative nursing care are provided.

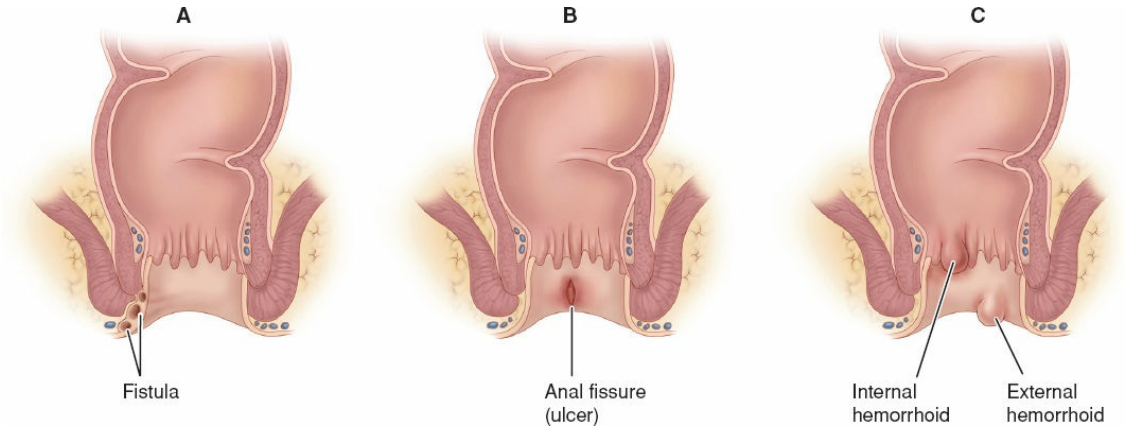

FIGURE 24-13 Various types of anal lesions. A. Fistula. B. Fissure. C. External and internal hemorrhoids.

DISEASES OF THE ANORECTUM

Diseases of the anorectum include anal fistulas and fissures, hemorrhoids, sexually transmitted anorectal diseases, and pilonidal cysts. Nursing management of these conditions is discussed in Box 24-3.

ANAL FISTULA

An anal fistula is a tiny, tubular, fibrous tract that extends into the anal canal from an opening located beside the anus (Fig. 24-13A). Fistulas usually result from an infection. They also may develop from trauma, fissures, or regional enteritis. Pus or stool may leak constantly from the cutaneous opening. Other symptoms may be the passage of flatus or feces from the vagina or bladder, depending on the fistula tract. Untreated fistulas may cause systemic infection with related symptoms.

Surgery is always recommended because few fistulas heal spontaneously. A fistulectomy (i.e., excision of the fistulous tract) is the recommended surgical procedure. The lower bowel is evacuated thoroughly with several prescribed enemas. The fistula is dissected out or laid open by an incision from its rectal opening to its outlet. The wound is packed with gauze.

ANAL FISSURE

An anal fissure is a longitudinal tear or ulceration in the lining of the anal canal (see Fig. 24-13B). Usually fissures are caused by the trauma of passing a large, firm stool or from persistent tightening of the anal canal because of stress and anxiety (leading to constipation). Other causes include childbirth, trauma, and overuse of laxatives.

BOX 24-3 Nursing Management of Anorectal Disorders

Relieving Constipation

The nurse encourages intake of at least 2 L of water daily to provide adequate hydration; in addition, the nurse recommends high-fiber foods to promote bulk in the stool and to make it easier to pass fecal matter through the rectum. In patients with pre-existing cardiopulmonary or kidney disease, consultation with the patient's provider regarding fluid intake should occur. Bulk laxatives such as psyllium (Metamucil) and stool softeners (e.g., docusate [Colace]) are administered as prescribed. The patient is advised to set aside a time for bowel movements and to heed the urge to defecate as promptly as possible. It may be helpful to have the patient perform relaxation exercises before defecating to relax the abdominal and perineal muscles, which may be constricted or in spasm. Administering an analgesic before a bowel movement is beneficial.

Reducing Anxiety

Patients facing rectal surgery may be upset and irritable because of discomfort, pain, and embarrassment. The nurse identifies specific psychosocial needs and individualizes the plan of care. The nurse maintains the patient's privacy while providing care and limits visitors, if the patient desires. Soiled dressings are removed from the room promptly to prevent unpleasant odors; room deodorizers may be needed if dressings are foul smelling.

Relieving Pain

During the first 24 hours after rectal surgery, painful spasms of the sphincter and perineal muscles may occur. Control of pain is a prime consideration. The patient is encouraged to assume a comfortable position. Flotation pads under the buttocks when sitting help decrease the pain, as may ice and analgesic ointments. Warm compresses may promote circulation and soothe irritated tissues. Sitz baths taken three or four times each day can relieve soreness and pain by relaxing sphincter spasm. Twenty-four hours after surgery, topical anesthetic agents may be beneficial in relieving local irritation and soreness. Medications may include topical anesthetics (i.e., suppositories), astringents, antiseptics, tranquilizers, and antiemetics. Patients are more compliant and less apprehensive if they are free of pain.

Wet dressings saturated with equal parts of cold water and witch hazel help relieve

edema. When wet compresses are being used continuously, petrolatum is applied around the anal area to prevent skin maceration. The patient is instructed to assume a prone position at intervals because this position reduces edema of the tissue.

Promoting Urinary Elimination

Voiding may be a problem after surgery because of a reflex spasm of the sphincter at the outlet of the bladder and a certain amount of muscle guarding from apprehension and pain. The nurse tries all methods to encourage voluntary voiding (i.e., increasing fluid intake, listening to running water, and pouring warm water over the urinary meatus) before resorting to catheterization. After rectal surgery, urinary output is monitored closely.

Monitoring and Managing Complications

The operative site is examined frequently for rectal bleeding. The nurse assesses the patient for systemic indicators of excessive bleeding (i.e., tachycardia, hypotension, restlessness, and thirst). After hemorrhoidectomy, hemorrhage may occur from the veins that were cut. If a tube has been inserted through the sphincter after surgery, blood may be visible on the dressings. If bleeding is obvious, direct pressure is applied to the area, and the surgeon is notified. It is important to avoid using moist heat because it encourages vessel dilation and bleeding.

Promoting Home and Community-Based Care

Teaching Patients Self-Care

Most patients with anorectal conditions are not hospitalized. Those who undergo surgical procedures to correct the condition often are discharged directly from the outpatient surgical center. If they are hospitalized, it is for a short time, usually only 24 hours.

The nurse instructs the patient to keep the perianal area as clean as possible by gently cleansing with warm water and then drying with absorbent cotton wipes. The patient should avoid rubbing the area with toilet tissue. Instructions are provided about how to take a sitz bath and how to test the temperature of the water.

Continuing Care

Sitz baths should follow each bowel movement for 1–2 weeks after surgery. The nurse encourages the patient to respond quickly to the urge to defecate to prevent constipation. The diet is modified to increase fluids and fiber. Moderate exercise is encouraged, and the patient is taught about the prescribed diet, the significance of proper eating habits and exercise, and the laxatives that can be taken safely.

Extremely painful defecation, burning, and bleeding characterize fissures. Bright red blood may be seen on the toilet tissue after a bowel movement.

Most fissures heal if treated by conservative measures, which include dietary modification with addition of fiber supplements, stool softeners and bulk agents, an

increase in water intake, sitz baths, and emollient suppositories. A suppository combining an anesthetic with a corticosteroid helps relieve the discomfort. Anal dilation under anesthesia may be required.

If fissures do not respond to conservative treatment, surgery is indicated. Most surgeons consider the procedure of choice to be the lateral internal sphincterotomy with excision of the fissure.

HEMORRHOIDS

Hemorrhoids are dilated portions of veins in the anal canal. They are very common: by 50 years of age, about 50% of people have hemorrhoids, although the prevalence is hard to estimate as many people do not report having hemorrhoids and rely on over-the-counter treatments (Ganz, 2013; NIH, U.S. Department of Health and Human Services, 2009). Shearing of the mucosa during defecation results in the sliding of the structures in the wall of the anal canal, including the hemorrhoidal and vascular tissues. Increased pressure in the hemorrhoidal tissue due to pregnancy may initiate hemorrhoids or aggravate existing ones. Hemorrhoids are classified as one of two types: those above the internal sphincter are called *internal hemorrhoids*, and those appearing outside the external sphincter are called *external hemorrhoids* (see Fig. 24-13C).

Hemorrhoids cause itching and pain and are the most common cause of bright red bleeding with defecation. External hemorrhoids are associated with severe pain from the inflammation and edema caused by thrombosis (i.e., clotting of blood within the hemorrhoid). This may lead to ischemia of the area and eventual necrosis. Internal hemorrhoids usually are not painful until they bleed or prolapse when they become enlarged.

Hemorrhoid symptoms and discomfort can be relieved by good personal hygiene and by avoiding excessive straining during defecation. A high-residue diet that contains fruit and bran along with an increased fluid intake may be all the treatment necessary to promote the passage of soft, bulky stools to prevent straining. If this treatment is not successful, the addition of hydrophilic bulk-forming agents such as psyllium (Metamucil) may help. Warm compresses, sitz baths, analgesic ointments and suppositories, astringents (e.g., witch hazel), and bed rest allow the engorgement to subside.

Nursing Alert
In addition to increasing fiber and good personal hygiene, light exercise should be included in patient teaching in order to help improve peristalsis and improve defecation.

There are several types of nonsurgical treatments for hemorrhoids. Infrared photocoagulation, bipolar diathermy, and laser therapy are used to affix the mucosa to the underlying muscle. Injection of sclerosing agents is also effective for small, bleeding hemorrhoids. These procedures help prevent prolapse.

A conservative surgical treatment of internal hemorrhoids is the rubber-band ligation procedure. The hemorrhoid is visualized through the anoscope, and its proximal portion above the mucocutaneous lines is grasped with an instrument. Then a small rubber band is slipped over the hemorrhoid. Tissue distal to the rubber band becomes necrotic after several days and sloughs off. Fibrosis occurs; the result is that the lower anal mucosa is drawn up and adheres to the underlying muscle. Although this treatment has been satisfactory for some patients, it has proven painful for others and may cause secondary hemorrhage. It also has been known to cause perianal infection.

Cryosurgical hemorrhoidectomy, another method for removing hemorrhoids, involves

freezing the hemorrhoid for a sufficient time to cause necrosis. Although it is relatively painless, this procedure is not used widely because the discharge is very foul smelling and wound healing is prolonged. The Nd:YAG laser is useful in excising hemorrhoids, particularly external hemorrhoidal tags. The treatment is quick and relatively painless. Hemorrhage and abscess are rare postoperative complications.

The previously described methods of treating hemorrhoids are not effective for advanced thrombosed veins, which must be treated by more extensive surgery. Hemorrhoidectomy, or surgical excision, can be performed to remove all the redundant tissue involved in the process. During surgery, usually the rectal sphincter is dilated digitally and the hemorrhoids are removed with a clamp and cautery or are ligated and then excised. After the surgical procedures are completed, a small tube may be inserted through the sphincter to permit the escape of flatus and blood; pieces of Gelfoam or Oxycel gauze may be placed over the anal wounds.

SEXUALLY TRANSMITTED ANORECTAL DISEASES

Three infectious syndromes that are related to sexually transmitted infections (STIs) have been identified: proctitis, proctocolitis, and enteritis. Proctitis involves the rectum. It is commonly associated with recent anal-receptive intercourse with an infected partner. Symptoms include a mucopurulent discharge or bleeding, pain in the area, and diarrhea. The pathogens most frequently involved are *Neisseria gonorrhoeae, Chlamydia,* herpes simplex virus, and *Treponema pallidum.* Proctocolitis involves the rectum and lowest portion of the descending colon. The most common pathogens causing proctocolitis are *Campylobacter, Shigella, Entamoeba histolytica,* and *Chlamydia trachomatis*. Symptoms are similar to proctitis but also may include watery or bloody diarrhea, cramps, and abdominal tenderness. Enteritis involves more of the descending colon, and symptoms include watery, bloody diarrhea; abdominal pain; and weight loss. The most common pathogens causing enteritis are *E. histolytica, Giardia lamblia, Shigella,* and *Campylobacter.*

Sigmoidoscopy is performed to identify portions of the anorectum involved. Samples are taken with rectal swabs, and cultures are obtained to identify the pathogens involved. Antibiotics (i.e., cefixime [Suprax], doxycycline [Vibramycin], and penicillin G) are the treatment of choice for bacterial infections. Acyclovir [Zovirax] is given to patients with viral infections. Antiamebic therapy (i.e., metronidazole [Flagyl]) is appropriate for infections with *E. histolytica* and *G. lamblia.* Ciprofloxacin (Cipro) is effective for *Shigella.* The antibiotics erythromycin (E-Mycin) and ciprofloxacin are the treatment of choice for *Campylobacter* infection.

PILONIDAL SINUS OR CYST

A pilonidal sinus or cyst is found in the intergluteal cleft on the posterior surface of the lower sacrum (Fig. 24-14). Current theories suggest that it results from local trauma, causing the penetration of hairs into the epithelium and subcutaneous tissue. It also may be formed congenitally by an infolding of epithelial tissue beneath the skin, which may communicate with the skin surface through one or several small sinus openings. Hair frequently is seen protruding from these openings, and this gives the cyst its name, *pilonidal* (i.e., a nest of hair). The cysts rarely cause symptoms until adolescence or early adult life, when infection produces an irritating drainage or an abscess. Perspiration and friction easily irritate this area.

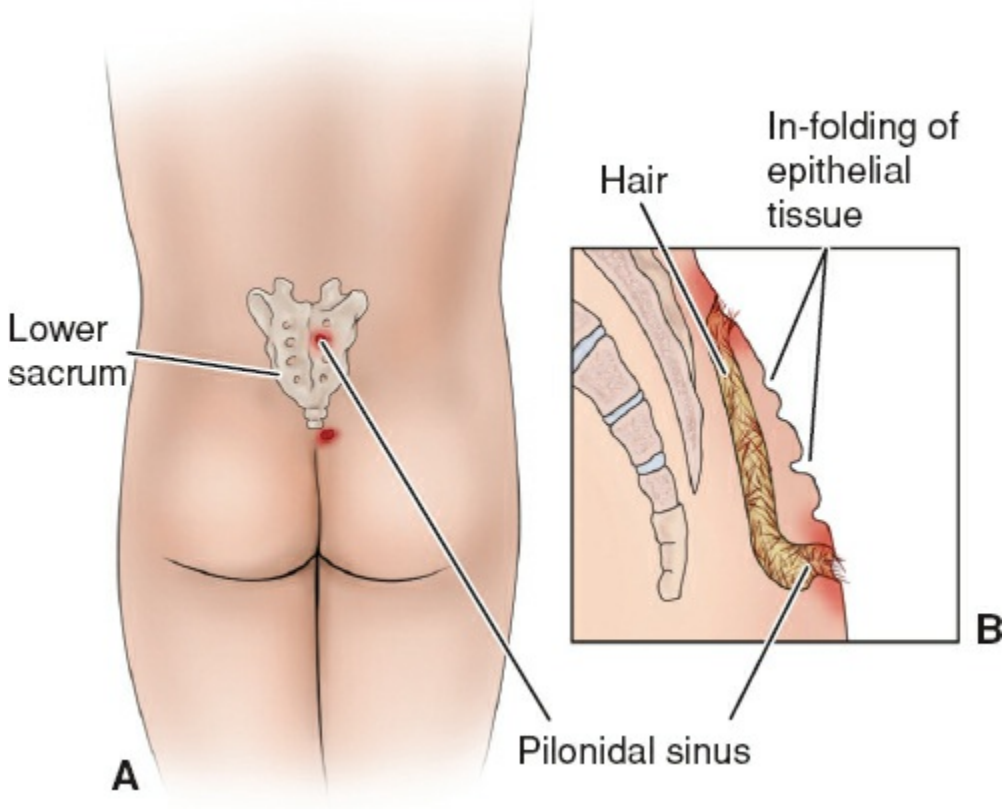

FIGURE 24-14 A. Pilonidal sinus on lower sacrum about 5 cm (2 in) above the anus in the intergluteal cleft. B. Hair particles emerge from the sinus tract, and localized indentations (pits) can appear on the skin near the sinus openings.

In the early stages of the inflammation, the infection may be controlled by antibiotic therapy, but after an abscess has formed, surgery is indicated. The abscess is incised and drained under local anesthesia. After the acute process resolves, further surgery is performed to excise the cyst and the secondary sinus tracts. The wound is allowed to heal by granulation. Gauze dressings are placed in the wound to keep its edges separated while healing occurs.

CHAPTER REVIEW

Critical Thinking Exercises

1. Discuss the antibiotic choices for spontaneous bacterial peritonitis using the current evidence-based practice.
2. Compare and contrast the pathophysiologic differences between Crohn disease and ulcerative colitis in their presentation, course of disease, and treatment regimens.

NCLEX-Style Review Questions

1. A patient returns to his room following a diagnostic colonoscopy after radiologic evidence of diverticulosis. He reports an increase in abdominal pain, fever, and chills. Which clinical condition is most concerning to the nurse?
   a. Colon cancer
   b. Hemorrhoids
   c. Bowel perforation
   d. Anal fissure
2. A patient is complaining of right lower quadrant pain, fever, and decreased appetite. What does the nurse suspect is the most likely cause?
   a. Diverticulitis
   b. Appendicitis
   c. Small bowel obstruction
   d. Sigmoid colon cancer
3. A patient complains of abdominal pain unrelieved by defecation, that typically occurs after meals along with diarrhea. What does the nurse recognize as the most likely diagnosis?
   a. Ulcerative colitis
   b. Regional enteritis
   c. Cholecystitis
   d. Diverticulosis
4. A patient complains of abdominal pain and distention, fever, tachycardia, and diaphoresis. An abdominal x-ray shows free air under the diaphragm. The emergency department nurse should suspect which condition?
   a. Intestinal obstruction
   b. Malabsorption
   c. Intestinal perforation
   d. Acute cholelithiasis
5. A patient has a bowel perforation from a recent surgery and now has been diagnosed with peritonitis. The patient has hypoactive bowel sounds, a temperature of 100.5°F, and an elevated WBC count. What is the most serious potential complication of peritonitis for which the nurse should monitor?

a. Nausea
b. Diarrhea
c. Sepsis
d. Abdominal tenderness

CHAPTER 25

Nursing Management: Patients with Hepatic and Biliary Disorders

Honore Kotler

Learning Objectives

After reading this chapter, you will be able to:

1. Relate jaundice, portal hypertension, ascites, varices, nutritional deficiencies, and hepatic coma to pathophysiologic alterations of the liver.
2. Describe the medical, surgical, and nursing management of patients with esophageal varices.
3. Compare the various types of hepatitis and their causes, prevention, clinical manifestations, management, prognosis, and home health care needs.
4. Discuss medical and nursing management of patients with cancer of the liver.
5. Describe the postoperative nursing care of the patient undergoing liver transplantation.
6. Discuss management of cholelithiasis.
7. Differentiate between acute and chronic pancreatitis.
8. Discuss nursing management of patients with acute pancreatitis.

Liver function is complex, and liver dysfunction affects all body systems. Liver disorders are common and may result from a virus, exposure to toxic substances such as alcohol, or tumors. Disorders of the biliary tract and pancreas also are common and include gallbladder stones and pancreatic dysfunction. An understanding of how biliary tract disorders are closely linked with liver disease is necessary to adequately care for patients.

HEPATIC DISORDERS

Understanding and managing liver disorders requires expert clinical assessment and management skills. Box 25-1 highlights important considerations for hepatic assessment.

MANIFESTATIONS OF HEPATIC DYSFUNCTION

JAUNDICE

Yellowing of the skin and sclerae of the eyes are caused by impairment of the liver's ability to metabolize and secrete bilirubin. Jaundice is apparent when the serum bilirubin level exceeds 3 mg/dL. Elevations of serum bilirubin levels can result from either acute or chronic liver injury. The differential diagnosis of jaundice can result from the following causes:

- Hepatocellular jaundice caused by viral hepatitis, hepatotoxins (including drugs, alcohol), metabolic disorders, ischemia, autoimmune hepatitis, or pregnancy
- Obstructive jaundice caused by obstruction of the bile ducts; gallstones; inflammation of bile ducts caused by primary sclerosing cholangitis, biliary strictures, malignancies of the biliary system, pancreatic cancer, liver cancer, or pancreatitis
- Hemolytic jaundice caused by increased production of bilirubin due to hemolysis, hematologic disorders, resorption of a hematoma, or multiple transfusions
- Hereditary hyperbilirubinemia caused by the inherited disorders of bilirubin metabolism, including various syndromes, some of which may require transplantation

PORTAL HYPERTENSION

Portal hypertension is caused by increased resistance to blood flow through the liver and increased blood flow due to vasodilatation in the splanchnic circulation (see Fig. 25-1). The two major complications of portal hypertension are ascites and gastroesophageal varices (discussed below) (Garcia-Tso, 2016).

BOX 25-1 Review of Hepatic Assessment

The initial presentation of a patient with liver disease varies greatly and can range from elevated liver enzymes on routine screening with no clinical signs or symptoms of disease to the patient who presents in liver failure with jaundice, hepatic coma, or esophageal bleeding. A comprehensive and complete health history is critical to determine exposure to hepatoxic substances (including alcohol) or infectious agents causing liver dysfunction and to distinguish between acute and chronic hepatic dysfunction.

Health History Findings

Common Symptoms

- General: Lethargy, weakness, fatigue, fever, jaundice, pruritus (itching)
- Neurologic: Changes in mental acuity, personality changes, sleep disturbances,

confusion, and outright coma in advanced chronic liver disease or acute failure

- Cardiopulmonary: Dyspnea resulting from increased fluid retention
- GI: Abdominal pain, increasing abdominal girth, anorexia, nausea, vomiting, hematemesis (vomiting blood), melena (black, tarry stool), hematochezia (stool that contains blood)
- Hematologic/Circulatory: Increased bruising, spontaneous bleeding, dependent and or/pedal edema
- Endocrine: Decreased libido in both men and women

Past Medical History

A prior history of inflammatory bowel disease or ulcerative colitis may lead to the diagnosis of primary sclerosing cholangitis (inflammation of the bile ducts). Chronic liver disease is commonly caused by alcohol and viruses, such as hepatitis B or C. Frequently patients with nonalcoholic fatty liver disease (NAFLD) may have prior medical history of diabetes, hyperlipidemia, and obesity.

Family History

Wilson disease, hemochromatosis, and autoimmune liver disease are genetically based. A positive family history of hepatitis B may indicate vertical transmission (Greenberger, 2012).

Social History

- *Lifestyle:* Current and prior drug use (i.e., IV drug abuse, inhalation of drugs), sexual practices, tattoos, piercings, blood transfusions, needlestick injury, shared razors, toothbrushes
- *Occupational:* Exposure to toxins in workplaces; health care worker exposure to patients in trauma areas, operating rooms, Hemodialysis unit or Center
- *Travel history:* Recent travel to endemic areas such as Mexico, Africa, India, or Latin America with ingestion of contaminated food or water, and raw shellfish
- *Alcohol use:* Information regarding current and prior alcohol use should be obtained from both patient and family (i.e., amount of alcohol ingested daily). Intake of 60 g/day for men and 30 g/day for women (10 g of alcohol is equivalent to 1-oz bourbon, or 12-oz beer, or 4-oz red wine) is sufficient to cause liver injury. The impact of alcohol-induced liver injury or disease is increased in the presence of other risk factors, such as hepatitis C (Greenberger, 2012).
- *Medications:* Review all prescription medications, over-the-counter, herbal supplements or home remedies, and intake of vitamins (especially vitamin A). Medications are frequent culprits in acute hepatic dysfunction and may lead to fulminant hepatic failure (e.g., acetaminophen overdose).

Physical Examination Findings

- *Integumentary and oral:* Jaundice, ecchymosis, spider angiomas and palmar erythema, scleral icterus or yellowing of the sclerae, leukonychia of the nails (white spots on nails), and clubbing of the fingers
- *Oral:* Hepatic fetor, a sweet, mildly fecal breath odor associated with encephalopathy
- *Neurologic:* Impairment of the patient's neurologic or cognitive status (slurred speech, confusion, poor recall, or slowed responses)
- *Musculoskeletal:* Muscle wasting; tremors or asterixis (flapping of the hands when wrists dorsiflexed) with altered mental status indicate hepatic encephalopathy.
- *Abdominal:* Signs of abdominal distention indicating ascites, or prominent dilated veins visible through the skin. Umbilical hernia or ventral hernias also may be observed. The patient with liver disease may also show striae, excoriations, or petechiae of the abdominal skin. Palpation of the liver is important to determine its size, shape, and consistency, and percussion is necessary to assess for ascites. The normal liver has a sharp, smooth edge and is firm, but not hard, with a nonpalpable left lobe. Presence of an enlarged liver indicates liver disease (Greenberger, 2012).
- *Other:* Pitting edema of the lower extremities; males may demonstrate gynecomastia and testicular atrophy (Greenberger, 2012).

Diagnostic Evaluation

Diagnostic evaluation includes liver biopsy, liver function tests, and ultrasound (see Chapter 21).

ASCITES

In ascites, fluid accumulates in the peritoneal cavity. Increased blood flow in the veins draining the portal system results in dilation and the development of varicose veins.

Pathophysiology

The mechanisms responsible for the development of ascites are not completely understood. Portal hypertension and the resulting increase in capillary pressure and obstruction of venous blood flow through the damaged liver are contributing factors. The vasodilation that occurs in the splanchnic circulation is also a suspected causative factor. The failure of the liver to metabolize aldosterone increases sodium and water retention by the kidney. Sodium and water retention, increased intravascular fluid volume, increased lymphatic flow, and decreased synthesis of albumin by the damaged liver all contribute to the movement of fluid from the vascular system into the peritoneal space. The process becomes self-perpetuating as loss of fluid into the peritoneal space causes further sodium and water retention by the kidney in an effort to maintain the vascular fluid volume. As a result of liver damage, large amounts of albumin-rich fluid, 15 L or more, may accumulate in the peritoneal cavity as ascites (Runyon, 2013). Figure 25-2 illustrates the pathogenesis of ascites.

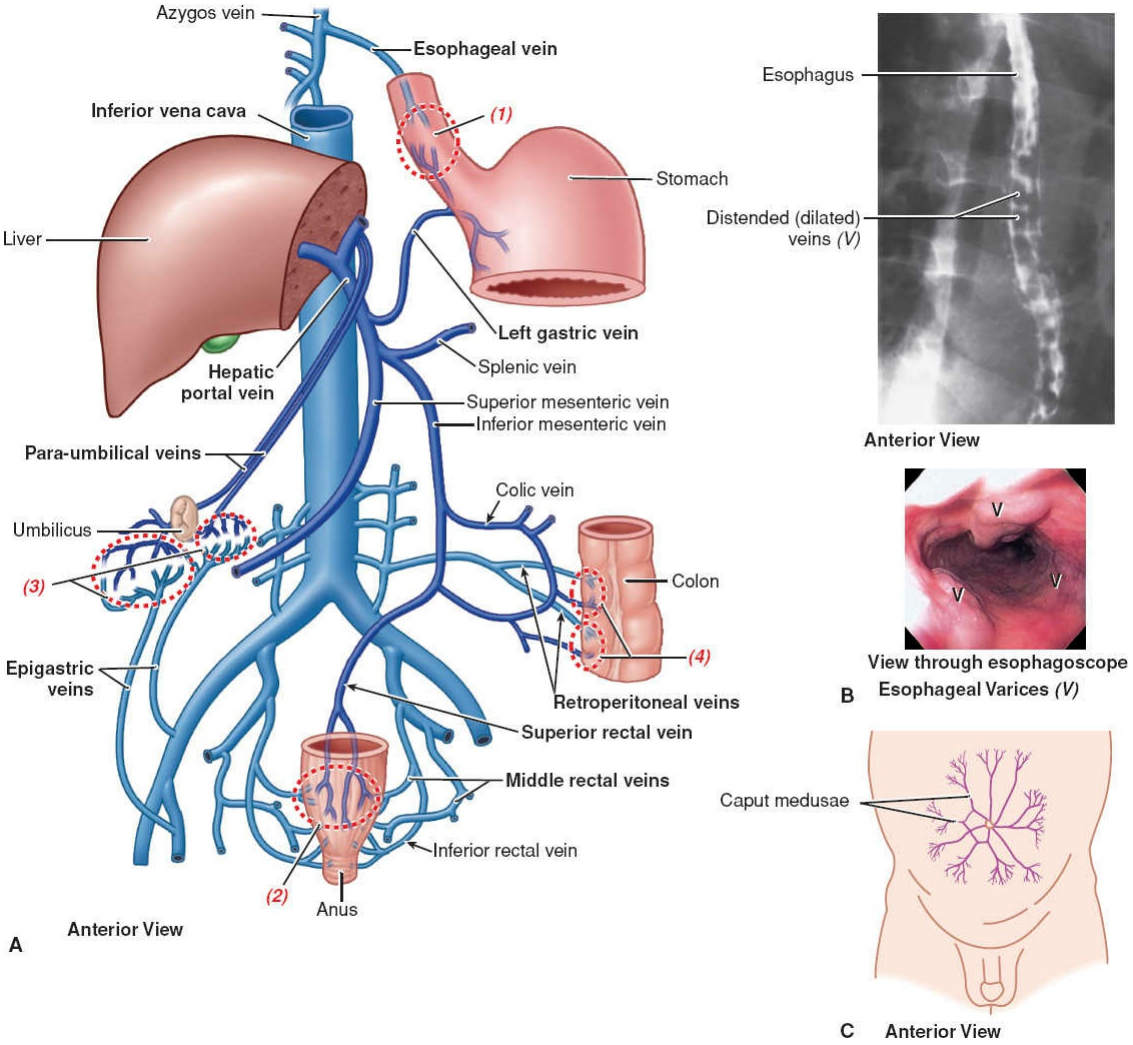

FIGURE 25-1 A. Portacaval system. In this diagram, portal tributaries (*dark blue*) and systemic tributaries and communicating veins (*light blue*). In portal hypertension (as in hepatic cirrhosis), the portal blood cannot pass freely through the liver, and the portocaval anastomoses become engorged, dilated, or even varicose; as a consequence, these veins may rupture. The sites of the portocaval anastomosis shown are between (1) esophageal veins draining into the azygos vein (systemic) and left gastric vein (portal), which when dilated are esophageal varices; (2) the inferior and middle rectal veins, draining into the inferior vena cava (systemic), and the superior rectal vein continuing as the inferior mesenteric vein (portal) (hemorrhoids result if the vessels are dilated); (3) paraumbilical veins (portal) and small epigastric veins of the anterior abdominal wall (systemic), which when varicose form "caput medusae" (so named because of the resemblance of the radiating veins to the serpents on the head of Medusa, a character in Greek mythology); and (4) twigs of colic veins (portal) anastomosing with systemic retroperitoneal veins. B. Esophageal varices. C. Caput medusae. (Grant's Atlas of Anatomy, Anne M. R. Agur; Arthur F Dalley.)

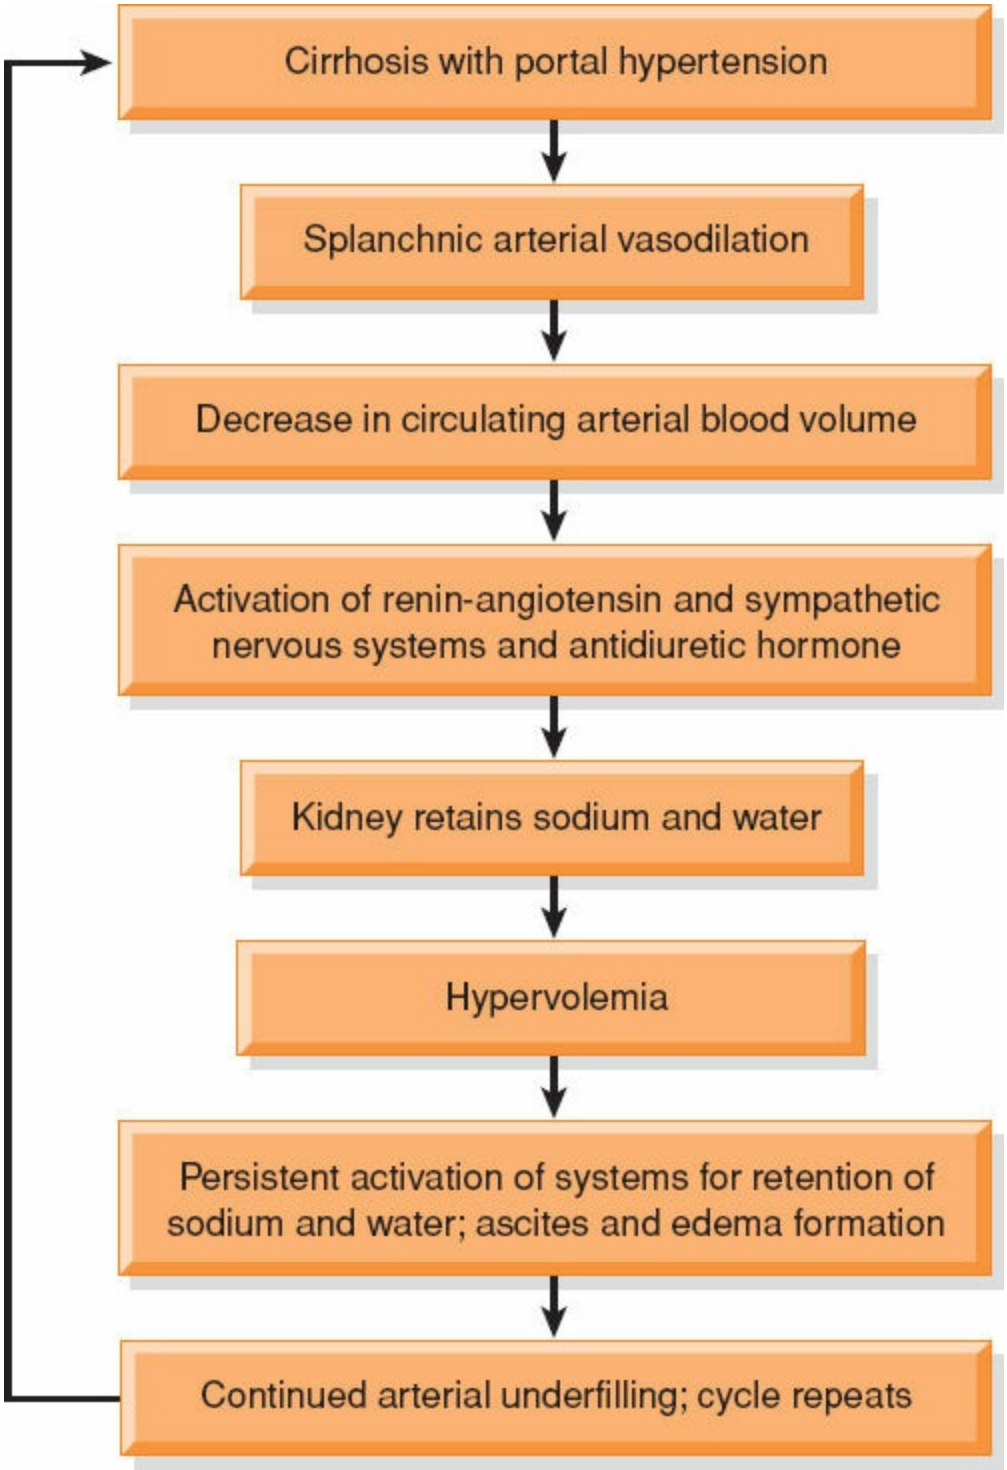

FIGURE 25-2 Pathogenesis of ascites (arterial vasodilation theory).

Clinical Manifestations and Assessment

Common symptoms of the patient presenting with ascites include increased abdominal girth, weight gain, and swelling of the lower extremities (pedal edema). Dyspnea may be present as the result of abdominal distention or pleural effusions. Abdominal hernias due to increased intra-abdominal pressure may be visible as well as visible collateral veins and striae (stretch marks). The patient also may experience early satiety, anorexia, and general weakness (Runyon, 2013).

The detection of ascites by physical examination can be assessed by percussion for shifting dullness. With the patient supine, the free fluid in the abdomen will accumulate in the flanks; percussion of the abdomen will reveal tympany over the anterior abdomen and dullness over the flanks. Turning the patient to one side with repeat percussion will reveal shifting dullness (the uppermost area will sound tympanic while the lower area will sound dull to percussion). Assessing for abdominal fluid wave also detects ascites (Fig. 25-3). Bulging flanks also may reveal the presence of ascites. Accurate physical assessment of ascites through examination may be decreased if ascitic fluid is less than 1,500 mL or if the patient is obese (Runyon, 2013).

Ultrasonography of the liver and abdomen will definitively confirm the presence of ascites (Runyon, 2013). Diagnostic paracentesis (discussed in Chapter 21) is performed routinely on patients presenting with ascites upon hospital admission to detect the presence of spontaneous bacterial peritonitis (SBP). This complication of cirrhosis has a high mortality rate and will be discussed later in the chapter (Runyon, 2013).

Medical and Nursing Management

Dietary Modification

Dietary restriction of salt intake is the mainstay of treatment of ascites to achieve a negative sodium balance to reduce fluid retention. The recommended daily sodium intake of patients with ascites should be 2,000 mg or less (Runyon, 2013). Patients on sodium-restricted diets should receive nutritional education and guidance on foods that contain high sodium content (i.e., all processed foods, frozen and canned foods not indicated as low sodium) and avoid the use of added salt in meals and food preparation. Ongoing patient education and referral to a licensed nutritionist will facilitate dietary adherence.

Diuretics

The addition of diuretics with sodium restriction will result in decreased ascites in approximately 90% of patients. Combination drug therapy using spironolactone (Aldactone), an aldosterone-blocking agent, and furosemide (Lasix), a loop diuretic agent, is the most effective regimen to control ascites and pedal edema. Patients should be monitored for daily weight changes (not to exceed 0.5 kg/day (1.1 lb) gain or loss in patients without peripheral edema, whereas in patients with peripheral edema, there may be no limit on daily weigh loss (Runyon, 2013). Frequently failure to achieve weight reduction and decrease in ascites with the use of therapeutic doses of diuretics is due to insufficient salt restriction (Runyon, 2013).

FIGURE 25-3 Assessing for abdominal fluid wave. The examiner places the hands along the sides of the patient's flanks and then strikes one flank sharply, detecting any fluid wave with the other hand. An assistant's hand is placed (ulnar side down) along the patient's midline to prevent the fluid wave from being transmitted through the tissues of the abdominal wall.

