Contributors

Deborah S. Adelman, PhD, RN, NE-BC
Professor
Graduate Nursing Programs
School of Nursing
Kaplan University
Chicago, Illinois
Chapter 56, Nursing Management: Emergencies and Disasters

Laura Kierol Andrews, PhD, APRN, ACNP-BC
Associate Professor
Yale University School of Nursing
New Haven, Connecticut
And
Senior Acute Care Nurse Practitioner
Critical Care Medicine
Hospital of Central Connecticut at New Britain General
New Britain, Connecticut
Chapter 10, Nursing Management: Patients with Chest and Lower Respiratory Tract Disorders

Donna M. Avanecean, RN, FNP-BC, CNRN, DNPc
Nurse Practitioner
Yale New Haven Hospital
New Haven, Connecticut
Chapter 43, Nursing Assessment: Neurologic Function

Mei Bai, RN, PhD
Post-Doctoral Associate
Yale University School of Medicine
New Haven, Connecticut
Chapter 3, Chronic Illness and End-of-Life Care

Lisa M. Barbarotta, MSN, AOCNS, APRN-BC
Program Manager
Oncology Nursing Education & Practice
Smilow Cancer Hospital at Yale-New Haven
New Haven, Connecticut
Chapter 6, Cancer Care
Chapter 19, Nursing Assessment: Hematologic Function
Chapter 20, Nursing Management: Patient with Hematologic Disorders

Mary E. Bartlett, DNP, APRN, FNP-BC, AAHIVS
Family Nurse Practitioner and HIV Specialist
Assistant Professor
Linfield Good Samaritan School of Nursing
Portland, Oregon
Chapter 36, Nursing Assessment: Immune Function
Chapter 37, Nursing Management: Patients with Immunodeficiency, HIV Infection, and AIDS

Cynthia Bautista, PhD, RN, CNRN, SCRN, CCNS, ACNS-BC, FNCS
Associate Professor
Marion Peckham Egan School of Nursing and Health Studies

Fairfield University
Fairfield, Connecticut
Chapter 46, Nursing Management: Patients with Neurologic Disorders

Dawn K. Beland, RN, MSN, CCRN-K, ACNS-BC, CNRN, SCRN
Stroke Center Coordinator
Hartford Hospital
Hartford, Connecticut
Chapter 43, Nursing Assessment: Neurologic Function

Lynn S. Bickley, MD, FACP
Clinical Professor of Internal Medicine School of Medicine
University of New Mexico
Albuquerque, New Mexico
Chapter 48, Nursing Assessment: Sensorineural Function

Carolynn Spera Bruno, PhD, APRN, CNS, FNP-C
Clinical Assistant Professor of Nursing
New York University
Rory Meyers College of Nursing
New York, New York
Chapter 49, Nursing Management: Patients with Eye and Vision Disorders
Chapter 50, Nursing Management: Patients with Hearing and Balance Disorders

Nicole C. Colline, RN, MSN, APRN-BC
Clinical Faculty
Yale University School of Nursing
New Haven, Connecticut
And
Nurse Practitioner & Clinical Manager
MedNow Family Walk-In & Industrial Medical Center
Stratford, Connecticut
Chapter 38, Nursing Management: Patients with Allergic Disorders

Preface

I have researched the experience of becoming a nurse and have discovered what you already know—that learning nursing is more difficult than you anticipated. I have also taught educators of nursing and can tell you that they too discover that teaching basic nursing is more difficult than anticipated. Thus, the idea for this book was to meet the needs of both students and teachers. I began this journey with a thoughtful analysis of what core content, values, and skills should form the foundation of medical-surgical nursing, and that is how this book was built. No, this book will not provide all answers to questions related to internal medical and surgical care; rather it focuses on what is essential. That said, it is not a cursory viewpoint but one that will give depth and breadth to essential content. You, the reader, will be the judge of our success.

Additionally, I wanted expert clinicians to write this book. Nurses who continue to live in the real world of clinical practice and have strong opinions about essential nursing knowing have informed this book with their wisdom.

I also know that often seeing the weight and thickness of medical-surgical texts scares you to the point that you never crack the binding. Thus, we have aimed to distill the essential and place the rest online. As an example, although we rigorously researched current references, we have placed them online for you, if needed, rather than add to the pages in this text. I am hoping for cracked binding, dog-eared pages, multicolored highlights, and notes in the margins of this book. They will stand as evidence of our success.

FEATURES

We have designed some special features to help engage you, the reader, and assist you in your understanding of the content and the nurse's role in caring for patients.

Guidelines for Nursing Care provide steps and rationales for important procedures.

Focused Assessment boxes summarize important assessment criteria and significant findings related to a particular disorder.

Risk Factors provide a bulleted list of risk factors for a particular disorder, drawing attention to factors that can impair health.

Patient Education summarizes patient teaching, home care, and discharge planning.

Health Promotion reviews important points the nurse should discuss with the patient to prevent common health problems from developing.

Gerontologic Considerations highlight information that pertains specifically to the care of older adults who comprise the fastest-growing segment of our population.

Laboratory and Diagnostic Tests tables list common lab tests for particular disorders along with normal values, critical values, and nursing implications.

Nursing Research: Bridging the Gap to Evidence-Based Practice demonstrates the nursing implications of important research.

Focus on Pathophysiology highlights and describes important pathophysiologic processes.

Nutrition Alert highlights nutritional considerations for particular disorders.

NURSING ALERTS offer brief tips or highlight red-flag warnings for clinical practice.

DRUG ALERTS highlight key nursing considerations and drug safety information.

Pathophysiology Alerts highlight key pathophysiology concerns.

Unfolding Patient Stories feature patients from Wolters Kluwer's *vSim for Nursing*.

PEDAGOGICAL FEATURES

The following features will help you focus your attention on important content and relate it to the challenges of nursing and patient care.

Unit Case Study Each unit opens with a short case study and related questions to help prepare you for the content to be presented and to engage your critical thinking skills. Answers to the unit case studies appear at the end of the book so that you can instantly check your knowledge of the subject.

Learning Objectives appear at the beginning of each chapter to help guide and focus you on the important content in the chapter.

Critical Thinking Exercises appear at the end of each chapter and use situation-based questions to aid you in applying the knowledge you have gained.

NCLEX-Style Review Questions test your comprehension and application of the content. Answers to these review questions are available on the Instructor's Resource DVD-ROM and the Instructor's Resources on the Point.

References and Selected Readings can be found on the Point in addition to a large array of resources that will aid your comprehension and expand your knowledge of the subject matter.

Glossary appears at the end of the book to assist you in understanding key terminology.

COMPREHENSIVE LEARNING PACKAGE

A carefully designed ancillary package is available to students who purchase the book and to faculty who adopt the book to further facilitate teaching and learning. A wide variety of multimedia tools are readily available and are just a click away on the Web site that accompanies the text. Visit http://thepoint.lww.com/Honan2e.

Resources for Students

Find the following resources on

- E-book
- NCLEX-Style Student Review Questions
- Animations
- Video clips
- Audio glossary
- Journal articles
- Learning objectives
- Breath sounds
- Internet resources
- References from the book
- Plan of Nursing Care for selected chapters
- And more!

Resources for Instructors

Instructor resources are available online at http://thepoint.lww.com/Honan2e.

In addition to all of the student assets, instructor resources include the following items:

- Test Generator Questions
- PowerPoint Presentations
- Image Bank
- Pre-lecture Quizzes
- Guided Lecture Notes
- Topics for Discussion and Suggested Answers
- Assignments and Suggested Answers
- Case Studies and Suggested Answers
- Syllabus
- E-book
- Answers to NCLEX-Style Chapter Review Questions from the book
- QSEN Competency KSAs Mapped to *Focus on Adult Health: Medical-Surgical Nursing*

Linda Honan, RN, PhD, CNS-BC, ANEF, FAAN

Acknowledgments

I must acknowledge and thank the following people who helped clear cobwebs in my understanding. They include Walter Zawalich, my GEPN soul mate who always came through with answers to my pathophysiology questions; Lisa B. Meland, my pharmacology guru who answered questions from standard dosages to interactions, and everything in between; and, finally, my anatomy sages William Stewart and Shanta Kapadia for all their support. To all the nursing staff on 6-4 at Yale New Haven Hospital and all the GEPNs who have honed my skills as a nurse and educator for over a quarter of a century. I am in your debt. To Helen Kogut and Stephanie Kelly who edited this edition with care. Finally, my thanks to all the clinician colleagues who wrote chapters about their day-to-day practice so that this book is grounded in the real world of clinical.

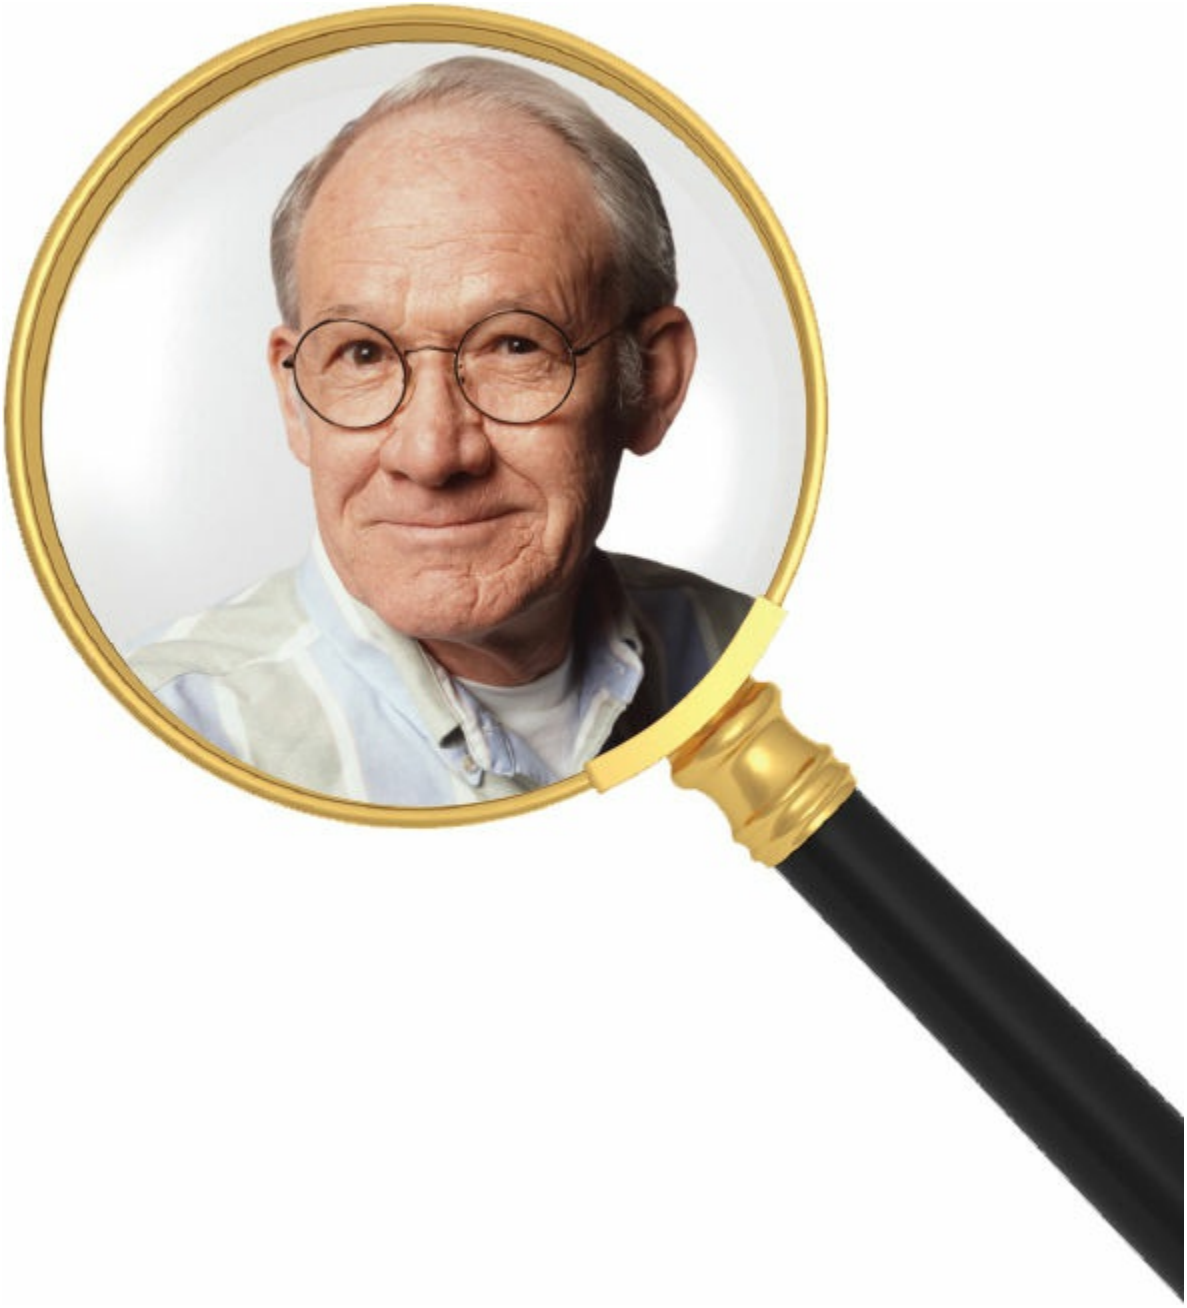
Contents

Brief Contents

UNIT 15 Other Acute Problems

Basics of Adult Health Nursing!

A 70-year-old patient diagnosed with hypertension is being seen in the health clinic. When gathering information on the patient, the nurse notes a definite problem with medication compliance. The patient states, "I just forget to take the medication. It's no big deal!" His current BP is 170/90. His history notes that he has had previous TIAs and a stroke. He also has visual and hearing deficits.



- What areas of health education would be important to emphasize for this patient?
- Discuss variables that could effect this patient's medication compliance.
- What teaching strategies could be incorporated into the plan of care for this 70-year-old patient?

CHAPTER 1

The Nurse's Role in Adult Health Nursing

Kelly S. Grimshaw

Learning Objectives

After reading this chapter, you will be able to:

1. Define nursing.
2. Understand nursing's role in the health care industry and society.
3. Describe the practitioner, leadership, and research roles of nursing.
4. Describe nursing care delivery models.
5. Describe factors causing significant changes in the health care delivery system and their impact on the health care field and the nursing profession.

THE NURSING PROFESSION AND THE HEALTH CARE INDUSTRY

To obtain a foundation for examining the role of the nurse and delivery of nursing care, it is necessary to understand the nursing profession, health care consumers, and the health care delivery system, including their interactions and the forces acting upon them.

Nursing Defined

Since Florence Nightingale wrote (1859) that the goal of nursing was "to put the patient in the best condition for nature to act upon him," nursing leaders have described nursing as both an art and a science. In the 20th century, Virginia Henderson (1966) defined nursing as the professional that "[assists] the individual, sick or well, in the performance of those activities contributing to health or its recovery (or to peaceful death) that he would perform unaided if he had the necessary strength, will, or knowledge. This is done in such a way as to help him gain independence as rapidly as possible." The American Nurses Association (ANA), which is the professional organization representing the interests of the nation's 3.4 million registered nurses (RNs) highlighted the evolving nature of this definition by delineating essential features of professional nursing in its Social Policy Statement (ANA, 2010):

- Provision of a caring relationship that facilitates health and healing
- Attention to the range of human experiences and responses to health and illness within the physical and social environments
- Integration of assessment data with knowledge gained from an appreciation of the patient or the group
- Application of scientific knowledge to the processes of diagnosis and treatment through the use of judgment and critical thinking
- Advancement of professional nursing knowledge through scholarly inquiry
- Influence on social and public policy to promote social justice
- Assurance of safe, quality, and evidence-based practice.

The Health Care Industry

Since Philadelphia Hospital first opened its doors in 1753 with the help of private donations, health care has grown into an industry consuming 17.9% of our gross domestic product spending (World Health Organization [WHO], 2015). Today there are almost 5,700 hospitals registered in the United States with the American Hospital Association (AHA), totaling more than 35.4 million annual admissions and an annual expenditure of $859.4 billion (Fast Facts on US Hospitals, 2015). The health care industry is now comprised of public and private organizations and individuals who provide preventative, diagnostic, and therapeutic services (Health Care Industry, 2015). It also includes research and development groups, professional associations and societies, medical equipment and pharmaceutical manufacturers, regulatory bodies, and health insurance companies. These groups encompass all goods and services designed to maintain and promote health for individuals and populations.

Nursing's Role in the Health Care Industry

There are roughly 150 million adults in the US workforce, of whom approximately 3.4 million are RNs (National Center for Health Workforce Analysis, 2013; ANA, 2015). Nurses comprise the largest professional group in the health care industry. Each individual nurse is placed in the unique position of standing with the patient and the patient's family at the center of the health care industry. Clinical nurses are at the bedside to act as a care provider and liaison to other health care workers in an effort to provide and coordinate this care (Fig. 1-1).

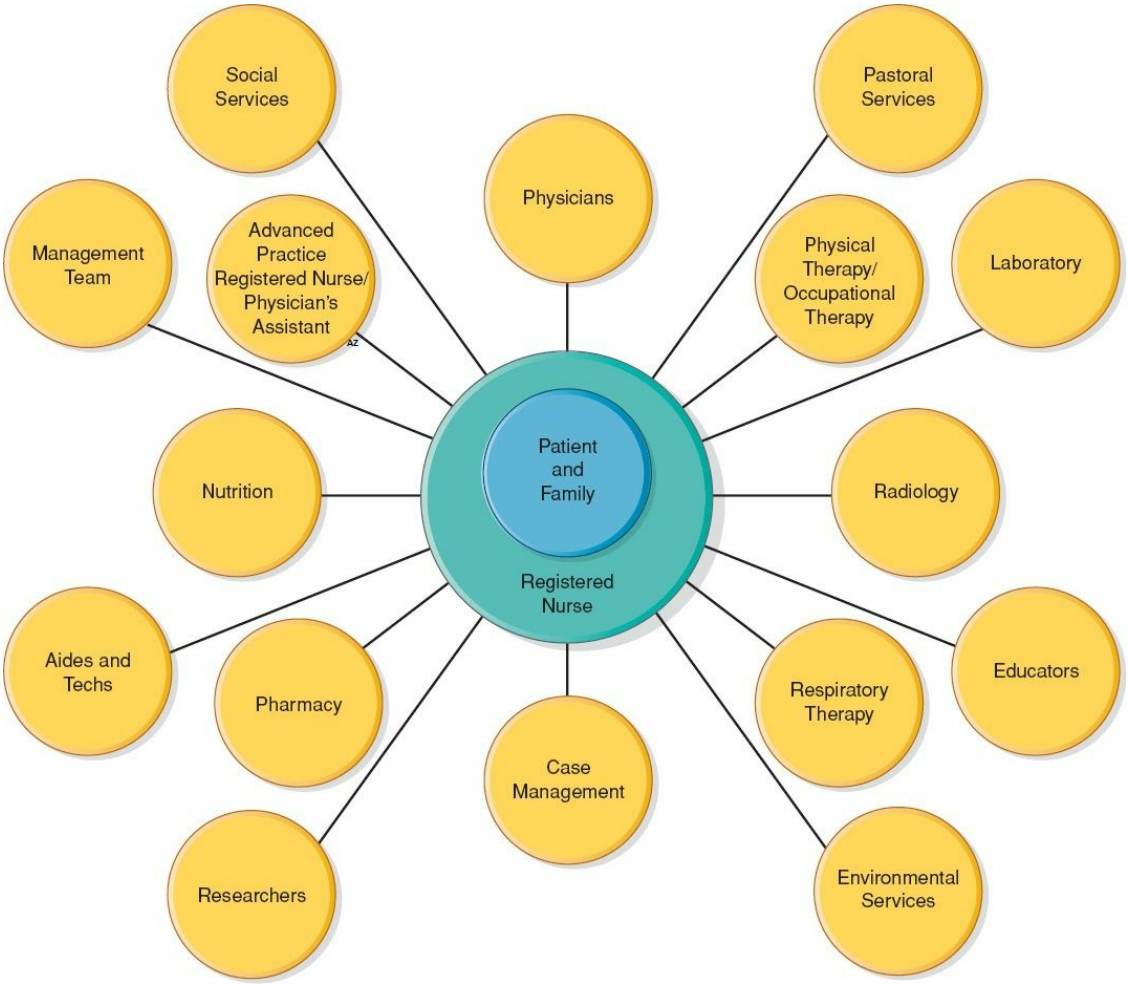


FIGURE 1-1 The Team Player.

General Professional Nursing

Each individual nurse has the responsibility to carry out his or her role as described in the Social Policy Statement (ANA, 2010) and to comply with the Code for Nurses (ANA, 2015) and the Nurse Practice Act of the state in which he or she practices. These documents support the definition of nursing and the claim that nurses must be actively involved in the decision-making process regarding ethical concerns surrounding health care and human responses.

The Code of Ethics (Box 1-1), established by the ANA, consists of ethical standards, each with its own interpretive statements. The interpretive statements provide guidance in addressing nursing responsibilities and ethical decision making.

The role of nurses is specified by individual state boards of nursing and is termed *scope of practice*. Scope of practice is used to delineate actions that are legally permitted for a particular profession, based on specific educational qualifications. It behooves nurses to know and understand their scope of practice, as well as those of other professions with which they interact during patient care. Some actions are described as *dependent*, meaning that a specific action depends upon an order from a medical doctor (MD) or licensed independent practitioner (LIP). An example of a dependent action is a task such as administering medications that have been ordered. Other actions are *interdependent* and are done in a collaborative manner with others. These might include medication titration or

participation in interdisciplinary rounds. *Independent* actions can be performed by the nurse without input from others. This type of action includes performing nursing assessments. Nurses may also delegate tasks to other colleagues, such as the taking of vital signs to nursing assistants. When a nurse delegates a task to another, the delegating nurse remains ultimately responsible for both the action and its outcome (Box 1-2).

BOX 1-1 American Nurses Association Code of Ethics for Nurses

1. The nurse, in all professional relationships, practices with compassion and respect for the inherent dignity, worth, and uniqueness of every individual, unrestricted by considerations of social or economic status, personal attributes, or the nature of health problems.
2. The nurse's primary commitment is to the patient, whether an individual, family, group, or community.
3. The nurse promotes, advocates for, and strives to protect the health, safety, and rights of the patient.
4. The nurse is responsible and accountable for individual nursing practice and determines the appropriate delegation of tasks consistent with the nurse's obligation to provide optimum patient care.
5. The nurse owes the same duties to self as to others, including the responsibility to preserve integrity and safety, to maintain competence, and to continue personal and professional growth.
6. The nurse participates in establishing, maintaining, and improving health care environments and conditions of employment conducive to the provision of quality health care and consistent with the values of the profession through individual and collective action.
7. The nurse participates in the advancement of the profession through contributions to practice, education, administration, and knowledge development.
8. The nurse collaborates with other health professionals and the public in promoting community, national, and international efforts to meet health needs.
9. The profession of nursing, as represented by associations and their members, is responsible for articulating nursing values, for maintaining the integrity of the profession and its practice, and for shaping social policy.

Expanded Nursing Roles

The explosions of knowledge and technology, and changing societal demographics, have provided nursing with unique challenges and opportunities. General nursing has become specialized, with many nurses focusing their practice on a particular population or category of illness. Professional nursing has also adapted with expanded roles to meet evolving health needs and expectations.

BOX 1-2 Nursing Delegation

Who?
The RN

To the LPN or Nursing Assistant or other (e.g., Transport Aide)

What?
Gives authority to a competent individual to perform a selected nursing task

Each task falls within the Nursing Scope of Practice, but can be done by another

Where?
On the nursing unit

When?
When the nurse requires

When the person performing the task has been trained and is deemed competent

When the patient is stable, without unexpected changes in condition

Why?
To achieve a desired patient outcome

To efficiently and effectively make use of personal, financial, and material resources

To efficiently and effectively deliver patient care

How?
Assess the patient need(s), the task(s) required, and the ability of another to perform the task(s)

Delegate the task with clear directions as to priority, timing, and communicating the outcome

Monitor the process of task performance and its completion

Evaluate the patient outcome

Examples of Tasks that Can Be Delegated
Vital signs

Assisting patient out of bed to a chair or to the bathroom

Assisting patient with activities of daily living

Feeding a patient

Phlebotomy

Advanced Practitioner Role

The advanced practitioner role, developed in the 1960s, was designed with a direct clinical

focus, to help fill gaps in the health care delivery system by providing care to those in geographically and socially underserved areas. These advanced practice RNs who are educated and regulated by state boards of nursing, are present in all specialties. They include, among others, nurse practitioners (NPs), certified nurse–midwives (CNMs), and certified registered nurse anesthetists (CRNA). These and similar advanced practice roles have helped distribute health care services at a decreased cost. The advanced practice role has also provided the nurse with an avenue of personal and professional development. With advanced practice roles has come a continuing effort by professional nursing organizations to yet again define nursing. The nursing profession is coming closer to a single definition of advanced practice with the APRN Consensus Model as explained by Kleinpell and Hudspeth (2013). The model advocates practice to the full extent of licensure, which is defined by the population and health needs of the individuals, not by practice setting. It also states that national standards of preparatory education and completion of ongoing competencies reflect these needs.

More specifically, nurses who function in these roles provide direct care to patients through independent practice, practice within a health care agency, or collaboration with a physician. Advanced practice nurses are credentialed by the American Nurses Credentialing Center (ANCC) or by a specialty's national certification body, such as the Council on Certification for Nurse Anesthetists. Advanced practice professionals have the ability to diagnose disease; order, perform, and interpret diagnostic tests; and prescribe medications.

Concept Mastery Alert

Underserved populations in geographically remote areas prompted the development of the advanced practitioner role (which first emerged in the 1960s), not government intervention.

Leadership Roles

Nursing has many avenues of practice, and the leadership role is inherent in all of them. Leadership is essentially the art of providing vision, knowledge, and inspiration, and leading change toward a common goal, which in nursing is holistic quality patient care. Leadership involves those actions that all nurses execute when they assume responsibility for the actions of others directed toward determining and achieving patient care goals. Staff nurses work in settings in which they demonstrate leadership as they are held accountable for the nursing care delivered by unlicensed assistive personnel (UAPs), who work under their direct supervision. Beyond the role of direct caregiver, there are a number of leadership roles.

Nurse executives are charged with developing a vision or strategy of a particular institution and ensuring that the processes required to reach this vision are in place. An example of this may be setting the goal of achieving Magnet status within the Magnet Recognition Program®, in which a hospital is accredited by the ANCC for meeting certain criteria that attract and retain high-functioning nursing staff in order to obtain improved patient outcomes. Nurse Managers are charged with applying the Magnet strategy on the unit level, and they act as translators for putting strategy into actual practice. This may mean scheduling staff to facilitate participation in educational programs or in an institutional activity outside normal job limits, such as community health fairs. Other areas of focus include team coordination, financial responsibilities, policy implementation, staff

development, and monitoring of quality of care.

Clinical Nurse Leaders (CNLs), Clinical Nurse Specialists (CNSs), and Clinical Nurse Educators (CNEs) have different advanced degrees, and each role continues to change and develop. These leaders work on improving patient care outcomes in overlapping and complementary ways. According to Moore (2013), CNLs work at the point of care to help nurses improve knowledge, clinical judgment and compliance with evidence-based standards of care. Moore reports that the CNL role has helped institute changes involving improvement in patient care outcomes, patient satisfaction, and decreased length of stay. CNSs are advanced practice nurses whose focus involves advanced assessment skills for assistance to patients, families, and nurses as well as work in the wider system. Harwood (2013) describes their role as "… working across the system to align scientific evidence, necessary resources, provider groups, and organizational policies and practices for improved clinical outcomes." CNEs work within a specific facility or specialty with a focus on nursing education as it relates to orientation, professional development, regulatory requirements, and quality improvement.

The Patient Safety Nurse is one of the newer roles with a focus on prevention of patient and employee harm. They work with all health care disciplines to trend issues that may cause or actually have caused patient harm. This is done in an effort to implement safer practices that, in turn, will prevent future harm. Their role was developed by the health care industry as part of an effort to transform patient care in the wake of two seminal works from the Institute of Medicine (IOM) highlighting preventable harm to our patients: To Err Is Human: Building a Safer Health System (Kohn, Corrigan, & Donaldson, 1999) and Crossing the Quality Chasm: A New Health System for the 21st Century (Kohn, Corrigan, & Donaldson, 2001).

Nurse Researchers

Like other disciplines, nursing strives for scholarship, to obtain new information and advance the art and science of the profession. This would not be possible without nurse researchers. Researchers are prepared at the doctoral level, obtaining degrees such as a doctor of philosophy (PhD) or doctor of nursing science (DNSc), in order to work in academic or research-intensive settings. The goal of nurse researchers is to establish the effectiveness of nursing interventions and nursing care and to further evidence-based practice. Evidence is researched and evaluated to formulate guidelines to be used in clinical practice. This evidence, in turn, is evaluated by the nurse in clinical practice, who is often in the best position to participate in data collection and facilitate the study through communication with the patient, family, and other health care professionals. The nurse directly involved in patient care is also ideally suited to identify nursing problems and important issues that can serve as a basis for research.

THE PATIENT: CONSUMER OF NURSING AND HEALTH CARE

The central figure in health care services is the patient. The term *patient* is derived from a Latin verb meaning "to suffer." It has traditionally been used to describe those who are recipients of care. Patients' needs vary, depending on their roles (as a member of a family, as a member of a particular community), associated circumstances, and past experiences, as well as the problem or problems for which they sought health care. Among the nurse's important functions in health care delivery is obtaining an understanding of the patient's situation and identifying his or her immediate needs, in order to address them.

Certain needs are basic to all people. Noted psychologist Abraham H. Maslow (1954) developed a theory describing basic human needs and how these needs build upon one another to achieve physical, social, and spiritual health and well-being. This model is now known as Maslow's *hierarchy of needs* (Fig. 1-2). Maslow ranked human needs as physiologic needs, safety and security, sense of belonging and affection, esteem and self-respect, and self-actualization. This last level—self-actualization—refers to fulfilling one's individual potential and includes the desire to know and understand, as well as aesthetics. Once a basic or essential need is met, people usually experience a need on the next level. Depending on an individual's certain situation (e.g., minor vs. major illness or injury), he or she may move among levels. Lower-level needs always remain, but a person's ability to pursue higher-level needs generally indicates movement toward improved health and well-being. This hierarchy provides a useful framework that can be applied to the patient when assessing strengths, limitations, and needs as a consumer of nursing and health care.

FIGURE 1-2 Maslow's hierarchy of needs.

The patient who seeks care for a health issue is also an individual person, a member of a family, and a citizen of the community. The ultimate goal of care is to return the patient to the various roles that he or she holds in life. Many patients, as consumers of health care, have become more knowledgeable about health care options and are assuming a collaborative approach with the nurse and the health care system.

Consumers of nursing and health care are as varied as their numbers are large. There are countless differences in demographics, personalities, and abilities that must be understood, so that the patient can participate in his or her own health care decisions. A basic tenet of nursing is to determine the consumers' needs and wants, in order to guide them through their health care experience.

HEALTH, WELLNESS, AND HEALTH PROMOTION

The health care system of the United States, which traditionally has been disease oriented, is placing increasing emphasis on health and health promotion. Many nurses who would formerly have been involved in the care of acutely ill patients are engaged in health promotion and illness prevention. Further, there is a movement toward outpatient care for both acute and chronic conditions.

Health

How health is perceived depends on how health is defined. The WHO, in the preamble to its constitution, defines health as a "state of complete physical, mental, and social well-being and not merely the absence of disease and infirmity" (WHO, 1948). Although this definition of health does not allow for any variation in degrees of wellness or illness, the concept of a health–illness continuum allows for a greater range in describing a person's health status. By viewing health and illness on a continuum, it is possible to consider a person as being neither completely healthy nor completely ill. Instead, a person's state of health is ever-changing and has the potential to range from high-level wellness to extremely poor health and imminent death. Use of the health–illness continuum makes it possible to view a person as simultaneously possessing degrees of both health and illness.

The limitations of the WHO definition of health are clear in relation to chronic illness and disability. Chronically ill people do not meet the standards of health as established by the WHO definition. However, when viewed from the perspective of the health–illness continuum, people with a chronic illness or disability may be viewed as having the potential to attain a high level of wellness, if they are successful in meeting their health potential within the limits of their chronic illness or disability. Refer to Chapter 3 for details on chronic illnesses.

Wellness

Wellness has been thought of as being equivalent to health. One model of wellness (Hewner, 2014) focuses on various aspects of life that lead to health: emotional, environmental, financial, intellectual, occupational, physical, social, and spiritual.

With this in mind, it is the goal of health care providers to promote positive changes that are directed toward health and well-being. Wellness has a subjective aspect, and the nurse must understand the importance of recognizing and responding to patient individuality and diversity in health care.

Health Promotion

Today, increasing emphasis is placed on health, health promotion, wellness, and self-care. Health is seen as resulting from a lifestyle oriented toward wellness. The result has been the evolution of a wide range of health promotion strategies, including screening, genetic testing, lifetime health monitoring, environmental and mental health programs, risk reduction, and nutrition and health education.

A growing interest in self-care skills is evidenced by the large number of health-related publications, Internet sites, conferences, and workshops designed for the lay public. These programs are designed to promote self-care education, often emphasizing health promotion and disease prevention. As people become increasingly knowledgeable about their health, they often take more interest in and responsibility for their health and well-being.

Special efforts need to be made by health care professionals to determine which organizations, websites, and other venues are providing peer-reviewed and up-to-date information, to ensure people's ability to obtain accurate information concerning health-promoting behaviors. Health-related information and sources of health promotion, whether received from health care professionals, through self-help groups, or from publications, is intended to reach and motivate members of various cultural and socioeconomic groups about lifestyle and health practices.

MODELS OF NURSING CARE

Nursing has evolved from the hospital or home care of the individual during illness to caring for individuals, communities, and populations across the health care continuum in an ever-growing number of ambulatory and inpatient settings. Shortened hospital stays, combined with economic constraints, an aging population, and a greater number of individuals with chronic disease, have necessitated changes in models of nursing care to those best suited to a particular population or setting. Nursing models, such as team nursing, in which nursing staff performed different functions such as medication administration or dressing changes, and primary nursing, in which one nurse provided all assessments and assistance for an individual throughout his or her health care visit, have changed.

Patient- and Family-Centered Care

Patient- and family-centered care can best be described as a model in which the patient and family are cared for by an interdisciplinary group of health care professionals. Active participation of the patient and family and their collaboration in informed decision-making is included.

In their efforts to improve health care quality and safety, hospital leaders today increasingly realize the importance of including a perspective too long missing from the health care equation: the perspective of patients and families. The experience of care, as perceived by the patient and family, is a key factor in health care quality and safety. Bringing the perspectives of patients and families directly into the planning, delivery, and evaluation of health care, and thereby improving its quality and safety, is what patient- and family-centered care is all about. Studies increasingly show that when health care administrators, providers, and patients and families work in partnership, the quality and safety of health care rise, costs decrease, and provider and patient satisfaction increase.

This model appears adaptable to the many facilities through which a person may move during the period of care.

Collaborative Practice

The patient- and family-centered model is a collaborative model and should be a primary goal for nursing. The nursing profession recognizes that it does not practice in a vacuum, and acknowledges the need for participation by the patient and family. With the greater focus on patient safety and improved outcomes at a lower cost, nursing continues to recognize the importance of interaction and communication with other professionals, support staff, and patients and their families in an effort known as *collaborative practice*. Nurses, physicians, and ancillary health personnel perform their particular functions but share in the responsibility of making clinical decisions. The importance of interdisciplinary rounding and collaborative decision-making cannot be underestimated in terms of its ability to provide improved patient care while fostering team cohesion. This is a venture that promotes shared participation, responsibility, and accountability in a health care environment that is striving to meet the complex health care needs of the public.

Care across the Continuum

Regulatory requirements and their financial implications dictate the need for health care organizations to provide the consumer with services of increased value; better health outcomes at a lower price. In order for this to happen, patient- and family-centered care provided by interdisciplinary collaboration needs to happen across the health care continuum. This means that clinicians are aware of the care plan whether in the inpatient or outpatient setting. Hewner (2014) describes the role of nurses in coordinating patient care across providers and settings. Coordinators focus on a group of patients; addressing complex chronic diseases, improving outcomes while reducing hospitalizations and other medical expenses.

INFLUENCES ON HEALTH CARE DELIVERY

Scientific and technologic advances throughout the 20th and into the 21st century have led to social, political, and economic changes. These profound changes have forced the health care industry in general, and nursing practice in particular, to adapt.

Population Demographics

There have been many significant shifts in the demographics of the United States. First of these includes the US Census Bureau (2015) estimation of population increase from 319 million in 2014 to 417 million by the year 2060.

Immigration and Diversity

The United States has been home to an increasingly culturally diverse population, as growing numbers of people from different national backgrounds enter the country.

Again, US Census Bureau (2015) projections indicate that by 2060, one out of every five people will be from a different country, and three out of every fifty people will identify as belonging to two or more races.

As the cultural composition of the population changes, it is increasingly important to address cultural considerations in the delivery of health care. Patients from diverse sociocultural groups not only bring various health care beliefs, values, and practices to the health care setting, but also they have a variety of risk factors for some disease conditions and unique reactions to treatment. These factors significantly affect an individual's responses to health care problems or illnesses, to caregivers, and to the care itself. Unless these factors are understood and respected by health care providers, the care delivered may be ineffective, and health care outcomes may be negatively affected. In addition, the profession of nursing has set as a goal parity between the nursing workforce and the population of the United States. Thus, a priority is encouraging and fostering the education of ethnic minority groups in health care professions. If achieved, one day a balance will be struck between the health care professional staff and the actual population it serves.

Acknowledging and adapting to the cultural needs of patients and significant others are important components of nursing care. In addition, facilitating access to culturally appropriate health care is critical if nursing care is to be holistic. Culturally competent nursing care is a dynamic process that requires comprehensive knowledge of culture-specific information and an awareness of and sensitivity to the effect that culture has on the care situation. Exploring one's own cultural beliefs and how they might differ from the beliefs of the patient being cared for is a first step toward becoming culturally competent. Specific areas to be considered when providing care include the amount of space and distance needed to feel comfortable, the amount of eye contact, attitudes related to time, the use of touch, observance of civil and religious holidays, and the cultural meanings associated with food. Because the nurse–patient interaction is the focal point of nursing, nurses should consider their own cultural orientation when conducting assessments of patients and patients' families and friends. The guidelines in Box 1-3 may prove useful to nurses wishing to provide culturally appropriate care. Box 1-4 provides suggestions on overcoming language barriers.

BOX 1-3 Culturally Appropriate Care

- Know your own cultural attitudes, values, beliefs, and practices.
- Regardless of good intentions, everyone has cultural "baggage" that ultimately results

in ethnocentrism.

- Maintain a broad, open attitude. Expect the unexpected. Enjoy surprises.
- Avoid seeing all people as alike; that is, avoid cultural stereotypes, such as "all Chinese like rice" or "all Italians eat spaghetti."
- Try to understand the reasons for any behavior by discussing commonalities and differences.
- If a patient has said or done something that you do not understand, ask for clarification. Be a good listener. Most patients will respond positively to questions that arise from a genuine concern for and interest in them.
- If at all possible, speak the patient's language (even simple greetings and social courtesies are appreciated). Avoid feigning an accent or using words that are ordinarily not part of your vocabulary.
- Be yourself. There is no right or wrong way to learn about cultural diversity.

BOX 1-4 Overcoming Language Barriers

- Greet the patient using the last or complete name. Avoid being too casual or familiar. Point to yourself and say your name. Smile.
- Proceed in an unhurried manner. Pay attention to any effort by the patient or family to communicate.
- Speak in a low, moderate voice. Avoid talking loudly. Remember that there is a tendency to raise the volume and pitch of your voice when the listener appears not to understand. The listener may perceive that you are shouting and/or angry.
- Organize your thoughts. Repeat and summarize frequently. Use audiovisual aids when feasible.
- Use short, simple sentence structure and speak in the active voice.
- Use simple words, such as "pain" rather than "discomfort." Avoid medical jargon, idioms, and slang. Avoid using contractions, such as *don't, can't, won't.*
- Use nouns repeatedly instead of pronouns. *Example*: Do not say: "He has been taking his medicine, hasn't he?" Do say: "Does Juan take medicine?"
- Pantomime words (use gestures) and simple actions while verbalizing them.
- Give instructions in the proper sequence. *Example*: Do not say: "Before you rinse the bottle, sterilize it." Do say: "First, wash the bottle. Second, rinse the bottle."
- Discuss one topic at a time, and avoid giving too much information in a single conversation. Avoid using conjunctions. *Example*: Do not say: "Are you cold and in pain?" Do say (while pantomiming/gesturing): "Are you cold?" "Are you in pain?"
- Talk directly to the patient, rather than to the person who accompanied him or her.
- Validate whether the person understands by having him or her repeat instructions,

demonstrate the procedure, or act out the meaning.

- Use any words you know in the person's language. This indicates that you are aware of and respect the patient's primary means of communicating.
- Try a third language. Many Indo-Chinese speak French. Europeans often know three or four languages. Try Latin words or phrases, if you are familiar with the language.
- Be aware of culturally based gender and age differences and diverse socioeconomic, educational, and tribal/regional differences when choosing an interpreter.
- Obtain phrase books from a library or bookstore, make or purchase flash cards, contact hospitals for a list of interpreters, and use both formal and informal networking to locate a suitable interpreter. Although they are costly, some telecommunication companies provide translation services.

Aging Population

The increase in lifespan experienced in the United States over the last century has resulted in a tripling of the number of elderly citizens, most of whom are women. The elderly population in the United States has increased significantly and will continue to grow in future years with one in four over the age of 65 years (2015). In addition, people 85 years of age and older will continue to increase in numbers. The health care needs of older adults are often chronic in nature, with intermittent exacerbations or acute episodes. This makes their care more complex and demands significant human, material, and financial investment by the health care industry.

Changing Patterns of Disease

The past century has seen a dramatic shift in disease patterns. This is generally considered to be a move from the predominance of infectious disease to that of chronic illness and injury. Perusal of literature and popular media leads us to ask about the impact of major issues on our health: population growth, aging, urbanization, immigration, environmental challenges, and increasing costs of mitigating their effects. The good news is that innovation continues and science and technology is giving us ever new ways of preventing, treating, and or living with illness and injury.

Advances in Technology

Advances in technology have occurred with greater frequency during the past several decades than in all other periods of civilization. Sophisticated devices have revolutionized how disease is prevented, how patients are diagnosed and treated, and even how communication to and about patients is conducted. Advanced technology has provided access to faster, less invasive, and less painful testing and procedures. In fact, many tests and procedures that once required a hospital stay are performed routinely on an outpatient basis. A disorder that once may have required an operation for diagnosis many times can be diagnosed via computed tomography (CT) or magnetic resonance imaging (MRI). Computers are also significantly changing workflow, as medical records become completely electronic, resulting in improved communication among caregivers, efficient documentation, and ease of medical investigation and research.

Public Safety

The US health care system is based on public trust. This translates to people's confidence that the care they will receive in a hospital or other health care setting will meet legal and social standards. Thus, this large and diverse system is charged with the protection and maintenance of these standards when providing a safe work environment for employees and a healing environment for clients and patients.

Regulatory Bodies

To ensure that minimum standards are maintained, governing and oversight bodies regulate the health care system. Agencies involved in oversight include those in the following discussion.

Occupational Safety and Health Administration

Under the Occupational Safety and Health Act of 1970, employers are responsible for providing a safe and healthy workplace for their employees. The role of the Occupational Safety and Health Administration (OSHA) is to promote the safety and health of working people by setting and enforcing standards; providing training, outreach, and education; establishing partnerships; and encouraging continual process improvement in workplace safety and health.

The Joint Commission

The Joint Commission is a private, nonprofit organization whose mission is to "continuously improve the safety and quality of care provided to the public through the provision of health care accreditation and related services that support performance improvement in health care organizations" (Joint Commission, 2009). At present, the Joint Commission accredits approximately 89% of the nation's hospitals (Joint Commission, 2015).

Patient Protection and Affordable Care Act of 2010

The Patient Protection and Affordable Care Act (PPACA) of 2010 (2015) was designed to improve the health of the population at reduced per capita cost. This is to be accomplished by increasing the number of people with health insurance, improving the insurance policies and reimbursing facilities (hospitals, etc.) based on the quality of care. While relatively new and unstudied, the act has been the target of numerous legal and political challenges. This act is likely to remain a part of the health care landscape impacting both the public and private sectors of health care for the foreseeable future.

Centers for Medicare and Medicaid Services

The Centers for Medicare and Medicaid Services (CMS) is the federal agency that manages Medicare, which is the health insurance program for people over 65 years of age, people under age 65 with certain disabilities, and those with end-stage kidney disease (ESKD). The CMS also manages Medicaid, which is a state-administered program for low-income

individuals and families who fit into an eligibility group recognized by federal and state law. In addition, the CMS manages the children's health insurance program (CHIP), which provides coverage for millions of uninsured children. The CMS exists to ensure effective up-to-date health care coverage and to promote quality care for beneficiaries.

Department of Public Health

Each state has its own Department of Public Health (DPH) with its own mission.

They all are generally charged with the protection of the health and well-being of the state's population and environment. The State Board of Nursing falls within this department and serves to regulate the practice of nursing and the licensing of individual nurses.

Professional Societies and Associations

Associations and societies have a specific focus. They help ensure basic standards as well as promote and recognize advanced knowledge and expertise.

The ANA is the only full-service professional organization representing the nation's more than 3.4 million RNs through its 54 constituent member associations. The ANA advances the nursing profession by fostering high standards of nursing practice, promoting the rights of nurses in the workplace, projecting a positive and realistic view of nursing, and lobbying Congress and regulatory agencies on health care issues affecting nurses and the public.

Hospitals and Institutions

In the 1980s, hospitals and other health care agencies implemented programs designed to measure the quality of care they provided. These programs, known as *quality assurance* (QA) or *quality improvement* (QI), were required to be in place for reimbursement for services and for accreditation by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO; now known simply as the Joint Commission). They sought to establish and maintain accountability to society on the part of the health professions by meeting minimum criteria for the quality, appropriateness, and cost of health services.

In the early 1990s, *continuous quality improvement* (CQI) was identified as a more effective mechanism for improving the quality of health care. Unlike QA, which focuses on individual incidents or errors and minimum expectations, CQI focuses on the processes used to provide care, with the aim of improving quality by assessing and improving those interrelated processes that most affect patient care outcomes and patient satisfaction. CQI involves analyzing, understanding, and improving clinical, financial, and operational processes. Problems that occur as more than isolated events are subject to examination, and all issues that may affect patient outcome are studied. Nurses directly involved in the delivery of care are engaged in analyzing data and refining the processes used in CQI. Their knowledge of the processes and conditions that affect patient care is critical in designing changes to improve the quality of the care provided and ensuring that this care meets or exceeds Joint Commission standards.

Individual Employees

Every individual accepts responsibility for his or her position. For nurses, this entails:

- Maintaining licensure
- Maintaining health requirements, such as annual tuberculosis screening
- Maintaining annual competencies, such as those established by corporate compliance
- Participating in continuing education and certification activities
- Participating in hospital committee and quality review activities
- Providing safe and current care to patients and families.

Economics

The belief that comprehensive, quality health care should be provided for all citizens prompted government concern about rising health care costs and wide variations in charges among providers. In 1983, the US Congress passed significant health legislation termed *prospective payment system* for hospital inpatient services. The federal government was no longer able to afford to reimburse hospitals for patient care that was delivered without any defined limits on costs. Therefore, a *prospective payment system* was approved for hospital inpatient services. Based on diagnosis-related groups (DRGs), prospective payment sets the rates of reimbursement for hospital services for Medicare patients. Hospitals receive payment at a fixed rate for patients with diagnoses that fall into a specific DRG. A fixed payment has been predetermined for more than 470 possible diagnostic categories, covering the majority of medical diagnoses of patients admitted to the hospital. Hospitals receive the same payment for every patient with a given diagnosis or who falls within a given DRG. If the cost of the patient's care is lower than the payment, the hospital makes a profit; if the cost is higher, the hospital incurs a loss. As a result, hospitals are placing greater emphasis on reducing costs, monitoring utilization of services, and limiting length of patient stay.

There is also the renewed focus on overhauling the nation's health care system in an effort to control its ever-increasing cost. As of this writing, attempts at health care reform are under way although the results and effects remain far from certain. Any future changes most likely will prove to have profound effects on regulatory agencies, health care organizations, individual practitioners, and patients.

Nurses in hospitals now care for patients who are older and sicker and require more nursing services. Nurses in the community are caring for patients who have been discharged earlier and need high-technology acute care services as well as long-term care. The importance of effective discharge planning, along with utilization review and quality improvement, cannot be overstated. Nurses in acute care settings must work with other health care team members to maintain quality care while facing pressures to discharge patients earlier and decrease costs.

CHAPTER REVIEW

Critical Thinking Exercises

1. The roles of nurses continue to develop and change. What avenues of continued education are available to the new nurse in order to adapt to these changing roles?
2. What responsibilities do individual nurses have regarding their participation in monitoring and evaluating patient safety and the quality of care they provide?
3. What other influences on the health care delivery system are not necessarily discussed in this chapter?

NCLEX-Style Review Questions

1. Under the Occupational Safety and Health Act (OSHA) of 1970, employers are

responsible for providing a safe and healthy workplace for their employees. Which of the following would be inconsistent with the role of OSHA?

a. Financial assistance
b. Outreach
c. Education
d. Establishing partnerships

2. Nursing has evolved from the hospital or home care of the individual during illness to caring for individuals, communities, and populations across the health care continuum. Which of the following necessitated changes in models of nursing care?

a. Fewer individuals with chronic disease
b. Increased aging population
c. Fewer inpatient settings
d. Lengthened hospital stays

3. Which of the following entities is charged with the protection of health and well-being of the state's population and environment?

a. Joint Commission
b. Occupational Health and Safety Administration
c. Department of Public Health
d. Centers of Medicare and Medicaid Services

4. Based on DRGs, prospective payment sets the rates of reimbursement for hospital services for Medicare patients. Which of the following is an accurate statement regarding the use of DRGs?

a. If the cost of the patient's care is lower than the payment, the hospital takes a loss.
b. If the cost of the patient's care is higher than the payment, the hospital takes a loss.
c. Hospitals receive various payments for every patient with a given diagnosis.
d. If the cost of the patient's care is higher than the payment, the hospital makes a profit.

5. Nurses should consider their own cultural orientation when interacting with patients. Which of the following is a technique that can be used to overcome a language barrier when interacting with a patient?

a. Talk loudly so that the patient will understand.
b. Give the patient a substantial amount of information.
c. Give instructions in proper sequence.
d. Talk directly to the person that accompanied the patient.

CHAPTER 2

Health Education and Health Promotion

Carol Ann Wetmore

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the purposes and significance of health education.
2. Describe the concept of adherence to a therapeutic regimen.
3. Identify variables influencing a person's adherence to a therapeutic regimen.
4. Describe strategies that facilitate adults' learning abilities.
5. Describe the relationship of health education to the nursing process.
6. Develop a teaching plan for a patient.
7. Define health promotion and discuss the role of the nurse related to it.

HEALTH EDUCATION

Teaching, as a function of nursing, is included in all state nurse practice acts and in the *Scope and Standards of Clinical Nursing Practice* of the American Nurses Association (2015, p. 65). Health education is an independent function of nursing practice and is a primary nursing responsibility. All nursing care is directed toward promoting, maintaining, and restoring health; preventing illness; and helping people adapt to the residual effects of illness. Many of these nursing activities are accomplished through health education or patient teaching. Nurses who serve as teachers are challenged to focus on the educational needs of communities, as well as on specific patient and family educational needs. Health education is important to nursing care because it affects the abilities of people and families to perform important self-care activities.

Every contact an individual nurse has with a health care consumer, whether or not that person is ill, should be considered an opportunity for health teaching. Although people have a right to decide whether or not to learn, nurses have the responsibility to present information that motivates people to recognize the need to learn. Therefore, nurses must use opportunities in all health care settings to promote wellness. Educational environments may include homes, hospitals, community health centers, schools, places of business, service agencies, shelters, and consumer action or support groups.

Trends in Health Education

Much of the core of health education today is focused on increasing patient involvement and accountability for individual care and treatment plans. Health education programs are often designed as patient safety initiatives and are geared toward encouraging increased communication between patients and care providers. The effect of improved communication between patients and providers is multifaceted and includes improved patient outcomes, patient safety, and patient perception of quality. The Joint Commission has found consistently that adverse events are caused by breakdowns in communication among caregivers and between caregivers and patients (The Joint Commission, 2016). Therefore, there has been much collaboration to develop processes that encourage improved communication.

The Agency for Healthcare Research and Quality (AHRQ) continues to be a leader in helping both providers and patients to not only understand how important communication is but also develop tools and programs to improve those skills (e.g., evidence-based strategy that hospitals can implement to improve communication and quality [2013, p. 4]). Also AHRQ has built on the foundation of the program, *Questions Are the Answer.* The website offers 10 questions all patients should ask and a "Question Builder" tool to create a list of questions specific to the purpose of the visit—checkup, talking about a problem or health condition, getting a prescription, or discussing a medical test or surgery (AHRQ, 2012). Whatever the reason for your patient's visit, he or she should be prepared. Even the popular press reveals a number of articles encouraging the public to be active and engaged with their care and providers. One blogger developed the acronym, HEALING, to help patients remember their responsibilities:

- Health summary
- Expert—become an expert yourself
- Accept support
- Look for a second opinion
- Involve yourself
- No—speak up if something does not seem right
- Give thanks to outstanding medical providers (Zeppieri-Caruana, 2016).

Purpose of Health Education

The goal of patient and family education is to improve patient outcomes. For purposes of this discussion, family shall be considered to be the person(s) who plays a significant role in the patient's life. This may include person(s) not legally related to the patient. Effective health education lays a solid foundation for individual and community wellness. Teaching is an integral tool that all nurses use to assist patients and families in developing effective health behaviors and in altering lifestyle patterns that predispose people to health risks.

People with chronic illnesses and disabilities are among those most in need of health education. As the lifespan of the population increases, the number of people with such illnesses also increases. People with chronic illness need health care information to participate actively in and assume responsibility for much of their own care. Health education can help change a patient's behavior favorably, increase the ability to cope with and manage health, and improve understanding of the options, risks, and benefits of care, treatment, and services. It can also prevent crisis situations and reduce the potential for rehospitalization resulting from inadequate information about self-care. The goal of health education is to teach people to live life to its healthiest—that is, to strive toward achieving their maximum health potential.

In addition to the public's right to and desire for health education, patient education is also a strategy for promoting self-care at home and in the community, reducing health care costs by preventing illness, avoiding expensive medical treatments, decreasing lengths of hospital stays, and facilitating earlier discharge.

Adherence to the Therapeutic Regimen

One of the goals of patient education is to encourage people to adhere to their therapeutic regimen. Adherence to treatment usually requires that a person make one or more lifestyle changes to carry out specific activities that promote and maintain health. Common examples of behaviors facilitating health include taking prescribed medications, maintaining a healthy diet, increasing daily activities and exercise, self-monitoring for signs and symptoms of illness, practicing specific hygiene measures, seeking recommended health evaluations and screenings, and performing other therapeutic and preventive measures.

Many people do not adhere to their prescribed regimens; rates of adherence are generally low, especially when the regimens are complex or of long duration. Nonadherence to prescribed therapy has been the subject of many studies; a wide range of variables appears to influence the degree of adherence, including the following:

- Inadequate cognitive, psychomotor, or language skills
- Personal values, beliefs, misconceptions, and attitudes coupled with their associated anxiety, depression, and/or fear
- Distrust if loss of control occurs in the decision-making process
- Difficulty in adopting recommended changes
- Insufficient social support or outright sabotage by that support
- Poor self-concept or self-efficacy

Nurses' success with promoting adherence can be improved by creating a collaborative relationship that addresses patient's priorities, circumstances, and goals. Motivational Interviewing (MI) is a collaborative conversational technique intended to strengthen a patient's motivation to change. It has been shown to be effective in addressing many different lifestyle problems as well as in chronic disease management, and many disease prevention guidelines promote use of motivational interviewing. There are four basic principles that are the basis of MI—show empathy, support self-efficacy, roll with resistance, and develop discrepancy. The communication skills often employed include: (1) asking open-ended questions rather than instructing the patient on what they should do, (2) affirming, (3) reflecting, (4) summarizing, and (5) providing individualized information and advice with the patient's permission (Miller & Rollnick, 2013).

Health Literacy and Willingness to Learn

Before initiating a teaching–learning program, it is important to assess the person's physical and emotional readiness to learn, as well as his or her ability to learn what is being taught. This information then becomes the basis for establishing goals that can motivate the person. Involving learners in establishing mutually acceptable goals serves the purpose of encouraging active involvement in the learning process and shared responsibility for learning.

Health literacy is the degree to which an individual has the capacity to obtain, communicate, process, and understand basic health information and services to make appropriate health decisions. Low literacy has been linked to poor health outcomes such as higher rates of hospitalization and less frequent use of preventive services (Cajita, Cajita, & Han, 2016). Nearly nine out of ten adults may lack the skills needed to manage their own health and prevent disease. Considering the complexity of medication regimens (dosing, timing, calculations), informed consent, and technology (peak flow meters, glucose monitoring devices, etc.), it is important for the nurse to have insight into how health literacy impacts the patients' well-being. Current evidence shows that nurses overestimate their patients' health literacy consistently and, therefore, may be unaware of creating difficulties for their patients by not providing adequate information or assuming the patient knows more than he or she does (Dickens, Lambert, Cromwell, & Piano, 2013). There are two methods that can be used to quickly assess a patient's health literacy. The *Newest Vital Sign* tests literacy skills for both numbers and words in both English and Spanish and takes approximately 3 minutes to administer ("NVS," n.d.). An alternative health literacy assessment tool is the *Single Item Literacy Screener* (SILS). The SILS is a single question intended to identify adults in need of help with printed health material. The SILS asks, "How often do you need to have someone help you when you read instructions, pamphlets, or other written material from your doctor or pharmacy?" Possible responses are 1—Never, 2—Rarely, 3—Sometimes, 4—Often, and 5—Always. Scores greater than 2 are considered positive, indicating some difficulty with reading printed health-related material (Brice et al., 2014; Morris, MacLean, Chew, & Littenberg, 2006).

BOX 2-1 Gerontologic Considerations

Elderly people frequently have one or more chronic illnesses that are managed with numerous medications and complicated by periodic acute episodes. Elderly people also may have other problems that affect adherence to therapeutic regimens, such as increased sensitivity to medications and their side effects, difficulty in adjusting to change and stress, financial constraints, forgetfulness, inadequate support systems, lifetime habits of self-treatment with over-the-counter medications, visual and hearing impairments, and mobility limitations. An important predictor of patient adherence to a therapeutic regimen is concordance of the patient's and providers' perception of their health.

Changes in cognition with age may include slowed mental functioning; decreased

short-term memory, abstract thinking, and concentration; and slowed reaction time. Often these changes are accentuated by the health problems that cause the elderly person to seek health care in the first place. Effective teaching strategies include a slow-paced presentation of small amounts of material at a time; frequent repetition of information; and the use of reinforcement techniques, such as audiovisual and written materials and repeated practice sessions. Distracting stimuli should be minimized as much as possible in the teaching environment.

Sensory changes associated with aging also affect teaching and learning. Teaching strategies to accommodate decreased visual acuity include large-print and easy-to-read materials printed on nonglare paper. To maximize hearing, teachers must speak distinctly with a normal or lowered pitch, facing the person so that speech reading can occur as needed. Visual cues often help to reinforce verbal teaching.

Family members should be involved in teaching sessions when possible. They provide another source for reinforcement of material and can help the elderly person recall instructions later. Also family members can provide valuable assessment information about the person's living situation and related learning needs.

When nurses, families, and other involved health care professionals work collaboratively to facilitate the elderly person's learning, chances of success are maximized. Successful learning for the elderly should result in improved self-care management skills, enhanced self-esteem, confidence, and a willingness to learn in the future. Above all, health care professionals must work together to provide continuous, coordinated care; otherwise, the efforts of one health care professional may be negated by those of another.

Boxes 2-1 and 2-2 provide guidance for patient education in the geriatric population.

NURSING PROCESS

Patient Teaching

The steps of the nursing process—assessment, diagnosis, planning, implementation, and evaluation—are used when constructing a teaching plan to meet people's teaching and learning needs (Box 2-3).

ASSESSMENT

Assessment in the teaching–learning process is directed toward the systematic collection

of data about the person's learning needs and style and readiness to learn, as well as the family's learning needs. Box 2-4 discusses the Stages of Change model in relation to teaching and behavior change.

LEARNING READINESS

One of the most significant factors influencing learning is a person's learning readiness. This is a crucial step in the assessment process. If patients are not ready to learn, change, or alter their behavior, education can be fruitless. For adults, readiness is based on culture, attitude, personal values, physical and emotional status, and past experiences in learning. Experiential readiness to learn refers to past experiences that may influence a person's ability to learn. Previous educational experiences and life experiences in general are significant determinants of a person's approach to learning. People with little or no formal education may not be able to understand the instructional materials presented. People who have had difficulty learning in the past may be hesitant to try again. Many behaviors required for reaching maximum health potential require knowledge, physical skills, and positive attitudes. In their absence, learning may be very difficult and very slow. For example, a person who does not understand the basics of normal nutrition may not be able to understand the restrictions of a specific diet. A person who does not view the desired learning as personally meaningful may reject teaching efforts. A person who is not future-oriented may be unable to appreciate many aspects of preventive health teaching. Experiential readiness is closely related to emotional readiness, because motivation tends to be stimulated by an appreciation for the need to learn and by those learning tasks that are familiar, interesting, and meaningful.

BOX 2-2 10 Tips for Educating Elderly Patients (HCPro, 2013)

Consider the following tips for teaching elderly patients:

1. Maintain a positive and patient attitude. Treat the older person as intelligent and capable of learning.
2. Take a few minutes to talk and problem-solve before starting to teach. Ask the patient about experience in a given area. Find out what's worked or what hasn't worked in the past.
3. Identify significant cultural or social factors that may affect the teaching–learning process.
4. Include the patient in setting learning goals. Keep the material relevant to the learner's needs.
5. Identify and try to accommodate any disability that may affect the learning process. For example, for patients with visual impairment, encourage the use of glasses (if appropriate), and investigate special learning tools, such as large-print material.
6. Slow the pace of instruction and gear teaching to the patient's rate of absorption.

Stop teaching if the patient appears tired or stressed.

7. Break each topic into small parts. Repeat sessions when necessary. Give pertinent, positive feedback.
8. Ask the patient to talk through the procedure before trying it. Provide opportunities for practice sessions and repeat demonstrations. Include role playing, discussion, and problem-solving.
9. Avoid tests or challenges—these can create too much stress and impede learning.
10. Assess responses carefully to make sure the information was understood correctly. Gear the frequency and duration of your teaching to match your patient's learning ability and need to know.

Invite family caregivers to be part of the teaching process. At teaching sessions, you can further assess family dynamics. If one of your goals is to promote patient independence, make sure family members understand that their role is to support the patient, not to take over for the patient. And vice versa, if your goal is to teach the family members—make sure that they understand that it will become their sole responsibility to provide this service for the patient for as long as the need remains. Encourage family caregivers to review and reinforce frequently what the patient is learning.

BOX 2-3 Patient Education

A Nursing Process Guide to Patient Education

Assessment

1. Assess the person's readiness for health education.
   - A. What are the person's health beliefs and behaviors?
   - B. What physical and psychosocial adaptations does the person need to make?
   - C. Is the learner ready to learn?
   - D. Is the person able to learn these behaviors?
   - E. What additional information about the person is needed (such as availability of resources and tools)?
   - F. Are there any variables (e.g., hearing or visual impairment, cognitive issues, and literacy issues) that will affect the choice of teaching strategy or approach?
   - G. What are the person's expectations?
   - H. What does the person want to learn?
2. Organize, analyze, synthesize, and summarize the collected data.

Planning and Goals

1. Specify the learning goals established by teacher and learner together.
2. Identify teaching strategies appropriate for goal attainment.
3. Establish expected outcomes.

4. Develop the written teaching plan.
   A. Include diagnoses, goals, teaching strategies, and expected outcomes.
   B. Put the information to be taught in logical sequence.
   C. Write down the key points.
   D. Select appropriate teaching aids.
   E. Keep the plan current and flexible to meet the person's changing learning needs.
5. Involve the learner, family or significant others, nursing team members, and other health care team members in all aspects of planning.

Implementation

1. Put the teaching plan into action.
2. Use language the person can understand.
3. Use appropriate teaching aids and provide Internet resources if appropriate.
4. Use the same equipment that the person will use after discharge.
5. Encourage the person to participate actively in learning.
6. Record the learner's responses to the teaching actions.
7. Provide feedback.

Evaluation

1. Collect objective data.
   A. Observe the person.
   B. Ask questions to determine whether the person understands.
   C. Use rating scales, checklists, anecdotal notes, and written tests when appropriate.
2. Compare the person's behavioral responses with the expected outcomes. Determine the extent to which the goals were achieved.
3. Include the person, family or significant others, nursing team members, and other health care team members in the evaluation.
4. Identify alterations that need to be made in the teaching plan.
5. Make referrals to appropriate sources or agencies for reinforcement of learning after discharge.
6. Continue all steps of the teaching process: assessment, diagnosis, planning, implementation, and evaluation.

BOX 2-4 Stages of Change

An approach to health teaching is the use of the transtheoretical model to conceptualize the process of intentional behavior change. This model considers decisional balance (weighing the pros and cons of the proposed behavioral change),

self-efficacy (confidence in one's ability to change), and the relationship between stage of change and behavior (Prochaska & Prochaska, 2014). The model considers educational interventions that are not "one size fits all" but rather individualized interventions based upon a patient's current stage of readiness to learn or motivational readiness. At any given time, less than 20% of a population at risk is prepared to take action and make changes, thus this model helps nurses determine teaching interventions for the whole population, not just those prepared to change. Transtheoretical model-based measures have been developed for smoking, alcohol use, sun exposure, and exercise, to name a few. The model is not linear but expects that patients will move between stages until successful behavioral changes are established. The nurse considers the patient's current stage when planning educational needs.

- Precontemplation (the patient is not considering any change in behavior in the next 6 months)
- Contemplation (the patient has serious consideration of change, but it is sometime in the future)
- Preparation (the patient has taken initial behavioral steps toward change and intends to make changes in the next 30 days)
- Action (concrete activities that lead to the desired change have been made for less than 6 months)
- Maintenance (active efforts to sustain the changes made for more than 6 months)

The expectation would be for the patient in the precontemplation stage to disagree with suggestions that a change in behavior is needed. The patient would not be expected to exert effort toward making changes in the "risk" behavior. At this stage, the nurse would offer suggestions and material for the patient to consider the need for behavior change and encourage the patient to consider behavioral changes in the future. On the other hand, the nurse may expect an individual in the action stage to endorse the need for change and engage in specific behaviors that would lead to behavioral change. Engagement in educational activities would be expected at this stage.

A practical way of assessing the patient's learning readiness is to ask how they view their health-related problem and what actions do they see that can be taken. Other open-ended questions that might be asked include, "What changes would you like to make now?" and "Are there any problems that prevent you from learning right now?" Research continues to find that these questions are best asked early in a meeting with a patient. In addition, asking "Do you have any other concerns?" as opposed to "Do you have any other questions?" will illicit more information (Robinson, Tate, & Heritage, 2015, Section 4.1).

DETECTING COMMUNICATION ISSUES

Lack of communication skills is one of the most significant barriers to patient education. This can include both a patient's reading and computer skills. Patients who struggle with written material may appear disinterested in learning rather than admitting that they may not understand. Watch a patient's eyes while he is "reading"; the eyes should move left to right as he examines a document. Using computerized resources to support learning with inexperienced users requires careful assessment and planning. Computer-based education will work best and make the most efficient use of time when it is matched to the skill level of the patient.

Improved health outcomes are achieved when culturally competent nurses acknowledge the patient's culture care values and preferred care practices, and incorporate them into their patient's plan of care. Cultural competence is a recognized standard of care in *Holistic Nursing: Scope and Standards of Practice* (AHNA/ANA, 2007). Completing a cultural assessment will allow the nurse to adapt information and delivery to a patient's cultural beliefs and preferences (Box 2-5). An individual's culture can affect his or her viewpoint in many ways, such as the meaning of a diagnosis, the expectation of reporting symptoms, how much information is desired, how death and dying will be managed, gender roles, family participation, and decision making. Culturally competent communication skills play an important role in your success in influencing your patients' health.

There are a number of cultural mores and rules that a nurse can learn and follow:

- Understand nonverbal behavior (e.g., the cultural meaning of touch, eye contact)
- Allow time to build a relationship and establish a rapport:
  - exchange information
  - greet and respond in culturally appropriate ways
  - smile and be genuine
  - pay attention to children
  - listen carefully, don't interrupt or put words in one's mouth
  - value stories
- Notice eye contact and body language
- Reach out to the appropriate family member
- Check for understanding and ask questions
- Avoid jargon and stereotyping
- Do not impose your personal values, morals, or beliefs on to your patients

BOX 2-5 Cultural Assessment Components to Consider When Formulating a Teaching Plan

When formulating a teaching plan, consider the patient's beliefs about:

- Body size, shape, boundaries, and functions
- Beauty and strength

- Value of the mind or brain
- Nature and function of blood
- Diet and nutrition
- Communication
- Gender
- Family and social support
- Physical health and illness
- Mental health and illness
- Age-related changes
- Pain
- Medicine, herbs, and talismans
- Spirituality or religion

One very important key is to learn to laugh at yourself and listen to lessons brought to you by humor (Margalit et al., 2013, pp. 56–57). A balance is necessary; it is important to avoid overemphasizing cultural-specific beliefs so as not to reinforce stereotypes.

Language barriers, once identified, must be addressed. The Joint Commission developed patient-centered communication standards that detail hospital staff's obligation to respect patients' right to and need for effective communication, including the provision of interpreter and translation services when needed (The Joint Commission, 2010). Hospitals are required to provide professional language services to every patient with limited English proficiency (LEP) and tailor written materials to the patient's age, language, and ability to understand (Rorie, 2015). Interpreters must be competent and trained as medical interpreters. Using family members or even untrained support staff as interpreters raises quality, ethical, and possible legal issues. Family members, including children, may incorporate bias into their interpretations; patient confidentiality is compromised; issues about sharing sensitive, private matters with family or friends are an additional issue; and concern over the withholding of bad news or information should also be considered. Often interpreter services are delivered via the telephone, or remote video-phone; however, it does not have applicability for all patients (e.g., for patients who are deaf, where eye contact and nonverbal gestures are essential). Box 2-6 discusses using interpreter services effectively.

DIAGNOSIS

Diagnoses related to health education may include:

- Effective therapeutic regimen management
- Ineffective therapeutic regimen management

- Ineffective family therapeutic regimen management
- Health-seeking behaviors
- Ineffective health maintenance
- Readiness for enhanced management of therapeutic regimen
- Deficient knowledge
- Readiness for enhanced knowledge

PLANNING

Once assessment data are collected, the planning component of the teaching–learning process is established in accordance with the steps of the nursing process:

1. Specify the immediate, intermediate, and long-term goals of learning.
2. Identify specific teaching strategies appropriate for attaining goals.
3. Specify the expected outcomes.
4. Document the goals, teaching strategies, and expected outcomes of the teaching plan.

Developing the plan and goals of teaching should be a joint effort by the nurse and the patient and family members. Consideration must be given to the urgency of the patient's learning needs; the most critical needs should receive the highest priority.

After the learning priorities have been established, it is important to identify the immediate and long-term goals and the teaching strategies appropriate for attaining those goals. A partnership between patients and providers, based on both shared decision making and two-way communication, will develop your patient's skills and confidence needed to self-manage his or her health and prevent chronic disease progression (Gittner, 2015, p. 277). Learning begins with the establishment of goals that are appropriate to the situation and realistic in terms of the patient's ability and desire to achieve them. Involving the patient and family in establishing goals and in planning teaching strategies promotes their cooperation in implementing the teaching plan.

Expected outcomes of teaching strategies can be stated in terms of behaviors of patients, families, or both. Outcomes should be realistic and measurable, and the critical time periods for attaining them should be identified. The desired outcomes and the critical time periods serve as a basis for evaluating the effectiveness of the teaching strategies.

During the planning phase, the nurse must consider the sequence in which the subject matter is presented in each of the teaching strategies. Critical information (e.g., blood glucose monitoring for a patient with diabetes) and material that the person or family identifies to be of particular importance will be high priority and, thus, should be presented earlier than other information. An outline is often helpful for arranging the subject matter and for ensuring that all necessary information is included. In addition, appropriate teaching aids to be used in implementing teaching strategies are prepared or selected at this time.

BOX 2-6 Working Effectively Through an Interpreter

Knowing the patient:

- Determine ethnicity and nationality of the patient.
- Determine what language(s) the patient speaks, and preferred language.
- Offer an interpreter to all patients where English is not their first language.
- Determine patient preference for face-to-face or telephone interpreter service.

Preparing for the meeting:

- Ensure a private, quiet environment, with space for all meeting participants.
- Maintain a warm, non-rushed environment where patient and interpreter can raise concerns.
- Meet with the interpreter before the meeting to discuss the goals of the meeting and the process (such as pausing for interpretation); if repeat meetings are required, try to use the same interpreter.
- Explain that interpreters are bound by their code of ethics to treat everything that is said as confidential.

Seating arrangements:

- Ensure that the seating is arranged to facilitate communication. When the meeting involves only a client, interpreter, and a clinician, arrange seating in a triangle formation.
- When interpreting with family, caregivers or more than two people, it is advisable to arrange the seating in a horseshoe or circle formation, with the interpreter seated next to the clinician.
- In a large or group meeting situation, arrange the seating in a circular formation, seat the interpreter next to the clinician and close to the client so they are able to understand the proceedings with minimum disruption to others.
- For telephone interpreting, use a dual handset or hands-free phone, and sit facing your client.

Verbal and nonverbal communication (telephone and face-to-face interpreter):

- Speak directly to the patient, not to the interpreter.
- Maintain eye contact and face your patient.
- Speak more slowly rather than more loudly.
- Keep your sentences or questions brief.
- Pause at the end of each statement to allow the interpreter time to interpret, explaining the need to pause to the client.
- Be aware that the interpreter may sometimes have to clarify a statement or answer with the client, family member, or caregiver.

During the medical interview:

- Assume, and insist, that everything you say, everything the patient says, and everything that family members say is interpreted.
- Do not hold the interpreter responsible for what the patient says or doesn't say. The interpreter is the medium, not the source, of the message.
- If you feel that you are not getting the type of response you were expecting, restate the question or consult with the interpreter to better understand if there is a cultural barrier that is interfering with communication.
- Be aware that many concepts you express have no linguistic or conceptual equivalent in other languages. The interpreter may have to paint word pictures of many terms you use. This may take longer than your original speech.
- Respond to nonverbal cues (e.g., quizzical or frightened look, stiffening of body posture)
- If you need to ask questions that may be extremely personal or sensitive, explain to the patient that doing so is part of your evaluation and reiterate that the information will remain confidential.
- Avoid: highly idiomatic speech, complicated sentence structure, sentence fragments, changing your idea in the middle of a sentence, and asking multiple questions at one time. Also avoid making assumptions or generalizations about your patients or their experiences. Common practices or beliefs in a community may not apply to everyone in that community.
- Encourage the interpreter to ask questions and to alert you about potential cultural misunderstandings that may come up. Respect an interpreter's judgment that a particular question is culturally inappropriate and either rephrase the question or ask the interpreter's help in eliciting the information in a more appropriate way.
- Ask the patients what they believe the problem is, what causes it, and how it would be treated in their country of origin.
- Ask the patient to repeat back important information that you want to make sure is understood.
- Be patient. Providing care across a language barrier takes time. However, the time spent up front will be paid back by good rapport and clear communication that will avoid wasted time and dangerous misunderstandings later in the process.

Adapted from Miletic et al. (2006), p. 18–26; Kaur (2014).

THE LEARNING ENVIRONMENT

Although learning can take place without teachers, most people who are attempting to learn new or altered health behaviors benefit from the services of nurses. The interpersonal interaction between the person and the nurse who is attempting to meet

the person's learning needs may be formal or informal, depending on the method and techniques of teaching.

Learning may be optimized by minimizing factors that interfere with the learning process. For example, the room temperature, lighting, noise levels, and other environmental conditions should be appropriate to the learning situation.

TIMING

The time selected for teaching should be suited to the needs of the individual person. Scheduling a teaching session at a time of day when a patient is fatigued, uncomfortable, or anxious about a pending diagnostic or therapeutic procedure, or when visitors are present, is not conducive to learning. However, if the family is to participate in providing care, the sessions should be scheduled when family members are present, so that they can learn any necessary skills or techniques.

TEACHING TECHNIQUES

Teaching techniques and methods enhance learning if they are appropriate to the patient's needs (Table 2-1). Numerous techniques are available, including lectures, group teaching, and demonstrations, all of which can be enhanced with specially prepared teaching materials.

TABLE 2-1 Teaching People with Disabilities

Type of Disability	Teaching Strategy
Physical, Emotional, or Cognitive Disability	Adapt information to accommodate the person's cognitive, perceptual, and behavioral disabilities. Give clear written and oral information. Highlight significant information for easy reference. Avoid medical terminology.
Hearing Impairment	Use slow, directed, deliberate speech. Use sign language or interpreter services if appropriate. Position yourself so that the person can see your mouth if speech reading. Use telecommunication devices (TTY[a] or TDD[b]) for the hearing impaired. Use written materials and visual aids, such as models and diagrams. Use captioned videos, films, and computer-generated materials. Teach on the side of the "good ear" if unilateral deafness is present.
Visual Impairment	Use optical devices such as a magnifying lens. Use proper lighting and proper contrast of colors on materials and equipment. Use large-print materials. Use Braille materials if appropriate. Convert information to auditory and tactile formats. Obtain audiotapes and talking books. Explain noises associated with procedures, equipment, and treatments. Arrange materials in clockwise pattern.
Learning Disabilities	
Input disability—process of recording information in the brain ("LD," n.d.)	If visual perceptual disorder: • Explain information verbally, repeat, and reinforce frequently. • Use audiotapes. • Encourage learner to verbalize information received. If auditory perceptual disorder: • Speak slowly with as few words as possible, repeat, and reinforce frequently. • Use direct eye contact to focus person on task. • Use demonstration and return demonstration such as modeling, role playing, and hands-on experiences. • Use visual tools, written materials, and computers.
Output disability—communication of information from the brain to other people or translation of the information into action ("LD," n.d.)	Use all senses as appropriate. Use written, audiotape, and computer information. Review information and give time to interact and ask questions. Use hand gestures and motions.
Developmental disability	Base information and teaching on developmental stage, not chronologic age. Use nonverbal cues, gestures, signing, and symbols as needed. Use simple explanations and concrete examples with repetition. Encourage active participation. Demonstrate information and have the person perform return demonstrations.

[a]TTY, a special device that lets people who are deaf, hard of hearing, or speech-impaired use the telephone for communication needs (messages are typed back and forth).
[b]TDD, operates similarly to a TTY but is a much smaller desktop machine.

In general, patients remember information in approximately the following ratios:

- 10% of what they read
- 25% of what they hear
- 45% of what they see
- 65% of what they hear and see
- 70% of what they say and write
- 90% of what they say as they perform a task

The lecture or explanation method of teaching is commonly used but should always be accompanied by discussion. Discussion is important because it affords learners opportunities to express their feelings and concerns, to ask questions, and to receive clarification. Group teaching is appropriate for some people because it allows them not only to receive needed information but also to feel secure as members of a group.

People with similar issues or learning needs have the opportunity to identify with each other and gain moral support and encouragement. Interactive group education has shown a significant increase in patient knowledge and better outcomes in terms of chronic disease self-management (Lu et al., 2015). Group visits allow interactions in a more natural setting, and conversations between patients help them feel less isolated and, possibly, less threatened. If group teaching is used, assessment and follow-up are imperative to ensure that each person has gained sufficient knowledge and skills. Demonstration and practice are essential ingredients of a teaching program, especially when the nurse is teaching skills to the patient. It is best to demonstrate the skill and then give the learner ample opportunity for practice. When special equipment is involved, such as syringes, colostomy bags, dialysis equipment, dressings, or suction apparatus, it is important to teach with the same equipment that will be used in the home setting. Learning to perform a skill with one kind of equipment and then having to change to a different kind may lead to confusion, frustration, and mistakes.

A tool such as the plan-do-study-act (PDSA) model is a framework for quality improvement activities. This model, or others like it, is used often by health care organizations to approach performance improvement work in a consistent way. A key finding of research about improving the effectiveness of chronic care models found that using the Plan-Do-Study-Act cycle with patients allowed for faster turnaround of information in formats that patients would use and could be individualized (Varkey et al., 2009, pp. 208–209). The PDSA model is a way to engage patients with their own care and have a role in developing their own plan. In addition, it provides opportunity to create learning collaboratives with other patients and health care providers (Davy et al., 2015). Other steps or tools that can improve success include collaborative agendas or goal setting, in which the patient and the nurse build the agenda together regarding items for discussion. Patients should be engaged to help prioritize items for best time management. A communication/demonstration technique known as *ask–tell–ask–close the loop* can help improve communication and patient understanding:

- *Ask* permission to give information about a topic of importance to the patient.
- *Tell:* Explanations and written materials are most effective when given in response to the patient's expressed agenda and tailored to his ability to understand.
- *Ask* for understanding, and provide additional information or clarification as necessary.
- *Close the loop:* Ask the patient to restate the information as the patient understands it (Goldman et al., 2015)

Teaching aids used to enhance learning include books, pamphlets, pictures, films, slides, audio and video tapes, models, programmed instruction, CD-ROMs, and computer-assisted learning modules. These are made available as needed for home, clinic, or hospital use, and they allow review and reinforcement of content and enhanced visual and auditory learning. Such teaching aids are invaluable when used

appropriately and can save a significant amount of personnel time and related cost. However, all such aids should be reviewed before use to ensure that they meet the patient's learning needs. Developing tools as part of a multidisciplinary group also has been shown to yield benefits not only for patients who will use the tools but for the staff involved in creating them. Multidisciplinary teams have been shown to be more productive, have less stress, and have enriched professional experience (Reckery et al., 2015).

Reinforcement and follow-up are important because learning takes time. Allowing ample time to learn, and then reinforcing what is learned, are important teaching strategies; rarely is a single teaching session adequate. Follow-up sessions are imperative to promote the learner's confidence in his or her abilities and to plan for additional teaching sessions. For hospitalized patients who may not be able to transfer what they have learned in the hospital to the home setting, follow-up after discharge is essential to ensure that they have realized the full benefits of a teaching program.

The entire planning phase of the teaching–learning process concludes with the documentation of the teaching plan. This teaching plan communicates information to all members of the nursing and health care team. Documentation enhances the continuity of care for the patient and communication among caregivers. Documentation should include:

- The learner, instructor, and interpreter (if used)
- The patient's need assessment
- Learning objectives and goals
- Information and skills taught
- Teaching methods used
- Teaching materials provided or used
- Patient and family response to teaching
- Evaluation of what the patient learned
- Further learning needs
- Revised goals (if necessary)

IMPLEMENTATION

In the implementation phase of the teaching–learning process, the patient, the family, and other members of the nursing and health care team carry out the activities outlined in the teaching plan. The nurse coordinates these activities.

During the implementation phase of the teaching–learning process and throughout the ongoing assessment of patient responses to the teaching strategies, flexibility is indispensable to support modification of the teaching plan as necessary. Creativity is essential in promoting and sustaining the patient's motivation to learn. Be sure to consider new learning needs that may arise after discharge from the hospital or after home care visits have ended.

Feedback about progress also motivates learning. Such feedback should be presented in the form of positive reinforcement when the learner is successful and in the form of constructive suggestions for improvement when he or she is unsuccessful.

The implementation phase ends when the teaching strategies have been completed and when the patient's responses to the actions have been recorded. This record serves as the basis for evaluating how well the defined goals and expected outcomes have been achieved.

EVALUATION

Evaluation of the teaching–learning process determines how effectively the patient has responded to teaching and to what extent the goals have been achieved. An evaluation must be made to determine what was effective and what needs to be changed or reinforced. It cannot be assumed that patients have learned just because teaching has occurred; learning does not automatically follow teaching. An important part of the evaluation phase addresses the question, "What can be done to improve teaching and enhance learning?" Answers to this question direct the changes to be made in the teaching plan.

A variety of measurement techniques can be used to identify changes in patient behavior as evidence that learning has taken place. These techniques include directly observing the behavior; using rating scales, checklists, or anecdotal notes to document the behavior; and indirectly measuring results using oral questioning and written tests. All direct measurements should be supplemented with indirect measurements whenever possible. Using more than one measuring technique enhances the reliability of the resulting data and decreases the potential for error from a measurement strategy.

In many situations, measurement of actual behavior is the most accurate and appropriate technique. Nurses often perform comparative analyses using patient admission data as the baseline: selected data points observed when nursing care is given and self-care is initiated are compared with the patient's baseline data. In other cases, indirect measurement may be used such as patient satisfaction surveys, attitude surveys, and instruments that evaluate specific health status variables.

However, measurement is only the beginning of evaluation, which must be followed by data interpretation and value judgments about learning and teaching. These aspects of evaluation should be conducted periodically throughout the teaching–learning program, at its conclusion, and at varying periods after the teaching has ended.

Evaluation of learning after hospitalization is highly desirable because the analysis of teaching outcomes must extend into home care. With shortened lengths of hospital stay and with short-stay and same-day surgical procedures, follow-up evaluation in the home is especially important. Coordination of efforts and sharing of information between hospital- and community-based nursing personnel facilitate postdischarge teaching and home care evaluation.

Evaluation is not the final step in the teaching–learning process, but the beginning of the iterative process of a new patient assessment. The information gathered during

evaluation should be used to redirect teaching actions, with the goal of improving the patient's responses and outcomes.

HEALTH PROMOTION

Health teaching and health promotion are linked by a common goal—to encourage people to achieve as high a level of wellness as possible so that they can live maximally healthy lives and avoid preventable illnesses. Patients are the primary managers of their health conditions. Nurses are in an ideal position to provide the kind of support that patients need to manage their conditions. Health promotion has become a cornerstone in health policy because of the need to control costs and reduce unnecessary sickness and death.

The US Department of Health and Human Services' Healthy People initiative was designed to establish a program of nationwide health-promotion and disease-prevention goals. The first set of goals established in the publication *Healthy People 2000* focused on disease prevention. *Healthy People 2010* added the priorities of health promotion, health protection, and the use of preventive services. *Healthy People 2020* builds on past achievements, reaffirms the overarching goals from the past decade, and adds: promoting quality of life, healthy behaviors across life stages, eliminating health disparities, and creating social and physical environments that promote good health.

Definition

Health promotion is defined as the process of enabling people to increase control over their health and its determinants, thereby improving their health (World Health Organization [WHO], 2016). The purpose of health promotion is to focus on the person's potential for wellness and to encourage appropriate alterations in personal habits, lifestyle, and environment in ways that reduce risks and enhance health and well-being. Health promotion is an active process; that is, it is not something that can be prescribed or dictated. It is up to each person to decide whether to make changes to promote a higher level of wellness. Only the individual can make these choices.

The concepts of health, wellness, health promotion, and disease prevention have been a topic of extensive discussion in the lay literature and news media, as well as in professional journals. As a result, public demand for health information has increased, and health care professionals and agencies have responded by providing this information. As employers strive to reduce costs associated with absenteeism, health insurance, hospitalization, disability, excessive turnover of personnel, and premature death, the workplace has become an important site for health-promotion programs. The concept of health promotion has evolved because of a changing definition of health and an awareness that wellness exists at many levels of functioning. Health is viewed as a dynamic, ever-changing condition that enables people to function at an optimal potential at any given time. The ideal health status is one in which people are successful in achieving their full potential, regardless of any limitations they might have.

Wellness, as a reflection of health, involves a conscious and deliberate attempt to maximize one's health. Wellness does not just happen; it requires planning and conscious commitment and is the result of adopting lifestyle behaviors for the purpose of attaining one's highest potential for well-being. Wellness is not the same for every person. The person with a chronic illness or disability may still be able to achieve a desirable level of wellness. The key to wellness is to function at the highest potential within the limitations over which there is no control.

Self-Responsibility

Taking responsibility for oneself is the key to successful health promotion. The concept of self-responsibility is based on the understanding that the individual controls his or her life. Each person alone must make the choices that determine how healthy his or her lifestyle is. As more people recognize that lifestyle and behavior significantly affect health, they may assume responsibility for avoiding high-risk behaviors such as smoking, alcohol and drug abuse, overeating, driving while intoxicated, risky sexual practices, and other unhealthy habits. Also they may assume responsibility for adopting routines that have been found to have a positive influence on health, such as engaging in regular exercise, wearing seat belts, and eating a healthy diet.

A variety of different techniques has been used to encourage people to accept responsibility for their health, ranging from extensive educational programs to reward systems (see Table 2-2). No one technique has been found to be superior to any other. Instead, self-responsibility for health promotion is very individualized and depends on a person's desires and inner motivations. Health-promotion programs are important tools for encouraging people to assume responsibility for their health and to develop behaviors that improve health.

Unfolding Patient Stories: Vincent Brody • Part 1

Vincent Brody, a 67-year-old male with chronic obstructive pulmonary disease (COPD), is experiencing increased fatigue. He spends most of the day in a recliner chair watching television and smoking 1 to 2 packs per day. His nutritional intake is poor due to shortness of breath. What patient education can the nurse provide to promote self-care behaviors for symptom improvement and a healthier lifestyle? (Vincent Brody's story continues in Chapter 51.)

Care for Vincent and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in DocuCare (www.lww.com/DocuCareEHR).

Health Promotion throughout the Lifespan

Health promotion is a concept and a process that extends throughout the lifespan. Studies have shown that the health of a child can be affected either positively or negatively by the health practices of the mother during the prenatal period. Therefore, health promotion starts before birth and extends through childhood, adolescence, adulthood, and old age. At any stage of the lifespan, health promotion includes health screening. Screenings are tests that look for diseases before symptoms are present. In general, screening tests can find diseases early, when they are easier to treat. Some conditions that health care providers commonly screen for include breast cancer and cervical cancer in women, prostate cancer in men, as well as colorectal cancer, diabetes, high blood pressure, high cholesterol, osteoporosis, and obesity. Tests needed depend on age, sex, family history, and whether there are risk factors for certain diseases. The Center for Disease Control and Prevention (CDC) offers a website titled *CDC Prevention Checklist* where the public can obtain specific recommendations based upon age and sex for clinical preventative services (see www.cdc.gov, search: prevention checklist).

TABLE 2-2 Guidelines for Developing Patient Education Materials (The American Academy of Ambulatory Care Nursing Patient Education Special Interest Group [AAACN], n.d.)

- Use visuals as much as possible (DVDs or printed illustrations) of anatomical features of the specific system that relates to the patient's problem or need
- Choose books, pamphlets, and/or brochures that are written at a third to fifth grade level
- Use short sentences (10 words or less) when developing printed materials
- Write paragraphs with no more than two or three sentences with one key point per paragraph
- Focus efforts on key bullet points of "must know" information
- Use visual terms such as "runny nose" and "redness"
- Explain measurements, e.g., "pain that lasts more than 30 minutes"
- Clearly list when the patient needs to call the health care provider and what phone number to call
- Focus on actions patients should do using familiar words
- Use plain language: Define any terms that are difficult to understand
- Have patient and family members "teach back" the information to you to ensure understanding
- Be aware of language, customs, and values to create a culturally sensitive and effective tool
- Use wide margins and leave white space between sections
- Find an advocate for the person with low literacy who will ensure that the individual understands and follows through with instructions

Young and Middle-Aged Adults

People of all ages are challenged to find the best way to make health behavior changes. Even when highly motivated, people can find it difficult to achieve and or sustain success. Younger people can be driven by different factors than middle-aged and older adults. Physical activity may be more strongly related to personality traits such as achievement orientation and sensation-seeking than to specific beliefs about the behavior (Sallis, Prochaska, & Taylor, 2000). Young adults also have fewer health problems than their older counterparts and unrealistic optimism about health risks. Therefore, young adults' beliefs about their health status may be less dominant in shaping their responses to health communications than their intrinsic motivations. Young and middle-aged adults can differ in their disposition as to the extent to which people are motivated to approach favorable outcomes or avoid unfavorable outcomes. Updegraff, Brick, Emanuel, Mintzer, and

Sherman (2015) found that a gain-framed message promoted more interest in a preventive supplement than a loss-framed message among young people told that they were at low risk. In contrast, a loss-framed message promoted more interest for those told that they were at high risk.

Frequently adults are motivated to change their lifestyles in ways that they believe will enhance their health and wellness. Middle to older adults' beliefs can have a moderating effect because beliefs about susceptibility to health issues become more real with age. Many adults who wish to improve their health turn to health-promotion programs to help them make the desired changes in their lifestyles. Many have responded to programs that focus on topics such as general wellness, smoking avoidance or cessation, exercise, physical conditioning, weight control, conflict resolution, and stress management. Because of the nationwide emphasis on health during the reproductive years, young adults actively seek programs that address prenatal health, parenting, family planning, and women's health issues.

There is a long, broad list of barriers that prevent or limit individuals from taking up and maintaining healthy behaviors in mid-life. The findings are surprisingly consistent across developed countries. Recurring themes include: lack of time (due to family, household and occupational responsibilities), access issues (to transportation, facilities and resources), financial costs, entrenched attitudes and behaviors, restrictions in the physical environment, low socioeconomic status, and lack of knowledge (Kelly et al., 2016). Likewise, research has identified a number of recurring factors that act as facilitators to healthy behaviors such as a focus on enjoyment of the healthy behavior, doing other healthy behaviors, health benefits, prevention of illness, the potential benefits for healthy aging and well-being as motivation; social support and encouragement; clear, accurate health messages, and integration of behaviors into lifestyle and routine (Kelly et al., 2016). Programs should be geared toward minimizing these barriers while maximizing the facilitators.

Programs that provide health screening, such as those that screen for cancer, high cholesterol, hypertension, diabetes, abdominal aneurysm, and visual and hearing impairments, are quite popular with young and middle-aged adults. Programs that involve health promotion for people with specific chronic illnesses, such as cancer, diabetes, heart disease, and pulmonary disease, are also popular. It is becoming more evident that chronic disease and disability do not preclude health and wellness; rather, positive health attitudes and practices can promote optimal health for people who must live with the limitations imposed by their chronic illnesses and disabilities.

Health-promotion programs can be offered almost anywhere in the community. Common sites include the workplace, local clinics, elementary and high schools, community colleges, recreation centers, churches, and even private homes. Frequently health fairs are held in civic centers and shopping malls. The outreach idea for health-promotion programs has served to meet the needs of many adults who otherwise would not avail themselves of opportunities to strive toward a healthier lifestyle.

Workplace programs usually include employee health screening and counseling, physical fitness, nutritional awareness, work safety, and stress management and stress reduction. Many large businesses provide exercise facilities for their employees and offer their health-promotion programs to retirees. If employers can show cost-containment benefits from such programs, their dollars will be considered well spent, and more businesses will provide

health-promotion programs as a benefit of employment.

Older Adults 

Health promotion is as important for the elderly as it is for other adults and children. Although their chronic illnesses and disabilities cannot be eliminated, these adults can benefit from activities that help them maintain independence and achieve an optimal level of health. Older adults have different health and social circumstances compared to younger people. Because of these differences, there are other strategies that can be used to help promote healthy behaviors. Motivators for older adults include physical and psychological well-being, maintenance of independent lifestyles, social connections, and enjoyment. Older adults who can self-report excellent or very good health, have no history of hip fracture after age 55, no cardiovascular disease, no depression, and have a BMI <25 are predicted to have greater independence. In addition, older adults who self-report "excellent" or "very good" health are also predicted to have little decline in activities of daily living. Older adults also believe that physical activity can protect cognitive health (Vaughan et al., 2016). Health-promotion materials could include information about healthy actions, nutritional information based on ethnicity and a healthy diet, as well as the frequency, duration, and intensity of physical activity and their effect on health. Box 2-1 provides gerontologic considerations.

Nursing Implications

Nurses have a unique relationship with the American public, topping Gallup's Honesty and Ethics ranking of professions every year but one since they were added to the list in 1999. The exception is 2001, when firefighters were included on the list on a one-time basis, shortly after the September 11 terrorist attacks. (Firefighters earned a record-high 90% honesty and ethics rating in that survey.) With an 85% honesty and ethics rating—tying their high point—nurses have no serious competition atop the Gallup rankings (Gallup, 2016). By virtue of nurses' expertise in health and health care and our long-established credibility with consumers, nurses play a vital role in health promotion. In many instances, nurses have initiated health-promotion and health-screening programs or have participated with other health care personnel in developing and providing wellness services in a variety of settings. As health care professionals, nurses have a responsibility to promote activities that foster well-being, self-actualization, and personal fulfillment. Every interaction with consumers of health care must be viewed as an opportunity to promote positive health attitudes and behaviors.

CHAPTER REVIEW

Critical Thinking Exercises

1. A history of GI disease is an independent risk factor for the development of GI adverse reactions during alendronate therapy. Severe reactions requiring hospitalization have occurred. Alendronate should be used with caution in patients with esophageal and GI disease, including dysphagia, esophagitis, gastritis, gastroesophageal reflux disease (GERD), hiatal hernia, duodenitis, ulcers, or GI perforation. What variables made the clinician prescribe this therapy?

2. A home health nurse is instructing a 55-year-old man with a history of coronary artery disease and systolic heart failure about healthy eating habits. He has recently been widowed. What physiologic and psychosocial variables would be relevant to understanding this patient's needs? How would a teaching plan be constructed to promote adequate nutrition? How would you modify the teaching plan if the patient is visually impaired?

3. A 72-year-old man is informed by an advanced practice nurse about a health fair being held at the local community center across the street from his home. He declines to attend, saying, "I am too old, and it is too late to be concerned about health promotion. The damage to my body has already been done." What resources would you use to identify evidence of the effectiveness of health-promotion activities for the elderly? Discuss the strength of the evidence. Identify the criteria used to evaluate the strength of the evidence. What information would you then include in a discussion with the patient about promoting health in the elderly?

NCLEX-Style Review Questions

1. A nurse is providing discharge teaching for an elderly patient who is fully dressed, watching television, and waiting for family. The nurse sits in a chair facing the patient and shows the patient a handout. The patient squints while reading and periodically looks at the television. The nurse is about to review the information and determine the patient's understanding of the material when the family enters the room. The nurse determines the need for further education due to learning barriers. Which barriers affected the patient's ability to comprehend the information? Select all that apply.
   a. Patient is watching television.
   b. The patient is elderly.
   c. The patient squints while reading.
   d. The family entered the room while teaching.
   e. The patient is fully dressed.

2. The nurse is to provide discharge teaching to a patient with newly diagnosed coronary artery disease. In what order should the following steps be prioritized and completed?
   a. Implement teaching plan.
   b. Collect and analyze data regarding the patient's knowledge of coronary artery disease.
   c. Form nursing diagnoses related to patient teaching.
   d. Reassess patient's knowledge as needed.
   e. Develop teaching plan.
   f. Identify learning needs.
   g. Update and change plan.

3. The nurse is discussing postoperative discharge instructions with an Asian American patient. The patient looks at the floor, smiles, and then nods his head. Using cultural awareness, how should the nurse interpret this behavior?
   a. Acceptance of the instructions
   b. Understanding of the material
   c. A reflection of cultural values
   d. The patient's ability to follow through on the instructions

4. When constructing a teaching plan, the steps of the nursing process are utilized. In which step are teaching strategies identified?
   a. Assessment
   b. Planning
   c. Implementation
   d. Evaluation

5. Which of the following is an accurate statement with regard to adult learner readiness?
   a. Learning readiness is based solely on past life experiences.
   b. Physical skills play little role in learner readiness.

c. Experimental readiness is not related to emotional readiness.
d. Learner readiness is based on culture, attitude, and personal values.

CHAPTER 3

Chronic Illness and End-of-Life Care

James Mark Lazenby • Ruth McCorkle • Mei Bai

Learning Objectives

After reading this chapter, you will be able to:

1. Define "chronic illness."
2. Identify factors related to the increasing incidence of chronic diseases.
3. Describe characteristics of chronic illness and its impact on patients.
4. Describe implications of caring for patients with chronic illnesses for nursing practice.
5. Define and compare palliative and hospice care.
6. Describe the principles and components of hospice care.
7. Identify barriers to improving care at the end of life.
8. Identify and describe eight tasks that are essential for nurses to manage at the end of a patient's life.
9. Apply skills for communicating with terminally ill patients and their families.

Chronic diseases account for seven of the ten leading causes of death in the United States, including the four most frequently occurring diseases (heart disease, stroke, cancer, and diabetes) that result from preventable causes (tobacco use, improper diet and physical inactivity, and alcohol use). Chronic illnesses affect people of all ages and ethnic, cultural, and racial groups, although some illnesses occur more frequently in some groups than in others (Ward, Schiller, & Goodman, 2014). Although chronic disease occurs in all socioeconomic groups, people who have low incomes and disadvantaged backgrounds are more likely to report poor health (Blackwell, Lucas, & Clarke, 2014). Factors such as poverty and inadequate health insurance decrease the likelihood that people with chronic illness receive health care and preventative services (Office of Disease Prevention and Health Promotion, 2014).

Many people with chronic illnesses function independently with only minor inconvenience to their everyday lives; others require frequent and close monitoring or placement in long-term care facilities. Certain illnesses require advanced technology for survival, as in the late stages of amyotrophic lateral sclerosis or end-stage kidney disease, or intensive care for periods of weeks or months. People with diseases such as these have been described as chronically critically and progressively ill. Some chronic illnesses have little effect on quality of life, but others have a considerable effect because they can result in progressive decline. The nurse recognizes that many patients admitted to acute care institutions have pre-existing chronic diseases that must continue to be managed in concert

with their acute illnesses.

OVERVIEW OF CHRONICITY

Although each chronic disease has its own specific physiologic characteristics, chronic diseases do share common features. Many chronic diseases, for example, have pain and fatigue as associated symptoms. Usually some degree of physical decline is present in severe or advanced chronic illness, limiting the patient's participation in many activities. Many chronic diseases require therapeutic regimens to keep them under control. Unlike the term "acute," which implies a curable and relatively short course of disease, the term "chronic" describes a long course of disease and illnesses that may be incurable. This often makes managing chronic illnesses difficult for those who must live with them (Schulman-Green, Wagner, & McCorkle, 2015).

People who develop chronic illnesses may react with shock, disbelief, depression, anger, resentment, or a number of other emotions. How people react to and cope with chronic illness is usually similar to how they react to other events in their lives, depending, in part, on their understanding of the illness and their perceptions of its potential impact on their own and their family's lives. Adjustment to chronic illness is affected by various factors:

- Suddenness, extent, and duration of lifestyle changes necessitated by the illness
- Family and individual resources for dealing with stress
- Stages of individual/family life cycle
- Previous experience with illness and crises
- Underlying personality characteristics
- Unresolved anger or grief from the past

Psychological, emotional, and cognitive reactions to chronic illnesses are likely to occur at the onset of the illness and recur if symptoms worsen or reappear after a period of remission. Often symptoms associated with chronic illnesses are unpredictable and may be perceived as crisis events by patients and their families, who must contend with both the uncertainty of the chronic illness and the changes it brings to their lives. These possible effects can guide nursing assessment and interventions for the patient who has a chronic illness.

Definition of Chronic Illnesses

The literature does not support a single uniform definition for chronic disease, recurrent themes include the non–self-limited nature, the association with persistent and recurring health problems, and a duration measured in months and years, not days and weeks (Goodman, Posner, Huang, Parekh, & Koh, 2013). Traditionally, chronic diseases have focused on individual chronic pathologies. Now, however, health initiatives have expanded to include not only chronic disease but also chronic conditions such as functional limitations; anatomic problems that are not manifestations of physical disease but are permanent or long-standing; and a broad spectrum of behavioral health problems, some of which have traditionally not been classified as diseases (Goodman et al., 2013). The specific condition may be a result of illness, genetic factors, or injury; it may be a consequence of illnesses or unhealthy behaviors that began during childhood and young adulthood. Management of chronic illnesses includes learning to live with symptoms and coming to terms with identity changes resulting from having a chronic condition. It also consists of carrying out the lifestyle changes and regimens designed to control symptoms and to prevent complications. Although some people assume what might be called a "sick role" identity, most people with chronic illness wish to be involved in health care decision-making, and perform as active participants in their health care with preferences for their treatment and management of disease (Schulman-Green et al., 2015).

Prevalence and Causes of Chronic Illnesses

Chronic illnesses occur in people of every age group, socioeconomic level, and culture. In the United States, as of 2012, about half of all adults—117 million people—had one or more chronic health conditions. One of four adults had two or more chronic health conditions (Table 3-1) (Ward et al., 2014). As the incidence of chronic illnesses increases, the costs associated with these illnesses (i.e., hospital costs, equipment, medications, supportive services) also increase. Expenditures for health care for people with chronic illnesses exceed billions of dollars every year, and 86% of all health care spending in 2010 was for people with one or more chronic medical conditions in the United States (Gerteis et al., 2014).