Possible complications of diuretic therapy are dehydration, volume depletion, and electrolyte abnormalities, such as hypokalemia or hyperkalemia, hyponatremia, kidney impairment, and hepatic encephalopathy. Gynecomastia is a common side effect caused by Spironolactone. If patients with ascites develop dilutional hyponatremia (serum sodium below 134 mmol/L), then diuretics should be discontinued and fluid restriction initiated. Dietary salt restriction to less than 2,000 mg daily should be reinforced (Runyon, 2013).

Paracentesis

Paracentesis is the removal of fluid (ascites) from the peritoneal cavity through a puncture or a small surgical incision through the abdominal wall under sterile conditions. Therapeutic paracentesis provides only temporary removal of fluid; ascites rapidly recurs, necessitating repeated fluid removal. See Chapter 21 for detailed discussion of paracentesis.

Transjugular Intrahepatic Portosystemic Shunt

Transjugular intrahepatic portosystemic shunt (TIPS) is a method of treating ascites in which a cannula is threaded into the portal vein by the transjugular route (Fig. 25-4). To reduce portal hypertension, an expandable stent is inserted to serve as an intrahepatic shunt between the portal circulation and the hepatic vein. This diverts blood flow from a high-pressure vascular bed (portal) to a lower-pressure vascular bed (hepatic veins/inferior vena cava), allowing for the return of blood to the heart and decompressing portal hypertension (Maruyama & Sanyal, 2012). It is extremely effective in decreasing sodium retention, improving the renal response to diuretic therapy, and preventing recurrence of fluid accumulation (Runyon, 2013).

Although TIPS is an effective treatment for patients with refractory ascites, it does not increase survival benefit and it increases hepatic encephalopathy (Garcia-Tsao, 2016).

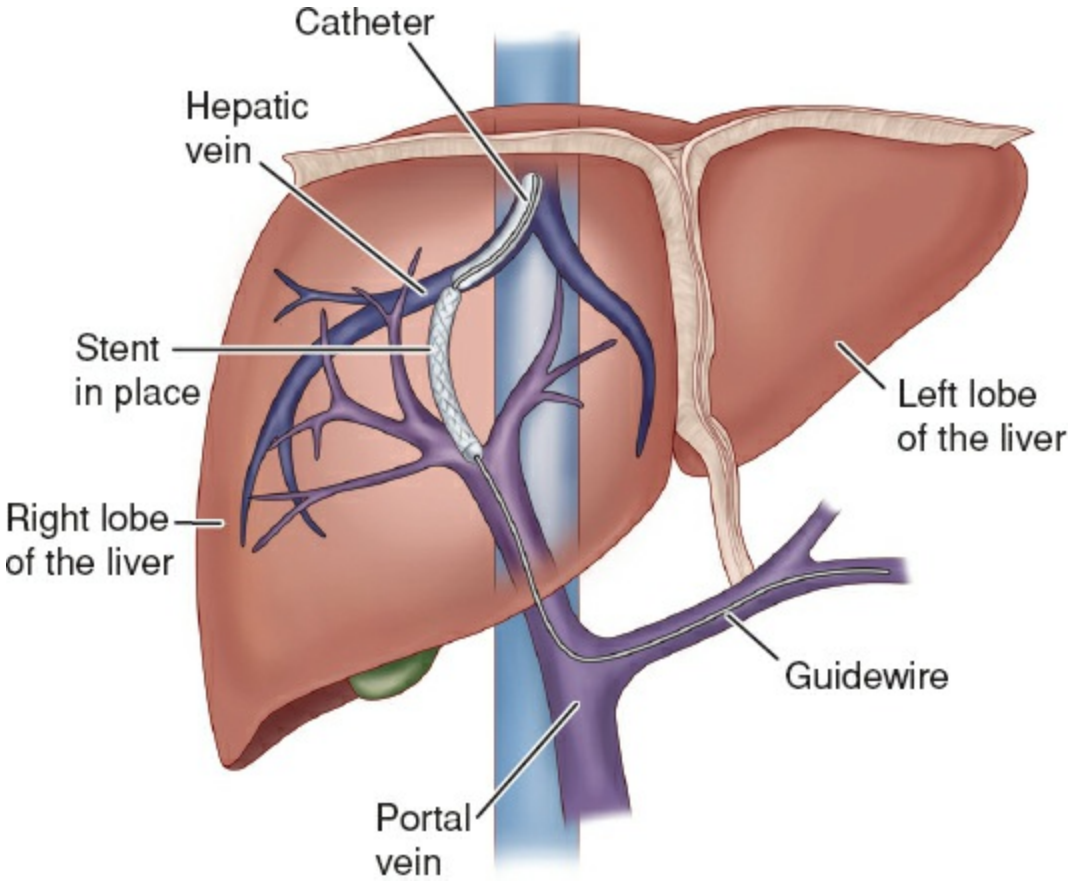

FIGURE 25-4 Transjugular intrahepatic portosystemic shunt (TIPS). A stent is inserted via catheter to the portal vein to divert blood flow and reduce portal hypertension.

Complications

An important complication of ascites is the development of SBP, in which infection develops in the ascitic fluid, usually from *Escherichia coli*, a gram-negative bacteria. Prompt detection of SBP is required as this complication has a high mortality rate. Diagnostic paracentesis should be performed in all patients with cirrhosis and ascites admitted to the hospital and in any inpatient with cirrhosis showing signs of infection (i.e., fever, chills, abdominal pain) or with abnormalities in liver or kidney function. This procedure removes a small amount of ascitic fluid from the abdomen percutaneously and can be performed at the bedside. The specimen is analyzed for cell count and differential, albumin, total protein, and susceptible organisms (Runyon, 2013). The treatment of SBP includes the use of IV antibiotics or oral treatment if tolerated. Long-term prophylaxis with oral antibiotic therapy is recommended to prevent future infection in patients who have had a diagnosis of SBP (Garcia-Tsao, 2016; Runyon, 2013).

ESOPHAGEAL VARICES

Gastroesophageal varices are present in 50% of patients with cirrhosis and are the most life-threatening complication in patients with chronic liver disease. Bleeding or hemorrhage from esophageal varices is associated with significantly decreased overall lifespan with a mortality rate as high as 20% within the first 6 weeks of initial bleeding episode (Garcia-Tsao, 2016).

Pathophysiology

Esophageal varices are dilated, tortuous veins that usually are found in the submucosa of the lower esophagus but may develop higher in the esophagus or extend into the stomach. Portal hypertension is the primary mechanism by which collateral circulation develops.

Because of increased obstruction of the portal vein, venous blood from the intestinal tract and spleen seeks an outlet through collateral circulation (new pathways for return of blood to the right atrium). The effect is increased pressure, particularly in the vessels in the submucosal layer of the lower esophagus and upper part of the stomach. These collateral vessels are not very elastic; rather, they are tortuous and fragile, and they bleed easily (Maruyama & Sanyal, 2012). Gastroesophageal bleeding (Fig. 25-5) is due to high portal pressure and increased collateral blood flow, causing dilation and thinning of varices. Any additional increase in pressure or defect in the varices will cause rupture and hemorrhage. Factors that may precipitate hemorrhage are alcohol intake, physical exercise, and any activity that would increase intra-abdominal pressure (e.g., lifting, straining to pass stool, vomiting, coughing) (Maruyama & Sanyal, 2012).

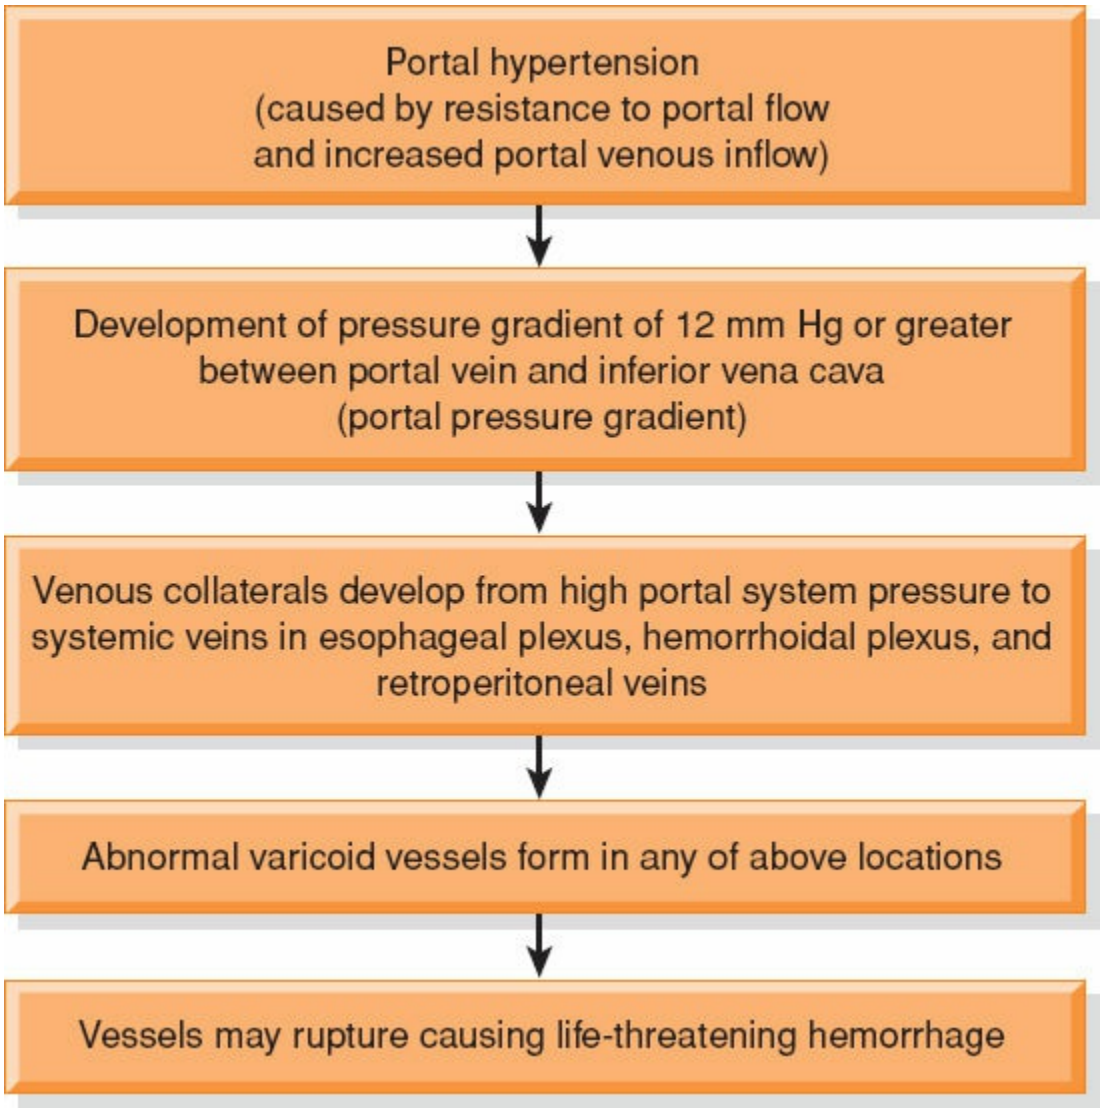

FIGURE 25-5 Pathogenesis of bleeding esophageal varices.

Bleeding esophageal varices are life-threatening and can result in hemorrhagic shock that produces decreased cerebral, hepatic, and renal perfusion. In turn, there is an increased nitrogen load from bleeding into the GI tract and an increased serum ammonia level, increasing the risk for encephalopathy.

Clinical Manifestations and Assessment

The patient with bleeding esophageal varices may present with hematemesis, melena, or general deterioration in mental or physical status and often has a history of alcohol abuse. Signs and symptoms of shock (cool clammy skin, hypotension, tachycardia) may be present. Endoscopic evaluation (or esophagogastroduodenoscopy [EGD]) is used in the diagnosis and treatment of varices, in both the acute and outpatient settings. Assessment of variceal size, location, and features are used to predict the risk of bleeding. Variceal size is an important factor that determines both pharmacologic and endoscopic therapies to prevent and manage risk of bleeding. In the acute setting, endoscopy should take place within 12 hours after stabilization of the patient (Garcia-Tsao, 2016).

Medical Management

Acute bleeding from esophageal varices is an emergency that can quickly lead to hemorrhagic shock. The patient is critically ill, requiring aggressive medical care and expert nursing care, and he or she should be transferred to the intensive care unit (ICU) for close monitoring and management. Assessment and protection of the patient's airway and peripheral venous access is required. Endotracheal intubation may be necessary to prevent aspiration of blood (Garcia-Tsao, 2016).

The extent of bleeding is evaluated, and vital signs are monitored continuously if hematemesis and melena are present. Signs of potential hypovolemia are noted, such as cold clammy skin, tachycardia, a drop in blood pressure, decreased urine output, restlessness, and weak peripheral pulses. The volume of circulating blood is estimated and monitored with a central venous catheter or pulmonary artery catheter. Blood pressure is monitored noninvasively or via an arterial catheter. Oxygen is administered to prevent hypoxia and to maintain adequate blood oxygenation, which is evaluated via pulse oximetry or arterial blood gases (ABGs).

Because patients with bleeding esophageal varices have intravascular volume depletion and are subject to electrolyte imbalance, IV fluids with electrolytes and volume expanders are provided to restore fluid volume and replace electrolytes. Transfusion of blood components also may be required to maintain hemodynamic stability and correct coagulopathy. Caution must be taken with volume resuscitation so that overhydration does not occur because this would raise portal pressure and increase bleeding (Maruyama & Sanyal, 2012; Garcia-Tsao, 2016). Usually an indwelling urinary catheter is inserted to permit frequent monitoring of urine output.

Although a variety of pharmacologic, endoscopic, and surgical approaches are used to treat bleeding esophageal varices, none is ideal, and most are associated with considerable risk to the patient. Nonsurgical treatment of bleeding esophageal varices still is preferable because of the high mortality rate of emergency surgery to control bleeding esophageal varices and because of the poor physical condition that is typical of the patient with severe liver dysfunction.

Pharmacologic Therapy

The medical management of the patient with acute variceal hemorrhage includes the use of antibiotic therapy (IV ciprofloxacin, or ceftriaxone in patients with advanced cirrhosis) to prevent infection and improve survival. The most effective specific therapy for the control of active variceal hemorrhage is the combination of a vasoconstrictor with endoscopic therapy. Vasoconstrictors include somatostatin or octreotide because they decrease the splanchnic arterial blood and decrease portal pressure with fewer side effects and equal efficacy compared with vasopressin (discussed below). Octreotide has a longer half-life than somatostatin (100 minutes vs. 2 to 3 minutes) and, as a result, has become the agent of choice in managing acute variceal hemorrhage (Rigberg & Gelabert, 2013). Octreotide is maintained for 2 to 5 days in conjunction with endoscopic therapy (discussed below). Nonselective beta blockers are used for the prevention of variceal bleeding in patients with cirrhosis and also to reduce episodes of rebleeding after an initial episode (Garcia-Tsao,

2016).

In a patient who is actively bleeding, medications are administered initially because other therapies take longer to take effect. Although vasopressin (pitressin) is no longer considered first-line therapy in the management of active bleeding varices, it may be used to slow variceal hemorrhage because it produces constriction of the splanchnic arterial bed and decreases portal pressure (Rigberg & Gelabert, 2013). It may be administered by IV infusion. Stable vital signs and the decreasing presence or absence of blood in the gastric aspirate indicate the effectiveness of vasopressin. Monitoring of fluid intake and output and electrolyte levels is necessary because hyponatremia may develop, and vasopressin may have an antidiuretic effect.

The use of vasopressin may be used in conjunction with nitroglycerin or isoproterenol to prevent the side effects of vasoconstriction, including cardiac ischemia, arrhythmias, and hypertension (Maruyama & Sanyal, 2012; Rigberg & Gelabert, 2013).

Nursing Alert

If vasopressin is administered in acute esophageal bleed (because of its vasoconstrictive properties in the splanchnic, portal, and intrahepatic vessels), the nurse understands that this medication also causes coronary artery constriction that may dispose patients with coronary artery disease to cardiac ischemia. Thus the nurse observes the patient for evidence of chest pain, electrocardiogram (ECG) changes, and vital sign changes. A high degree of suspicion is maintained as many patients may have silent ischemia. Nitroglycerine may be administered concurrently with vasopressin.

Endoscopic Therapies

Esophageal Banding Therapy (Variceal Band Ligation)

In variceal banding (Fig. 25-6), an esophagogastroduodenoscopy is performed using a modified endoscope loaded with an elastic rubber band that is passed through an overtube directly onto the varix (or varices) to be banded. After the bleeding varix is suctioned into the tip of the endoscope, the rubber band is slipped over the tissue, causing necrosis, ulceration, and eventual sloughing of the varix. Complications include superficial ulceration and dysphagia (difficulty swallowing), transient chest discomfort, and, rarely, esophageal strictures (Maruyama & Sanyal, 2012).

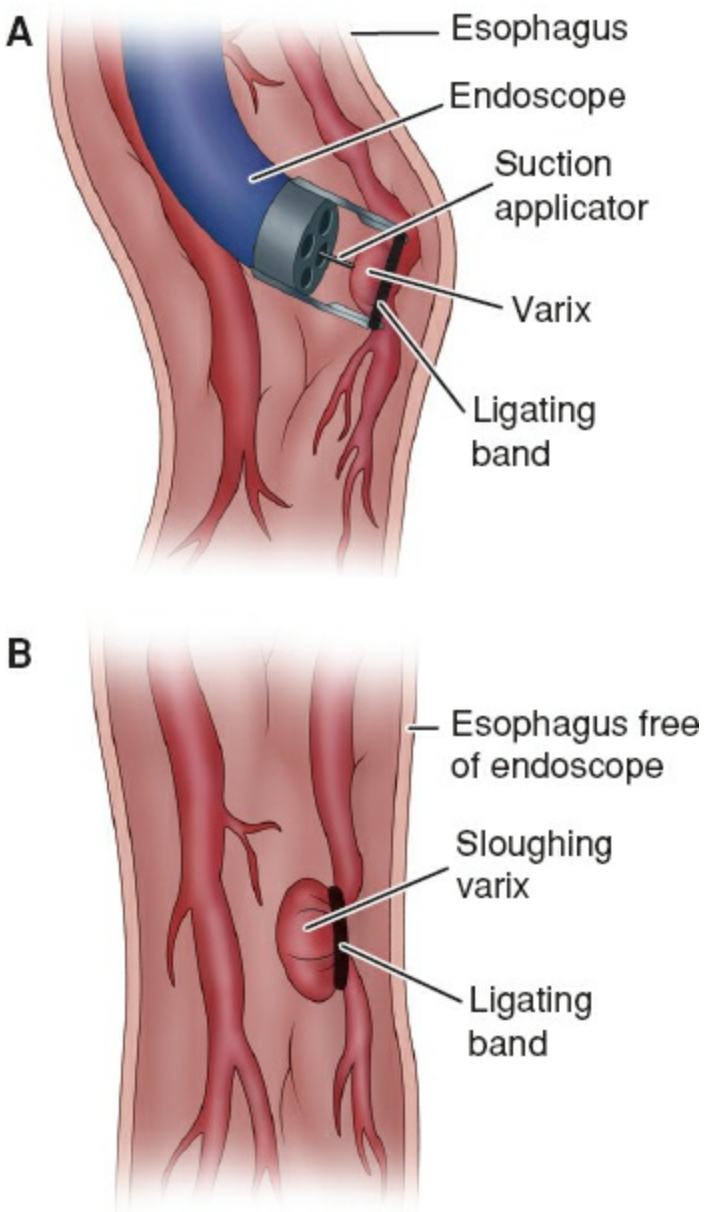

FIGURE 25-6 Esophageal banding. A. A rubber band–like ligature is slipped over an esophageal varix via an endoscope. B. Necrosis results, and the varix eventually sloughs off.

Esophageal banding is the most effective therapy to treat acute hemorrhage. After an acute episode of bleeding, the combination of beta-blocker therapy and routine esophageal banding is the treatment of choice and has been shown to effectively prevent rebleeding and improve survival (Garcia-Tsao, 2016).

Endoscopic Injection Sclerotherapy

In endoscopic injection sclerotherapy (EIS), a sclerosing agent is injected through a fiberoptic endoscope into the bleeding esophageal varices to promote thrombosis and eventual sclerosis (Fig. 25-7). This therapy is used only to treat an acute variceal bleed if esophageal banding is not feasible. Because of unproven efficacy and a high incidence of complications, endoscopic variceal sclerotherapy use is limited (Maruyama & Sanyal, 2012).

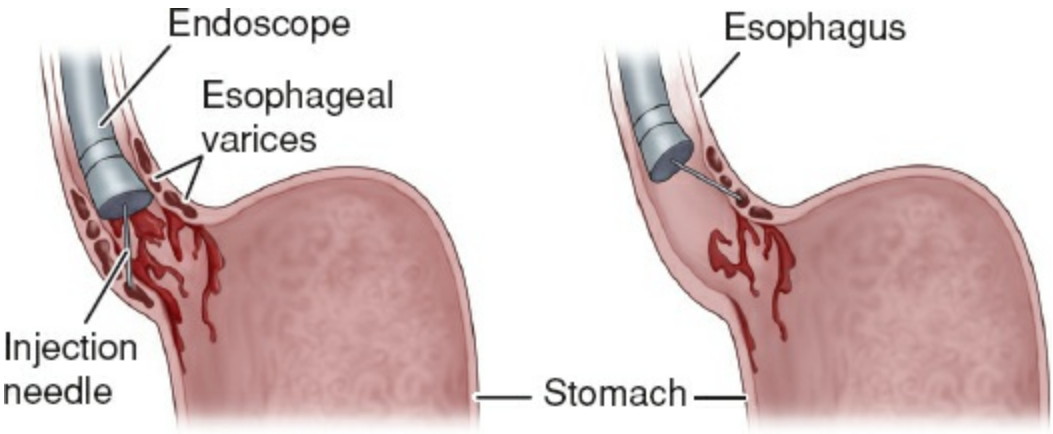

FIGURE 25-7 Endoscopic injection sclerotherapy. Injection of sclerosing agent into esophageal varices through an endoscope promotes thrombosis and eventual sclerosis, thereby obliterating the varices.

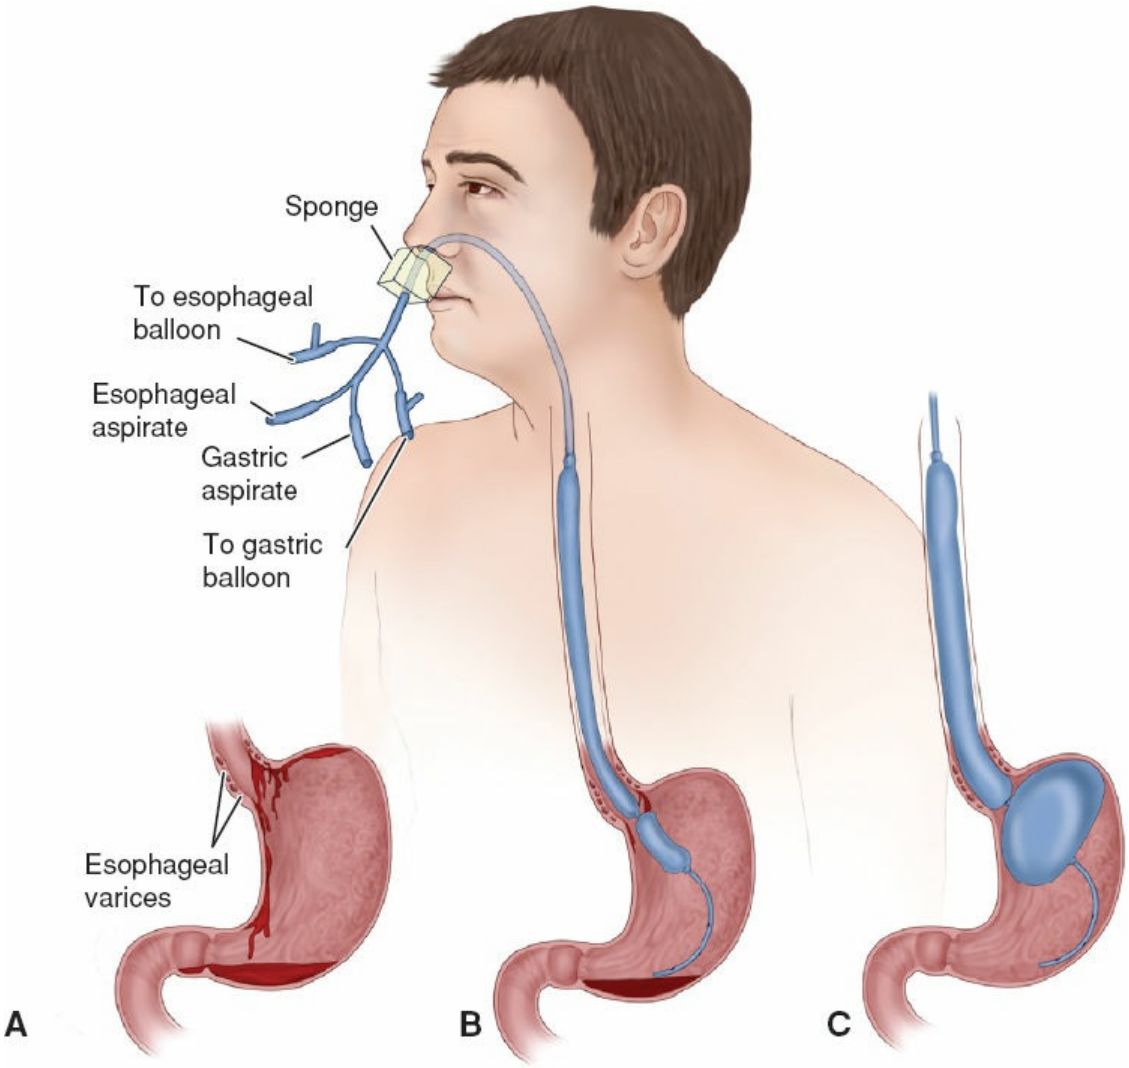

FIGURE 25-8 Balloon tamponade to treat esophageal varices. A. Dilated, bleeding esophageal veins (varices) of the lower esophagus. B. A four-lumen esophageal tamponade tube with balloons (uninflated) in place. C. Compression of bleeding esophageal varices by inflated esophageal and gastric balloons. The gastric and esophageal outlets permit the nurse to aspirate secretions.

Balloon Tamponade

Balloon tamponade may be used as a temporary measure to control bleeding in an active hemorrhage. In this procedure, pressure is exerted on the cardia (upper orifice of the stomach) and against the bleeding varices by a double-balloon tamponade (Sengstaken-Blakemore tube) (Fig. 25-8). The tube has four openings, each with a specific purpose: gastric aspiration, esophageal aspiration, gastric balloon inflation, and esophageal balloon inflation. This method is effective in controlling bleeding in 80% of patients; however, it is associated with lethal complications, including esophageal rupture, aspiration, and rebleeding, and it carries a high risk of mortality. Its use is restricted to patients with uncontrolled bleeding and as a temporary bridge to other treatments, such as TIPS or endoscopy (Maruyama & Sanyal, 2012).

Nursing Alert

The patient being treated with balloon tamponade must remain under close observation in the ICU because of the risk for serious complications. The patient must be monitored closely and continuously. Precautions must be taken to ensure that the patient does not pull on or inadvertently displace the tube.

Transjugular Intrahepatic Portosystemic Shunting

A TIPS procedure is indicated for the treatment of an acute episode of variceal bleeding refractory to pharmacologic or endoscopic therapy. In 10% to 20% of patients for whom urgent band ligation and medications are not successful in eradicating bleeding, a TIPS procedure can control acute variceal hemorrhage effectively by rapidly lowering portal pressure. TIPS is also indicated for those patients who rebleed after pharmacologic or endoscopic prophylaxis has failed. This technique also is used as a bridge to liver transplantation. Potential complications include bleeding, sepsis, increased hepatic encephalopathy, heart failure, organ perforation, shunt thrombosis, and progressive liver failure (Maruyama & Sanyal, 2012).

Nursing Management

After treatment for acute hemorrhage, the patient must be observed for bleeding, perforation of the esophagus, aspiration pneumonia, and esophageal stricture. Antacids, histamine-2 antagonists such as cimetidine (Tagamet), or proton pump inhibitors such as pantoprazole (Protonix) may be administered after the procedure.

After the examination, fluids are not given until the gag reflex returns. Lozenges and gargles may be used to relieve throat discomfort if the patient's physical condition and mental status permit. If the patient is actively bleeding, oral intake will not be permitted, and the patient will be prepared for further diagnostic and therapeutic procedures.

Overall nursing assessment includes monitoring the patient's physical condition and evaluating emotional responses and cognitive status. The nurse monitors and records vital signs and assesses the patient's nutritional and neurologic status. This assessment assists in identifying hepatic encephalopathy, which results from the breakdown of blood in the GI tract and a rising serum ammonia level. Manifestations range from drowsiness to encephalopathy and coma.

If complete rest of the esophagus is indicated because of bleeding, parenteral nutrition is initiated. Gastric suction usually is initiated to keep the stomach as empty as possible and to prevent straining and vomiting. The patient often complains of severe thirst, which may be relieved by frequent oral hygiene and moist sponges to the lips. The nurse closely monitors the blood pressure. Vitamin K therapy and multiple blood transfusions often are indicated because of blood loss and coagulation abnormalities. A quiet environment and calm reassurance may help to relieve the patient's anxiety and reduce agitation.

Bleeding anywhere in the body is anxiety-provoking, resulting in a crisis for the patient and family. If the patient has been a heavy user of alcohol, delirium secondary to alcohol withdrawal can complicate the situation. The nurse provides support and explanations about medical and nursing interventions. Close monitoring of the patient helps in detecting and managing complications. Management modalities and nursing care of the patient with bleeding esophageal varices are summarized in Table 25-1.

Hepatic Encephalopathy and Coma

Hepatic encephalopathy, a life-threatening complication of liver disease, occurs with profound liver failure and may result from the accumulation of ammonia and other toxic metabolites in the blood. Hepatic coma represents the most advanced stage of hepatic encephalopathy.

Pathophysiology

Ammonia is produced in the liver as a by-product of protein and amino acid breakdown. The colon and small intestine are also sites of ammonia production resulting from bacterial action. The liver converts ammonia into urea, which is excreted into the urine. In normal liver function, this process prevents the toxic buildup of ammonia in the blood (Porth, 2015). Damaged liver cells fail to detoxify and convert the ammonia to urea, and the elevated quantity of ammonia enters the bloodstream.

Circumstances that increase serum ammonia levels tend to aggravate or precipitate hepatic encephalopathy. The largest source of ammonia is the enzymatic and bacterial digestion of dietary and blood proteins in the GI tract. Ammonia from these sources increases as a result of GI bleeding (i.e., bleeding esophageal varices, chronic GI bleeding), a high-protein diet, bacterial infection, or uremia. In the presence of alkalosis or hypokalemia, increased amounts of ammonia are absorbed from the GI tract and from the renal tubular fluid. Conversely, serum ammonia is decreased by elimination of protein from the diet, administration of nonabsorbable disaccharides such as lactulose, and by the administration of antibiotic agents such as rifaximin or neomycin sulfate, reducing the amount of ammonia produced and absorbed in the intestine (Garcia-Tsao, 2016; Prakash & Mullen, 2012). Other factors unrelated to increased serum ammonia levels that can cause hepatic encephalopathy in susceptible patients include excessive diuresis, dehydration, infections, constipation, surgery, fever, and some medications (sedatives, tranquilizers, analgesics, and diuretics that cause potassium loss). The increased ammonia concentration in the blood causes brain dysfunction and damage, resulting in hepatic encephalopathy. Table 25-2 presents the stages of hepatic encephalopathy, common signs and symptoms, and potential nursing diagnoses for each stage (Garcia-Tsao, 2016).

Clinical Manifestations and Assessment

The earliest symptoms of hepatic encephalopathy include minor mental changes and motor disturbances. The patient appears slightly confused and unkempt and has alterations in mood and sleep patterns. The patient tends to sleep during the day and have restlessness and insomnia at night. As hepatic encephalopathy progresses, the patient may become difficult to awaken, eventually resulting in coma (Garcia-Tsao, 2016).

Asterixis (flapping tremor of the hands) may occur (Fig. 25-9). Simple tasks, such as handwriting, become difficult. A handwriting or drawing sample (e.g., star figure), taken daily, may provide graphic evidence of progression or reversal of hepatic encephalopathy; *constructional apraxia* is the inability to reproduce a simple figure (Fig. 25-10). In the early stages of hepatic encephalopathy, the deep tendon reflexes are hyperactive; with worsening of the encephalopathy, these reflexes disappear and the extremities may become flaccid (Vilstrup et al., 2014).

The electroencephalogram (EEG) shows generalized slowing, an increase in the amplitude of brain waves, and characteristic triphasic waves (Garcia-Tsao, 2016). Occasionally, fetor hepaticus, a sweet, slightly fecal odor to the breath that is presumed to be of intestinal origin, may be noticed (Greenberger, 2012). The odor also has been described as similar to that of freshly mowed grass, acetone, or old wine. Fetor hepaticus is prevalent with extensive collateral portal circulation in chronic liver disease. In a more advanced stage, there are gross disturbances of consciousness and the patient is completely disoriented with respect to time and place (Vilstrup et al., 2014).

Medical Management

Medical management of hepatic encephalopathy focuses on identifying and correcting the precipitating cause if possible. Lactulose (Cephulac) is administered to reduce serum ammonia levels. It acts by several mechanisms that promote the excretion of ammonia in the stool:

- Ammonia is kept in the ionized state, resulting in a decrease in colon pH, reversing the normal passage of ammonia from the colon to the blood.
- Evacuation of the bowel takes place, which decreases the ammonia absorbed from the colon.
- Fecal flora are changed to organisms that do not produce ammonia from urea.

TABLE 25-1 Management Modalities and Nursing Care for the Patient with Bleeding Esophageal Varices

Treatment Modality[a]	Action	Nursing Priorities
Nonsurgical Modalities		
Pharmacologic Agents		
Propranolol (Inderal)/nadolol (Corgard)	Reduces portal pressure by beta-adrenergic blocking action	*Propranolol* and *nadolol*—decreased pulse pressure, impaired cardiovascular response to hemorrhage.
Somatostatin/octreotide (Sandostatin)	Reduces portal pressure by selective vasodilation of portal system	Support patient during treatment.
Vasopressin (Pitressin)	Reduces portal pressure by constricting splanchnic arteries	Observe response to therapy. Monitor for side effects: *vasopressin*—angina; nitroglycerin may be prescribed to prevent or treat angina.
Balloon tamponade	Exerts pressure directly to bleeding sites in esophagus and stomach	Explain procedure to patient briefly to obtain cooperation with insertion and maintenance of esophageal/gastric tamponade tube and reduce patient's fear of the procedure. Monitor closely to prevent inadvertent removal or displacement of tube, subsequent airway obstruction, and aspiration. Provide frequent oral hygiene.
Room-temperature saline lavage	Clears blood and secretions before endoscopy and other procedures	Ensure patency of the nasogastric tube to prevent aspiration. Observe gastric aspirate for blood and cessation of bleeding.
Injection sclerotherapy	Promotes thrombosis and sclerosing of bleeding sites by injection of sclerosing agent into the esophageal varices	Observe for aspiration, perforation of the esophagus, and recurrence of bleeding after treatment.
Variceal banding	Provides thrombosis and mucosal necrosis of bleeding sites by band ligation	Observe for recurrence of bleeding, esophageal perforation.
Surgical Modalities		
Transjugular intrahepatic portosystemic shunt (TIPS)	Reduces portal pressure by creating a shunt within the liver between the portal and systemic venous systems	Observe for rebleeding and signs of infection. Observe for development of portal-systemic encephalopathy (altered mental status, neurologic dysfunction), liver failure, hypertension due to increased volume after surgery, and coagulopathy. Requires intensive, expert nursing care for prolonged period. Follow-up may include ultrasound with Doppler to evaluate for shunt patency.
Surgical ligation of varices	Ties off blood vessels at the site of bleeding	Observe for rebleeding.
Esophageal transection and devascularization	Separates bleeding site from portal system	Observe for rebleeding.

[a]Several modalities may be used concurrently or in sequence.

TABLE 25-2 Stages of Hepatic Encephalopathy and Possible Nursing Diagnoses*a*

Stage	Clinical Symptoms	Clinical Signs	Electroencephalogram (EEG) Changes	Selected Potential Nursing Diagnoses
1	Normal level of consciousness with periods of lethargy and euphoria; reversal of day–night sleep patterns	Asterixis; impaired writing and ability to draw line figures	Normal EEG	Activity intolerance Self-care deficit Disturbed sleep pattern
2	Increased drowsiness; disorientation; inappropriate behavior; mood swings; agitation	Asterixis; fetor hepaticus	Abnormal EEG with generalized slowing	Impaired social interaction Ineffective role performance Risk for injury
3	Stuporous; difficult to rouse; sleeps most of time; marked confusion; incoherent speech	Asterixis; increased deep tendon reflexes; rigidity of extremities	EEG markedly abnormal	Imbalanced nutrition Impaired mobility Impaired verbal communication
4	Comatose; may not respond to painful stimuli	Absence of asterixis; absence of deep tendon reflexes; flaccidity of extremities	EEG markedly abnormal	Risk for aspiration Impaired gas exchange Impaired tissue integrity Disturbed sensory perception

[a]Nursing diagnoses are likely to progress so that most nursing diagnoses present at earlier stages will continue during later stages as well.

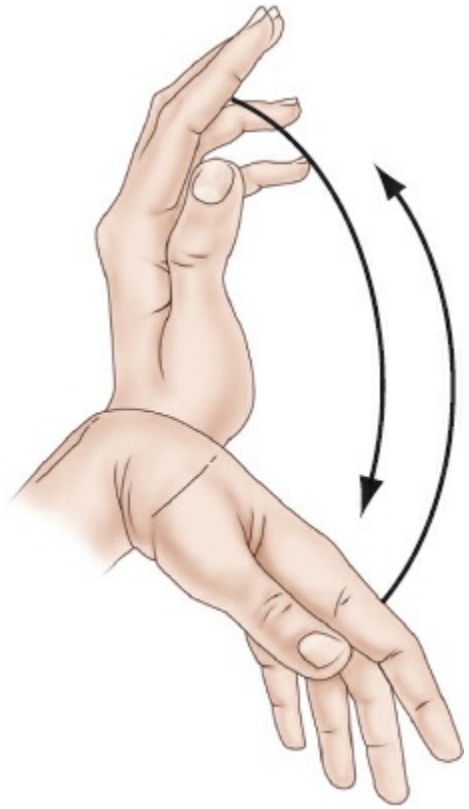

FIGURE 25-9 Asterixis or "liver flap" may occur in hepatic encephalopathy. The patient is asked to hold the arm out with the hand held upward (dorsiflexed). Within a few seconds, the hand falls forward involuntarily and then quickly returns to the dorsiflexed position.