TABLE 3-1 Percentage of Adults with Chronic Diseases in the United States (2013)

Chronic Diseases	Adults with the Disease (%)
Arthritis	23.7[a]
Asthma	9.0[a]
Cardiovascular Disease	
Hypercholesterolemia	33.6[a]
Hypertension	29.0[a]
Heart attack (myocardial infarction)	4.4
Angina or coronary artery disease	4.1
Stroke	2.8
Diabetes	8.9[a]
Physical, emotional, or psychological problems that causes limitations in activities	35.9[b]

[a]Age-adjusted prevalence%.
[b]Crude prevalence, data for disability among adults aged ≥65 years old (Year 2012).
Adapted from CDC (2015a, 2015b).

Although some chronic health illnesses cause little or no inconvenience, others are severe enough to cause major activity limitations. When people with activity limitations are unable to meet their needs for health care and personal services, they may be unable to carry out their therapeutic regimens or have their prescriptions filled on time, may miss appointments and office visits with their health care providers, and may be unable to carry out their activities of daily living (ADLs).

Chronic disease is a global issue that affects both rich and poor nations. With the advent and distribution of highly active antiretroviral therapies and other treatments for communicable diseases, and, thus, longer lifespans, the incidence of chronic illness is increasing in developing countries of the Global South, even while they try to cope with new and emerging infectious diseases. In developed Western countries of the Global North, chronic illnesses have become the major cause of health-related problems. The Global

North represents the economically developed societies of Europe, North America, Australia, Israel, South Africa, among others, the Global South represents the economically developing or less-developed countries of Africa, India, China, Brazil, Mexico among others.

Causes of the increasing number of people with chronic illnesses include the following:

- A decrease in mortality from infectious diseases, such as smallpox, diphtheria, and other serious illnesses
- Longer lifespans because of advances in technology and pharmacology, improved nutrition, safer working conditions, and greater access (for some people) to health care
- Improved screening and diagnostic procedures, enabling early detection and treatment of diseases
- Prompt and aggressive management of acute illnesses, such as myocardial infarction and AIDS-related infections
- The tendency to develop chronic illnesses with advancing age
- Lifestyle factors, such as smoking, chronic stress, and sedentary lifestyle, which increase the risk for chronic health problems such as respiratory disease, hypertension, cardiovascular disease, and obesity

Consequences of unhealthy lifestyles include an alarming increase in the incidence of diabetes, hypertension, obesity, and cardiac and chronic respiratory disorders. Physiologic changes in the body often occur before the appearance of symptoms of chronic disease. Therefore, the goal of emphasizing healthy lifestyles early in life is to improve overall health status and slow the development of such disorders.

Characteristics of Chronic Illnesses

Sometimes it is difficult for people who are disease-free to understand the often profound effect of chronic illness on the lives of patients and their families. It is easy for health professionals to focus on the illness itself while overlooking the person who has the disorder. In all illnesses, but even more so with chronic illnesses, the illness cannot be separated from the person. People with chronic illness must contend with it daily. To relate to what people must cope with or to plan effective interventions, nurses must understand what it means to have a chronic illness. Characteristics of chronic illness include the following:

- Managing chronic illness involves more than managing medical problems. Also associated psychological and social problems must be addressed because living for long periods with illness symptoms and disability can threaten identity, bring about role changes, alter body image, and disrupt lifestyles. These changes require continuous adaptation and accommodation, depending on age and situation in life. Each decline in functional ability requires physical, emotional, and social adaptation for patients and their families.
- Chronic illnesses usually involve many different phases over the course of a person's lifetime. There can be acute periods, stable and unstable periods, flare-ups, and remissions. Each phase brings its own set of physical, psychological, and social problems, and each requires its own regimens and types of management. Table 3-2 describes the phases in the trajectory model of chronic illness.
- Keeping chronic illnesses under control requires persistent adherence to therapeutic regimens. Failing to adhere to a treatment plan or to adhere consistently increases the risks of developing complications and accelerating the disease process. However, the realities of daily life, including the impact of culture, values, and socioeconomic factors, affect the degree to which people adhere to a treatment regimen. Managing a chronic illness takes time, requires knowledge and planning, and can be uncomfortable and inconvenient. It is not unusual for patients to stop taking medications or alter dosages because of side effects that are more disturbing or disruptive than symptoms of the illness, or to cut back on regimens they consider overly time-consuming, fatiguing, or costly.
- One chronic disease can lead to the development of other chronic illnesses. Diabetes, for example, can affect many parts of the body and is associated with serious complications, such as heart disease and stroke, blindness, kidney failure, and lower-limb amputation (Centers for Disease Control and Prevention [CDC], 2014). The presence of a chronic illness also contributes to a higher risk of morbidity and mortality in patients admitted to the intensive care unit with acute health illnesses.
- Chronic illness affects the entire family. Family life can be altered dramatically as a result of role reversals, unfilled roles, loss of income, time required to manage the illness, decreases in family socialization activities, and the costs of treatment. Stress and caregiver

fatigue are common with severe chronic illnesses, and the entire family rather than just the patient may need care. However, some families are able to master the treatment regimen and changes that accompany chronic illness, as well as make the treatment regimen a routine part of life. Furthermore, they are able to keep the chronic illness from becoming the focal point of family life.

- The day-to-day management of illness is largely the responsibility of people with chronic disorders and their families. As a result, the home, rather than the hospital, is the center of care in chronic illnesses. Hospitals, clinics, physicians' offices, nursing homes, nursing centers, and community agencies (home care services, social services, and disease-specific associations and societies) are considered adjuncts or backup services to daily home management.
- The management of chronic illnesses is a process of discovery. People can be taught how to self-manage their illnesses. However, each person must discover how his or her own body reacts under varying circumstances—for example, what it is like to be hypoglycemic, what activities are likely to bring on angina, and how these or other illnesses can best be prevented and managed.
- Managing chronic illnesses must be a collaborative process that involves many different health care professionals working together with patients and their families to provide the full range of services that often are needed for management at home. Often the medical, social, and psychological aspects of chronic health problems are complex, especially in severe illnesses. The goal is to help patients to self-manage and have ultimate responsibility for their own health.
- The management of chronic illnesses is expensive. Many of the expenses incurred by an individual patient (e.g., costs for hospital stays, diagnostic tests, equipment, medications, and supportive services) may be covered by health insurance and by federal and state agencies. However, the cost increases affect society as a whole as insurance premiums increase to cover these costs. Cost increases at the government level decrease resources that might benefit society. In addition, many out-of-pocket expenses are not reimbursed. Many people with chronic disorders, including the elderly and people who are working, are uninsured, or underinsured, and may be unable to afford the high costs of care often associated with chronic illnesses. Absence from work because of chronic disorders may jeopardize job security and income, and consequently health coverage.
- Chronic illnesses raise difficult ethical issues for patients, health care professionals, and society. Problematic questions include how to establish cost controls, how to allocate scarce resources (e.g., organs for transplantation), and what constitutes quality of life and when life support should be withdrawn.
- Living with chronic illness means living with uncertainty. Although health care providers may be aware of the usual progression of a chronic disease such as Parkinson disease, no one can predict with certainty a person's illness course because of individual variation. Even when a patient is in remission or symptom-free, he or she often fears that the illness will reappear.

TABLE 3-2 Phases in the Trajectory Model of Chronic Illness

Phase	Description	Focus of Nursing Care
Pre-trajectory	Genetic factors or lifestyle behaviors that place a person or community at risk for a chronic condition	Refer for genetic testing and counseling if indicated; provide education about prevention of modifiable risk factors and behaviors
Trajectory onset	Appearance or onset of noticeable symptoms associated with a chronic disorder; includes period of diagnostic workup and announcement of diagnosis; may be accompanied by uncertainty as patient awaits a diagnosis and begins to discover and cope with implications of diagnosis	Provide clear explanations of diagnostic tests and procedures and reinforce information and explanations given by primary health care provider; provide emotional support to patient and family
Stable	Illness course and symptoms are under control as symptoms, resulting disability and everyday life activities are being managed within limitations of illness; illness management centered in the home	Reinforce positive behaviors and offer ongoing monitoring; provide education about health promotion and encourage participation in health-promoting activities and health screening
Unstable	Characterized by an exacerbation of illness symptoms, development of complications, or reactivation of an illness in remission Period of inability to keep symptoms under control or reactivation of illness; difficulty in carrying out everyday life activities May require more diagnostic testing and trial of new treatment regimens or adjustment of current regimen, with care usually taking place at home	Provide guidance and support; reinforce previous teaching
Acute	Severe and unrelieved symptoms or the development of illness complications necessitating hospitalization, bed rest, or interruption of the person's usual activities to bring illness course under control	Provide direct care and emotional support to the patient and family members
Crisis	Critical or life-threatening situation requiring emergency treatment or care and suspension of everyday life activities until the crisis has passed	Provide direct care, collaborate with other health care team members to stabilize patient's condition
Comeback	Gradual recovery after an acute period and learning to live with or to overcome disabilities and return to an acceptable way of life within the limitations imposed by the chronic condition or disability; involves physical healing, limitations stretching through rehabilitative procedures, psychosocial coming-to-terms, and biographical reengagement with adjustments in everyday life activities	Assist in coordination of care; rehabilitative focus may require care from other health care providers; provide positive reinforcement for goals identified and accomplished
Downward	Illness course characterized by rapid or gradual worsening of a condition; physical decline accompanied by increasing disability or difficulty in controlling symptoms; requires biographical adjustment and alterations in everyday life activities with each major downward step	Provide home care and other community-based care to help patient and family adjust to changes and come to terms with these changes; assist patient and family to integrate new treatment and management strategies; encourage identification of end-of-life preferences and planning
Dying	Final days or weeks before death; characterized by gradual or rapid shutting down of body processes, biographical disengagement and closure, and relinquishment of everyday life interests and activities	Provide direct and supportive care to patients and their families through hospice programs

Adapted from Corbin, J. M. (1998). The Corbin and Stauss chronic illness trajectory model: An update. *Scholarly Inquiry for Nursing Practice*, *12*(1), 33–41.

Implications of Managing Chronic Illnesses

Chronic illnesses have implications for everyday living and management for people and their families as well as for society at large. Most importantly, individual efforts should be directed at preventing chronic illnesses, because many chronic illnesses or disorders are linked to unhealthy lifestyles or behaviors such as smoking, inactivity, and overeating. Therefore, changes in lifestyle can prevent some chronic disorders, or at least delay onset until a later age. Because most people resist change, bringing about alterations in people's lifestyles is a major challenge for nurses today.

Once a chronic condition has emerged, the focus shifts to managing symptoms, avoiding complications (e.g., eye complications in a person with diabetes), and avoiding the development of other acute illnesses (e.g., pneumonia in a person with chronic obstructive pulmonary disease). Quality of life, often overlooked by health professionals in their approach to people with chronic illnesses, is also important. Health-promoting behaviors, such as exercise, are essential to quality of life, even in people who have chronic illnesses, because regular exercise helps to maintain functional status.

Although coworkers, extended family, and health care professionals are affected by chronic illnesses, the problems of living with chronic illnesses are most acutely experienced by patients and their immediate families. They experience the greatest impact, with lifestyle changes that directly affect quality of life. Nurses provide direct care, especially during acute episodes, but they also provide the teaching and secure the resources and other supports that enable people to integrate their illness into their lives and to have an acceptable quality of life despite the illness. To understand what nursing care is needed, it is important to recognize and appreciate the issues that people with chronic illness and their families contend with and manage, often on a daily basis. The challenges of living with chronic illnesses include the need to accomplish the following:

- Alleviate and manage symptoms
- Psychologically adjust to and physically accommodate disabilities
- Prevent and manage crises and complications
- Carry out regimens as prescribed
- Validate individual self-worth and family functioning
- Manage threats to identity
- Normalize personal and family life as much as possible
- Live with altered time, social isolation, and loneliness
- Establish the networks of support and resources that can enhance quality of life
- Return to a satisfactory way of life after an acute debilitating episode (e.g., another myocardial infarction or stroke) or reactivation of a chronic condition
- Die with dignity and comfort

Many people with chronic illness must face an additional challenge: the need to deal with more than one chronic illness at a time. Multiple illnesses are termed comorbidities. The symptoms or treatment of a second chronic condition may aggravate the first chronic condition. Patients need to be able to deal with their various chronic illnesses separately, as

well as in combination. Some Medicare beneficiaries have 5 or more chronic illnesses, see an average of 12 physicians per year, and fill an average of 50 prescriptions per year (Gerteis et al., 2014). Furthermore, the effects of increasing longevity among Americans are likely to increase health care costs in the future.

Even more challenging for many people with chronic illness is the need to hire and oversee caregivers who come into their homes to assist with ADLs and instrumental activities of daily living (IADLs). ADLs and IADLs are the activities that let an individual live independently in a community such as preparing meals, shopping, telephone use, and taking medications correctly. It is difficult for many people to be in a position of hiring, supervising, and, sometimes, firing people who may provide them with intimate physical care. The need to balance the role of recipient of care and oversight of the person providing care may lead to blurring of role boundaries.

The challenges of living with and managing a chronic illness are well known, and people with chronic illnesses often report receiving inadequate care, information, services, and counseling. This provides an opportunity for nurses to be responsible for addressing many of the issues experienced, coordinating care, and serving as an advocate for patients and their families who need additional assistance to manage the patient's illness while maintaining a quality of life that is acceptable to all of them.

Phases of Chronic Illnesses

Chronic illnesses can pass through different phases, as described in Table 3-2. However, this course may be too uncertain to predict with any degree of accuracy. The course of an illness can be thought of as a trajectory that can be managed or shaped over time, to some extent, through proper illness management strategies. It is important to keep in mind that not all phases occur in all patients; some phases do not occur at all, and some phases may recur. Each phase is characterized by different medical and psychosocial issues. For example, the needs of a patient with a stroke who is a good candidate for rehabilitation are very different from those of a patient with terminal cancer. By thinking in terms of phases and individual patients within a phase, nurses can target their care more specifically to each person. Not every chronic condition is necessarily life-threatening, and not every patient passes through each possible phase of a chronic condition in the same order.

Using the trajectory model enables the nurse to put the current situation into the context of what might have happened to the patient in the past—that is, the life factors and understandings that might have contributed to the current state of the illness. In this way, the nurse can more readily address the underlying issues and problems.

NURSING CARE OF PATIENTS WITH CHRONIC ILLNESSES

Nursing care of patients with chronic illnesses is varied and occurs in a variety of settings. Care may be direct or supportive. *Direct care* may be provided in the clinic or health provider's office, the hospital, or the patient's home, depending on the status of the illness. Examples of direct care include assessing the patient's physical status, providing wound care, managing and overseeing medication regimens, and performing other technical tasks. The availability of this type of nursing care may allow the patient to remain at home and return to a more normal life after an acute episode of illness. *Supportive care* may include ongoing monitoring, teaching, counseling, serving as an advocate for the patient, navigating the system to coordinate care, making referrals, and case-managing. Giving supportive care is just as important as giving technical care. For example, through ongoing monitoring, either in the home or in a clinic, a nurse might detect early signs of impending complications and make a referral (i.e., contact the provider or consult the medical protocol in a clinic) for medical evaluation, thereby preventing a lengthy and costly hospitalization.

Working with people with chronic illness requires not only dealing with the medical aspects of their disorders but also working with the whole person—physically, emotionally, and socially. This holistic approach to care requires nurses to draw on their knowledge and skills, including knowledge from the social sciences and psychology in particular. Although quality of life usually is affected by chronic illness, especially if the illness is severe, patients' perceptions of what constitutes quality of life often drive their management behaviors or affect how they view advice about health care. Nurses and other health care professionals need to recognize this, even though it may be difficult to see patients make unwise choices and decisions about lifestyles and disease management. People have the right to receive care without fearing ridicule or refusal of treatment, even if their behaviors (e.g., smoking, substance abuse, overeating, and failure to follow health care providers' recommendations) may have contributed to their chronic disorder.

Unfolding Patient Stories: Skyler Hansen • Part 1

Skyler Hansen is an 18-year-old male recently diagnosed with type 1 diabetes. He lives with his parents and two younger siblings and is active in high school sports. He now requires insulin injections, glucose monitoring, and a diabetic diet. Examine how the psychological, physical, and teaching needs for managing a new diagnosis can be a great

source of stress to the patient and family. How can the nurse enhance their ability to cope with and adapt to diabetes management? (Skyler Hansen's story continues in Chapter 30.)

Care for Skyler and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

Skills for Communicating with the Chronically Ill

Nurses need to develop skill and comfort in assessing patients' and families' responses to chronic illness and planning interventions that will support their values and choices throughout the continuum of care. Patients and families need ongoing assistance: telling a patient something once is not teaching, and hearing the patient's words is not the same as active listening. Throughout the course of illness, patients and their families encounter complicated treatment decisions, bad news about disease progression, and recurring emotional responses. In addition to the time of initial diagnosis, lack of response to the treatment course, decisions to continue or withdraw particular interventions, and decisions about hospice care are examples of critical points on the treatment continuum that demand patience, empathy, and honesty from nurses. Discussing sensitive issues such as progressive illness, hopes for survival, and fears associated with death is never easy. However, the art of therapeutic communication can be learned and, like other skills, must be practiced to gain expertise. Similar to other skills, communication should be practiced in a "safe" setting, such as a classroom or clinical skills laboratory with other students or clinicians.

Although communication with each patient and family should be tailored to their particular level of understanding and values concerning disclosure, general guidelines for nurses include the following:

- Deliver and interpret the technical information necessary for making decisions without hiding behind medical terminology.
- Realize that the best time for the patient to talk may be when it is least convenient for you.
- Being fully present during any opportunity for communication is often the most helpful form of communication.
- Allow the patient and family to set the agenda regarding the depth of the conversation.
- Realize that beginning the conversation requires additional opportunities to continue the conversation.

When Patients and Families Receive Bad News

Communicating about a life-threatening diagnosis or about disease progression is best accomplished by the interdisciplinary team in any setting: a physician, advanced practice nurse, nurse, and social worker should be present whenever possible to provide information, facilitate discussion, and address concerns. Most importantly, the presence of the team conveys caring and respect for the patient and family. If the patient wishes to have family present for the discussion, arrangements should be made to have the discussion at a time that is best for everyone. A quiet area with a minimum of disturbances should be used. All clinicians present should turn off beepers, cell phones, and other electronic devices for the duration of the meeting and should allow sufficient time for the patient and family to absorb and respond to the news. Finally, the space in which the meeting takes place should be conducive to seating all participants at eye level.

After the initial discussion of a life-threatening illness or progression of a disease, the patient and family have many questions and may need to be reminded of factual information. Coping with news about a serious diagnosis or poor prognosis is an ongoing process. The nurse should be sensitive to these ongoing needs and may need to repeat previously provided information or simply be present while the patient and family react emotionally. Seriously ill patients and their families need time and support to cope with the changes brought about by changes in the patient's condition and the prospect of impending death. The nurse who is able to sit comfortably with another's suffering, time and time again, without judgment and without the need to solve the patient's and family's problems, provides an intervention that is a gift beyond measure.

THE CHANGING TRAJECTORY OF CHRONIC ILLNESS TO END-OF-LIFE CARE

As individuals become chronically ill, their health shifts between stable and unstable and acute and crisis events. During these periods of health status changes, patients will use increased health care services to regain their balance and recover. There are peaks and valleys to these patterns, and eventually patients reach a point from which they do not rebound, and they become progressively ill, decline, and die. It is during these periods of times when chronically ill patients come in contact with members of the health care team who should evaluate them for palliative and supportive services to enhance their care and improve and sustain their quality of living.

Providing end-of-life care for someone chronically ill is very different from providing it to someone who may have died suddenly from an accident, trauma, disaster, or homicide. When a death is sudden, there is tremendous shock and disbelief by the person's survivors that the person has died. The shock is compounded if the death was thought to be preventable, or if it resulted from a reckless act of irresponsibility, such as from a drunken driving accident. When a person has a chronic disease that progresses with a known trajectory, it gives the patient and family members opportunities to plan and participate in decisions about treatment choices and resources to use to facilitate their quality of life individually and as a family.

Sociocultural Context

Although each person experiences terminal illness uniquely, that illness is also shaped substantially by the social and cultural contexts in which it occurs. In the United States, life-threatening illness, life-sustaining treatment decisions, dying, and death occur in a social environment in which illness is largely considered a foe and battles are either lost or won (Benoliel, 1993). A care–cure dichotomy emerged early on in modern medicine, in which health care providers may view cure as the ultimate goal and care as second best, and only acceptable when cure is no longer possible. In this model of health care, alleviating suffering is not as valued as curing disease, and patients who cannot be cured feel distanced from the health care team, concluding that, when treatment has failed, they too have failed. Patients and families who have internalized the socially constructed meaning of care as second-best to cure may fear that any shift from curative goals in the direction of comfort-focused care will result in no care or lower-quality care, and that the clinicians on whom they have come to rely will abandon them if they withdraw from the battle for cure.

The reduction of patients to their diseases is exemplified in the frequently relayed message in late-stage illness that "nothing more can be done." This all-too-frequently used statement communicates the belief of many clinicians that there is nothing of value to offer patients who are beyond cure. In a care-focused perspective, mind, body, and spirit are inextricable, and treating the body without attending to the mind and spirit is considered inadequate to evoke true healing. The idea of healing as care, along with and beyond cure, implies that healing can take place throughout life and outside the boundaries of contemporary medicine. In this expanded definition, there continue to be opportunities for physical, spiritual, emotional, and social healing, even as body systems begin to fail at the end of life.

Clinicians' attitudes toward the terminally ill and dying remain the greatest barrier to improving care at the end of life. Kübler-Ross illuminated the concerns of the seriously ill and dying in her seminal work, *On Death and Dying,* published in 1969. At that time, it was common for patients to be kept uninformed about life-threatening diagnoses, particularly cancer, and for physicians and nurses to avoid open discussion of death and dying with their patients. Kübler-Ross taught the health care community that having open discussion about life-and-death issues did not harm patients and that the patients, in fact, welcomed such openness. She was openly critical of what she called "a new but depersonalized science in the service of prolonging life rather than diminishing human suffering" (Kübler-Ross, 1969). She taught the health care community that healing could not take place in a conspiracy of silence, and that as clinicians break the silence and enter the patient's world, they too can be enriched by being partners with their patients. Her work revealed that, given adequate time and some help in working through the process, patients could reach a stage of acceptance in which they were neither angry nor depressed about their fate.

Clinicians' reluctance to discuss disease and death openly with patients may stem from their own anxieties about death, as well as misconceptions about what and how much patients want to know about their illnesses. In a seminal study of care of the dying in hospital settings, sociologists Glaser and Strauss (1965) identified that health care professionals in hospital settings avoided direct communication about dying in hopes that

the patient would discover it on his or her own. They identified four "awareness contexts" that described awareness of the patient's status by providers, patients, and family members.

- *Closed awareness,* in which the patient is unaware of his or her terminal state
- *Suspected awareness,* in which the patient suspects what others know and attempts to find out details about his or her condition
- *Mutual pretense,* in which the patient, family, and providers are aware that the patient is dying but all pretend otherwise
- *Open awareness,* in which the patient, family, and providers are aware that the patient is dying and openly acknowledge that reality (Glaser & Strauss, 1965).

The two major reasons they identified that clinicians avoided direct communication with patients about the seriousness of their illness were (1) patients already knew the truth or would ask if they wanted to know, or (2) patients would subsequently lose all hope, give up, or be psychologically harmed by disclosure. Glaser and Strauss' findings were published decades ago, yet their observations remain valid today. Although a growing number of health care providers are becoming comfortable with assessing patients' and families' information needs and disclosing honest information about the seriousness of illness, many still avoid the topic of death in hope that the patient will ask or find out on his or her own. Despite progress on many health care fronts, those who work with dying patients have identified the persistence of a "conspiracy of silence" about dying.

The Importance of Palliative Care in Chronic Illness

As patients decline and treatments become complex, there has been an international recognition of the need to help patients transition from a cure orientation to one of care.

Palliative care and hospice care have been recognized as important bridges between a medical bias in the direction of cure-oriented treatment and the needs of the terminally ill patients and their families for comprehensive care in the final years, months, or weeks of life. This bridge has been built by experts in the field who advocate that palliative care needs to be extended throughout the course of life-threatening illness from the time when the patient is first diagnosed and not limited to end-of-life care (World Health Organization [WHO], 2015).

Palliative care encompasses a wide range of therapeutic interventions that aim to prevent and relieve suffering caused by multiple issues that patients and family caregivers face at any stage during an acute or chronic illness. In providing palliative care to the whole person (Lazenby, 2014), health care providers attend to all domains of the human experience of illness that may be involved: physical, psychological, social, and spiritual. A number of models of care have described the difference in these approaches to treatment. An exclusively "cure-oriented" approach to chronic illness care can be conceptualized in Figure 3-1; here, the treatment is compartmentalized by the type of illness and disease events. In Figure 3-2, the treatment of a disease diminishes over time as treatment becomes less effective. In Figure 3-3, "comfort care" is instituted when the patient with a chronic illness is not responding to the previous treatments and additional symptom management efforts are needed. Figure 3-4 illustrates how palliative care can begin at diagnosis and become integrated throughout the entire course of the chronic illness trajectory for the patient and family caregiver. Ideally, palliative care should precede the time when the provider recognizes that hospice care is needed. When palliative care coexists with disease-oriented treatment, patients and their families benefit from the more comprehensive management of the illness experience.

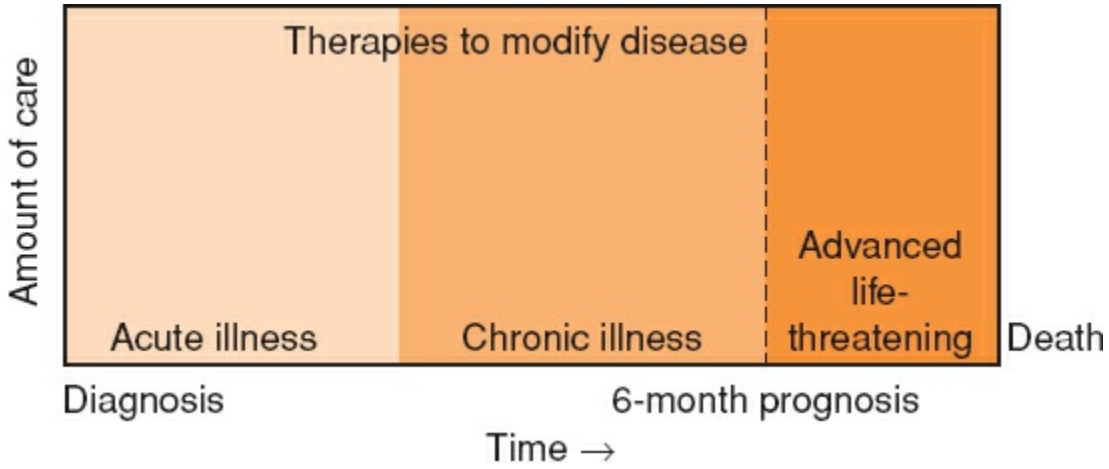

FIGURE 3-1 Model of cancer care in which only therapies directed at the disease are considered as part of standard care. From Irwin, S. A., & von Guntun, C. F. (2010). The role of palliative care in cancer care transitions. In J. C. Holland, W. S. Bretibart, P. B. Jacobsen, M. S. Lederberg, M. J. Loscalzo, & R. McCorkle (Eds.). *Psycho-Oncology* (2nd ed., pp. 277–283). New York: Oxford University Press.

Goal Setting in Palliative Care

As treatment goals begin to shift in the direction of comfort care over aggressive disease-focused treatment, symptom relief and patient- and family-defined quality of life assume greater prominence in treatment decision-making. Patients, families, and health care providers all may be accustomed to an almost automatic tendency to pursue exhaustive diagnostic testing to locate and treat the source of patients' illnesses or symptoms. Each decision to withdraw treatment or discontinue diagnostic testing is an extremely emotional one for the patient and family. They may fear that the support from health care providers on whom they have come to rely will be withdrawn along with the treatment.

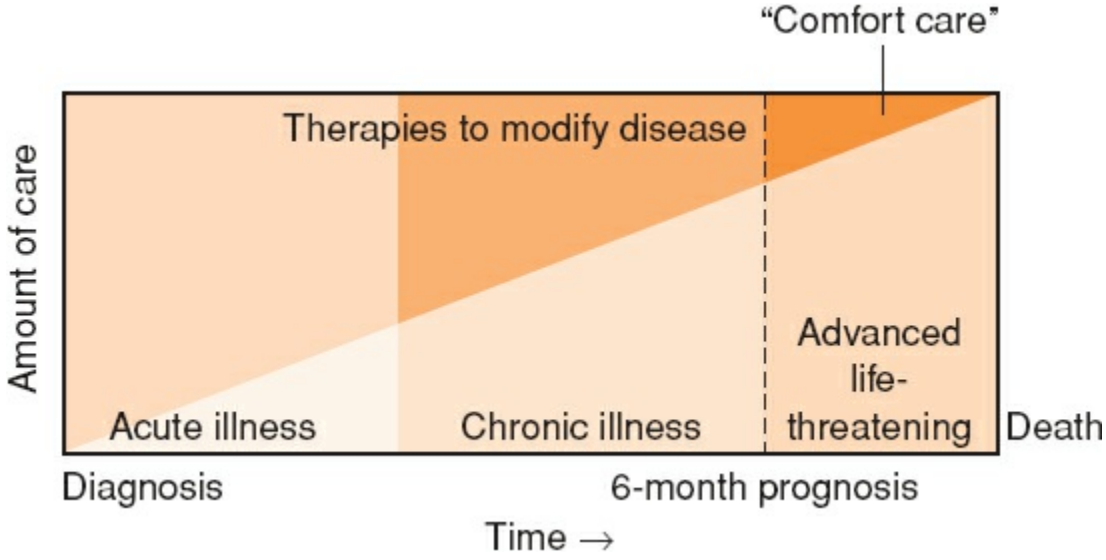

FIGURE 3-2 Model of cancer care in which antidisease treatment diminishes over time as it becomes less and less effective. From Irwin, S. A., & von Guntun, C. F. (2010). The role of palliative care in cancer care transitions. In J. C. Holland, W. S. Bretibart, P. B. Jacobsen, M. S. Lederberg, M. J. Loscalzo, & R. McCorkle (Eds.). *Psycho-Oncology* (2nd ed., pp. 277–283). New York: Oxford University Press.

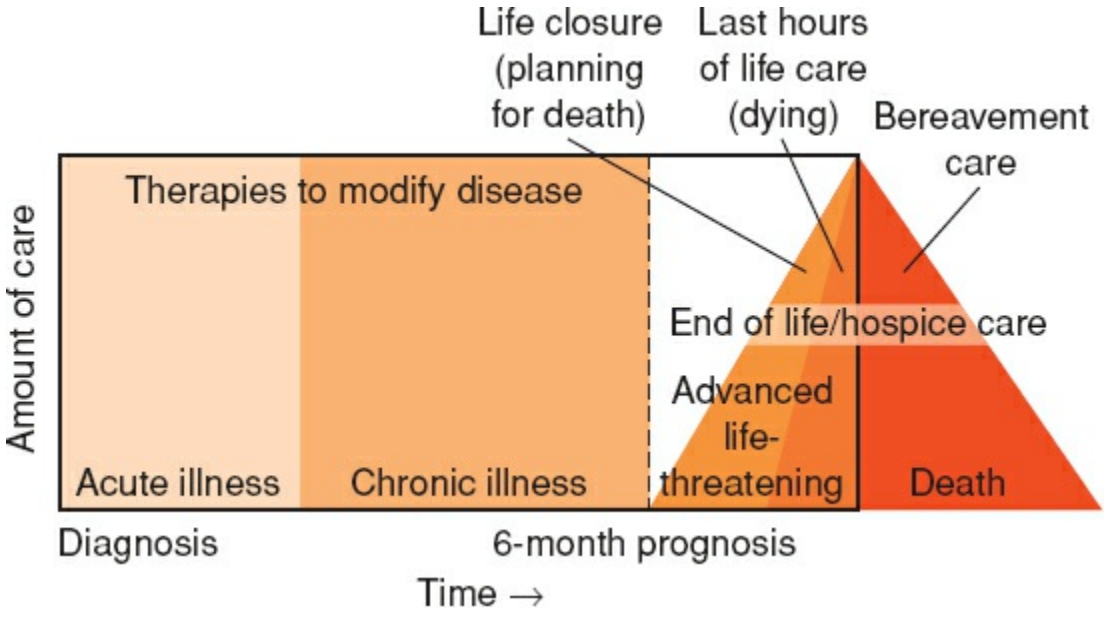

FIGURE 3-3 Model of cancer care in which palliative care begins after efforts directed at the disease end. From Irwin, S. A., & von Guntun, C. F. (2010). The role of palliative care in cancer care transitions. In J. C. Holland, W. S. Bretibart, P. B. Jacobsen, M. S. Lederberg, M. J. Loscalzo, & R. McCorkle (Eds.). *Psycho-Oncology* (2nd ed., pp. 277–283). New York: Oxford University Press.

Throughout the course of the illness, and especially as the patient's functional status and symptoms indicate approaching death, the provider should help the patient and family weigh the benefits of continued diagnostic testing and disease-focused medical treatment against the burdens of those activities. The patient and family may be extremely reluctant to forego monitoring that has become routine throughout the illness (e.g., blood testing, x-rays) but that may contribute little to comfort. Likewise, health care providers from other disciplines may have difficulty discontinuing such diagnostic testing or medical treatment.

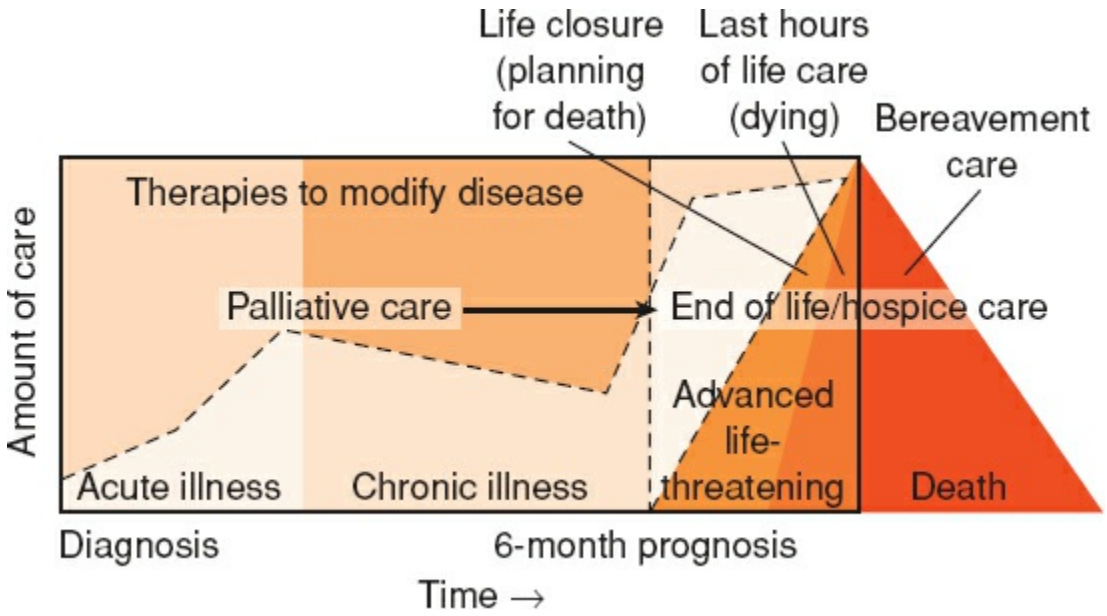

FIGURE 3-4 Model of cancer care in which palliative care begins at diagnosis and is integrated throughout the course of treatment. From Irwin, S. A., & von Guntun, C. F. (2010). The role of palliative care in cancer care transitions. In J. C. Holland, W. S. Bretibart, P. B. Jacobsen, M. S. Lederberg, M. J. Loscalzo, & R. McCorkle (Eds.). *Psycho-Oncology* (2nd ed., pp. 277–283). New York: Oxford University Press.

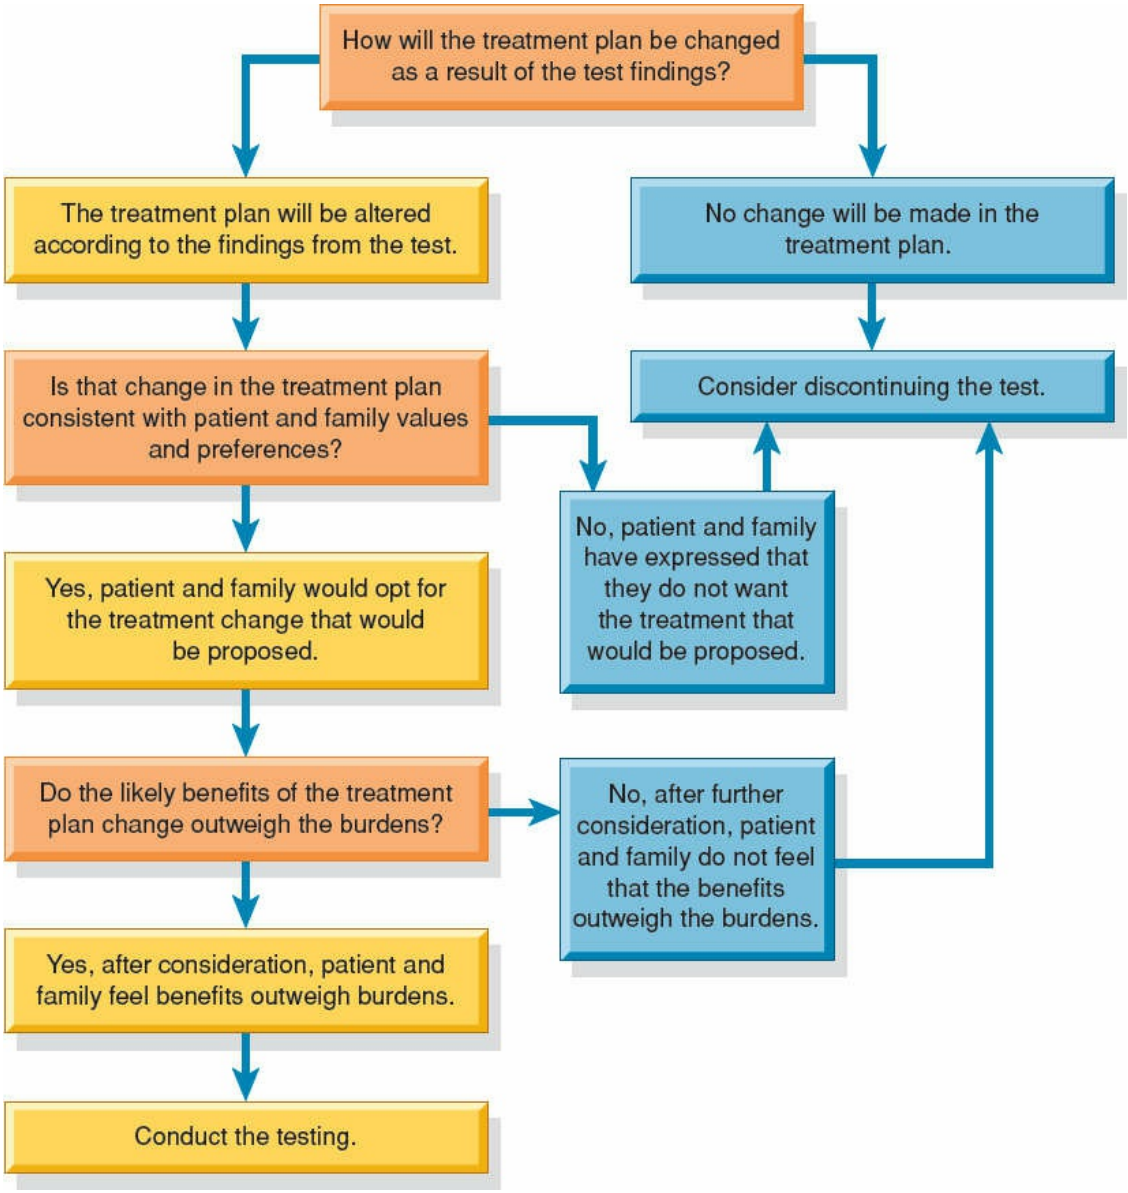

FIGURE 3-5 An algorithm for decision-making about diagnostic testing at the end of life.

Specifically, the nurse should collaborate with other members of the interdisciplinary team to share assessment findings and develop a coordinated plan of care (Fig. 3-5). In addition, the nurse should help the patient and family clarify their goals, expected outcomes, and values as they consider treatment options (Box 3-1). The nurse should work with interdisciplinary colleagues to ensure that the patient and family are referred for continuing psychosocial support, symptom management, and assistance with other care-related challenges (e.g., arrangements for home care or hospice support, referrals for financial assistance).

Hospice Care in the United States

The broadening of the concept of palliative care actually followed the development of the hospice movement in the United States. Hospice care is, in fact, palliative care. The difference is that hospice care is associated with the end of the patient's life, and although it focuses on quality of life, hospice care by necessity usually includes realistic emotional, social, spiritual, and financial preparation for death. The hospice movement in the United States is based on the belief that meaningful living is achievable during terminal illness and that it is best supported in the home, free from technologic interventions that prolong physiologic dying.

BOX 3-1 Assessing the Patient and Family Perspective: Goal Setting in Palliative Care

Patient and Family

- Awareness of diagnosis, illness stage, and prognosis: "Tell me your understanding of your illness right now."
- Values: "Tell me what is most important to you as you are thinking about the treatment options available to you/your loved one."
- Preferences: "You've said that being comfortable and pain-free is most important to you right now. Where would you like to receive care (home, hospital, long-term care facility, doctor's office), and how can I help?"
- Expected/desired outcomes: "What are your hopes and expectations for this (diagnostic test [e.g., CT scan] or treatment)?"
- Benefits and burdens: "Is there a point at which you would say that the testing or treatment is outweighed by the burdens it is causing you (e.g., getting from home to the hospital, pain, nausea, fatigue, interference with other important activities)?"

The landmark Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT Principal Investigators, 1995) documented troubling deficiencies in the care of the dying in hospital settings:

- Many patients received unwanted care at the end of life.
- Clinicians were not aware of patient preferences for life-sustaining treatment, even when preferences were documented in the clinical record.
- Often pain was poorly controlled at the end of life.
- Efforts to enhance communication were ineffective.

Despite more than 40 years of existence in the United States, hospice remains an option for end-of-life care that has not been integrated fully into mainstream health care. Although hospice care is available to people with any life-limiting condition, it has been used primarily by patients with advanced cancer, in which the disease staging and trajectory lend

themselves to more reliable prediction about the timing of a person's dying. Many reasons have been suggested to explain the reluctance of providers to refer patients to hospice and the reluctance of patients to accept this form of care. These include the difficulties in making a terminal prognosis and advances in "curative" treatment options in late-stage illness, as well as the values and attitudes of health care providers. The result is that patients who could benefit from the comprehensive, interdisciplinary support offered by hospice programs frequently do not enter hospice care until their final days (or hours) of life.

After hospice care was recognized as a distinct program of services under Medicare in the early 1980s, organizations providing hospice care were able to receive Medicare reimbursement if they could demonstrate that the hospice program met the Medicare "conditions of participation." State Medical Assistance (Medicaid) also provides coverage for hospice care, as do most commercial insurers. Federal reimbursement for hospice care ushered in a new era in hospice, in which program standards developed and published by the federal government codified what had formerly been a grassroots, loosely organized, and somewhat undefined ideal for care at the end of life. In many aspects, Medicare standards have come to largely define hospice philosophy and services.

In most programs, the Medicare definitions for patient eligibility are used to guide all enrollment decisions. According to Medicare, the patient who wishes to use his or her Medicare Hospice Benefit must be certified by a physician as terminally ill, with a life expectancy of 6 months or less if the disease follows its natural course (Box 3-2). Thus, hospice has come to be defined as care provided to terminally ill persons and their families in the last 6 months of the patient's life. Most hospice care is provided at the "routine home care" level and includes the services depicted in Box 3-3. Because of additional Medicare rules concerning completion of all cure-focused medical treatment before the Medicare Hospice Benefit may be accessed, many patients delay enrollment in hospice programs until very close to the end of life. Patients are reassessed for extension of eligibility at regular intervals, and then there is no limit on the amount of time a patient can spend under hospice care (The National Hospice and Palliative Care Organization [NHPCO], 2015).

BOX 3-2 Eligibility Criteria for Hospice Care

General

- Serious, progressive illness
- Limited life expectancy
- Informed choice of palliative care over cure-focused treatment

Hospice-Specific

- Presence of a family member or other caregiver continuously in the home when the patient is no longer able to safely care for him- or herself (some hospices have created special services within their programs for patients who live alone, but this varies widely)

Medicare and Medicaid Hospice Benefits

- Medicare Part A; Medical assistance eligibility
- Waiver of traditional Medicare/Medicaid benefits for the terminal illness
- Life expectancy of 6 months or less
- Provider certification of terminal illness
- Care must be provided by a Medicare-certified hospice program

Federal rules for hospices require that patients' eligibility be reviewed periodically. There is no limit to the length of time that eligible patients may continue to receive hospice care. Patients who live longer than 6 months under hospice care are not discharged if their physician and the hospice medical director continue to certify that the patient is terminally ill with a life expectancy of 6 months or less, assuming that the disease continues its expected course.

BOX 3-3 Home Hospice Services Covered Under the Medicare/Medicaid Hospice Benefit Routine Home Care Level

- Nursing care provided by or under the supervision of a registered nurse, available 24 hours a day
- Medical social services
- Physician's services
- Counseling services, including dietary counseling
- Home health aide/homemaker
- Physical/occupational/speech therapists
- Volunteers
- Bereavement follow-up (for up to 13 months after the death of the patient)
- Medical supplies for the palliation of the terminal illness
- Medical equipment for the palliation of the terminal illness
- Medications for the palliation of the terminal illness

NURSING CARE OF TERMINALLY ILL PATIENTS

Nurses can have a significant and lasting effect on the way in which patients live until they die, the manner in which the death occurs, and the enduring memories of that death for the patient's survivors. Knowledge about end-of-life principles of care and patients' and families' unique responses to illness is essential to supporting their unique values and goals (Box 3-4). There is an opportunity to bring research, education, and practice together to change the culture of dying, bringing much needed improvement to care that is relevant across practice settings, age groups, cultural backgrounds, and illnesses.

Factors that Influence Dying

Many factors can directly or indirectly affect how a person dies and what happens to one's body and one's survivors after death. It is useful for nurses to think of these factors as those that cannot be changed by one's actions and those that can be influenced in some fashion.

BOX 3-4 Nursing Research

Bridging the Gap to Evidence-Based Practice

The End-of-Life Nursing Education Consortium (ELNEC) project is a national education initiative to improve palliative care in the nursing community and make it readily available and accessible throughout the United States. In the year 2000, the City of Hope and the American Association of Colleges of Nursing (AACN) partnered to develop the ELNEC, with the intent to educate health professionals on how to address the unique needs of the dying and the dying process itself.

The project provides training in palliative care to undergraduate and graduate nursing faculty; CE providers; staff development educators; specialty nurses in pediatrics, oncology, critical care and geriatrics; and other nurses so they can teach this essential information to nursing students and practicing nurses. The project, which began in February 2000, was funded initially by a major grant from The Robert Wood Johnson Foundation (RWJF). Additional funding has been received from the National Cancer (NCI) and Open Society institutes; the Aetna, Archstone, Oncology Nursing, California HealthCare, Milbank, and Cambia Health foundations; and the Department of Veterans Affairs (VA).

The training is comprised of eight modules: an introduction to palliative nursing; pain management; symptom management; ethical issues; cultural and spiritual considerations; communication; loss, grief, and bereavement; and final hours.

The ELNEC curriculum has been translated into many languages, including Spanish, Russian, German, Korean, Japanese, Chinese, Romanian, Armenian, and Chinese.

From Ferrell, Malloy, & Virani (2015); American Association of Colleges of Nursing (AACN, 2015).

Unalterable Factors

Unalterable factors are those that are constant, including the age, gender, and personality of the dying person. Cultural attitudes toward death and dying also cannot be changed and must be taken into account in providing care. Other factors that need to be assessed, and that may affect a person's dying or bereavement, are previous experiences with illness and death, the type of disease of the dying person and its expected course, and the actual cause of death for the bereaved. Death by suicide or from neglected care will affect the family's recovery and grief process negatively compared to a death that is expected. The survivors of people who die suddenly or take their own lives have more emotional and physical problems than do survivors of people with long-term illnesses. In contrast, an expected

death provides opportunities for the family to bring closure to their relationships and participate in maintaining the dying person's comfort. Certain diseases are associated, with a trajectory or expected course of dying. Some patients will die very suddenly, and others will have ample time to participate in decisions surrounding their care. The nurse needs to understand the natural course of diseases and the changes that can be expected from treatment regimens in tandem with the responses of those family members left behind.

Changeable Factors

Changeable factors are those that can be influenced by nurses. These factors need ongoing reassessment because they *are* subject to change. These factors include the dying person's previous and current relationship with health care providers, the medical management of the illness, treatment effects, the projected prognosis, the meaning the dying person invests in the experience, and the resources available for support, including the primary caregiver's health and willingness to provide care. The overwhelming majority of patients repeatedly report they prefer to die at home, and if these factors are assessed and the patient's goals are taken into account, dying at home is possible for those patients and families who work together with the nurse and medical staff to accomplish the patient's wishes.

Critical Time Periods of Terminal Care

There are three critical time periods during terminal care: Before death, the death event, and bereavement. In each period, guiding principles can direct nursing care for people who are dying and for their survivors (Institute of Medicine [IOM], 2014). Although a dying person and the survivors progress sequentially through the three time periods of terminal care, unfortunately the same nurse does not care for the patient and family throughout all three phases; therefore, it is essential there is consensus about the critical aspects of care, so that continuity can be provided to the patient and family regardless of who the health care provider is.

Predeath Period

Quint-Benoliel (1967), in her landmark study of the nurse and the dying patient, determined that progressively ill patients need the opportunity for three kinds of experiences that are difficult to achieve in today's society. They need to (1) know what is happening to them and be able to talk about its reality with someone who will listen, (2) be allowed to experience the pain of "feeling bad" instead of having to hide their feelings to protect other people from the pain of their own feelings, and (3) participate in the decisions affecting how they will live their final days and how they will die (Quint, 1967). The primary responsibility of the nurse during the predeath period is to establish a relationship with the dying person. Through this relationship, the nurse should share information with the dying person about what is happening to him or her, as well as the available choices for care. It is important to establish this relationship while the dying person feels well enough to converse with the nurse about his or her goals and wishes as death approaches. It is primarily a time of assessment, not action, in which the nurse gathers data on how the person and family are coping with what is happening to them and how the options available fit within the person's lifestyle and goals for the future. Documentation regarding the person's disease state, responses to treatment, personal goals, and changes in family interactions is essential so that consistent care can be provided over time. As symptoms occur or change, the nurse elicits the meaning of the experience and helps the patient be informed about alternatives in treatment. Specific interventions are planned and evaluated after discussing with the patient the alternatives available, their effects, and long-term consequences.

The Death Event

Many people have misconceptions about how people die and whether dying patients are aware of what is happening to them. Most health care providers have seen people die only in institutional settings and when advanced medical technology had been used to sustain life. The majority of health care providers have not had an opportunity to witness a person dying without medical intervention and in the natural setting of home or another place of preference. Gradually, as the patient becomes more socially and physically dependent on others for assistance, the dying person and the family need increased supervision by providers. The primary purpose in being present as death becomes imminent is to anticipate problems, such as distressing symptoms or family disruptions, before they

interfere with the dying person's wishes. The best of plans, well made over a period of months or weeks of preparation, can easily be undermined unintentionally by any member of the health care team or family. Distressing symptoms that warrant hospitalization generally can be prevented if the nurse and provider are working closely together, and the family has the resources for maintaining the person in the home. Some patients may prefer to be institutionalized because they do not want to be a burden on their family.

If possible, the nurse is present when the patient dies or arranges to be called shortly thereafter, to assist with the preparation of the body and to support the family. If the patient dies in the hospital, the family needs ample time in private to be with the body. The nurse assists the family with answering questions, making telephone calls, and expressing grief. The nurse may assist with helping to clean the patient's room after the death. Some families may want these tasks done for them, and others have a need to do them themselves. Nothing should be removed without the family's permission. Once the death event is over, most nurses need an opportunity to debrief with someone they trust about the experience. It is important for nurses to develop a support network of their own to share their feelings and validate their care with others.