Two or three soft stools per day are desirable; this indicates that lactulose is performing as intended.

Possible side effects include intestinal bloating and cramps, which usually disappear within a week. To mask the sweet taste, which some patients dislike, lactulose can be diluted with fruit juice. The patient is monitored closely for hypokalemia (due to GI loss of

potassium) and dehydration. Other laxatives are not prescribed during lactulose administration because their effects disturb dosage regulation. Lactulose may be administered by nasogastric (NG) tube or enema for patients who are comatose or for those in whom oral administration is contraindicated or impossible (Vilstrup et al., 2014).

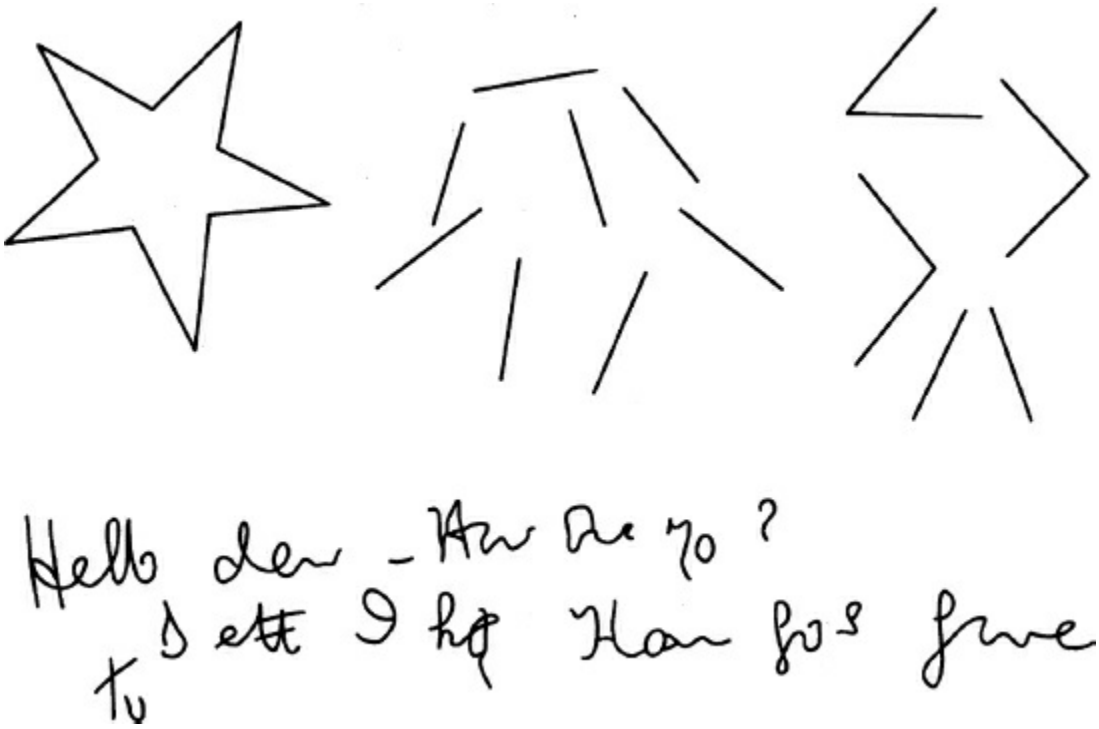

FIGURE 25-10 Effects of constructional apraxia. Deterioration of handwriting and inability to draw a simple star figure occurs with progressive hepatic encephalopathy. (With permission from Sherlock, S., & Dooley, J. (2002). *Diseases of the liver and biliary system* (11th ed.). Oxford, UK: Blackwell Scientific Ltd.)

Nursing Alert
The patient receiving lactulose is monitored closely for the development of watery diarrheal stools because they indicate a medication overdose.

The addition of antibiotic therapy to alter the intestinal flora and reduce nitrogenous waste from the gut can be used as adjunct therapy to lactulose. Agents such as neomycin and rifaximin have been used; only short-term use (less than 2 weeks) of neomycin is recommend due to possible auditory loss and nephrotoxicity (Vilstrup et al., 2014).

Other aspects of management include IV administration of glucose to minimize protein breakdown, administration of vitamins to correct deficiencies, and correction of electrolyte imbalances (especially potassium). Additional principles of management of hepatic encephalopathy include the following (Garcia-Tsao, 2016; Prakash & Mullen, 2012; Vilstrup et al., 2014):

- Therapy is directed toward treating or removing the cause.
- Neurologic status is assessed frequently.
- Mental status is monitored by keeping a daily record of handwriting and arithmetic performance.

- Fluid intake and output and body weight are recorded each day.
- Vital signs are measured and recorded every 4 hours.
- Potential sites of infection (peritoneum, lungs) are assessed frequently, and abnormal findings are reported promptly.
- Serum ammonia level is monitored.
- Protein intake is moderately restricted in patients who are comatose or who have encephalopathy that is refractory to lactulose and antibiotic therapy (Box 25-2).
- Reduction in the absorption of ammonia from the GI tract is accomplished by the use of gastric suction, enemas, or oral antibiotics.
- Electrolyte status is monitored and corrected if abnormal.
- Sedatives, tranquilizers, and analgesic medications are discontinued.
- Benzodiazepine antagonists, such as flumazenil (Romazicon), may be administered to improve encephalopathy, whether or not the patient has taken benzodiazepines previously.

Nursing Management

The nurse is responsible for maintaining a safe environment to prevent injury, bleeding, and infection. The nurse administers the prescribed treatments and monitors the patient for the numerous potential complications. The nurse also communicates with the patient's family, to inform them about the patient's status, and supports them by explaining the procedures and treatments that are part of the patient's care. If the patient recovers from hepatic encephalopathy and coma, rehabilitation is likely to be prolonged. Therefore, the patient and family will require assistance to understand the causes of this severe complication and to recognize that it may recur.

BOX 25-2

Nutrition Alert 

Management of Hepatic Encephalopathy

- Prevent the formation and absorption of toxins, principally ammonia, from the intestine.
- Keep daily protein intake between 1.0 and 1.5 g/kg, depending on the degree of decompensation.
- Avoid protein restriction if possible, even in those with encephalopathy. If necessary, implement temporary restriction of 0.5–0.8 g/kg.
- For patients who are truly protein-intolerant, provide additional nitrogen in the form of an amino acid supplement. Use of branched-chain amino acids is still controversial.
- Provide small, frequent meals and an evening snack of complex carbohydrates to avoid protein loading.
- Substitute vegetable protein for animal protein in as high a percentage as possible.

Vitamin Deficiency

Decreased production of several clotting factors may be due in part to deficient absorption of vitamin K from the GI tract. This probably is caused by the inability of liver cells to use vitamin K to make prothrombin. Absorption of the other fat-soluble vitamins (vitamins A, D, and E) as well as dietary fats also may be impaired because of decreased secretion of bile salts into the intestine.

Another group of problems common to patients with severe chronic liver dysfunction results from inadequate intake of sufficient vitamins. These include the following:

- Vitamin A deficiency, resulting in night blindness and eye and skin changes
- Thiamine deficiency, leading to beriberi, polyneuritis, and Wernicke–Korsakoff psychosis
- Riboflavin deficiency, resulting in characteristic lesions of the skin and mucous membrane
- Vitamin B_6 deficiency, resulting in lesions of the skin and mucous membrane and neurologic changes
- Vitamin C deficiency, resulting in the hemorrhagic lesions of scurvy
- Vitamin K deficiency, resulting in hypoprothrombinemia, characterized by spontaneous bleeding and ecchymosis
- Folic acid deficiency, resulting in macrocytic anemia

Because of these avitaminoses (vitamin deficiencies), the diet of patients with chronic liver disease (especially if alcohol-related) is supplemented with vitamins.

Nursing Alert

Patients with liver disease frequently have abnormal bleeding times. If the prolonged prothrombin time (PT) is due to a vitamin K deficiency, generally the PT will normalize within 24 to 48 hours after parenteral repletion. However, if the etiology of the prolonged PT is due to decreased synthesis of clotting factors (which is reflective of hepatocyte dysfunction), there may be little or no response to vitamin K (Berk & Korenblat, 2016).

Other Manifestations

The patient with advanced chronic liver disease and cirrhosis frequently will develop other systemic complications, such as altered respiratory or cardiac function, resulting from hepatopulmonary syndrome (HPS) and renal function hepatorenal syndrome (HRS). HPS symptoms include exertional dyspnea, clubbing, and cyanosis; in addition, vascular spiders may be observed on physical examination. HPS is related to pulmonary capillary dilatation. Normally one red blood cell fits through the pulmonary capillary, facilitating oxygenation; with pulmonary dilation, many RBCs are passing through the capillary, resulting in a large number of red cells that are not oxygenated. This is equivalent of a right-to-left shunt (see Chapter 10). HRS is a type of prerenal kidney injury that occurs in patients with cirrhosis and ascites. It is the result of maximal peripheral vasodilation and maximal activation of hormones that cause the retention of sodium and water and intense vasoconstriction of the renal arteries (Garcia-Tsao, 2016, p. 1026).

Hematologic abnormalities in patients with cirrhosis are common due to a decrease in clotting factors, resulting from vitamin K deficiency, decreased platelets (thrombocytopenia), anemia, and decreased white cells (neutropenia). The patient with cirrhosis will demonstrate easy bruising and bleeding as well as increased susceptibility to infection (Garcia-Tsao, 2016; Martin, 2016). Endocrine dysfunction in the regulation of glucose control and altered synthesis of sex hormones by the liver result in gynecomastia, testicular atrophy, and decreased libido and impotence in men. Women may have irregular or absent menstrual cycles and decreased sexual function as well.

VIRAL HEPATITIS

Viral hepatitis is a systemic, viral infection in which necrosis and inflammation of liver cells produce a characteristic cluster of clinical, biochemical, and cellular changes. To date, several types of viral hepatitis have been identified: hepatitis A, B, C, D, and E (Pawlotsky, 2016a) (Table 25-3). These viruses infect the liver and can result in either acute or chronic liver dysfunction and disease. Initial presentation of viral hepatitis may be asymptomatic or result in fulminant liver failure or chronic liver disease. Patients may have nonspecific symptoms of malaise, GI distress, or present with frank jaundice and elevations of aminotransferases (Pawlotsky, 2016a). Terms associated with viral hepatitis are listed in Box 25-3.

Hepatitis A Virus

Pathophysiology

The mode of transmission of hepatitis A virus (HAV) occurs through the fecal–oral route, primarily through person-to-person contact and/or ingestion of fecally contaminated food or water. Uncooked food or poor food-handling practices are common methods of transmission of HAV.

HAV replicates in the liver, is excreted in bile, and is shed in the stool. The incubation period is 2 to 4 weeks, with signs and symptoms typically lasting less than 2 months (although in some patients, these can extend up to 6 months). The peak period for transmission of HAV from one person to another occurs in the 2-week period prior to development of jaundice or symptoms, when the concentration of virus in the stool is highest (Watson & Sjogren, 2012). Typically, persons infected with HAV spontaneously recover; however, adults over 50 years of age or those with chronic liver disease may progress to fulminant liver failure (Pawlotsky, 2016a).

Clinical Manifestations and Assessment

Infection by HAV can present either asymptomatically or with acute symptoms such as fever, malaise, anorexia, nausea, diarrhea, vomiting, abdominal pain, and jaundice. Jaundice presents in over 70% of patients, primarily in adults. Serologic testing is required for accurate diagnosis of hepatitis A infection. A positive anti-HAV (IgM) signifies serum IgM antibodies that are reactive to the HAV and confirms an acute infection.

Anti-HAV (IgG) becomes positive shortly after the onset of infection, will remain positive throughout the person's life, and confers immunity. Total positive anti-HAV and negative anti-HAV (IgM) indicate exposure or vaccination (Pawlotsky, 2016a).

Prevention

Current recommendations to prevent the transmission of HAV are to vaccinate all children routinely, to identify and vaccinate persons at high risk for contracting HAV, and to vaccinate any person who wishes to prevent HAV (Pawlotsky, 2016a).

TABLE 25-3 Comparison of Major Forms of Viral Hepatitis

	Hepatitis A	Hepatitis B	Hepatitis C	Hepatitis D	Hepatitis E
Previous names	Infectious hepatitis	Serum hepatitis	Non-A, non-B hepatitis		
Epidemiology					
Cause	Hepatitis A virus (HAV)	Hepatitis B virus (HBV)	Hepatitis C virus (HCV)	Hepatitis D virus (HDV)	Hepatitis E virus (HEV)
Mode of transmission	Fecal–oral route; poor sanitation. Person-to-person contact Waterborne; foodborne Transmission possible with oral–anal contact during sex	Parenterally; by intimate contact with carriers or those with acute disease; sexual and oral–oral contact Perinatal transmission from mothers to infants An important occupational hazard for health care personnel	Transfusion of blood and blood products; exposure to contaminated blood through equipment or drug paraphernalia Transmission possible with sex with infected partner; risk increased with STD	Same as HBV HBV surface antigen necessary for replication; pattern similar to that of hepatitis B	Fecal–oral route; person-to-person contact may be possible, although risk appears low
Incubation (days)	14–35 days	60–150 days	14–160 days	21–140 days	14–65 days
Immunity	Average: 30 days Homologous	Average: 70–80 days Homologous	Average: 50 days Second attack may indicate weak immunity or infection with another agent.	Average: 35 days Homologous	Average: 42 days Unknown
Nature of Illness					
Signs and symptoms	May occur with or without symptoms; flulike illness *Preicteric phase:* Headache, malaise, fatigue, anorexia, fever *Icteric phase:* Dark urine, jaundice of sclera and skin, tender liver	May occur without symptoms May develop arthralgias, rash	Similar to HBV; less severe and anicteric	Similar to HBV	Similar to HAV; very severe in pregnant women
Outcome	Usually mild with recovery. Fatality rate: less than 1% No carrier state or increased risk of chronic hepatitis, cirrhosis, or hepatic cancer	May be severe. Fatality rate: 1–10%. Carrier state possible Increased risk of chronic hepatitis, cirrhosis, and hepatic cancer	Frequent occurrence of chronic carrier state and chronic liver disease Increased risk of hepatic cancer	Similar to HBV but greater likelihood of carrier state, chronic active hepatitis, and cirrhosis	Similar to HAV except very severe in pregnant women

BOX 25-3 Hepatitis Terms and Abbreviations

Hepatitis A	
HAV	Hepatitis A virus; etiologic agent of hepatitis A (formerly infectious hepatitis)
IgG anti-HAV IgM anti-HAV	Antibody to hepatitis A virus; appears in serum soon after onset of symptoms; persists indefinitely, indicates life-long immunity: IgM antibody to HAV; indicates recent infection with HAV; positive up to 6 months after infection
Hepatitis B	
HBV	Hepatitis B virus; etiologic agent of hepatitis B (formerly serum hepatitis)
HBsAG	Hepatitis B surface antigen (Australian antigen); indicates acute or chronic hepatitis B or carrier state; indicates infectious state
Anti-HBs	Antibody to hepatitis B surface antigen; indicates prior exposure and immunity to hepatitis; may indicate passive antibody from HBIG or immune response from hepatitis B vaccine
HBeAg	Hepatitis B e-antigen; present in serum early in course; indicates highly infectious stage of hepatitis B; persistence in serum indicates progression to chronic hepatitis
Anti-HBe	Antibody to hepatitis B e-antigen; suggests low titer of HBV
HBcAg	Hepatitis B core antigen; found in liver cells; not easily detected in serum
Anti-HBc	Antibody to hepatitis B core antigen; most sensitive indicator of hepatitis B; appears late in the acute phase of the disease; indicates infection of HBV at some time in the past
IgM anti-HBc	IgM antibody to HBcAg; present for up to 6 months after HBV infection
Hepatitis C	
HCV	Hepatitis C virus (formerly non-A, non-B virus); may be more than one virus
Hepatitis D	
HDV	Hepatitis D virus (delta agent); etiologic agent to hepatitis D; HBV required for replication
HDAg	Hepatitis delta antigen; detectable in early acute HDV infection
Anti-HDV	Antibody to HDV; indicates past or present infection with HDV
Hepatitis E	
HEV	Hepatitis E virus; etiologic agent of hepatitis E

At-risk persons who should be vaccinated include:

- Travelers or visitors to countries with increased incidence of HAV (Mexico, Latin America, Africa, Middle East, Asia, India)
- Men having sex with men
- Illicit drug users
- Persons with occupational risk (e.g., research with primates or HAV in laboratory settings)
- Persons with clotting factor disorders
- Persons with chronic liver disease

Active immunization for HAV is through vaccination with hepatitis A antigen in two dose schedules and is administered intramuscularly in the deltoid muscle. Passive immunization is achieved through administration of immune globulin–containing hepatitis A antibodies to persons for prophylaxis after exposure to the virus. Its use is indicated for patients with no evidence of immunity (Robinson & Advisory Committee on Immunization Practices [ACIP], 2016).

Box 25-4 discusses community prevention of hepatitis A.

Medical Management

Acute HAV infection in most patients is managed with supportive care. The patient may experience decreased appetite due to alterations in GI function. Dehydration should be prevented; if necessary, IV fluids may be administered. Patients can participate in physical activity as tolerated. Signs and symptoms indicating possible fulminant liver failure, such as altered mental status or severe vomiting, should be identified promptly with referral to a liver transplant center (Watson & Sjogren, 2012).

BOX 25-4 Community Prevention of Hepatitis A

- Proper community and home sanitation
- Conscientious individual hygiene
- Safe practices for preparing and dispensing food
- Effective health supervision of schools, dormitories, extended-care facilities, barracks, and camps
- Community health education programs
- Mandatory reporting of viral hepatitis to local health departments
- Vaccination for travelers to developing countries, illegal drug users (injection and noninjection drug users), men who have sex with men, and persons with chronic liver disease
- Vaccination to interrupt community-wide outbreaks

Nursing Management

Management usually occurs in the home unless symptoms are severe. Therefore, the nurse assists the patient and family in coping with the temporary disability and fatigue that are common in hepatitis and instructs them to seek additional health care if the symptoms persist or worsen. The patient and family also need specific guidelines about diet, rest, follow-up blood work, and the importance of avoiding alcohol, as well as sanitation and hygiene measures (particularly hand washing after bowel movements and before eating) to prevent spread of the disease to other family members, environmental sanitation (safe food and water supply, effective sewage disposal), proper food storage, and thorough cooking of foods to recommended temperatures.

HEPATITIS B VIRUS

Hepatitis B virus (HBV) infection is an important public health problem with as many as 350 million people worldwide diagnosed with chronic infection (Pawlotsky, 2016a). HBV is highly prevalent in Asia, Africa, Middle East, parts of Europe, the Caribbean, and Central and South America (Lok & Negro, 2012).

Pathophysiology

HBV is transmitted primarily through blood (percutaneous and mucosal routes). HBV can be found in blood, saliva, and semen and can be transmitted through mucous membranes and breaks in the skin. HBV is also transferred from carrier mothers to their babies, especially in areas with a high incidence (Pawlotsky, 2016a). HBV is primarily transmitted by perinatal, percutaneous, sexual exposure, and close person-to-person contact via contact with open cuts or sores or by use of shared razors or toothbrushes. HBV-contaminated surfaces also are possible sources of infection as the virus can survive outside of the body for extended periods (Pawlotsky, 2016a).

HBV has a long incubation period. It replicates in the liver and remains in the serum for relatively long periods, allowing transmission of the virus. Most people (more than 95%) who contract HBV infection develop antibodies and recover spontaneously (Pawlotsky, 2016a). The risk of developing chronic HBV infection is significantly higher in persons from endemic countries and when infected from birth (e.g., chronicity rate higher than 95% among patients infected at birth) (Pawlotsky, 2016a). Acute HBV infection can result in fulminant liver failure or progress to chronic infection. Patients with chronic HBV infection eventually may develop cirrhosis, end-stage liver disease, and cancer of the liver (Lok & Negro, 2012; Pawlotsky, 2016a).

Risk Factors

Those at risk for development of hepatitis B include individuals born in areas with high rates of HBV infection. Risk factors for HBV infection are summarized in Box 25-5 (Pawlotsky, 2016a).

BOX 25-5 Risk Factors for Hepatitis B

- Frequent exposure to blood, blood products, or other body fluids
- Being a health care worker: hemodialysis staff, oncology and chemotherapy nurses, personnel at risk for needlesticks, operating room staff, respiratory therapists, surgeons, dentists
- Hemodialysis
- Male homosexual and bisexual activity
- IV/injection drug use
- Close contact with carrier of HBV
- Travel to or residence in area with uncertain sanitary conditions
- Multiple sexual partners
- Recent history of sexually transmitted disease
- Receipt of blood or blood products (e .g., clotting factor concentrate)

Clinical Manifestations and Assessment

Signs and symptoms of acute hepatitis B may be insidious and variable. The patient may have anorexia, sleep disturbances, fevers, dyspepsia, pain in the upper right quadrant, generalized aching, malaise, and weakness. Jaundice may or may not be evident. Skin rashes and arthralgias (pain in the joints) may occur (Ferri, 2016a). Chronic hepatitis B may remain largely asymptomatic until the development of cirrhosis and signs of hepatic decompensation (Pawlotsky, 2016a).

The evaluation of a patient with HBV infection includes a complete history and physical examination, a family history of liver disease, and potential risk factors for disease transmission.

Laboratory testing should include complete blood counts (CBC with platelets), hepatic function panel, and prothrombin time and international normalized ratio (INR). Laboratory tests to detect hepatitis B replication and other viral coinfections (HAV, HCV, HIV) should be included in the assessment (Terrault et al., 2015).

Prevention

The goals of prevention are to interrupt the chain of transmission, to protect people who are at high risk by active immunization through the use of hepatitis B vaccine, and to use passive immunization for unprotected people exposed to HBV.

Preventing Transmission

Recommendations to prevent transmission of hepatitis B include vaccination of sexual contacts of individuals with chronic hepatitis B, use of barrier protection during sexual intercourse, avoidance of sharing toothbrushes and razors with others, and covering of open sores or skin lesions. Blood spills should be cleaned with bleach diluted to a 10:1 concentration. Persons with HBV infection should be advised to avoid donation of blood, organs, or sperm.

Active Immunization: Hepatitis B Vaccine

The most effective strategy to prevent hepatitis B infection is through vaccination. Current prevention recommendations include:

- Universal vaccination of infants at birth
- Screening of pregnant women for hepatitis B surface antigen (HBsAg)
- Prophylaxis of infants with HBsAg-positive mothers or those with unknown HBsAg status
- Vaccination of unvaccinated children and adolescents
- Vaccination of unvaccinated adults at risk for HBV infection (i.e., health care workers, sexual or household contacts of HBV carriers) (Pawlotsky, 2016a)

The hepatitis B vaccine series is administered in three doses intramuscularly: the initial injection, then 1-month, and 6-month intervals for adults (Robinson & ACIP, 2016).

Nursing Alert
The U.S. Food and Drug Administration (FDA) has approved a combined vaccine for both hepatitis A and B (Twinrix) for vaccination of people 18 years of age and older with indications for both hepatitis A and B vaccination. Vaccination consists of three doses on the same schedule as that used for single-antigen hepatitis B vaccine (Robinson & ACIP, 2016).

Passive Immunity: Hepatitis B Hyperimmune Globulin

Hepatitis B hyperimmune globulin (HBIG) provides passive immunity to hepatitis B and is indicated for people exposed to HBV who have never had hepatitis B, who have had sexual exposure (within 14 days), infants who have had exposure at birth, and those who have never received hepatitis B vaccine. A second dose of HBIG is given in 28 days for those refusing vaccine or vaccine nonresponders (Ferri, 2016a). It has demonstrated efficacy in the prevention of HBV infection in high-risk persons (exposure to blood-containing HBV,

sexual partners of patients with hepatitis B, and newborn infants of HBsAg-positive mothers) (Gold Standard, 2015).

Medical Management

The goals of treatment for hepatitis B are to prevent replication of active HBV (viral suppression) and reduce the effects of chronic liver inflammation. The ultimate goal of medical management of hepatitis B is to prevent cirrhosis, liver failure, and hepatocellular carcinoma (HCC) (Pawlotsky, 2016a). Multiple antiviral therapies are available to treat hepatitis B; of these, pegylated interferon alfa, adefovir, entecavir, telbivudine, lamivudine, and tenofovir are the preferred medications, either as single agents or in combination. Patients with HBV infection should have periodic laboratory testing to assess elevations in liver function and replication of HBV DNA. Patients at high risk for HCC (discussed later in this chapter), including patients with cirrhosis, should receive ultrasound screening every 6 months (Terrault et al., 2015).

Nursing Management

In patients with acute hepatitis B, management of the symptoms of malaise, anorexia, nausea, vomiting, and fever primarily is supportive to maintain nutrition, fluid intake, and adequate rest during recovery. The nurse must be vigilant for signs of progression to fulminant liver failure (discussed later in the chapter); however, alterations in mental status, severe vomiting, and increasing jaundice should initiate referral to a tertiary care center or liver transplant center. In patients with chronic hepatitis B, the nursing role is geared to patient education in the prevention of transmission and avoidance of lifestyle factors that may exacerbate existing liver disease.

HEPATITIS C VIRUS

Hepatitis C virus (HCV) infection is the leading cause of liver disease and is the primary indication for liver transplantation.

Pathophysiology

HCV is a blood-borne RNA virus and is avidly replicated in the liver. Transmission of hepatitis C occurs primarily through injection of drugs and through transfusion of blood products prior to 1992. Its route is through parenteral contact with blood. Sexual transmission also may occur, with high risk associated with multiple sex partners. Other less common modes of transmission include via hemodialysis, health care worker exposure to needlestick injury or contaminated blood, and tattooing (AASLD/IDSA HCV Guidance Panel, 2015; Pawlotsky, 2016a). Box 25-6 summarizes risk factors for hepatitis C.

Patients infected with this virus spontaneously clear the acute infection in 20% to 50% of cases; the majority of individuals will develop chronic infection, with evidence of hepatitis C RNA viremia (Pawlotsky, 2016b). Unlike other hepatitis viruses, the acute stage of hepatitis C often is asymptomatic for decades. Hepatitis C infection with progression to cirrhosis occurs in up to 20% of patients over a period of 20 years or longer if untreated. Factors contributing to the severity of liver disease include increased alcohol use, male gender, older age at infection, HIV or HBV coinfection, and obesity (AASLD/IDSA HCV Guidance Panel, 2015; Pawlotsky, 2016b). Individuals with HCV cirrhosis are at higher risk of developing hepatic decompensation and HCC, and in industrialized countries, hepatitis C remains the most common cause of HCC (Pawlotsky, 2016b).

BOX 25-6 Risk Factors for Hepatitis C

- Receiving blood products or organ transplant before 1992 or clotting factor concentrates before 1987
- Being a health care or public safety worker (needlestick injuries or mucosal exposure to blood)
- Being a child born to a woman infected with hepatitis C virus
- Past/current illicit IV/injection drug use
- Past treatment with chronic hemodialysis
- Multiple sex partners, history of sexually transmitted disease, unprotected sex

Clinical Manifestations and Assessment

Most patients with acute or chronic hepatitis C are asymptomatic. Some patients will develop jaundice, nausea, vomiting, and malaise during the acute stage (Pawlotsky, 2016a) (Box 25-7). Patients with chronic hepatitis C frequently will be diagnosed incidentally during routine laboratory testing or not until cirrhosis develops. Extrahepatic signs of hepatitis C are common, such as skin rashes, joint aches, and purpura (small blood vessels leaking under the skin and causing purple bruising) (Pawlotsky, 2016a).

The diagnosis of HCV infection is confirmed by serology with anti-HCV antibodies present and measurement of viremia through HCV RNA. Genotype testing and liver biopsy will provide information to assist in the management and treatment of hepatitis C as well as to stage the severity of disease. Other tests to assess the extent of liver disease include laboratory tests (i.e., bilirubin, albumin, aminotransferases, prothrombin time, and INR). Ultrasound or other imaging may be used to assess for cirrhosis or the presence of lesions (AASLD/IDSA HCV Guidance Panel, 2015).

Medical and Nursing Management

Treatment of hepatitis C aims to reduce mortality by preventing the progression of fibrosis and evolution to cirrhosis by reducing HCV RNA levels to nondetectable levels. A nondetectable viral load or HCV RNA 12 weeks after completion of therapy is considered curative. This is called a *sustained viral response (SVR).* New antiviral therapies with direct acting agents (DAA), called protease inhibitors, have revolutionized treatment of hepatitis C. Use of these drugs and drug combinations is evolving rapidly, resulting in SVR in genotypes or comorbidities that previously had been difficult to treat. Clinical trial evidence has demonstrated protease inhibitor therapy is well tolerated with less to no symptomatic complaints from patients during treatment course unlike its predecessor, pegylated interferon, given weekly by injection and associated with many side effects (AASLD/IDSA HCV Guidance Panel, 2015). The specific protease inhibitor or drug combination, dosage, and length of therapy are determined by HCV genotype, history or prior HCV treatment, and presence of cirrhosis and level of decompensation. Patients who previously failed therapy with interferon and/or other types of protease inhibitors and patients with recurrent HCV after liver transplant are eligible to receive alternative regimens in hopes of achieving SVR as well. Patients are monitored with serum laboratory testing, including CBC, metabolic panel, hepatic function panel, and HCV viral load testing at prescribed intervals in conjunction with telephone and monitoring visits to evaluate adherence, tolerance, and compliance (AASLD/IDSA HCV Guidance Panel, 2015).

BOX 25-7 Nursing Research

Bridging the Gap to Evidence-Based Practice

Incidence of Preventable Postoperative Readmissions Following Pancreaticoduodenectomy: Implications for Patient Education. Hari, M., & Rosenzweig, M. (2012). *Oncology Nursing Forum, 39*(4), 408–412.

Purpose

The purpose of this article is to determine readmission rates post-pancreaticoduodenectomy (PD), readmission reasons following PD, and patients' postoperative education prior to discharge.

Design

A retrospective, descriptive study was conducted using established medical records of patients who had undergone PD from 2006 to 2008. Records were reviewed from the PD cohort within a pancreatic cancer program where there were 62 patients aged 18 years or older diagnosed with pancreatic cancer who had PD. Data were abstracted from inpatient and outpatient electronic records per study protocol and entered into an Excel® spreadsheet for analysis. Incidences of and reasons for readmissions post the PD procedure were reviewed. Discharge education given to patients prior to discharge was reviewed.

Findings

Patients were discharged at mean postoperative day 11.3. Readmission rate was 28%. Reasons for readmission were dehydration or malnutrition (n = 10, 16%) and surgical site infection (n = 7, 11%); 10% of patients (n = 6) had documented difficulties with dehydration, malnutrition, and failure to thrive noted at follow-up. PD discharge teaching was documented in a mandatory discharge form. No standard curriculum was used. Conclusions: Patients undergoing PD experienced an increase in self-care demand postdischarge. Poor discharge education can lead to high rates of readmission, specifically for dehydration and malnutrition, mandating an assessment of patient education prior to discharge.

Nursing Implications

Close attention must be given to the needs of patients with pancreatic cancer postdischarge. Trying to identify the areas of educational deficit at patient readmission could help nurses identify what they can do to minimize preventable complications. Educational focus for patients undergoing PD should be on prevention of dehydration, malnutrition, and surgical site infections.

HEPATITIS D VIRUS

Hepatitis D virus (delta agent) (HDV) infection occurs in some cases of hepatitis B. Because the virus requires hepatitis B surface antigen for its replication, only individuals with hepatitis B are at risk for hepatitis D. Anti-HDV antibodies (IGg) in patients with chronic hepatitis B confirms the diagnosis (Pawlotsky, 2016b; Lok & Negro, 2012).

The symptoms of hepatitis D are similar to those of hepatitis B, except that patients are more likely to develop fulminant hepatitis and to progress to chronic active hepatitis and cirrhosis. Current treatment for hepatitis D is the use of interferon or pegylated interferon alfa for 12 months (Pawlotsky, 2016b).

HEPATITIS E VIRUS

It is believed that hepatitis E virus (HEV) is transmitted by the fecal–oral route, principally through contaminated water in endemic areas with poor sanitation. This form of hepatitis usually is self-limiting, with acute onset and subsequent recovery with no chronicity. HEV is responsible for most cases of fulminant hepatitis in India. Pregnant women infected with hepatitis E infection have a high mortality rate (between 15% and 25%); this is increased during the last trimester (Watson & Sjogren, 2012). Currently, there is no vaccine or specific treatment for HEV; however, research in vaccine development may be promising in the near future.

Prevention of transmission is focused on improvement of sanitation, development of clean water supplies in endemic countries, and safe food-handling practices (Pawlotsky, 2016a).

NONVIRAL HEPATITIS

Liver inflammation and disease can be caused by nonviral etiologies, such as toxins, infections, alcoholic overuse, and autoimmune disorders.

ALCOHOLIC LIVER DISEASE (ALCOHOLIC HEPATITIS)

Excessive ingestion or abuse of alcohol is a common cause of acute hepatitis, and chronic use results in cirrhosis. Alcoholic liver disease (ALD) is a major public health problem and accounts for approximately 40% of deaths related to cirrhosis of the liver. It is estimated that fatty liver results from alcohol in 80% to 90% of heavy drinkers, while 30% to 40% of that population progress toward more problematic forms of liver disease, such as fibrosis, cirrhosis, and HCC (Chalasani, 2016; Dasarathy & McCullough, 2012; Orman, Odena, & Batallar, 2013).

The impact of alcohol ingestion upon the liver is dose-dependent; women will develop advanced liver disease at lower amounts of alcohol than will men. Other cofactors contributing to the development of cirrhosis in ALD is hepatitis C infection, smoking, and obesity. The amount of alcohol consumed to result in significant liver disease is more than 20 g of alcohol daily over a 10-year period in females and 60 to 80 g of alcohol daily in men (Dasarathy & McCullough, 2012; Singal et al., 2014).

Pathophysiology

Ethanol (alcohol) is metabolized by the liver by alcohol dehydrogenases, cytochrome P450, and catalase. The resultant product, acetaldehyde, is toxic to the liver, resulting in impairment of liver function and cells. Other factors contributing to the pathogenesis of ALD are oxidative stress, hypoxia or oxygen depletion of cells, and mitochondrial injury. Fatty infiltration of liver cells (hepatic steatosis) is a common finding in liver biopsies of patients with ALD (Chalasani, 2016; Dasarathy & McCullough, 2012).

Clinical Manifestations and Assessment

Patients presenting with alcoholic hepatitis are universally jaundiced. The patient may have symptoms of anorexia, nausea, vomiting, and abdominal pain. Fever, muscle wasting, and *stigmata*—such as spider angiomas (Fig. 25-11) or palmar erythema (redness of the palm)—are common findings. The liver may be enlarged, or hard and small. The spleen will be enlarged, and late signs of hepatic decompensation may be evident, such as ascites, pedal edema, and hepatic encephalopathy (Chalasani, 2016).

FIGURE 25-11 Spider angioma. This vascular (arterial) spider appears on the skin. Beneath the elevated center and radiating branches, the blood vessels are looped and tortuous.

There is no specific evaluation or test for the diagnosis of ALD; the clinical history and physical presence of liver disease correlated with information regarding alcohol overuse is diagnostic. An AST/ALT ratio of greater than two indicates ALD in over 70% of cases (Chalasani, 2016).

A complete history and physical examination is important in the assessment of patients with ALD. Patients should be screened for frequency, amount of alcohol use, type of alcohol, and patterns of alcohol use. Several evidence-based screening instruments for assessment of alcohol dependence exist, such as the CAGE and AUDIT tools to assist clinicians with detection and diagnosis (Dasarathy & McCullough, 2012). Additional information regarding the negative impact of alcohol abuse upon employment, health (i.e., falls, fractures), or driving status provides more data to assess the extent of alcohol use (Dasarathy & McCullough, 2012).

Nursing Alert
CAGE (Cut down, Annoyed, Guilty, and Eye-opener)

Ask your patients these four questions and use the scoring method described below to determine if substance abuse exists and needs to be addressed.

CAGE Questions

1. *Have you ever felt you should cut down on your drinking?*
2. *Have people annoyed you by criticizing your drinking?*
3. *Have you ever felt bad or guilty about your drinking?*
4. *Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (eye-opener)?*

Scoring: *Item responses on the CAGE questions are scored 0 for "no" and 1 for "yes" answers, with a higher score being an indication of alcohol problems. A total score of two or greater is considered clinically significant.*

Medical Management

The mainstay of treatment for ALD is abstinence and either oral or enteral nutritional therapy. Patients with ALD frequently are malnourished, with depleted protein stores and vitamin deficiencies; the complex nutritional management of these patients is best suited to clinical nutritionists with expertise in this area. In patients with severe alcoholic hepatitis, prednisolone may be used. Clinical trials have demonstrated improved survival of patients treated for severe alcoholic hepatitis with corticosteroids; however, this remains controversial and is contraindicated in the presence of infection, bleeding, or renal impairment (Orman et al., 2013; Dasarathy & McCullough, 2012). Box 25-8 reviews dietary management appropriate for patients with hepatitis.

BOX 25-8

Nutrition Alert 

Dietary Management of Viral or Drug-Related Hepatitis

- Recommend small, frequent meals.
- Provide intake of 2,000–3,000 kcal/day during acute illness.
- Although early studies indicate that a high-protein, high-calorie diet may be beneficial, advise patient not to force food and to restrict fat intake.
- Carefully monitor fluid balance.
- If anorexia and nausea and vomiting persist, enteral feedings may be necessary.
- Instruct patient to abstain from alcohol during acute illness and for at least 6 months after recovery.
- Advise patient to avoid substances (medications, herbs, illicit drugs, and toxins) that may affect liver function.

General management includes supportive care with adequate rest, correction of bleeding abnormalities, treatment of infection, and management of fluid overload. Providers trained in alcohol addiction should be employed once the patient is able to engage in therapy to maintain abstinence.

DRUG-INDUCED LIVER DISEASE (DRUG-RELATED HEPATITIS)

Drug-induced hepatotoxicity is very common and can range from mild elevations in aminotransferases to fulminant liver failure due to ingestion or exposure to medications, toxins, or herbal remedies alone or in combination (Larson, 2012). It is the most common cause of acute liver failure, accounting for more than 50% of all cases in the United States and the United Kingdom (Lee, 2016).

Pathophysiology

Although any medication can affect liver function, use of acetaminophen (found in many over-the-counter medications used to treat fever and pain) has been identified as a leading cause of acute liver failure (Everson, 2016). Other medications commonly associated with liver injury include antibiotics, anticonvulsants, NSAIDs, and antituberculosis agents (Lee, 2016).

Clinical Manifestations and Assessment

Manifestations of sensitivity to a medication may occur on the first day of its use or not until several months later, depending on the medication. Usually the onset is abrupt, with chills, fever, rash, pruritus, arthralgia, anorexia, and nausea. Later, there may be jaundice, dark urine, and an enlarged and tender liver. After the offending medication is withdrawn, symptoms may subside gradually. However, reactions can be severe, or even fatal, even if the medication is stopped. If fever, rash, or pruritus occurs from any medication, its use should be stopped immediately. A thorough history of all medications, over-the-counter medications, and supplements should be obtained from all patients presenting with signs or symptoms of acute or chronic liver disease.

Medical and Nursing Management

The management of drug-induced liver injury includes discontinuation of the suspected medication or medications; evaluation of liver damage, including hospitalization if jaundice or impaired hepatic function is present; and, in cases of fulminant or acute liver failure, referral to a liver transplant center. Antidotes should be delivered if available. N-acetylcysteine (Mucomyst) is administered routinely in the setting of overdose of acetaminophen by restoring hepatic concentration of glutathione (Lee, 2016).

Although its efficacy is uncertain, a short course of high-dose corticosteroids may be used in patients with severe hypersensitivity (Chitturi & Farrell, 2012).

Nursing Alert

The liver metabolizes many medications, such as barbiturates, opioids, sedative agents, anesthetics, and amphetamines. Metabolism generally results in inactivation of the medication, although in some cases activation of the medication may occur. One of the important pathways for medication metabolism involves conjugation (binding) of the medication with a variety of compounds to form more soluble substances that may be excreted in the feces or urine, similar to bilirubin excretion. Bioavailability is the fraction of the administered medication that actually reaches the systemic circulation. The bioavailability of an oral medication (absorbed from the GI tract) can be decreased if the medication is metabolized to a great extent by the liver before it reaches the systemic circulation; this is known as first-pass effect. *Some medications have such a large first-pass effect that their use is limited essentially to the parenteral route, or oral doses must be substantially larger than parenteral doses to achieve the same effect. If medications are administered that have a high hepatic metabolism, bioavailability increases and hepatic clearance decreases in liver disease. It is important for the nurse to understand the clearance of medications and to observe patients for signs of further deterioration.*

FULMINANT HEPATIC FAILURE

Fulminant hepatic failure is the clinical syndrome of sudden and severely impaired liver function in a previously healthy person.

Pathophysiology

Fulminant liver failure is caused by many different etiologies. Viral hepatitis caused by A, B, and E is a common culprit worldwide. Acetaminophen overdose, drug-induced liver injury, autoimmune hepatitis, metabolic disorders such as Wilson disease, poisonous mushroom ingestion, and obstruction to hepatic blood flow (Budd–Chiari syndrome) are the most common causes of acute liver failure in the United States (Everson, 2016).

Clinical Manifestations and Assessment

The clinical manifestations of fulminant liver failure are hepatic encephalopathy, jaundice, nausea, anorexia, vomiting, and coagulopathy in a patient with no history of prior liver disease (Larson, 2012). The onset is abrupt, and the patient or family may or may not be able to identify the precipitating event.

Medical and Nursing Management

The clinical decision whether a patient will recover from acute liver injury with intense medical management or require liver transplantation typically is made on a case-by-case basis after careful evaluation of the patient. Multiple selection criteria have been developed to determine survival outcome (i.e., risk of death with or without transplant) and assist in the selection of patients appropriate for liver transplant, including time from jaundice to encephalopathy, prothrombin time, and levels of bilirubin, arterial pH, and creatinine (Everson, 2016).

Currently, in the United States, the United Network for Organ Sharing (UNOS) has defined criteria to determine which patients qualify for urgent transplant listing for fulminant liver failure:

- Onset of hepatic encephalopathy within 8 weeks of first symptoms of liver disease
- Absence of pre-existing liver disease
- Transaminases ALT/AST of greater than 3,000
- INR greater than 2.0

Patients may require one of the following interventions:

- Ventilator dependence
- Dialysis or continuous veno-venous hemofiltration (CVVH) or continuous veno-venous hemofiltration with dialysis (CVVD) (refer to Chapter 27)
- Care within an ICU

Patients with fulminant liver failure must have a life expectancy of less than 7 days without liver transplant to qualify for the highest active status for liver allocation, status 1A (United Network of Organ Sharing [UNOS], 2016).

The key to optimized treatment is rapid recognition of acute liver failure and intensive intervention. Supporting the patient in the ICU and assessing the indications for and feasibility of liver transplantation are hallmarks of management in this population. Often fulminant hepatic failure is accompanied by coagulation defects, kidney failure and electrolyte disturbances, cardiovascular abnormalities, infection, hypoglycemia, encephalopathy, and cerebral edema. The use of antidotes for certain conditions may be indicated, such as *N*-acetylcysteine for acetaminophen toxicity.

In patients who have fulminant liver failure with stage three (somnolent but can be aroused) or four (coma) encephalopathy, or elevated serum ammonia, there is a high risk for cerebral edema, a life-threatening complication. These patients may require intracranial pressure monitoring, although its use remains controversial. Measures to promote adequate cerebral perfusion include careful fluid balance and hemodynamic assessments, a quiet environment, and diuresis with mannitol, an osmotic diuretic. Use of barbiturate anesthesia or pharmacologic paralysis and sedation is indicated to prevent surges in intracranial pressure related to agitation. Other support measures include monitoring for and treating hypoglycemia, coagulopathy, kidney impairment, and infection. Despite these treatment modalities, the mortality rate remains high. Consequently, liver transplantation (discussed later) has become the treatment of choice for fulminant hepatic failure (Everson, 2016).

Cirrhosis

The most common causes of chronic liver disease are viral hepatitis B and C, ALD, nonalcoholic fatty liver disease (NAFLD), primary biliary cirrhosis, and autoimmune disorders of the liver. Acute forms of liver dysfunction and failure can occur from viral agents, drug hepatotoxicity, toxins, parasites, or metabolic disorders, such as Wilson disease (Garcia-Tsao, 2016). The development of cirrhosis is the final stage of all chronic liver disease and is one of the leading causes of death in the United States (Runyon, 2013).

Pathophysiology

Cirrhosis of the liver occurs when the normal liver tissue is replaced by fibrotic tissue in response to damage to liver cells, resulting in accumulation of extracellular matrix or "scar." The progression from fibrosis to cirrhosis results in the loss of normal structure and function in the liver (Schiff et al., 2012). The progression and severity of chronic liver disease can be classified as either compensated or decompensated cirrhosis.

Clinical Manifestations and Assessment

Typically compensated cirrhosis is asymptomatic. The transition from compensated cirrhosis to decompensated cirrhosis results in the development of jaundice, ascites, GI bleeding from esophageal varices, and hepatic encephalopathy. Box 25-9 provides guidelines for assessing cirrhosis. The development of any of these complications of hepatic dysfunction signals that the patient has progressed to decompensated cirrhosis. The hallmarks of decompensated cirrhosis are the development of jaundice, ascites (fluid collection in the peritoneum), pedal edema, gastroesophageal varices, and hepatic encephalopathy. Other complications, such as spontaneous bacterial peritonitis, hepatorenal syndrome (kidney dysfunction), and hepatopulmonary syndrome (causes symptoms such as shortness of breath and hypoxemia) may occur as well (Garcia-Tsao, 2016; Runyon, 2013).

BOX 25-9 Focused Assessment

Cirrhosis

Be alert for the following signs and symptoms:

Compensated Cirrhosis

- Intermittent mild fever
- Vascular spiders
- Palmar erythema (reddened palms)
- Unexplained epistaxis
- Ankle edema
- Vague morning indigestion
- Flatulent dyspepsia
- Abdominal pain
- Firm, enlarged liver
- Splenomegaly

Decompensated Cirrhosis

- Ascites
- Jaundice
- Weakness
- Muscle wasting
- Weight loss
- Continuous mild fever

- Clubbing of fingers
- Purpura (due to decreased platelet count)
- Spontaneous bruising
- Epistaxis
- Hypotension
- Sparse body hair
- White nails
- Gonadal atrophy

The Patient with Cirrhosis

ASSESSMENT

Nursing assessment focuses on the onset of symptoms and the history of precipitating factors, particularly long-term alcohol abuse, as well as dietary intake and changes in the patient's physical and mental status. The patient's past and current patterns of alcohol use (duration and amount) are assessed and documented. It is also important to document any exposure to toxic agents encountered in the workplace or during recreational activities. The nurse documents and reports exposure to potentially hepatotoxic substances, including medications, illicit IV/injection drugs, inhalants, and general anesthetic agents.

The nurse assesses the patient's mental status during the interview and other interactions with the patient; orientation to person, place, and time is noted. The patient's ability to carry out a job or household activities provides some information about physical and mental status. The patient's relationships with family, friends, and coworkers may give some indication about incapacitation secondary to alcohol abuse and cirrhosis. Abdominal distention, GI bleeding, bruising, and weight changes are noted.

The nurse assesses nutritional status, which is of major importance in cirrhosis, by obtaining daily weights and monitoring plasma proteins, transferrin, and creatinine levels. A plan of nursing care for a patient with impaired liver function is available online at http://thepoint.lww.com/Honan2e.

DIAGNOSIS

Nursing diagnoses may include the following:

- Activity intolerance related to fatigue, general debility, muscle wasting, and discomfort
- Imbalanced nutrition, less than body requirements, related to chronic gastritis, decreased GI motility, and anorexia
- Impaired skin integrity related to compromised immunologic status, edema, and poor

nutrition
- Risk for injury and bleeding related to altered clotting mechanisms

Potential complications may include the following:

- Bleeding and hemorrhage
- Hepatic encephalopathy
- Fluid volume excess

PLANNING

The goals for the patient may include increased participation in activities, improvement of nutritional status, improvement of skin integrity, decreased potential for injury, improvement of mental status, and absence of complications.

NURSING INTERVENTIONS

PROMOTING REST

The patient with active liver disease requires rest and other supportive measures to permit the liver to reestablish its functional ability. If the patient is hospitalized, weight and fluid intake and output are measured and recorded daily. The nurse adjusts the patient's position in bed for maximal respiratory efficiency, which is especially important if ascites is marked because it interferes with adequate thoracic excursion. Oxygen therapy may be required in liver failure.

Rest reduces the demands on the liver and increases the liver's blood supply. Because the patient is susceptible to the hazards of immobility, efforts to prevent respiratory, circulatory, and vascular disturbances are initiated, such as range-of-motion exercises, turning every 2 hours, and the use of an incentive spirometer (IS) every hour while awake. These measures may help prevent such problems as pneumonia, thrombophlebitis, and pressure ulcers. After nutritional status improves and strength increases, the nurse encourages the patient to increase activity gradually. Activity and mild exercise, as well as rest, are planned.

IMPROVING NUTRITIONAL STATUS

The patient with cirrhosis who has no ascites or edema and exhibits no signs of impending hepatic coma should receive a nutritious, high-protein diet, if tolerated, supplemented by vitamins of the B complex and others as indicated (including vitamins A, C, K, and folic acid). Because proper nutrition is so important, the nurse makes every effort to encourage the patient to eat. Proper nutrition is as important as any medication. Often, small, frequent meals are better tolerated than three large meals because of the abdominal pressure exerted by ascites. Protein supplements also may be indicated.

Patient preferences are considered. Patients with prolonged or severe anorexia and those who are vomiting or eating poorly for any reason may receive nutrients by the

enteral or parenteral route.

Patients with fatty stools (steatorrhea) should receive water-soluble forms of fat-soluble vitamins—A, D, and E (Aquasol A, D, and E). Folic acid and iron are prescribed to prevent anemia. If the patient shows signs of impending or advancing coma, the amount of protein in the diet is decreased temporarily. In the absence of hepatic encephalopathy, a moderate-protein, high-calorie intake is provided, with protein foods of high biologic value. A diet containing 1 to 1.5 g of protein per kilogram of body weight per day is required unless the patient is malnourished. Protein is restricted if encephalopathy develops. Incorporating vegetable protein to meet protein needs may decrease the risk for encephalopathy. Also sodium restriction is indicated to prevent ascites.

PROVIDING SKIN CARE

Providing careful skin care is important because of subcutaneous edema, the patient's immobility, jaundice, and increased susceptibility to skin breakdown and infection. Frequent changes in position are necessary to prevent pressure ulcers. To prevent trauma to the skin, it is important to avoid irritating soaps and the use of adhesive tape. Lotion may be soothing to irritated skin; the nurse takes measures to minimize scratching by the patient.

REDUCING RISK OF INJURY

The nurse protects the patient with cirrhosis from falls and other injuries. The side rails should be in place and padded with blankets or other materials in case the patient becomes agitated or restless. To minimize agitation, the nurse orients the patient to time and place and explains all procedures. The nurse instructs the patient to ask for assistance to get out of bed. The nurse carefully evaluates any injury because of the possibility of internal bleeding.

Nursing Alert
Because of the risk for bleeding from abnormal clotting, the patient should use an electric razor rather than a safety razor. A soft-bristled toothbrush helps minimize bleeding gums, and pressure applied to all venipuncture sites helps minimize bleeding.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Bleeding and Hemorrhage. The patient is at increased risk for bleeding and hemorrhage because of decreased production of prothrombin and decreased ability of the diseased liver to synthesize the necessary substances for blood coagulation. Precautionary measures include protecting the patient with padded side rails, applying pressure to injection sites, and avoiding injury from sharp objects. The nurse observes for melena and assesses stools for blood (signs of possible internal bleeding). Vital signs are monitored regularly. Precautions are taken to minimize rupture of esophageal varices by avoiding further increases in portal pressure (see earlier discussion). Dietary modification and appropriate

use of stool softeners may help prevent straining during defecation. The nurse closely monitors the patient for GI bleeding and keeps readily available equipment (e.g., balloon tamponade tube), IV fluids, and medications needed to treat hemorrhage from esophageal and gastric varices.

If hemorrhage occurs, the nurse helps the provider initiate measures to halt the bleeding and administers fluid and blood component therapy and medications. The patient with massive hemorrhage from bleeding esophageal or gastric varices is transferred to the ICU and requires emergency surgery or other treatment modalities. The patient and family require explanations about the event and the necessary treatment.

HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy and coma, possible complications of cirrhosis, may manifest as deteriorating mental status and dementia or as physical signs, such as abnormal voluntary and involuntary movements. Hepatic encephalopathy is caused mainly by the accumulation of ammonia in the blood and its effect on cerebral metabolism. Many factors predispose the patient with cirrhosis to hepatic encephalopathy. Therefore, the patient may require extensive diagnostic testing to identify hidden sources of bleeding and increased ammonia production.

Treatment may include the use of lactulose and nonabsorbable intestinal tract antibiotics to decrease ammonia levels, modification of medications to eliminate those that may precipitate or worsen hepatic encephalopathy, and bed rest to minimize energy expenditure.

Monitoring is an essential nursing function to identify early deterioration in mental status. The nurse monitors the patient's mental status closely and reports changes, so that treatment of encephalopathy can be initiated promptly. Because electrolyte disturbances can contribute to encephalopathy, serum electrolyte levels are carefully monitored and corrected if abnormal. Oxygen is administered if oxygen desaturation occurs. The nurse monitors for fever or abdominal pain, which may signal the onset of bacterial peritonitis or other infection (see earlier discussion of hepatic encephalopathy).

Nursing Alert
Signs and symptoms of bacterial peritonitis include fever with abdominal pain, nausea, vomiting, and diarrhea; however, in patients with cirrhosis, a low-grade temperature with or without abdominal pain may be noted (Ferri, 2016b).

Fluid Volume Excess. Patients with advanced chronic liver disease develop cardiovascular abnormalities. These occur due to an increased cardiac output and decreased peripheral vascular resistance, possibly resulting from the release of vasodilators. A hyperdynamic circulatory state develops in patients with cirrhosis, and plasma volume increases. The greater the degree of hepatic decompensation, the more severe the hyperdynamic state. Close assessment of cardiovascular and respiratory status is of key importance for the care of patients with this disorder. Pulmonary compromise, which is

always a potential complication of ESLD because of plasma volume excess, makes prevention of pulmonary complications an important role for the nurse. Administering diuretics, implementing fluid restrictions, and enhancing patient positioning can optimize pulmonary function. Fluid retention may be noted in the development of ascites, lower extremity swelling, and dyspnea. Monitoring of intake and output, daily weight changes, changes in abdominal girth, and edema formation is part of nursing assessment in the hospital or in the home setting. Patients also are monitored for any changes in kidney function.

PROMOTING HOME AND COMMUNITY-BASED CARE

During the hospital stay, the nurse and other health care providers prepare the patient with cirrhosis for discharge, focusing on dietary instruction. Of greatest importance is the exclusion of alcohol from the diet. The patient may need referral to Alcoholics Anonymous, psychiatric care, or counseling or may benefit from support from a spiritual advisor. Also the patient should avoid the consumption of raw meats and shellfish due to the increased risk of foodborne illness in immunosuppressed patients.

Sodium restriction will continue for a considerable time, if not permanently. The patient will require written instructions, teaching, reinforcement, and support from the staff as well as family members.

Successful treatment depends on convincing the patient of the need to adhere completely to the therapeutic plan. The nurse also instructs the patient and family about symptoms of impending encephalopathy, possible bleeding tendencies, and susceptibility to infection.

Recovery is neither rapid nor easy; there are frequent setbacks and apparent lack of improvement. Many patients find it difficult to refrain from using alcohol for comfort or escape. The nurse plays a significant role in offering support and encouragement to the patient.

EVALUATION

Expected patient outcomes may include the following:

1. Participates in activities:
   a. Plans activities and exercises to allow alternating periods of rest and activity
   b. Reports increased strength and well-being
   c. Participates in hygiene care
2. Increases nutritional intake:
   a. Demonstrates intake of appropriate nutrients and avoidance of alcohol as reflected by diet log
   b. Gains weight without increased edema and ascites formation
   c. Reports decrease in GI disturbances and anorexia
   d. Identifies foods and fluids that are nutritious and allowed on or restricted from the diet

e. Adheres to vitamin therapy regimen
f. Describes the rationale for small, frequent meals

3. Exhibits improved skin integrity:
   a. Has intact skin without evidence of breakdown, infection, or trauma
   b. Demonstrates normal turgor of skin of the extremities and trunk, and decreased edema
   c. Changes position frequently and inspects bony prominences daily
   d. Uses lotions to decrease pruritus
4. Avoids injury:
   a. Is free of ecchymotic areas or hematoma formation
   b. States rationale for side rails and asks for assistance to get out of bed
   c. Uses measures to prevent trauma (e.g., uses electric razor and soft toothbrush, blows nose gently, arranges furniture to prevent bumps and falls, avoids straining during defecation)
5. Is free of complications:
   a. Reports absence of frank bleeding from the GI tract (i.e., absence of melena and hematemesis)
   b. Is oriented to time, place, and person and demonstrates normal attention span
   c. Has a serum ammonia level within normal limits
   d. Identifies early, reportable signs of impaired thought processes

HEPATOCELLULAR CARCINOMA

HCC is the most common hepatic malignancy. It is the third leading cause of cancer death worldwide and the ninth leading cause of cancer death in the United States (Crissien & Frenette, 2014).

Risk Factors

HCC is strongly linked to cirrhosis and chronic hepatitis B and C infections. ALD, nonalcoholic steatohepatitis (inflammation and fat accumulation of the liver), primary biliary cirrhosis, and hemochromatosis (excessive retained iron in the body) also are thought to increase risk for HCC. Persons over 50 years of age and male gender also increase the likelihood of HCC developing in patients with cirrhosis (Forner, Ayuso, & Bruix, 2012). HCC may arise in patients without cirrhosis; typically these are individuals with chronic hepatitis B infection.

Clinical Manifestations and Assessment

Usually the clinical manifestations of HCC are found in the context of the patient with known cirrhosis: jaundice, ascites, varices, and the stigmata of chronic liver disease are common features. Unintentional weight loss, anorexia, and right upper quadrant pain may be additional presenting signs. In late cases, the patient may present with intra-abdominal bleeding from tumor rupture. In patients deemed high risk, routine screening with abdominal ultrasound and measurement of alpha fetoprotein levels has improved the detection of liver cancer (Bruix & Sherman, 2011; Crissien & Frenette, 2014).

The diagnosis of liver cancer is based on clinical signs and symptoms, the history and physical examination, and the results of laboratory and imaging studies. Increased serum levels of bilirubin, alkaline phosphatase, GGT, and alpha fetoprotein may occur. Anemia is a common finding, and leukocytosis (increased white blood cells [WBCs]), hypercalcemia, hypoglycemia, and hypocholesterolemia also may be seen on laboratory assessment.

Confirmation of the diagnosis of HCC is made radiologically with use of computed tomography (CT) scan imaging or magnetic resonance imaging (MRI) to determine the number, size, and location of tumors and if vascular invasion has occurred. In equivocal cases, liver biopsy may be used to obtain tissue samples of the lesion to determine malignancy (Crissien & Frenette, 2014).

Medical and Nursing Management

Currently there are multiple treatment options for the patient with HCC. Surgical resection is the preferred treatment for patients without cirrhosis and with adequate hepatic reserve; average 5-year survival outcomes after resection now exceed 50%; however, recurrence rates are as high as 70% at 5 years (Crissien & Frenette, 2014). In patients with HCC and cirrhosis, liver transplantation (discussed in detail below) is the treatment of choice. Liver transplantation is curative for patients with both HCC and ESLD; however, careful patient selection is critical to achieve good outcomes (Crissien & Frenette, 2014; Bruix & Sherman, 2011).

Other treatments for HCC are percutaneous ethanol injection (PEI) and radiofrequency (RFA) or microwave ablation (MWA), which directly induce tumor necrosis. Transarterial chemoembolization (TACE) is used to block the hepatic blood flow feeding the tumor and is used in combination with chemotherapeutic agents (Crissien & Frenette, 2014; Bruix & Sherman, 2011). Systemic chemotherapy includes sorafenib and other agents; currently multiple clinical trials are underway to study the effectiveness of chemotherapeutic agents to treat HCC (Crissien & Frenette, 2014).

LIVER TRANSPLANTATION

With recent advances in surgical techniques, immunosuppressant medications, and increased knowledge of immunology, liver transplantation has become the treatment of choice for patients with ESLD and acute liver failure. Because liver transplantation now is recognized as an established therapeutic modality, rather than an experimental procedure to treat these disorders, the number of liver transplantation centers is increasing. Often patients requiring transplantation are referred from distant hospitals to these sites. To prepare the patient and family for liver transplantation, nurses in all settings must understand the processes and procedures of liver transplantation.

The transplantation procedure involves total surgical removal of the diseased liver and replacement with a healthy donor organ in the same anatomic location (orthotopic liver transplantation [OLT]). The efficacy of this therapeutic modality is demonstrated by survival outcomes of 70.5% at 5 years (Kim et al., 2014). The important benefit of this option for patients with ESLD or fulminant liver failure is limited by the shortage of cadaveric donor organs. As of 2016, 14,000 patients were on the national UNOS transplant list awaiting liver transplant (HRSA/OPTN, 2016).

Indications and Contraindications

Indications for liver transplantation include:

- Advanced chronic liver disease
- Fulminant hepatic failure
- Metabolic liver diseases
- HCC
- Hepatocellular liver diseases (e.g., viral hepatitis, drug- or alcohol-induced liver disease, Wilson disease)
- Cholestatic diseases (interruption in bile flow seen in primary biliary cirrhosis, sclerosing cholangitis, and biliary atresia)

Other less common diseases requiring liver transplantation are polycystic liver disease, vascular disease (Budd–Chiari), and rare metabolic disorders (Everson, 2016).

Medical contraindications for liver transplant include uncontrolled infection, extrahepatic malignancy or advanced hepatobiliary metastatic disease, irreversible brain damage, anatomic difficulties, and multiorgan failure. Psychosocial contraindications include active substance use, medical nonadherence, and severe psychiatric instability (Everson, 2016; Martin et al., 2014). Other factors that may present obstacles to successful transplant are comorbidities, such as advanced cardiac or pulmonary disease, and poor psychosocial support.

Selection and Evaluation for Liver Transplant

The selection and evaluation of a patient for liver transplantation is a multidisciplinary process that requires a complete assessment of the patient, including etiology and stage of liver disease, and evaluation of comorbidities and/or contraindications, psychosocial status, and any medical or surgical issues. The patient being considered for liver transplantation frequently has many systemic problems that influence preoperative and postoperative care. The medical condition of the patient must be optimized as well as possible to prevent complications and to ensure good outcomes. Patients must undergo complete medical, surgical, and psychosocial testing to determine if liver transplant is feasible, and for organ matching.

Once the patient is evaluated and deemed appropriate for liver transplant by the transplant center, he or she is placed on the national transplant wait-list administered by the UNOS. The priority for obtaining a cadaveric liver organ is determined by the Model of End Stage Liver Disease (MELD) score, which stratifies the level of illness of those awaiting a liver transplant. The MELD score is derived from a complex formula incorporating sodium levels, bilirubin levels, prothrombin time (reported as INR), and creatinine levels. The MELD score is an indicator of short-term mortality for those with ESLD. Additional priority beyond the patient's physiologic MELD score may be provided for selected diseases that increase the patient's mortality risk, such as HCC, HPS, and metabolic diseases of the liver. The highest priority on the transplant wait-list is provided to patients with acute or fulminant liver failure (HRSA/OPTN, 2016).

Surgical Procedure

The transplant operation involves total removal of the diseased liver, or hepatectomy, replacement with the donor organ, vascular anastomoses of the donor liver to the recipient, and biliary reconstruction. This complex surgical procedure is divided in three stages or phases: hepatectomy, anhepatic (no liver) phase, and reperfusion phase.

The first stage involves the total removal of the diseased liver. Vascular clamps are placed on the portal vein and the inferior vena cava above and below the liver, and the native liver is dissected from the recipient. Hemostasis is maintained using sutures and cauterization of bleeding vessels. After preparation of the donor liver, anastomoses of the suprahepatic inferior vena cava, infrahepatic inferior vena cava, and portal vein surgically connect the donor liver to the recipient. Reperfusion of the new donor liver is achieved by removal of vascular clamps and perfusion of portal venous blood. Then hepatic artery anastomosis is performed and, last, biliary reconstruction.

Multiple surgical innovations have been developed to prevent complications, such as bleeding, bile leaks, and reperfusion injury of the new graft, to improve outcomes (Eghtesad & Fung, 2012).

Liver transplantation is a long surgical procedure, partly because the patient with liver failure often has portal hypertension that requires the ligation of many venous collateral vessels. Blood loss during the surgical procedure may be extensive. If the patient has adhesions from previous abdominal surgery, lysis of adhesions is often necessary. If a shunt procedure was performed previously, it must be surgically reversed to permit adequate portal venous blood supply to the new liver. During the lengthy surgery, it is helpful to provide regular updates to the family about the progress of the operation and the patient's status.

Complications

Immediate postoperative complications may include bleeding, infection, rejection, and delayed graft function. Other complications include biliary leaks and obstruction, hepatic artery thrombosis, and portal vein thrombosis (Everson, 2016).

Primary Graft Nonfunction

Primary graft nonfunction is the most severe complication of liver transplant and occurs in up to 8.5% of cases. Ongoing encephalopathy, coagulopathy, jaundice, metabolic acidosis, and hemodynamic instability are clinical indications of primary graft nonfunction (Everson, 2016). Transplant recipients with primary graft nonfunction require immediate retransplantation and receive priority on the transplant wait-list (HRSA/OPTN, 2016).

Bleeding

Bleeding is common in the postoperative period and may result from coagulopathy, portal hypertension, and fibrinolysis (breakdown of fibrin clots) caused by ischemic injury to the donor liver. Hypotension may occur in this phase, secondary to blood loss. Administration of platelets, fresh-frozen plasma, or other blood products may be necessary. Hypertension is more common, although its cause is uncertain. Blood pressure elevation that is significant or sustained is treated.

Infection

Infection is a life-threatening complication after liver transplantation. Pulmonary and fungal infections are common; susceptibility to infection is increased by the immunosuppressive therapy that is needed to prevent rejection (Everson, 2016). Therefore, precautions must be taken to prevent health care–associated infections. The nurse uses strict asepsis when manipulating central venous catheters, arterial lines, and drainage systems for urine, bile, and any body fluids; when obtaining specimens; and when changing dressings. Meticulous hand hygiene and contact precautions are crucial to prevent infection in the recipient of a liver transplant.

Rejection

Rejection is a primary concern. A transplanted liver is perceived by the immune system as a foreign antigen. This triggers an immune response, leading to the activation of T lymphocytes that attack and destroy the transplanted liver. Immunosuppressive agents are used as long-term therapy to prevent this response and rejection of the transplanted liver. These agents inhibit the activation of immunocompetent T lymphocytes to prevent the production of effector T cells. Most transplant centers use two or three immunosuppressants in combination to prevent rejection (Lucey et al., 2013; Wiesner, 2012). The recipient of the liver transplant requires intensive education in dosing, side effects, and the drug interactions of these medications and will require lifelong immunosuppression.

Although the 1- and 5-year survival rates have increased dramatically with the use of

new immunosuppressive therapies, these therapies are not without side effects. Both cyclosporine and tacrolimus have important side effects, such as kidney dysfunction, hypertension, hyperlipidemia, and hyperkalemia. Neurotoxicity may occur with use of tacrolimus, and patients may experience tremors to more severe complications, such as psychosis or seizures. Optimal dosing of immunosuppression must be monitored carefully to prevent rejection and to reduce side effects (Lucey et al., 2013).

Despite the success of immunosuppression in reducing the incidence of rejection of transplanted organs, liver transplantation is not routine and may be accompanied by complications related to the lengthy surgical procedure, immunosuppressive therapy, infection, and the technical difficulties encountered in reconstructing the blood vessels and biliary tract.

Nursing Management

The patient considering transplantation, together with the family, must make difficult choices about treatment, use of financial resources, and relocation to another area to be closer to the medical center. They also must cope with the patient's longstanding health problems and any social and family problems associated with behaviors that may have caused the patient's liver failure. As a result, considerable emotional stress occurs while the patient and family consider liver transplantation and wait for an available liver. The nurse must be aware of these issues and attuned to the emotional and psychological status of the patient and family. Referral to a psychiatric liaison nurse, psychologist, psychiatrist, or spiritual advisor may help them cope with the stressors associated with ESLD and liver transplantation.

Preoperative Nursing Interventions

The nurse, surgeon, hepatologist, and other members of the health care team provide the patient and family with full explanations about the procedure, the chances of success, and the risks, including the side effects of long-term immunosuppression. The need for close follow-up and lifelong compliance with the therapeutic regimen, including immunosuppression, is explained to the patient and family.

The nurse coordinator is an integral member of the transplant team and plays an important role in preparing the patient for liver transplantation. The nurse serves as advocate for the patient and family and assumes the important role of liaison between the patient and the other members of the transplant team. The nurse also serves as a resource to other nurses and members of the health care team involved in evaluating and caring for the patient.

Postoperative Nursing Interventions

The patient is maintained in an environment as free from bacteria, viruses, and fungi as possible because immunosuppressive medications reduce the body's natural defenses. In the immediate postoperative period, cardiovascular, pulmonary, renal, neurologic, and metabolic functions are monitored continuously. Mean arterial pressures and pulmonary artery pressures (PAPs) also are monitored. Ventilator support and airway management are priorities. Cardiac output (CO), central venous pressure (CVP), PAPs, pulmonary capillary wedge pressure (PCWP), arterial and mixed venous blood gases, oxygen saturation, oxygen demand and delivery, urine output, heart rate, and blood pressure are used to evaluate the patient's hemodynamic status and intravascular fluid volume. Liver function tests, electrolyte levels, the coagulation profile, chest x-ray, electrocardiogram, and fluid output (including urine, bile from the T tube, and output from NG and drainage tubes) are monitored closely. Because the liver is responsible for the storage of glycogen and the synthesis of protein and clotting factors, these substances need to be monitored and replaced in the immediate postoperative period. The nurse monitors for signs of excess bleeding in the immediate postoperative period and notifies the provider immediately if bleeding is suspected (hypotension, tachycardia, tachypnea, decreasing CO, melena, increasing abdominal girth, bloody NG drainage, etc.).

There is a high risk for atelectasis and an altered ventilation–perfusion ratio, caused by insult to the diaphragm during the surgical procedure, prolonged anesthesia, immobility, and postoperative pain. Because of this risk, the patient will have an endotracheal tube in place and will require mechanical ventilation during the initial postoperative period. Suctioning is performed as required, and sterile humidification is provided.

As the vital signs and condition stabilize, efforts are made to assist the patient to recover from the trauma of this complex surgery. After removal of the endotracheal tube, the nurse encourages the patient to use an IS to decrease the risk for atelectasis. Once the arterial lines and the urinary catheter are removed, the patient is assisted to get out of bed, to ambulate as tolerated, and to participate in self-care to prevent the complications associated with immobility. Close monitoring for signs and symptoms of liver dysfunction and rejection continue throughout the hospital stay. Plans are made for close follow-up after discharge as well. Teaching is initiated during the preoperative period and continues after surgery.

Promoting Home and Community-Based Care

Teaching the patient and family about long-term measures to promote health is crucial for the success of transplantation and represents an important role of the nurse. The patient and family must understand why they need to adhere continuously to the therapeutic regimen, with special emphasis on the methods of administration, rationale, and side effects of the prescribed immunosuppressive agents. The nurse provides written as well as verbal instructions about how and when to take the medications. To avoid running out of medication or skipping a dose, the patient must make sure that an adequate supply of medication is available. Also instructions are provided about the signs and symptoms that indicate problems necessitating consultation with the transplant team.

The nurse emphasizes the importance of follow-up blood tests and appointments with the transplant team. Trough blood levels (the lowest concentration reached by a medication before the next dose is administered) of immunosuppressive agents are obtained along with other blood tests that assess the function of the liver and kidneys. During the first months, the patient is likely to require blood tests two or three times a week. As the patient's condition stabilizes, blood studies and visits to the transplant team are less frequent. The importance of routine ophthalmologic examinations is emphasized because of the increased incidence of cataracts and glaucoma associated with the long-term corticosteroid therapy used with transplantation. Regular oral hygiene and follow-up dental care, with administration of prophylactic antibiotics before dental examinations and treatments, are recommended because of the immunosuppression.

The nurse reminds the patient that preventing rejection and infection leads to a successful transplantation and increases the chances for survival and living a more normal life than before transplantation. Many patients have lived successful and productive lives after receiving a liver transplant.

DISORDERS OF THE GALLBLADDER

Several disorders affect the biliary system and interfere with normal drainage of bile into the duodenum. These disorders include inflammation of the biliary system and carcinoma that

obstructs the biliary tree. Gallbladder disease with gallstones is the most common disorder of the biliary system. Although not all occurrences of gallbladder inflammation (cholecystitis) are related to gallstones (cholelithiasis), more than 90% of patients with acute cholecystitis have gallstones. However, most of the 20 million Americans with gallstones have no pain and are unaware of the presence of stones.

CHOLELITHIASIS

Calculi, or gallstones, usually form in the gallbladder from the solid constituents of bile; they vary greatly in size, shape, and composition (Fig. 25-12).

Pathophysiology

There are two major types of gallstones: those composed predominantly of pigment and those composed primarily of cholesterol. Pigment stones form when unconjugated pigments in the bile precipitate to form stones. The risk of developing such stones is increased in patients with cirrhosis, hemolysis, and infections of the biliary tract. Pigment stones cannot be dissolved and must be removed surgically.

Cholesterol stones account for over 70% to 80% of gallbladder disease in the United States. Cholesterol, a normal constituent of bile, is insoluble in water. Its solubility depends on bile acids and lecithin (phospholipids) in bile. In patients who are gallstone prone, there is decreased bile acid synthesis and increased cholesterol synthesis in the liver, resulting in bile supersaturated with cholesterol, which precipitates out of the bile to form stones. The cholesterol-saturated bile predisposes to the formation of gallstones and acts as an irritant that produces inflammatory changes in the gallbladder (Fogel & Sherman, 2016).

Risk Factors

Gallstones are uncommon in children and young adults but become increasingly prevalent after 40 years of age, especially in women (Box 25-10).

Clinical Manifestations and Assessment

Gallstones may be silent, producing no pain and only mild GI symptoms. Such stones may be detected incidentally during surgery or evaluation for unrelated problems.

The patient with gallbladder disease resulting from gallstones may develop two types of symptoms: those due to disease of the gallbladder itself, and those due to obstruction of the bile passages by a gallstone. The symptoms may be acute or chronic. Epigastric distress, such as fullness, abdominal distention, and vague pain in the right upper quadrant of the abdomen, may occur. This distress may follow a meal rich in fried or fatty foods. Clinical manifestations of gallstones are largely asymptomatic; however, 15% to 20% of patients with gallstones will develop pain and biliary colic with repeated episodes of obstruction. Increased frequency of biliary colic typically will result in cholecystitis. If the gallstone is dislodged and no longer obstructs the cystic duct, the gallbladder drains and the inflammatory process subsides after a relatively short time. If the gallstone continues to obstruct the duct, abscess, necrosis, and perforation with generalized peritonitis may result.