Bereavement

The third critical time period is the time after the death. Most members of the family may need several opportunities to relive the events surrounding the death, and the nurse is in a unique position to listen, having been a part of the experience. Often family and friends do not want to hear the events over and over from each other and frequently send messages that the grieving person should get on with living. Part of the support given in reliving the death experience involves reinforcing the family's sense that they did a good job supporting the dead person's wishes and communicating to the family that everything was done that could be done. The length of time a nurse sees a family for bereavement varies. Usually, at least 3 months are needed to assist with making decisions and disposing of the dead person's belongings as well as to assess the family's coping with the loss. Family members need encouragement not to act impulsively and to think through the consequences of their decisions. The nurse helps the family to discuss options available and to talk not only about the major loss associated with the death but also the consequential losses (e.g., financial, emotional, and social). If a family member needs additional help, the nurse can make a referral to a mental health provider, support group, or primary care provider.

Communicating with the Terminally Ill

To develop a level of comfort and expertise in communicating with seriously and terminally ill patients and their families, nurses and other clinicians should first consider their own experiences with and values concerning illness and death. Reflection, reading, and talking with family members, friends, and colleagues can help nurses examine beliefs about death and dying. Talking with people from different cultural backgrounds can help nurses view personally held beliefs through a different lens and can help nurses become sensitive to death-related beliefs and practices in other cultures. Discussion with nursing and nonnursing colleagues also can be useful; it may reveal the values shared by many health care professionals and identify diversity in the values of patients in their care. Values clarification and personal death awareness exercises can provide a starting point for self-discovery and discussion. Asking a person to share a personal experience of someone who has died and what that experience was like for the person is a place to start.

Ethical Decision-Making in End-of-Life Care

Nurses are responsible for educating patients about the possibilities and probabilities inherent in their illness and their life with the illness, and for supporting them as they conduct life review, values clarification, treatment decision-making, and end-of-life closure. The only way to do this effectively is to try to appreciate and understand the illness from the patient's perspective. It is also important that patients have had an opportunity to identify their preferences for how decisions are made at the end-of-life through legal documents recognized on a federal and state level (Box 3-5).

At the same time, nurses should be both culturally aware and sensitive in their approaches to communication with patients and families about death. Attitudes toward open disclosure about terminal illness vary widely among different cultures, and direct communication with patients about such matters may be viewed as harmful. To provide effective patient- and family-centered care at the end of life, nurses must be willing to set aside their own assumptions and attitudes so that they can discover what type and amount of disclosure is most meaningful to each patient and family within their unique belief systems.

Providing Culturally Sensitive Care at the End of Life

Although death, grief, and mourning are universally accepted aspects of living, one's values, expectations, and practices during serious illness, as death approaches, and after death are culturally bound and expressed. Health care providers may share very similar values concerning end-of-life care or may find that they are inadequately prepared to assess for and implement care plans that support culturally diverse perspectives. Historical mistrust of the health care system and unequal access to even basic medical care may underlie the beliefs and attitudes among ethnically diverse populations. In addition, lack of education or knowledge about end-of-life care treatment options and language barriers influence decisions among many socioeconomically disadvantaged groups.

Much of the formal structure concerning health care decisions in the United States is rooted in the Western notions of autonomy, truth telling, and the acceptability of withdrawing or withholding life-prolonging medical treatment at the end of life. In many cultures, however, interdependence is valued over autonomy, leading to communication styles that favor relinquishment of decision-making to family members or to perceived authority figures, such as physicians. In addition, there is variation in preference regarding the use of life-prolonging medical treatments such as cardiopulmonary resuscitation and artificially provided nutrition and hydration at the end of life; some groups are less likely to agree with withholding or withdrawing such life supports from the patient with a terminal illness.

The nurse's role is to assess the values, preferences, and practices of every patient, regardless of ethnicity, socioeconomic status, or background. The nurse can share knowledge about a patient's and family's cultural beliefs and practices with the health care team and facilitate the adaptation of the care plan to accommodate these practices. For example, a nurse may find that a male patient prefers to have his eldest son make all of his care decisions. Institutional practices and laws governing informed consent are also rooted in the Western notion of autonomous decision-making and informed consent. If a patient wishes to defer decisions to his son, the nurse can work with the team to negotiate informed consent, respecting the patient's right not to participate in decision-making and honoring his family's cultural practices.

BOX 3-5 Methods of Stating End-of-Life Preferences

Advance directives: Written documents that allow the individual of sound mind to document preferences regarding end-of-life care that should be followed when the signer is terminally ill and unable to communicate his or her wishes verbally. In general, the documents are completed in advance of serious illness but may be completed after a diagnosis of serious illness if the signer is still of sound mind. The most common types are the durable power of attorney for health care and the living will.

Durable power of attorney for health care: A legal document through which the signer appoints and authorizes another individual to make medical decisions on his or her

behalf when he or she is no longer able to speak for him- or herself. This is also known as a *health care power of attorney* or a *proxy directive.*

Living will: A type of advance directive in which the individual documents treatment preferences. It provides instructions for care in the event that the signer is terminally ill and not able to communicate his or her wishes directly and often is accompanied by a durable power of attorney for health care. This is also known as a *medical directive* or *treatment directive.*

Information about the advance care planning and state-specific advance directive documents and instructions are available from the website of Caring Connections (http://caringinfo.org). The legality of these documents may vary across states and within institutions, and it is important that people have someone they have spoken to and trust who can advocate for individual preferences if needed.

The nurse should assess and document the patient's and family's specific beliefs, preferences, and practices regarding end-of-life care, preparation for death, and after-death rituals. The nurse must use judgment and discretion about the timing and setting for eliciting this information. Some patients may wish to have a family member speak for them or may be unable to provide information because of advanced illness. The nurse should give the patient and family a context for the discussion, such as, "It is very important to us to provide care that addresses your needs and the needs of your family. We want to honor and support your wishes, and want you to feel free to tell us how we are doing, and what we could do to better meet your needs. I'd like to ask you some questions; what you tell me will help me to understand and support what is most important to you at this time. You don't need to answer anything that makes you uncomfortable. Is it all right to ask some questions?" The assessment of end-of-life beliefs, preferences, and practices probably should be carried out in short segments over a period of time (e.g., across multiple days of an inpatient hospital stay or in conjunction with multiple patient visits to an outpatient setting). The discomfort of novice nurses with asking questions and discussing this type of sensitive content can be reduced by prior practice in a classroom or clinical skills laboratory, observation of interviews conducted by experienced nurses, and partnering with experienced nurses during the first few assessments.

Symptom Management

Many patients suffer unnecessarily when they do not receive adequate attention for the symptoms accompanying serious illness. Careful evaluation of the patient should include not only the physical problems but also the psychological, social, and spiritual dimensions of the patient's and family's experience of serious illness. This approach contributes to a more comprehensive understanding of how the patient's and family's lives have been affected by illness and leads to nursing care that addresses the needs in every dimension.

Clinical depression should not be accepted as an inevitable consequence of dying, nor should it be confused with sadness and anticipatory grieving, which are normal reactions to the losses associated with impending death. Emotional and spiritual support and control of disturbing physical symptoms are appropriate interventions for situational depression associated with terminal illness. Cancer patients in advanced stages of the disease are especially vulnerable to delirium, depression, suicidal ideation, and severe anxiety. Higher levels of debilitation predict higher levels of pain and depressive symptoms, and the presence of pain increases the likelihood of developing major psychiatric complications of illness. Patients and their families must be given space and time to experience sadness and to grieve, but patients should not have to endure untreated depression at the end of their lives. An effective combined approach to clinical depression includes relief of physical symptoms, attention to emotional and spiritual distress, and pharmacologic interventions.

Patients approaching the end of life experience many of the same symptoms, regardless of their underlying disease processes. Symptoms in terminal illness may be caused by the disease, either directly (e.g., dyspnea due to chronic obstructive pulmonary disease) or indirectly (e.g., nausea and vomiting related to pressure in the gastric area); by the treatment for the disease; or by a coexisting disorder that is unrelated to the disease. Some of the most frequently encountered symptoms as death approaches include pain, dyspnea, anorexia and cachexia, delirium, and depression (Hinkle & Cheever, 2014). Chapter 7 presents assessment principles for pain that include identifying the effect of the pain on the patient's life, the importance of believing the patient's report of the pain and its effect, and the importance of systematic assessment of pain. Similarly, symptoms such as dyspnea, nausea, weakness, and anxiety should be carefully and systematically assessed and managed. Questions that guide the assessment of symptoms are listed in Box 3-6.

The patient's goals should guide symptom management. Medical interventions may be aimed at treating the underlying causes of the symptoms or reducing the impact of symptoms. For example, a medical intervention such as thoracentesis (an invasive procedure in which fluid is drained from the pleural space) may be performed to relieve dyspnea temporarily in a patient with pleural effusion secondary to lung cancer. Pharmacologic and nonpharmacologic methods for symptom management may be used in combination with medical interventions to modify the physiologic causes of symptoms. For example, in addition to having a thoracentesis, many patients find symptoms are reduced by the use of a handheld fan, which has been associated with a reduction in breathlessness (Galbraith, Fagan, Perkins, Lynch, & Booth, 2010). In addition, pharmacologic management with low-dose oral morphine is very effective in relieving dyspnea, and guided relaxation may reduce the anxiety associated with the sensation of breathlessness. As is true with pain, the principles of pharmacologic symptom management call for the use of the

smallest dose of the medication to achieve the desired effect, avoidance of polypharmacy, anticipation and management of medical side effects, and creation of a therapeutic regimen that is acceptable to the patient based on his or her goals for maximizing quality of life.

BOX 3-6 Assessing Symptoms Associated with Terminal Illness

Questions to consider:

- When did the symptom start?
- How long has the symptom been present?
- Has the symptom changed in any way?
- Is the symptom intermittent or constant/continuous?
- Are there any other symptoms?

(if symptom is pain specific)

- Does the pain radiate or move anywhere?
- What makes the pain worse or better?
- What has been tried to treat the pain? Has it helped? Are there side effects? What are the scheduled doses?
- What are the patient's goals and expectations regarding pain management for comfort and function? What about those of the family/caregivers?
- How much distress is the pain causing?
- What does the patient think that the pain means (e.g., tumor spread)?
- Who does the patient have for support? Are family members or others available?
- What are cultural, spiritual, or religious concerns about pain?

Adapted from Tickoo, Key, & Breitbart (2015); National Comprehensive Cancer Network (NCCN, 2014).

The patient's goals take precedence over the clinicians' goals to relieve all symptoms at all costs. Although clinicians may believe that symptoms must be relieved completely whenever possible, the patient might choose instead to decrease symptoms to a tolerable level rather than to relieve them completely if the side effects of medications are unacceptable to him or her. This often allows the patient to have greater independence, mobility, and alertness, and to devote attention to issues that he or she considers of higher priority and greater importance.

Anticipating and planning interventions for symptoms that have not yet occurred is a cornerstone of end-of-life care. Both patients and family members cope more effectively with new symptoms and exacerbations of existing symptoms when they know what to expect and how to manage it. Hospice programs typically provide "emergency kits" containing ready-to-administer doses of a variety of medications that are useful to treat symptoms in advanced illness. For example, a kit might contain small doses of oral morphine liquid for pain or shortness of breath, a benzodiazepine for restlessness, and an acetaminophen suppository for fever. Family members can be instructed to administer a prescribed dose from the emergency kit, often avoiding prolonged suffering for the patient

as well as rehospitalization for symptom management.

Pain Management

Numerous studies have shown that patients with advanced illness, particularly cancer, experience considerable pain. Pain is a significant symptom for many cancer patients throughout their treatment and disease course; it results from both the disease and the modalities used to treat it. Pain and suffering are among the most feared consequences of cancer. Poorly managed pain affects the psychological, emotional, social, and financial well-being of patients and families.

Patients who are taking an established regimen of analgesics should continue to receive those medications as they approach the end of life. Inability to communicate pain should not be equated with the absence of pain. Although most pain can be managed effectively using the oral route, as the end of life nears, patients may be less able to swallow oral medications due to somnolence or nausea. Patients who have been receiving opioids should continue to receive equianalgesic doses via rectal or sublingual routes. Concentrated morphine solution can be delivered very effectively by the sublingual route because the small liquid volume is well tolerated even if swallowing is not possible. As long as the patient continues to receive opioids, a regimen to combat constipation must be implemented. If the patient cannot swallow laxatives or stool softeners, rectal suppositories or enemas may be necessary.

The nurse should teach the family about continuation of comfort measures as the patient approaches the end of life, how to administer analgesics via alternative routes, and how to assess for pain when the patient cannot verbally report pain intensity. Because the analgesics administered orally or rectally are short-acting, typically scheduled as frequently as every 3 to 4 hours around the clock, there is always a strong possibility that a patient approaching the end of life will die in close proximity to the time of analgesic administration. If the patient is at home, family members administering analgesics should be prepared for this possibility. They need reassurance that they did not "cause" the death of the patient by administering a dose of analgesic medication.

Nutrition and Hydration at the End of Life

Anorexia and cachexia are common problems in the seriously ill. The profound changes in the patient's appearance and the concomitant lack of interest in the socially important rituals of mealtime are particularly disturbing to families. The approach to this problem varies depending on the patient's stage of illness, level of disability associated with the illness, and desires. The anorexia–cachexia syndrome is characterized by disturbances in carbohydrate, protein, and fat metabolism; endocrine dysfunction; and anemia. The syndrome results in severe asthenia (loss of energy).

Although causes of anorexia may be controlled for a period of time, progressive anorexia is an expected and natural part of the dying process. Anorexia may be related to or exacerbated by situational variables (e.g., the ability to have meals with the family vs. eating alone in the "sick room"), progression of the disease, treatment for the disease, or psychological distress. The patient and family should be instructed in strategies to manage the variables associated with anorexia (Table 3-3).

A number of pharmacologic agents are commonly used to stimulate appetite in anorexic

patients. Commonly used medications for appetite stimulation include dexamethasone (Decadron), megestrol acetate (Megace), and dronabinol (Marinol). Although several of these agents may result in temporary weight gain, their use is not associated with an increase in lean body mass in the terminally ill patient.

TABLE 3-3 Measures for Managing Anorexia

Nursing Interventions	Patient and Family Teaching Tips
Initiate measures to ensure adequate dietary intake without adding stress to the patient at mealtimes.	Reduce the focus on "balanced" meals; offer the same food as often as the patient desires it.
Assess the impact of medications (e.g., chemotherapy, antiretrovirals) or other therapies (radiation therapy, dialysis) that are being used to treat the underlying illness. Administer and monitor effects of prescribed treatment for nausea, vomiting, and delayed gastric emptying.	Increase the nutritional value of meals. For example, add dry milk powder to milk, and use this fortified milk to prepare cream soups, milkshakes, and gravies.
Encourage patient to eat when effects of medications have subsided.	Allow and encourage the patient to eat when hungry, regardless of usual meal times.
Assess and modify environment to eliminate unpleasant odors and other factors that cause nausea, vomiting, and anorexia.	Eliminate or reduce noxious cooking odors, pet odors, or other odors that may precipitate nausea, vomiting, or anorexia.
Remove items that may reduce appetite (soiled tissues, bedpans, emesis basins, clutter).	Keep patient's environment clean, uncluttered, and comfortable.
Assess and manage anxiety and depression to the extent possible.	Make mealtime a shared experience away from the "sick" room whenever possible. Reduce stress at mealtimes. Avoid confrontations about the amount of food consumed. Reduce or eliminate routine weighing of the patient.
Position to enhance gastric emptying.	Encourage patient to eat in a sitting position; elevate the head of the patient's bed. Plan meals (food selection and portion size) that the patient desires.
Assess for constipation and/or intestinal obstruction.	Provide small, frequent meals if they are easier for patient to eat. Ensure that patient and family understand that prevention of constipation is essential, even when the patient's intake is minimal.
Prevent and manage constipation on an ongoing basis, even when the patient's intake is minimal.	Encourage adequate fluid intake, dietary fiber, and use of bowel program to prevent constipation.
Provide frequent mouth care, particularly following nourishment.	Assist the patient to rinse after every meal. Avoid mouthwashes that contain alcohol or glycerine, which dry mucous membranes.
Ensure that dentures fit properly.	Weight loss may cause dentures to loosen and cause irritation. Remove them to inspect the gums and to provide oral care.
Administer and monitor effects of topical and systemic treatment for oropharyngeal pain.	The patient's comfort may be enhanced if medications for pain relief given on an as-needed basis for breakthrough pain are administered before mealtimes.

Dexamethasone initially increases appetite and may provide short-term weight gain in some patients. However, therapy may need to be discontinued in patients with a longer life expectancy, because after 3 to 4 weeks, corticosteroids interfere with the synthesis of muscle protein.

Megestrol acetate produces temporary weight gain of primarily fatty tissue, with little effect on protein balance. Because of the time required to see any effect from this agent, therapy should not be initiated if life expectancy is less than 30 days.

Dronabinol is a psychoactive compound found in cannabis that may be helpful in reducing nausea and vomiting, appetite loss, pain, and anxiety, thereby improving food and

fluid intake in some patients. However, dronabinol is not as effective as the other agents for appetite stimulation in most patients.

Cachexia

Cachexia refers to severe muscle wasting and weight loss associated with illness. Although anorexia may exacerbate cachexia, it is not the primary cause. Cachexia is associated with changes in metabolism that include hypertriglyceridemia, lipolysis, and accelerated protein turnover, leading to depletion of fat and protein stores. However, the pathophysiology of cachexia in terminal illness is not well understood. In terminal illness, the severity of tissue wasting is greater than would be expected from reduced food intake alone, and typically increasing appetite or food intake does not reverse cachexia in the terminally ill.

Anorexia and cachexia differ from starvation (simple food deprivation) in several important ways. In the case of anorexia and cachexia, appetite is lost early in the process, the body becomes catabolic in a dysfunctional way, and supplementation by gastric feeding (tube feeding) or parenteral nutrition in advanced disease does not replenish lean body mass that has been lost. At one time, it was believed that cancer patients with rapidly growing tumors developed cachexia because the tumor created an excessive nutritional demand and diverted nutrients from the rest of the body. Research links cytokines produced by the body in response to a tumor to a complex inflammatory-immune response present in patients whose tumors have metastasized, leading to anorexia, weight loss, and altered metabolism.

Artificial Nutrition and Hydration 

Along with breathing, eating and drinking are essential to survival throughout life. Near the end of life, the body's nutritional needs change, and the desire for food and fluids may diminish. People may no longer be able to use, eliminate, or store nutrients and fluids adequately. For patients with progressive illness, food preparation and mealtimes often become battlegrounds in which well-meaning family members argue, plead, and cajole to encourage ill people to eat. It is not unusual for seriously ill patients to lose their appetites entirely, to develop strong aversions for foods they have enjoyed in the past, or to crave a particular food to the exclusion of all other foods.

Although nutritional supplementation may be an important part of the treatment plan in early or chronic illness, unintended weight loss and dehydration are expected sequelae of progressive illness. As illness progresses, patients, families, and clinicians may believe that, without artificial nutrition and hydration, terminally ill patients will "starve," causing profound suffering and hastened death. However, starvation should not be viewed as the failure to implant tubes for nutritional supplementation or hydration of terminally ill patients with irreversible progression of disease. Studies have demonstrated that terminally ill patients who were hydrated had neither improved biochemical parameters nor improved states of consciousness. Similarly, survival was not increased when terminally ill patients with advanced dementia received enteral feeding. Furthermore, in patients who are close to death, there are beneficial effects to withholding or withdrawing artificial nutrition and hydration, such as decreased complications associated with tube feeding or total parenteral nutrition, which include dislodgement, infection, discomfort, and aspiration (Capasso, Kim, & Perret, 2013).

As the patient approaches the end of life, the family and health care providers should offer the patient what he or she prefers and can tolerate most easily. The nurse should instruct the family how to separate feeding from caring, demonstrating love, and sharing by being with the loved one in other ways. Preoccupation with appetite, feeding, and weight loss diverts energy and time that the patient and family could use in other meaningful activities. Here are tips to promote nutrition for terminally ill patients:

- Offer small portions of favorite foods.
- Do not be overly concerned about a "balanced" diet.
- Cool foods may be better tolerated than hot foods.
- Offer cheese, eggs, peanut butter, mild fish, chicken, or turkey. Meat (especially beef) may taste bitter and unpleasant.
- Add milkshakes, powdered instant drinks, or other liquid supplements.
- Add dry milk powder to milkshakes and cream soups to increase protein and calorie content.
- Place nutritious foods at the bedside (fruit juices, milkshakes in insulated drink containers with straws).
- Schedule meals when family members can be present to provide company and stimulation.
- Avoid arguments at mealtime.
- Help the patient to maintain a schedule of oral care. Rinse the mouth after each meal or snack. Avoid mouthwashes that contain alcohol. Use a soft toothbrush. Treat oral ulcers or lesions. Make sure dentures fit well.
- Treat pain and other symptoms.
- Offer ice chips made from frozen fruit juices.
- Allow the patient to refuse foods and fluids.

Changes in Consciousness and Delirium

Many patients remain alert, arousable, and able to communicate until very close to death. Others sleep for long intervals and awaken only intermittently, with eventual somnolence until death. Delirium refers to concurrent disturbances in level of consciousness, psychomotor behavior, memory, thinking, attention, and sleep–wake cycle. In some patients, a period of agitated delirium precedes death, sometimes causing families to be hopeful that patients who are suddenly active may be getting better. Confusion may be related to underlying, treatable conditions such as medication side effects or interactions, pain or discomfort, hypoxia or dyspnea, or a full bladder or impacted stool. In patients with cancer, confusion may be secondary to brain metastases. Delirium also may be related to metabolic changes, infection, and organ failure.

Patients with delirium may become hypoactive or hyperactive, restless, irritable, and fearful. Sleep deprivation and hallucinations may occur. If treatment of the underlying factors contributing to these symptoms brings no relief, a combination of pharmacologic intervention with neuroleptics or benzodiazepines may be effective in decreasing distressing symptoms. Haloperidol (Haldol) may reduce hallucinations and agitation (Powney, Adams, & Jones, 2012). Benzodiazepines (e.g., lorazepam [Ativan]) can reduce anxiety but do not

clear the sensorium and may contribute to worsening cognitive impairment if used alone.

Nursing interventions are aimed at identifying the underlying causes of delirium, acknowledging the family's distress over its occurrence, reassuring family members about what is normal, teaching family members how to interact with and ensure safety for the patient with delirium, and monitoring the effects of medications used to treat severe agitation, paranoia, and fear. Confusion may mask the patient's unmet needs and fears about dying. Spiritual intervention, music therapy, gentle massage, and therapeutic touch may provide some relief. Reduction of environmental stimuli, avoidance of harsh lighting or very dim lighting (which may produce disturbing shadows), presence of familiar faces, and gentle reorientation and reassurance are also helpful.

Dyspnea

Dyspnea is an uncomfortable awareness of breathing or breathlessness that is common in patients approaching the end of life. Dyspnea is a highly subjective symptom that often is not associated with visible signs of distress, such as tachypnea, diaphoresis, or cyanosis. Patients with primary lung tumors, lung metastases, pleural effusion, or obstructive lung disease may experience significant dyspnea. Although the underlying cause of the dyspnea can be identified and treated in some cases, the burdens of additional diagnostic evaluation and treatment aimed at the physiologic problem may outweigh the benefits. The treatment of dyspnea varies depending on the patient's general physical condition and imminence of death. For example, a blood transfusion may provide temporary symptom relief for a patient with anemia earlier in the disease process; however, as the patient approaches the end of life, the benefits are typically short-lived or absent. As with assessment and management of pain, reports of dyspnea by patients must be believed. As is true for physical pain, what dyspnea means to an individual patient may increase his or her suffering. For example, the patient may interpret increasing dyspnea as a sign that death is approaching. For some patients, sensations of breathlessness may invoke frightening images of drowning or suffocation, and the resulting cycle of fear and anxiety may increase the sensation of breathlessness. Therefore, the nurse should conduct a careful assessment of the psychosocial and spiritual components of the dyspnea. Physical assessment parameters include:

- Symptom intensity, distress, and interference with activities (scale of 0 to 10)
- Auscultation of lung sounds
- Assessment of fluid balance
- Measurement of dependent edema (circumference of lower extremities)
- Measurement of abdominal girth
- Temperature
- Skin color
- Sputum quantity and character
- Cough

To determine the intensity of dyspnea and its interference with daily activities, the nurse can ask the patient to report the severity of the dyspnea using a scale of 0 to 10, where 0 is no dyspnea and 10 is the worst imaginable dyspnea. Ongoing objective evidence for the

efficacy of the treatment plan is provided by the patient's baseline measurement before treatment and then subsequent measurements taken during exacerbation of the symptom, periodically during treatment, and whenever the treatment plan changes. In addition, physical assessment findings may assist in locating the source of the dyspnea and selecting appropriate nursing interventions to relieve the symptom. The components of the assessment change as the patient's condition changes. Like other symptoms at the end of life, dyspnea can be managed effectively in the absence of assessment and diagnostic data that are standard when a patient's illness or symptom is reversible (i.e., arterial blood gases).

Nursing management of dyspnea at the end of life is directed toward administering medical treatment for the underlying pathology, monitoring the patient's response to treatment, helping the patient and family manage anxiety (which exacerbates dyspnea), altering the perception of the symptom, and conserving energy (Box 3-7). Pharmacologic intervention is aimed at modifying lung physiology and improving performance, as well as in altering the perception of the symptom. Bronchodilators and corticosteroids are examples of medications used to treat underlying obstructive pathology, thereby improving overall lung function. Low doses of opioids are very effective in relieving dyspnea, although the mechanism of relief is not entirely clear. Although dyspnea in terminal illness is typically not associated with diminished blood oxygen saturation, low-flow oxygen often provides psychological comfort to both patients and families, particularly in the home setting.

As previously mentioned, dyspnea may be exacerbated by anxiety, and anxiety may trigger episodes of dyspnea, setting off a respiratory crisis in which the patient and family may panic. For patients receiving care at home, patient and family instruction should include anticipation and management of crisis situations and a clearly communicated emergency plan. The patient and family should be instructed about medication administration, condition changes that should be reported to the provider and nurse, and strategies for coping with diminished reserves and increasing symptomatology as the disease progresses. The patient and family need reassurance that the symptom can be managed effectively at home without the need for activation of the emergency medical services or hospitalization, and that a nurse will be available at all times via telephone or to make a visit.

BOX 3-7 Palliative Nursing Interventions for Dyspnea

Decrease Anxiety

- Administer prescribed anxiolytic medications as indicated for anxiety or panic associated with dyspnea.
- Assist with relaxation techniques, guided imagery.
- Provide the patient with a means to call for assistance (call bell/light within reach in a hospital or long-term care facility; handheld bell or other device for home).

Treat Underlying Pathology

- Administer prescribed bronchodilators and corticosteroids (obstructive pathology).
- Administer blood products, erythropoietin as prescribed (typically not beneficial in

advanced stages of disease).
- Administer prescribed diuretics and monitor fluid balance.

Alter Perception of Breathlessness

- Administer prescribed oxygen therapy via nasal cannula, if tolerated; masks may not be well tolerated.
- Administer prescribed low-dose opioids via oral route (morphine sulfate is used most commonly).
- Provide air movement in the patient's environment with a portable fan or a cool draft of air as from a handheld fan.

Reduce Respiratory Demand

- Teach the patient and family to implement energy conservation measures.
- Place needed equipment, supplies, and nourishment within reach.
- For home or hospice care, offer a bedside commode, electric bed (with head that elevates).

Secretions

If family members have been prepared for the time of death, they are less likely to panic and are better able to be with their loved ones in a meaningful way. Noisy, gurgling breathing or moaning is generally most distressing to family members. In most cases, the sounds of breathing at the end of life are related to oropharyngeal relaxation and diminished awareness. Family members may have difficulty believing that the patient is not in pain or that the patient's breathing could not be improved by suctioning secretions. Patient positioning and family reassurance are the most helpful responses to these symptoms.

When death is imminent, patients may become increasingly somnolent and unable to clear sputum or oral secretions, which may lead to further impairment of breathing from pooled or dried and crusted secretions. Often the sound ("terminal bubbling") and appearance of the secretions are more distressing to family members than is the presence of the secretions to the patient. Family distress over the changes in the patient's condition may be eased by supportive nursing care. Continuation of comfort-focused interventions and reassurance that the patient is not in any distress can do much to ease family concerns. Gentle mouth care with a moistened swab or very soft toothbrush helps maintain the integrity of the patient's mucous membranes. In addition, gentle oral suctioning, positioning to enhance drainage of secretions, and sublingual or transdermal administration of anticholinergic drugs reduces the production of secretions and provides comfort to the patient and support to the family. Deeper suctioning may cause significant discomfort to the dying patient and is rarely of any benefit, because secretions reaccumulate rapidly. Based on the authors' clinical experience, if anticholinergic drugs are used prophylactic prior to secretions occurring, the drug has an increased chance of being effective. Mercadamte (2014) made a similar suggestion that anticholinergics be used before starting

palliative sedation. Refer to Table 3-4 for pharmacologic management of excess oral/respiratory secretions with dying patients.

Palliative Sedation at the End of Life

Effective control of symptoms can be achieved under most conditions, but some patients may experience distressing, intractable symptoms. Although palliative sedation remains controversial, it is offered in some settings to patients who are close to death or who have symptoms that do not respond to conventional pharmacologic and nonpharmacologic approaches, resulting in unrelieved suffering. Palliative sedation is distinguished from euthanasia or physician-assisted suicide in that the intent of palliative sedation is to relieve symptoms, not to hasten death. Palliative sedation is most commonly used when the patient exhibits intractable pain, dyspnea, seizures, or delirium, and it is generally considered appropriate in only the most difficult situations. Before implementing palliative sedation, the health care team should assess for the presence of underlying and treatable causes of suffering, such as depression or spiritual pain. Finally, the patient and family should be informed fully about the use of this treatment and alternatives.

TABLE 3-4 Pharmacologic Management of Excess Oral/Respiratory Secretions When Death is Imminent

Medication	Dose
Atropine sulfate drops 1%	1 or 2 drops 1% PO/sublingual q4–6h p.r.n. or around the clock (ATC) up to 12 drops/d
Atropine injection	0.4–0.6 mg IV/SC/IM q4–6h p.r.n. or ATC (if PO therapy is ineffective)
Glycopyrrolate (Robinul)	1–2 mg PO/rectal/sublingual TID p.r.n. or ATC (maximum dose 6 mg/d)
Hyoscyamine (Levsin)	0.125–0.25 mg PO/sublingual q4–6h p.r.n. or ATC (maximum dose 1.5 mg/d)
Scopolamine (Transderm Scop)	1–3 patches q3d (maximum dose 3 patches every 72 h)

Palliative sedation is accomplished through infusion of sedative drugs such as benzodiazepines to achieve the desired level of sedation to provide relief from the refractory symptoms in the last hours and days of life (Beller, Driel, McGregor, Truong, & Mitchell,

2015). Nurses act as collaborating members of the interdisciplinary health care team, providing emotional support to patients and families, facilitating clarification of values and preferences, and providing comfort-focused physical care. Once sedation has been induced, the nurse should continue to comfort the patient, monitor the physiologic effects of the sedation, support the family during the final hours or days of their loved one's life, and maintain communication within the health care team and between the team and family.

NURSING CARE OF PATIENTS AND FAMILIES IN THE FINAL HOURS OF LIFE

Providing care to patients who are close to death and being present at the time of death can be one of the most rewarding experiences a nurse can have. Patients and their families are understandably fearful of the unknown, and the approach of death may prompt new concerns or cause previous fears or issues to resurface. Family members who have always had difficulty communicating or who are part of families in which there are old resentments and hurts may experience heightened difficulty as their loved ones near death. In contrast, the time at the end of life can also afford opportunities to resolve old hurts and learn new ways of being a family. Regardless of the setting, skilled practitioners can make the dying patient comfortable, make space for their loved ones to remain present when they wish, and can give family members the opportunity to experience growth and healing. Likewise, regardless of setting, the patient and family may be less apprehensive near the time of death if they know what to expect and how to respond.

Expected Physiologic Changes

As death approaches and organ systems begin to fail, observable, expected changes in the body take place. Nursing care measures aimed at patient comfort should be continued: pain medications (administered rectally or sublingually), turning, mouth care, eye care, positioning to facilitate draining of secretions, and measures to protect the skin from urine or feces (if the patient is incontinent) should be continued. The nurse should consult with the provider about discontinuing measures that no longer contribute to patient comfort, such as drawing blood, administering tube feedings, suctioning (in most cases), and invasive monitoring. The nurse should prepare the family for the normal, expected changes that accompany the period immediately preceding death. Although the exact time of death cannot be predicted, it is often possible to identify when the patient is very close to death. Hospice programs frequently provide written information for families so they know what to expect and what to do as death nears (Box 3-8).

Although every death is unique, it is often possible for experienced clinicians to assess that the patient is "actively" or imminently dying and to prepare the family in the final days or hours leading to death. As death nears, the patient may withdraw, sleep for longer intervals, or become somnolent. Family members should be encouraged to be with the patient, to speak and reassure the patient of their presence, to stroke or touch the patient, or to lie alongside the patient (even in the hospital or long-term care facility) if the family members are comfortable with this degree of closeness and can do so without causing discomfort to the patient.

The family may have gone to great lengths to ensure that their loved one will not die alone. However, despite the best intentions and efforts of the family and clinicians, the patient may die at a time when no one is present. In any setting, it is unrealistic for family members to be at the patient's bedside 24 hours a day, and it is not unusual for a patient to die when family members have stepped away from the bedside just briefly. Experienced hospice clinicians have observed and reported that some patients appear to "wait" until family members are away from the bedside to die, perhaps to spare their loved ones the pain of being present at the time of death. Nurses can reassure family members throughout the death vigil by being present intermittently or continuously, modeling behaviors (such as touching and speaking to the patient), providing encouragement in relation to family caregiving, providing reassurance about normal physiologic changes, and encouraging family rest breaks. If a patient dies while family members are away from the bedside, they may express feelings of guilt and profound grief and may need emotional support.

After-Death Care

The time of death is generally preceded by a period of gradual diminishment of bodily functions in which increasing intervals between respirations, a weakened and irregular pulse, diminishing blood pressure, and skin color changes or mottling may occur. For patients who have received adequate management of symptoms and for families who have received adequate preparation and support, the actual time of death is commonly peaceful and occurs without struggle. Nurses may or may not be present at the time of a patient's death. In many states, nurses may be authorized to make the pronouncement of death and sign the death certificate. The determination of death is made through a physical examination that includes auscultation for the absence of breathing and heart sounds. Home care or hospice programs in which nurses make the time-of-death visit and pronouncement of death have policies and procedures to guide the nurse's actions during this visit. Immediately on cessation of vital functions, the body begins to change. It becomes dusky or bluish, waxen-appearing, and cool; blood darkens and pools in dependent areas of the body (e.g., the back and sacrum if the body is in a supine position); and urine and stool may be evacuated.

BOX 3-8 Patient Education

Signs of Approaching Death

The person will show less interest in eating and drinking. For many patients, refusal of food is an indication that they are ready to die. Fluid intake may be limited to that which will keep the mouth from feeling too dry.

- What you can do: Offer, but do not force, fluids and medication. Sometimes, pain or other symptoms that have required medication in the past may no longer be present. For most patients, pain medications still will be needed and can be provided by concentrated oral solutions placed under the tongue or by rectal suppository.

Urinary output may decrease in amount and frequency.

- What you can do: No response is needed unless the patient expresses a desire to urinate and cannot. Call the hospice nurse for advice if you are not sure.

As the body weakens, the patient will sleep more and begin to detach from the environment. He or she may refuse your attempts to provide comfort.

- What you can do: Allow your loved one to sleep. You may wish to sit with him or her, play soft music, or hold hands. Your loved one's withdrawal is normal and is not a rejection of your love.

Mental confusion may become apparent as less oxygen is available to supply the brain. The patient may report strange dreams or visions.

- What you can do: As he or she awakens from sleep, remind him or her of the day and time, where he or she is, and who is present. This is best done in a casual, conversational way.

Vision and hearing may become somewhat impaired, and speech may be difficult to understand.

- What you can do: Speak clearly but no more loudly than necessary. Keep the room as light as the patient wishes, even at night. Carry on all conversations as if they can be heard, because hearing may be the last of the senses to cease functioning.
- Many patients are able to talk until minutes before death and are reassured by the exchange of a few words with a loved one.

Secretions may collect in the back of the throat and rattle or gurgle as the patient breathes though the mouth. He or she may try to cough, and his or her mouth may become dry and encrusted with secretions.

- What you can do: If the patient is trying to cough up secretions and is experiencing choking or vomiting, call the hospice nurse for assistance.
- Secretions may drain from the mouth if you place the patient on his or her side and provide support with pillows.
- Cleansing the mouth with moistened mouth swabs will help to relieve the dryness that occurs with mouth breathing.
- Offer water in small amounts to keep the mouth moist. A straw with one finger placed over the end can be used to transfer sips of water to the patient's mouth.

Breathing may become irregular with periods of no breathing (apnea). The patient may be working very hard to breathe and may make a moaning sound with each breath. As the time of death nears, the breathing remains irregular and may become more shallow and mechanical.

- What you can do: Raising the head of the bed may help the patient to breathe more easily. The moaning sound does not mean that the patient is in pain or other distress; it is the sound of air passing over very relaxed vocal cords.

As the oxygen supply to the brain decreases, the patient may become restless. It is not unusual for the patient to pull at the bed linens, to have visual hallucinations, or even to try to get out of bed at this point.

- What you can do: Reassure the patient in a calm voice that you are there. Prevent him or her from falling out of bed. Soft music or a back rub may be soothing.

The patient may feel hot one moment and cold the next as the body loses its ability to control its temperature. As circulation slows, the arms and legs may become cool and bluish. The underside of the body may darken. It may be difficult to feel a pulse at the wrist.

- What you can do: Provide and remove blankets as needed. Avoid using electric blankets, which may cause burns because the patient cannot tell you if he or she is too warm.
- Sponge the patient's head with a cool cloth if this provides comfort.

Loss of bladder and bowel control may occur around the time of death.

- What you can do: Protect the mattress with waterproof padding and change the

padding as needed to keep the patient comfortable.

As people approach death, many times they report seeing gardens, libraries, or family or friends who have died. They may ask you to pack their bags and find tickets or a passport. Sometimes they may become insistent and attempt to do these chores themselves. They may try getting out of bed (even if they have been confined to bed for a long time) so that they can "leave."

- What you can do: Reassure the patient that it is all right; he or she can "go" without getting out of bed. Stay close, share stories, and be present.

Used with permission from the Family Home Hospice of the Visiting Nurse Association of Greater Philadelphia.

Immediately after death, family members should be allowed and encouraged to spend time with the deceased. Normal responses of family members at the time of death vary widely and range from quiet expressions of grief to overt expressions that include wailing and prostration. The family's desire for privacy during their time with the deceased should be honored. Family members may wish to independently manage or assist with care of the body after death. If the death occurs in a long-term care facility, nurses follow the facility's procedure for preparation of the body and transportation to the facility's morgue. However, the needs of families to remain with the deceased, to wait until other family members arrive before the body is moved, and to perform after-death rituals should be honored. When an expected death occurs in the home setting, the funeral director often transports the body directly to the funeral home or mortuary.

Loss, Grief, and Bereavement

A wide range of feelings and behaviors are normal, adaptive, and healthy reactions to the loss of a loved one. Grief refers to the personal feelings that accompany an anticipated or actual loss. Mourning refers to individual, family, group, and cultural expressions of grief and associated behaviors. Bereavement refers to the period of time during which mourning takes place. Both grief reactions and mourning behaviors change over time as people learn to live with the loss. Although the pain of the loss may be tempered by the passage of time, loss is an ongoing developmental process, and time may never heal the bereaved individual completely. That is, the bereaved do not get over a loss entirely, nor do they return to who they were before the loss. Rather, they develop a new sense of who they are and where they fit in a world that has changed dramatically and permanently without their loved one and that relationship.

Anticipatory Grief and Mourning

Denial, sadness, anger, fear, and anxiety are normal grief reactions in people with life-threatening illness and those close to them. Kübler-Ross (1969) described five common emotional reactions to dying that are applicable to the experience of any loss: denial, anger, bargaining, depression, and acceptance. Kübler-Ross cautioned that not every patient or family member experiences every stage; many patients never reach a stage of acceptance, and patients and families fluctuate on a sometimes daily basis in their emotional responses. Individual and family coping with the anticipation of death is complicated by the varied and conflicting trajectories that grief and mourning may assume in families. For example, although the patient may be experiencing sadness while contemplating role changes that have been brought about by the illness, the patient's spouse or partner may be expressing or suppressing feelings of anger about the current changes in role and impending loss of the relationship. Others in the family may be engaged in denial (e.g., "Dad will get better; he just needs to eat more"), fear ("Who will take care of us?" or "Will I get sick too?"), or profound sadness and withdrawal. Although each of these behaviors is normal, tension may arise when one or more family members perceive that others are less caring, too emotional, or too detached.

The nurse should assess the characteristics of the family system and intervene in a manner that supports and enhances the cohesion of the family unit. The nurse can encourage family members to talk about their feelings and help them understand what is happening to them in the broader context of anticipatory grief and mourning. Acknowledging and expressing feelings, continuing to interact with the patient in meaningful ways, and planning for the time of death and bereavement are adaptive family behaviors. Professional support provided by grief counselors and social workers, whether in the community, at a local hospital, in the long-term care facility, or associated with a hospice program, can help both the patient and the family sort out and acknowledge feelings and make the end of life as meaningful as possible.

Grief and Mourning After Death

When a loved one dies, the family members enter a new phase of grief and mourning as

they begin to accept the loss, feel the pain of permanent separation, and prepare to live a life without the deceased. Even if the loved one died after a long illness, preparatory grief experienced during the terminal illness does not preclude the grief and mourning that follow the death. With a death after a long or difficult illness, family members may experience conflicting feelings of relief that the loved one's suffering has ended, compounded by guilt and grief related to unresolved issues or the circumstances of death. Grief work may be especially difficult if a patient's death was painful, prolonged, accompanied by unwanted interventions, or unattended. Families who had no preparation or support during the period of imminence and death may have a more difficult time finding a place for the painful memories.

Although some family members may experience prolonged or complicated mourning, most grief reactions fall within a "normal" range. The feelings are often profound, but bereaved people eventually reconcile the loss and find a way to reengage with their lives. Grief and mourning are affected by several factors, including individual characteristics, coping skills, and experiences with illness and death; the nature of the relationship to the deceased; factors surrounding the illness and the death; family dynamics; social support; and cultural expectations and norms. Uncomplicated grief and mourning are characterized by emotional feelings of sadness, anger, guilt, and numbness; physical sensations such as hollowness in the stomach and tightness in the chest, weakness, and lack of energy; cognitions that include preoccupation with the loss and a sense of the deceased as still present; and behaviors such as crying, visiting places that are reminders of the deceased, social withdrawal, and restless overactivity.

After-death rituals, including preparation of the body, funeral practices, and burial rituals, are socially and culturally significant ways in which family members begin to accept the reality and finality of death. Preplanning of funerals is becoming increasingly common, and hospice professionals in particular help the family make plans for death, often involving the patient, who may wish to play an active role. Preplanning of the funeral relieves the family of the burden of making decisions in the intensely emotional period after a death.

In general, the period of mourning is an adaptive response to loss during which mourners come to accept the loss as real and permanent, acknowledge and experience the painful emotions that accompany the loss, experience life without the deceased, overcome impediments to adjustment, and find a new way of living in a world without the loved one. Particularly, immediately after the death, mourners begin to recognize the reality and permanence of the loss by talking about the deceased and telling and retelling the story of the illness and death. Societal norms in the United States are frequently at odds with the normal grieving processes of people; time excused from work obligations is typically measured in days, and often mourners are expected to get over the loss quickly and get on with life.

In reality, the work of grief and mourning takes time, and avoiding grief work after the death often leads to long-term adjustment difficulties. Mourning for a loss involves the "undoing" of psychosocial ties that bind mourners to the deceased, personal adaptation to the loss, and learning to live in the world without the deceased. In his classic work, Worden (1991) described four tasks of mourning:

- Acceptance of the reality of the loss
- Working through the pain of grief

- Adjusting to the environment from which the deceased has gone
- Emotional "relocation" of the deceased to move on with life

Although many people complete the work of mourning with the informal support of families and friends, many find that talking with others who have had a similar experience, such as in formal support groups, normalizes the feelings and experiences and provides a framework for learning new skills to cope with the loss and create a new life. Hospitals, hospices, religious organizations, and other community organizations often sponsor bereavement support groups. Groups for parents who have lost a child, children who have lost a parent, widows, widowers, and gay men and lesbians who have lost a life partner are some examples of specialized support groups available in many communities.

Complicated Grief and Mourning

Complicated grief and mourning are characterized by prolonged feelings of sadness and feelings of general worthlessness or hopelessness that persist long after the death, prolonged symptoms that interfere with ADLs (anorexia, insomnia, fatigue, panic), or self-destructive behaviors such as alcohol or substance abuse and suicidal ideation or attempts. Complicated grief and mourning require a referral for a psychiatric assessment and evaluation to determine if pharmacologic and additional psychological interventions are needed. It is important that family members at risk for complicated grief be recognized early so that resources can be identified and mobilized.

COPING WITH DEATH AND DYING: PROFESSIONAL CAREGIVER ISSUES

Whether practicing in the trauma center, intensive care unit or other acute care setting, home care, hospice, long-term care, or the many locations where patients and their families receive ambulatory services, the nurse is closely involved with complex and emotionally laden issues surrounding loss of life. To be most effective and satisfied with the care he or she provides, the nurse should attend to his or her own emotional responses to the losses witnessed every day. Like family members, nurses need opportunities to grieve and express sorrow at the losses experienced and the sadness associated with a person dying before fulfilling one's dreams, leaving children prematurely, or completing one's commitments. Well before the nurse exhibits symptoms of stress or burnout, he or she should acknowledge the difficulty of coping with others' pain on a daily basis and put healthy practices in place that guard against emotional exhaustion. In hospice settings, where death, grief, and loss are expected outcomes of patient care, interdisciplinary colleagues rely on each other for support, using meeting time to express frustration, sadness, anger, and other emotions; to learn coping skills from each other; and to speak about how they were affected by the lives of those patients who have died since the last meeting. In many settings, staff members organize or attend memorial services to support families and other caregivers, who find comfort in joining each other to remember and celebrate the lives of patients. Finally, healthy personal habits, including diet, exercise, stress reduction activities (e.g., dance, yoga, tai chi, meditation), and sleep, help guard against the detrimental effects of stress.

SUMMARY

Chronic illnesses, those that last longer than 3 months, may be caused by injury or disease. Some of these diseases may be the result of genetic factors, while others may be the result of unhealthy lifestyles and behaviors earlier in life. Chronic illness is not merely a disease that has a nonreversible pathology; it is also the slow, progressive decline in normal function that brings with it disability and the need for long-term surveillance. Given its prevalence, chronic illness touches many lives, meaning nurses encounter many people who have been living with the symptoms or disabilities that accompany chronic illness. When they do, nurses will encounter people who are living with uncertainty. Chronic illness waxes and wanes, and with these modulations come a different set of health care regimens and types of management, often placing variable demands on family caregivers. Nurses need to be aware of the phases of the trajectory model of chronic illness, and they need to tailor the care they give to the care demanded, depending on the phase.

As people with chronic illness move in and out of the different phases of the trajectory model of care, and treatments become more complex, focus shifts from cure to care. There has been an international movement to recognize the need to help patients and families transition from cure to care. The goal of this movement is a seamless integration of palliative care into treatment from the beginning—at the time of diagnosis. Palliative care, encompassing a wide range of therapeutic interventions, seeks to prevent and relieve suffering. Because suffering has many and varied sources, nurses who provide palliative care should attend to the whole patient—that is, to the physical, psychological, social, and spiritual domains of human experience. As patients move into the downward phase of chronic illness, they need hospice or hospice-like care. Hospice care includes palliative care, but unlike palliative care, hospice care is associated with the patient's end of life: it helps patients and families prepare for death—emotionally, socially, spiritually, and financially. Nurses who provide end-of-life care have eight tasks: (1) They provide pain and symptom management. (2) With an ease that comes from expertise, they communicate effectively with dying patients and their families. (3) They educate patients and families about end-of-life decision-making and (4) help other professional caregivers to develop a coordinated plan of care that coheres with the wishes of patients and families. (5) They provide care to patients who are close to death, and (6) often, are present at death. (7) After death, they attend to families' loss, grief, and bereavement. (8) Finally, they achieve quality of care at the end of life by providing culturally sensitive care throughout the entire hospice-care experience.

Providing nursing care for patients and families who live with chronic illness is nursing at its fullest and deepest, for from the onset of disease to the end of life, care of the chronically ill centers on the whole person.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 55-year-old married mother of three adult children has been referred for hospice care.

During your initial visit to the patient's home, you assess that she is experiencing severe pain in her ribs and pelvis (she reports a score of 8 on a 0–10 pain intensity scale). In addition, she reports that she is unable to sleep. Her provider has prescribed morphine for her pain, but you assess that she has used very few doses of the morphine. Her husband tells you privately that he has discouraged her use of the medicine because it has made her very sleepy and nauseated in the past. The interdisciplinary team is meeting to discuss the patient's treatment plan. What additional assessment data are needed to determine the wishes and expectations of the patient as well as the husband? What are the team's options for intervention? What are the pros and cons of each option?

2. A 28-year-old woman with two children younger than 3 years of age has recently been diagnosed with type 1 diabetes. She is very active in her community and church and states that she cannot fit learning about diabetes, treatments, or blood glucose testing into her busy life. Identify approaches you would use to establish a plan of care with her. Link your teaching to the trajectory onset phase of chronic illness. How would your teaching plan change in the acute and crisis stages of chronic illness?

3. After having a seizure at her law office, a 34-year-old woman, a wife and mother of a 3-year-old son, was diagnosed 2 months ago with an aggressive form of brain cancer. The tumor's growth progresses rapidly. As a result, she experiences uncontrolled seizures, and her cognitive abilities decline. The neuro-oncologist has prognosticated death within a few months. What is one of the primary responsibilities of the nurse in this period of the patient's and family's life? What should the nurse document in the nursing assessment? How should the nurse respond to the patient and family when symptoms, such as seizure and cognitive decline, occur and intensify?

NCLEX-Style Review Questions

1. When educating patients about chronic diseases, such as diabetes, which of the following should the nurse include in the rationale for effective management of the disease? Select all that apply.
   a. An unmanaged chronic disease may lead to the development of other chronic illnesses.
   b. When a patient is admitted to the ICU with a comorbid chronic disease, that patient faces a greater risk of morbidity and mortality.
   c. Although chronic disease affects the entire family system, management of the disease is the patient's sole responsibility.
   d. By managing a chronic disorder early in the disease process, the patient may be able to save him- or herself the high costs associated with the sequelae of unmanaged disease.
   e. Chronic illness management is not influenced by life style changes.

2. A patient is nearing death from metastatic cancer and is receiving hospice care in the

home. The home care nurse visits. The patient's family caregiver states that the patient has not eaten well for the last several days and rarely wishes to drink, only sucking on ice now and then. The caregiver thinks that it is cruel to let the dying patient starve to death, or die from dehydration. What would the nurse's best response be?

a. "I think it is cruel, too. If this were my mother, I would not let her die like that."
b. "Tell me why you feel that way?"
c. "It's okay, because this may hasten death and relieve suffering."
d. "This is what happens when people die."

3. The sounds of breathing, including terminal bubbling, at the time of death may be distressing for families to hear. When the nurse hears these sounds, she should do which of the following? Select all that apply.

a. Reposition the patient in an attempt to move secretions out of the oropharynx.
b. Educate the family about what they are hearing and that the sound does not mean that the patient is in any distress.
c. Suction the patient deeply and often to rid the oropharynx of the build-up of secretions.
d. Suggest to the provider that now is the time for an anticholinergic drug (such as glycopyrrolate).

4. Chronic illnesses are characterized by which of the following? Select all that apply.

a. A nonreversible pathology.
b. A slow, progressive decline in normal physiologic function.
c. A decreasing prevalence nationally and internationally.
d. Necessitating long-term surveillance.

5. A dying patient has sudden onset of confusion, waxing and waning consciousness, and loss of orientation, thinking she is at home when she is in the hospital. The nurse recognizes this as _____ and knows that the most appropriate pharmacologic treatment for it includes _____.

a. Dementia, acetylcholinesterase inhibitor
b. Delirium, benzodiazepine
c. Delirium, haloperidol
d. Dementia, haloperidol

Concepts and Challenges in Patient Management

A 45-year-old patient has recently been diagnosed with brain cancer. She will be undergoing surgery, followed by chemotherapy. She is very anxious and has fears about her overall prognosis.

- What psychosocial aspects may be affected by this diagnosis?

- Explain postoperative risks that may occur following surgery.
- Discuss the special needs of a patient undergoing chemotherapy.

CHAPTER 4

Fluid and Electrolyte and Acid–Base Imbalances

Philip R. Martinez, Jr. • Linda Honan

Learning Objectives

After reading this chapter, you will be able to:

1. Differentiate between osmosis, diffusion, filtration, and active transport.
2. Describe the role of kidneys, lungs, and endocrine glands in regulating the body's fluid composition and volume.
3. Identify the effects of aging on fluid and electrolyte regulation.
4. Plan effective care of patients with the following imbalances: hypovolemia, hypervolemia, hyponatremia, hypernatremia, hypokalemia, and hyperkalemia.
5. Describe the cause, clinical manifestations, management, and nursing interventions for the following imbalances: hypocalcemia, hypercalcemia, hypomagnesemia, hypermagnesemia, hypophosphatemia, hyperphosphatemia, hypochloremia, and hyperchloremia.
6. Explain the roles of lungs, kidneys, and chemical buffers in maintaining acid–base balance.
7. Compare metabolic acidosis and alkalosis with regard to causes, clinical manifestations, diagnosis, and management.
8. Compare respiratory acidosis and alkalosis with regard to causes, clinical manifestations, diagnosis, and management.
9. Interpret arterial blood gas measurements.
10. Describe measures used for preventing complications of IV therapy.

Fluid and electrolyte balance is a dynamic process that is crucial for life and homeostasis. Potential and actual disorders of fluid and electrolyte balance occur in every setting, with nearly every disorder, and with a variety of changes that affect healthy people as well as those who are ill. The blood's acid–base balance is precisely controlled, and because deviations from the normal pH range of 7.35 to 7.45 can cause severe effects in body function, the nurse needs to competently interpret arterial blood gases (ABGs).

FUNDAMENTAL CONCEPTS

AMOUNT AND COMPOSITION OF BODY FLUIDS

Approximately 60% of the weight of a typical adult consists of fluid (water and electrolytes). Factors that influence the amount of body fluid are age, gender, and body fat. In general, younger people have a higher percentage of body fluid than older people, and men have proportionately more body fluid than women. People who are obese have less fluid than those who are thin because fat cells contain little water.

Body fluid is located in two fluid compartments: the intracellular space (ICS, fluid inside the cells) and the extracellular space (ECS, fluid outside the cells). Approximately two thirds of body fluid is intracellular fluid (ICF) and is located primarily in the skeletal muscle mass; approximately one third is in the extracellular fluid (ECF).

The ECF compartment is further divided into the intravascular, interstitial, and transcellular fluid spaces. The intravascular space (IVS, the fluid within the blood vessels) contains plasma. Plasma is water, along with molecules, electrolytes, and proteins, minus blood cells and platelets. Approximately 3.5 L of the average 6 L of blood volume is made up of plasma, which has a straw-colored appearance. The remaining 2.5 L is made up of erythrocytes (red blood cells [RBC]), leukocytes (white blood cells [WBC]), and thrombocytes (platelets). The interstitial space contains the fluid between the cells, tissues, organs, and blood vessels and totals about 10 L in an adult. Lymph fluid is an interstitial fluid. The transcellular space is the smallest division of the ECF compartment and contains approximately 1 L. Examples of transcellular fluids are cerebrospinal, pericardial, synovial, intraocular, pleural, and the peritoneal cavity. Figure 4-1 demonstrates the composition of body compartments.

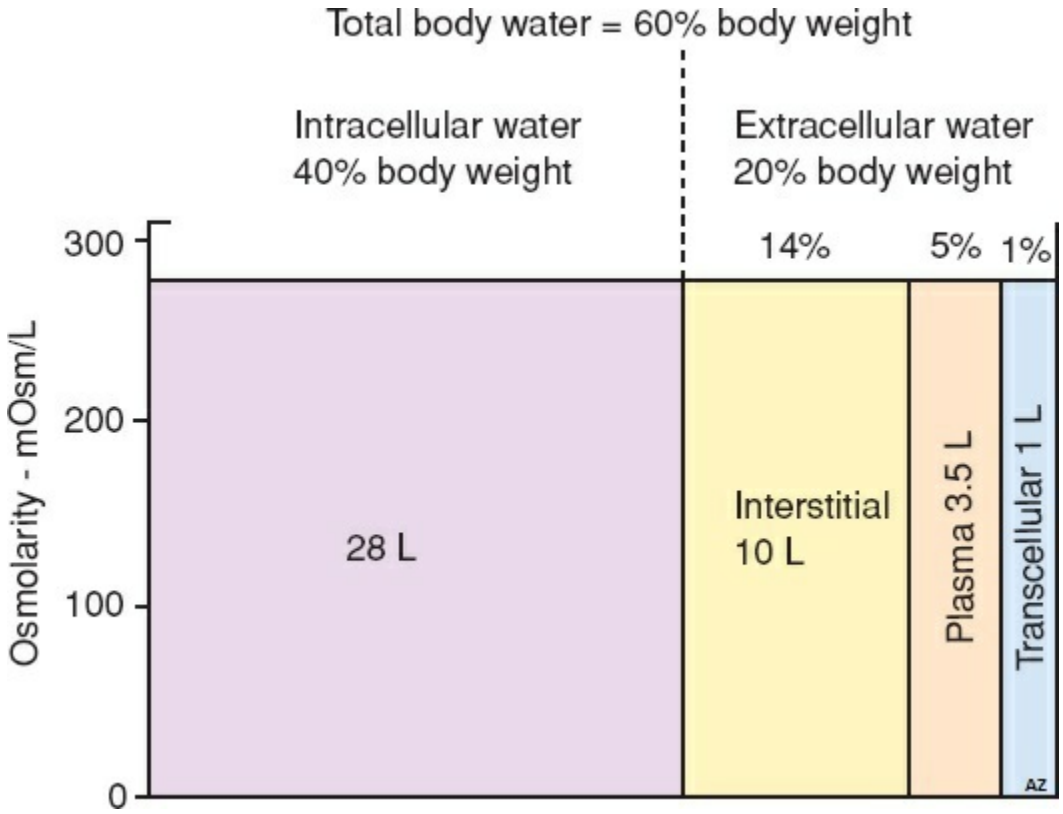

FIGURE 4-1 Approximate size of body compartments in a 70-kg man. (From Porth, C.M., & Matfin, G. (2009). *Pathophysiology: Concepts of altered health status* (8th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Body fluid normally shifts between the two major compartments or spaces (ICS and ECS) in an effort to transport gases, nutrients, and wastes while maintaining overall bodily function. Loss of fluid from the body can disrupt this equilibrium. Sometimes fluid is not lost from the body but is unavailable for use by either the ICF or ECF. Loss of ECF into a space that does not contribute to equilibrium between the ICF and the ECF is referred to as an *interstitial fluid shift,* or *third-spacing.*

Nursing Alert
Early evidence of third-space fluid shifting is a decrease in urine output despite adequate fluid intake. Urine output decreases because fluid shifts out of the IVS; the kidneys then receive less blood and attempt to compensate by decreasing urine output. Other signs and symptoms of third-spacing that indicate an intravascular fluid volume deficit (FVD) include increased heart rate, decreased blood pressure, decreased central venous pressure (CVP), edema, increased body weight, and imbalances in fluid intake and output (I&O). Third-space shifts occur in ascites, burns, peritonitis, bowel obstruction, and massive bleeding into a joint or body cavity.

Electrolytes in body fluids are active chemicals (cations that carry positive charges and anions that carry negative charges). The major cations in body fluid are sodium (Na^+), potassium (K^+), calcium (Ca^{+2}), magnesium (Mg^{+2}), and hydrogen (H^+) ions. The major anions are chloride (Cl^-), bicarbonate (HCO_3^-), phosphate (PO_4^{3-}), sulfate (SO_4^{2-}), and proteinate ions.

These chemicals unite in varying combinations. Therefore, electrolyte concentration in the body is expressed in terms of milliequivalents (mEq) per liter, a measure of chemical activity, rather than in terms of milligrams (mg), a unit of weight. More specifically, a milliequivalent is defined as being equivalent to the electrochemical activity of 1 mg of hydrogen. In a solution, cations and anions are equal in milliequivalents per liter.

Although all body fluid contains equal amounts of cations and anions, the electrolyte concentrations in the ICF are markedly different from those in the ECF, as reflected in Table 4-1. Sodium ions, which are positively charged, far outnumber the other cations in the ECF. Because sodium concentration affects the overall concentration of the ECF, sodium is important in regulating the volume of body fluid. Approximately 90% of the serum osmolality (discussed later) is determined by the serum sodium level. Retention of sodium is associated with fluid retention, and conversely excessive loss of sodium is usually associated with decreased volume of body fluid.

As shown in Table 4-1, the major electrolytes in the ICF are potassium and phosphate. The ECF has a low concentration of potassium and can tolerate only small changes in potassium concentrations. Therefore, any condition that causes the release of large stores of intracellular potassium (e.g., trauma to the cells and tissues) can be extremely dangerous.

TABLE 4-1 Approximate Major Electrolyte Content in Body Fluid

Electrolytes	mEq/L[a]
Extracellular Fluid (Plasma)	
Cations	
Sodium (Na)	142
Potassium (K)	5
Calcium (Ca^{+2})	5
Magnesium (Mg^{+2})	2
Total cations	154
Anions	
Chloride (Cl^-)	103
Bicarbonate (HCO_3^-)	26
Phosphate (PO_4^{3-})	2
Sulfate (SO_4^{2-})	1
Organic acids	5
Proteinate	17
Total anions	154
Intracellular Fluid	
Cations	
Potassium (K^+)	150
Magnesium (Mg^{+2})	40
Sodium (Na^+)	10
Total cations	200
Anions	
Phosphates and sulfates	150
Bicarbonate (HCO_3^-)	10
Proteinate	40
Total anions	200

[a]Values may vary depending on the method of analysis used.

Nursing Alert
The nurse understands that the intracellular concentration of K^+ is approximately 140 to 150 mEq/L and that the kidneys are primarily responsible for K^+ excretion. The nurse recognizes that hyperkalemia (generally defined as a plasma K^+ of greater than 5.0 mEq/L) is associated with cardiac arrhythmias (discussed in Chapter 17), muscle weakness and acute muscle damage from rhabdomyolysis (discussed in Chapter 42), kidney failure (discussed in Chapter 27), and acidosis (discussed later in this chapter). One of the most

common metabolic causes of cardiac arrest is hyperkalemia, which is associated most frequently in patients with kidney failure.

The body expends a great deal of energy maintaining the high extracellular concentration of sodium and the high intracellular concentration of potassium. It does so by means of cell membrane pumps that exchange sodium and potassium ions.

Normal movement of fluid through the capillary wall into the tissues is dependent on two primary forces (called Starling forces): (1) the capillary hydrostatic pressure generated by cardiac contraction and exerted by plasma fluids on the walls of the blood vessel, and (2) the plasma oncotic (colloid osmotic) pressure, exerted by plasma proteins (primarily by capillary-impermeable albumin). At the arterial end of the capillary bed, fluids are filtered because the hydrostatic pressure exceeds the oncotic pressure; thus, water and electrolytes leave the capillary and enter the interstitial space and/or ICS. Because hydrostatic pressure decreases as blood moves along the capillary bed, the relatively constant plasma oncotic pressure exceeds the hydrostatic pressure at the venous end of the capillary; therefore, fluids now re-enter the capillary. In many capillary beds, the forces favoring filtration slightly exceed those that favor reabsorption. However, excessive interstitial fluid accumulation is prevented since the lymphatic drainage returns this excess fluid to the systemic circulation.

In addition to electrolytes, the ECF transports other substances, such as enzymes and hormones. It also carries blood components, such as RBCs, WBCs, and platelets, throughout the body.

REGULATION OF BODY FLUID COMPARTMENTS

Osmosis and Osmolality

When two different solutions are separated by a membrane that is impermeable to the dissolved substances, fluid shifts through the membrane from the region of low solute concentration to the region of high solute concentration until the solutions are of equal concentration. The movement of water caused by a concentration gradient is known as osmosis (Fig. 4-2A). The magnitude of this force depends on the number of particles dissolved in the solutions, not on their weights. The number of dissolved particles contained in a unit of fluid determines the osmolality of a solution, which influences the movement of fluid between the fluid compartments. Tonicity is the ability of all the solutes to cause an osmotic driving force that promotes water movement from one compartment to another (Porth, 2015). Intravenous (IV) solutions are termed isotonic, hypotonic, or hypertonic. If a solution is isotonic (e.g., 0.9% sodium chloride), it has the same effective osmolality as body fluids (close to 285 milliosmolal [mOsm]). Sodium, mannitol, glucose, and sorbitol are all effective osmoles (capable of affecting water movement; see later discussion of IV solutions).

Nursing Alert
It is important to understand osmotic diuresis, which is an increase in urine output caused by the excretion of substances such as glucose, mannitol, or contrast agents in the urine, which exert an osmotic pull on water. For example, because glucose is an osmotic agent (capable of affecting water movement), when glucose is excreted in the urine, it will bring water with it, causing polyuria with resulting FVD.

Diffusion

Diffusion is the natural tendency of a substance to move from an area of higher concentration to one of lower concentration (see Fig. 4-2B). Examples of diffusion are the exchange of oxygen and carbon dioxide between the pulmonary capillaries and alveoli.

Filtration

Hydrostatic pressure in the capillaries tends to filter fluid out of the intravascular compartment into the interstitial fluid. Movement of water and solutes occurs from an area of high hydrostatic pressure to an area of low hydrostatic pressure. Filtration allows the kidneys to filter 180 L of plasma per day.

Sodium–Potassium Pump

As previously stated, the sodium concentration is greater in the ECF than in the ICF, and, because of this, sodium tends to enter the cell by diffusion. This tendency is offset by the sodium–potassium pump, which is located in the cell membrane and actively moves sodium from the cell into the ECF. Conversely, the high intracellular potassium concentration is maintained by pumping potassium into the cell. By definition, active transport implies that energy must be expended for the movement to occur against a concentration gradient.

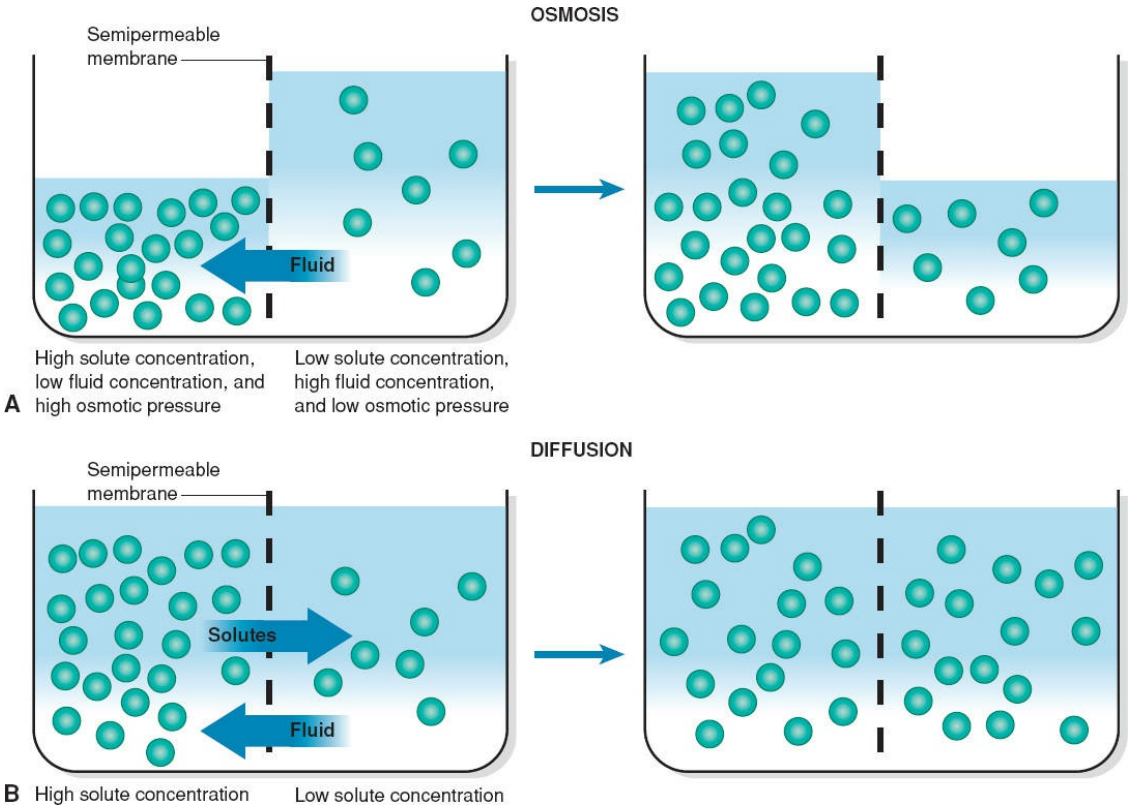

FIGURE 4-2 A. Osmosis: Movement of fluid from an area of lower solute concentration to an area of higher solute concentration with eventual equalization of the solute concentrations. B. Diffusion: Movement of solutes from an area of greater concentration to an area of lesser concentration, leading ultimately to equalization of the solute concentrations.

ROUTES OF GAINS AND LOSSES

Water and electrolytes are gained in various ways. A healthy person gains fluids by drinking and eating. Fluids may also be provided by the parenteral route (IV or subcutaneously) or by means of an enteral feeding tube in the stomach or intestine.

Kidneys

The usual daily urine volume in the adult is 1.5 L. A general rule is that the output is approximately 0.5 to 1 mL of urine per kilogram of body weight per hour (0.5 to 1 mL/kg/hr) in all age groups, with boundaries of 0.5 to 2 mL/kg/hr.

Skin

Sensible perspiration refers to visible water and electrolyte loss through the skin (sweating). The chief solutes in sweat are sodium, chloride, and potassium. Actual sweat loss can vary from 0 to 1,000 mL or more every hour, depending on the environmental temperature. Continuous water loss by evaporation (approximately 600 mL/day) occurs through the skin as insensible perspiration, a nonvisible form of water loss. Fever greatly increases insensible water loss through the lungs and the skin as does loss of the natural skin barrier (e.g., through major burns). Although sodium content in sweat is low (ranging from approximately 20 to 50 mmol/L), with increased sweat loss, sodium deficit and FVD can occur (Slotki & Skorecki, 2016).

Lungs

The lungs normally eliminate water vapor (insensible loss) at a rate of approximately 400 mL every day. The loss is much greater with increased respiratory rate or depth, or in a dry climate.

Gastrointestinal Tract

The usual loss through the gastrointestinal (GI) tract is only 100 mL daily, even though approximately 8 L of fluid circulates through the GI system every 24 hours. Because the bulk of fluid is normally reabsorbed in the small intestine, diarrhea and fistulas cause large losses. To illustrate, worldwide, infectious diarrhea is a leading cause of death from hypovolemia (Slotki & Skorecki, 2016). In healthy people, the daily average I&O of water are approximately equal (Table 4-2).

TABLE 4-2 Average Daily Intake and Output in an Adult

Intake (mL)			
Oral liquids	1,300	Urine	1,500
Water in food	1,000	Stool	100
Water produced by metabolism	300	Insensible	
		Lungs	400
		Skin	600
Total gain[a]	2,600	Total loss[a]	2,600

[a]Approximate volumes.

LABORATORY TESTS FOR EVALUATING FLUID STATUS

Osmolality is the concentration of fluid that affects the movement of water between fluid compartments by osmosis. Osmolality measures the solute concentration per kilogram of solvent in blood and urine. It is also a measure of a solution's ability to create osmotic pressure and affect the movement of water. Serum osmolality primarily reflects the concentration of sodium, although blood urea nitrogen (BUN) and glucose also play a major role in determining serum osmolality (Porth, 2015). Urine osmolality is determined by urea, creatinine, and uric acid. When measured with serum osmolality, urine osmolality is the most reliable indicator of the concentrating ability of kidneys. Osmolality is reported as milliosmoles per kilogram of water (mOsm/kg).

Osmolarity, another term that describes the concentration of solutions, is measured in milliosmoles per liter (mOsm/L). The term *osmolality* is used more often in clinical practice. Normal serum osmolality is 275 to 300 mOsm/kg, and normal urine osmolality is 50 to 1,400 mOsm/kg in a random urine test and 300 to 900 mOsm/kg in a 24-hour urine collection (Fischbach & Dunning, 2015).

Nursing Alert
When concerned about renal concentrating ability, a serum and urine osmolality test is obtained at the same time. In general, the normal ratio of urine and serum is 3:1. Higher ratios are seen in concentrated urine, whereas lower ratios are seen with poor concentrating ability.

Factors that increase and decrease serum and urine osmolality are identified in Table 4-3. Serum osmolality may be measured directly through laboratory tests or estimated at the bedside by doubling the serum sodium level or by using the following formula:
Plasma osmolality (mOsm/kg) = 2 [serum sodium] + Glucose/18 + BUN/2.8

TABLE 4-3 Factors Affecting Serum and Urine Osmolality

Fluid	Factors Increasing Osmolality	Factors Decreasing Osmolality
Serum (275–300 mOsm/kg water)	• Severe dehydration • Free water loss • Diabetes insipidus • Hypernatremia • Hyperglycemia • Stroke or head injury • Renal tubular necrosis • Consumption of methanol or ethylene glycol (antifreeze)	• Fluid volume excess • Syndrome of inappropriate antidiuretic hormone (SIADH) • Kidney failure • Diuretic use • Adrenal insufficiency • Hyponatremia • Overhydration • Paraneoplastic syndrome associated with lung cancer
Urine (250–900 mOsm/kg water)	• Fluid volume deficit (FVD) • SIADH • Congestive heart failure • Acidosis	• Fluid volume excess • Diabetes insipidus • Hyponatremia • Pyelonephritis

The calculated value usually is within 10 mOsm of the measured osmolality.

The specific gravity of urine measures the kidneys' ability to excrete or conserve water. The specific gravity of urine is compared to the weight of distilled water, which has a specific gravity of 1.000. The normal range of urine specific gravity is 1.010 to 1.025. Specific gravity of urine can be measured at the bedside by placing a calibrated hydrometer or urinometer in a cylinder of approximately 20 mL of urine. Specific gravity can also be assessed with a refractometer or dipstick with a reagent for this purpose. Specific gravity varies inversely with urine volume; normally, the larger the volume of urine, the lower the specific gravity.

Nursing Alert

Specific gravity is a less reliable indicator of concentration than urine osmolality because it is influenced by both the number and size of particles in urine; increased

glucose or protein in urine can cause a falsely elevated specific gravity. Factors that increase or decrease urine osmolality are the same as those for urine specific gravity.

The laboratory value BUN, part of the basic metabolic panel, is made up of urea, which is an end product of the metabolism of protein (from both muscle and dietary intake) by the liver. The normal BUN is 10 to 20 mg/dL (3.6 to 7.2 &b.mu;mol/L). The BUN level varies with urine output. Factors that increase BUN include decreased kidney function, GI bleeding, dehydration, increased protein intake, fever, and sepsis. Any condition that increases tissue necrosis and protein catabolism will cause the BUN to rise; a critical value for BUN is when it is over 100 mg/dL (Fischbach & Dunning, 2015). Those factors that decrease BUN include end-stage liver disease, a low-protein diet, starvation, syndrome of inappropriate antidiuretic hormone (SIADH), and any condition that results in expanded fluid volume (e.g., pregnancy).

Creatinine is the end product of muscle metabolism. It is a better indicator of kidney function than BUN because it does not vary with protein intake and metabolic state. The normal serum creatinine is approximately 0.6 to 1.4 mg/dL (53 to 124 mmol/L); however, its concentration depends on lean body mass and varies from person to person. Serum creatinine levels increase when kidney function decreases.

Hematocrit measures the volume percentage of RBC (erythrocytes) in whole blood and normally ranges from 42% to 52% for males and 36% to 48% for females. Conditions that increase the hematocrit value are dehydration and polycythemia, and conditions that decrease hematocrit are overhydration and anemia.

Urine sodium values change with sodium intake and the status of fluid volume: as sodium intake increases, excretion increases; as the circulating fluid volume decreases, sodium is conserved. Normal urine sodium levels range from 40 to 220 mEq every 24 hours (40 to 220 mmol/day). A random specimen usually contains more than 40 mEq/L of sodium. Urine sodium levels are used to assess volume status and are useful in the diagnosis of hyponatremia and acute kidney failure (AKF).

HOMEOSTATIC MECHANISMS

The body is equipped with remarkable homeostatic mechanisms to keep the composition and volume of body fluid within narrow limits of normal. Organs involved in homeostasis include the kidneys, lungs, heart, adrenal glands, parathyroid glands, and pituitary gland.

Kidney Functions

Vital to the regulation of fluid and electrolyte balance, the kidneys normally filter 170 L of plasma every day in the adult, while excreting only 1.5 L of urine. They act both autonomously and in response to blood-borne messengers, such as aldosterone and antidiuretic hormone (ADH) (Porth, 2015). Major functions of the kidneys in maintaining normal fluid balance include the following:

- Regulation of ECF volume and osmolality by selective retention and excretion of body fluids;
- Regulation of electrolyte levels in the ECF by selective retention of needed substances and excretion of unneeded substances;
- Regulation of pH of the ECF by excretion or retention of hydrogen ions and/or bicarbonate ions (HCO_3^-);
- Excretion of metabolic wastes and toxic substances.

Given these functions, it is readily apparent that kidney failure results in multiple fluid and electrolyte abnormalities. Kidney function declines with advanced age, as do muscle mass and daily exogenous creatinine production. Therefore, high-normal and minimally elevated serum creatinine values actually may indicate substantially reduced kidney function in the elderly.

Heart and Blood Vessel Functions

The pumping action of the heart circulates blood through the kidneys under sufficient pressure to allow for urine formation. Failure of this pumping action interferes with renal perfusion and thus with water and electrolyte regulation.

Lung Functions

The lungs are also vital in maintaining homeostasis. Through exhalation, the lungs remove approximately 400 mL of water daily in the normal adult. Abnormal conditions, such as hyperpnea (abnormally deep respiration) or continuous coughing, increase this loss; mechanical ventilation with excessive moisture decreases it. The lungs also play a major role in maintaining acid–base balance. Normal aging results in decreased respiratory function, causing increased difficulty in pH regulation in older adults, especially those with major illness or trauma.

Pituitary Functions

The hypothalamus manufactures ADH, which is stored in the posterior pituitary gland and released as needed. ADH is sometimes called the *water-conserving hormone* because it causes the body to retain water. Functions of ADH include maintaining the osmotic pressure of the cells by controlling the retention or excretion of water by the kidneys and by regulating blood volume (Fig. 4-3).

Adrenal Functions

Aldosterone, a mineralocorticoid secreted by the zona glomerulosa (outer zone) of the adrenal cortex, has a profound effect on fluid balance. Increased secretion of aldosterone causes sodium retention (and, thus, water retention) and potassium loss. Conversely, decreased secretion of aldosterone causes sodium and water loss and potassium retention.

Cortisol, another adrenocortical hormone, has only a fraction of the mineralocorticoid potency of aldosterone. However, when secreted in large quantities (or administered as corticosteroid therapy), it can also produce sodium and fluid retention.

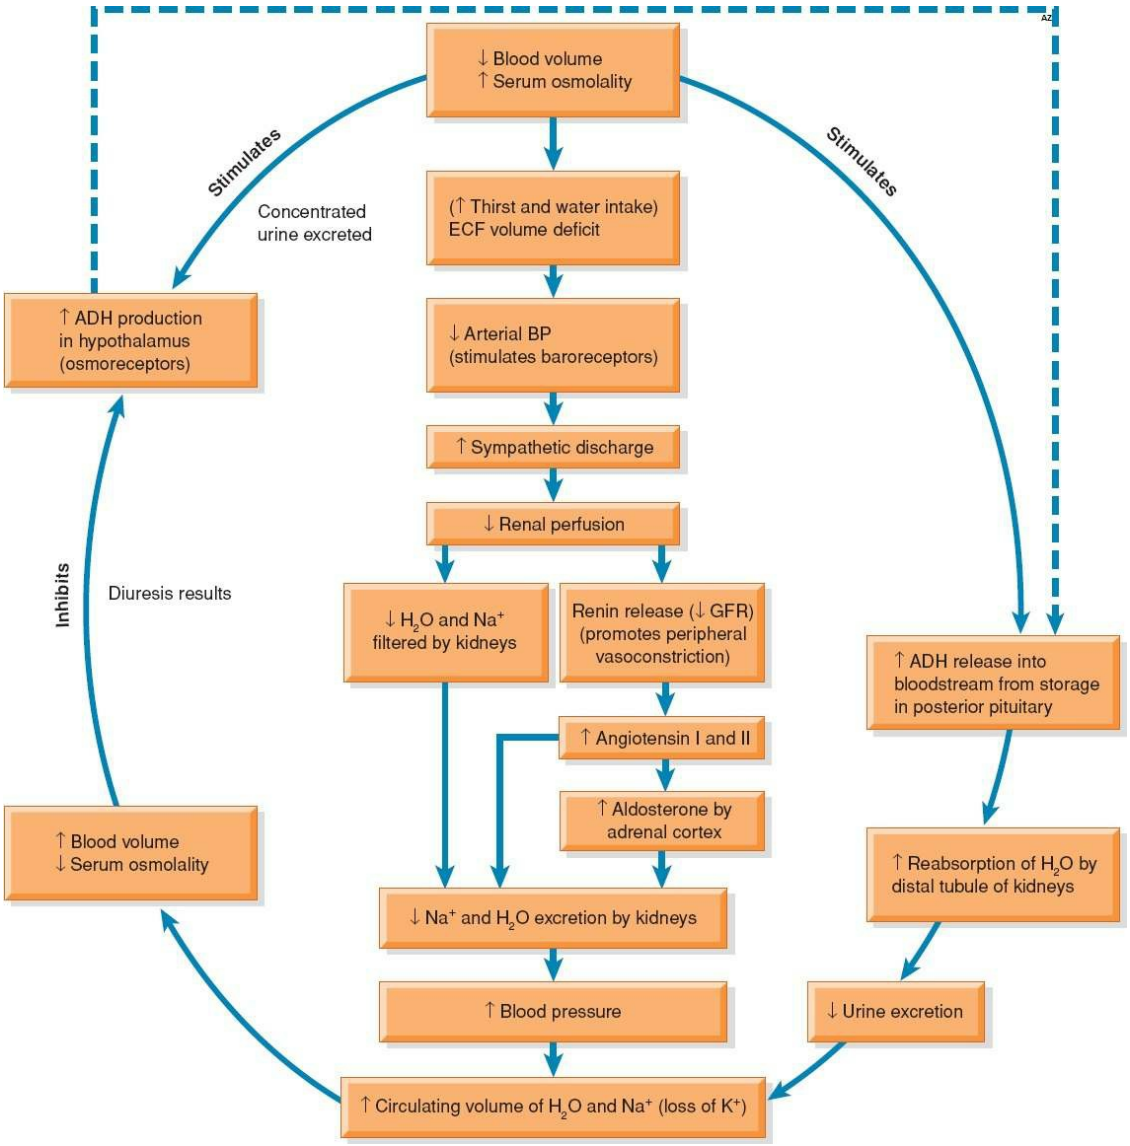

FIGURE 4-3 Fluid regulation cycle.

Parathyroid Functions

The parathyroid glands, embedded in the thyroid gland, regulate calcium and phosphate balance by means of parathyroid hormone (PTH). PTH influences bone resorption (movement of calcium out of bone to the blood), calcium absorption from the intestines, and calcium reabsorption from the renal tubules. A decrease in serum calcium is the primary stimulus for PTH secretions, whereas a rise in serum calcium inhibits secretion.

Other Mechanisms

Changes in the volume of the interstitial compartment within the ECF can occur without affecting body function. However, the vascular compartment cannot tolerate change as readily and must be carefully maintained to ensure that tissues receive adequate nutrients.

Baroreceptors

The baroreceptors are small nerve receptors that detect changes in pressure within blood vessels and transmit this information to the central nervous system (CNS). They are responsible for monitoring the circulating volume, and they regulate sympathetic and parasympathetic neural activity as well as endocrine activities. They are categorized as either low-pressure or high-pressure baroreceptors. Low-pressure baroreceptors are in the cardiac atria, particularly the left atrium. High-pressure baroreceptors are nerve endings in the aortic arch and the carotid sinus, as well as in the afferent arteriole of the juxtaglomerular apparatus of the nephron.

As arterial pressure decreases, baroreceptors transmit fewer impulses from the carotid sinuses and the aortic arch to the vasomotor center. A decrease in impulses stimulates the sympathetic nervous system and inhibits the parasympathetic nervous system. The outcome is an increase in cardiac rate, conduction, and contractility as well as an increase in circulating blood volume. Sympathetic stimulation constricts renal arterioles; this increases the release of aldosterone, decreases glomerular filtration, and increases sodium and water reabsorption and potassium loss (discussed below). Conversely, if high-pressure baroreceptors are stimulated, the outcome is a lowered heart rate and lowered blood vessel resistance.

Renin–Angiotensin–Aldosterone System

Renin is an enzyme that converts angiotensinogen, an inactive substance formed by the liver, into angiotensin I (AI) (Porth, 2015). Renin is released by the juxtaglomerular cells of the kidneys in response to decreased renal perfusion. Angiotensin-converting enzyme (ACE) converts AI to angiotensin II (AII). AII, with its vasoconstrictor properties, increases arterial perfusion pressure and also stimulates thirst. When the sympathetic nervous system is stimulated, aldosterone is released in response to an increased release of renin. Aldosterone is a volume regulator and is also released as serum potassium increases, serum sodium decreases, or adrenocorticotropic hormone (ACTH) increases. The net effect of aldosterone is to increase the reabsorption of sodium, which increases water reabsorption thus increasing plasma volume.

Antidiuretic Hormone and Thirst

ADH and the thirst mechanism play important roles in maintaining sodium concentration and oral intake of fluids. Oral intake is controlled by the thirst center, located in the hypothalamus (Porth, 2015). As serum concentration or osmolality increases or blood volume decreases, neurons in the hypothalamus are stimulated by intracellular dehydration; thirst then occurs, and the person increases his or her intake of oral fluids. An increase in

osmolality of only 1% to 2% is sufficient to stimulate thirst. Water excretion is controlled by ADH, aldosterone, and baroreceptors, as mentioned previously. The presence or absence of ADH is the most significant factor in determining whether the urine that is excreted is concentrated or dilute.

Osmoreceptors

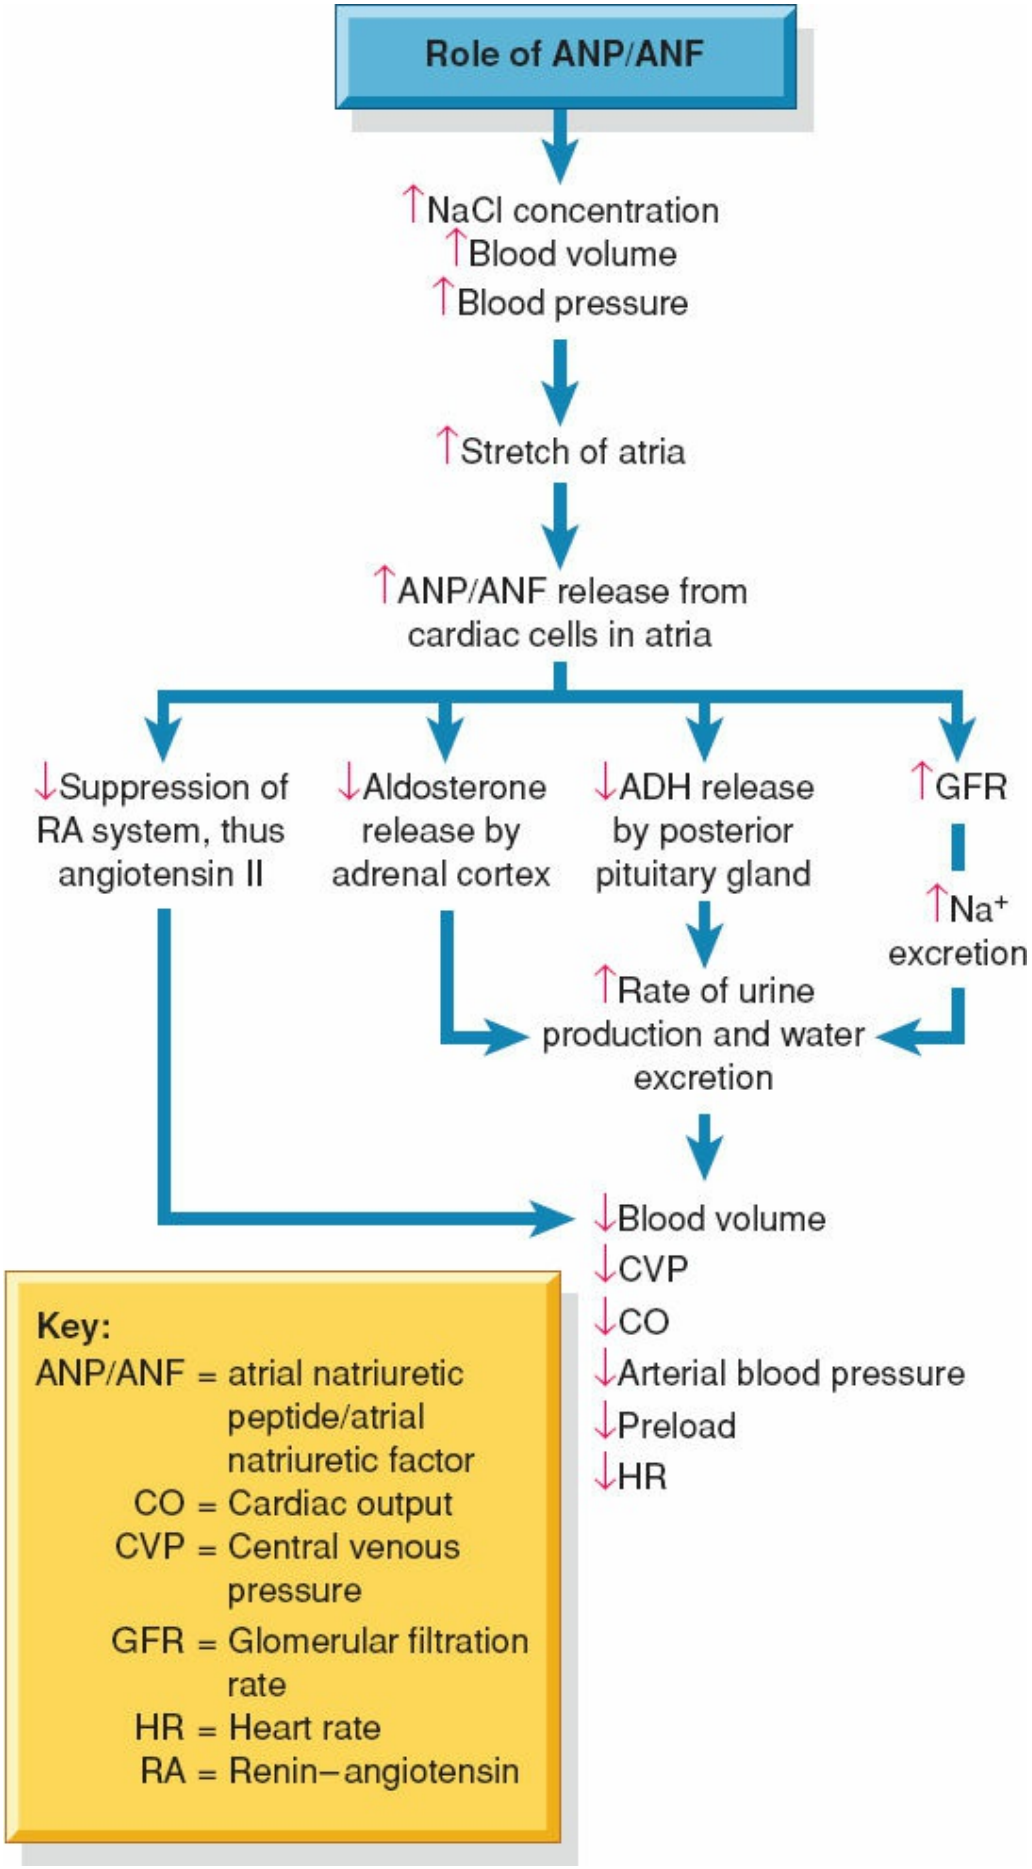
Located on the surface of the hypothalamus, osmoreceptors sense changes in sodium concentration. As the serum osmolality increases, the neurons become dehydrated and quickly generate action potentials resulting in increased release of ADH from the posterior pituitary. The ADH then travels in the blood to the kidneys, where it alters permeability to water, causing increased reabsorption of water and decreased urine output. The retained water dilutes the ECF and returns its concentration to normal. Restoration of normal serum osmolality provides feedback to the osmoreceptors to inhibit further ADH release (see Fig. 4-3).

Release of Atrial Natriuretic Peptide

Atrial natriuretic peptide (ANP), also called *atrial natriuretic factor,* is synthesized, stored, and released by muscle cells of the atria of the heart in response to several factors. ANP secretion is enhanced by increases in atrial pressure, endothelin (a powerful peptide vasoconstrictor of vascular smooth muscle released from damaged endothelial cells in the kidneys or other tissues) and sympathetic stimulation (Porth, 2015). In addition, any condition that results in volume expansion (e.g., pregnancy), hypoxia, or increased cardiac filling pressures (e.g., high sodium intake, heart failure, chronic kidney failure (CKF), atrial tachycardia, or use of vasoconstrictor agents such as epinephrine) increases the release of ANP. The action of ANP is the direct opposite of the renin–angiotensin–aldosterone system (RAAS); ANP decreases blood pressure and volume (Fig. 4-4). The ANP measured in plasma is normally 20 to 77 pg/mL (20 to 77 ng/L). This level increases in paroxysmal atrial tachycardia, hyperthyroidism, subarachnoid hemorrhage, and small cell lung cancer. In congestive heart failure and cirrhosis with ascites, ANP is elevated but not sufficiently to prevent fluid volume excess (FVE). Brain natriuretic peptide (BNP) that is stored primarily in ventricular myocardium and released when ventricular diastolic pressure rises, has actions similar to ANP. Normal BNP levels are less than 100 pg/mL. For reasons that are not understood, the renal effects of the natriuretic peptides appear to become dampened with advancing heart failure, leaving the effects of RAS unopposed (Hasenfuss & Mann, 2015).

Gerontologic Considerations 

Normal physiologic changes of aging, including reduced cardiac, kidney, and respiratory function and reserve; and alterations in the ratio of body fluids to muscle mass, may alter the responses of elderly people to fluid and electrolyte changes and acid–base disturbances. In addition, the frequent use of medications in the older adult can affect kidney and cardiac function and fluid balance, thereby increasing the likelihood of fluid and electrolyte disturbances. Routine procedures, such as the vigorous administration of laxatives before GI studies, may produce a serious FVD, necessitating the use of IV fluids to prevent hypotension and other effects of hypovolemia.



Role of ANP/ANF
↑NaCl concentration
↑Blood volume
↑Blood pressure
↑Stretch of atria
↑ANP/ANF release from cardiac cells in atria
↓Suppression of RA system, thus angiotensin II
↓Aldosterone release by adrenal cortex
↓ADH release by posterior pituitary gland
↑GFR
↑Na+ excretion
↑Rate of urine production and water excretion
↓Blood volume
↓CVP
↓CO
↓Arterial blood pressure
↓Preload
↓HR
Key:
ANP/ANF = atrial natriuretic peptide/atrial natriuretic factor
CO = Cardiac output
CVP = Central venous pressure
GFR = Glomerular filtration rate
HR = Heart rate
RA = Renin–angiotensin

FIGURE 4-4 Role of atrial natriuretic peptide (ANP) in maintenance of fluid balance.

Alterations in fluid and electrolyte balance that may produce minor changes in young and middle-aged adults have the potential to produce profound changes in older adults, accompanied by a rapid onset of signs and symptoms. In elderly patients, the clinical manifestations of fluid and electrolyte disturbances may be subtle or atypical. For example, fluid deficit may cause confusion or cognitive impairment in the elderly person, whereas in the young or middle-aged person the first sign commonly is increased thirst. Rapid infusion of an excessive volume of IV fluids may produce fluid overload and cardiac failure in the elderly patient. These reactions are likely to occur more quickly and with the administration of smaller volumes of fluid than in healthy young and middle-aged adults because of the decreased cardiac reserve and reduced kidney function that accompany aging. Dehydration in the elderly is common as a result of decreased reserve capacity of the kidney from the aging process, disease, and use of medications.

Increased sensitivity to fluid and electrolyte changes in elderly patients requires careful assessment, with attention to I&O of fluids from all sources and to changes in daily weight; careful monitoring of side effects and interactions of medications; and prompt reporting and management of disturbances.

FLUID VOLUME DISTURBANCES

Appendix A summarizes the major fluid and electrolyte imbalances that are described in this chapter.

HYPOVOLEMIA

FVD, or hypovolemia, occurs when loss of ECF volume exceeds the intake of fluid. It occurs when water and electrolytes are lost in the same proportion as they exist in normal body fluids, so that the ratio of serum electrolytes to water remains the same. FVD should not be confused with the term *dehydration,* which refers to loss of water alone, with increased serum sodium levels. FVD may occur alone or in combination with other imbalances. Unless other imbalances are present concurrently, serum electrolyte concentrations remain essentially unchanged.

Pathophysiology

FVD results from loss of body fluids and occurs more rapidly when coupled with decreased fluid intake. FVD can develop from inadequate intake alone if the decreased intake is prolonged. The nurse considers NPO status of patients for diagnostic tests, those with difficulty swallowing, nausea, decreased level of consciousness (LOC), or depression when IV fluids are not administered. The elderly are at risk for FVD because of poor oral intake and potential difficulty gaining access to water. Causes of FVD also include abnormal fluid losses, such as those resulting from vomiting, diarrhea, GI suctioning (nasogastric or intestinal tubes, drains [biliary, pancreatic]), fever, and sweating. Additional risk factors include burns, surgery, diabetes insipidus, adrenal insufficiency, osmotic diuresis, hemorrhage, and coma. Third-space fluid shifts, or the movement of fluid from the vascular system to other body spaces (e.g., with edema formation in burns, ascites with liver dysfunction), also cause FVD because although the fluid has not left the body, it is not available in the IVS.

Clinical Manifestations and Assessment

FVD can develop rapidly and can be mild, moderate, or severe, depending on the degree of fluid loss. Important signs include acute weight loss; decreased skin turgor; oliguria (urinary output below 400 mL/day); concentrated urine with a high specific gravity; postural hypotension (a 20 mm Hg decrease in systolic pressure or a 10 mm Hg decrease in diastolic pressure with position change); a weak, rapid heart rate; flattened neck veins; decreased CVP; cool, clammy skin related to peripheral vasoconstriction; a smaller tongue with additional longitudinal furrows; dry oral mucous membranes; delayed capillary refill (greater than 2 seconds); altered sensorium; and thirst. Diagnostic testing includes BUN and its relation to serum creatinine concentration. A volume-depleted patient has a BUN elevated out of proportion to the serum creatinine (ratio greater than 20:1). The BUN can also be elevated because of decreased renal perfusion and function. The cause of abnormal laboratory findings may be determined through the health history and physical findings.

The hematocrit level is greater than normal in dehydration because the RBC become suspended in a decreased plasma volume, which is also known as *hemoconcentration.*

Serum electrolyte changes may also exist. Potassium and sodium levels can be reduced (hypokalemia, hyponatremia) or elevated (hyperkalemia, hypernatremia):

- Hypokalemia occurs with GI and kidney losses;
- Hyperkalemia occurs with adrenal insufficiency;
- Hyponatremia occurs with increased thirst and ADH release;
- Hypernatremia results from increased insensible losses and diabetes insipidus.

Specific gravity of urine is increased in relation to the kidneys' attempt to conserve water and decreased with diabetes insipidus. The range of urine specific gravity will vary with

- the hydration status of the patient (increased with FVD, decreased with FVE),
- the volume of urine (increased with decreased urine output, decreased specific gravity with increased urine output), and
- the number of the particles in the urine (increased with increased particles, decreased with less particles).

A urine specific gravity of 1.005 or less indicates the diluting ability of the kidney, whereas 1.020 or greater indicates concentrating ability of the kidney. For example, a patient with preserved kidney function who is volume depleted will have a specific gravity greater than 1.020 because the patient is able to concentrate his or her urine. However, there are times that the specific gravity is falsely elevated, such as during kidney excretion of radiopaque x-ray contrast (high-molecular-weight substance). Thus, a urine osmolality test is a more exact measurement than specific gravity and may be required when assessment of the concentrating or diluting function of the kidney is needed.

Medical Management

When planning the correction of fluid loss for the patient with FVD, the health care provider considers the usual maintenance requirements of the patient and other factors (e.g., fever) that can influence fluid needs. If the deficit is not severe, the oral route is preferred, provided the patient can drink. However, if fluid losses are acute or severe, the IV route is required. Isotonic electrolyte solutions (e.g., lactated Ringer solution, 0.9% sodium chloride) are frequently used to treat the hypotensive patient with FVD because those solutions expand plasma volume. ICS is essentially sodium free; thus, for every liter of 0.9% sodium chloride administered, 1,000 mL will remain in the ECS, of which approximately 250 mL will remain in the IVS, re-expanding the plasma volume. Because this solution can expand the IVS, patients must be assessed for signs and symptoms of FVE (discussed shortly). As soon as the patient becomes normotensive (normalization of their blood pressure), a hypotonic electrolyte solution (e.g., 0.45% sodium chloride) is often used to provide both electrolytes and water for renal excretion of metabolic wastes. These and additional fluids are discussed later in the chapter.

Nursing Alert

The nurse understands that when the patient is hypotensive, restoration of the IVS is imperative. If an isotonic solution such as Dextrose 5% Water (D5W) (primarily water as the sugar is metabolized quickly) was administered, two thirds of the fluid would move to the ICS (approximately 666 mL); recall the discussion earlier when we noted two thirds of the water in the body is intracellular, which will not increase the blood pressure! The remaining 333 mL will be in the ECS, but approximately 75% will move to the interstitial space, leaving only 83 mL in the IVS, which is unlikely to increase the blood pressure significantly. Thus, in emergency situations, a solution such as normal saline (0.9% NaCl) is selected because 75% of the solution will move to the interstitial space, leaving 25% in the circulating blood volume (IVS).

Accurate and frequent assessments of I&O, weight, vital signs, CVP, LOC, breath sounds, and skin color should be performed to determine when therapy should be slowed to avoid volume overload. The rate of fluid administration is based on the severity of loss and the patient's hemodynamic response to volume replacement.

If the patient with severe FVD is not excreting enough urine and is, therefore, oliguric (less than 400 mL/24 hrs), the health care provider needs to determine whether the depressed function is caused by reduced renal blood flow secondary to FVD (prerenal azotemia or increased nitrogen levels in the blood) or, more seriously, by acute tubular necrosis from prolonged FVD. The test used in this situation is referred to as a *fluid challenge test.* During a fluid challenge test, volumes of fluid are administered at specific rates and intervals while the patient's hemodynamic response to this treatment is monitored (i.e., vital signs, breath sounds, sensorium, CVP, pulmonary capillary wedge pressure values, and urine output).

An example of a typical fluid challenge involves administering 100 to 200 mL of normal saline solution over 15 minutes. The goal is to provide fluids rapidly enough to attain

adequate tissue perfusion without compromising the cardiovascular system. The response by a patient with FVD but normal kidney function is increased urine output and an increase in blood pressure and CVP.

Shock can occur when the volume of fluid lost exceeds 25% of the intravascular volume, or when fluid loss is rapid. Shock and its causes and treatment are discussed in detail in Chapters 20 and 54.

Nursing Management

Assessing Fluid Status

To assess for FVD, the nurse monitors and measures fluid I&O at least every 8 hours; depending on the patient's status, the assessment may be done hourly. As FVD develops, body fluid losses exceed fluid intake. This loss may be in the form of excessive urination (polyuria), diarrhea, vomiting, and so on. Later, after FVD progresses, the kidneys attempt to conserve needed body fluids, leading to a urine output of less than 30 mL/hr in an adult. Urine in this instance is concentrated; the specific gravity generally is greater than 1.020, indicating healthy renal conservation of fluid.

Daily body weights are monitored; an acute loss of 1 lb represents a fluid loss of approximately 500 mL, whereas 1 L is approximately 1 kg, or 2.2 lbs.

Nursing Alert
The nurse recognizes that the FVD is associated with weight loss; however, if the patient is edematous or third-spacing (e.g., developing ascites), weight gain may be seen despite FVD.

Vital signs are closely monitored. The nurse observes for a weak, rapid pulse and postural hypotension (i.e., a decrease in systolic pressure exceeding 20 mm Hg when the patient moves from a lying to a sitting position). Skin and tongue turgor is monitored on a regular basis. In a healthy person, pinched skin immediately returns to its normal position when released. This elastic property, referred to as *turgor,* is partially dependent on interstitial fluid volume. In a person with FVD, the skin flattens more slowly after the pinch is released. In a person with severe FVD, the skin may remain elevated for many seconds. Skin turgor is best measured by pinching the skin over the sternum, inner aspects of the thighs, or forehead.