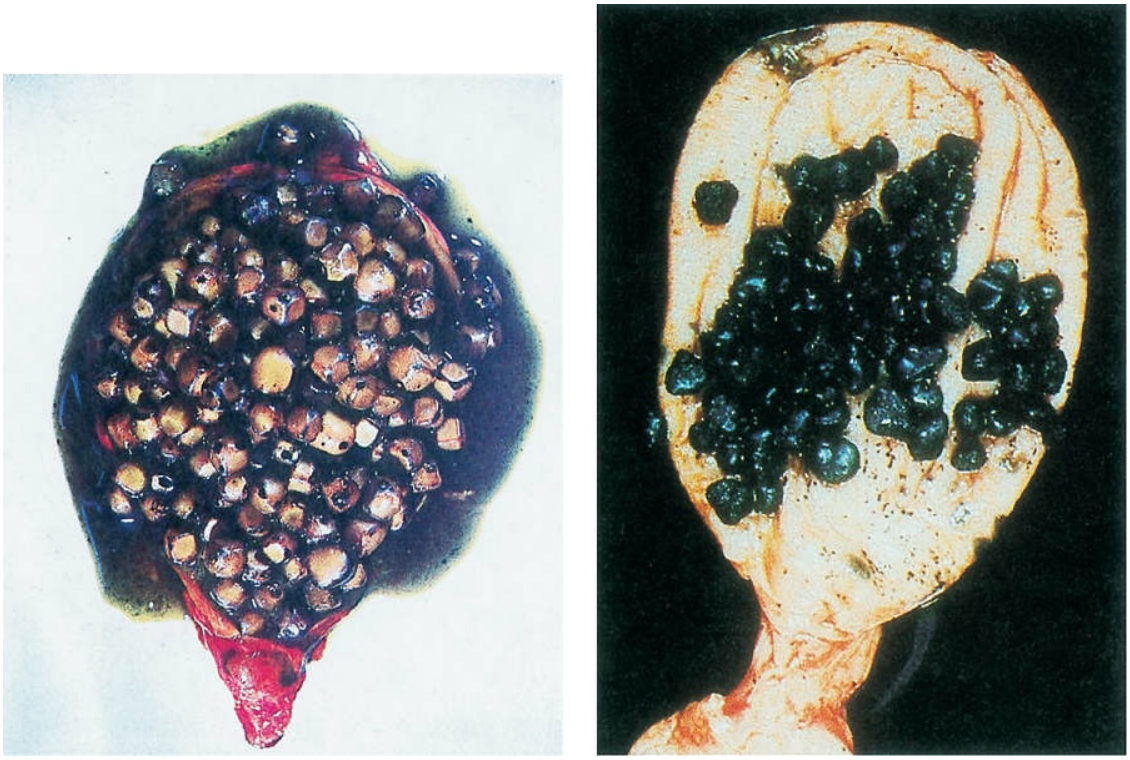

FIGURE 25-12 Examples of cholesterol gallstones (*left*) made up of a coalescence of multiple small stones and pigment gallstones (*right*) composed of calcium bilirubinate. (From Rubin, R., & Strayer, D. S. (2008). *Rubin's Pathology* (5th ed). Philadelphia, PA: Lippincott Williams & Wilkins.)

BOX 25-10 Risk Factors for Cholelithiasis

- Obesity
- Female gender, especially women who have had multiple pregnancies or who are of Native American or U.S. Southwestern Hispanic ethnicity

- Frequent changes in weight
- Rapid weight loss (leads to rapid development of gallstones and high risk of symptomatic disease)
- Treatment with high-dose estrogen (e.g., in prostate cancer)
- Low-dose estrogen therapy; a small increase in the risk of gallstones
- Ileal resection or disease
- Gastric bypass
- Total parental nutrition
- Cystic fibrosis
- Diabetes mellitus
- Family history

Nursing Alert

The nurse is alert to the signs and symptoms of peritonitis, including abdominal pain that initially may be vague and generalized but becomes increasingly severe and constant; abdominal distention and tenderness with rebound tenderness; anxiety, paleness, and diaphoresis; anorexia; nausea; vomiting; inability to pass feces and flatus; rigidity of the abdomen; an absence of bowel sounds; cautious movement; and knee–chest position for comfort.

If a gallstone obstructs the cystic duct, the gallbladder becomes distended, inflamed, and, eventually, infected (acute cholecystitis). The patient develops a fever and may have a palpable abdominal mass. The patient may have biliary colic with excruciating upper right abdominal pain that radiates to the back or right shoulder. Usually biliary colic is associated with nausea and vomiting, and it is noticeable several hours after a heavy meal. The patient moves about restlessly, unable to find a comfortable position. The pain will fluctuate, lasting from 30 minutes to up to 6 hours. The patient may experience other symptoms, including nausea, chills, and gastric distress, including belching and bloating.

Such a bout of biliary colic is caused by contraction of the gallbladder, which cannot release bile because of obstruction by the stone. This produces marked tenderness in the right upper quadrant on deep inspiration and prevents full inspiratory excursion when the examiner's fingers are under the liver border, known as *Murphy sign* (Fogel & Sherman, 2016). See management under cholecystitis.

CHOLECYSTITIS

Cholecystitis is acute inflammation of the gallbladder. An empyema of the gallbladder develops if the gallbladder becomes filled with purulent fluid (pus). Repeated episodes of obstruction of the cystic duct by gallstones will cause cholecystitis.

Pathophysiology

Calculous cholecystitis is the cause of more than 90% to 95% of cases of acute cholecystitis (Fogel & Sherman, 2016). In calculous cholecystitis, a gallbladder stone obstructs bile outflow. Bile remaining in the gallbladder initiates a chemical reaction; autolysis and edema occur. The gallbladder becomes inflamed and distended due to increased pressure and vascular compromise, resulting in ischemia and necrosis. The release of inflammatory agents additionally plays a role in the pathophysiology of acute cholecystitis. Secondary infection with bacteria complicates the course of this disorder in up to 50% of patients (Fogel & Sherman, 2016).

Acalculous cholecystitis describes acute gallbladder inflammation in the absence of obstruction by gallstones. It occurs after major surgical procedures, severe trauma, or burns. Other factors associated with this type of cholecystitis include congestive heart failure, diabetes mellitus, cystic artery embolism, immunosuppression, abdominal vasculitis, multiorgan failure, and acute renal failure. It is speculated that acalculous cholecystitis is caused by further progression of multiple systemic failures, resulting in gallbladder stasis, increased bacterial colonization, and ischemia. Bile stasis (lack of gallbladder contraction) and increased viscosity of the bile are also thought to play a role (Fogel & Sherman, 2016; Treinen et al., 2015).

Clinical Manifestations and Assessment

Cholecystitis causes pain, tenderness, and rigidity of the upper right abdomen; usually the pain radiates to the back or right shoulder or scapula. Nausea and vomiting are common. The patient will have leukocytosis (elevated WBCs), and physical examination may reveal a positive Murphy sign (right subcostal tenderness) (Fogel & Sherman, 2016).

Medical Management

The major objectives of medical therapy are to reduce the incidence of acute episodes of gallbladder pain and cholecystitis by supportive and dietary management and, if possible, to remove the cause of cholecystitis by pharmacologic therapy, endoscopic procedures, or surgical intervention. Asymptomatic cholelithiasis can be treated with prophylactic cholecystectomy, especially with findings of large gallstones (greater than 3 cm) due to their malignant potential. Initial management of cholecystitis involves bowel rest (i.e., nothing by mouth [NPO]), management of fluids and electrolyte balance, pain management, and antibiotic coverage (Fogel & Sherman, 2016).

Pharmacologic Therapy

Ursodeoxycholic acid (UDCA) and chenodeoxycholic acid (chenodiol or CDCA) have been used to dissolve small, radiolucent gallstones composed primarily of cholesterol in patients with symptomatic cholecystitis. Because of the high long-term risk of recurrence, laparoscopic cholecystectomy (50% within 5 years), and widespread availability of laparoscopic cholecystectomy, rarely is this method of treatment used today. However, it may be beneficial in prevention of gallstone disease during periods of rapid weight loss (EASL, 2016; Fogel & Sherman, 2016).

Surgical Management

Laparoscopic or open cholecystectomy is more appropriate for symptomatic patients with acceptable operative risk. Removal of the gallbladder (cholecystectomy) through traditional surgical approaches was considered the standard treatment for more than 100 years. There is now widespread use of laparoscopic cholecystectomy (removal of the gallbladder through a small incision through the umbilicus). As a result, surgical risks have decreased, along with the length of hospital stay and the long recovery period required after standard surgical cholecystectomy (Fogel & Sherman, 2016).

Laparoscopic Cholecystectomy

Laparoscopic cholecystectomy (Fig. 25-13) has dramatically changed the approach to the management of cholecystitis. It has become the new standard for therapy of symptomatic gallstones. Approximately 750,000 patients in the United States require surgery each year for removal of the gallbladder, and greater than 90% of them are candidates for laparoscopic cholecystectomy (Fogel & Sherman, 2016).

Before the procedure, the patient is informed that an open abdominal procedure may be necessary, and general anesthesia is administered. Laparoscopic cholecystectomy is performed through a small incision or puncture made through the abdominal wall at the umbilicus. The abdominal cavity is insufflated with carbon dioxide (pneumoperitoneum) to assist in inserting the laparoscope and to aid in visualizing the abdominal structures. The fiberoptic scope is inserted through the small umbilical incision. Several additional punctures or small incisions are made in the abdominal wall to introduce other surgical instruments into the operative field. The surgeon visualizes the biliary system through the

laparoscope; a camera attached to the scope permits a view of the intra-abdominal field to be transmitted to a television monitor. After the cystic duct is dissected, the common bile duct can be visualized by ultrasound or cholangiography (imaging of the bile ducts with contrast medium) to evaluate the anatomy and identify stones. The cystic artery is dissected free and clipped. The gallbladder is separated from the hepatic bed and dissected. Then the gallbladder is removed from the abdominal cavity after bile and small stones are aspirated. Stone forceps also can be used to remove or crush larger stones.

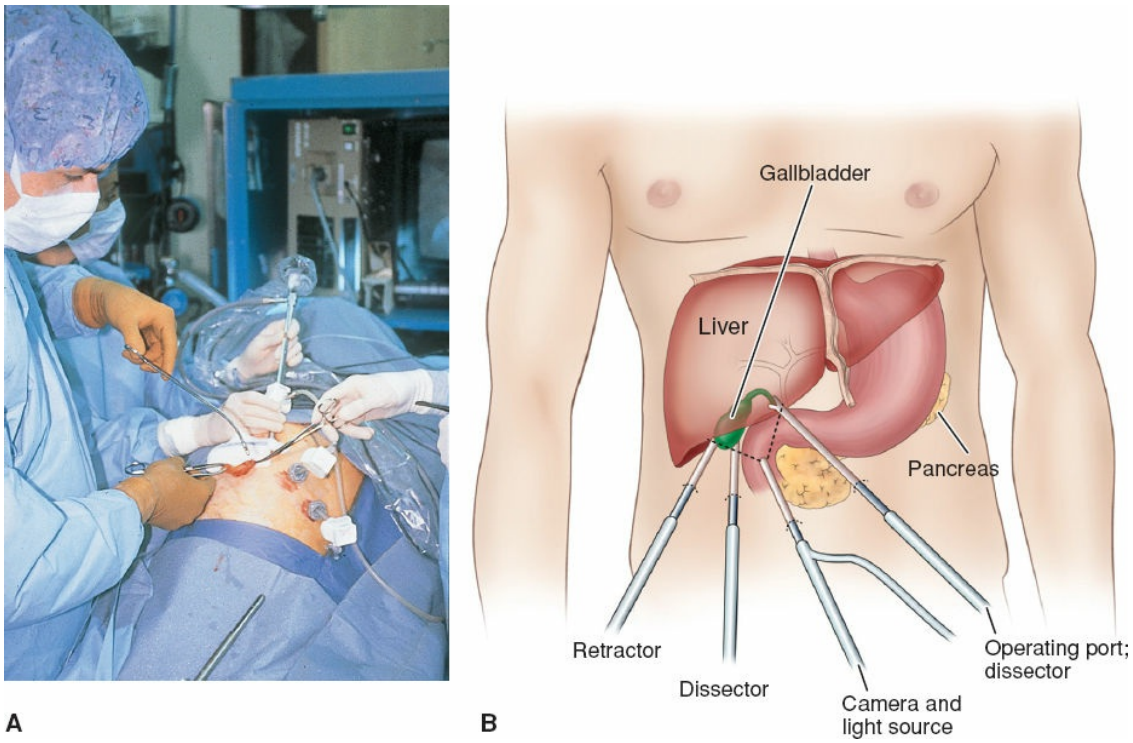

FIGURE 25-13 In laparoscopic cholecystectomy (A), the surgeon makes four small incisions (less than 12 in each) in the abdomen (B) and inserts a laparoscope with a miniature camera through the umbilical incision. The camera apparatus displays the gallbladder and adjacent tissues on a screen, allowing the surgeon to visualize the sections of the organ for removal.

Advantages of the laparoscopic procedure are that the patient does not experience the paralytic ileus that occurs with open abdominal surgery and has less postoperative abdominal pain. Early laparoscopic cholecystectomy (within 24 of symptoms) is the preferred intervention for treatment of acute cholecystitis and results in reduced length of stay, fewer surgical complications, and faster recovery for the patient (Fogel & Sherman, 2016; Gurusamy et al., 2013).

Conversion to a traditional abdominal surgical procedure may be necessary if problems are encountered during the laparoscopic procedure; this occurs in 3% of reported surgical cases (Fogel & Sherman, 2016). Careful screening of patients and identification of those at low risk for complications limit the frequency of conversion to an open abdominal procedure. However, with increasing use of laparoscopic procedures, the number of such conversions may increase. The most serious complication after laparoscopic cholecystectomy is a bile duct injury, which may be identified and corrected at the time of the procedure. A bile leak that develops from an unrecognized injury may result in fluid collections that usually can be managed by endoscopic stent placement. Bile peritonitis, a

more serious but rare complication, may result in critical illness or death.

Because of the short hospital stay with uncomplicated laparoscopic cholecystectomies, it is important to provide written and verbal instructions about managing postoperative pain and reporting signs and symptoms of intra-abdominal complications, including loss of appetite, vomiting, pain, distention of the abdomen, and temperature elevation. Although recovery from laparoscopic cholecystectomy is rapid, patients are drowsy afterward. The patient must have assistance at home during the first 24 to 48 hours. Box 25-11 details patient self-care after a laparoscopic cholecystectomy.

Cholecystectomy

In cholecystectomy, the gallbladder is removed through an abdominal incision (usually right subcostal) after the cystic duct and artery are ligated. The procedure is performed for acute and chronic cholecystitis. In some patients, a drain is placed close to the gallbladder bed and brought out through a puncture wound if there is a bile leak. A small leak should close spontaneously in a few days, with the drain preventing accumulation of bile. Usually, only a small amount of serosanguineous fluid drains in the initial 24 hours after surgery; afterward, the drain is removed. Typically the drain is maintained if there is excess oozing or bile leakage. Bile duct injury is a rare but serious complication of cholecystectomy, but it occurs less frequently than with the laparoscopic approach. Patients with multiple comorbidities or with high surgical risk may be treated with the open cholecystectomy (Fogel & Sherman, 2016).

BOX 25-11 Patient Education

Managing Self-Care After Laparoscopic Cholecystectomy

Resuming Activity

- Begin light exercise (walking) immediately.
- Take a shower or bath after 1 or 2 days.
- Wait to drive a car for 3 or 4 days.
- Avoid lifting objects exceeding 5 lb after surgery, usually for 1 week.
- Resume sexual activity when cleared by surgical team.

Caring for the Wound

- Check puncture site daily for signs of infection.
- Wash puncture site with mild soap and water.
- Allow special adhesive strips on the puncture site to fall off. Do not pull them off.

Resuming Eating

- Resume your normal diet.
- If you had fat intolerance before surgery, gradually add fat back into your diet in small increments.

Managing Pain

- You may experience pain or discomfort in your right shoulder from the gas used to inflate your abdominal area during surgery. Sitting upright in bed or a chair,

walking, or use of a heating pad may ease the discomfort.

- Take analgesics as needed and as prescribed. Report to surgeon if pain is unrelieved even with analgesic use.

Managing Follow-Up Care

- Make an appointment with your surgeon for 7–10 days after discharge.
- Call your surgeon if you experience any signs or symptoms of infection at or around the puncture site: redness, tenderness, swelling, heat, or drainage.
- Call your surgeon if you experience a fever of 37.7°C (100°F) or more for 2 consecutive days.
- Call your surgeon if you develop nausea, vomiting, or abdominal pain.

DISORDERS OF THE PANCREAS

Pancreatitis

Pancreatitis (inflammation of the pancreas) is a serious disorder. The most basic classification system used to describe or categorize the various stages and forms of pancreatitis divides the disorder into acute and chronic forms. Acute pancreatitis can be a medical emergency associated with a high risk for life-threatening complications and mortality, whereas chronic pancreatitis may not be detected until significant exocrine and endocrine tissue is destroyed. Approximately 10% of patients with acute pancreatitis will develop chronic pancreatitis, which can be characterized by acute episodes or may be subclinical (Forsmark, 2016). Frequently common causes for pancreatitis are due to alcohol abuse or gallstones; however, drugs, trauma, infection, autoimmune disease, or infection also may result in pancreatitis (Forsmark, 2016; Ito et al., 2015).

Although the mechanisms causing pancreatic inflammation are unknown, pancreatitis is commonly described as autodigestion of the pancreas. It is believed that the pancreatic duct becomes temporarily obstructed, accompanied by hypersecretion of the exocrine enzymes of the pancreas. These enzymes enter the bile duct, where they are activated and, together with bile, back up (reflux) into the pancreatic duct, causing pancreatitis.

ACUTE PANCREATITIS

Acute pancreatitis ranges from a mild, self-limited disorder to a severe, rapidly fatal disease that does not respond to any treatment. Mild acute pancreatitis is characterized by edema and inflammation confined to the pancreas. Minimal organ dysfunction is present, and return to normal function usually occurs within 6 months. Although this is considered the milder form of pancreatitis, the patient is acutely ill and at risk for hypovolemic shock, fluid and electrolyte disturbances, and sepsis. A more widespread and complete enzymatic digestion of the gland characterizes severe acute pancreatitis. Enzymes damage the local blood vessels, and bleeding and thrombosis can occur. The tissue may become necrotic, with damage extending into the retroperitoneal tissues. Local complications consist of pancreatic cysts or abscesses and acute fluid collections in or near the pancreas. Patients who develop systemic complications with organ failure, such as pulmonary insufficiency with hypoxia, shock, kidney failure, and GI bleeding, also are characterized as having severe acute pancreatitis (Forsmark, 2016). The severity of acute pancreatitis and its outcomes can be predicted based on clinical and laboratory data (Box 25-12).

Pathophysiology

Self-digestion of the pancreas by its own proteolytic enzymes, principally trypsin in a critical initial step, causes acute pancreatitis. Activation of the enzymes can lead to, inflammation, necrosis, erosion, and hemorrhage. This cascade of events also may result in multiorgan failure (Forsmark, 2016).

Long-term use of alcohol is commonly associated with acute episodes of pancreatitis, but the patient usually has had undiagnosed chronic pancreatitis before the first episode of acute pancreatitis occurs.

BOX 25-12 Criteria for Predicting Severity of Pancreatitis*a*

Criteria on Admission to Hospital

- Age over 55 years
- WBC more than 16,000 mm^3
- Serum glucose greater than 200 mg/dL (greater than 11.1 mmol/L)
- Serum LDH greater than 350 IU/L (greater than 350 U/L)
- AST greater than 250 U/mL (120 U/L)

Criteria within 48 Hours of Hospital Admission

- Fall in hematocrit greater than 10% (greater than 0.10)
- Blood urea nitrogen (BUN) increase greater than 5 mg/dL (greater than 1.7 mmol/L)
- Serum calcium less than 8 mg/dL (less than 2.0 mmol/L)
- Base deficit greater than 4 mEq/L (greater than 4 mmol/L)
- Fluid retention or sequestration greater than 6 L
- PO_2 less than 60 mm Hg
- Two or fewer signs, 1% mortality; three or four signs, 15% mortality; five or six signs, 40% mortality; more than six signs, 100% mortality

*a*The more risk factors a patient has, "the greater the severity and likelihood of complications or death".

Other, less common causes of pancreatitis include bacterial or viral infection, with pancreatitis occasionally developing as a complication of a virus, such as cytomegalovirus (CMV) and mumps (Forsmark, 2016). Blunt abdominal trauma, peptic ulcer disease, ischemic vascular disease, hyperlipidemia, hypercalcemia, and the use of corticosteroids, thiazide diuretics, oral contraceptives, and other medications also have been associated with an increased incidence of pancreatitis. Acute pancreatitis may develop after surgery on or near the pancreas or after instrumentation of the pancreatic duct. Acute idiopathic pancreatitis accounts for up to 10% of the cases of acute pancreatitis. In addition, there is a

small incidence of hereditary pancreatitis (Forsmark, 2016).

Clinical Manifestations and Assessment

Severe abdominal pain is the major symptom of pancreatitis that causes the patient to seek medical care. Typically, the pain occurs in the midepigastrium. Frequently pain is acute in onset, occurring 24 to 48 hours after a very heavy meal or alcohol ingestion, and it may be diffuse and difficult to localize. In general, it is more severe after meals and is unrelieved by antacids. Pain may be accompanied by abdominal distention; a poorly defined, palpable abdominal mass; and decreased peristalsis. Pain caused by pancreatitis is accompanied frequently by vomiting that fails to relieve the pain or nausea.

The patient appears acutely ill. Abdominal guarding is present. A rigid or board-like abdomen may develop and is generally an ominous sign; the abdomen may remain soft in the absence of peritonitis. Ecchymosis (bruising) in the flank (Grey–Turner sign) or around the umbilicus (Cullen sign) may indicate severe pancreatitis with retroperitoneal hemorrhage (see Chapter 27, Fig. 27-10). Nausea and vomiting are common in acute pancreatitis. The emesis is usually gastric in origin but also may be bile-stained. Fever, jaundice, mental confusion, and agitation also may occur.

Hypotension is typical and reflects hypovolemia and shock caused by the loss of large amounts of protein-rich fluid into the tissues and peritoneal cavity. In addition to hypotension, the patient may develop tachycardia, cyanosis, and cold, clammy skin. Respiratory distress and peritonitis also are associated with acute pancreatitis (Forsmark, 2016). In addition, the patient may develop a pleural effusion which would present as dullness to percussion on the affected lung.

The diagnosis of acute pancreatitis is based on a history of abdominal pain, the presence of known risk factors, and findings from the physical examination and diagnostics. Serum amylase and lipase levels are used in making the diagnosis of acute pancreatitis. Serum amylase and lipase levels will be elevated three times the upper limit of normal in most cases. The lipase remains elevated longer than amylase. A history of gallstones, alcohol use, and viral infection is used to diagnose acute pancreatitis. Usually the WBC count is elevated; hypocalcemia is present in many patients and correlates well with the severity of pancreatitis. Transient hyperglycemia and glucosuria and elevated serum bilirubin levels occur in some patients with acute pancreatitis. Plasma lipids and calcium are additional laboratory tests used to diagnose acute pancreatitis.

Ultrasound and contrast-enhanced CT or MRI scans are used to identify an increase in the diameter of the pancreas and to detect pancreatic cysts, abscesses, or pseudocysts. CT or MRI imaging is the modality of choice for the assessment of both acute and chronic pancreatitis (Forsmark, 2016).

Medical Management

The overall mortality rate of patients with severe acute pancreatitis is high because of shock, anoxia, hypotension, or fluid and electrolyte imbalances. Attacks of acute pancreatitis may result in complete recovery, may recur without permanent damage, or may progress to chronic pancreatitis. The patient who is admitted to the hospital with a diagnosis of pancreatitis is acutely ill and needs expert nursing and medical care (Forsmark, 2016).

Management of acute pancreatitis is directed toward relieving symptoms and preventing or treating complications. All oral intake is withheld to inhibit stimulation of the pancreas and its secretion of enzymes. The current recommendation is that, whenever possible, the enteral route should be used to meet nutritional needs in patients with pancreatitis. This strategy also has been found to prevent infectious complications and is safe and cost effective in doing so.

The mainstay of therapy for acute pancreatitis is analgesic management of pain, IV fluids to maintain intravascular volume, and elimination of oral intake. Aggressive IV therapy will be needed in patients with severe pancreatitis; however, it is important to prevent fluid overload because of the potential development of abdominal compartment syndrome (refer to Chapter 53). In cases of severe or necrotizing acute pancreatitis, the use of antibiotics is recommended (Forsmark, 2016; Gurusamy et al., 2013).

Although surgery is often risky because the acutely ill patient is a poor surgical risk, it may be performed to assist in the diagnosis of pancreatitis (diagnostic laparotomy), to establish pancreatic drainage, or to resect or débride a necrotic pancreas (Forsmark, 2016; Gurusamy et al., 2013).

Nursing Management

A plan of nursing care for a patient with acute pancreatitis is available online at http://thepoint.lww.com/Honan2e.

Relieving Pain and Discomfort

Because the pathologic process responsible for pain is autodigestion of the pancreas, the objectives of therapy are to relieve pain and decrease secretion of pancreatic enzymes. The pain of acute pancreatitis is often very severe, necessitating the liberal use of analgesics. The current recommendation for pain management in this population is parenteral narcotics, such as hydromorphone (Forsmark, 2016). Oral feedings are withheld to decrease the formation and secretion of secretin. The patient is maintained on parenteral fluids and electrolytes to restore and maintain fluid balance. NG suction may be used to relieve nausea and vomiting or to treat abdominal distention and paralytic ileus (refer to Chapter 22 for care of NG tube). The nurse provides frequent oral hygiene and care to decrease discomfort from the NG tube and relieve dryness of the mouth.

The acutely ill patient is maintained on bed rest to decrease the metabolic rate and reduce the secretion of pancreatic and gastric enzymes. If the patient experiences increasing severity of pain, the nurse reports this to the provider because the patient may be experiencing hemorrhage of the pancreas or the dose of analgesic may be inadequate.

The patient with acute pancreatitis often has a clouded sensorium because of severe pain, fluid and electrolyte disturbances, and hypoxia. Therefore, the nurse provides frequent and repeated but simple explanations about the need for withholding fluids, maintenance of gastric suction, and bed rest.

Improving Breathing Pattern

The nurse maintains the patient in a semi-Fowler position to decrease pressure on the diaphragm by a distended abdomen and to increase respiratory expansion. Frequent changes of position are necessary to prevent atelectasis and pooling of respiratory secretions. Pulmonary assessment and monitoring of pulse oximetry or ABGs are essential to detect changes in respiratory status so that early treatment can be initiated. The nurse instructs the patient in techniques of deep breathing and in the use of an IS to improve respiratory function, and the nurse encourages and assists the patient to perform these activities every hour. Intubation may be necessary to support ventilation.

Improving Nutritional Status

In general, the patient with acute pancreatitis has not been permitted food or oral fluid intake. However, recent studies suggest that maintaining NPO but use of enteral feedings with nasojejunum tubes, thereby preventing pancreatic enzyme release maintains gut integrity, enhances immune system functioning, and demonstrates lower complication rates when compared to parenteral feedings (Wu & Banks, 2013). It is important to assess the patient's nutritional status and to note factors that alter the patient's nutritional requirements (e.g., temperature elevation, surgery, drainage). Laboratory test results and

daily weights are useful to monitor the nutritional status.

In addition to administering enteral or parenteral nutrition, the nurse monitors serum glucose levels every 4 to 6 hours. As the acute symptoms subside, the nurse gradually reintroduces oral feedings. Between acute attacks, the patient receives a diet that is high in carbohydrates and low in fats and proteins. The patient should avoid heavy meals and alcoholic beverages.

Improving Skin Integrity

The patient is at risk for skin breakdown because of poor nutritional status, enforced bed rest, and restlessness, which may result in pressure ulcers and breaks in tissue integrity. In addition, the patient who has undergone surgery may have multiple drains or an open surgical incision and is at risk for skin breakdown and infection. The nurse carefully assesses the wound, drainage sites, and skin for signs of infection, inflammation, and breakdown. The nurse carries out wound care as prescribed and takes precautions to protect intact skin from contact with drainage. It is important to turn the patient every 2 hours; use of specialty beds may be indicated to prevent skin breakdown. Often consultation with an enterostomal therapist (also referred to as a wound care specialist or wound-ostomy-continence nurse) is helpful in identifying appropriate skin care devices and protocols.

Monitoring and Managing Potential Complications

Fluid and electrolyte disturbances are common complications because of nausea, vomiting, movement of fluid from the vascular compartment to the peritoneal cavity, diaphoresis, fever, and the use of gastric suction. The nurse assesses the patient's fluid and electrolyte status by noting skin turgor and moistness of mucous membranes. The nurse weighs the patient daily and carefully measures fluid intake and output, including urine output, NG secretions, and diarrhea. In addition, it is important to assess for other factors that may affect fluid and electrolyte status, including increased body temperature and wound drainage. Inflammation can lead to significant fluid depletion as well as extravasation of fluid into the retroperitoneal space and abdominal cavity.

The nurse assesses the patient for ascites and measures abdominal girth daily if ascites is suspected.

Fluids are administered intravenously and may be accompanied by infusion of blood or blood products to maintain the blood volume and to prevent or treat hypovolemic shock. It is important to keep emergency medications readily available because of the risk for circulatory collapse and shock. The nurse promptly reports decreased blood pressure and reduced urine output because these signs may indicate hypovolemia and shock or kidney failure. Low serum calcium and magnesium levels may occur and require prompt treatment.

Pancreatic necrosis is a major cause of morbidity and mortality in patients with acute pancreatitis. The patient who develops necrosis is at risk for hemorrhage, septic shock, and multiple organ failure. The patient may undergo diagnostic procedures to confirm pancreatic necrosis; surgical débridement or insertion of multiple drains may be performed. The patient with pancreatic necrosis is usually critically ill and requires expert medical and nursing management, including hemodynamic monitoring in the ICU.

In addition to carefully monitoring vital signs and other signs and symptoms, the nurse

is responsible for administering prescribed fluids, medications, and blood products; assisting with supportive management, such as use of a ventilator; preventing additional complications; and attending to the patient's physical and psychological care.

Shock and multiple organ failure may occur with acute pancreatitis. Hypovolemic shock may occur as a result of hypovolemia and sequestering of fluid in the peritoneal cavity. Hemorrhagic shock may occur with hemorrhagic pancreatitis. Septic shock may occur with bacterial infection of the pancreas. Cardiac dysfunction may occur as a result of fluid and electrolyte disturbances, acid–base imbalances, and release of toxic substances into the circulation.

The nurse closely monitors the patient for early signs of neurologic, cardiovascular, renal, and respiratory dysfunction. The nurse must be prepared to respond quickly to rapid changes in the patient's status, treatments, and therapies. In addition, it is important to inform the family about the status and progress of the patient and to allow them to spend time with the patient.

Promoting Home and Community-Based Care

The patient who has survived an episode of acute pancreatitis has been acutely ill. A prolonged period is needed to regain strength and return to the previous level of activity. Often the patient is still weak and debilitated for weeks or months after an acute episode of pancreatitis. Because of the severity of the acute illness, the patient may not recall many of the explanations and instructions given during the acute phase. Teaching often needs to be repeated and reinforced. The nurse instructs the patient about the factors implicated in the onset of acute pancreatitis and about the need to avoid high-fat foods, heavy meals, and alcohol. It is important to give the patient and family verbal and written instructions about signs and symptoms of acute pancreatitis and possible complications that should be reported promptly to the provider.

If acute pancreatitis is a result of biliary tract disease, such as gallstones and gallbladder disease, additional explanations are needed about required dietary modifications. If the pancreatitis is a result of alcohol abuse, the nurse reminds the patient of the importance of eliminating all alcohol.

Often a referral for home care is indicated. This enables the nurse to assess the patient's physical and psychological status and adherence to the therapeutic regimen. The nurse also assesses the home situation and reinforces instructions about fluid and nutrition intake and avoidance of alcohol. The nurse provides specific information about resources and support groups that may be of assistance in avoiding alcohol in the future. Referral to Alcoholics Anonymous or other appropriate support groups is essential.

CHRONIC PANCREATITIS

Chronic pancreatitis is an inflammatory disorder that is characterized by progressive anatomic and functional destruction of the pancreas.

Pathophysiology

As cells are replaced by fibrous tissue with repeated attacks of pancreatitis, pressure within the pancreas increases. The end result is mechanical obstruction of the pancreatic and common bile ducts and the duodenum. In addition, there is atrophy of the epithelium of the ducts, inflammation, and destruction of the secreting cells of the pancreas.

Alcohol consumption in Western societies and malnutrition worldwide, frequently associated with cigarette smoking, are the major causes of chronic pancreatitis. Excessive and prolonged consumption of alcohol accounts for 40% of cases of chronic pancreatitis in the United States, although 25% of cases may be attributed to smoking alone (Forsmark, 2016). Long-term alcohol consumption causes hypersecretion of protein in pancreatic secretions, resulting in protein plugs and calculi within the pancreatic ducts. Alcohol also has a direct toxic effect on the cells of the pancreas. Some research suggests that hypertriglyceridemia, dyslipidemia, and diet also may contribute to the development of chronic pancreatitis. Less common causes of chronic pancreatitis are due to genetic mutations, autoimmune pancreatitis, duct obstruction, and idiopathic pancreatitis. Patients with chronic pancreatitis are at increased risk for the development of pancreatic cancer (Forsmark, 2016).

Clinical Manifestations and Assessment

Chronic pancreatitis is characterized by recurring attacks of severe upper abdominal and back pain, accompanied by vomiting. Often attacks are so painful that opioids, even in large doses, do not provide relief. As the disease progresses, recurring attacks of pain are more severe, more frequent, and of longer duration. Some patients experience continuous severe pain, others have a dull, nagging constant pain, and a small percentage of other patients does not have pain and instead presents with exocrine (steatorrhea, weight loss) or endocrine (diabetes) pancreatic insufficiency (Forsmark, 2016, p. 964). The risk of opioid dependence is increased in pancreatitis because of the chronic nature and severity of the pain.

Weight loss is a major problem in chronic pancreatitis: more than 75% of patients experience significant weight loss, usually caused by decreased dietary intake secondary to anorexia or fear that eating will precipitate another attack. Malabsorption occurs late in the disease due to decreases in lipase production. As a result, digestion, especially of proteins and fats, is impaired. The stools become frequent, frothy, and foul-smelling because of impaired fat digestion, which results in stools with a high fat content (referred to as steatorrhea). As the disease progresses, calcification of the gland may occur, and calcium stones may form within the ducts. Diabetes mellitus occurs due to loss of pancreatic beta cells.

Various imaging procedures, including MRI, CT scans, and ultrasound, have been useful in the diagnostic evaluation of patients with suspected pancreatic disorders. A CT scan or ultrasound study also is helpful to detect pancreatic cysts. Steatorrhea can be confirmed by laboratory analysis of fecal fat content and determination of exocrine pancreatic insufficiency via the secretin-cholecystokinin test. In most cases, the diagnosis of chronic pancreatitis is based upon clinical findings, history, and imaging modalities such as ERCP, CT, and MRI to detect abnormalities of the pancreas (Forsmark, 2016).

Nursing Alert

Endoscopic retrograde cholangiopancreatography (ERCP) provides detail about the anatomy of the pancreas and the pancreatic and biliary ducts, and it is helpful in obtaining tissue for analysis and differentiating pancreatitis from other conditions, such as carcinoma. However, because of its risk, ERCP should be undertaken only when therapy involving the pancreatic duct is appropriate.

Medical Management

Nonsurgical Management

Nonsurgical approaches are focused primarily on complete abstinence of alcohol and tobacco, pain management, nutritional management, and treatment of diabetes mellitus. Pain management is achieved through use of analgesics as first-line therapy and for refractory pain. Pancreatic enzyme replacement is indicated for the patient with malabsorption and steatorrhea. A proton pump inhibitor (omeprazole [Prilosec], lansoprazole [Prevacid]) is administered with enzyme therapy to reduce gastric acid inactivation of enzymes. Also supplementation of fat-soluble vitamins is indicated. Improved nutrition and resolution of steatorrhea usually are indicators of clinical improvement in the patient with chronic pancreatitis.

Diabetes mellitus resulting from dysfunction of the pancreatic islet cells is treated with diet, insulin, or oral antidiabetic agents. Use of insulin is the preferred therapy; however, administration should be adjusted carefully to avoid hypoglycemic events (Forsmark, 2016).

Surgical Management

Surgery or interventional therapies are used primarily to address complications of pancreatitis and to relieve abdominal pain and discomfort, restore drainage of pancreatic secretions, and reduce the frequency of acute attacks of pancreatitis. The type of surgery that is performed depends on the anatomic and functional abnormalities of the pancreas, including the location of disease within the pancreas, the presence of diabetes, exocrine insufficiency, biliary stenosis, and pseudocysts of the pancreas.

Pancreaticojejunostomy (also referred to as Roux-en-Y), with a side-to-side anastomosis or joining of the pancreatic duct to the jejunum, allows drainage of the pancreatic secretions into the jejunum. Other surgical procedures may be performed for different degrees and types of underlying disorders. These procedures include revision of the sphincter of the ampulla of Vater, internal drainage of a pancreatic cyst into the stomach, insertion of a stent, and wide resection or removal of the pancreas. A Whipple resection (pancreaticoduodenectomy) can be carried out to relieve the pain of chronic pancreatitis. Endoscopic therapy is used for pancreatic duct stones and strictures. The use of surgical and endoscopic treatment is based upon patient presentation, complications, and the availability of surgical expertise (Forsmark, 2016).

PANCREATIC CANCER

Pancreatic cancer is the fourth leading cause of cancer death in the United States. Cancer may develop in the head, body, or tail of the pancreas; most pancreatic cancers originate in the head of the pancreas. Patients usually do not seek medical attention until late in the disease; most patients have an advanced, unresectable tumor when first detected. In fact, pancreatic carcinoma has a survival rate of only 6% at 5 years regardless of the stage of disease at diagnosis or treatment, the lowest among all cancers (Muniraj, Jamidar, & Aslanian, 2013).

Risk Factors

The average patient age at diagnosis of most pancreatic cancers is 71 years old, with higher prevalence in men and African Americans. Use of tobacco, obesity, and nonhereditary chronic pancreatitis are risk factors for pancreatic cancer. Diabetes mellitus is also associated with pancreatic cancer; however, whether it is a cause or a result of pancreatic cancer is unclear. Genetic predisposition also may play a role; up to 10% of patients with this cancer have a first-degree relative diagnosed with pancreatic cancer (Muniraj et al., 2013).

Clinical Manifestations and Assessment

The majority of patients present with pain and/or jaundice, which, along with weight loss, are considered classic signs of pancreatic carcinoma. However, they often do not appear until the disease is far advanced. Other signs include rapid, profound, and progressive weight loss as well as vague upper or midabdominal pain or discomfort that is unrelated to any GI function and is often difficult to describe. Such discomfort radiates as a boring pain in the midback and is unrelated to posture or activity. Often it is progressive and severe, requiring the use of opioids. The formation of ascites is common. An important sign, if it is present, is the onset of symptoms of insulin deficiency: glucosuria, hyperglycemia, and abnormal glucose tolerance. Therefore, diabetes may be an early sign of carcinoma of the pancreas. Meals often aggravate epigastric pain, which usually occurs before the appearance of jaundice and pruritus. Diarrhea and steatorrhea also commonly are present in pancreatic cancer (Muniraj et al., 2013).

CT and MRI imaging are currently the most useful preoperative imaging technique. CT or MRI can accurately image pancreatic masses, show dilatation of pancreatic duct, and indicate if metastases are present in the liver or peritoneum. Endoscopic retrograde pancreatography (ERCP), endoscopic ultrasound (EUS), and magnetic resonance cholangiopancreatography (MRCP) also are used to diagnose pancreatic cancer. Cells obtained during ERCP/EUS are sent to the laboratory for histologic analysis. Although cancer-associated antigen (CA 19-9) serum levels may be elevated, this tumor marker is used primarily to monitor disease progression and treatment efficacy (Muniraj et al., 2013).

Medical Management

Only 10% to 20% of patients with pancreatic cancer benefit from surgical resection; the majority of patients present at a late stage, frequently with metastatic spread to other organs or vascular invasion. In patients with early-stage disease, the Whipple procedure (pancreaticoduodenectomy) is used to remove the pancreatic head, duodenum, part of the jejunum, common bile duct, and gallbladder (Fig. 25-14). Use of adjuvant therapy (i.e., chemotherapy) continues to be controversial and nonstandard in this small group of surgical patients, with ongoing clinical trials to evaluate potential benefits of treatment. The chemotherapy agent gemcitabine alone or in combination with other chemotherapeutic agents remains the treatment of choice for most patients with pancreatic cancer. Overall, patients with pancreatic cancer have a high mortality rate and poor survival outcomes even with chemotherapy or surgical treatment. Palliative measures to address symptoms of pancreatic cancer include nutritional support and pain management (Muniraj et al., 2013).

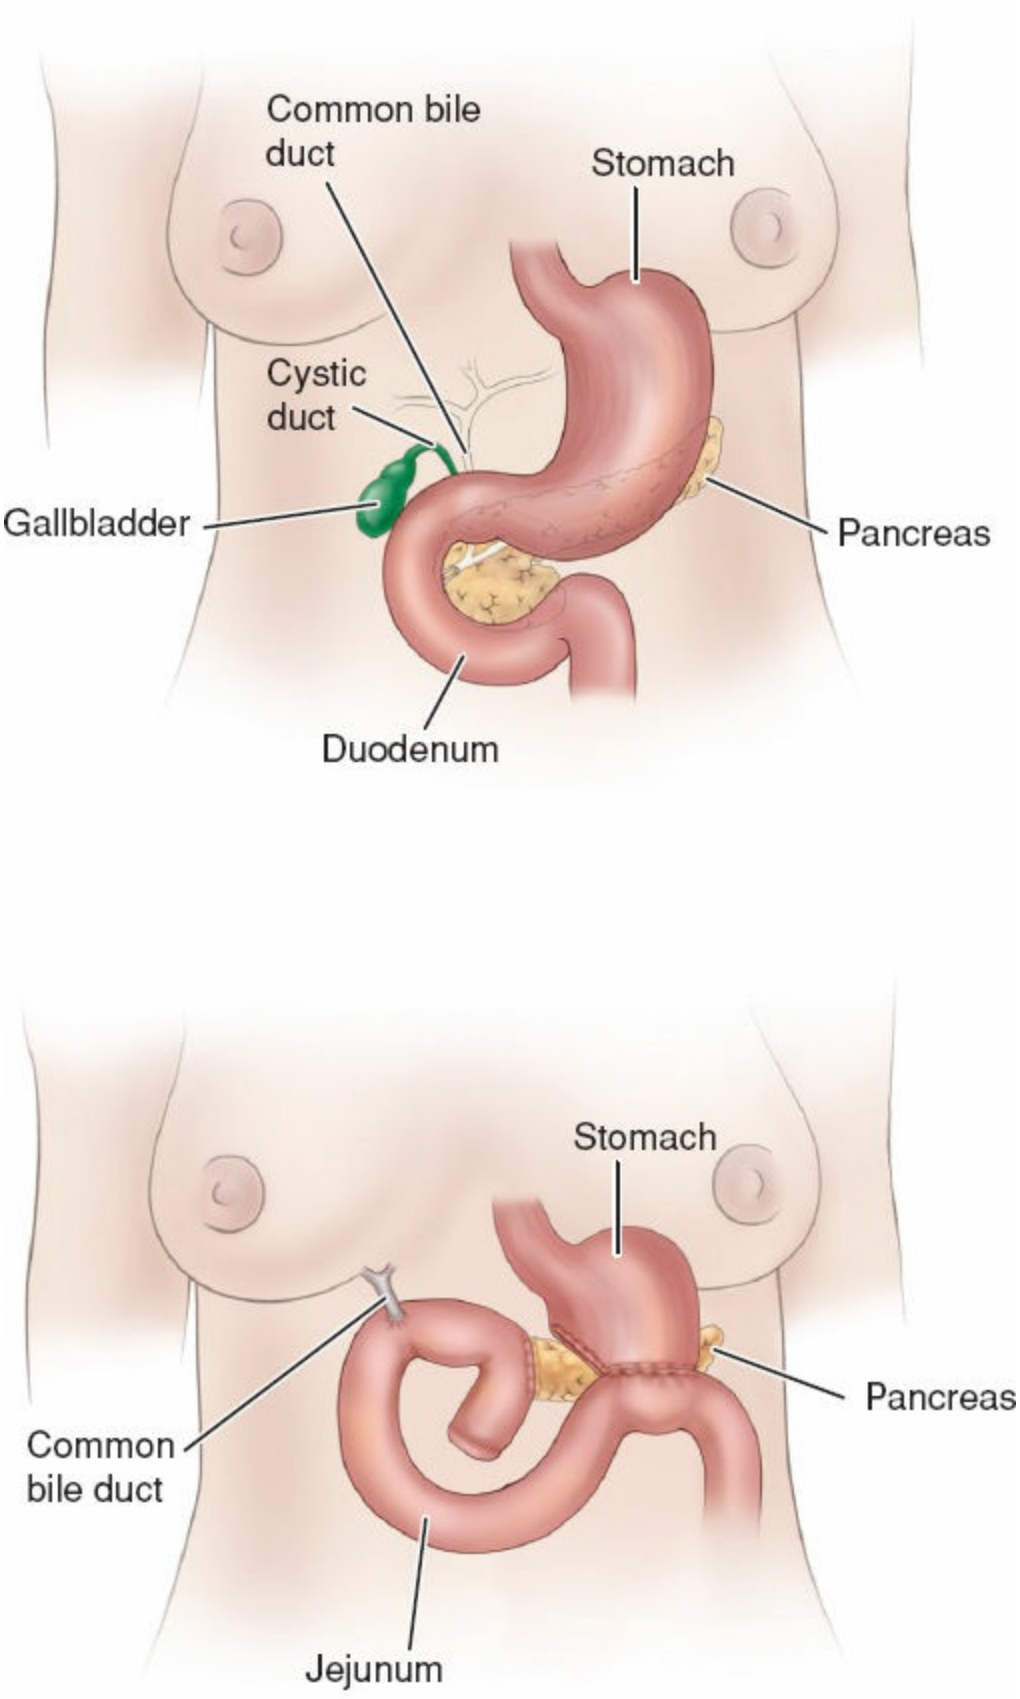

FIGURE 25-14 Pancreatoduodenectomy (Whipple procedure or resection). End result of resection of carcinoma of the head of the pancreas or the ampulla of Vater. The common duct is sutured to the end of the jejunum, and the remaining portion of the pancreas and the end of the stomach are sutured to the side of the jejunum.

Nursing Management

Pain management and attention to nutritional requirements are important nursing measures that improve the level of patient comfort. Refer to Chapter 7 for treatment of cancer pain. Skin care and nursing measures are directed toward relief of pain and discomfort associated with jaundice, anorexia, and profound weight loss. Specialty mattresses are beneficial and protect bony prominences from pressure. Pain associated with pancreatic cancer may be severe and may require liberal use of opioids; patient-controlled analgesia should be considered for the patient with severe, escalating pain.

Because of the poor prognosis and likelihood of short survival, end-of-life preferences are discussed and honored. If appropriate, the nurse refers the patient to hospice care (see Chapter 3 for further discussion).

The postoperative management of patients who have undergone a pancreaticoduodenectomy is similar to the management of patients after extensive GI or biliary surgery. The patient's physical status is often suboptimal, increasing the risk for postoperative complications. Hemorrhage, vascular collapse, and hepatorenal failure remain the major complications of these extensive surgical procedures. The mortality rate associated with these procedures has improved because of advances in nutritional support and improved surgical techniques. An NG tube with suction, NPO status, and nutrition that allows the GI tract to rest while promoting adequate nutrition is anticipated (Fig. 25-15).

Preoperatively and postoperatively, nursing care is directed toward promoting patient comfort, preventing complications, and assisting the patient to return to and maintain as normal and comfortable a life as possible. The nurse closely monitors the patient in the ICU after surgery; in the immediate postoperative period, multiple IV and arterial lines are used for fluid and blood replacement and hemodynamic monitoring, and a mechanical ventilator is used. It is important to note and report changes in vital signs, ABGs and pressures, pulse oximetry, laboratory values, and urine output. The nurse also must consider the patient's compromised nutritional status and risk for bleeding. Depending on the type of surgical procedure performed, malabsorption syndrome and diabetes mellitus are likely; the nurse must address these issues during acute and long-term patient care.

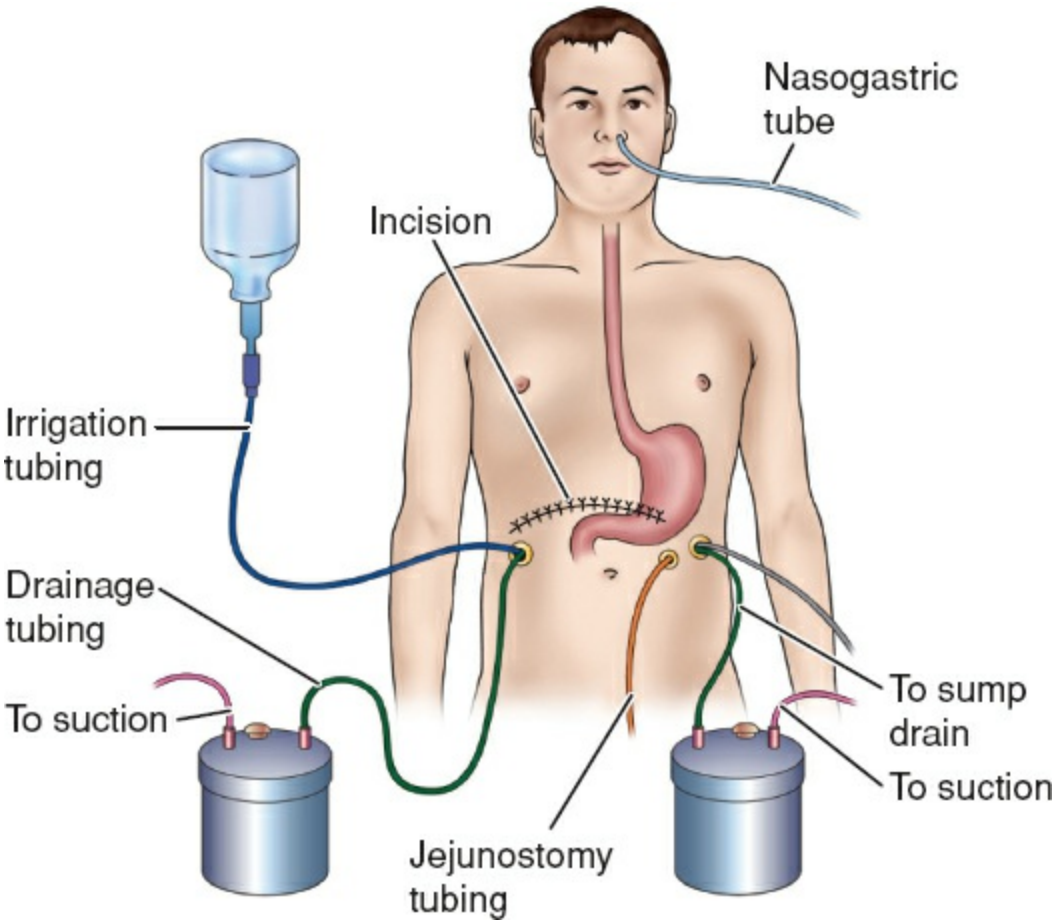

FIGURE 25-15 Multiple sump tubes are used after pancreatic surgery. Triple-lumen tubes consist of ports that provide tubing for irrigation, air venting, and drainage.

Although the patient's physiologic status is the focus of the health care team in the immediate postoperative period, the patient's psychological and emotional state must be considered, along with that of the family. The patient has undergone a major high-risk surgery and is critically ill; anxiety and depression may affect recovery. The immediate and long-term outcomes of this extensive surgical resection are uncertain, and the patient and family require emotional support and understanding in the critical and stressful preoperative and postoperative periods.

Promoting Home and Community-Based Care

The specific teaching for the patient and family varies with the stage of disease and the treatment choices made by the patient. The patient who has undergone this extensive surgery requires careful and thorough preparation for self-care at home. The nurse instructs the patient and family about the need for modifications in the diet because of malabsorption and hyperglycemia resulting from the surgery. It is important to instruct the patient and family about the continuing need for pancreatic enzyme replacement, a low-fat diet, and vitamin supplementation.

The nurse teaches the patient and family strategies to relieve pain and discomfort, along with strategies to manage drains, if present, and to care for the surgical incision. The patient and family members may require instruction about use of patient-controlled

analgesia, enteral/parenteral nutrition, wound care, skin care, and management of drainage. It is important to describe, verbally and in writing, the signs and symptoms of complications and to teach the patient and family about indicators of complications that should be reported promptly.

Discharge of the patient to a long-term care or rehabilitation facility may be warranted after surgery as extensive as a pancreaticoduodenectomy, particularly if the patient's preoperative status was not optimal. Information about the teaching that has been provided is shared with the long-term care staff so that instructions can be clarified and reinforced.

If the patient elects to receive chemotherapy, the nurse focuses teaching on prevention of side effects and complications of the agents used. If surgery is performed to relieve obstruction and establish biliary drainage, teaching addresses management of the drainage system and monitoring for complications. The nurse instructs the family about changes in the patient's status that should be reported to the provider.

A referral for home care may be indicated when the patient returns home. The home care nurse assesses the patient's physical status, fluid and nutritional status, and skin integrity as well as the adequacy of pain management. The nurse teaches the patient and family strategies to prevent skin breakdown and relieve pain, pruritus, and anorexia. The home care nurse assesses the patient's physical and psychological status and the ability of the patient and family to manage needed care. The home care nurse provides needed physical care and monitors the adequacy of pain management. In addition, it is important to assess the patient's nutritional status and monitor the use of parenteral nutrition. The nurse discusses the use of hospice services with the patient and family and makes a referral if indicated.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 28-year-old African woman came to the United States from Nigeria 3 years ago to live with relatives. She is being treated for end-stage liver disease (ESLD) with cirrhosis related to hepatitis B and is undergoing evaluation for liver transplantation. The sequelae of ESLD that she was experiencing included encephalopathy and ascites. What would you anticipate this patient's treatment regimen to include? What medications would be most appropriate for her? What would you include in your cultural assessment when you develop a preoperative teaching plan for this patient? What alternative therapies might be employed preoperatively? Once the patient receives a liver transplant, what medications would you expect to be prescribed for her in addition to an immunosuppressant regimen?

2. A 64-year-old man is admitted to the hospital with end-stage liver disease (ESLD), ascites, and impending hepatic encephalopathy. Dietary modifications and lactulose (Cephulac) are prescribed to minimize hepatic encephalopathy. What is the evidence base for use of dietary measures and lactulose in reducing or reversing hepatic encephalopathy? What is the strength of that evidence? What are the nursing implications associated with prescribed dietary modifications, lactulose, and other

measures to reduce the severity and progression of hepatic encephalopathy?

3. A 34-year-old woman is scheduled for a cholecystectomy. Since undergoing bariatric surgery a year ago, she has lost 150 lb. What postoperative care is indicated for this patient? What impact, if any, does her previous surgical procedure have on her postoperative recovery?

4. A 56-year-old man with a history of alcoholism and cirrhosis is admitted to your unit with a diagnosis of pancreatitis. He is complaining of severe epigastric pain, vomiting, and diarrhea. What medications and laboratory tests would you expect to see prescribed for this patient? What physical assessment findings will you see? Describe nursing care for this patient, and compare and contrast care with and without the diagnosis of cirrhosis. What issues would be of high priority in caring for this patient during his hospital stay? What issues would be of high priority in preparing him for hospital discharge?

NCLEX-Style Review Questions

1. The nurse is caring for a patient diagnosed with ascites. What would the nurse expect to be restricted from the patient's diet?
   a. Potassium
   b. Calcium
   c. Sodium
   d. Magnesium

2. A patient diagnosed with hepatic encephalopathy is receiving lactulose. When preparing to administer this medication, the nurse understands that it is used to decrease which serum level?
   a. Calcium
   b. Ammonia
   c. Potassium
   d. Sodium

3. Patients with severe chronic liver dysfunction often have problems related to inadequate intake of sufficient vitamins. What vitamin deficiency would result in hemorrhagic lesions of scurvy?
   a. Riboflavin
   b. Vitamin C
   c. Vitamin A
   d. Vitamin K

4. A patient with hepatitis A is admitted to a general medical-surgical floor. The nurse knows that this type of hepatitis is spread through which mode of transmission?
   a. Injection of drugs

b. Blood
c. Semen
d. Fecal–oral

5. A patient is being seen in the clinic to rule out pancreatitis. The nurse expects which diagnostic test will be performed to diagnose this disease process? *Select all that apply.*
   a. MR/CT
   b. Abdominal ultrasound
   c. Lumbar puncture
   d. Endoscopy
   e. Amylase and lipase

Problems Related to Urinary Tract Function

A nurse is caring for a patient diagnosed with kidney failure. He is currently receiving hemodialysis three times a week. He is very anxious about the lifestyle change that is occurring due to his health problems.

- What areas of teaching would be important for the nurse to emphasize for this

patient?

- Explain the various treatment modalities available for this patient population.
- Discuss areas of nursing management that would apply to this patient.

CHAPTER 26

Nursing Assessment: Renal and Urinary Tract Function

Deborah Bain Fahs

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the anatomy and physiology of the renal and urinary systems.
2. Discuss the role of the kidney in regulating fluid and electrolyte balance, acid–base balance, and blood pressure.
3. Identify the assessment parameters used for determining the status of upper and lower urinary tract function.
4. Describe the diagnostic studies used to determine upper and lower urinary tract function.

Proper function of the renal and urinary systems is essential to life. Dysfunction of the kidneys and lower urinary tract is common and may occur at any age and with varying degrees of severity. Assessment of upper and lower urinary tract function is part of every health examination and necessitates an understanding of the anatomy and physiology of the urinary system as well as of the effects of changes in the system on other physiologic functions.

ANATOMIC AND PHYSIOLOGIC OVERVIEW

The primary function of the renal and urinary systems is to maintain the body's state of homeostasis by carefully regulating fluid and electrolytes, removing wastes, and providing hormones that are involved in red blood cell (RBC) production, bone metabolism, and blood pressure. A thorough understanding of the renal and urinary systems is necessary for assessing people with acute or chronic dysfunction and implementing appropriate nursing care.

Anatomy of the Renal and Urinary Systems

The renal and urinary systems include the kidneys, ureters, bladder, and urethra. Urine is formed by the kidney and flows through the other structures to be eliminated from the body.

Kidneys

The kidneys are a pair of bean-shaped, brownish-red structures located retroperitoneally (behind and outside the peritoneal cavity) on the posterior wall of the abdomen—from the 12th thoracic vertebra to the 3rd lumbar vertebra in the adult (Fig. 26-1A). The average adult kidney weighs approximately 113 to 170 g (about 4.5 oz) and is 10 to 12 cm long, 6 cm wide, and 2.5 cm thick (Tortora & Derrickson, 2014). The right kidney is slightly lower than the left due to the location of the liver.

The kidneys are well protected by the ribs and by the muscles of the abdomen and back. Internally, fat deposits surround each kidney, providing protection against jarring. The kidneys and surrounding fat are suspended from the abdominal wall by renal fascia made of connective tissue. The fibrous connective tissue, blood vessels, and lymphatics surrounding each kidney are known as the *renal capsule* (Grossman & Porth, 2014) (Fig. 26-1B).

An adrenal gland lies on top of each kidney. Each organ is independent in terms of its function, blood supply, and innervation.

The renal parenchyma (organ tissue) is divided into two parts: the cortex and the medulla. The medulla is the inner portion of the kidney. It contains the loops of Henle, the vasa recta, and the collecting ducts of the juxtamedullary nephrons. The collecting ducts from both the juxtamedullary and the cortical nephrons connect to the renal pyramids, which are triangular and are situated with the base facing the concave surface of the kidney and the point (papilla) facing the hilum, or pelvis. Each kidney contains approximately 8 to 18 pyramids. The pyramids drain into 4 to 13 minor calices, which drain into 2 to 3 major calices that open directly into the renal pelvis. The renal pelvis is the beginning of the collecting system and is composed of structures that are designed to collect and transport urine. Once the urine leaves the renal pelvis, the composition or amount of urine does not change.

The cortex, which is approximately 1 cm wide, is located farthest from the center of the kidney and around the outermost edges. It contains the nephrons (the functional units of the kidney), which are discussed below.

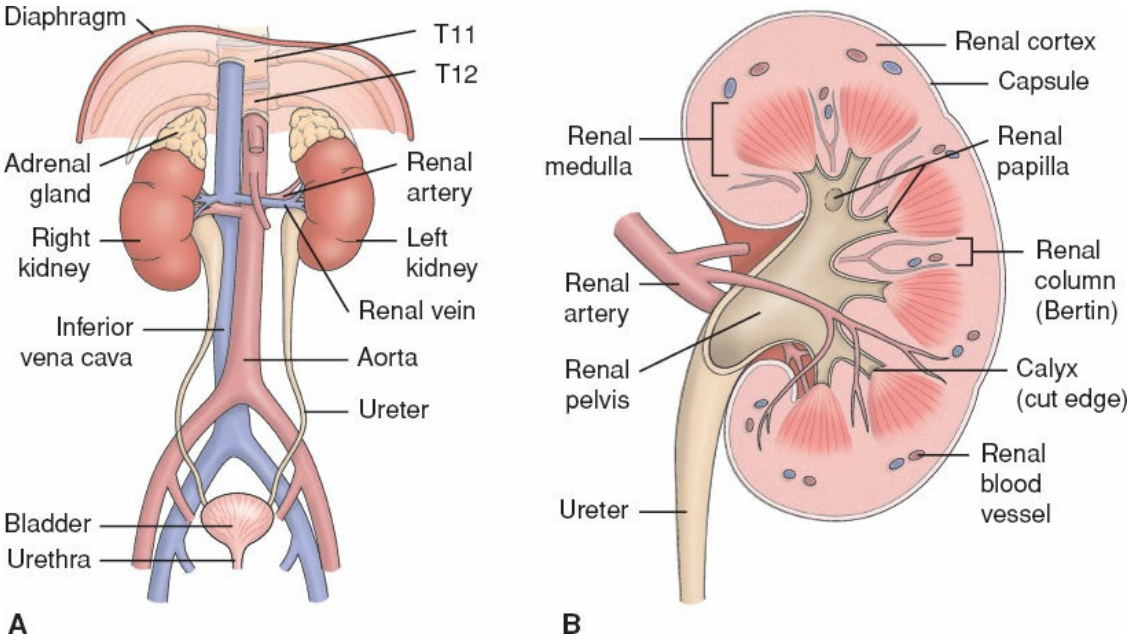

FIGURE 26-1 A. Kidneys, ureters, and bladder. (The right kidney is usually lower than the left.) B. Internal structure of the kidney. (Grossman, S., & Porth. C. M. (2014). *Porth's pathophysiology concepts of altered health states* (9th ed.). Philadelphia, PA: Wolters Kluwer/Lippincott Williams & Wilkins.)

Blood Supply to the Kidneys

The hilum, or pelvis, is the concave portion of the kidney through which the renal artery enters and the ureters and renal vein exit. The kidneys receive 20% to 25% of the total cardiac output; all of the body's blood circulates through the kidneys approximately 12 times per hour. The renal artery arises from the abdominal aorta and divides into smaller and smaller vessels, eventually forming the afferent arterioles. Each afferent arteriole branches to form a glomerulus, which is the capillary bed responsible for glomerular filtration. Blood leaves the glomerulus through the efferent arteriole and flows back to the inferior vena cava through a network of capillaries and veins.

Nursing Alert

The nurse auscultates for renal artery bruits, which indicate turbulent blood flow and are associated with a narrowing of the blood vessel or increased flow. Any patient with hypertension should be evaluated for bruits. Typically they are noted with renal artery stenosis just above (2 cm) and to the right or left of the umbilicus. A whooshing sound is indicative of a bruit.

Nephrons

Each kidney has 1 million nephrons, which usually allow for adequate kidney function even if the opposite kidney is damaged or becomes nonfunctional. The nephrons are the structures located within the renal parenchyma that are responsible for the initial formation of urine. If the total number of functioning nephrons is less than 20% of normal, renal replacement therapy needs to be considered.

There are two kinds of nephrons. The cortical nephrons, making up 80% to 85% of the total number, are located in the outermost part of the cortex. The juxtamedullary

nephrons, distinguished by long loops of Henle, make up the remaining 15% to 20%, are located deeper in the cortex, and are surrounded by long capillary loops called *vasa recta* that dip into the medulla of the kidney. The length of the tubular component of the nephron is related directly to its ability to concentrate urine.

Nephrons are made up of two basic components: a filtering element composed of an enclosed capillary network (the glomerulus) and the attached tubule (Fig. 26-2). The glomerulus is a unique network of capillaries suspended between the afferent and efferent blood vessels, which are enclosed in an epithelial structure called *Bowman capsule*. The glomerular membrane is composed of three filtering layers: the capillary endothelium, the basement membrane, and the epithelium. This membrane normally allows filtration of fluid and small molecules yet limits passage of larger molecules, such as blood cells and albumin. Pressure changes and the permeability of the glomerular membrane of Bowman capsule facilitate the passage of fluids and various substances from the blood vessels, filling the space within Bowman capsule with this filtered solution.

The tubular component of the nephron begins in the Bowman capsule. The filtrate created in the Bowman capsule travels first into the proximal tubule, then the loop of Henle, the distal tubule, and either the cortical or medullary collecting ducts. Changes are made continually as the filtrate travels through the tubules until it enters the collecting system and is expelled as urine from the body (see Fig. 26-2).

The structural arrangement of the tubule allows the distal tubule to lie in close proximity to where the afferent and efferent arteriole, respectively, enter and leave the glomerulus. The distal tubular cells located in this area, known as the *macula densa*, function with the adjacent afferent arteriole and create what is known as the *juxtaglomerular apparatus*. This is the site of renin production. Renin is a hormone involved directly in the control of arterial blood pressure; it is essential for proper functioning of the glomerulus (see later discussion).

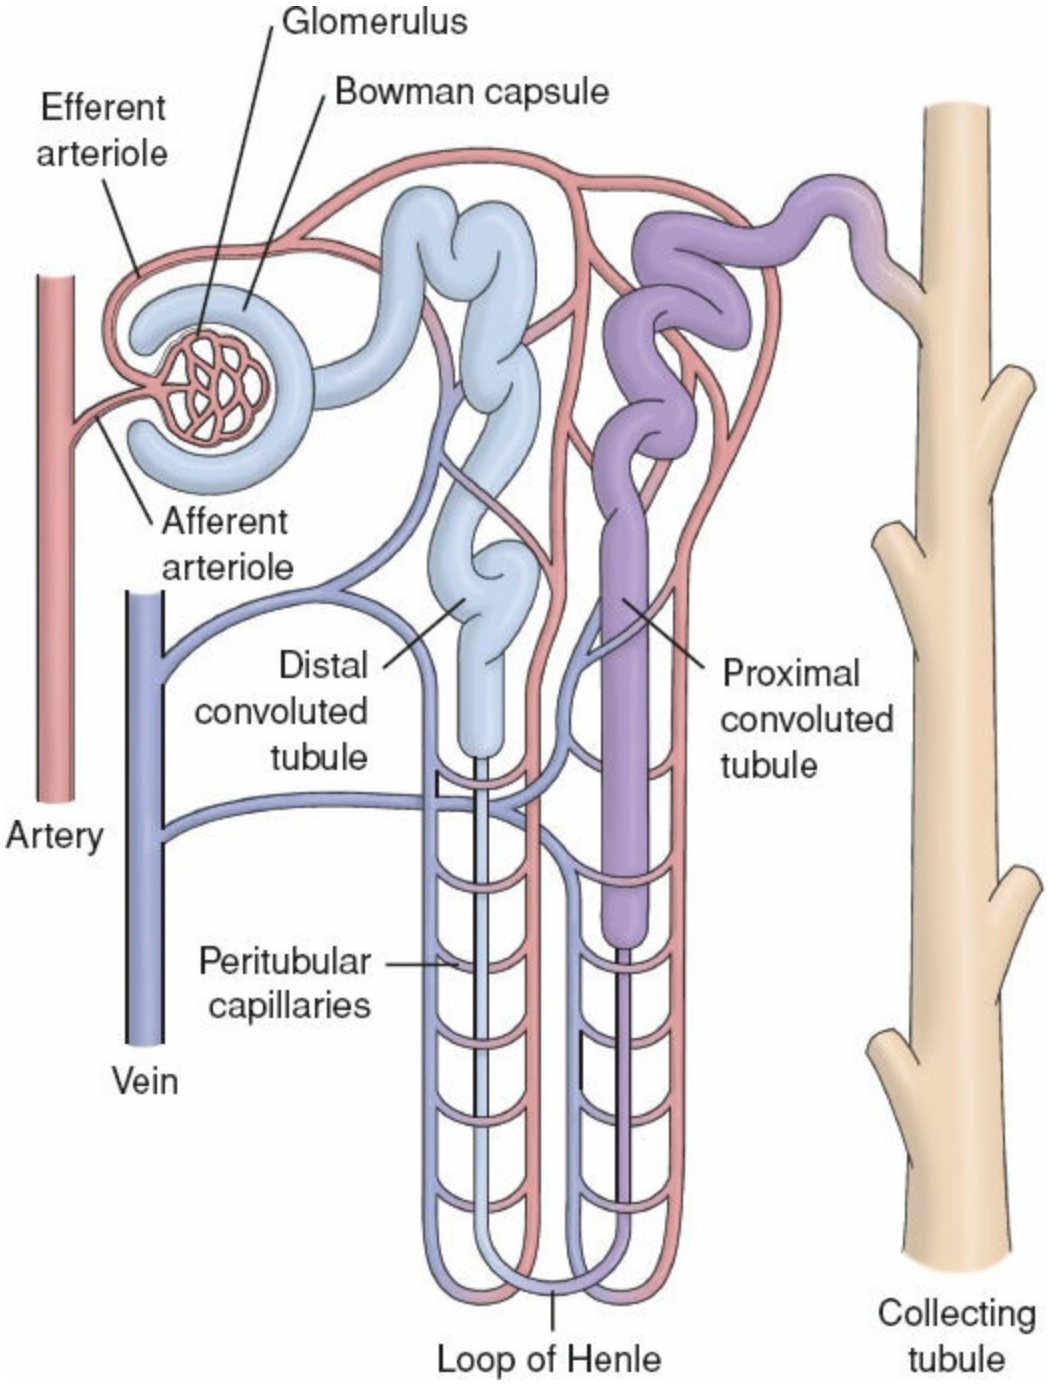

FIGURE 26-2 Representation of a nephron. Each kidney has about 1 million nephrons, which take two forms: cortical and juxtamedullary. Cortical nephrons are located in the cortex of the kidney; juxtamedullary nephrons are adjacent to the medulla.

Ureters, Bladder, and Urethra

The urine formed in the nephrons flows into the renal pelvis and then into the ureters, which are long fibromuscular tubes that connect each kidney to the bladder. Each is 24 to 30 cm long, originates at the lower portion of the renal pelvis, and terminates in the trigone of the bladder wall.

The lining of the ureters is made up of transitional cell epithelium called *urothelium.* The urothelium maintains bladder and blood impermeability as well as monitors for the

presence of foreign substances or bacteria (Lu & Chai, 2014). The movement of urine from each renal pelvis through the ureter into the bladder is facilitated by peristaltic contraction of the smooth muscles in the ureter wall. There are three narrowed areas of each ureter: the ureteropelvic junction, the ureteral segment near the sacroiliac junction, and the ureterovesical junction. These three areas of the ureters have a propensity for obstruction by renal calculi (kidney stones) or stricture (narrowing). Obstruction of the ureteropelvic junction is the most serious because of its close proximity to the kidney and the risk of associated kidney dysfunction.

The urinary bladder is a muscular, hollow sac located just behind the pubic bone. The functional capacity of the adult bladder is about 300 to 500 mL. The bladder has two inlets (the ureters), which are angled to prevent retrograde flow of urine into the ureters and one outlet (the urethra). The area surrounding the bladder neck is called the *urethrovesical junction.*

The wall of the bladder contains four layers. The outermost layer is the adventitia, which is made up of connective tissue. Beneath the adventitia is a smooth muscle layer known as the *detrusor*; beneath the detrusor is a submucosal layer of loose connective tissue that serves as an interface between the detrusor and the innermost layer, a mucosal lining. This inner layer contains specialized transitional cell epithelium, a membrane that is impermeable to water and prevents reabsorption of urine stored in the bladder.

When the detrusor muscle contracts, urine is released from the bladder; thus, the detrusor is responsible for micturition (voiding). This muscle is continuous with the bladder neck, which forms a portion of the urethral sphincter often referred to as the *internal urethral sphincter.* When the bladder is relaxed, the muscle fibers are closed and functions as a sphincter (Grossman & Porth, 2014). The sphincteric mechanism helps maintain continence. Another muscle involved in continence is the external urinary sphincter at the anterior urethra, the segment most distal from the bladder (Grossman & Porth, 2014). During micturition, increased intravesical pressure keeps the ureterovesical junction closed and keeps urine within the ureters. As soon as micturition is completed, intravesical pressure returns to its normal low baseline value, allowing efflux of urine to resume. The only time that the bladder is completely empty is in the last seconds of micturition, before efflux of urine resumes.

The urethra arises from the base of the bladder: In the male, it passes through the penis; in the female, it opens just anterior to the vagina. In the male, the prostate gland, which lies just below the bladder neck, surrounds the urethra posteriorly and laterally.

Functions of the Upper and Lower Urinary Tracts

Urine Formation

The healthy human body is composed of approximately 60% water. Water balance is regulated by the kidneys and results in the formation of urine. Urine is formed in the nephrons through a complex three-step process: glomerular filtration, tubular reabsorption, and tubular secretion (Fig. 26-3). The various substances normally filtered by the glomerulus, reabsorbed by the tubules, and excreted in the urine include sodium, chloride, bicarbonate, potassium, glucose, urea, creatinine, and uric acid. Within the tubule, some of these substances are reabsorbed selectively into the blood to maintain electrolyte and acid–base balance. Others are secreted from the blood into the filtrate as it travels down the tubule.

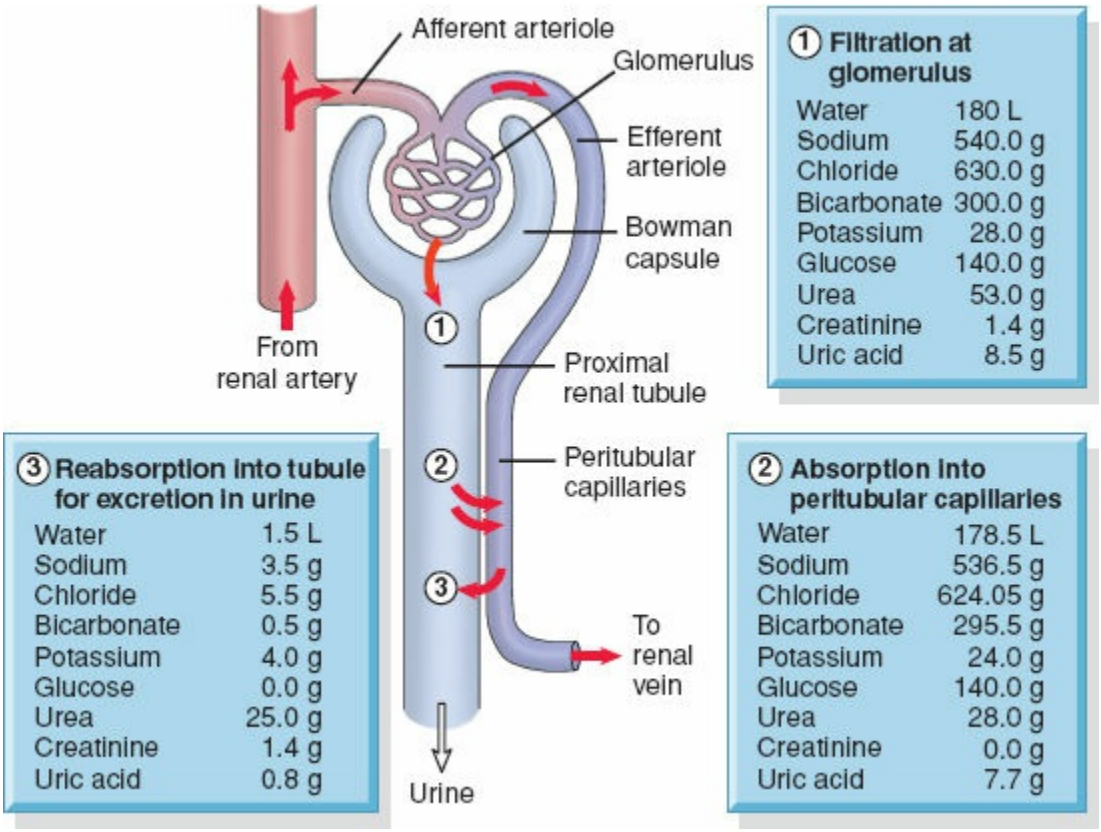

FIGURE 26-3 Urine is formed in the nephrons in a three-step process: filtration, reabsorption, and excretion. Water, electrolytes, and other substances, such as glucose and creatinine, are filtered by the glomerulus; varying amounts of these substances are reabsorbed in the renal tubule or excreted in the urine. Approximate normal volumes of these substances during the steps of urine formation are shown at the top. Wide variations may occur in these values depending on diet.

Usually amino acids and glucose are filtered at the level of the glomerulus and reabsorbed so that neither is excreted in the urine. Normally, glucose does not appear in the urine. However, glycosuria occurs if the amount of glucose in the blood and glomerular filtrate exceeds the amount that the tubules are able to reabsorb. Renal glycosuria occurs in

cases of diabetes and is the most common clinical expression of a blood glucose level exceeding the kidneys' reabsorption capacity. In general, the serum glucose level is greater than 180 to 200 mg/dL when glycosuria is seen.

Protein molecules also are not usually found in the urine; however, low–molecular-weight proteins (globulins and albumin) may be excreted periodically in small amounts. Recall that the glomerulus filters the blood, similar to a strainer. Therefore, when significant proteinuria is found, glomerular disease is suspected. Levels of greater than 3.5 g/day are indicative of severe proteinuria and are associated with nephrotic syndrome as well as a variety of glomerular disorders (see Chapter 27).