Nursing Alert
Skin turgor is a less valid assessment in the elderly patient because the skin has lost some of its elasticity due to the decreased number of papillae and collagen fibers; therefore, other assessment measures become more useful in detecting FVD (e.g., slowness in filling of veins of the hands and feet: veins in hands generally fill within 3 to 5 seconds; if filling takes longer than 5 seconds, consider FVD or hypovolemia). In elderly patients, skin turgor is best tested over the forehead or the sternum because alterations in skin elasticity are less marked in these areas.

Tongue turgor is not affected by age. In a normal person, the tongue has one longitudinal furrow. In the person with FVD, there are additional longitudinal furrows, and the tongue is smaller because of fluid loss. The degree of oral mucous membrane moisture is also assessed; a dry mouth may indicate either FVD or mouth breathing.

Mental function is eventually affected in severe FVD as a result of decreasing cerebral perfusion. Decreased peripheral perfusion can result in cold extremities. In patients with relatively normal cardiopulmonary function, a low CVP is indicative of hypovolemia.

Patients with acute cardiopulmonary decompensation require more extensive hemodynamic monitoring of pressures in both sides of the heart to determine if hypovolemia exists.

Preventing Fluid Volume Deficit

To prevent FVD, the nurse identifies patients at risk and takes measures to minimize fluid losses. The nurse recognizes that patients who are semidependent on another for care (related to sensorium or mobility) are at a higher risk for limited fluid intake. For example, if the patient has diarrhea, diarrhea-control measures should be implemented and replacement fluids administered. These measures may include administering antidiarrheal medications and small volumes of oral fluids at frequent intervals or, if necessary, IV therapy. Given the typical sensible and insensible loss of approximately 2,600 mL per day, if a patient is NPO, the nurse expects that the total daily water requirement for a 70-kg man is about 2,000 mL: This translates to approximately 30 mL/kg/day. However, fluid and electrolyte therapy should be individualized based upon physical examination findings, daily weight, and serum electrolytes.

Nursing Alert
The nurse is aware that when a patient has an increased insensible loss, it is associated with FVD. As an example, when the patient has an elevated temperature between 101°F and 103°F, an increase of 1,000 mL of fluid may be needed; fluid needs also increase in clinical scenarios such as diarrhea, vomiting, and an increased respiratory rate (greater than 35 breaths per minute). In general, insensible loss is calculated as 5 to 10 mL/kg per day (Mount, 2015).

Correcting Fluid Volume Deficit

When administering oral fluids, consideration is given to the patient's likes and dislikes. The type of fluid the patient has lost is also considered, and attempts are made to select fluids most likely to replace the lost electrolytes. If the patient is reluctant to drink because of oral discomfort, the nurse assists with frequent mouth care and provides nonirritating fluids. If nausea is present, antiemetics may be ordered and administered before oral fluid replacement is initiated.

If the patient cannot eat and drink, fluid may need to be administered by an alternative route (enteral or parenteral) until adequate circulating blood volume and renal perfusion are achieved. Isotonic fluids are prescribed to increase ECF volume.

Nursing Alert
When fluid balance is critical, all routes of gain and all routes of loss must be recorded and all volumes compared. Organs of fluid loss include the kidneys, skin, lungs, and GI tract.

HYPERVOLEMIA

FVE, or hypervolemia, refers to an isotonic expansion of the ECF caused by the abnormal retention of water and sodium in approximately the same proportions in which they normally exist in the ECF. It is always secondary to an increase in the total body sodium content, which, in turn, leads to an increase in total body water. Because there is isotonic retention of body substances, the serum sodium concentration remains essentially normal.

Nursing Alert

There are conditions that cause retention of water relative to sodium, such as SIADH. In these situations, hemodilution of the ECF will be reflected by decreased sodium, as well as BUN, and hematocrit. The term used for this situation is hypervolemic (increased volume) hyponatremia (decreased sodium related to dilution).

Pathophysiology

The maintenance of an effective circulating volume—that part of the "extracellular fluid that is in the arterial system and, therefore, effectively perfusing tissues" (Rennke & Denker, 2010)—is essential to sustain blood pressure to ensure organ vitality is monitored and tightly regulated. It may be increased in a number of situations, including fluid overload; excessive water ingestion; iatrogenic overadministration of IV fluids; or the ectopic secretion of ADH. Since the kidneys are responsible for regulating fluid excretion, kidney failure, either acute or chronic, is also associated with FVE. Excessive salt intake or the administration of sodium-containing fluids in a patient with impaired renal regulatory mechanisms may predispose the patient to serious FVE. On the other hand, a decrease in the effective circulating volume results in activation of the RAAS. Consider that since circulation is critical for survival, if the heart pump does not work effectively to generate enough volume for perfusion and function of vital organs, this "underfilling" results in activation of RAAS. This activation of RAAS results in increased circulating ADH or AVP and aldosterone, which increases sodium reabsorption and renal water reabsorption. This occurs in situations where cardiac output is decreased (heart failure) or when the patient suffers from hypovolemia (blood loss), increased capillary permeability (anaphylaxis), or extreme vasodilation (neurogenic shock).

Nursing Alert

The nurse understands that a normal serum sodium is 135 to 145 mEq/L (135 to 145 mmol/L), and that normal saline or 0.9% NaCl has 154 mEq/L of sodium, thus overadministration of normal saline leads to hypernatremia and potential for FVE.

Clinical Manifestations and Assessment

Clinical manifestations of FVE stem from expansion of the ECF and include edema, distended neck veins or jugular vein distention (JVD), and crackles (abnormal lung sounds) in lung fields. Other manifestations include tachycardia; increased blood pressure, pulse pressure, and CVP; increased weight; increased urine output (with normal kidney function); shortness of breath, and/or wheezing.

Laboratory data useful in diagnosing FVE include BUN and hematocrit levels. In FVE, both of these values may be decreased because of plasma dilution, termed *hemodilution.* Other causes of abnormalities in these values include low protein intake and anemia. Azotemia (increased nitrogen levels in the blood) can also occur with FVE when urea and creatinine are not excreted due to decreased perfusion by the kidneys and decreased excretion of wastes. In CKF, both serum osmolality and the sodium level are decreased due to excessive retention of water (inability of the kidneys to excrete the normal 1.5 L/day). The urine sodium level is increased if the kidneys are attempting to excrete excess volume. Chest x-rays may reveal pulmonary congestion. Hypervolemia occurs when aldosterone is chronically stimulated (i.e., cirrhosis, heart failure, and nephrotic syndrome). Therefore, the urine sodium level does not increase in these conditions.

Medical Management

Management of FVE is directed at the causes. If the fluid excess is related to excessive administration of sodium-containing fluids, discontinuing the infusion may be all that is needed. Symptomatic treatment consists of administering diuretics and restricting fluids and sodium.

Pharmacologic Therapy

Diuretics are prescribed when dietary restriction of sodium alone is insufficient to reduce fluid excess, which inhibits the reabsorption of sodium and water by the kidneys. The choice of diuretic is based on the severity of the hypervolemic state, the degree of impairment of kidney function, and the potency of the diuretic. Thiazide diuretics block sodium reabsorption in the distal tubule, where only 5% to 10% of filtered sodium is reabsorbed. Loop diuretics, such as furosemide (Lasix), or bumetanide (Bumex), can cause a greater loss of both sodium and water because they block sodium reabsorption in the ascending limb of the loop of Henle, where 20% to 30% of filtered sodium is normally reabsorbed. Generally, thiazide diuretics, such as hydrochlorothiazide or metolazone (Zaroxolyn), are prescribed for mild to moderate hypervolemia and loop diuretics for severe hypervolemia.

Electrolyte imbalances may result from the effect of the diuretic. Hypokalemia can occur with all diuretics except those that work in the last distal tubule of the nephrons (e.g., spironolactone). Potassium supplements can be prescribed to avoid this complication. Hyperkalemia can occur with diuretics that work in the last distal tubule, especially in patients with decreased kidney function.

Hemodialysis

If kidney function is so severely impaired that pharmacologic agents cannot act efficiently, other modalities are considered to remove sodium and fluid from the body. Hemodialysis or peritoneal dialysis may be used to remove nitrogenous wastes and control potassium and acid–base balance, and to remove sodium and fluid. Continuous renal replacement therapy may also be required. See Chapter 27 for discussion of these treatment modalities.

Nutritional Therapy

Treatment of FVE usually involves dietary restriction of sodium. An average daily diet not restricted in sodium contains 6 to 15 g of salt, whereas low-sodium diets can range from a mild restriction to as little as 250 mg of sodium per day, depending on the patient's needs. A mild sodium-restricted diet allows only light salting of food (about half the usual amount) in cooking and at the table as well as no addition of salt to commercially prepared foods that are already seasoned. Of course, foods high in sodium must be avoided. It is the sodium salt, sodium chloride, rather than sodium itself that contributes to edema. Therefore, patients are instructed to read food labels carefully to determine salt content.

Because about half of ingested sodium is in the form of seasoning, seasoning substitutes can play a major role in decreasing sodium intake. Lemon juice, onions, and garlic are

excellent substitute flavorings, although some patients prefer salt substitutes. Most salt substitutes contain potassium and, therefore, must be used cautiously by patients taking potassium-sparing diuretics (e.g., spironolactone, triamterene, amiloride). They should not be used at all in conditions associated with potassium retention, such as advanced kidney disease. Salt substitutes containing ammonium chloride can be harmful to patients with liver damage.

In some communities, the drinking water may contain too much sodium for a sodium-restricted diet. Depending on its source, water may contain as little as 1 mg or more than 1,500 mg per quart. Patients may need to use distilled water if the local water supply is very high in sodium. Bottled water can have a sodium content from 0 to 1,200 mg/L; therefore, if sodium is restricted, the label must be examined carefully for sodium content before purchasing and drinking bottled water. Also, patients on sodium-restricted diets should be cautioned to avoid water softeners that add sodium to water in exchange for other ions, such as calcium.

Nursing Management

Assessing the Patient

To assess for FVE, the nurse measures I&O at regular intervals to identify excessive fluid retention. The patient is weighed daily, and acute weight gain is noted. An acute weight gain of 2.2 lb (1 kg) is equivalent to a gain of approximately 1 L of fluid. The nurse also needs to assess breath sounds at regular intervals in at-risk patients, particularly if parenteral fluids are being administered. The nurse monitors the degree of edema in the most dependent parts of the body, such as the feet and ankles in ambulatory patients and the sacral region in patients confined to bed. The degree of pitting edema is assessed, and the extent of peripheral edema is monitored by measuring the circumference of the extremity or the abdomen (in ascites) with a tape marked in millimeters. In general, edema that is apparent is associated with a minimum of 2.5 L of fluid in the interstitial space, and pitting edema is associated with a gain of 4.5 L (approximately 10 lb) (Longo et al., 2015). Often a history of weight gain will correlate with the edema.

Nursing Alert

The etiology of edema—visible or palpable (pitting) tissue swelling produced by the expansion of interstitial fluid volume—is not as simple as it may appear. Edema occurs in response to many factors, including increased venous pressure, as with a deep vein thrombosis (DVT) or venous clot; lymphatic drainage obstruction (often an unwanted side effect of removal of the breast [mastectomy] and underarm lymph tissue); decreased plasma albumin oncotic pressure (seen in malnutrition, nephrotic syndrome, or liver damage); increased capillary leakage (caused by burns, sepsis); local injury (a result of sprains, fractures, surgery); infection (cellulitis), or inadequate valves in the venous system (chronic venous insufficiency) (Nadler & Gonzales, 2016). The nurse must consider a variety of etiologies when assessing edema.

Preventing Fluid Volume Excess

Specific interventions vary somewhat with the underlying condition and the degree of FVE. However, most patients require sodium-restricted diets in some form, and adherence to the prescribed diet is strongly recommended. Patients are instructed to avoid over-the-counter medications without first checking with a health care provider because these substances may contain sodium. If fluid retention persists despite adherence to a prescribed diet, hidden sources of sodium, such as the water supply or use of water softeners, should be considered.

Correcting Fluid Volume Excess

It is important to detect FVE before the condition becomes critical. Interventions include restricting sodium intake, monitoring parenteral fluid therapy, and administering appropriate medications.

Sodium and fluid restriction should be instituted as indicated. Because most patients

with FVE require diuretics, the patient's response to these agents is monitored. The rate of parenteral fluids and the patient's response to these fluids are also closely monitored. If dyspnea or orthopnea is present, the patient is placed in a semi-Fowler position to promote lung expansion. The patient is turned and positioned at regular intervals, and skin is assessed at regular intervals because edematous tissue is fragile and more prone to skin breakdown than normal tissue. Because conditions predisposing to FVE are likely to be chronic, patients are taught to monitor their response to therapy by monitoring their fluid I&O and documenting daily body weight changes.

Teaching Patients about Edema

Because edema is a common manifestation of FVE, patients need to recognize its symptoms and understand its importance. As noted earlier, edema can occur as a result of increased capillary fluid pressure, decreased capillary oncotic pressure, or increased interstitial oncotic pressure, causing expansion of the interstitial fluid compartment (Porth, 2015). Edema can be localized (e.g., in the ankle, as in rheumatoid arthritis) or generalized (as in cardiac and kidney failure). Severe generalized edema is called *anasarca.*

Edema occurs when there is a change in the capillary membrane, increasing the formation of interstitial fluid or decreasing the removal of interstitial fluid. Sodium retention is a frequent cause of the increased ECF volume. Burns and infection are examples of conditions associated with increased interstitial fluid volume. Obstruction to lymphatic outflow, decreased plasma albumin levels, or a decrease in plasma oncotic pressure contributes to increased interstitial fluid volume. The kidneys retain sodium and water when decreased ECF volume occurs as a result of decreased cardiac output from heart failure. A thorough medication history is necessary to identify any medications that could cause edema, such as nonsteroidal anti-inflammatory drugs (NSAIDs), estrogens, corticosteroids, and antihypertensive agents.

Ascites is a form of edema in which fluid accumulates in the peritoneal cavity; it results from nephrotic syndrome, cirrhosis, and some malignant tumors. The patient commonly reports shortness of breath and a sense of pressure because of pressure on the diaphragm.

Edema usually affects dependent areas. It can be seen in the ankles, sacrum, scrotum, or the periorbital region of the face. Pitting edema is so named because a pit forms after a finger is pressed into edematous tissue. In pulmonary edema, the amount of fluid in the pulmonary interstitium and the alveoli increases. Manifestations include shortness of breath, increased respiratory rate, diaphoresis, and crackles and wheezing on auscultation of the lungs. Decreased hematocrit resulting from hemodilution as well as decreased serum sodium and osmolality from retention of fluid may occur with edema. The goal of treatment is to preserve or restore the circulating intravascular fluid volume. In addition to treating the cause, other treatments may include diuretic therapy, restriction of fluids and sodium, elevation of the extremities, application of elastic compression stockings, paracentesis, dialysis, and continuous renal replacement therapy in cases of kidney failure or life-threatening fluid volume overload.

ELECTROLYTE IMBALANCES

Disturbances in electrolyte balances are common in clinical practice and must be corrected for the patient's health and safety.

SODIUM IMBALANCES

Sodium is the most abundant electrolyte in the ECF; its concentration ranges from 135 to 145 mEq/L (135 to 145 mmol/L). Consequently, sodium is the primary determinant of ECF osmolality. Sodium plays a major role in controlling water distribution throughout the body because it does not easily cross the intracellular membrane and because of its abundance and high concentration in the body. Sodium also functions in establishing the electrochemical state necessary for muscle contraction and the transmission of nerve impulses. Sodium is regulated by ADH, thirst, and the RAAS. A loss or gain of sodium is usually accompanied by a loss or gain of water.

The sodium imbalances commonly seen are: sodium deficit (hyponatremia) and sodium excess (hypernatremia).

HYPONATREMIA (SODIUM DEFICIT)

Hyponatremia refers to a serum sodium level that is below normal (less than 135 mEq/L [135 mmol/L]).

Pathophysiology

Plasma sodium concentration represents the ratio of total body sodium to total body water. A decrease in this ratio can occur because of salt loss that is greater than water loss (e.g., diarrhea, diuretics, NG tube suctioning), or there is an excess of water relative to total body sodium (e.g., congestive heart failure, cirrhosis of the liver, excessive water intake without salt, SIADH). Therefore, a hyponatremic state can be superimposed on an existing FVD or FVE.

Sodium may be lost by way of vomiting, diarrhea, fistulas, or prolonged or excessive sweating, or it may be lost as the result of the use of diuretics, particularly in combination with a low-salt diet. A deficiency of aldosterone, as occurs in adrenal insufficiency, also predisposes a patient to sodium deficiency. Potomania, otherwise known as beer potomania, due to the chronic consumption of large amounts of beer (a hypotonic solution) and protein malnutrition, may also cause hyponatremia due to an inability of the kidneys to excrete free water.

In dilutional hyponatremia (water intoxication), the patient's serum sodium level is diluted by an increase in the ratio of water to sodium. Dilutional hyponatremia, therefore, results from an increased ECF volume and a normal or increased total body sodium. Predisposing conditions for this type of hyponatremia include cirrhotic ascites; SIADH; hyperglycemia, which causes increased water to be drawn into the IVS; and increased water intake through the administration of electrolyte-poor parenteral fluids, the use of tap-water enemas, or the irrigation of nasogastric tubes with water instead of normal saline solution. Water may be gained abnormally by the excessive parenteral administration of hypotonic solutions such as dextrose and water solutions, particularly during periods of stress. It may also be gained by compulsive water drinking (psychogenic polydipsia).

Nursing Alert
Psychogenic polydipsia has been linked to a number of psychiatric conditions; however, it can also occur in a variety of individuals, including high endurance athletes, users of 3,4-Methylenedioxymethamphetamine (MDMA, commonly known as ecstasy), and in patients receiving total parenteral nutrition (TPN) or partial parenteral nutrition (PPN) (Gill & McCauley, 2015).

The basic physiologic disturbances in SIADH are excessive ADH activity, with water retention and dilutional hyponatremia, and inappropriate urinary excretion of sodium in the presence of hyponatremia. SIADH can be the result of either sustained secretion of ADH by the hypothalamus or production of an ADH-like substance from a tumor (aberrant ADH production). Conditions associated with SIADH include oat-cell lung tumors, head injuries, endocrine and pulmonary disorders, physical or psychologic stress, and a variety of medications (e.g., vincristine, phenothiazines, tricyclic antidepressants, and thiazide diuretics). SIADH is discussed in more detail in Chapter 31.

Clinical Manifestations and Assessment

Clinical manifestations of hyponatremia depend on the cause, magnitude, and speed with which the deficit occurs. Patients can present with FVD, as euvolemic (SIADH), or with FVE. With true salt loss, a number of conditions occur, including poor skin turgor, dry mucosa, headache, decreased saliva production, orthostatic blood pressure (decreased with position changes), nausea, and abdominal cramping. With water gain in excess of sodium, clinical manifestations are associated with FVE, such as edema, crackles, ascites, and JVD. Symptoms are primarily neurologic. They are related to osmotic water shift as water from the relatively dilute ECF is pulled into the cell, leading to increased ICF volume, specifically brain cell swelling or cerebral edema (Fig. 4-5). The skull limits the brain's ability to expand, which results in increased intracranial pressure (ICP), the precursor to brain damage. Neurologic changes include altered mental status, headache, lethargy, seizures, and a progressively decreased LOC eventuating in coma. When the serum sodium level decreases to less than 115 mEq/L (115 mmol/L), signs of increasing intracranial pressure may occur, such as lethargy, confusion, muscle twitching, focal weakness, hemiparesis, papilledema, and seizures. In general, patients with an acute decrease in serum sodium levels have more cerebral edema and higher mortality rates than those with more slowly developing hyponatremia. Acute decreases in sodium, developing in less than 48 hours, may be associated with brain herniation and compression of midbrain structures.

Regardless of the cause of hyponatremia, the serum sodium level is less than 135 mEq/L; in SIADH it may be as low as 100 mEq/L (100 mmol/L) or even less. Serum osmolality is also decreased, except in azotemia or ingestion of toxins. When hyponatremia is due primarily to sodium loss, the urinary sodium content is less than 20 mEq/L (20 mmol/L), suggesting increased renal reabsorption of sodium secondary to ECF volume depletion, and the specific gravity is low (1.002 to 1.004). However, when hyponatremia is due to SIADH, the urinary sodium content is greater than 20 mEq/L, and the urine specific gravity is usually greater than 1.012. Although the patient with SIADH retains water abnormally and, therefore, gains body weight, there is no peripheral edema; instead, fluid accumulates equally within the three compartments (intracellular, interstitial, and intravascular).

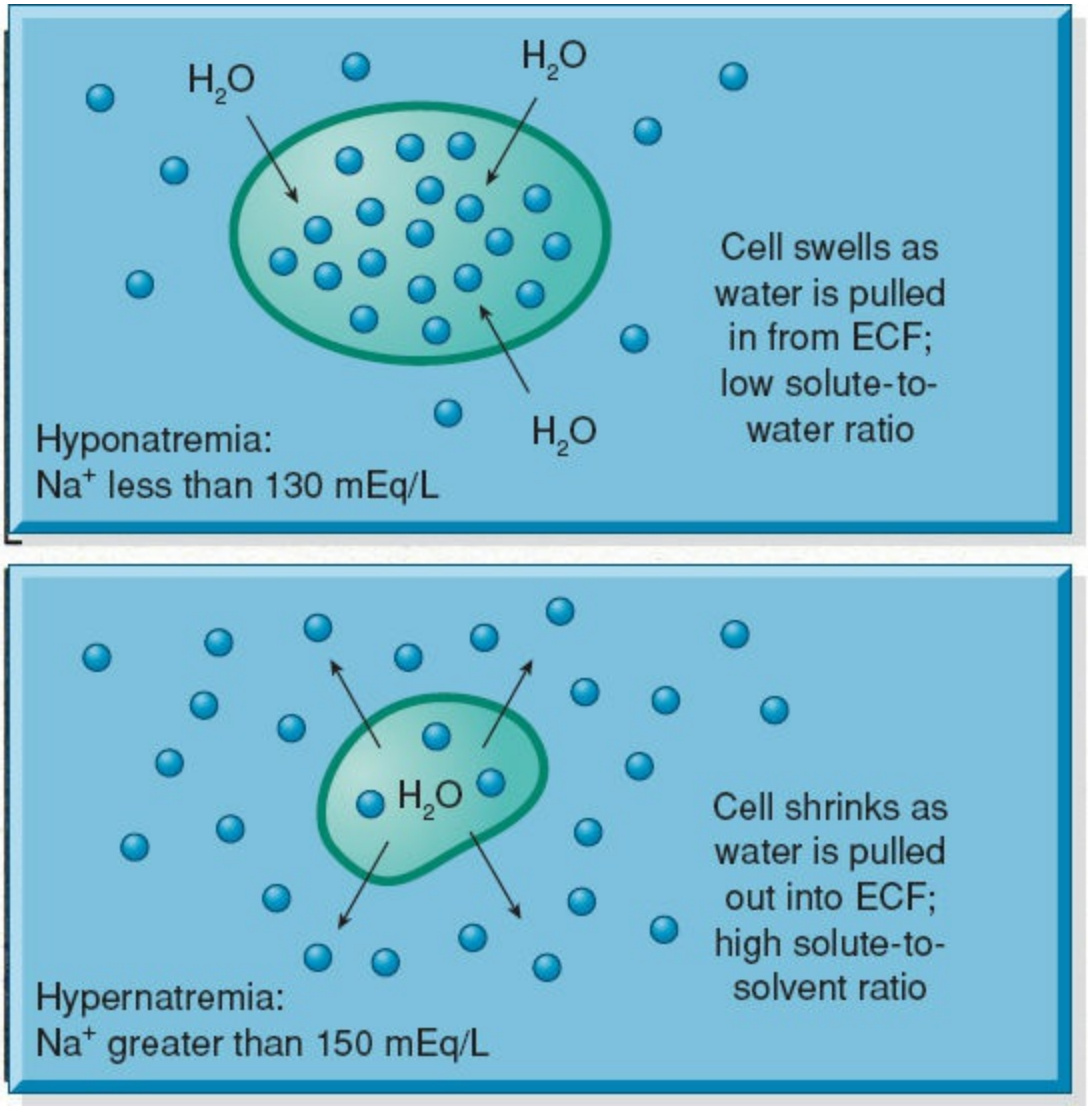


FIGURE 4-5 Effect of extracellular sodium level on cell size.

Medical Management

Treatment depends on the cause of the hyponatremia, the amount of time the individual has had hyponatremia, and the presence of signs and symptoms. Hyponatremia is considered acute if it developed within the last 24 hours and chronic if the duration of time since the initiation of hyponatremia is more than 24 hours or unknown. If the etiology is related to sodium and (to a lesser extent) water loss, sodium and water replacement is expected; if the etiology is related to water intoxication, restriction of fluid intake and diuretics are anticipated.

Sodium Replacement

If treatment for hyponatremia is warranted, careful administration of sodium by mouth, nasogastric tube, or a parenteral route may be ordered. For patients who can eat and drink, sodium is easily replaced because sodium is consumed abundantly in a normal diet. For those who cannot consume sodium, lactated Ringer solution or isotonic saline (0.9% sodium chloride) solution may be prescribed. Serum sodium must not be increased by more than 12 mEq/L in the first 24 hours to avoid neurologic damage due to osmotic demyelination. This condition, termed *central pontine myelinolysis (CPM),* may occur when the serum sodium concentration is overcorrected (exceeding 140 mEq/L) too rapidly, causing a relatively hypotonic ICS compared to the ECS. This causes water to flow from the ICS to the ECS, causing cell volume collapse. Osmotic demyelination presents as flaccid paralysis, dysarthria (speech that is slurred, slow, and difficult to produce), dysphagia (difficulty in swallowing), and quadriparesis. The usual daily sodium requirement in adults is approximately 100 mEq, provided no abnormal losses occur. Selected water and electrolyte solutions are described later in the chapter.

In SIADH, the administration of hypertonic saline solution alone cannot change the plasma sodium concentration. Excess sodium would be excreted rapidly in highly concentrated urine. With the addition of the diuretic furosemide (Lasix), urine is not concentrated, and isotonic urine is excreted to effect a change in water balance. In patients with SIADH, in whom water restriction is difficult, lithium or demeclocycline can antagonize the osmotic effect of ADH on the medullary collecting tubule.

In patients with severe symptoms of hyponatremia, such as seizures or obtundation, or in patients with acute hyponatremia, administration of hypertonic saline solution may be ordered to stabilize the patient and prevent brain herniation. In this setting, the goal increase of sodium is 4 to 6 mEq/L and a maximum of 8 mEq/L in a 24-hour period; however, these values are often debated. The adage of "go slow" has particular utility in symptomatic hyponatremia.

Water Restriction

In a patient with normal or excess fluid volume, hyponatremia is treated by restricting fluid to a total of 800 mL in 24 hours. This is far safer than sodium administration and is usually effective. However, if neurologic symptoms are present, it may be necessary to administer small volumes of a hypertonic sodium solution, such as 3% sodium chloride. Incorrect use of these fluids is extremely dangerous because 1 L of 3% sodium chloride solution contains

513 mEq of sodium with an osmolality of 1,026! Recall normal serum osmolality is 275 to 300 mOsm/kg. A 3% saline solution is three times higher; thus if administered rapidly, the blood osmolality would increase dramatically. However, because of the blood–brain barrier, the osmolality in the brain would be the same, thus intracellular water would attempt to try to dilute the bloodstream causing CPM (see alert below). If edema exists alone, sodium is restricted; if edema and hyponatremia occur together, both sodium and water are restricted.

Nursing Alert

A 3% saline solution has an osmolality of 1,026 mOsm/kg. A normal serum osmolality varies from approximately 275 to 300 mOsm/kg. Thus, a 3% saline solution is three times more concentrated than normal blood osmolality. Rapid administration would have an adverse impact on the brain. The blood osmolality would increase dramatically. However, because the blood–brain barrier limits capillary sodium but not water permeability, the movement of interstitial and neuronal intracellular water into the capillary may potentially culminate in cerebral shrinkage, osmotic demyelination, and the constellation of clinical symptoms (including paraparesis, dysphagia, and coma) known as CPM. In addition, a solution this concentrated must be administered via a central IV line because it is too concentrated for peripheral veins; it is tolerated when administered in central lines because it is diluted by vena cavae blood.

Nursing Management

The nurse needs to identify patients at risk for hyponatremia so that they can be monitored. Early detection and treatment of this disorder are necessary to prevent serious consequences. For patients at risk, the nurse monitors fluid I&O as well as daily body weight. It is also necessary to note abnormal losses of sodium or gains of water as well as GI manifestations such as anorexia, nausea, vomiting, and abdominal cramping. The nurse must be particularly alert for CNS changes, such as lethargy, confusion, muscle twitching, and seizures. In general, more severe neurologic signs are associated with very low sodium levels that have fallen rapidly because of fluid overloading. Serum sodium is monitored very closely in patients who are at risk for hyponatremia; when indicated, urine sodium and specific gravity are also monitored.

Hyponatremia is a frequently overlooked cause of confusion in elderly patients, who have an increased risk for hyponatremia because of changes in kidney function and subsequent decreased ability to excrete excessive water loads. Administration of medications causing sodium loss or water retention is a predisposing factor.

Correcting Hyponatremia

For a patient who is experiencing abnormal losses of sodium and can consume a general diet, the nurse encourages foods and fluids with a high sodium content. For example, broth made with one beef cube contains approximately 900 mg of sodium; 8 oz of tomato juice contains approximately 700 mg of sodium. The nurse also needs to be familiar with the sodium content of parenteral fluids (see later discussion and Table 4-6 on page 93).

For the patient taking lithium, the nurse observes for lithium toxicity, particularly when sodium is lost by an abnormal route. In such instances, supplemental salt and fluid are administered. Because diuretics promote sodium loss, the patient taking lithium is instructed not to use diuretics without close medical supervision. For all patients on lithium therapy, adequate salt intake should be ensured.

Excess water supplements are avoided in patients receiving isotonic or hypotonic enteral feedings, particularly if abnormal sodium loss occurs or water is being retained abnormally (as in SIADH). Actual fluid needs are determined by evaluating fluid I&O, urine specific gravity, and serum sodium levels.

HYPERNATREMIA (SODIUM EXCESS)

Hypernatremia is a higher-than-normal serum sodium level (exceeding 145 mEq/L [145 mmol/L]).

Pathophysiology

Hypernatremia can be caused by a gain of sodium in excess of water or by a loss of water in excess of sodium. It can occur in the euvolemic patient or in those with FVD or FVE. With a water loss, the patient loses more water than sodium; as a result, the serum sodium concentration increases and the increased concentration pulls fluid out of the cell. This is both an extracellular and an intracellular FVD. In sodium excess, the patient ingests or retains more sodium than water.

A common cause of hypernatremia is fluid deprivation in unconscious patients who cannot perceive, respond to, or communicate their thirst (Soiza, Cumming, Clarke, Wood, Myint, 2014). Most often affected are very old, very young, and cognitively impaired patients. Administration of hypertonic enteral feedings without adequate water supplements leads to hypernatremia, as does watery diarrhea and greatly increased insensible water loss (e.g., hyperventilation, denuding effects of burns).

Diabetes insipidus, a deficiency of ADH or AVP from the posterior pituitary gland, leads to hypernatremia if the patient does not experience, or cannot respond to, thirst or if fluids are excessively restricted. Neurogenic or nephrogenic causes of diabetes insipidus should be considered in the assessment (refer to Chapter 31).

IV administration of hypertonic saline, hypertonic feeding preparations, or excessive use of sodium bicarbonate can also cause hypernatremia.

Clinical Manifestations and Assessment

The clinical manifestations of hypernatremia are primarily neurologic and are the consequence of increased plasma osmolality caused by an increase in plasma sodium concentration. Water moves out of the ICS into the ECS, resulting in cellular dehydration (see Fig. 4-5). Clinically, these changes may be manifested by restlessness and weakness in moderate hypernatremia and by disorientation, delusions, and hallucinations in severe hypernatremia. Dehydration (resulting in hypernatremia) is often overlooked as the primary reason for behavioral changes in elderly patients. If hypernatremia is severe, permanent brain damage can occur (especially in children). Brain damage is apparently due to subarachnoid hemorrhages that result from brain contraction. A primary characteristic of hypernatremia is thirst. Thirst is such a strong defender of serum sodium levels in healthy people that hypernatremia never occurs unless the person is unconscious or does not have access to water. However, ill people may have an impaired thirst mechanism. Other signs include a dry, swollen tongue and sticky mucous membranes. Flushed skin, peripheral and pulmonary edema, postural hypotension, and increased muscle tone and deep tendon reflexes are additional signs and symptoms of hypernatremia. Body temperature may increase mildly, but it returns to normal after the hypernatremia is corrected. In hypernatremia, the serum sodium level exceeds 145 mEq/L (145 mmol/L), and the serum osmolality exceeds 300 mOsm/kg (300 mmol/L). The specific gravity and osmolality of urine are increased as the kidneys attempt to conserve water (provided the water loss is from a route other than the kidneys).

Medical Management

Treatment of hypernatremia consists of a gradual lowering of the serum sodium level by the infusion of a hypotonic electrolyte solution or an isotonic nonsaline solution (e.g., dextrose 5% in water [D_5W]). D_5W is indicated when water needs to be replaced without sodium. Many clinicians consider a hypotonic sodium solution (e.g., 0.45% NaCl or ½ normal saline) to be safer than D_5W because it allows a gradual reduction in the serum sodium level, thereby decreasing the risk of cerebral edema. It is the solution of choice in severe hyperglycemia with hypernatremia. A rapid reduction in the serum sodium level temporarily decreases the plasma osmolality below that of the fluid in the brain tissue, causing dangerous cerebral edema. Diuretics also may be prescribed to treat the sodium gain.

There is no consensus about the exact rate at which serum sodium levels should be reduced. As a general rule, the serum sodium level is reduced at a rate no faster than 0.5 to 1 mEq/L/hr to allow sufficient time for readjustment through diffusion across fluid compartments. Desmopressin acetate (DDAVP), a synthetic ADH, may be prescribed to treat diabetes insipidus if it is the cause of hypernatremia (Grossman & Porth, 2014).

Nursing Alert

One of the most common causes of hypernatremia is the inadequate intake of free water accompanied by total body sodium depletion, deemed hypovolemic hypernatremia. This may be seen in elderly or severely debilitated individuals who may be unable to ask for or take in water adequately. In this population, restoration of ECF volume with 0.9% normal saline solution may occur prior to correcting the water deficit. Hypovolemic patients with signs of hemodynamic compromise (e.g., tachycardia, hypotension) should receive volume resuscitation initially to restore perfusion prior to administration of hypotonic fluids (to replace free water deficit).

Nursing Management

As in hyponatremia, fluid losses and gains are carefully monitored in patients who are at risk for hypernatremia. The nurse should assess for abnormal losses of water or low water intake and for large gains of sodium as might occur with ingestion of over-the-counter medications that have high sodium content (e.g., Alka-Seltzer). In addition, the nurse obtains a medication history because some prescription medications have high sodium content. The nurse also notes the patient's thirst or elevated body temperature and evaluates it in relation to other clinical signs. The nurse monitors for changes in behavior, such as restlessness, disorientation, and lethargy.

Preventing Hypernatremia

The nurse attempts to prevent hypernatremia by offering fluids at regular intervals, particularly in debilitated patients who may be unable to perceive or respond to thirst. If fluid intake remains inadequate, the nurse consults with the provider to plan an alternative route for intake, either by enteral feedings or by the parenteral route. If enteral feedings are used, sufficient water should be administered to keep the serum sodium and BUN within normal limits. As a rule, the higher the osmolality of the enteral feeding, the greater the need for water supplementation.

For patients with diabetes insipidus, adequate water intake must be ensured. If the patient is alert and has an intact thirst mechanism, merely providing access to water may be sufficient. If the patient has a decreased LOC or other disability interfering with adequate fluid intake, parenteral fluid replacement may be prescribed. This therapy can be anticipated in patients with neurologic disorders, particularly in the early postoperative period.

POTASSIUM IMBALANCES

Potassium is the major intracellular electrolyte; in fact, 98% of the body's potassium is inside the cells. The remaining 2% is in the ECF, and it is this 2% that is important in neuromuscular function. The normal serum potassium concentration ranges from 3.5 to 5.0 mEq/L (3.5 to 5 mmol/L), and even minor variations are significant.

To maintain potassium balance, the renal system must function because 80% of the potassium excreted daily leaves the body by way of the kidneys; the other 20% is lost through the bowel. Intestinal fluid may contain as much as 30 mEq/L of potassium. However, the kidneys are the primary regulators of potassium balance; they accomplish this by adjusting the amount of potassium that is excreted in the urine. Aldosterone also increases the excretion of potassium by the kidney. Because the kidneys do not conserve potassium as well as they conserve sodium, potassium may still be lost in urine in the presence of a potassium deficit. Potassium imbalances are commonly associated with a variety of diseases, injuries, medications (diuretics, laxatives, antibiotics), and special treatments, such as parenteral nutrition and chemotherapy.

HYPOKALEMIA (POTASSIUM DEFICIT)

Hypokalemia (below-normal serum potassium concentration) usually indicates an actual deficit in total potassium stores. However, it may occur in patients with normal potassium stores, such as when alkalosis is present, since it causes a temporary shift of serum potassium into the cells (see later discussion).

Pathophysiology

Hypokalemia (less than 3.5 mEq/L) is a common imbalance. It is associated with conditions that cause an increased output of K^+ (use of diuretics, diarrhea, vomiting, gastric suction, recent ileostomy, intestinal drains, villous adenoma [a tumor of the intestinal tract characterized by excretion of potassium-rich mucus]); decreased intake (NPO, anorexia, vomiting, alcoholism, fasting diets); or redistribution of K^+ (metabolic alkalosis).

The nurse considers clinical conditions that cause increased loss. Approximately 5 to 10 mEq/L K^+ are found in upper GI fluid, whereas 30 to 100 mEq/L are lost with diarrhea. Thus, relatively large amounts of potassium are lost in intestinal fluids.

Potassium-losing diuretics, such as the thiazides, can induce hypokalemia, particularly when administered in large doses to patients with inadequate potassium intake. Other medications that can lead to hypokalemia include corticosteroids, sodium penicillin, carbenicillin, and amphotericin B.

Increased loss is also seen with hyperaldosteronism, which causes reabsorption of sodium and renal excretion of K^+. Primary hyperaldosteronism is seen in patients with adrenal adenomas. Secondary hyperaldosteronism occurs in disorders that activate RAAS to maintain serum sodium concentrations such as cirrhosis, nephrotic syndrome, or heart failure.

Decreased intake occurs in patients who are unable or unwilling to eat a normal diet. This may occur in debilitated elderly people, patients with alcoholism, and patients with anorexia nervosa. In addition to poor intake, people with bulimia frequently suffer increased potassium loss through self-induced vomiting and abuse of laxatives and diuretics.

Redistribution is associated with alterations in acid–base balance or certain medications, such as insulin. In general, a hypokalemia is associated with an alkalosis and, in turn, an alkalosis can cause hypokalemia. The mechanism involves shifts of hydrogen and potassium ions between the ICS and the ECF. For example, hydrogen ions move out of the cells in alkalotic states to help correct the high pH, and potassium ions move in to maintain an electrically neutral state (see later discussion of acid–base balance).

Because insulin promotes the entry of potassium into skeletal muscle and hepatic cells, patients with persistent insulin hypersecretion may experience hypokalemia, which is often the case in patients receiving high-carbohydrate parenteral fluids (as in parenteral nutrition). The nurse anticipates that patients requiring IV insulin are at risk for hypokalemia.

Finally, a magnesium depletion can cause a renal potassium loss and must be corrected or loss of potassium in the urine will continue.

Clinical Manifestations and Assessment

Potassium deficiency can result in widespread derangements in physiologic function. Severe hypokalemia can cause death through cardiac or respiratory arrest. Clinical signs rarely develop before the serum potassium level has decreased to less than 3 mEq/L (3 mmol/L) unless the rate of decline has been rapid. Manifestations of hypokalemia include fatigue, anorexia, nausea, vomiting, muscle weakness, leg cramps, decreased bowel motility, paresthesias (numbness and tingling), arrhythmias, and increased sensitivity to digitalis.

If prolonged, hypokalemia can lead to an inability of the kidneys to concentrate urine, causing dilute urine (resulting in polyuria, nocturia) and excessive thirst. Potassium depletion depresses the release of insulin and results in glucose intolerance. Decreased muscle strength and tendon reflexes can be found on physical assessment.

In hypokalemia, the serum potassium concentration is less than the lower limit of normal. Electrocardiographic (ECG) changes can include flat T waves or inverted T waves or both, suggesting ischemia, and depressed ST segments (Fig. 4-6). An elevated U wave is specific to hypokalemia. Hypokalemia increases sensitivity to digitalis, predisposing the patient to digitalis toxicity at lower digitalis levels.

Medical Management

If hypokalemia cannot be prevented by conventional measures, such as increased intake in the daily diet, it is treated with oral or IV replacement therapy. Potassium loss must be corrected daily; administration of 40 to 80 mEq/day of potassium is adequate in the adult if there are no abnormal losses of potassium.

For patients who are at risk for hypokalemia, a diet containing sufficient potassium should be provided. Dietary intake of potassium in the average adult is 50 to 100 mEq/day. If dietary intake is inadequate for any reason, the provider may prescribe oral or IV potassium supplements. Many salt substitutes contain 50 to 60 mEq of potassium per teaspoon and may be sufficient to prevent hypokalemia.

If oral administration of potassium is not feasible, the IV route is indicated. The IV route is mandatory for patients with severe hypokalemia (e.g., serum level of less than 2 mEq/L). Although potassium chloride is usually used to correct potassium deficits, potassium acetate or potassium phosphate may be prescribed.

Nursing Alert
Serum potassium levels on average will rise by .1 mEq/L for each 10 mEq of potassium given to a patient.

Nursing Management

Because hypokalemia can be life-threatening, the nurse needs to monitor for its early presence in patients who are at risk. Fatigue, anorexia, muscle weakness, decreased bowel motility, paresthesias, and arrhythmias are signals that warrant assessing the serum potassium concentration. When available, the ECG may provide useful information. For example, patients receiving digitalis who are at risk for potassium deficiency should be monitored closely for signs of digitalis toxicity, because hypokalemia potentiates the action of digitalis.

Preventing Hypokalemia

Measures are taken to prevent hypokalemia when possible. Prevention may involve encouraging the patient at risk to eat foods rich in potassium (when the diet allows). If the hypokalemia is caused by abuse of laxatives or diuretics, patient education may help alleviate the problem.

Nursing Alert
Sources of potassium include fruit and fruit juices (bananas, melon, citrus fruit, avocado, coconut water), fresh and frozen vegetables, fresh meats, milk, and processed foods.

Correcting Hypokalemia

Great care should be exercised when administering potassium, particularly in older adults who have lower lean body mass and total body potassium levels and, therefore, lower potassium requirements. In addition, because of the physiologic loss of kidney function with advancing years, potassium may be retained more readily in older than in younger people.

Nursing Alert
Oral potassium supplements can produce small-bowel lesions; therefore, the patient must be assessed for and cautioned about abdominal distention, pain, or GI bleeding.

Potassium should be administered only after adequate urine flow has been established. A decrease in urine volume to less than 20 mL/hr for 2 consecutive hours is an indication to stop the potassium infusion until the situation is evaluated. Potassium is primarily excreted by the kidneys; therefore, when oliguria occurs, potassium administration can cause the serum potassium concentration to rise dangerously. Each health care facility has its own standard of care for the administration of potassium, which should be consulted; however, the maximum concentration of potassium that should be administered on a medical–surgical unit through a peripheral IV line is 10 mEq/100 mL at a rate no faster than 10 mEq/hr. Concentrations of potassium greater than 20 mEq/100 mL should be administered through a central IV catheter using an infusion pump with the patient

monitored by ECG. Caution must be used when selecting the correct premixed solution of IV fluid containing potassium chloride as the concentrations range from 10 to 40 mEq/100 mL. IV bags of 1,000 mL of fluid containing potassium are also available with 20 to 40 mEq/L. IV pumps should always be used with potassium administration. Rapid infusion can cause sudden hyperkalemia and cardiac arrest.

Nursing Alert
Potassium is never administered by IV push or intramuscularly. IV potassium is available as a premixed solution; the nurse is aware that it must be administered using an infusion pump.

Kidney function should be monitored through BUN and creatinine levels and urine output if the patient is receiving potassium replacements, and the provider should be notified of changes in kidney function to prevent complications.

Nursing Alert
Potassium supplements are extremely dangerous for patients who have impaired kidney function and thus decreased ability to excrete potassium. Even more dangerous is the IV administration of potassium to such patients because serum levels can rise very quickly. Aged (stored) blood should not be administered to patients with impaired kidney function because the serum potassium concentration of stored blood increases as the storage time increases, a result of deterioration of RBCs. It is possible to exceed the renal tolerance of any patient with rapid IV potassium administration, as well as when large amounts of oral potassium supplements are ingested.

HYPERKALEMIA (POTASSIUM EXCESS)

Hyperkalemia (greater-than-normal serum potassium concentration) seldom occurs in patients with normal kidney function.

Pathophysiology

Like hypokalemia, hyperkalemia is often caused by iatrogenic (treatment-induced) causes. Although hyperkalemia is less common than hypokalemia, it is usually more dangerous because cardiac arrest is more frequently associated with high serum potassium levels.

Pseudohyperkalemia (a variation of hyperkalemia) has a number of causes. The most common causes are the use of a tight tourniquet around an exercising extremity while drawing a blood sample and hemolysis of the sample before analysis. Other causes include marked leukocytosis (WBC count exceeding 200,000) or thrombocytosis (platelet count exceeding 1 million); drawing blood above a site where potassium is infusing; and familial pseudohyperkalemia, in which potassium leaks out of the RBC while the blood is awaiting analysis. Failure to be aware of these causes of pseudohyperkalemia can lead to aggressive treatment of a nonexistent hyperkalemia, resulting in serious lowering of serum potassium levels. Therefore, measurements of grossly elevated levels should be verified by retesting.

Hyperkalemia (K^+ greater than 5 meq/L) is associated with increased intake (salt substitutes, potassium supplements); administration of medications that increase K^+ load such as penicillin-K^+; K^+-sparing diuretics such as spironolactone and ACE inhibitors; or cell injuries such as crushing injuries, burns, trauma, intravascular hemolysis, rhabdomyolysis (see Chapter 42) or chemotherapy, decreased output (renal disease [AKF/CKF], hypoaldosteronism), or redistribution (acidosis).

The major cause of hyperkalemia is decreased renal excretion of potassium and is commonly seen in patients with untreated kidney failure, particularly those in whom potassium levels increase as a result of infection or excessive intake of potassium in food or medications. In addition, patients with hypoaldosteronism or Addison disease are at risk for hyperkalemia because of deficient aldosterone.

Although a high intake of potassium can cause severe hyperkalemia in patients with impaired kidney function, hyperkalemia rarely occurs in people with normal kidney function. However, improper use of potassium supplements predisposes all patients to hyperkalemia, especially if salt substitutes are used. Not all patients receiving potassium-losing diuretics require potassium supplements, and patients receiving potassium-conserving diuretics should not receive supplements.

In acidosis, potassium moves out of the cells and into the ECF. This occurs as hydrogen ions enter the cells, a process that buffers the pH of the ECF (see later discussion). An elevated ECF potassium level should be anticipated when extensive tissue trauma has occurred, as in burns, crushing injuries, or severe infections. Similarly, it can occur with lysis of malignant cells after chemotherapy.

Clinical Manifestations and Assessment

The most important consequence of hyperkalemia is its effect on the myocardium. Cardiac effects of elevated serum potassium are usually not significant when the level is less than 7 mEq/L (7 mmol/L), but they are almost always present when the level is 8 mEq/L (8 mmol/L) or greater. As the plasma potassium level rises, disturbances in cardiac conduction occur. The earliest changes, often occurring at a serum potassium level greater than 6 mEq/L (6 mmol/L), are peaked, narrow T waves; ST-segment depression; and a shortened QT interval. If the serum potassium level continues to increase, the PR interval becomes prolonged and is followed by disappearance of the P waves. Finally, there is decomposition and prolongation of the QRS complex (see Fig. 4-6). Ventricular arrhythmias and cardiac arrest may occur at any point in this progression. Severe hyperkalemia causes skeletal muscle weakness and even paralysis, related to a depolarization block in muscle. Similarly, ventricular conduction is slowed. Although hyperkalemia has marked effects on the peripheral nervous system, it has little effect on the CNS. Rapidly ascending muscular weakness leading to flaccid quadriplegia has been reported in patients with very high serum potassium levels. Paralysis of respiratory and speech muscles can also occur. In addition, GI manifestations, such as nausea, intermittent intestinal colic, and diarrhea, may occur in hyperkalemic patients. Serum potassium levels and ECG changes are crucial to the diagnosis of hyperkalemia, as discussed previously. ABG analysis may reveal metabolic acidosis; in many cases, hyperkalemia occurs with acidosis, owing to shifts of hydrogen and potassium ions between the ICS and the ECF. For example, hydrogen ions move into the cells in acidotic states to help correct the low serum pH, and potassium ions move out of the cells in exchange, causing a hyperkalemia.

Medical Management

In nonacute situations, restriction of dietary potassium and potassium-containing medications may suffice. For example, eliminating the use of potassium-containing salt substitutes in a patient who is taking a potassium-conserving diuretic may be all that is needed to deal with mild hyperkalemia.

Prevention of serious hyperkalemia by the administration, either orally or by retention enema, of cation exchange resins (e.g., Kayexalate) may be necessary in patients with renal impairment. Cation exchange resins were once used as the primary agent for physical removal of potassium in the body; they act by binding potassium within the bowel and excreting it within the stool. However, research now suggests that cation exchange resins actually increase the risk of bowel ischemia, and no study to date has clearly stated that cation exchange resins do, in fact, lower the potassium levels. Therefore, this practice has begun to fall out of favor among health care providers. A newer medication, patiromer, which reduces potassium levels by binding to potassium in the GI tract, has been approved by the FDA for use in hyperkalemia (Garimella & Jaber, 2016).

Emergency Pharmacologic Therapy

If serum potassium levels are dangerously elevated, it may be necessary to administer IV calcium gluconate. Within minutes after administration, calcium antagonizes the action of hyperkalemia on the heart. Infusion of calcium does not reduce the serum potassium concentration, but it immediately antagonizes the adverse cardiac conduction abnormalities. Calcium chloride and calcium gluconate are not interchangeable: calcium gluconate contains 4.5 mEq of calcium, and calcium chloride contains 13.6 mEq of calcium; therefore, caution must be used.

Monitoring the blood pressure is essential to detect hypotension, which may result from the rapid IV administration of calcium gluconate. The ECG should be monitored continuously during administration; the appearance of bradycardia is an indication to stop the infusion. The myocardial-protective effects of calcium are transient, lasting about 30 minutes. Extra caution is required if the patient has been "digitalized" (i.e., has received accelerated dosages of a digitalis-based cardiac glycoside to reach a desired serum digitalis level rapidly) because parenteral administration of calcium sensitizes the heart to digitalis and may precipitate digitalis toxicity.

IV administration of sodium bicarbonate may be necessary to alkalinize the plasma and cause a temporary shift of potassium into the cells. Also, sodium bicarbonate furnishes sodium to antagonize the cardiac effects of potassium. Effects of this therapy begin within 30 to 60 minutes and may persist for hours; however, they are temporary.

IV administration of regular insulin and a hypertonic dextrose solution causes a temporary shift of potassium into the cells. Glucose and insulin therapy has an onset of action within 30 minutes and lasts for several hours. Loop diuretics, such as furosemide (Lasix), increase excretion of water by inhibiting sodium, potassium, and chloride reabsorption in the ascending loop of Henle and distal renal tubule.

Beta-2 agonists, such as albuterol (Proventil, Ventolin), can be effective in decreasing potassium; however, large doses are needed to elicit potassium shifting into the cells. The

nurse is aware that beta-2 agonists may cause tachycardia and observes cardiac response to treatment, and the provider may consider other options in the patient with ischemic cardiac disease. Administration of these medications is a stopgap measure that only temporarily protects the patient from hyperkalemia. If the hyperkalemic condition is not transient, actual removal of potassium from the body is required; this may be accomplished by using peritoneal dialysis, hemodialysis, or other forms of renal replacement therapy.

Nursing Management

Patients at risk for potassium excess (e.g., those with kidney failure) should be identified so that they can be monitored closely for signs of hyperkalemia. The nurse observes for signs of muscle weakness and arrhythmias. The presence of paresthesias and GI symptoms, such as nausea and intestinal colic, should be monitored for and reported if identified.

Because measurements of elevated serum potassium levels may be erroneous, highly abnormal levels should always be verified by repeating the test. To avoid false reports of hyperkalemia, prolonged use of a tourniquet while drawing the blood sample is avoided, and the patient is cautioned not to exercise the extremity immediately before the blood sample is obtained. The blood sample is delivered to the laboratory as soon as possible because hemolysis of the sample results in a falsely elevated serum potassium level.

Preventing Hyperkalemia

Measures are taken to prevent hyperkalemia in patients at risk, when possible, by encouraging the patient to adhere to the prescribed potassium restriction. Potassium-rich foods to be avoided include many fruits and vegetables, legumes, whole-grain breads, meat, milk, eggs, coffee, tea, and cocoa. Conversely, foods with minimal potassium content include butter, margarine, cranberry juice or sauce, ginger ale, gumdrops or jellybeans, hard candy, root beer, sugar, and honey.

Correcting Hyperkalemia

As previously stated, it is possible to exceed the tolerance for potassium in any person if it is administered rapidly by the IV route. Therefore, great care should be taken to administer and monitor potassium solutions closely, paying attention to the solution's concentration and rate of administration. When potassium is added to parenteral solutions, the potassium is mixed with the fluid by inverting the bottle several times. Potassium chloride should never be added to a hanging bottle because the potassium might be administered as a bolus (potassium chloride is heavy and settles to the bottom of the container).

It is important to caution patients to use salt substitutes sparingly if they are taking other supplementary forms of potassium or potassium-conserving diuretics. Also, potassium-conserving diuretics, potassium supplements, and salt substitutes should not be administered to patients with kidney dysfunction. Most salt substitutes contain approximately 50 to 60 mEq of potassium per teaspoon.

CALCIUM IMBALANCES

More than 99% of the body's calcium is located in the skeletal system, where it provides strength and stability to the skeletal system and serves as a source for extracellular calcium (Grossman & Porth, 2014). Approximately 0.1% to 0.2% of calcium (8.5 to 10.5 mg/dL) circulates in the serum, 40% is bound to plasma proteins (mostly albumin), 10% is complexed or chelated with substances such as phosphorus and sulfate, and approximately 50% is ionized or free to leave the blood stream and participate in cellular function (Grossman & Porth, 2014). Calcium plays a major role in the transmission of nerve impulses, regulation of muscle contraction and relaxation including cardiac muscle, and coagulation pathways; thus, it is important for cardiac conduction, neuromuscular activity, and blood clotting. Calcium is also instrumental in activating enzymes that stimulate many essential chemical reactions in the body. Because many factors affect calcium regulation, both hypocalcemia and hypercalcemia are relatively common disturbances.

Calcium is absorbed from foods (milk and milk products) in the presence of normal gastric acidity and vitamin D. Calcium is excreted in feces and urine. The serum calcium level is controlled by PTH and calcitonin. As ionized or free serum calcium decreases, the parathyroid glands secrete PTH. This, in turn, increases calcium absorption from the GI tract (mediated by an increase in renal vitamin D synthesis), increases calcium reabsorption from the renal tubule, and releases calcium from the bone. The subsequent increase in calcium ion concentration suppresses PTH secretion. When calcium increases excessively, the thyroid gland secretes calcitonin, the antagonist of PTH. It briefly inhibits calcium reabsorption from bone, encourages calcium salt deposits in the bone matrix, and decreases the serum calcium concentration. In addition, blood phosphate (most phosphorus is present as phosphate) levels have a reciprocal relationship with calcium levels. Increases in blood phosphate result in a fall in free calcium concentrations. PTH secretion is stimulated, and this reduces renal excretion of calcium and increases renal phosphate excretion. These adaptations prevent the potentially damaging effects of calcium phosphate crystal deposition that can form in soft tissues when the normal calcium–phosphorus ratio is disturbed.

Nursing Alert

In conditions such as kidney failure, excess phosphate is not excreted, nor is vitamin D activated, which decreases absorption of calcium. This excess phosphate binds with free calcium, forming an insoluble compound that can be deposited in the heart, lungs, eyes, kidneys, skin, and soft tissues. The subsequent fall in serum calcium increases PTH secretion, which dissolves more calcium from the bone to attempt to maintain a normal serum calcium level. The net effect is the development of hyperparathyroidism and a variety of symptoms (renal osteodystrophy, bone pain, fractures, and bleeding) (see Chapters 27 and 31).

HYPOCALCEMIA (CALCIUM DEFICIT)

Hypocalcemia (lower-than-normal serum concentration of calcium), or less than 8.5 mg/dL and an ionized calcium of less than 4.6 mg/dL, occurs in a variety of clinical situations

(Fischbach & Dunning, 2015).

Pathophysiology

Factors associated with hypocalcemia include inadequate calcium intake, increased calcium loss, malabsorption of calcium, decreases in serum protein levels, and increased binding of calcium. Inadequate intake is associated with chronic alcoholism and malnutrition. Increased calcium loss is associated with pancreatic insufficiency and acute pancreatitis. Inflammation of the pancreas causes the breakdown of proteins and lipids. It is thought that calcium ions combine with the fatty acids released by lipolysis, forming soaps. As a result of this process, hypocalcemia occurs and is common in pancreatitis. It has also been suggested that hypocalcemia might be related to excessive secretion of glucagon from the inflamed pancreas, which results in increased secretion of calcitonin (a hormone that lowers serum calcium). Inadequate secretion of PTH by the parathyroid gland results in hypocalcemia and can be related to hypoparathyroidism or other parathyroid gland disorders, use of certain drugs, surgery of the thyroid gland with inadvertent removal of the parathyroids, radiation injury to the thyroid, and radical neck dissection. This is likely to occur in the first 24 to 48 hours postoperatively.

Medications predisposing the patient to hypocalcemia include aluminum-containing antacids, aminoglycosides, anticonvulsants (phenytoin and phenobarbital), corticosteroids, mithramycin, phosphates, isoniazid, and loop diuretics. Malabsorption of calcium may be seen in severe diarrhea, laxative abuse, decreased exposure to sunlight or conditions that impair vitamin D, high phosphorus level in the intestines, reduced gastric acidity, and kidney failure. In addition, hypoalbuminemia, alkalosis, and massive blood transfusion are associated with hypocalcemia. Recall that approximately 40% of calcium is bound to albumin; thus, a decrease in serum albumin will result in a decrease in total serum calcium, but it does not affect the concentration of the ionized form of calcium that is essential for body function (Fischbach & Dunning, 2015). When the arterial pH increases (alkalosis), more calcium binds to protein. As a result, the ionized portion decreases, thus symptoms of hypocalcemia may occur with alkalosis. Transient hypocalcemia can occur with massive administration of citrated blood (adults who experience massive hemorrhage and shock), because citrate (which is used in blood transfusions to prevent clotting in blood) can combine with ionized calcium and temporarily remove it from the circulation.

Clinical Manifestations and Assessment

If ionized calcium level is normal despite low total calcium levels, patients are generally asymptomatic, whereas large changes in ionized calcium levels lead to a variety of symptoms associated with neuromuscular hyperactivity and cardiovascular effects detailed below. Tetany (the most characteristic manifestation of hypocalcemia) and convulsions are seen when the total calcium level is less than 4.4 mg/dL and/or the ionized calcium is less than 2.0 mg/dL (Fischbach & Dunning, 2015). *Tetany* refers to the entire symptom complex induced by increased neural excitability. These symptoms are caused by spontaneous discharges of both sensory and motor fibers in peripheral nerves. Sensations of tingling may occur in the tips of the fingers, around the mouth, and, less commonly, in the feet. Spasms of the muscles of the extremities and face may occur. Pain may develop as a result of these spasms.

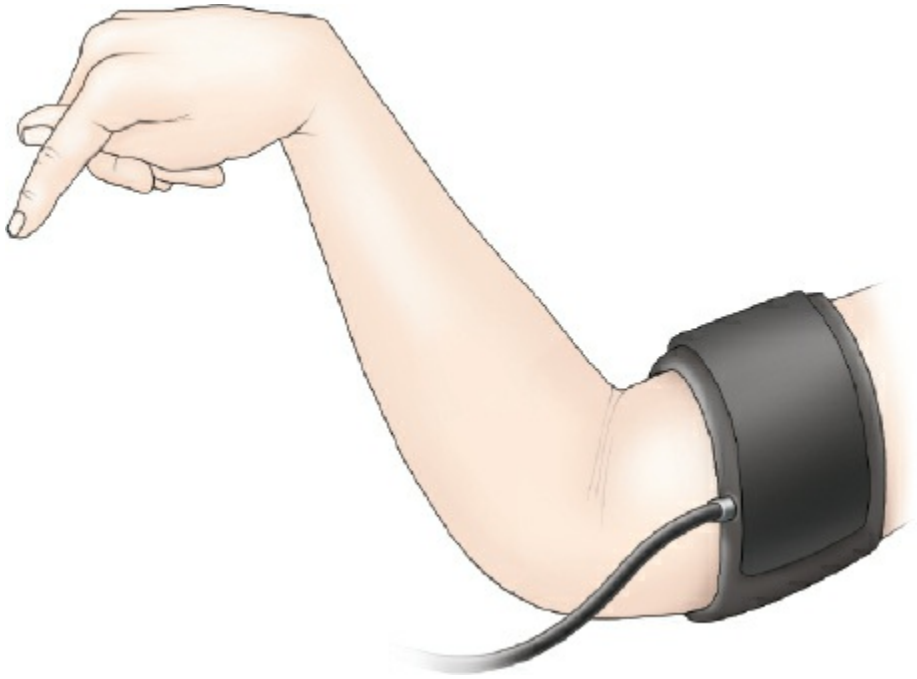

FIGURE 4-7 Trousseau sign. Ischemia-induced carpal spasm can occur with hypocalcemia or hypomagnesemia. Occluding the brachial artery with a blood pressure cuff for 3 minutes can produce carpal spasm that mimics the spasm that occurs with hypocalcemia or hypomagnesemia.

Trousseau sign (Fig. 4-7) can be elicited by inflating a blood pressure cuff on the upper arm to about 20 mm Hg above systolic pressure; within 2 to 5 minutes, carpal spasm (an adducted thumb, flexed wrist and metacarpophalangeal joints, extended interphalangeal joints with fingers together) occurs as ischemia of the ulnar nerve develops. *Chvostek sign* consists of twitching of muscles supplied by the facial nerve when the nerve is tapped about 2 cm anterior to the earlobe, just below the zygomatic arch.

Seizures occur because hypocalcemia causes irritability of the CNS as well as of the peripheral nerves. Other changes associated with hypocalcemia include mental changes, such as depression, impaired memory, confusion, delirium, and even hallucinations. A prolonged QT interval is seen on the ECG due to prolongation of the ST segment, which

predisposes patients to a form of ventricular tachycardia called *torsades de pointes* (see Chapter 17). Respiratory effects with decreasing calcium include dyspnea and laryngospasm (stridor). Signs and symptoms of chronic hypocalcemia include hyperactive bowel sounds, dry and brittle hair and nails, and abnormal clotting. When evaluating serum calcium levels, variables such as the serum albumin level and the arterial pH must be considered. Because abnormalities in serum albumin levels may affect interpretation of the serum calcium level, it may be necessary to calculate the corrected serum calcium if the serum albumin level is abnormal. For every decrease in serum albumin of 1 g/dL below 4 g/dL, the total serum calcium level is underestimated by approximately 0.8 mg/dL. The following is a quick method to calculate the corrected serum calcium level:

Corrected calcium = measured calcium
+ 0.8 (4.0 – measured serum albumin)

An example of the calculations needed to obtain the corrected total serum calcium level is as follows: A patient's reported serum albumin level is 2.5 g/dL; the reported serum calcium level is 10.5 mg/dL. First, the decrease in serum albumin level from normal (i.e., the difference from the normal albumin concentration of 4 g/dL) is calculated: 4 g/dL – 2.5 g/dL = 1.5 g/dL. Next, multiply 0.8 (1.5) = 1.2.

Finally, 1.2 mg/dL is added to 10.5 mg/dL (the reported serum calcium level) to obtain the corrected total serum calcium level: 1.2 mg/dL + 10.5 mg/dL = 11.7 mg/dL.

The ionized calcium level is usually normal in patients with reduced total serum calcium levels and concomitant hypoalbuminemia.

Ideally, the ionized level of calcium should be measured in the laboratory. However, in many laboratories, only the total calcium level is reported; therefore, the concentration of the ionized fraction must be estimated by simultaneous measurement of the serum albumin level or specifically ordered by the provider. In addition, PTH levels and magnesium and phosphorus levels need to be assessed to identify possible causes of decreased calcium.

Medical Management

Acute symptomatic hypocalcemia is life-threatening and requires prompt treatment with IV administration of calcium. Although calcium chloride produces a significantly higher ionized calcium level than calcium gluconate, it is not used as often because it is more irritating to the vasculature and can cause sloughing of tissue if it infiltrates. Administering IV calcium too rapidly can cause cardiac arrest, which may be preceded by bradycardia in patients. IV administration of calcium is particularly dangerous in patients receiving digitalis-derived medications because calcium ions exert an effect similar to that of digitalis and can cause digitalis toxicity, with adverse cardiac effects. Therefore, calcium should be diluted in D_5W and administered via a slow IV infusion using a volumetric infusion pump. The IV site must be observed often for any evidence of infiltration because of the risk of extravasation and resultant cellulitis or necrosis. A 0.9% sodium chloride solution should not be used with calcium because it increases renal calcium loss. Solutions containing phosphates or bicarbonate should not be used with calcium because they cause precipitation when calcium is added. The nurse must clarify with the provider which calcium salt to administer because calcium gluconate yields 4.5 mEq of calcium, and calcium chloride provides 13.6 mEq of calcium. Because calcium can cause postural hypotension, the patient is kept in bed during IV replacement, and blood pressure is monitored.

Vitamin D therapy may be instituted to increase calcium absorption from the GI tract. Aluminum hydroxide, calcium acetate, or calcium carbonate antacids may be prescribed to decrease elevated phosphorus levels before treating hypocalcemia in the patient with CKF. Increasing the dietary intake of calcium to at least 1,000 to 1,200 mg/day in the adult is recommended. Calcium-containing foods include milk products; green, leafy vegetables; canned salmon; sardines; and fresh oysters. Hypomagnesemia can also cause tetany; if the tetany does not respond to IV calcium, then a low magnesium level is considered as a possible cause.

Nursing Management

It is important to observe for hypocalcemia in patients at risk. Seizure precautions are initiated if hypocalcemia is severe. The status of the airway is closely monitored because laryngeal stridor can occur. A tracheotomy tray should be kept at the bedside and a manual resuscitation bag nearby in case of laryngospasm in patients with audible stridor. Safety precautions are taken, as indicated, if confusion is present. Because of the cardiac complications, ECG monitoring should be instituted to detect changes in heart rate and rhythm, especially if the patient is receiving digoxin.

People who have a high risk for osteoporosis are instructed about the need for adequate dietary calcium intake; it is important to teach the patient which foods are rich in calcium. The nurse must also advise the patient to consider calcium supplements if sufficient calcium is not consumed in the diet. Such supplements should be taken in divided doses with meals. In addition, the value of regular weight-bearing exercise in decreasing bone loss should be emphasized, as well as the effect of medications on calcium balance. For example, alcohol and caffeine in high doses inhibit calcium absorption, and moderate cigarette smoking increases urinary calcium excretion. Additional teaching includes discussion of bisphosphonate medications to reduce the rate of bone loss. Teaching also includes strategies to reduce the risk of falls. The patient is also cautioned to avoid the overuse of laxatives and antacids that contain phosphorus because their use decreases calcium absorption.

HYPERCALCEMIA (CALCIUM EXCESS)

Hypercalcemia (excess of calcium in the plasma) is a dangerous imbalance. Hypercalcemic crisis (an acute increase in calcium level) has an extremely high mortality rate if not corrected promptly, often related to cardiac arrest (Grossman & Porth, 2014).

Pathophysiology

Ninety percent of hypercalcemia cases are related to either malignancy or hyperparathyroidism (Thomas & Chung, 2016). Considered an oncologic emergency, hypercalcemia occurs in 20% to 30% of patients with cancer at some point in their disease process (Thomas & Chung, 2016). It is associated with increased osteoclast activity resulting in bone demineralization, direct bone destruction by tumor cells and subsequent release of calcium, and/or tumor-produced factors that affect bone resorption and/or tubular calcium reabsorption. Tumor cells can secrete PTH-related protein, resulting in increased serum calcium. The excessive PTH secretion associated with hyperparathyroidism causes increased release of calcium from the bones and increased intestinal and renal absorption of calcium. Calcifications of soft tissue occur when the calcium–phosphorus product (serum calcium × serum phosphorus) exceeds 70 mg/dL.

Bone mineral is lost during immobilization, and sometimes this causes elevation of total (and especially ionized) calcium in the bloodstream. Symptomatic hypercalcemia from immobilization is rare; when it does occur, it is virtually limited to people with high calcium turnover rates (e.g., adolescents during a growth spurt). Most cases of hypercalcemia secondary to immobility occur after severe or multiple fractures or spinal cord injury.

Thiazide diuretics can cause a slight elevation in serum calcium levels because they potentiate the action of PTH on the kidneys, reducing urinary calcium excretion. A rare condition, called *milk–alkali syndrome,* has occurred in patients with peptic ulcer treated previously for a prolonged period with milk and alkaline antacids, particularly calcium carbonate. Vitamin A and D intoxication, as well as the use of lithium, can cause calcium excess.

Clinical Manifestations and Assessment

As a rule, the symptoms of hypercalcemia are proportional to the degree of elevation of the serum calcium level. Hypercalcemia reduces neuromuscular excitability because it suppresses activity at the myoneural junction. Symptoms such as muscle weakness, incoordination, anorexia, and constipation may be caused by decreased tone in smooth and striated muscle. Cardiovascular effects include hypertension and a shortened QT interval, which can cause increased sensitivity to digitalis and deposition of calcium in heart valves, myocardium, or coronary arteries (Lycans et al., 2016). Cardiac standstill can occur when the serum calcium level is about 18 mg/dL (4.5 mmol/L).

Anorexia, nausea, vomiting, and constipation are common symptoms of hypercalcemia. Abdominal and bone pain may also be present. Abdominal distention and paralytic ileus may complicate severe hypercalcemic crisis. Excessive urination due to disturbed renal tubular function produced by hypercalcemia may occur. In fact, nephrogenic diabetes insipidus can be seen in patients with this disorder (Abbas, Iqbal, Iqbal, Javaid, & Ashraf, 2016). Severe thirst secondary to the polyuria caused by the high solute (calcium) load is expected. Although uncommon, patients with chronic hypercalcemia may develop symptoms similar to those of peptic ulcer because hypercalcemia increases the secretion of acid and pepsin by the stomach.

Confusion, impaired memory, slurred speech, lethargy, acute psychotic behavior, or coma may occur. The more severe symptoms tend to appear when the serum calcium level is approximately 16 mg/dL (4 mmol/L) or higher. However, some patients become profoundly disturbed with serum calcium levels of only 12 mg/dL (3 mmol/L). These symptoms resolve as serum calcium levels return to normal after treatment.

Hypercalcemic crisis refers to an acute rise in the serum calcium level to 17 mg/dL (4.3 mmol/L) or higher. Severe thirst and polyuria are often present. Other findings may include muscle weakness, intractable nausea, abdominal cramps, obstipation (very severe constipation) or diarrhea, peptic ulcer symptoms, and bone pain. Lethargy, confusion, and coma may also occur. This condition is very dangerous and may result in cardiac arrest.

The double-antibody PTH test may be used to differentiate between primary hyperparathyroidism and malignancy as a cause of hypercalcemia: PTH levels are increased in primary or secondary hyperparathyroidism and suppressed in malignancy. X-rays may reveal the presence of osteoporosis if the patient has hypercalcemia secondary to a malignancy or bone cavitation. A 24-hour urine calcium collection may be ordered; hypercalciuria is defined as calcium excretion of greater than 400 mg/day.

Nursing Alert

The mnemonic "bones (bone pain), stones (kidney), groans (pain), and psychic moans (anxiety, psychiatric symptoms)" may be helpful to recall the cascade of symptoms associated with hypercalcemia.

Medical Management

Therapeutic aims in hypercalcemia include decreasing the serum calcium level and reversing the process causing hypercalcemia. Treating the underlying cause (e.g., chemotherapy for a malignancy, partial parathyroidectomy for hyperparathyroidism) is essential. For example, drugs such as thiazides and Vitamin D compounds, as associated with hypercalcemia, may be discontinued and dietary calcium restricted (Thakker, 2016).

General measures include intravenous fluids to dilute serum calcium and promote its excretion by the kidneys, mobilizing the patient, and restricting intake of fluids and medications that contain calcium. IV administration of 0.9% sodium chloride solution is expected since it temporarily dilutes the serum calcium level and increases urinary calcium excretion by inhibiting tubular reabsorption of calcium. Furosemide (Lasix) is often used in conjunction with administration of a saline solution; in addition to causing diuresis, furosemide increases calcium excretion and is useful in preventing FVE associated with saline administration.

Bisphosphonates are the drugs of choice for hypercalcemia due to secondary hyperparathyroidism. Glucocorticoid therapy is effective when the hypercalcemia is due to diseases such as lymphoma, myeloma, or granulomatous disease. Dialysis using a low or zero calcium dialysate should be considered if these treatments are not effective or if the patient has kidney failure. When the acute management of hypercalcemia has been completed, appropriate treatment for the underlying cause needs to be undertaken. Calcitonin can be used to lower the serum calcium level and is particularly useful for patients with heart disease or kidney failure who cannot tolerate large sodium loads. Calcitonin reduces bone resorption, increases the depositing of calcium and phosphorus in the bones, and increases urinary excretion of calcium and phosphate. Although several forms are available, calcitonin derived from salmon is commonly used. Skin testing for allergy to salmon calcitonin is necessary before the hormone is administered. Systemic allergic reactions are possible because this hormone is a protein; resistance to the medication may develop later because of antibody formation. Calcitonin is administered by intramuscular injection rather than subcutaneously because patients with hypercalcemia have poor perfusion of subcutaneous tissue.

For patients with cancer, treatment is directed at controlling the condition by surgery, chemotherapy, or radiation therapy. Corticosteroids may be used to decrease bone turnover and tubular reabsorption for patients with sarcoidosis, myelomas, lymphomas, and leukemias; patients with solid tumors are less responsive. The bisphosphonates inhibit osteoclast activity and may be used to lower serum calcium levels. Mithramycin, a cytotoxic antibiotic, inhibits bone resorption and thus lowers the serum calcium level. This agent must be used cautiously because it has significant side effects, including thrombocytopenia, nephrotoxicity, rebound hypercalcemia when discontinued, and hepatotoxicity. Finally, hemodialysis or peritoneal dialysis with low calcium levels in dialysis fluid may be considered since both treatments are effective for removing calcium from circulation. In addition, dialysis may be considered for patients with renal insufficiency and congestive heart failure in which saline infusion is not suitable (Ahmad, Kuraganti, & Steenkamp, 2015).

Nursing Management

It is important to monitor for hypercalcemia in patients who are at risk. Interventions such as increasing patient mobility and encouraging fluids can help prevent hypercalcemia, or at least minimize its severity. Fluids containing sodium should be administered unless contraindicated because sodium favors calcium excretion. Patients are encouraged to drink 3 to 4 quarts of fluid daily. Adequate fiber should be provided in the diet to offset the tendency for constipation. Safety precautions are implemented, as necessary, when mental symptoms of hypercalcemia are present. The patient and family are informed that these mental changes are reversible with treatment. Increased calcium potentiates the effects of digitalis; therefore, the patient is assessed for signs and symptoms of digitalis toxicity. Because ECG changes (premature ventricular contractions, paroxysmal atrial tachycardia, and heart block) can occur, the cardiac rate and rhythm are monitored for any abnormalities.

MAGNESIUM IMBALANCES

Magnesium is the most abundant intracellular cation after potassium. It acts as an activator for many intracellular enzyme systems and plays a role in both carbohydrate and protein metabolism. The normal serum magnesium level is 1.3 to 2.3 mEq/L (1.8 to 3.0 mg/dL; 0.8 to 1.2 mmol/L). Approximately one third of serum magnesium is bound to protein; the remaining two thirds exists as free cations—the active component (Mg^{+2}). Magnesium balance is important in neuromuscular function. Because magnesium acts directly on the myoneural junction, variations in the serum concentration of magnesium affect neuromuscular irritability and contractility. Magnesium produces its sedative effect at the neuromuscular junction, probably by inhibiting the release of the neurotransmitter acetylcholine.

Magnesium exerts effects on the cardiovascular system, acting peripherally to produce vasodilation. Magnesium is thought to have a direct effect on peripheral arteries and arterioles, which results in a decreased total peripheral resistance. IV magnesium may also be helpful in patients with acute asthma by potentially improving both bronchodilation and airflow. Magnesium is predominantly found in bone and soft tissues. It is primarily eliminated by the kidneys.

HYPOMAGNESEMIA (MAGNESIUM DEFICIT)

Hypomagnesemia refers to a below-normal serum magnesium concentration (1.3 to 2.3 mEq/L; 1.8 to 3.0 mg/dL; 0.8 to 1.2 mmol/L). Magnesium is similar to calcium in two aspects: (1) it is the ionized fraction of magnesium that is primarily involved in neuromuscular activity and other physiologic processes, and (2) magnesium levels should be evaluated in combination with albumin levels. Low serum albumin levels decrease total magnesium.

Pathophysiology

Hypomagnesemia is a common yet often overlooked imbalance in acutely and critically ill patients. It may occur with withdrawal from alcohol and administration of tube feedings or parenteral nutrition.

An important route of magnesium loss is the GI tract. Loss of magnesium from the GI tract may occur with nasogastric suction, diarrhea, or fistulas. Because fluid from the lower GI tract has a higher concentration of magnesium (10 to 14 mEq/L) than fluid from the upper tract (1 to 2 mEq/L), losses from diarrhea and intestinal fistulas are more likely to induce magnesium deficit than are those from gastric suction. Although magnesium losses are relatively small in nasogastric suction, hypomagnesemia will occur if losses are prolonged and magnesium is not replaced through IV infusion. Because the distal small bowel is the major site of magnesium absorption, any disruption in small-bowel function, as in intestinal resection or inflammatory bowel disease, can lead to hypomagnesemia.

Alcoholism is currently the most common cause of symptomatic hypomagnesemia in the United States. Hypomagnesemia is particularly troublesome during treatment of alcohol withdrawal. Therefore, the serum magnesium level should be measured routinely in patients undergoing withdrawal from alcohol. The serum magnesium level may be normal on admission but may decrease as a result of metabolic changes, such as the intracellular shift of magnesium associated with IV glucose administration.

During nutritional replacement, the major cellular electrolytes move from the serum to newly synthesized cells. Patients on enteral (feeding that uses the GI tract) or parenteral (delivery of calories and nutrients into a vein, i.e., TPN, PPN) feedings should have magnesium levels measured routinely as serious hypomagnesemia can occur with magnesium-deficient formulas, especially in those who have undergone a period of starvation. Other causes of hypomagnesemia include the administration of aminoglycosides, cyclosporine, cisplatin, diuretics, digitalis, and amphotericin, as well as the rapid administration of citrated blood, especially to patients with kidney or hepatic disease. Magnesium deficiency often occurs in diabetic ketoacidosis, secondary to increased renal excretion during osmotic diuresis and shifting of magnesium into the cells with insulin therapy. Other contributing causes are sepsis, burns, and hypothermia.

Clinical Manifestations and Assessment

Clinical manifestations of hypomagnesemia are largely confined to the neuromuscular system. Some of the effects are due directly to the low serum magnesium level; others are due to secondary changes in potassium and calcium metabolism. Symptoms do not usually occur until the serum magnesium level has dropped to less than 1 mEq/L (0.5 mmol/L).

Among the neuromuscular changes are hyperexcitability with muscle weakness, tremors, and *athetoid movements* (slow, involuntary twisting and writhing). Others include tetany, generalized tonic–clonic or focal seizures, laryngeal stridor, and positive Chvostek and Trousseau signs (see earlier discussion), which occur, in part, because of accompanying hypocalcemia.

Hypomagnesemia may be accompanied by marked alterations in mood. Apathy, depression, apprehension, and extreme agitation have been noted, as well as ataxia, dizziness, insomnia, and confusion. At times, delirium, auditory or visual hallucinations, and frank psychoses may occur.

On laboratory analysis, the serum magnesium level is less than 1.3 mEq/L or 1.8 mg/dL (0.75 mmol/L). Hypomagnesemia is frequently associated with hypokalemia and hypocalcemia. About 25% of magnesium is protein-bound, principally to albumin. A decreased serum albumin level can, therefore, reduce the measured total magnesium concentration. ECG evaluations reflect magnesium, calcium, and potassium deficiencies, tachyarrhythmias, prolonged PR and QT intervals, widening QRS, depression of the ST-segment, flattened T waves, and a prominent U wave. Torsades de pointes is associated with a low magnesium level. Premature ventricular contractions, paroxysmal atrial tachycardia, and heart block may also occur. Digitalis toxicity is associated with low serum magnesium levels. This is important because patients receiving digoxin are also likely to be receiving diuretic therapy, predisposing them to renal loss of magnesium. Urine magnesium levels may be helpful in identifying causes of magnesium depletion and are measured after a loading dose of magnesium sulfate is administered.

Medical Management

Mild magnesium deficiency can be corrected by diet alone. Principal dietary sources of magnesium, which is a component of chlorophyll, are green leafy vegetables, nuts, seeds, legumes, whole grains, and seafood. Magnesium is also plentiful in peanut butter and cocoa.

If necessary, magnesium salts can be administered orally in an oxide or gluconate form to replace continuous excessive losses. Diarrhea is a common complication of excessive ingestion of magnesium. Patients receiving parenteral nutrition require magnesium in the IV solution to prevent hypomagnesemia. Magnesium sulfate must be administered intravenously by an infusion pump typically at a rate of 1 to 2 g over an hour. A bolus dose of magnesium sulfate given too rapidly can produce alterations in cardiac conduction, leading to heart block or asystole. Vital signs must be assessed frequently during magnesium administration to detect changes in cardiac rate or rhythm, hypotension, and respiratory distress. Monitoring urine output is essential before, during, and after magnesium administration; the provider is notified if urine volume decreases to less than 30 mL/hr (Nettina & Lippincott, 2014). Calcium gluconate must be readily available to treat hypocalcemic tetany or hypermagnesemia.

Overt symptoms of hypomagnesemia are treated with parenteral administration of magnesium. Magnesium sulfate is the most commonly used magnesium salt. Serial measurements of serum magnesium levels can be used to regulate the dosage.

Nursing Management

The nurse should be aware of patients who are at risk for hypomagnesemia and observe them for its signs and symptoms. Patients receiving digitalis are monitored closely because a deficit of magnesium can predispose them to digitalis toxicity. If hypomagnesemia is severe, seizure precautions are implemented. Other safety precautions are instituted, as indicated, if confusion is observed.

Because difficulty in swallowing (dysphagia) may occur in magnesium-depleted patients, a swallowing evaluation should be performed before oral medications or foods are offered. Dysphagia is probably related to the athetoid or *choreiform* (rapid, involuntary, and irregular jerking) movements associated with magnesium deficit. To determine neuromuscular irritability, the nurse needs to assess and grade deep tendon reflexes (refer to Chapter 43).

Teaching plays a major role in treating magnesium deficit, particularly that resulting from abuse of diuretic or laxative medications. In such cases, the nurse instructs the patient about the need to consume magnesium-rich foods. For patients experiencing hypomagnesemia from abuse of alcohol, the nurse provides teaching, counseling, support, and possible referral to alcohol abstinence programs or other professional help.

HYPERMAGNESEMIA (MAGNESIUM EXCESS)

Hypermagnesemia is a rare electrolyte abnormality because usually the kidneys are efficient in excreting magnesium. A serum magnesium level can appear falsely elevated if blood specimens are allowed to hemolyze or are drawn from an extremity with a tourniquet that was applied too tightly or for too long a period of time prior to blood draw.

Pathophysiology

By far the most common cause of hypermagnesemia is kidney failure. In fact, most patients with advanced kidney failure have at least a slight elevation in serum magnesium levels. This condition is aggravated when such patients receive magnesium to control seizures or inadvertently take one of the many commercial antacids that contain magnesium salts.

Hypermagnesemia can occur in a patient with untreated diabetic ketoacidosis when catabolism causes the release of cellular magnesium that cannot be excreted because of profound fluid volume depletion and resulting oliguria (less than 400 mL/24 hrs). An excess of magnesium can also result from excessive magnesium administered to treat hypertension of pregnancy or to treat low hypomagnesemia. Increased serum magnesium levels can also occur in adrenocortical insufficiency, Addison disease, or hypothermia. Excessive use of antacids (e.g., Maalox, Riopan, Mylanta); laxatives (Milk of Magnesia); and medications that decrease GI motility, including opioids and anticholinergics, can also increase serum magnesium levels. Decreased elimination of magnesium or its increased absorption due to intestinal hypomotility from any cause can contribute to hypermagnesemia. Lithium intoxication can also cause an increase in serum magnesium levels.

Clinical Manifestations and Assessment

Acute elevation of the serum magnesium level depresses the CNS as well as the peripheral neuromuscular junction. At mildly increased levels, there is a tendency for lowered blood pressure because of peripheral vasodilation. Nausea, vomiting, weakness, soft tissue calcifications, facial flushing, and sensations of warmth may also occur. At higher magnesium concentrations, lethargy, difficulty speaking (dysarthria), and drowsiness can occur. Deep tendon reflexes are lost, and muscle weakness and paralysis may develop. The respiratory center is depressed when serum magnesium levels exceed 10 mEq/L (5 mmol/L). Coma, atrioventricular heart block, and cardiac arrest can occur when the serum magnesium level is greatly elevated and not treated. High levels of magnesium also result in platelet clumping and delayed thrombin formation. On laboratory analysis, the serum magnesium level is greater than 2.5 mEq/L or 3.0 mg/dL (1.25 mmol/L). Increased potassium and calcium are present concurrently. ECG findings may include a prolonged PR interval, tall T waves, a widened QRS, and a prolonged QT interval, as well as an atrioventricular block.

Medical Management

Hypermagnesemia can be prevented by avoiding the administration of magnesium to patients with kidney failure and by carefully monitoring seriously ill patients who are receiving magnesium salts. In patients with severe hypermagnesemia, all parenteral and oral magnesium salts are discontinued. In emergencies, such as respiratory depression or defective cardiac conduction, ventilatory support and IV calcium gluconate are indicated. In addition, hemodialysis with a magnesium-free dialysate can reduce the serum magnesium to a safe level within hours. Administration of loop diuretics (Lasix) and sodium chloride or lactated Ringer IV solution enhances magnesium excretion in patients with adequate kidney function. IV calcium gluconate antagonizes the cardiovascular and neuromuscular effects of magnesium.

Nursing Management

Patients at risk for hypermagnesemia are identified and assessed. The nurse monitors the vital signs, noting hypotension and shallow respirations, or ECG abnormalities. The nurse also observes for decreased deep tendon reflexes and changes in the LOC. Medications that contain magnesium are not administered to patients with kidney failure or compromised kidney function, and patients with kidney failure are cautioned to check with their health care providers before taking over-the-counter medications. Caution is essential when preparing and administering magnesium-containing fluids parenterally because available parenteral magnesium solutions (e.g., 2 mL ampules, 50 mL vials) differ in concentration.

PHOSPHORUS IMBALANCES

Phosphorus is a critical constituent of all the body's tissues. It is essential to the function of muscle and RBC; the formation of adenosine triphosphate (ATP) and of 2,3-diphosphoglycerate, which facilitates release of oxygen from hemoglobin; and the maintenance of acid–base balance, as well as to the nervous system and the intermediary metabolism of carbohydrate, protein, and fat. It provides structural support to bones and teeth in the form of phosphate. Phosphorus is the primary anion of the ICF. About 85% of phosphorus is located in bones and teeth, 14% in soft tissue, and less than 1% in the ECF. The normal serum phosphorus level is 2.5 to 4.5 mg/dL (0.8 to 1.45 mmol/L).

HYPOPHOSPHATEMIA (PHOSPHORUS DEFICIT)

Pathophysiology

Hypophosphatemia is a below-normal serum concentration of inorganic phosphorus; it may occur under a variety of circumstances in which total body phosphorus stores are normal. Conversely, phosphorus deficiency is an abnormally low content of phosphorus in lean tissues that may exist in the absence of hypophosphatemia. It can be caused by an intracellular shift of potassium from serum into cells, by increased urinary excretion of potassium, or by decreased intestinal absorption of potassium.

Hypophosphatemia may occur during the administration of calories to patients with severe protein–calorie malnutrition. It is most likely to occur with overzealous intake or administration of simple carbohydrates. This syndrome can be induced in anyone with severe protein–calorie malnutrition, such as patients with anorexia nervosa or alcoholism, or elderly debilitated patients who are unable to eat. Approximately 50% of patients hospitalized due to chronic alcoholism have hypophosphatemia.

Marked hypophosphatemia may develop in malnourished patients who receive parenteral nutrition if the phosphorus loss is not adequately corrected. Other causes of hypophosphatemia include pain, heat stroke, prolonged intense hyperventilation, alcohol withdrawal, poor dietary intake, diabetic ketoacidosis, hepatic encephalopathy, and major thermal burns. Low magnesium levels, low potassium levels, and hyperparathyroidism related to increased urinary losses of phosphorus contribute to hypophosphatemia. Loss of phosphorus through the kidneys also occurs with acute volume expansion, osmotic diuresis, use of carbonic anhydrase inhibitors (acetazolamide [Diamox]), and some malignancies. Respiratory alkalosis can cause a decrease in phosphorus because of an intracellular shift of phosphorus, which often stimulates intracellular glycolysis.

Excess phosphorus binding by antacids containing magnesium, calcium, or albumin may decrease the phosphorus available from the diet to an amount lower than required to maintain serum phosphorus balance. The degree of hypophosphatemia depends on the amount of phosphorus in the diet compared to the dose of antacid. Phosphate loss can occur with chronic diarrhea or through severe potassium restriction. Vitamin D regulates intestinal ion absorption; therefore, a deficiency of vitamin D may cause decreased calcium and phosphate (phosphorus) levels, which may lead to osteomalacia (softened, brittle bones).

Clinical Manifestations and Assessment

A wide range of neurologic symptoms may occur, including irritability, fatigue, apprehension, weakness, numbness, paresthesias, dysarthria, dysphagia, diplopia, confusion, seizures, and coma. Low levels of diphosphoglycerate may reduce the delivery of oxygen to peripheral tissues, resulting in tissue anoxia. Hypoxia then leads to an increase in respiratory rate and respiratory alkalosis, causing phosphorus to move into the cells and potentiating hypophosphatemia. Hemolytic anemia may lead to pale skin and conjunctivae. It is thought that hypophosphatemia may predispose a person to infection due to a decrease in granulocyte function.

Muscle damage may develop as the ATP level in the muscle tissue declines. Clinical manifestations are muscle weakness, which may be subtle or profound and may affect any muscle group, muscle pain, and at times acute rhabdomyolysis (disintegration of striated muscle). Weakness of respiratory muscles may greatly impair ventilation. Hypophosphatemia also may predispose a person to insulin resistance and thus hyperglycemia. Chronic loss of phosphorus can cause bruising and bleeding from platelet dysfunction.

On laboratory analysis, the serum phosphorus level is less than 2.5 mg/dL (0.80 mmol/L) in adults. When reviewing laboratory results, the nurse should keep in mind that glucose or insulin administration causes a slight decrease in the serum phosphorus level. If hypophosphatemia is associated with hyperparathyroidism, the serum PTH levels are increased. Likewise, if etiology of hypophosphatemia is related to increased osteoblastic activity serum alkaline, phosphatase is increased. X-rays may show skeletal changes of osteomalacia or rickets.

Medical Management

Prevention of hypophosphatemia is the goal. In patients at risk for hypophosphatemia, serum phosphate levels should be monitored closely and correction initiated before deficits become severe. Adequate amounts of phosphorus should be added to parenteral solutions, and attention should be paid to the phosphorus levels in enteral feeding solutions.

Severe hypophosphatemia is dangerous and requires prompt attention. Aggressive IV phosphorus correction is usually limited to the patient whose serum phosphorus levels decrease to less than 1 mg/dL (0.3 mmol/L) and whose GI tract is not functioning. Possible dangers of IV administration of phosphorus include tetany from hypocalcemia and calcifications in tissues (blood vessels, heart, lung, kidney, eyes) from hyperphosphatemia. IV preparations of phosphorus are available as sodium or potassium phosphate. The rate of phosphorus administration should not exceed 10 mEq/hr, and the site should be monitored carefully because tissue sloughing and necrosis can occur with infiltration. In less acute situations, oral phosphorus replacement is usually adequate.

Nursing Management

The nurse identifies patients who are at risk for hypophosphatemia and monitors them. Because malnourished patients receiving parenteral nutrition are at risk when calories are introduced too aggressively, preventive measures involve gradually introducing the solution to avoid rapid shifts of phosphorus into the cells.

For patients with documented hypophosphatemia, careful attention is given to preventing infection because hypophosphatemia may alter the granulocytes. In patients requiring correction of phosphorus losses, the nurse frequently monitors serum phosphorus levels and documents and reports early signs of hypophosphatemia (apprehension, confusion, change in LOC). If the patient experiences mild hypophosphatemia, foods such as milk and milk products, organ meats, nuts, fish, poultry, and whole grains should be encouraged. With moderate hypophosphatemia, supplements such as Neutra-Phos capsules (250 mg phosphorus/capsule) or Fleet's Phospho-Soda (815 mg phosphorus/5 mL) may be prescribed.

HYPERPHOSPHATEMIA (PHOSPHORUS EXCESS)

Hyperphosphatemia is a serum phosphorus level that exceeds normal. Various conditions can lead to this imbalance, but the most common is kidney failure. Other causes include increased intake, decreased output, or a shift from the ICS to ECS. Other causes include chemotherapy for neoplastic disease, hypoparathyroidism, metabolic or respiratory acidosis, diabetic ketoacidosis, acute hemolysis, high phosphate intake, profound muscle necrosis, and increased phosphorus absorption. The primary complication of increased phosphorus is metastatic calcification (soft tissue, joints, and arteries), which occurs when the calcium–magnesium product (calcium × magnesium) exceeds 70 mg/dL.

Clinical Manifestations and Assessment

An increased serum phosphorus level causes few symptoms. Symptoms that do occur usually result from decreased calcium levels and soft tissue calcifications. The most important short-term consequence is tetany. Because of the reciprocal relationship between phosphorus and calcium, a high serum phosphate level tends to cause a low serum calcium concentration. Tetany can result, causing tingling sensations in the fingertips and around the mouth. Anorexia, nausea, vomiting, bone and joint pain, muscle weakness, hyperreflexia, and tachycardia may occur.

The major long-term consequence is soft tissue calcification, which occurs mainly in patients with a reduced glomerular filtration rate. High serum levels of inorganic phosphorus promote precipitation of calcium phosphate in nonosseous sites, decreasing urine output, impairing vision, and producing palpitations.

On laboratory analysis, the serum phosphorus level exceeds 4.5 mg/dL (1.5 mmol/L) in adults. Serum phosphorus levels are normally higher in children presumably because of the high rate of skeletal growth. The serum calcium level is useful also for diagnosing the primary disorder and assessing the effects of treatments. X-ray studies may show skeletal changes with abnormal bone development. PTH levels are decreased in hypoparathyroidism. BUN and creatinine levels are used to assess kidney function. Renal ultrasonography may be indicated as part of the diagnostic assessment for kidney failure; bone studies and coronary calcification studies also provide information about the chronicity and prognosis of kidney failure.

Medical Management

When possible, treatment is directed at the underlying disorder. For example, hyperphosphatemia may be related to volume depletion or respiratory or metabolic acidosis. In kidney failure, elevated PTH production contributes to a high phosphorus level and bone disease. Measures to decrease the serum phosphate level in these patients include vitamin D preparations, such as calcitriol, which is available in both oral and parenteral forms. IV administration of calcitriol does not increase the serum calcium unless its dose is excessive, thus permitting more aggressive treatment of hyperphosphatemia with calcium-binding antacids (calcium carbonate or calcium citrate), phosphate-binding gels or antacids, restriction of dietary phosphate, forced diuresis with a loop diuretic, volume repletion with saline, and dialysis. Surgery may be indicated for removal of large calcium–phosphorus deposits.

Nursing Management

The nurse monitors patients at risk for hyperphosphatemia. If a low-phosphorus diet is prescribed, the patient is instructed to avoid phosphorus-rich foods such as hard cheese, cream, nuts, meats, whole-grain cereals, dried fruits, dried vegetables, kidneys, sardines, sweetbreads, and foods made with milk. When appropriate, the nurse instructs the patient to avoid phosphate-containing substances such as laxatives and enemas. The nurse also teaches the patient to recognize the signs of impending hypocalcemia and to monitor for changes in urine output.

CHLORIDE IMBALANCES

Chloride, the major anion of the ECF, is found more in interstitial and lymph fluid compartments than in blood. Chloride is also contained in gastric and pancreatic juices, sweat, bile, and saliva. The choroid plexus, where cerebrospinal fluid forms in the brain, depends on sodium and chloride to attract water to form the fluid portion of the cerebrospinal fluid. Sodium and chloride in water make up the composition of the ECF and assist in determining osmotic pressure. The serum level of chloride reflects a change in dilution or concentration of the ECF and does so in direct proportion to the sodium concentration. Serum osmolality parallels chloride levels as well. The normal serum chloride level is 97 to 107 mEq/L (97 to 107 mmol/L). Inside the cell, the chloride level is 4 mEq/L.

Plasma bicarbonate has an inverse relationship with chloride. For example, the carbonic anhydrase reaction in RBCs generates both hydrogen and bicarbonate from metabolically produced CO_2. Hydrogen facilitates the dissociation of oxygen from hemoglobin. The intracellular accumulation of bicarbonate is prevented by its movement out of the cell into the plasma. To maintain electrical neutrality, chloride enters the RBC, a response referred to as the *chloride shift.* It is important to note that when the level of one of these three electrolytes (sodium, bicarbonate, or chloride) is disturbed, the other two are also affected. Chloride is important not only in maintaining acid–base balance, but it also mediates the hyperpolarizing effect of many neurotransmitters on the membrane potential. Chloride is primarily obtained from the diet as table salt.

HYPOCHLOREMIA (CHLORIDE DEFICIT)

Chloride control depends on the intake of chloride and the excretion and reabsorption of its ions in the kidneys. Chloride is produced in the stomach, where it combines with hydrogen to form hydrochloric acid. A small amount of chloride is lost in the feces. GI tube drainage and severe vomiting and diarrhea, laxatives, ileostomy, and fistulas are risk factors for hypochloremia. Administration of chloride-deficient formulas, low sodium intake, decreased serum sodium levels, metabolic alkalosis, prolonged therapy with IV dextrose (water intoxication), diuretic therapy, burns, and fever may also cause hypochloremia. As chloride decreases (usually because of volume depletion), sodium and bicarbonate ions are retained by the kidney to balance the loss. Bicarbonate accumulates in the ECF, which raises the pH and leads to hypochloremic metabolic alkalosis.

Clinical Manifestations and Assessment

Because hypochloremia rarely occurs in the absence of other abnormalities, signs and symptoms of hypochloremia are associated with hyponatremia, hypokalemia, and metabolic alkalosis. Metabolic alkalosis is a disorder that results in a high pH and a high serum bicarbonate level as a result of excess alkali intake or loss of hydrogen ions. With compensation, the partial pressure of carbon dioxide in arterial blood ($PaCO_2$) increases to 50 mm Hg. Hyperexcitability of muscles, tetany, hyperactive deep tendon reflexes, weakness, twitching, and muscle cramps may result. Hypokalemia can cause hypochloremia, resulting in cardiac arrhythmias. In addition, because low chloride levels parallel low sodium levels, a water excess may occur. Hyponatremia can cause seizures and coma.

In addition to the chloride level, sodium and potassium levels are also evaluated because these electrolytes are lost along with chloride. ABG analysis identifies the acid–base imbalance, which is usually metabolic alkalosis. The urine chloride level, which is also measured, decreases in hypochloremia.

Medical Management

Treatment involves correcting the cause of hypochloremia and the contributing electrolyte and acid–base imbalances. Normal saline (0.9% sodium chloride) or half-strength saline (0.45% sodium chloride) solution is administered by IV to replace the chloride. The provider may re-evaluate whether the patient receiving a diuretic (loop, osmotic, or thiazide) should discontinue the medications or change to another diuretic.

Foods high in chloride are provided; these include tomato juice, bananas, dates, eggs, cheese, milk, salty broth, canned vegetables, and processed meats. A patient who drinks free water (water without electrolytes) or bottled water excretes large amounts of chloride; therefore, the patient is instructed to avoid this kind of water. Ammonium chloride, an acidifying agent, may be prescribed to treat metabolic alkalosis; the dosage depends on the patient's weight and serum chloride level. This agent is metabolized by the liver, and its effects last for about 3 days. Its use should be avoided in patients with impaired liver or kidney function.

Nursing Management

The nurse monitors the patient's I&O, ABG values, and serum electrolyte levels as well as LOC and muscle strength and movement. Changes are reported to the provider promptly. Vital signs are monitored, and respiratory assessment is carried out frequently. The nurse teaches the patient about foods with high chloride content.

HYPERCHLOREMIA (CHLORIDE EXCESS)

Hyperchloremia exists when the serum level of chloride exceeds 107 mEq/L (107 mmol/L).

Pathophysiology

Because chloride has an affinity for sodium and an inverse relationship with bicarbonate, hyperchloremia is related to hypernatremia, bicarbonate loss, and metabolic acidosis. Hyperchloremic metabolic acidosis is also known as *normal anion gap acidosis* (see later discussion). It is usually caused by the loss of bicarbonate ions via the kidney or the GI tract with a corresponding increase in chloride ions. Chloride ions in the form of acidifying salts accumulate and acidosis occurs with a decrease in bicarbonate ions. Hyperchloremia results from increased intake either by mouth or by isotonic or hypertonic IV fluid administration (e.g., 9% NaCl has a chloride content of 154 mEq/L. Since normal chloride is 97 to 107 mEq/L, the nurse recognizes that prolonged administration of normal saline can results in hyperchloremic metabolic acidosis (electroneutrality is maintained by a decrease in the serum HCO_3^- [bicarbonate or base] concentration in the presence of a high chloride level, thus a hyperchloremic acidosis ensues). It can also result from decreased chloride excretion as in hyperparathyroidism, hyperaldosteronism, and kidney failure.

Clinical Manifestations and Assessment

The signs and symptoms of hyperchloremia are the same as those of metabolic acidosis, hypervolemia, and hypernatremia and can include tachypnea; weakness; lethargy; deep, rapid respirations; diminished cognitive ability; and hypertension. If untreated, hyperchloremia can lead to a decrease in cardiac output, arrhythmias, and coma. A high chloride level is often accompanied by a high sodium level and fluid retention. Laboratory analysis reveals the serum chloride level of 108 mEq/L (108 mmol/L) or greater, the serum sodium level greater than 145 mEq/L (145 mmol/L), the serum pH less than 7.35, and the serum bicarbonate level less than 22 mEq/L (22 mmol/L).

Medical Management

Correcting the underlying cause of hyperchloremia and restoring electrolyte, fluid, and acid–base balance are essential. Hypotonic IV solutions may be given to restore balance. Lactated Ringer solution may be prescribed to convert lactate to bicarbonate in the liver, which increases the base bicarbonate level and corrects the acidosis. IV sodium bicarbonate may be administered to increase bicarbonate levels, which leads to the renal excretion of chloride ions as bicarbonate and chloride compete to combine with sodium. Diuretics may be administered to eliminate chloride as well. Sodium, chloride, and fluids are restricted.

Nursing Management

Monitoring vital signs, ABG values, and the patient's I&O status is important to assess the patient's status and the effectiveness of treatment. Assessment findings related to respiratory, neurologic, and cardiac systems are documented, and changes are discussed with the provider. The nurse teaches the patient about the diet that should be followed to manage hyperchloremia and maintain adequate hydration.

ACID–BASE DISTURBANCES

Acid–base disturbances are commonly encountered in clinical practice. Identification of the specific acid–base imbalance is important in identifying the underlying cause of the disorder and determining appropriate treatment.

Plasma pH is an indicator of hydrogen ion (H^+) concentration. Homeostatic mechanisms keep pH within a normal range (7.35 to 7.45). These mechanisms consist of buffer systems, the kidneys, and the lungs. The H^+ concentration is extremely important: the greater the concentration, the more acidic the solution and the lower the pH; the lower the H^+ concentration, the more alkaline the solution and the higher the pH. The process causing an acidemia (condition when the blood is acid) is termed either *metabolic* or *respiratory acidosis,* whereas the process causing an alkalemia (condition when the blood is alkaline) is either *metabolic* or *respiratory alkalosis.* Blood pH must be kept within narrow limits because a pH outside the range of 6.8 to 7.8 is incompatible with life.