Glomerular Filtration

The normal blood flow through the kidneys is about 1,200 mL/min. As blood flows into the glomerulus from an afferent arteriole, filtration occurs. The filtered fluid enters the renal tubules. Under normal conditions, about 20% of the blood passing through the glomeruli is filtered into the nephron, amounting to about 180 L/day of filtrate. The filtrate normally consists of water, electrolytes, and other small molecules, whereas larger molecules stay in the bloodstream. Efficient filtration depends on adequate blood flow that maintains a consistent pressure through the glomerulus. Many factors can alter this blood flow and pressure, including hypotension, decreased oncotic pressure in the blood, and increased pressure in the renal tubules from an obstruction.

Tubular Reabsorption and Tubular Secretion

The second and third steps of urine formation occur in the renal tubules. In tubular reabsorption, a substance moves from the filtrate back into the peritubular capillaries or vasa recta. In tubular secretion, a substance moves from the peritubular capillaries or vasa recta into tubular filtrate. Of the 180 L (45 gallons) of filtrate that the kidneys produce each day, 99% is reabsorbed into the bloodstream, resulting in the formation of 1,000 to 1,500 mL of urine each day. Although most reabsorption occurs in the proximal tubule, reabsorption does occur along the entire tubule. Reabsorption and secretion in the tubule frequently involve passive and active transport. Filtrate becomes concentrated in the distal tubule and collecting ducts under hormonal influence and becomes urine, which then enters the renal pelvis.

Osmolarity and Osmolality

Osmolarity and osmolality refer to the ratio of solute (e.g., sodium, chloride, potassium, urea, and glucose) to water in blood or urine. While osmolarity refers to measuring the ratio of the amount of solutes (milliosmoles) to water using liters (expressed as mOsm/L), osmolality calculates the ratio of the amount of solutes (milliosmoles) to water using weight or kilograms (expressed as mOsm/kg). The terms are confusing and often misused; what is important to remember is that clinicians are attempting to determine the concentration of blood or urine. Because 1 L is roughly equivalent to 1 kg, generally they are similar. The regulation of salt and water is paramount for control of the extracellular volume and both serum and urine osmolarity. Controlling either the amount of water or the amount of solute can change the concentration of blood and urine. Osmolarity and ionic composition are maintained by the body within very narrow limits. Sodium levels elevated 2 mEq/L

above normal cause a change in the serum osmolarity (increased number of solute atoms or molecules), causing a conscious desire to drink and conservation of water by the kidneys (Hall, 2016). It is important for nurses to recognize that cognitive impairments can interfere with recognition of cues of thirst and predispose a patient to dehydration.

Nursing Alert

The terms isotonic, hypotonic, and hypertonic refer to the osmolarity of body fluids (measure of the number of dissolved particles). A serum osmolality test measures the amount of chemicals dissolved in the fluid portion of blood (serum). It could be imagined visually as the total number of molecules floating in the fluid. Normal serum osmolality equals 280 to 303 mOsm/kg of body weight (Fischbach & Dunning, 2014). When a hypotonic solution is administered intravenously (IV), the RBCs will swell; conversely, a hypertonic solution will cause the cells to shrink (Reddi, 2014). An isotonic solution will not cause a change in the size of the RBCs. Sodium chloride 0.9% (AKA normal saline) is an example of an IV isotonic solution, sodium chloride 0.45% (AKA half saline) is an example of a hypotonic solution, and sodium chloride 3% is an example of a hypertonic solution.

Nursing Alert

Nurses need to have some understanding of the concentration of an intravenous (IV) solution's osmolarity and its relationship to clinical practice. Isotonic solutions are equal to normal osmolarity (approximately 300 mOsm/L; e.g., lactated Ringer's [275 mOsm/L] and normal saline [308 mOsm/L]); hypotonic solutions have fewer molecules and more water in the solution (less than 275 mOsm/L; e.g., half-normal saline [154 mOsm/L]); and hypertonic solutions have a higher number of molecules and are more concentrated solutions (over 300 mOsm/L; e.g., dextrose 5% in half-normal saline [405 mOsm/L]). Any fluid or medication with an osmolarity greater than 600 mOsm/L should not be infused through a peripheral catheter; instead a peripherally inserted central catheter (PICC) is recommended by the Infusion Nurses Society (Wojnar & Beaman, 2013).

Regulation of Water Excretion

Regulation of the amount of water excreted is an important function of the kidney. Antidiuretic hormone (ADH), also known as *vasopressin*, plays a key role in the regulation of extracellular fluid by excreting or retaining water. ADH is secreted by the posterior portion of the pituitary gland and acts on the kidney in response to changes in osmolality of the blood; that is, ADH is secreted or suppressed depending on blood concentration or dilution, respectively. An increase in blood osmolality is seen with decreased water intake or increased water loss, stimulating ADH release. Consequently, a small volume of concentrated urine is excreted. ADH increases reabsorption of water and returns the osmolality of the blood to normal. With excess water intake or increased retention of water, as occurs in many disease states such as kidney failure, the blood becomes dilute, resulting in suppression of ADH secretion, causing less water to be reabsorbed by the kidney tubule. Assuming maintenance of kidney function, this would result in increased urine volume (diuresis).

TABLE 26-1 24-hour Balance of Intake and Output for Adults

Water Input	Input Volume (mL)	Output	Output Volume (mL)
Liquid	800–1,500	Urine	800–1,500
Solid	500–700	Lung/Skin	600–700
Oxidative metabolism	150–250	Sweat Stool	0–100 100–200
Total ~1,500–2,500 mL per day		**Total ~ 1,500–2,500 mL**	

In general, individuals require about 100 mL of water per 100 calories metabolized in order to rid the body of metabolic waste products. In other words, if a person uses 1,800 calories for energy, he/she will require 1,800 mL of water to metabolize them (Grossman & Porth, 2014). Fevers increase the metabolic and respiratory rate; therefore, the patient will lose additional water via the lungs and perspiration (Grossman & Porth, 2014). The greatest source of body water is through liquid (1,000 mL) and solid (700 mL) oral intake with an additional 200 mL gained through oxidation. Of the fluid ingested, the main source of loss is through the urine (1,500 mL); approximately 800 mL is lost through the skin and lungs (called *insensible loss*), and 200 mL through feces (Grossman & Porth, 2014). Normal urine output is approximately 1.5 L in 24 hours (Grossman & Porth, 2014) and intake is roughly equivalent to output in a healthy person (see Table 26-1). It is important to consider all fluid gained and lost when evaluating total fluid status. Daily weight measurements are a reliable means of determining overall fluid status. One pound equals approximately 500 mL so a weight change of as little as 1 lb could suggest an overall fluid gain or loss of 500 mL. The nurse is aware that edema is not present until 2.5 to 3 L of interstitial fluid has been retained (Sterns, 2015).

Nursing Alert
It is important to maintain consistency when assessing daily weight: the nurse uses the same scale, with the patient wearing the same clothes at the same time daily.

Regulation of Electrolyte Excretion

When the kidneys are functioning normally, the volume of electrolytes excreted per day is equal to the amount ingested. For example, the average American daily diet contains 6 to 8 g of sodium chloride (salt) and approximately the same amount is excreted in the urine.

Sodium

Normal serum sodium levels are between 135 and 145 mmol/L, making sodium the most plentiful extracellular ion (see Chapter 4). Sodium plays an important role in controlling the fluid and electrolyte balance: where sodium goes, water follows. Sodium is linked

inseparably to both blood volume and blood pressure. The kidneys are responsible for regulating electrolyte loss, and approximately 65% to 80% of sodium is reabsorbed by the proximal tubule and 20% to 25% in the loop of Henle (Grossman & Porth, 2014).

As water from the filtrate follows the reabsorbed sodium, the body's osmotic balance is maintained. If more sodium is excreted than ingested, fluid deficit results; if less sodium is excreted than ingested, fluid retention results. Under normal circumstances, the kidneys are quite efficient at preserving or excreting sodium depending on its loss via the gastrointestinal (GI) tract or skin as well as its gain via diet, medications, or IV therapy.

The regulation of sodium volume excreted depends on aldosterone, a hormone synthesized and released from the adrenal cortex. With increased aldosterone in the blood, less sodium is excreted in the urine, as aldosterone causes renal reabsorption of sodium. The release of aldosterone from the adrenal cortex is largely under the control of angiotensin II, the most effective physiologic vasoconstrictor known. Angiotensin II levels are controlled by renin, a proteolytic enzyme released from specialized juxtaglomerular cells in the renal afferent arteriole (see Fig. 26-4). Renin secretion is controlled by three distinct but overlapping regulatory systems: (1) renal afferent arteriolar pressure (if it decreases renin secretion increases); (2) cardiopulmonary baroreceptors that are capable of modulating sympathetic nervous system outflow (a fall in blood pressure increases renin secretion by increasing sympathetic tone); and (3) the delivery of NaCl to the macula densa, a group of modified distal tubular cells (a decrease in NaCl delivery to these cells increases renin secretion while an increase in NaCl delivery has the opposite effect). Activation of this system (by dehydration, e.g., shock or hypotension) will increase NaCl reclamation and, pari passu, water retention culminating in an expansion of the intravascular fluid volume. The net result is the maintenance of pressure within the glomerulus to ensure adequate glomerular filtration pressure and renal function.

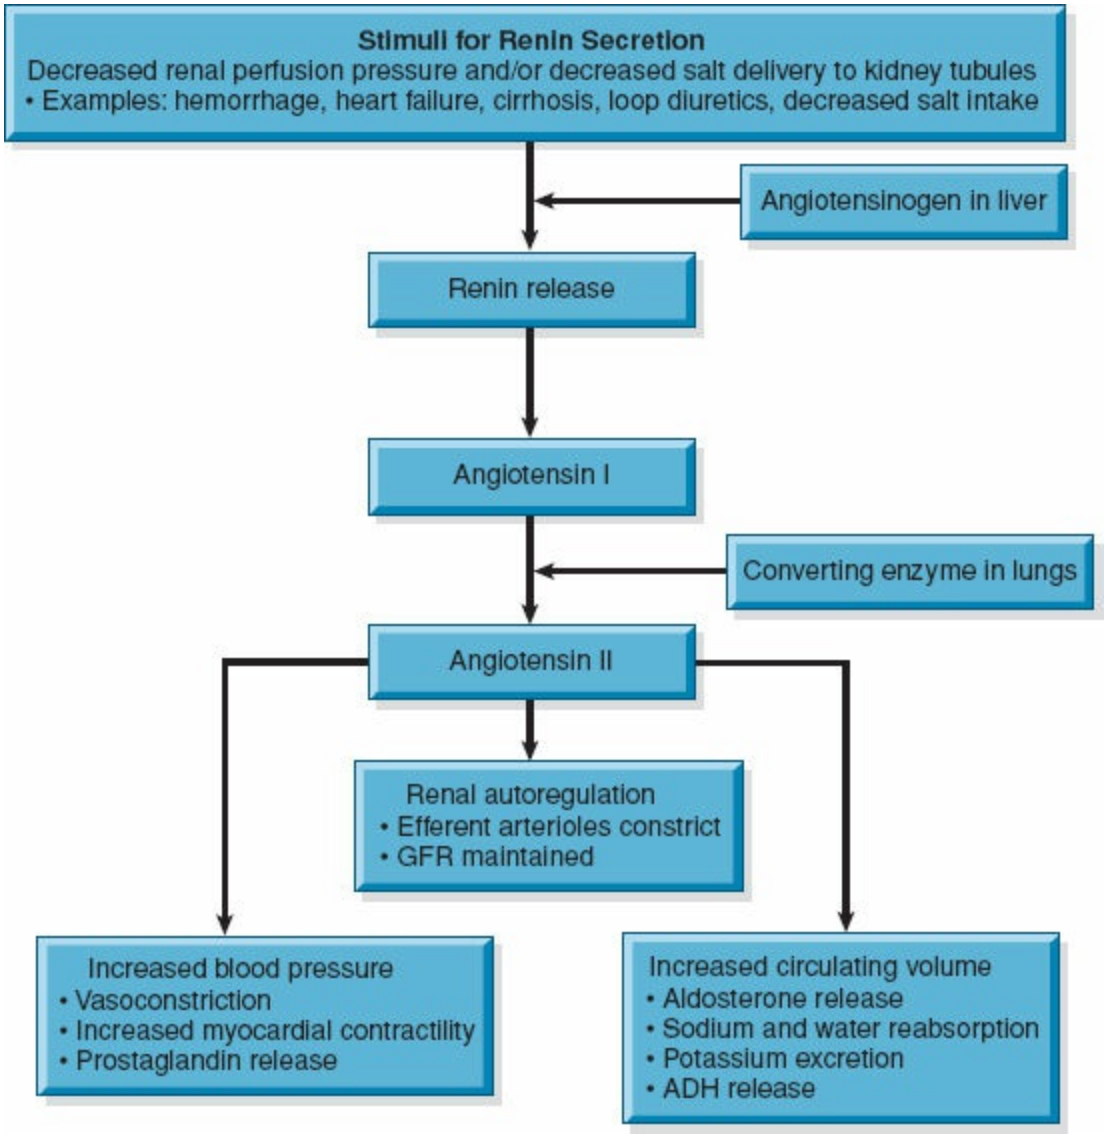

FIGURE 26-4 The renin–angiotensin system. ADH, antidiuretic hormone; GFR, glomerular filtration rate.

Nursing Alert

The nurse recognizes that a mean arterial pressure (MAP) should be at least 65 mm Hg or higher in order to maintain renal perfusion.

Potassium

Potassium is the most abundant intracellular ion; about 98% of the total body potassium is located intracellularly. To maintain a normal serum potassium balance (see Chapter 4), the kidneys are responsible for excreting more than 90% of the total daily potassium intake. Aldosterone causes the kidneys to excrete potassium, in contrast to its effects on sodium. The acid–base balance, the amount of dietary potassium intake, and the flow rate of the filtrate in the distal tubule also influence the amount of potassium secreted into the urine. Retention of potassium is the most life-threatening effect of kidney failure.

Nursing Alert

When the level of potassium is above 6.5 mEq/L, it represents a medical emergency, primarily due to its effect on the heart. Renal perfusion is essential for excretion of potassium; when the MAP decreases to less than 70 mm Hg, urine volumes begin to decrease, resulting in impaired potassium excretion. Therefore, the nurse is alert to minimal urinary output hourly (0.5 to 1.0 mL/kg/hr) and its effect on K^+. The nurse is aware that EKG changes include a progression from peaked T waves to a prolonged PR interval, and then to a widened QRS and heart block; a K^+ level above 7 mEq/L is associated with serious arrhythmias.

Regulation of Acid–Base Balance

The normal serum pH is about 7.35 to 7.45 and must be maintained within this narrow range for optimal physiologic function. The kidney reabsorbs and returns bicarbonate from the urinary filtrate to the body's circulation. It also excretes acid in the urine. Because bicarbonate is a small ion, it is filtered freely at the glomerulus and reabsorbed in the urinary filtrate. To replace any lost bicarbonate, new bicarbonate is generated by the renal tubular cells and then reabsorbed by the tubules and returned to the body.

The body's acid production is the result of the breakdown of proteins, which produces acid compounds. The normal daily diet also includes a certain amount of acid materials. Unlike carbon dioxide (CO_2), the phosphoric and sulfuric acids produced are nonvolatile (solid) and cannot be eliminated by the lungs. If these acids were not excreted in the urine, accumulation of these acids in the blood would lower its pH and inhibit cell function. A person with normal kidney function excretes about 70 mEq of acid each day. The kidney is able to excrete some of this acid directly into the urine until the urine pH reaches 4.5, which is 1,000 times more acidic than blood.

More acid may need to be eliminated from the body than can be secreted directly as free acid in the urine. These excess acids are bound to chemical buffers so that they can be excreted in the urine. Two important chemical buffers are phosphate ions and ammonia (NH_3). Through the buffering process, the kidney is able to excrete large quantities of acid in a bound form, without further lowering the pH of the urine.

Autoregulation of Blood Pressure

Regulation of blood pressure is also a function of the kidney. Specialized vessels of the kidney, called the *vasa recta*, constantly monitor blood pressure as blood begins its passage into the kidney. When the vasa recta detect a decrease in blood pressure, specialized juxtaglomerular cells near the afferent arteriole, distal tubule, and efferent arteriole secrete the hormone renin. Renin does not affect blood pressure directly. It converts a circulating plasma protein named angiotensinogen to angiotensin I, which is converted to angiotensin II and causes the blood pressure to increase by its vasoconstrictor properties and secretion of aldosterone (Grossman & Porth, 2014). Aldosterone causes renal reabsorption of sodium and water by the distal tubules and collecting ducts, thus volume is returned to systemic circulation. Any etiology that results in poor perfusion or increasing serum osmolality, such as hemorrhage or diarrhea, will cause activation of renin, which leads to activation of angiotensin II and aldosterone secretion. The result is an increase in blood pressure. When the vasa recta recognize the increase in blood pressure, renin secretion stops. Failure of this

feedback mechanism is one of the primary causes of hypertension.

Renal Clearance

Renal clearance refers to the ability of the kidneys to clear solutes from the plasma. A 24-hour collection of urine is the primary test of renal clearance. Renal clearance depends on several factors: how quickly the substance is filtered across the glomerulus, how much of the substance is reabsorbed along the tubules, and how much of the substance is secreted into the tubules. It is possible to measure the renal clearance of any substance, but the one measure that is particularly useful is the creatinine clearance: as renal function declines, creatinine clearance decreases; that is, the patient's serum creatinine rises.

Creatinine is an endogenous waste product of skeletal muscle that is filtered at the glomerulus, passed through the tubules with minimal change, and excreted in the urine, making creatinine clearance a good measure of the glomerular filtration rate (GFR). To calculate creatinine clearance, a 24-hour urine specimen is collected. Midway through the collection, the serum creatinine level is measured.

The GFR in a young, healthy individual is 120 to 130 mL/min/1.73 m^2 (Grossman & Porth, 2014).

Regulation of Red Blood Cell Production

When the kidneys sense a decrease in the oxygen tension in renal blood flow, they release erythropoietin. Erythropoietin stimulates the bone marrow to produce RBCs, thereby increasing the number of circulating RBCs, raising the O_2 carrying capacity of the blood. Some conditions, such as chronic kidney disease, require that patients receive exogenous erythropoietin in order to maintain RBC production.

Vitamin D Synthesis

The kidneys also are responsible for the final conversion of inactive vitamin D to its active form, 1,25-dihydroxycholecalciferol. Vitamin D is necessary for maintaining normal calcium balance in the body.

Secretion of Prostaglandins

The kidneys also produce prostaglandin E and prostacyclin, which have a vasodilatory effect and are important in maintaining renal blood flow.

Excretion of Waste Products

The kidney functions as the body's main excretory organ, eliminating the body's metabolic waste products. The major waste product of protein metabolism is urea, of which about 25 to 30 g are produced and excreted daily. All of this urea must be excreted in the urine; otherwise it accumulates in body tissues. Other waste products of metabolism that must be excreted are creatinine, phosphates, and sulfates. Uric acid, formed as a waste product of purine metabolism, also is eliminated in the urine. The kidneys serve as the primary mechanism for excreting drug metabolites.

Nursing Alert

The kidneys are responsible for excretion of waste products that account for a daily solute load of approximately 600 mOsm. It is approximated that 500 cc of urine is required daily to excrete that solute load. Without that excretion of 500 cc, toxins and waste products will rise in the serum or blood value. The term azotemia refers to the buildup of excessive nitrogenous wastes in the blood (refer to Chapter 27 for additional detail).

Urine Storage

The bladder is a hollow, distensible, muscular organ whose size, shape, and position vary in relation to the amount of urine it contains. Both filling and emptying of the bladder are mediated by coordinated sympathetic and parasympathetic nervous system control mechanisms involving the detrusor muscle and the bladder sphincters. Conscious awareness of bladder filling occurs as a result of sympathetic neuronal pathways that travel via the spinal cord to the level of T10 through T12, where peripheral, hypogastric nerve innervation allows for continued bladder filling. As bladder filling continues, stretch receptors in the bladder wall are activated, coupled with the desire to void. This information from the detrusor muscle is relayed back to the cerebral cortex via the parasympathetic pelvic nerves at the level of S1 through S4. Overall bladder pressure remains low due to the bladder's compliance (ability to expand or collapse) as urine volume changes.

Bladder compliance is due to the smooth muscle lining of the bladder and collagen deposits within the wall of the bladder, as well as to neuronal mechanisms that inhibit the detrusor muscle from contracting (specifically, adrenergic receptors that mediate relaxation). To maintain adequate kidney filtration rates, bladder pressure during filling must remain lower than 40 cm H_2O. This low pressure allows the urine to leave the renal pelvis and enter the ureters freely. The bladder is capable of holding 1,500 to 2,000 mL of urine. This is referred to as the *anatomic capacity* of the bladder. The sensation of bladder fullness is transmitted to the central nervous system when the bladder has reached about 150 to 250 mL in adults, and an initial desire to void occurs (Grossman & Porth, 2014). A marked sense of fullness and discomfort with a strong desire to void usually occurs when the bladder contains 350 mL or more of urine, referred to as the *functional capacity.* Neurologic changes to the bladder at the level of the supraspinal nerves, the spinal nerves, or the bladder wall itself can cause abnormally high volumes of urine to be stored due to a decreased or absent urge to void.

The bladder should be able to store urine for periods of 2 to 4 hours at a time during the day. At night, the release of vasopressin in response to decreased fluid intake causes a decrease in the production of urine and makes it more concentrated. It allows the bladder to continue filling for periods of 6 to 8 hours in adolescents and adults, making them able to sleep for longer periods before needing to void. This process, which is less pronounced in the elderly, coupled with decreasing bladder compliance and decreased vasopressin (ADH) levels, often causes nocturia.

Bladder Emptying

Micturition normally occurs approximately eight times in a 24-hour period. It is activated

via the micturition reflex arc within the sympathetic and parasympathetic nervous system, which causes a coordinated sequence of events. Initiation of voiding occurs when the efferent pelvic nerve, which originates at S1 to S4, stimulates the bladder to contract, resulting in complete relaxation of the striated urethral sphincter. This is followed by a decrease in urethral pressure, contraction of the detrusor muscle, opening of the vesicle neck and proximal urethra, and flow of urine. This coordinated effort by the parasympathetic system is mediated by muscarinic and, to a lesser extent, cholinergic receptors within the detrusor muscle. The pressure generated in the bladder during micturition is about 20 to 40 cm H_2O in females. It is somewhat higher and more variable in males 45 years of age and older due to the normal hyperplasia of the lobes of the prostate gland, which surround the proximal urethra. Any obstruction of the bladder outlet, such as in advanced benign prostatic hyperplasia (BPH), results in a high voiding pressure. High voiding pressures make it more difficult to start urine flow and maintain it.

If the spinal pathways from the brain to the urinary system are destroyed (e.g., after a spinal cord injury), reflex contraction of the bladder is maintained, but voluntary control over the process is lost. In both situations, the detrusor muscle can contract and expel urine, but generally the contractions are insufficient to empty the bladder completely so residual urine (urine left in the bladder after voiding) remains. Normally, residual urine amounts to no more than 50 mL in the middle-aged adult and less than 50 to 100 mL in the older adult.

Nursing Alert

Any anatomical or functional disorder causing urinary obstruction or stasis places the individual at risk for urinary tract infections (UTIs) (Kasper et al., 2015). A post-void residual (PVR) of less than 50 cc is considered normal bladder emptying, whereas a PVR of over 200 cc is a risk factor for a UTI (Grossman & Porth, 2014).

Gerontologic Considerations

Upper and lower urinary tract function changes with age (Table 26-2). The GFR decreases, starting between 35 and 40 years of age, and a yearly decline of about 1 mL/min continues thereafter (Kasper et al., 2015). In patients 80 years of age and over, system function is about one half to two thirds less efficient than in young adults (Griebling, 2014). The elderly are more susceptible to acute and chronic kidney failure due to the structural and functional changes in the kidney. As one ages, there is a decline in organ functioning but, in particular, in those organs that are paired, such as the lungs and the kidneys (Griebling, 2014). Examples include sclerosis of the glomerulus and renal vasculature, decreased blood flow, decreased GFR, altered tubular function, and acid–base imbalance. In addition, nephrons lose their ability to compensate as one becomes older (Greibling, 2014). Although kidney function usually remains adequate despite these changes, renal reserve is decreased and may reduce the kidneys' ability to respond effectively to drastic or sudden physiologic changes. This steady decrease in glomerular filtration, combined with the use of multiple medications in which metabolites are cleared by the kidneys, puts the older person at higher risk for adverse drug effects and drug–drug interactions (Greibling, 2014).

TABLE 26-2 GERONTOLOGIC CONSIDERATIONS / Age-Related Changes in the Renal System

Component	Structural and Functional Changes	History and Physical Findings
Kidney	Kidney weight and volume (primarily of the cortex) declines after age 40	Progressive decline of kidney reserve (the ability to respond to changes in water or electrolyte imbalances)
Renal blood flow	Blood flow decreases approximately 10% per decade Renal arteries thicken (similar to other vascular changes) Sclerosis of the glomerulus results in atrophy of the afferent and efferent arteriole	Increased risk for kidney failure due to polypharmacy, comorbidities, and decreased kidney function
Nephron	The number of nephrons declines after the age of 40 and is associated with decline in GFR The glomerular basement membrane thickens	Yearly decline in GFR of 1 mL per minute (after age 40) The elderly are at risk for altered drug excretion and drug–drug interaction
Tubule system	Degeneration of the tubule system, replaced with connective tissue Decrease in the length of the proximal tubule	Ability to conserve sodium or excrete hydrogen is decreased, predisposing the elderly to fluid and electrolyte and acid–base disturbances. Decline in maximal concentrating capacity, with increased difficulty in excreting a salt load or conserving water in the face of dehydration
Bladder	Reduced bladder tone Residual bladder urine volume increases Decreased bladder capacity In women, decreased estrogen causes changes to the urethral sphincter	Increased sense of urgency In women, increased risk of urinary incontinence Incomplete emptying of bladder, leading to urinary tract infection Increased irritability of bladder with advancing age and may generate less power, which is a problem especially in men with prostatic hypertrophy
Prostate	Enlargement of the prostate	Obstruction to urine flow, leading to frequency, oliguria, anuria
General	Decrease in muscle mass results in decreased production of creatinine Decreased vitamin D synthesis Vaginal and urethral atrophy	Serum creatinine levels remain constant; creatinine clearance is a better indicator of kidney function Osteomalacia Predisposition of women to urinary tract infections

Adapted from Criddle, L. (2009). Caring for the critically ill elderly patient. In K. Carlson (Ed.). *Advanced critical care nursing, American Association of Critical-Care Nursing*. St. Louis, MO: Saunders, Elsevier; Grossman, S., & Porth. C. M. (2014). *Porth's pathophysiology concepts of altered health states* (9th ed.). Philadelphia, PA: Wolters Kluwer/ Lippincott Williams & Wilkins; and Walston, J. (2015). Common clinical sequelae of aging. In *Cecil textbook of medicine* (25th ed.). Philadelphia, PA: Saunders.

The elderly are more prone to develop hypernatremia and fluid volume deficit because increasing age also is associated with diminished osmotic stimulation of thirst (Greibling, 2014). Thirst is a subjective sensory symptom that is defined as an awareness of the desire to drink. The elderly, because of both decreased thirst and/or diminished access to fluids and/or impaired urinary concentrating ability, are at the highest risk of developing hypernatremia (an increase in the plasma Na^+ concentration to at least 145 mEq/L).

Likewise, many older adults may be placed on diuretics, such as furosemide, to control congestive heart failure (CHF) meaning excess sodium may be lost in the urine. This sodium loss results in hyponatremia and a decrease in both central venous pressure (CVP) and arterial blood pressure, causing prerenal failure (Greibling, 2014). In addition, hypervolemic hyponatremia commonly occurs when patients have excess free water relative to serum sodium levels (e.g., kidney failure, cardiac failure, liver failure). Therefore the nurse is alert to sodium levels (hypernatremia or hyponatremia) and is aware of common causes and clinical presentation in order to alert practitioners to reverse this potentially life-threatening condition.

Structural or functional abnormalities that occur with aging also may prevent complete

emptying of the bladder. This may be due to decreased bladder wall contractility, secondary to myogenic or neurogenic factors, or it may be related to bladder outlet obstruction, such as in BPH (Grossman & Porth, 2014). Vaginal and urethral tissues atrophy (become thinner) in aging women due to decreased estrogen levels, resulting in decreased blood supply to the urogenital tissues, with subsequent urethral and vaginal irritation and possible urinary incontinence.

UTIs are common in individuals aged 65 years and over. Risk factors include patients residing in convalescent facilities as well as patients with chronic catheterizations and increasing antibiotic resistance. Symptoms present differently and more subtly than in younger adults and may include increasing confusion, falls, and a loss of appetite. In addition, older adults with impaired cognitive functioning may have difficulty communicating symptoms (Griebling, 2014).

Also nocturia is common in older adults, resulting in disturbed sleep that impacts daytime fatigue. Because the individual must awaken at night to void, the risk of falls increases and may results in fractures. Other urologic disorders affected by aging are prostate and bladder cancers, BPH, and urinary incontinence, which is the most prevalent urologic disorder in the older adult (Griebling, 2014).

As individuals age, the density of smooth muscle to connective tissue in the bladder decreases, increasing the likelihood of detrusor fibrosis. Because bladder capacity is reduced, patients may experience a decrease in the force of urinary stream, increased hesitancy, inability to empty the bladder fully, and urinary dribbling; although it may be unclear which symptoms are caused by comorbidities or are a result of aging (Griebling, 2014).

Hypertension increases in the geriatric population, contributing to kidney disease and erectile dysfunction. Polypharmacy is another factor impacting urologic health, resulting in drug-induced urgency, frequency, retention, and urinary incontinence (Griebling, 2014). Urinary incontinence is common in the older adult, particularly in females, negatively impacting quality of life; frailty is a major risk factor. About half of all American females experience incontinence at some point in their lives. The nurse should teach bladder-training exercises, such as Kegel maneuvers (refer to Chapter 33, Box 33-9). Incontinence caused by urinary or vaginal prolapse should be referred to a specialist. UTIs always should be considered as a cause of incontinence along with the use of medications, such as diuretics, antidepressant medications, sedative hypnotics, adrenergic agonists, anticholinergics, and calcium channel blockers. Whether estrogen replacement improves incontinence remains controversial. The nurse must become familiar with resources addressing the medical, social, and functional needs of the older adult, such as rehabilitative services, Medicare/Medicaid reimbursement in both in- and outpatient settings, home care services, assisted care facilities, day programs, and long-term care facilities. Also it is necessary to address other lifestyle changes:

- proper exercise (at least 150 minutes of brisk walking or other moderate forms of exercise per week),
- proper nutrition (increased consumption of fruits and vegetables),
- adequate fluid intake of at least 1,000 mL/day,
- consumption of fat-free and low-fat dairy products,
- decreased intake of sugar and sodium,
- moderate alcohol intake (1 drink per day), and

- increased dietary fiber (Kasper et al., 2015).

Treatment modalities for urinary incontinence are described in further detail in Chapter 28.

ASSESSMENT

Obtaining a comprehensive health history is the first step in assessing a patient with upper or lower urinary tract dysfunction.

Health History

Obtaining a urologic health history requires excellent communication skills because many patients are embarrassed or uncomfortable discussing genitourinary function or symptoms. It is important to use language the patient can understand and to avoid medical jargon while reviewing risk factors, particularly for those patients who are at high risk.

When obtaining the health history specific to the renal and urinary systems, the nurse should inquire about the following:

- The patient's chief concern or reason for seeking health care, the onset of the problem, and its effect on the patient's quality of life
- The location, character, and duration of pain, if present, and its relationship to voiding; factors that precipitate pain and those that relieve it
- History of UTIs, including past treatment or hospitalization for UTI
- Presence of fever or chills
- Previous renal or urinary diagnostic tests
- Use of indwelling urinary catheters, suprapubic tubes, condom catheters, or intermittent catheterization
- Dysuria or painful urination which may occur at initiation or termination of voiding
- Hesitancy, straining, or pain during or after urination
- Urinary incontinence (stress incontinence, urge incontinence, overflow incontinence, or functional incontinence)
- Hematuria (blood in urine) or change in color or volume of urine
- The presence of nocturia and number of episodes nightly
- Renal calculi (kidney stones), passage of stones or gravel in urine
- Female patients: Number and type (vaginal or cesarean) of deliveries; use of forceps; vaginal infection, discharge, or irritation; contraceptive practices
- History of anuria (less than 50 cc of urine a day) (Liangos & Jaber, 2015) or other renal problem
- Presence or history of genital lesions or sexually transmitted diseases
- Use of tobacco, alcohol, or recreational drugs
- Any prescription and over-the-counter medications (including those prescribed for renal or urinary problems)

Common Complaints

Fatigue, pain, changes in voiding, and GI symptoms are particularly suggestive of urinary tract disease. Dysfunction of the kidney can produce a complex array of symptoms throughout the body.

Fatigue

Gradual kidney dysfunction can be insidious in its presentation, although fatigue is a common symptom. Fatigue, shortness of breath, and exercise intolerance all result from the

condition known as *anemia of chronic disease.* Although historically hematocrit has been the blood test of choice when assessing a patient for anemia, currently the use of the hemoglobin level rather than hematocrit is recommended because that measurement is a better assessment of the oxygen transport ability of the blood.

Pain

Usually genitourinary pain is caused by distention of some portion of the urinary tract as a result of obstructed urine flow or inflammation and swelling of tissues. Severity of pain is related to the sudden onset rather than the extent of distention.

Table 26-3 lists the various types of genitourinary pain, characteristics of the pain, associated signs and symptoms, and possible causes. Initially a gradual decline in kidney functioning may be asymptomatic and only noted when the patient presents for routine examination; an elevation in serum creatinine or abnormal urinalysis may be the first clue to kidney disease. However, some patients present with flank pain or extrarenal symptoms, such as edema, hypertension, hematuria, and signs of uremia (Rosenberg, 2015), leading the nurse to further explore kidney function.

TABLE 26-3 Identifying Characteristics of Genitourinary Pain

Type	Location	Character	Associated Signs and Symptoms	Possible Etiology
Kidney	Costovertebral angle, may extend to umbilicus	Dull constant ache; if sudden distention of capsule, pain is severe, sharp, stabbing, and colicky in nature	Nausea and vomiting, diaphoresis, pallor, signs of shock	Acute obstruction, kidney stone, blood clot, acute pyelonephritis, trauma
Bladder	Suprapubic area	Dull, continuous pain, may be intense with voiding, may be severe if bladder full	Urgency, pain at end of voiding, painful straining	Overdistended bladder, infection, interstitial cystitis; tumor
Ureteral	Costovertebral angle, flank, lower abdominal area, testis, or labium	Severe, sharp, stabbing pain, colicky in nature	Nausea and vomiting, paralytic ileus	Ureteral stone, edema or stricture, blood clot
Prostatic	Perineum and rectum	Vague discomfort, feeling of fullness in perineum, vague back pain	Suprapubic tenderness, obstruction to urine flow; frequency, urgency, dysuria, nocturia	Prostatic cancer, acute or chronic prostatitis
Urethral	Male: along penis to meatus; female: urethra to meatus	Pain variable, most severe during and immediately after voiding	Frequency, urgency, dysuria, nocturia, urethral discharge	Irritation of bladder neck, infection of urethra, trauma, foreign body in lower urinary tract

Changes in Voiding

Micturition is normally a painless function that occurs approximately eight times in a 24-hour period. The average person voids approximately 1,500 mL of urine in 24 hours, although this amount varies depending on fluid intake, sweating, environmental temperature, vomiting, or diarrhea. Common problems associated with voiding include frequency, urgency, dysuria, hesitancy, incontinence, enuresis (bed wetting), polyuria (more than 3 L/day of urine), oliguria (less than 400 mL/day), and hematuria (two to five RBCs per high-powered field or a positive dipstick) (Kasper et al., 2015) (Table 26-4). Pain that may be associated with an overdistended bladder, difficulty starting the stream of urine or decrease in amount of urine, or straining to void all may be symptoms of urinary

retention (Bickley, 2013) and should be evaluated.

Gastrointestinal Symptoms

GI symptoms may occur with urologic conditions because of shared autonomic and sensory innervation and renointestinal reflexes (Tortora & Derrickson, 2014). For example, afferent stimulation from the renal pelvis may cause spasms of the pylorus of the stomach; thus the patient may experience symptoms similar to peptic ulcer disease (Tanagho & McAninch, 2012). The most common signs and symptoms are nausea, vomiting, diarrhea, abdominal discomfort, and abdominal distention.

Risk Factors

Various diseases or clinical situations can increase a patient's risk for renal and urinary tract dysfunction. Data collection about previous health problems or diseases provides the health care team with useful information for evaluating the patient's current urinary status. For example, the nurse needs to be aware that multiparous women delivering their children vaginally have a high risk for stress urinary incontinence. Elderly women and people with neurologic disorders, such as diabetic neuropathy, multiple sclerosis (MS), or Parkinson disease, often have incomplete emptying of the bladder and urinary stasis, which may result in UTI or increasing bladder pressure, leading to overflow incontinence, hydronephrosis, pyelonephritis, or renal insufficiency. People with diabetes who have consistent hypertension and those with primary hypertension are at risk for renal dysfunction as are those who suffer from autoimmune diseases, such as systemic lupus erythematosus (SLE). Older men are at risk for prostatic enlargement, which causes urethral obstruction and can result in UTIs and renal failure.

TABLE 26-4 Problems Associated with Changes in Voiding

Problem	Definition	Possible Etiology
Frequency	Frequent voiding; more than every 3 hours	Infection, obstruction of lower urinary tract leading to residual urine and overflow, anxiety, diuretics, benign prostatic hyperplasia, urethral stricture, diabetic neuropathy, interstitial cystitis (IC), neurologic conditions
Urgency	Strong desire to void	Infection, chronic prostatitis, urethritis, obstruction of lower urinary tract leading to residual urine and overflow, anxiety, diuretics, benign prostatic hyperplasia, urethral stricture, diabetic neuropathy, IC, neurologic conditions
Dysuria	Painful or difficult voiding	Lower urinary tract infection, inflammation of bladder or urethra, acute prostatitis, stones, foreign bodies, tumors in bladder, IC
Hesitancy	Delay, difficulty in initiating voiding	Benign prostatic hyperplasia, compression of urethra, outlet obstruction, neurogenic bladder, DSD (detrusor sphincter dyssynergia: the sphincter and bladder do not coordinate)
Nocturia	Wakening from sleep to void more than twice a night	Decreased renal concentrating ability, heart failure, diabetes mellitus, incomplete bladder emptying, excessive fluid intake at bedtime, nephrotic syndrome, cirrhosis with ascites
Incontinence	Involuntary loss of urine	External urinary sphincter injury, obstetric injury, lesions of bladder neck, detrusor dysfunction, infection, neurogenic bladder, medications, neurologic abnormalities
Enuresis	Involuntary voiding during sleep	Delay in functional maturation of central nervous system (bladder control usually achieved by 5 years of age), obstructive disease of lower urinary tract, genetic factors, failure to concentrate urine, urinary tract infection, psychological stress, neurologic conditions
Polyuria	Increased volume of urine voided (generally over 3 L/day)	Diabetes mellitus, diabetes insipidus, use of diuretics, excess fluid intake, lithium toxicity, some forms of kidney disease (hypercalcemic and hypokalemic nephropathy)
Oliguria	Urine output less than 400 mL/day	Acute or chronic kidney failure (see Chapter 27), inadequate fluid intake
Anuria	Urine output less than 50 mL/day	Acute or chronic kidney failure (see Chapter 27), complete obstruction
Hematuria	Red blood cells in the urine	Cancer of genitourinary tract, acute glomerulonephritis, kidney stones, renal tuberculosis, blood dyscrasia, trauma, extreme exercise, rheumatic fever, hemophilia, leukemia, sickle cell trait or disease
Proteinuria	Abnormal amounts of protein in the urine	Acute and chronic kidney disease, nephrotic syndrome, vigorous exercise, heat stroke, severe heart failure, diabetic nephropathy, multiple myeloma

Risk factors for specific disorders and kidney and lower urinary tract dysfunction are summarized in Table 26-5 and discussed in Chapters 27 and 28.

Family History

People with a family history of urinary tract problems are at increased risk for renal disorders, such as autosomal dominant polycystic kidney disease (which occurs in 1 of 400 to 1,000 people) (Torres & Bennett, 2015), heredity nephritis, or urolithiasis (Scheinman, 2015).

Social History

It is especially important to obtain a thorough medication history when assessing elderly patients, for whom the increased occurrence of chronic illness often leads to polypharmacy (concurrent use of multiple medications). Aging affects the way the body absorbs, metabolizes, and excretes drugs, placing the elderly patient at risk for adverse reactions. Aging also affects the genitourinary system, leading to compromise and dysfunction in the renal and urinary systems.

Other key information to obtain includes an assessment of the patient's psychosocial

status, level of anxiety, perceived threats to body image, available support systems, and sociocultural patterns. Obtaining this information during the initial and subsequent nursing assessments enables the nurse to uncover special needs, misunderstandings, lack of knowledge, and need for patient teaching.

TABLE 26-5 Risk Factors for Selected Renal or Urologic Disorders

Risk Factor	Possible Renal or Urologic Disorder
Childhood diseases: "strep throat" impetigo, nephrotic syndrome	Chronic kidney failure
Advanced age	Incomplete emptying of bladder, leading to urinary tract infection
Instrumentation of urinary tract, cystoscopy, catheterization	Urinary tract infection, incontinence
Immobilization	Kidney stone formation
Occupational, recreational, or environmental exposure to chemicals (plastics, pitch, tar, rubber)	Acute kidney failure
Diabetes mellitus	Chronic kidney failure, neurogenic bladder
Hypertension	Renal insufficiency, chronic kidney failure
Multiple sclerosis	Incontinence, neurogenic bladder
Parkinson disease	Incontinence, neurogenic bladder
Systemic lupus erythematosus	Nephritis, chronic kidney failure
Gout, hyperparathyroidism, Crohn disease, ileostomy	Kidney stone formation
Sickle cell anemia, multiple myeloma	Chronic kidney failure
Benign prostatic hyperplasia	Obstruction to urine flow, leading to frequency, oliguria, anuria
Radiation therapy to pelvis	Cystitis, fibrosis of ureter, or fistula in urinary tract, frequency, hematuria
Recent pelvic surgery	Inadvertent trauma to ureters or bladder
Pregnancy	Proteinuria, frequent voiding
Obstetric injury, tumors	Incontinence, fistulas
Spinal cord injury	Neurogenic bladder, urinary tract infection, incontinence

FIGURE 26-5 Technique for palpating the right kidney (*top*). Place one hand under the patient's back with the fingers under the lower rib. Place the palm of the other hand anterior to the kidney with fingers above the umbilicus. Push the hand on top forward as the patient inhales deeply. The left kidney (*bottom*) is palpated similarly by reaching over to the patient's left side and placing the right hand beneath the patient's lower left rib. (From Weber, J. W., & Kelley, J. (2013). *Health assessment in nursing* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Physical Examination

Several body systems can affect upper and lower urinary tract dysfunction, and that dysfunction can affect several end organs; therefore, a head-to-toe assessment is indicated. Areas of emphasis include the abdomen, suprapubic region, genitalia, lower back, and lower extremities.

Palpation of the Kidneys

A normal right kidney may be palpable especially in very thin patients with relaxed abdominal muscles; however, a left kidney is not usually palpated. Palpation of the kidneys may detect an enlargement that could prove to be very important (Bickley, 2013). The correct technique for palpation is illustrated in Figure 26-5. Renal dysfunction may produce tenderness over the costovertebral angle, which is the angle formed by the lower border of the 12th rib and the spine (Fig. 26-6).

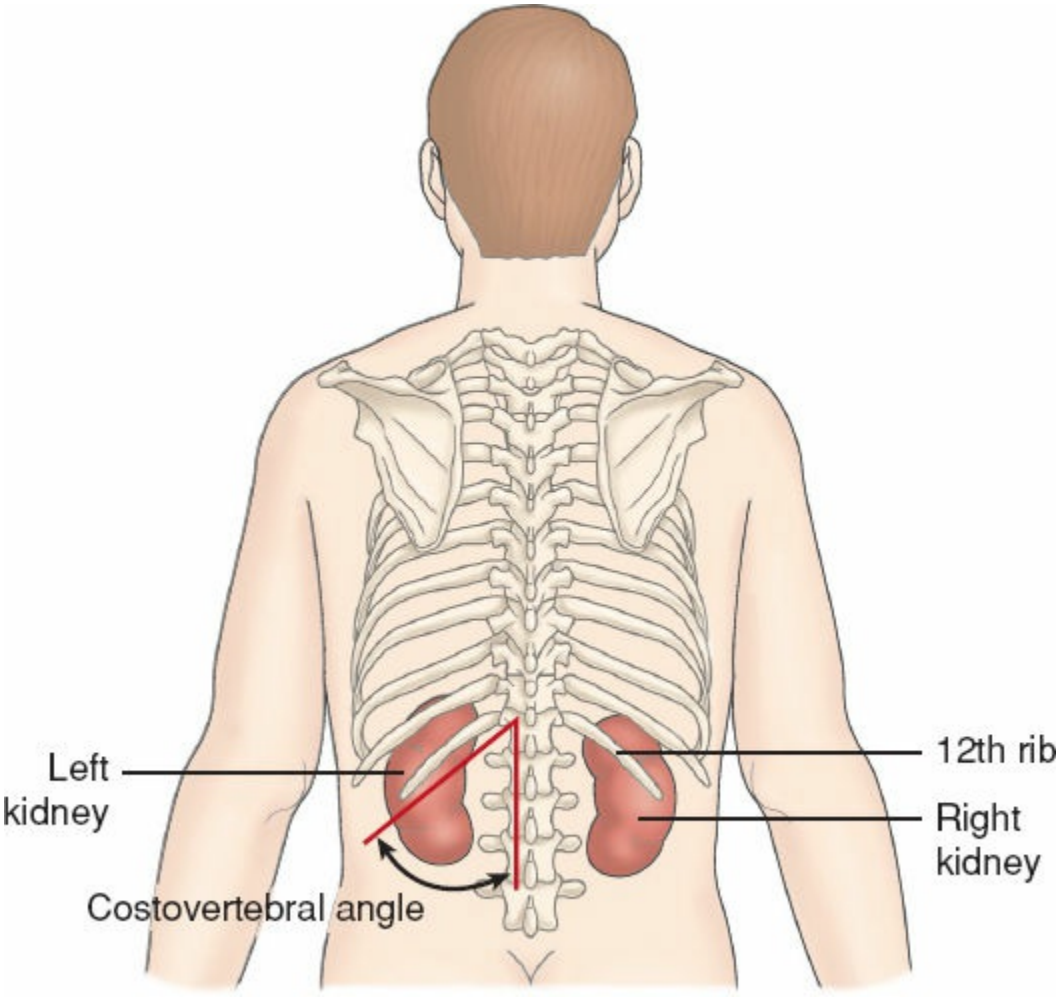

FIGURE 26-6 Location of the costovertebral angle.

Inspection, Palpation, Percussion, and Auscultation of the Abdomen

The abdomen (just slightly to the right and left of midline in both upper quadrants) is

auscultated to assess for bruits (low-pitched murmurs that indicate renal artery stenosis or an aortic aneurysm) (Fig. 26-7). The abdomen also is assessed for the presence of ascites (accumulation of fluid in the peritoneal cavity), which may occur with dysfunction of the kidney as well as the liver. On inspection, with the patient lying down, a distended abdomen is noted with bulging flanks (sides) due to the weight of fluid accumulation pressing against the flanks. On percussion, dullness is noted on the flank area (where the water is), whereas tympanic sounds are heard on the upper abdomen as the gas-filled intestines rise above the ascites fluid (refer to Chapter 21 for further details and techniques).

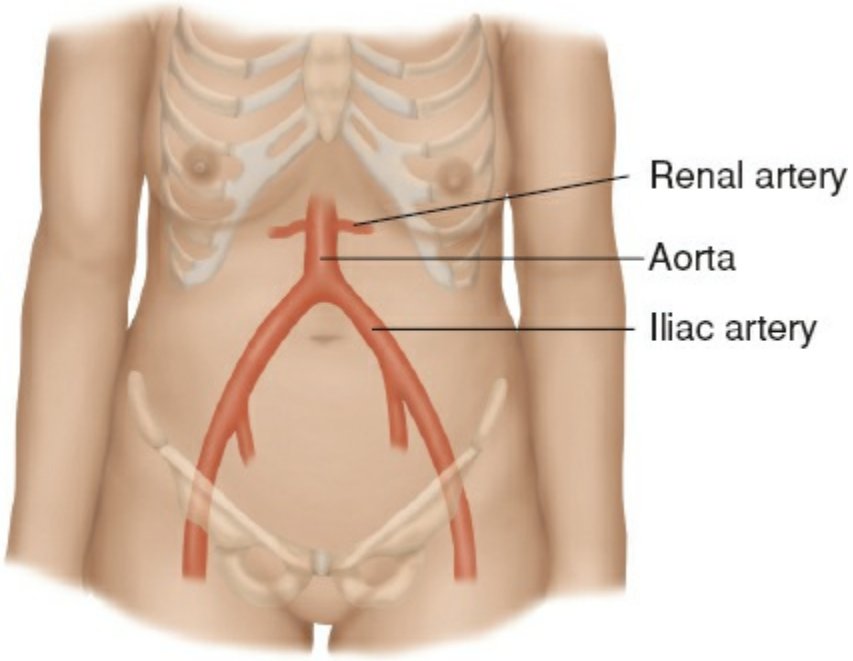

FIGURE 26-7 Arterial bruits with both systolic and diastolic components suggest partial occlusion of the aorta or large arteries. Partial occlusion of a renal artery may cause and explain hypertension. (From Bickley, L. S., & Szilagyi, P. (2003). *Bates' guide to physical examination and history taking* (8th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

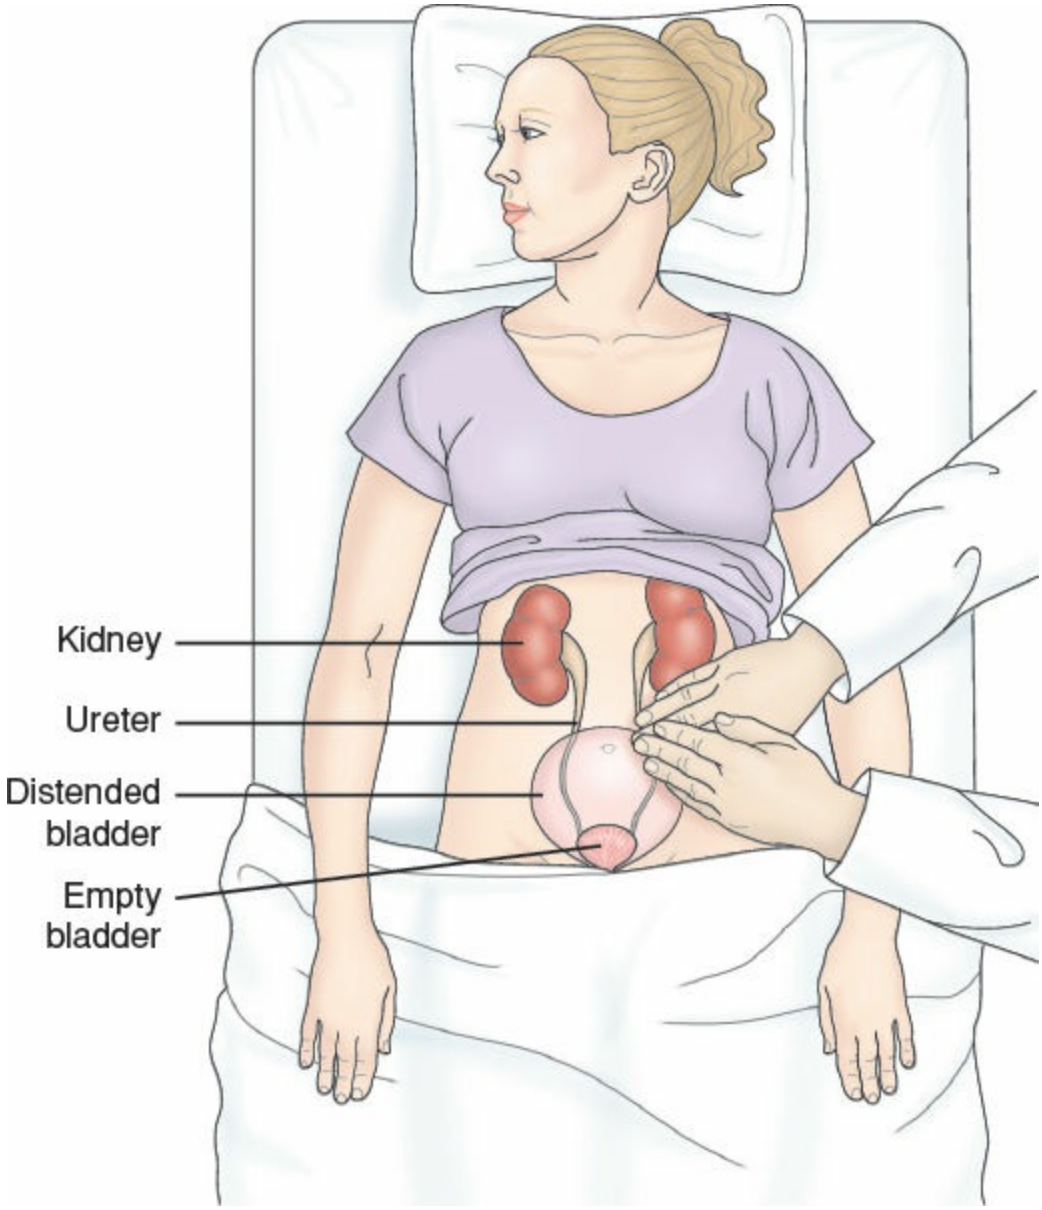

FIGURE 26-8 Palpation of the bladder.

Percussion of the Bladder

To check for residual urine, the bladder may be percussed after the patient voids. Percussion of the bladder begins at the midline just above the umbilicus and proceeds downward. The sound changes from tympanic to dull when percussing over the bladder. If dullness is noted, the bladder volume is typically 400 to 500 mL (Bickley, 2013). The bladder, which can be palpated only if it is moderately distended, feels like a smooth, firm, round mass rising out of the abdomen, usually at midline (Fig. 26-8). Dullness to percussion of the bladder after voiding indicates incomplete bladder emptying. A bladder scan can be performed to assess volume of urine retained after voiding.

Unfolding Patient Stories: Lloyd Bennett • Part 2

Recall from Chapter 19 Lloyd Bennett, who presented to the emergency department with a hip fracture. What effect can significant blood loss from surgery to repair the fracture have on renal function? What clinical findings would indicate to the nurse that kidney function is impaired? What clinical assessment findings would alert the nurse of potential trauma to the urinary tract resulting from the hip fracture? What diagnostic tests may be used to identify a urinary tract complication that the nurse would consider for preparatory patient education?

Care for Lloyd and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

Palpation of the Prostate and Inguinal Area

In older men, BPH or prostatitis can cause difficulty with urination. The prostate gland is palpated by digital rectal examination (DRE) as part of the yearly physical examination in men 50 years of age and older (see Chapters 32 and 34). A blood specimen to test the prostate-specific antigen (PSA) level is recommended for younger men (40 to 45 years of age) if they are at high risk for prostate cancer; namely, African American men and men who have a first-degree relative (father, brother, or son) diagnosed with prostate cancer at an early age (under 65 years of age) (American Cancer Society, 2015); then the results of the DRE and PSA are correlated. If a PSA is to be drawn, the sample should be obtained before the DRE because manipulation of the prostate can cause the PSA level to increase temporarily. Refer to Chapter 34 for further details on prostate cancer. The inguinal area is examined for enlarged nodes or an inguinal or femoral hernia.

Inspection and Palpation of the Female Genitalia

In women, the vulva, urethral meatus, and vagina are examined; refer to Chapter 33 for additional details regarding the vaginal examination. The urethra is palpated for diverticula, and the vagina is assessed for adequate estrogen effect and any evidence of herniation. A *urethrocele* is the bulging of the anterior vaginal wall into the urethra. When the pelvic floor muscles, fascia, or supporting ligaments fail, pelvic organs may fall through the vagina. A *cystocele* is the herniation of the bladder wall into the anterior vaginal vault. Urinary stasis with a cystocele is a risk factor for the development of UTIs. A *rectocele* is herniation of the terminal rectum into the posterior vagina (LeBlond, Brown, Suneja, & Szot, 2015).

Assessment for Edema and Body Weight

The patient is assessed for edema and changes in body weight. Edema may be observed, particularly in the face and dependent parts of the body, such as the ankles and sacral areas, and suggests fluid retention. An increase in body weight commonly accompanies edema. A weight gain of 1 kg equals approximately 1,000 mL of fluid (1 lb ≈ 500 mL).

Assessment of Lower Extremities

The deep tendon reflexes of the knee are assessed for quality and symmetry. This is an important part of testing for neurologic causes of bladder dysfunction because the sacral area, which innervates the lower extremities, is the same peripheral nerve area responsible for urinary continence. The gait pattern of the person with bladder dysfunction is also noted, as well as the patient's ability to walk heel to toe. These tests evaluate possible supraspinal causes for urinary incontinence.

Diagnostic Evaluation

A comprehensive health history and physical examination are used to determine the appropriate laboratory and diagnostic tests. Most patients undergoing urologic testing or imaging studies are apprehensive, even those who have had these tests in the past. Patients frequently feel discomfort and embarrassment about such a private and personal function as voiding. Voiding in the presence of others frequently can cause guarding, a natural reflex that inhibits voiding due to situational anxiety. Because the outcomes of these studies determine the plan of care, the nurse must help the patient relax by providing as much privacy and explanation about the procedure as possible. The following sections review some of the tests that might be used.

Urinalysis and Urine Culture

The urinalysis provides important clinical information about kidney function and helps diagnose other diseases, such as diabetes. The urine culture determines whether bacteria are present in the urine, as well as their strains and concentration. Urine culture and sensitivity (C&S) also identify the antimicrobial therapy that is best suited for the particular strains identified, taking into consideration the antibiotics that have the best rate of resolution in that particular geographic region. Appropriate evaluation of any abnormality can assist in detecting serious underlying diseases. Refer to Table 26-6 for the details regarding urinalysis components and potential significance.

Renal Function Tests

Renal function tests are used to evaluate the severity of kidney disease and to assess the status of the patient's kidney function. These tests also provide information about the effectiveness of the kidney in carrying out its excretory function. Renal function test results may be within normal limits until the GFR is reduced to less than 50% of normal. Renal function can be assessed most accurately if several tests are performed and their results are analyzed together. Common tests of renal function include renal concentration tests, creatinine clearance, and serum creatinine and blood urea nitrogen (BUN) levels. Table 26-7 describes the purpose and gives the normal range for each test. Other tests for evaluating kidney function that may be helpful include serum electrolyte levels (see Chapter 4). A plan of nursing care for a patient undergoing diagnostic testing of the renal/urologic system is available online at http://thepoint.lww.com/Honan2e.

TABLE 26-6 Select Urinalysis Components

Component	Discussion
Color	Colorless to pale yellow (possible causes: Dilute urine due to diuretics, alcohol consumption, diabetes insipidus, glycosuria, excess fluid intake, renal disease) Yellow to milky white (possible causes: Pyuria, infection, vaginal cream) Bright yellow (possible causes: Multiple vitamin preparations) Pink to red (possible causes: Hemoglobin breakdown, red blood cells, gross blood, menses, bladder or prostate surgery, beets, blackberries, medications [phenytoin, rifampin, phenothiazine, cascara, senna products]) Blue, blue green (possible causes: Dyes, methylene blue, *Pseudomonas* species organisms, medications [amitriptyline, triamterene, phenyl salicylate]) Orange to amber (possible causes: Concentrated urine due to dehydration, fever, bile, excess bilirubin or carotene, medications [phenazopyridium HCl, nitrofurantoin, sulfasalazine, docusate calcium, thiamine]) Brown to black (possible causes: Old red blood cells, urobilinogen, bilirubin, melanin, porphyrin, extremely concentrated urine due to dehydration, medications [cascara, metronidazole, iron preparations, quinine, senna products, methyldopa, nitrofurantoin]; myoglobinuria)
Specific gravity	Evaluates ability of kidneys to concentrate solutes in urine and is altered by the presence of blood, protein, and casts in the urine. Disorders or conditions that cause *decreased* urine-specific gravity (i.e., dilute urine) include diabetes insipidus, glomerulonephritis, and severe kidney damage, which may cause a fixed specific gravity of 1.010. Glucose, protein, or dyes excreted in the urine *increase* the specific gravity (concentrated urine); therefore, etiologies include diabetes mellitus, patients who recently received high-density radiopaque dyes, and fluid deficit.
Osmolality	Concentrating ability is lost early in kidney disease; these test findings may disclose early defects in kidney function.
Red blood cells (hematuria)	Can develop from an abnormality anywhere along the genitourinary tract and is more common in women than in men. Common causes include acute infection (cystitis, urethritis, or prostatitis), renal calculi, and neoplasm. Other causes include systemic disorders, such as bleeding disorders; malignant lesions; and medications, such as warfarin and heparin.
White blood cells	Should be very few; increased numbers indicate infection or inflammation.
Protein	Occasional loss of up to 150 mg/day of protein in the urine primarily is considered normal and usually does not require further evaluation. Urine concentration, pH, hematuria, and radiocontrast materials all affect the results. Microalbuminuria (excretion of 20–200 mg/dL of protein in the urine) is an early sign of diabetic nephropathy. Common benign causes of transient proteinuria are fever, strenuous exercise, and prolonged standing. Causes of persistent proteinuria include glomerular diseases, malignancies, collagen diseases, diabetes mellitus, pre-eclampsia, UTI, hyperthyroidism, hypertension, heart failure, and use of a wide variety of medications (Fischbach & Dunning, 2014).
Glucose	Should be absent; its presence is suspicious for diabetes.

TABLE 26-7 Additional Tests of Renal Function

Test	Description	Normal Range
Creatinine clearance	Detects and evaluates progression of kidney disease. Test measures volume of blood cleared of endogenous creatinine in 1 minute, which provides an approximation of the glomerular filtration rate. Sensitive indicator of kidney disease used to follow progression of disease.	Measured in mL/min/1.73 m^2 Age — Male — Female Under 30 years — 88–146 — 81–134 30–40 years — 82–140 — 75–128 40–50 years — 75–133 — 69–122 50–60 years — 68–126 — 64–116 60–70 years — 61–120 — 58–110 70–80 years — 55–113 — 52–105
Creatinine level	Measures effectiveness of kidney function. In normal function, the level of creatinine remains fairly constant in the body.	0.6–1.2 mg/dL (50–110 mmol/L)
Urea nitrogen (blood urea nitrogen [BUN])	Serves as index of kidney function. Urea is a nitrogenous end product of protein metabolism. Test values are affected by protein intake, tissue breakdown, and fluid volume changes.	7–18 mg/dL Patients over 60 years: 8–20 mg/dL
BUN to creatinine ratio	Evaluates hydration status. An elevated ratio is seen in hypovolemia (may rise to 20:1); a normal ratio with an elevated BUN and an elevated creatinine is seen with intrinsic kidney disease.	About 10:1

Nursing Alert

The nurse understands that a normal BUN/creatinine (Cr) ratio is approximately 10:1. As

kidney function declines, both the BUN and the Cr rise, thus although elevated the ratio remains within normal limits. If a BUN is elevated but the creatinine is normal (BUN/Cr greater than 20:1), the nurse must assess for causes excluding renal dysfunction. Reasons may include GI bleeding such as gastric ulcers, duodenal ulcers, and gastric cancer (digestion of RBCs elevates the protein level which is transported to the liver and metabolized to BUN), or dehydration (less water available in the intravascular space) where the BUN may increase in a higher proportion than the creatinine, thus indicators of intravascular depletion include an elevated hematocrit value, and a BUN/Cr ratio of greater than 20:1. In situations where the BUN/Cr ratio is less than 10:1, the nurse considers conditions where there is decreased urea synthesis such as severe liver disease or starvation, syndrome of inappropriate ADH (increased water in the intravascular space), and pregnancy (since the GFR increases 50% in pregnancy, there is a resultant decrease in serum creatinine).

Imaging Modalities

Several imaging modalities play a vital role in the evaluation of renal and urologic disease.

X-Ray: Kidneys, Ureters, Bladder (KUB)

This x-ray delineates the size, shape, and position of the kidneys and reveals abnormalities, such as calculi in the kidneys or urinary tract, hydronephrosis, cysts, tumors, or kidney displacement by abnormalities in surrounding tissues.

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) scans and magnetic resonance imaging (MRI) are noninvasive techniques that provide excellent cross-sectional views of the kidney and urinary tract. They are used to evaluate genitourinary masses, nephrolithiasis, chronic kidney infections, renal or urinary tract trauma, metastatic disease, and soft tissue abnormalities. Occasionally, an oral or IV radiopaque contrast agent is used in CT scanning to enhance visualization, although the use of a CT scan should take into account the patient's previous exposures to radiation via imaging studies. In addition, the risks associated with contrast agents should be considered. Contrast-induced nephropathy is associated with a pre-existing renal insufficiency, history of diabetes, and reduced intravascular volume (Reekers, 2015). Preprocedure hydration, along with recognition of the lowest dose of contrast as possible for the study, is recommended.

Intravenous Urography

This test shows the kidneys, ureters, and bladder via x-ray imaging as a radiopaque contrast agent that is administered intravenously moves through the upper and then the lower urinary system. It may be used as the initial assessment of many suspected urologic problems, especially lesions in the kidneys and ureters and provides an approximate estimate of kidney function.

Retrograde Pyelography

If an IV urography provides inadequate visualization of the collecting systems, a retrograde

pyelography may be performed. It involves advancing catheters through the ureters into the renal pelvis by means of cystoscopy, followed by injection of a contrast agent.

Cystography

In cystography, a catheter is inserted into the bladder, and a contrast agent is instilled to outline the bladder wall. This study aids in evaluating vesicoureteral reflux (backflow of urine from the bladder into one or both ureters) and in assessing for bladder injury.

Voiding Cystourethrography

In a voiding cystourethrography, a urethral catheter is inserted, and a contrast agent is instilled into the bladder. When the bladder is full and the patient feels the urge to void, the catheter is removed, and the patient voids. This study uses fluoroscopy to visualize the lower urinary tract and assess urine storage in the bladder. It is used as a diagnostic tool to identify vesicoureteral reflux. Retrograde urethrography, in which a contrast agent is injected retrograde into the urethra, is always performed before urethral catheterization if urethral trauma is suspected.

Nursing Alert

The presence of urethral injury should be ruled out prior to Foley catheter placement in patients with blood at the urethra and suspicion of injury to the lower urinary tract. Catheter placement may potentially convert a partial urethral tear to a complete urethral disruption (Tibbles, 2015, p. 232).

Nuclear Scans

A nuclear scan requires injection of a radioisotope into the circulatory system; then the isotope is monitored as it moves through the blood vessels of the kidneys. The test provides information about kidney perfusion and function. It is used to evaluate acute and chronic kidney failure, renal masses, and blood flow before and after kidney transplantation.

Renal Angiography

In renal angiography, a catheter is threaded up through the femoral and iliac arteries into the aorta or renal artery. A contrast agent is injected to opacify the renal arterial supply. Angiography is used to evaluate renal blood flow, to differentiate renal cysts from tumors, to evaluate hypertension, and preoperatively, for renal transplantation.

Bladder Ultrasonography

Ultrasonography is a noninvasive procedure that uses sound waves passed into the body through a transducer to detect abnormalities of internal tissues and organs. A bladder ultrasonography is a noninvasive method of measuring urine volume in the bladder; it automatically calculates and displays urine volume. The test requires a full bladder; therefore, fluid intake should be encouraged before the procedure. This test also can be used to determine if a patient is emptying the bladder after urination.

Urologic Endoscopic Procedures

Endourology, or urologic endoscopic procedures, can be performed in one of two ways: using a cystoscope (Fig. 26-9) inserted into the urethra, or percutaneously, through a small incision (Table 26-8).

Bladder Scan

A portable ultrasound device provides a 3D image of the bladder and measures bladder volume noninvasively, providing immediate details on the volume of urine retained within the bladder.

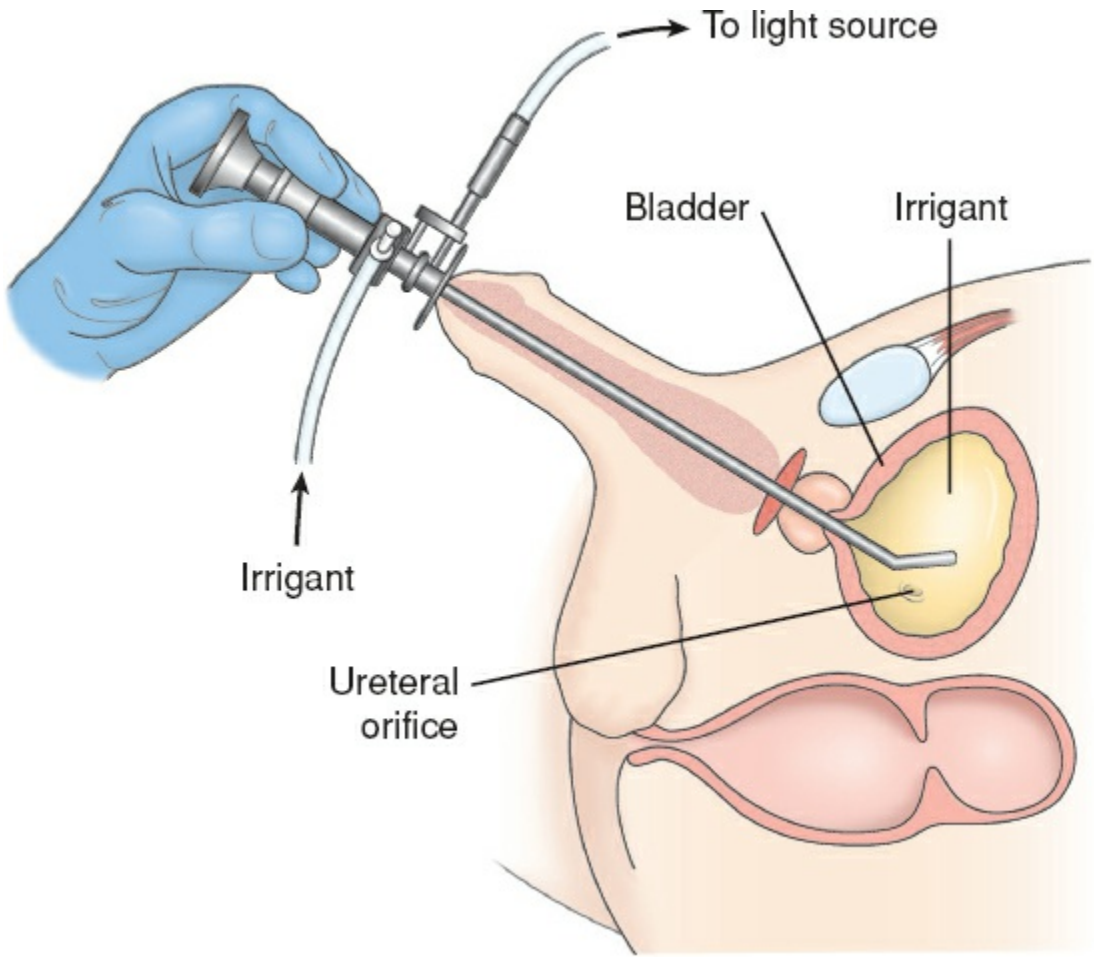

FIGURE 26-9 Cystoscopic examination. A rigid or semirigid cystoscope is introduced into the bladder. The upper cord is an electric line for the light at the distal end of the cystoscope. The lower tubing leads from a reservoir of sterile irrigant that is used to inflate the bladder.

TABLE 26-8 Common Urologic Procedures

Procedure	Description	Purpose
Cystoscopy	Cystoscope is inserted through the urethra into the bladder.	Used to visualize the urethra and bladder directly, as well as the urethral orifices and prostatic urethra. Calculi may be removed from the urethra, bladder, and ureter.
Renal and ureteral brush biopsy	Ureteral catheter is introduced via cystoscope, followed by a biopsy brush that is passed through the catheter.	Suspected lesion is brushed back and forth to obtain cells and surface tissue fragments for histologic analysis.
Kidney biopsy	Small section of renal cortex is obtained either percutaneously (needle biopsy) or by open biopsy through small flank incision.	Helps diagnose and evaluate the extent of kidney disease. Indications for biopsy include unexplained acute kidney failure, persistent proteinuria/hematuria, transplant rejection, glomerulopathies.

CHAPTER REVIEW

Critical Thinking Exercises

1. Discuss the changes to kidney function in an otherwise healthy 28-year-old female patient who becomes dehydrated during a marathon.
2. Discuss some of the changes that are likely to be seen when examining the urine of a diabetic patient with poor control of his or her blood sugar. How do you explain each finding?

NCLEX-Style Review Questions

1. A patient who has been diagnosed with a small kidney stone has been told to increase fluid intake. The patient wants to know why this is necessary. What is the nurse's best response?
   a. "This will decrease your pain."
   b. "This will increase urine production and help move the stone from your system."
   c. "This will help pain medications work more quickly."
   d. "This will help prevent any nausea you are having."
2. A male patient is concerned about changes to his urinary stream. Which of the following are associated with lower urinary tract symptoms? *Select all that apply.*
   a. Urgency
   b. Incontinence
   c. Frequency
   d. Dribbling
   e. Costovertebral angle (CVA) tenderness
3. The nurse recognized that a patient with chronic kidney disease will need which hormone replaced?
   a. Anterior pituitary
   b. Parathyroid
   c. Erythropoietin
   d. Corticotropin-releasing

4. The nurse knows that a frequent cause of white blood cells (WBCs) in the patient's urine is which condition?
   a. Prostate enlargement
   b. Hypertension
   c. Bladder cancer
   d. Genitourinary infection

5. A 42-year-old male patient complains of nausea, vomiting, and right flank pain. What is the most likely cause of these symptoms?
   a. Interstitial cystitis
   b. Renal colic
   c. Ureterocele
   d. Nephritic syndrome

CHAPTER 27

Nursing Management: Patients with Renal Disorders

Andrea Rothman Mann

Learning Objectives

After reading this chapter, you will be able to:

1. Compare and contrast the pathophysiology, assessment, nursing management, and medical management of the glomerular diseases.
2. Identify the causes of acute and chronic renal failure.
3. Summarize the nursing management of the patient with renal failure.
4. Describe renal replacement therapies.
5. Provide patient education for the patient undergoing kidney transplantation.
6. Describe care for the patient sustaining renal trauma.
7. Evaluate outcomes of care for the patient with renal disorders.

The renal system is an important regulator of the body's internal environment and is essential for the maintenance of life. The kidneys regulate fluid volume and electrolyte balance; they also play a role in acid–base balance, excrete waste products, regulate blood pressure (BP) and blood osmolarity, and contribute to red blood cell (RBC) production and vitamin D metabolism. Kidney dysfunction may be acute or chronic and can affect all body systems. Renal disease is often asymptomatic or presents with nonspecific complaints. Its presence is frequently first noted on abnormal routine laboratory data (Godara, Hirbe, Nassif, Otepka, & Rosenstock, 2014). Various factors contribute to kidney dysfunction; Box 27-1 addresses gerontologic considerations. This chapter addresses glomerular dysfunction, acute kidney injury (AKI), chronic kidney failure, and treatment options, as well as kidney trauma and transplant.

GLOMERULAR DISEASES

Acute Glomerulonephritis

Glomerulonephritis is an inflammation of the glomerular capillaries. Acute glomerulonephritis is more common in children older than 2 years of age, but it can occur at any age.

Pathophysiology

Acute glomerulonephritis (GN) comprises a specific set of renal diseases in which an immunologic mechanism triggers inflammation and proliferation of glomerular tissue that can result in damage to the basement membrane, mesangium (thin membrane supporting the capillary loops in renal glomeruli), or capillary endothelium. Acute poststreptococcal glomerulonephritis (PSGN) is the archetype of acute GN (Parmar & Batuman, 2015; Ballestas & Caico, 2014). Examples of primary diseases are postinfectious glomerulonephritis, rapidly progressive glomerulonephritis, membrane proliferative glomerulonephritis, and membranous glomerulonephritis. HIV-associated nephropathy also may occur (Godara et al., 2014). Acute nephritic syndrome is the clinical manifestation of glomerular inflammation. In acute glomerulonephritis, the kidneys become large, edematous, and congested. All renal tissues, including the glomeruli, tubules, and blood vessels, are affected to varying degrees. Box 27-2 depicts the pathophysiology of glomerulonephritis.