Buffer systems prevent major changes in the pH of body fluids by removing or releasing H^+; they can act quickly to prevent excessive changes in H^+ concentration. Hydrogen ions are buffered by both intracellular and extracellular buffers. The body's major extracellular buffer system is the bicarbonate–carbonic acid buffer system, which is assessed when ABGs are measured. The sources for bicarbonate (HCO_3^-) are the intestinal lumen, the pancreas, kidney, and, to a lesser extent, diet. The role of the kidneys is to reabsorb filtered bicarbonate and make new bicarbonate. The bicarbonate ion acts as a H^+ ion acceptor and is responsible for buffering 90% of the hydrogen ions in blood. Normally, there are 20 parts of bicarbonate (HCO_3^-) to one part of carbonic acid (H_2CO_3). If this ratio is altered, the pH will change. It is the ratio of HCO_3^- to H_2CO_3 that is important in maintaining pH, not absolute values. Carbon dioxide (CO_2) is regulated by the lungs and, when dissolved in water, becomes carbonic acid ($CO_2 + H_2O = H_2CO_3$). Therefore, when CO_2 is increased, the carbonic acid content is also increased, and vice versa. If either bicarbonate or carbonic acid is increased or decreased so that the 20:1 ratio is no longer maintained, an acid–base imbalance will result. Less important buffer systems in the ECF include the inorganic phosphates and the plasma proteins. Intracellular buffers include proteins, organic and inorganic phosphates, and, in RBC, hemoglobin.

The kidneys regulate the bicarbonate level in the ECF; they can regenerate bicarbonate ions as well as reabsorb them from the renal tubular cells. In respiratory acidosis, the kidneys respond to the increased CO_2 (carbon dioxide) and decreased pH by excreting hydrogen ions and conserving bicarbonate ions to help restore balance. Conversely, in

respiratory alkalosis, the kidneys' response to the decreased CO_2 and increased pH is to retain hydrogen ions and excrete bicarbonate ions to help restore balance. However, the renal compensation for imbalances described above is relatively slow (a matter of hours or days).

The lungs, under the control of the pons and the medulla, regulate the CO_2 and, thus, the carbonic acid content of the ECF. They do so by adjusting ventilation in response to the amount of CO_2 in the blood. A rise in the partial pressure of CO_2 in arterial blood ($PaCO_2$) is a powerful stimulant to respiration. Of course, the partial pressure of oxygen in arterial blood (PaO_2) also influences respiration. However, its effect is not as marked as that produced by the $PaCO_2$.

In metabolic acidosis, the respiratory rate increases, causing greater elimination of CO_2 (to reduce the acid load). In contrast, in metabolic alkalosis, the respiratory rate decreases, causing CO_2 to be retained (to increase the acid load). Both mechanisms are an attempt to return the pH to normal, and the respiratory response is instantaneous.

To review, a normal pH is 7.35 to 7.45 and is associated with three conditions: (1) a normal level of acid and base; (2) an abnormal process in which too many bases are produced (alkalosis), and the body counteracts this base load by allowing more acids to accumulate (20 base to 1 acid ratio maintained); (3) an abnormal process in which too many acids are produced, and the body counteracts by allowing more base to accumulate (20 base to 1 acid ratio maintained). The second and third conditions are considered compensation and will be discussed later in the chapter. If the pH is greater than 7.45, an alkalemia (blood is excessively alkaline) exists. If the pH is less than 7.35, an acidemia (blood is excessively acid) exists.

BASE BICARBONATE IMBALANCES

ACUTE AND CHRONIC METABOLIC ACIDOSIS (BASE BICARBONATE DEFICIT)

Metabolic acidosis is a clinical disturbance characterized by a low pH (increased H^+ concentration) and a low plasma bicarbonate concentration (less than 22 mEq/L). It can be produced by a gain of hydrogen ions or a loss of bicarbonate, and it is divided clinically into two forms according to the values of the serum anion gap: high anion gap acidosis and normal anion gap acidosis. The anion gap reflects unmeasured anions (phosphates, sulfates, and proteins) in plasma. Recall cations are positively charged ions (Na^+, K^+, H^+), and anions are negatively charged ions (HCO_3^-, Cl^-). Under normal conditions the ratio of cation to anion is not equal; that is, the Na^+ and K^+ levels are greater than the number of HCO_3^- and Cl^-. In actuality, the ECF is, under normal circumstances, electroneutral, and the sum of cations does equal the sum of anions. However, since not all anions are measured, there is a gap. The anion gap can be calculated by either one of the following equations:

$$(Na^+ + K^+) - (HCO_3^- + Cl^-)$$

or

$$Na+ - (HCO_3^- + Cl^-)$$

Potassium is often omitted from the equation because of its low level in the plasma; therefore, the second equation is used more often than the first.

The normal value for an anion gap is about 8 to 12 mEq/L (8 to 12 mmol/L) without potassium in the equation. If potassium is included in the equation, the normal value for the anion gap is 12 to 16 mEq/L (12 to 16 mmol/L). An anion gap greater than 16 mEq/L (16 mmol/L) is termed a *high anion gap metabolic acidosis* and results from excessive accumulation of fixed acid. High anion gap occurs in the ketoacidosis of uncontrolled diabetes or starvation, lactic acidosis, the late phase of salicylate poisoning, uremia, and methanol or ethylene glycol toxicity. In each of these situations the excess hydrogen is buffered by HCO_3^-, causing the bicarbonate concentration to fall. This is the reason for the high anion gap.

Normal anion gap acidosis results from the direct loss of bicarbonate, and can occur in diarrhea, lower intestinal fistulas, ureterostomies, diuretic therapy, early renal insufficiency, excessive administration of chloride (recall 0.9% NaCl contains 154 mEq of Cl^- per liter), and the administration of parenteral nutrition without bicarbonate or bicarbonate-producing solutes (e.g., lactate). Pancreatic drains are also associated with the direct loss of bicarbonate. In these situations, the direct loss of HCO_3^- is associated with an increase in plasma chloride, and the anion gap remains normal. This condition is also referred to as *hyperchloremic acidosis.*

Clinical Manifestations and Assessment

Signs and symptoms of metabolic acidosis vary with the severity of the acidosis. They may include headache, lethargy, confusion, sluggishness, increased respiratory rate and depth, nausea, and vomiting. Peripheral vasodilation and decreased cardiac output occur when the pH drops to less than 7. Additional physical assessment findings include decreased blood pressure, arrhythmias, and shock. Chronic metabolic acidosis is usually seen with CKF. The bicarbonate and pH decrease slowly, and the patient is asymptomatic until the bicarbonate is approximately 15 mEq/L or less.

ABG measurements reveal a low bicarbonate level (less than 22 mEq/L) and a low pH (less than 7.35). Hyperkalemia may accompany metabolic acidosis as a result of the shift of potassium out of the cells. Later, as the acidosis is corrected, potassium moves back into the cells and hypokalemia may occur. Hyperventilation decreases the CO_2 level as a compensatory action. As stated previously, calculation of the anion gap is helpful in determining the cause of metabolic acidosis. An ECG detects arrhythmias caused by the associated increased serum potassium.

Medical and Nursing Management

Treatment is directed at correcting the underlying metabolic defect. When the problem results from excessive intake of chloride, treatment is aimed at eliminating the source of the chloride (discontinuation of offending medication). When necessary, in general bicarbonate is administered if the pH is less than 7.1 and the serum bicarbonate level is less than 10 mEq/L. Although hyperkalemia occurs with acidosis, hypokalemia may occur with reversal of the acidosis and subsequent movement of potassium back into the cells. Therefore, the serum potassium level is monitored closely, and hypokalemia is corrected as acidosis is reversed.

In chronic metabolic acidosis, low serum calcium levels are treated before the chronic metabolic acidosis is treated, to avoid tetany resulting from an increase in pH and subsequent decrease in ionized calcium. Alkalizing agents may be administered if the serum bicarbonate level is less than 12 mEq/L. Treatment modalities may also include hemodialysis or peritoneal dialysis.

ACUTE AND CHRONIC METABOLIC ALKALOSIS (BASE BICARBONATE EXCESS)

Metabolic alkalosis is a clinical disturbance characterized by a high pH (decreased H^+ concentration) and a high plasma bicarbonate concentration. It can be produced by a gain of bicarbonate or a loss of H^+.

Pathophysiology

A common cause of metabolic alkalosis is related to volume depletion from vomiting or gastric suction, with loss of hydrogen and chloride ions. The disorder also occurs in pyloric stenosis, in which only gastric fluid is lost. Gastric fluid has an acid pH (usually 1 to 3), and loss of this highly acidic fluid increases the alkalinity of body fluids. Other situations predisposing the patient to metabolic alkalosis include those associated with loss of potassium, such as diuretic therapy that promotes excretion of potassium (e.g., thiazides, furosemide), and excessive adrenocorticoid hormones (as in hyperaldosteronism and Cushing syndrome).

Hypokalemia produces alkalosis in two ways: (1) the kidneys conserve potassium, and, therefore, H^+ excretion increases; and (2) cellular potassium moves out of the cells into the ECF in an attempt to maintain near-normal serum levels (as potassium ions leave the cells, hydrogen ions must enter to maintain electroneutrality). A helpful cue to recall the association of a decreased K^+ to alkalosis is "al-K^+-low-sis" (Diepenbrock, 2015).

Excessive alkali ingestion from antacids containing bicarbonate or from use of sodium bicarbonate during cardiopulmonary resuscitation can also cause metabolic alkalosis.

Chronic metabolic alkalosis can occur with long-term diuretic therapy (thiazides or furosemide), villous adenoma (GI polyp), external drainage of gastric fluids, significant potassium depletion, cystic fibrosis, and the chronic ingestion of milk and calcium carbonate.

Clinical Manifestations and Assessment

Alkalosis is primarily manifested by symptoms related to decreased calcium ionization, such as tingling of the fingers and toes, dizziness, and hypertonic muscles. The ionized fraction of serum calcium decreases in alkalosis as more calcium combines with serum proteins. Because it is the ionized fraction of calcium that influences neuromuscular activity, symptoms of hypocalcemia are often the predominant symptoms of alkalosis. Respirations are depressed as a compensatory action by the lungs. Atrial tachycardia may occur. As the pH increases to greater than 7.6 and hypokalemia develops, ventricular disturbances may occur. Decreased motility and paralytic ileus may also occur.

Symptoms of chronic metabolic alkalosis are the same as for acute metabolic alkalosis, and as potassium decreases, frequent premature ventricular contractions or U waves are seen on the ECG.

Evaluation of ABG reveals a pH greater than 7.45 and a serum bicarbonate concentration greater than 26 mEq/L. The $PaCO_2$ increases as the lungs attempt to compensate for the excess bicarbonate by retaining CO_2. This hypoventilation is more pronounced in semiconscious, unconscious, or debilitated patients than in alert patients. The former may develop marked hypoxemia as a result of hypoventilation. Hypokalemia and hypocalcemia are expected.

Medical and Nursing Management

Treatment of metabolic alkalosis is aimed at correcting the underlying acid–base disorder. Because of volume depletion from GI loss, the patient's fluid I&O must be monitored carefully.

Sufficient chloride must be supplied for the kidney to absorb sodium with chloride (allowing the excretion of excess bicarbonate). Treatment also includes restoring normal fluid volume by administering sodium chloride fluids (because continued volume depletion serves to maintain the alkalosis). In patients with hypokalemia, potassium is administered as KCl to replace both K^+ and Cl^- losses. Carbonic anhydrase inhibitors are useful in treating metabolic alkalosis in patients who cannot tolerate rapid volume expansion (e.g., patients with heart failure).

CARBONIC ACID IMBALANCES

ACUTE AND CHRONIC RESPIRATORY ACIDOSIS (CARBONIC ACID EXCESS)

Respiratory acidosis is a clinical disorder in which the pH is less than 7.35 and the $PaCO_2$ is greater than 45 mm Hg. It may be either acute or chronic.

Pathophysiology

Respiratory acidosis is always due to inadequate excretion of CO_2 with inadequate ventilation, resulting in elevated plasma CO_2 concentrations and, consequently, increased levels of carbonic acid. Any condition that causes hypoventilation is associated with an elevated $PaCO_2$, and usually a decrease in PaO_2. Acute respiratory acidosis occurs in emergency situations, such as aspiration of a foreign object, atelectasis, diaphragmatic paralysis, overdose of sedatives, sleep apnea syndrome, administration of high-flow oxygen to a patient with chronic hypercapnia (excessive CO_2 in the blood), severe pneumonia, and acute respiratory distress syndrome. Respiratory acidosis can also occur in diseases that impair respiratory muscles, such as muscular dystrophy, myasthenia gravis, and Guillain–Barré syndrome.

Mechanical ventilation may be associated with hypercapnia if the rate of effective alveolar ventilation is inadequate (respiratory rate or tidal volume too low).

In addition, some disorders, such as pulmonary edema and pneumothorax, may initially cause hyperventilation, but as respiratory fatigue develops, the CO_2 level will rise and acidosis will develop. Therefore, the nurse cannot assume that a clinical condition will cause a predicted disturbance. Rather, the nurse considers whether the respiratory center is capable of continuing to exhale the respiratory acid.

Clinical Manifestations and Assessment

Clinical signs in acute and chronic respiratory acidosis vary. Sudden hypercapnia (elevated $PaCO_2$) can cause increased pulse and respiratory rate, mental cloudiness, dull headache, or weakness. An elevated $PaCO_2$ causes cerebrovascular vasodilation and increased cerebral blood flow, particularly when it is greater than 60 mm Hg. Ventricular fibrillation may be the first sign of respiratory acidosis in anesthetized patients.

If respiratory acidosis is severe, intracranial pressure may increase, resulting in papilledema and dilated conjunctival blood vessels. Hyperkalemia may result as the hydrogen concentration overwhelms the compensatory mechanisms and H^+ moves into cells, causing a shift of potassium out of the cell.

Chronic respiratory acidosis occurs with pulmonary diseases such as chronic emphysema and bronchitis, obstructive sleep apnea, and obesity. As long as the $PaCO_2$ does not exceed the body's ability to compensate, the patient will be asymptomatic. However, if the $PaCO_2$ increases rapidly, cerebral vasodilation will increase the intracranial pressure, and cyanosis and tachypnea will develop. Patients with chronic obstructive pulmonary disease (COPD) who gradually accumulate CO_2 over a prolonged period (days to months) may not develop symptoms of hypercapnia because compensatory renal changes have had time to occur.

ABG analysis reveals a pH lower than 7.35, a $PaCO_2$ greater than 45 mm Hg, and a variation in the bicarbonate level, depending on the duration of the acute respiratory acidosis. When compensation (renal retention of bicarbonate) has fully occurred, the arterial pH may be within the lower limits of normal. Depending on the cause of respiratory acidosis, other diagnostic measures would include monitoring of serum electrolyte levels, chest x-ray for determining any respiratory disease, and a drug screen if an overdose is suspected. An ECG to identify any cardiac arrhythmias may be indicated.

Medical and Nursing Management

Treatment is directed at treating the cause of the hypoventilation; exact measures vary with the cause of inadequate ventilation. Pharmacologic agents are used as indicated. For example, bronchodilators help reduce bronchial spasm, antibiotics are used for respiratory infections, and thrombolytics or anticoagulants are used for pulmonary emboli.

Pulmonary hygiene measures are initiated, when necessary, to clear the respiratory tract of mucus and purulent drainage. Adequate hydration (2 to 3 L/day) is indicated to keep the mucous membranes moist and thereby facilitate the removal of secretions as long as not contraindicated by cardiac, liver, or kidney disease. Supplemental oxygen is administered as necessary.

Nursing Alert

If the $PaCO_2$ is chronically higher than 50 mm Hg, the respiratory center becomes relatively insensitive to CO_2 as a respiratory stimulant, leaving hypoxemia as the major drive for respiration. Oxygen administration may remove the stimulus of hypoxemia, and the patient develops "carbon dioxide narcosis" unless the situation is quickly reversed. Additional reasons for the increased CO_2, beyond oxygen administration, include oxygen administration increases the release of CO_2 from hemoglobin (which would cause the CO_2 to rise), or pulmonary arteriolar vasodilation increases perfusion to poorly ventilated alveoli with O_2 administration, causing a rise in the CO_2 (Effros & Swenson, 2015; Reid & Innes, 2014). While the exact etiology has not been elucidated for carbon dioxide narcosis, it is prudent to administer the amount of oxygen necessary to improve the patient's oxygen saturation to approximately 90%. Typically low flow oxygen (24% or 28% or 1–2 L/min) is administered; however, oxygen administration may need to be above this level. Therefore, the nurse recognizes that failure to achieve appropriate oxygenation is an indication for assisted ventilation.

Mechanical ventilation may be required to improve pulmonary ventilation. Inappropriate mechanical ventilation (e.g., increased dead space, insufficient rate or volume settings, high fraction of inspired oxygen [FiO_2] with excessive CO_2 production) must be corrected with appropriate changes to the ventilator setting. Proper patient positioning in a semi-Fowler position facilitates expansion of the chest wall.

ACUTE AND CHRONIC RESPIRATORY ALKALOSIS (CARBONIC ACID DEFICIT)

Respiratory alkalosis is a clinical condition in which the arterial pH is greater than 7.45 and the $PaCO_2$ is less than 35 mm Hg. As with respiratory acidosis, acute and chronic conditions can occur.

Pathophysiology

Respiratory alkalosis is always caused by hyperventilation, which causes excessive "blowing off" of CO_2 and, hence, a decrease in the plasma carbonic acid concentration. Causes of respiratory alkalosis can include extreme anxiety, hypoxemia, the early phase of salicylate intoxication (since the medulla is directly stimulated by the drug and the respiratory rate increases), high fever, gram-negative bacteremia, or inappropriate ventilator settings that do not match the patient's requirements. Acute exposure to a high altitude also can result in a hypoxia-induced hyperventilation, which can take several days before the patient is fully adapted.

Chronic respiratory alkalosis results from chronic hypocapnia, and decreased serum bicarbonate levels are the consequence. Chronic hepatic insufficiency and cerebral tumors are predisposing factors.

Clinical Manifestations and Assessment

Clinical signs consist of lightheadedness due to vasoconstriction and decreased cerebral blood flow, inability to concentrate, numbness and tingling from decreased calcium ionization, tinnitus, and, sometimes, loss of consciousness. Recall that cerebral blood flow is significantly decreased by hypocapnia, which is a potent vasoconstrictor; thus many of the clinical manifestations of respiratory alkalosis are related to the CNS and reduced free calcium. Cardiac effects of respiratory alkalosis include tachycardia and ventricular and atrial arrhythmias.

Analysis of ABG reveals an elevated pH (greater than 7.45) as a result of a low $PaCO_2$ (less than 35 mm Hg) and a normal bicarbonate level. (The kidneys cannot alter the bicarbonate level quickly; it will take up to 3 days for compensation to occur). The response of the kidneys will be to reduce hydrogen ion excretion (holding on to acids to maintain the 20:1 relationship) and increase bicarbonate excretion. In the compensated state, the kidneys have had sufficient time to lower the bicarbonate level to a near-normal level. Evaluation of serum electrolytes is indicated to identify a decrease in potassium as hydrogen is pulled out of the cells in exchange for potassium. As the blood pH rises and blood becomes more alkaline, proteins such as albumin become more negatively charged causing a higher affinity for binding with free calcium in the bloodstream. As a result, the ionized portion of calcium decreases, thus symptoms of carpopedal spasms and tetany occur. A toxicology screen should be performed to rule out salicylate intoxication.

Patients with chronic respiratory alkalosis are usually asymptomatic, and the diagnostic evaluation and plan of care are the same as for acute respiratory alkalosis.

Medical and Nursing Management

Treatment depends on the underlying cause of respiratory alkalosis. If the cause is anxiety, the patient is instructed to breathe more slowly to allow CO_2 to accumulate. A sedative may be required to relieve hyperventilation in very anxious patients. Treatment of other causes of respiratory alkalosis is directed at correcting the underlying problem.

MIXED ACID–BASE DISORDERS

Patients can simultaneously experience two or more independent acid–base disorders. A normal pH in the presence of changes in the $PaCO_2$ and plasma HCO_3^- concentration immediately suggests a mixed disorder. The only mixed disorder that cannot occur is a mixed respiratory acidosis and alkalosis because it is impossible to have alveolar hypoventilation and hyperventilation at the same time. An example of a mixed disorder is the simultaneous occurrence of metabolic acidosis and respiratory acidosis during respiratory and cardiac arrest.

Compensation

Generally, the pulmonary and renal systems compensate for each other to return the pH to normal. In a single acid–base disorder, the system not causing the problem will try to compensate by returning the ratio of bicarbonate to carbonic acid to the normal 20:1. The lungs compensate for metabolic disturbances by changing CO_2 excretion. The kidneys compensate for respiratory disturbances by altering bicarbonate retention and H^+ secretion.

In respiratory acidosis, excess hydrogen is excreted in the urine, and bicarbonate is retained. In respiratory alkalosis, the renal excretion of bicarbonate increases, and hydrogen ions are retained. In metabolic acidosis, the compensatory mechanisms increase the ventilation rate; in metabolic alkalosis, the respiratory system compensates by decreasing ventilation to conserve CO_2 and increase the $PaCO_2$. Because the lungs respond to acid–base disorders within minutes, compensation for metabolic imbalances occurs faster than does compensation for respiratory imbalances. Table 4-4 summarizes compensation effects.

Blood Gas Analysis

Blood gas analysis is often used to identify the specific acid–base disturbance and the degree of compensation that has occurred (see Boxes 4-1 and 4-2). The analysis is usually based on an arterial blood sample, but if an arterial sample cannot be obtained, a mixed venous sample may be used. Results of ABG analysis provide information about alveolar ventilation, oxygenation, and acid–base balance. The health history, physical examination, previous blood gas results, and serum electrolytes should always be part of the assessment used to determine the cause of the acid–base disorder. Before obtaining an ABG from the radial artery, the nurse assesses patency of the ulnar artery by performing the Allen test (refer to Chapter 12). Treatment of the underlying condition usually corrects most acid–base disorders. Table 4-5 compares normal ranges of venous and ABG values.

TABLE 4-4 Acid–Base Disturbances and Compensation

Disorder	Initial Event	Compensation
Respiratory acidosis	↓ pH, ↑ or normal HCO_3^-, ↑ $PaCO_2$	↑ Renal acid excretion and ↑ serum HCO_3^-
Respiratory alkalosis	↑ pH, ↓ or normal HCO_3^-, ↓ $PaCO_2$	↓ Renal acid excretion and ↓ serum HCO_3^-
Metabolic acidosis	↓ pH, ↓ HCO_3^-, ↓ $PaCO_2$	Hyperventilation with resulting ↓ $PaCO_2$
Metabolic alkalosis	↑ pH, ↑ HCO_3^-, ↑ $PaCO_2$	Hypoventilation with resulting ↑ $PaCO_2$

PARENTERAL FLUID THERAPY

When no other route of administration is available, fluids are administered intravenously in hospitals, outpatient diagnostic and surgical settings, clinics, and homes to replace fluids, administer medications, and provide nutrients. Typical indications for giving a fluid bolus include hypotension, low urine output, and inadequate cardiac output for tissue needs (Rewa & Bagshaw, 2015).

Purpose

The choice of an IV solution depends on the purpose of its administration. Generally, IV fluids are administered to achieve one or more of the following goals:

BOX 4-1 Assessing Arterial Blood Gases

The following steps are recommended to evaluate arterial blood gas (ABG) values. They are based on the assumption that the average values are:

pH = 7.4
$PaCO_2$ = 40 mm Hg (normal 35 to 45 mm Hg)
HCO_3^- = 24 mEq/L (normal 22 to 26 mEq/L)

First, note the pH. It can be high, low, or normal, as follows:

pH greater than 7.4 (alkalosis)
pH less than 7.4 (acidosis)
pH equal to 7.4 (normal)

A normal pH may indicate perfectly normal blood gases, *or* it may be an indication of a *compensated* imbalance. A compensated imbalance is one in which the body has been able to correct the pH by either respiratory or metabolic changes (depending on the primary problem). For example, a patient with primary metabolic acidosis starts out with a low bicarbonate level but a normal CO_2 level. Soon afterward, the lungs try to compensate for the imbalance by exhaling large amounts of CO_2 (hyperventilation). As another example, a patient with primary respiratory acidosis starts out with a high CO_2 level; soon afterward, the kidneys attempt to compensate by retaining bicarbonate. If the compensatory mechanism is able to restore the bicarbonate to carbonic acid ratio back to 20:1, full compensation (and thus normal pH) will be achieved.

The next step is to determine the primary cause of the disturbance. This is done by evaluating the $PaCO_2$ and HCO_3^- in relation to the pH.

Example: pH greater than 7.4 (alkalosis)

a. If the $PaCO_2$ is less than 35 mm Hg, the primary disturbance is respiratory alkalosis. (This situation occurs when a patient hyperventilates and "blows off" too much CO_2. Recall that CO_2 dissolved in water becomes carbonic acid, the acid side of the "carbonic acid–bicarbonate buffer system.")
b. If the HCO_3^- is greater than 26 mEq/L, the primary disturbance is metabolic alkalosis. (This situation occurs when the body gains too much bicarbonate, an alkaline substance. Bicarbonate is the basic or alkaline side of the "carbonic acid–

bicarbonate buffer system.")

Example: pH less than 7.4 (acidosis)

a. If the $PaCO_2$ is greater than 45 mm Hg, the primary disturbance is respiratory acidosis. (This situation occurs when a patient hypoventilates and thus retains too much CO_2, an acidic substance.)
b. If the HCO_3^- is less than 22 mEq/L, the primary disturbance is metabolic acidosis. (This situation occurs when the body's bicarbonate level drops, either because of direct bicarbonate loss or because of gains of acids such as lactic acid or ketones.)

The next step involves determining if compensation has begun. This is done by looking at the value other than the primary disorder. If it is moving in the same direction as the primary value, compensation is under way. Consider the following gases:

pH	$PaCO_2$	HCO_3^-
(1) 7.2	60 mm Hg	24 mEq/L
(2) 7.4	60 mm Hg	37 mEq/L

The first set (1) indicates acute respiratory acidosis without compensation (the $PaCO_2$ is high, the HCO_3^- is normal). The second set (2) indicates chronic respiratory acidosis. Note that compensation has taken place; that is, the HCO_3^- has elevated to an appropriate level to balance the high $PaCO_2$ and produce a normal pH.

Two distinct acid–base disturbances may occur simultaneously. These can be identified when the pH does not explain one of the changes.

Example: Metabolic and respiratory acidosis

a. pH	7.2 decreased acid
b. $PaCO_2$	52 increased acid
c. HCO_3	13 decreased acid

This is an example of metabolic and respiratory acidosis.

BOX 4-2 Nursing Research

Bridging the Gap to Evidence-Based Practice

Guérin, L., Teboul, J., Persichini, R., Dres, M., Richard, C., & Monnet, X. (2015). Effects of passive leg raising and volume expansion on mean systemic pressure and venous return in shock in humans, *Critical Care*, *19*, 411.

Purpose

The aim of this study was to assess how mean systemic pressure and resistance to venous return (RVR) behave during passive leg raising (PLR) in cases of fluid responsiveness and fluid unresponsiveness.

Design

In 30 patients with an acute circulatory failure, in order to estimate the venous return curve, the authors constructed the regression line between pairs of cardiac index (CI) and central venous pressure (CVP). Values were measured during end-inspiratory and end-expiratory ventilatory occlusions performed at two levels of positive end-expiratory pressure. The x-axis intercept was used to estimate the mean systemic pressure and the inverse of the slope to quantify RVR. These measurements were obtained at baseline, during PLR, and after fluid infusion. Patients in whom fluid infusion increased CI by more than 15% were defined as "fluid-responders."

Findings

In fluid-responders (n = 15), CVP and mean systemic pressure significantly increased (from 7 ± 3 to 9 ± 4 mm Hg and from 25 ± 13 to 31 ± 13 mm Hg, respectively) during PLR. The mean systemic pressure -CVP gradient significantly increased by 20% to 30% while RVR did not change significantly during PLR. In fluid-nonresponders, CVP and mean systemic pressure increased significantly, but the mean systemic pressure -CVP gradient did not change significantly during PLR. PLR did not change the intra-abdominal pressure in the whole population (14 ± 6 mm Hg before vs. 13 ± 5 mm Hg during PLR, $p = 0.26$) and in patients with intra-abdominal hypertension at baseline (17 ± 4 mm Hg before vs. 16 ± 4 mm Hg during PLR, $p = 0.14$). In the latter group, PLR increased mean systemic pressure from 22 ± 11 to 27 ± 10 mm Hg ($p < 0.01$) and did not change RVR (5.1 ± 2.6 to 5.2 ± 3 mm Hg/min/m^2/mL, $p = 0.71$). In fluid-responders, mean systemic pressure, CVP and the mean systemic pressure -CVP gradient significantly increased during fluid infusion while the RVR did not change. In fluid-nonresponders, CVP and mean systemic pressure increased significantly during fluid infusion while the mean systemic pressure -CVP gradient and RVR did not change.

Nursing Implications

Passive leg raising (PLR) significantly increased mean systemic pressure and central venous pressure (CVP), confirming that it represents a powerful preload challenge without modifying resistance to venous return. In acute circulatory failure, PLR is a test that predicts whether cardiac output will increase with volume expansion by transferring a volume of around 300 mL of venous blood from the lower body toward the right side of the heart. There are specific rules: the head of the bed should be 45 degrees to begin. PLR should start from the semi-recumbent since trunk lowering and leg raising should mobilize venous blood from the large splanchnic compartment, thus magnifying the increasing effects of leg elevation on cardiac preload and increasing the test's sensitivity. The nurse should follow institutional protocols on PLR as this represents a potential test that will mimic a fluid challenge but has the advantage of having no fluid infused and being rapidly reversible (by lowering the extremities), thereby avoiding the risks of fluid overload (Monnet & Teboul, 2015).

- To provide water, electrolytes, and/or nutrients to meet daily requirements;
- To replace water and correct electrolyte deficits;
- To administer medications and blood products.

IV solutions contain dextrose or electrolytes mixed in various proportions with water. Pure, electrolyte-free water can never be administered IV because it enters RBCs rapidly and causes them to rupture.

TABLE 4-5 Normal Values for Arterial and Mixed Venous Blood

Parameter	Arterial Blood	Mixed Venous Blood
pH	7.35–7.45	7.33–7.41
$PaCO_2$	35–45 mm Hg	41–51 mm Hg
PaO_2[a]	80–100 mm Hg	35–40 mm Hg
HCO_3^-	22–26 mEq/L	22–26 mEq/L
Base excess/deficit	±2 mEq/L	±2 mEq/L
Oxygen saturation	over 94%	75%

[a]At altitudes of 3,000 feet and higher, the values for oxygen are decreased.

Types of IV Solutions

Crystalloid solutions are often categorized as isotonic, hypotonic, or hypertonic, according to whether their total osmolality is the same as, less than, or greater than that of plasma (see earlier discussion of osmolality). Crystalloid fluids generally contain three basic components: water, electrolytes, and sugar (dextrose).

Electrolyte solutions are considered isotonic if the total electrolyte content (anions + cations) is approximately 310 mEq/L, hypotonic if the total electrolyte content is less than 250 mEq/L, and hypertonic if the total electrolyte content is greater than 375 mEq/L. The nurse must also consider a solution's osmolality, keeping in mind that the osmolality of plasma is approximately 300 mOsm/L (300 mmol/L). For example, a 10% dextrose solution has an osmolality of approximately 505 mOsm/L.

When administering parenteral fluids, the nurse monitors the patient's response to the fluids, considering the fluid volume, the content of the fluid, and the patient's clinical status. Some fluids may actually initiate an inflammatory process within the body, especially when overused in patients with hemorrhage shock (Horeczko, Green, & Panacek, 2014). Refer to Table 4-6 for various IV solutions.

Nursing Alert

When administering fluids to patients with cardiovascular disease, the nurse assesses for signs of circulatory overload (e.g., cough, dyspnea, puffy eyelids, dependent edema, weight gain in 24 hours). The lungs are auscultated for crackles. Extreme care is taken when administering highly hypertonic sodium fluids (e.g., 3% or 5% sodium chloride) because these fluids can be lethal if infused carelessly.

TABLE 4-6 Selected Water and Electrolyte Solutions

Solution	Comments
Isotonic Solutions 0.9% NaCl (isotonic, also called normal saline [NS]) Na^+ 154 mEq/L Cl^- 154 mEq/L (308 mOsm/L) Also available with varying concentrations of dextrose (the most frequently used is a 5% dextrose concentration)	• An isotonic solution that expands the ECF volume • Used in hypovolemic states, resuscitative efforts, shock, diabetic ketoacidosis, metabolic alkalosis, hypercalcemia, mild Na^+ deficit • Supplies an excess of Na^+ and Cl^-; can cause FVE and hyperchloremic acidosis if used in excessive volumes, particularly in patients with compromised kidney function, heart failure, or edema • Not desirable as a routine maintenance solution as it provides only Na^+ and Cl^- (and these are provided in excessive amounts) • When mixed with 5% dextrose, the resulting solution becomes hypertonic in relation to plasma and, in addition to the above described electrolytes, provides 170 cal/L • Only solution that may be administered with blood products
Lactated Ringer solution Na^+ 130 mEq/L K^+ 4 mEq/L Ca^{+2} 3 mEq/L Cl^- 109 mEq/L Lactate (metabolized to bicarbonate) 28 mEq/L (274 mOsm/L) Also available with varying concentrations of dextrose (the most common is 5% dextrose)	• An isotonic solution that contains multiple electrolytes in roughly the same concentration as found in plasma (note that solution is lacking in Mg^{+2}): provides 9 cal/L • Used in the treatment of hypovolemia, burns, fluid lost as bile or diarrhea, and for acute blood loss replacement • Lactate is rapidly metabolized into HCO_3^- in the body. Lactated Ringer solution should not be used in lactic acidosis because the ability to convert lactate into HCO_3^- is impaired in this disorder • Not to be given with a pH over 7.5 because bicarbonate is formed as lactate breaks down, causing alkalosis • Should not be used in kidney failure (because it contains potassium and can cause hyperkalemia) or in liver disease (due to altered lactate metabolism) • Similar to plasma
5% dextrose in water (D_5W) No electrolytes 50 g of dextrose	• Initially an isotonic solution, once the dextrose is metabolized it becomes a hypotonic solution that supplies 170 cal/L and free water to aid in renal excretion of solutes • Used in treatment of hypernatremia, fluid loss, and dehydration • Should not be used in excessive volumes in the early postoperative period (when antidiuretic hormone secretion is increased due to stress reaction) • Should not be used solely in treatment of FVD because it dilutes plasma electrolyte concentrations • Contraindicated in head injury because it may cause increased intracranial pressure • Should not be used for fluid resuscitation because it can cause hyperglycemia and will not expand the IVS • Should be used with caution in patients with kidney or cardiac disease because of risk of fluid overload • Electrolyte-free solutions may cause peripheral circulatory collapse, anuria in patients with sodium deficiency, and increased body fluid loss • Over time, D_5W without NaCl can cause water intoxication (ICF volume excess [FVE]) because the solution is hypotonic
Hypotonic Solutions 0.45% NaCl (half-strength saline) Na^+ 77 mEq/L Cl^- 77 mEq/L (154 mOsm/L) Also available with varying concentrations of dextrose (the most common is a 5% concentration)	• Provides Na^+, Cl^-, and free water • Free water is desirable to aid the kidneys in elimination of solute • Lacking in electrolytes other than Na^+ and Cl^- • When mixed with 5% dextrose, the solution becomes slightly hypertonic to plasma and, in addition to the above-described electrolytes, provides 170 cal/L • Used to treat hypertonic dehydration, Na^+ and Cl^- depletion, and gastric fluid loss • Not indicated for third-space fluid shifts or increased intracranial pressure • Administer cautiously because it can cause fluid shifts from vascular system into cells, resulting in cardiovascular collapse and increased intracranial pressure.
Hypertonic Solutions 3% NaCl (hypertonic saline) Na^+ 513 mEq/L Cl^- 513 mEq/L (1,026 mOsm/L)	• Used to increase ECF volume, decrease cellular swelling • Highly hypertonic solution used only in critical situations to treat hyponatremia • Must be administered slowly and cautiously because it can cause intravascular volume overload and pulmonary edema • Supplies no calories • Assists in removing ICF excess
5% NaCl (hypertonic solution) Na^+ 855 mEq/L Cl^- 855 mEq/L (1710 mOsm/L)	• Highly hypertonic solution used to treat symptomatic hyponatremia • Administered slowly and cautiously because it can cause intravascular volume overload and pulmonary edema • Supplies no calories
Colloid Solutions Dextran in NS or 5% D_5W Available in low-molecular-weight (Dextran 40) and high-molecular-weight (Dextran 70) forms	• Colloid solution used as volume/plasma expander for intravascular part of ECF • Affects clotting by coating platelets and decreasing ability to clot • Remains in circulatory system up to 24 hours • Used to treat hypovolemia in early shock to increase pulse pressure, cardiac output, and arterial blood pressure • Improves microcirculation by decreasing RBC aggregation • Contraindicated in hemorrhage, thrombocytopenia, kidney disease, and severe dehydration • Not a substitute for blood or blood products

Isotonic Fluids

Isotonic fluids have a total osmolality close to that of the ECF and do not cause RBCs to shrink or swell. The composition of these fluids may or may not approximate that of the ECF. Isotonic fluids expand the ECF volume. One liter of isotonic fluid expands the ECF by 1 L; however, it expands the plasma by only 0.25 L because it is a crystalloid fluid and diffuses quickly into the ECF compartment. In patients hospitalized for shock, as much as 20 to 40 mL/kg of isotonic fluid boluses may be required initially to maintain renal perfusion. However, since these fluids expand the IVS, patients with hypertension and heart failure should be monitored carefully for signs of fluid overload.

D_5W

A solution of D_5W has a serum osmolality of 252 mOsm/L. Once administered, the glucose is metabolized rapidly, and this initially isotonic solution then disperses as a hypotonic fluid, one third extracellular and two thirds intracellular. It is essential to consider this action of D_5W, especially if the patient is at risk for ICP. During fluid resuscitation, this solution should not be used because of its limited ability to expand the intravascular volume. Therefore, D_5W is used mainly to supply water and to correct an increased serum osmolality. About 1 L of D_5W provides fewer than 200 kcal and is a minor source of the body's daily caloric requirements.

Normal Saline Solution

Normal saline (0.9% sodium chloride) solution has a total osmolality of 308 mOsm/L. Because the osmolality is contributed entirely by electrolytes, the solution remains within the ECF. For this reason, normal saline solution is often used to correct an extracellular volume deficit. Normal saline contains only sodium and chloride and does not actually simulate the ECF. It is used with administration of blood transfusions and to replace large sodium losses, as in burn injuries. It is not used for heart failure, pulmonary edema, kidney impairment, or sodium retention. Normal saline does not supply calories. Historically, in patients with trauma or penetrating injury, initial treatment consisted of large amounts of isotonic saline administration to maintain a systolic blood pressure greater than 90 mm Hg. Hemorrhage can also begin a process of coagulopathy, acidosis, and hypothermia within the body, necessitating a decision for light versus aggressive parenteral fluid administration (Rewa & Bagshaw, 2015).

Other Isotonic Solutions

Several other solutions contain ions in addition to sodium and chloride and are somewhat similar to the ECF in composition. Lactated Ringer solution contains potassium and calcium in addition to sodium and chloride and can be used to correct dehydration and sodium depletion or to replace GI losses. Lactated Ringer solution contains bicarbonate precursors as well. Lactated Ringer is typically not used in patients with severe acidosis or in advanced liver disease, which can affect lactate metabolism.

Hypotonic Fluids

One purpose of hypotonic solutions is to replace cellular fluid. Another is to provide free water for excretion of body wastes. At times, hypotonic sodium solutions are used to treat hypernatremia and other hyperosmolar conditions. Half-strength saline (0.45% sodium chloride) solution, with an osmolality of 154 mOsm/L, is frequently used. Multiple-electrolyte solutions are also available. Excessive infusions of hypotonic solutions can lead to intravascular fluid depletion by causing a fluid shift from blood vessels to cells, resulting in decreased blood pressure, cellular edema, and cell damage. These solutions exert less osmotic pressure than the ECF.

Hypertonic Fluids

When normal saline solution or lactated Ringer solution contains 5% dextrose, the total osmolality exceeds that of the ECF. However, the dextrose is quickly metabolized, and only the isotonic solution remains. Therefore, any effect on the intracellular compartment is temporary.

Higher concentrations of dextrose, such as 50% dextrose in water, are administered to help meet caloric requirements or to treat hypoglycemia in the NPO patient. These solutions are strongly hypertonic and must be administered into central veins so that they can be diluted by rapid blood flow.

Saline solutions are also available in osmolar concentrations greater than that of the ECF. These solutions draw water from the ICF to the ECF and cause cells to shrink. If administered rapidly or in large quantity, they may cause an extracellular volume excess and precipitate circulatory overload. As a result, these solutions must be administered cautiously and usually only when the serum osmolality has decreased to dangerously low levels. Hypertonic solutions exert an osmotic pressure greater than that of the ECF.

Nursing Alert

Highly hypertonic sodium solutions (3% and 5% sodium chloride) should be administered only in intensive care settings under close observation because only small volumes are needed to elevate the serum sodium concentration. These fluids are administered slowly and in small volumes, and the patient is monitored closely for fluid overload. Frequent checks of the patient's electrolyte panel are warranted. The purpose is to relieve acute manifestations of cerebral edema and to prevent neurologic complications rather than to specifically correct the sodium concentration. Along with the sodium solution, the patient may receive a loop diuretic to prevent ECF volume overload and to increase water excretion.

Other IV Substances

When the patient's GI tract is unable to tolerate food, nutritional requirements are often met using the IV route. Parenteral solutions may include high concentrations of glucose, protein, or fat to meet nutritional requirements (see Chapter 22). The parenteral route may also be used to administer colloids, plasma expanders, and blood products including packed RBCs, fresh frozen plasma, and platelets.

Many medications are also delivered by the IV route, either by infusion or directly into the vein. Because IV medications enter the circulation rapidly, administration by this route is potentially very hazardous. While all medications may produce reactions, IV medications

are especially dangerous due to the rapid introduction and absorption within the bloodstream. Astute nursing includes knowledge of the administration rates and recommended dilutions for any medication given.

Nursing Management of the Patient Receiving IV Therapy

The ability to perform venipuncture to gain access to the venous system for administering fluids and medication is an expected nursing skill in many settings. This responsibility includes selecting the appropriate venipuncture site and type of cannula and being proficient in the technique of vein entry. This skill should be mastered by all bedside nurses, and it is up to each individual nurse to seek out the opportunity to learn and practice venipuncture.

Preparing to Administer IV Therapy

Before performing venipuncture, the nurse performs hand hygiene, applies gloves, and informs the patient about the procedure. Next, the nurse selects the most appropriate insertion site and type of cannula for a particular patient. See Box 4-3 for the factors that influence these choices. Some institutions have organized specialized "IV therapy" teams who assist in IV placement and management.

Choosing an IV Site

Veins of the extremities are designated as peripheral locations and are ordinarily the only sites used by nurses. Because they are relatively safe and easy to enter, arm veins are most commonly used (Fig. 4-8). The metacarpal, cephalic, basilic, and median veins and their branches are recommended sites because of their size and ease of access. More distal sites should be used first, with more proximal sites used subsequently. Leg veins should rarely, if ever, be used because of the high risk of thromboembolism. Additional sites to avoid include veins distal to a previous IV infiltration or phlebitic area, sclerosed or thrombosed veins, an arm with an arteriovenous shunt or fistula, and an arm affected by edema, infection, blood clot, or skin breakdown.

BOX 4-3 Factors in Selecting a Venipuncture Site

The following factors should be considered when selecting a site for venipuncture:

- Condition of the vein
- Type of fluid or medication to be infused
- Duration of therapy
- Patient's age and size
- Whether the patient is right- or left-handed
- Patient's medical history and current health status
- Skill of the person performing the venipuncture

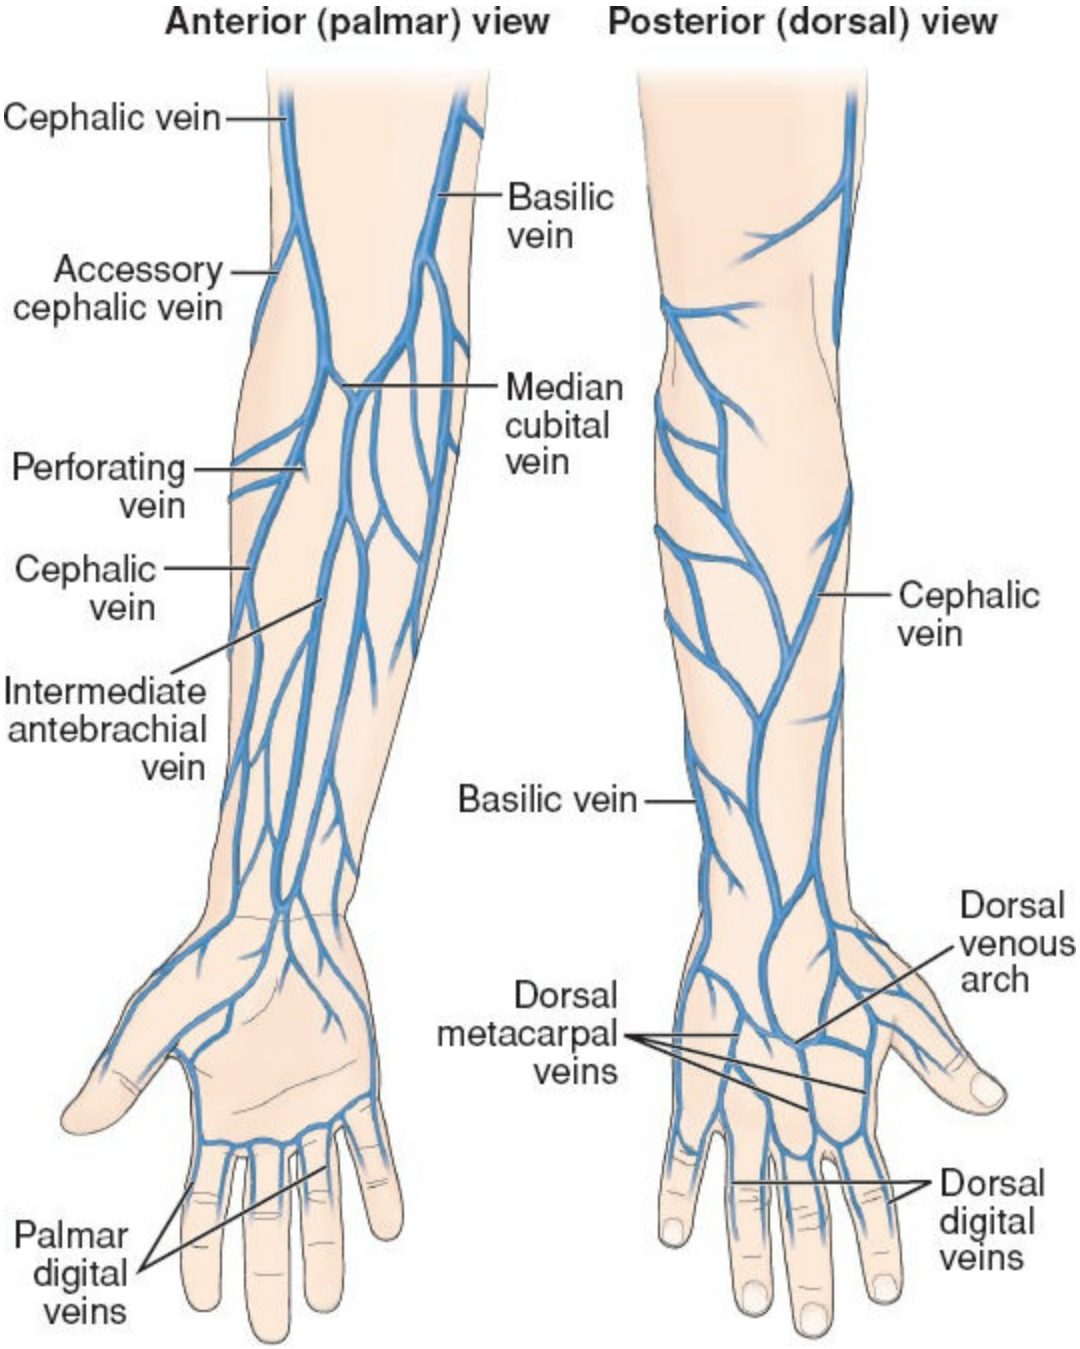

FIGURE 4-8 Site selection for peripheral cannulation of veins: anterior (palmar) veins at left, posterior (dorsal) veins at right.

Nursing Alert
Due to the interruption in the lymphatic system in patients who have had a mastectomy or lymph node removal, blood pressure measurements (both manual and automatic) or IV therapy placement should not occur on the same side. Performing either of these procedures on the affected arm can cause fluid to back up in the arm, and lymphedema (accumulation of lymph fluid) can develop. This is a painful condition that also increases the risk of infection to the patient.

Central veins commonly used by physicians and trained advanced practice providers include the subclavian and internal jugular veins. It is possible to gain access to (or cannulate) these larger vessels even when peripheral sites have collapsed, and they allow for the administration of hyperosmolar solutions and vasoconstrictive drugs. However, the potential hazards are much greater and include inadvertent entry into an artery or the pleural space, as well as a higher risk of infection.

Ideally, both arms and hands are carefully inspected before choosing a specific venipuncture site that does not interfere with mobility. For this reason, the antecubital fossa is avoided, except as a last resort. The most distal site of the arm or hand is generally used first so that subsequent IV access sites can be moved progressively upward. Refer back to Box 4-3 for factors to consider in selecting an IV site.

After applying a tourniquet, the nurse palpates and inspects the vein. The tourniquet remains applied for a maximum of 3 minutes before the tension must be released. The vein should feel firm, elastic, engorged, and round—not hard, flat, or bumpy. Because arteries lie close to veins in the antecubital fossa, the vessel should be palpated for arterial pulsation (even with a tourniquet on), and cannulation of pulsating vessels should be avoided.

Using Venipuncture Devices

Cannulas. Most peripheral access devices are cannulas. "Catheter" and "cannula" are terms that are used interchangeably. General guidelines for selecting a cannula include the following:

- Length: 0.75 to 1.25 in long
- Diameter: Narrow diameter of the cannula to occupy minimal space within the vein
- Gauge: 20 to 22 gauge for most IV fluids; a larger gauge for caustic or viscous solutions; 14 to 18 gauge preferred for trauma patients and those undergoing surgery; and blood administration can now safely use as small as a 24-gauge needle (Infusion Nurses Society, 2011).

Cannulas have an obturator inside a tube that is later removed. The main types of cannula devices available are those referred to as winged infusion sets (butterfly) with a steel needle or as over-the-needle catheters with wings; indwelling plastic cannulas that are inserted over a steel needle; and indwelling plastic cannulas that are inserted through a steel needle. Scalp vein or butterfly needles are short steel needles with plastic wing handles. These are easy to insert, but because they are small and nonpliable, infiltration occurs easily. The use of these needles should be limited to obtaining blood specimens and not for IV medications because they increase the risk of vein injury and infiltration.

Plastic cannulas inserted through a hollow needle are usually called *intracatheters.* They are available in long lengths and are well suited for placement in central locations. Because insertion requires threading the cannula through the vein for a relatively long distance, these can be difficult to insert. The most commonly used infusion device is the over-the-needle catheter. A hollow metal stylet is preinserted into the catheter and extends through the distal tip of the catheter to allow puncture of the vessel in an effort to guide the catheter as the venipuncture is performed. The vein is punctured and a flashback of blood appears in the closed chamber behind the catheter hub. Once the flashback has occurred, the catheter is threaded through the stylet into the vein, and then the stylet is removed. All

institutions should carry safety over-the-needle catheter designs with retracting stylets to protect health care workers from needlestick injuries.

Many types of cannulas are available for IV therapy. Some of the variations in these cannulas include the thickness of the cannula wall (affects rate of flow), the sharpness of the insertion needles (determines needle insertion technique), the softening properties of the cannula (influences the length of time the cannula can remain in place), safety features (minimizes risk of needlestick injuries and blood-borne exposure), and the number of lumens (determines the number of solutions that can be infused simultaneously).

Needleless IV Delivery Systems. The federal Needlestick Safety and Prevention Act, which was signed into law in November 2000, requires needleless systems in an effort to decrease needlestick injuries and exposure to HIV, hepatitis, and other blood-borne pathogens. These systems have built-in protection against needlestick injuries and provide a safe means of using and disposing of an IV administration set (which consists of tubing, an area for inserting the tubing into the container of IV fluid, and an adapter for connecting the tubing to the needle). Numerous companies produce needleless components. IV line connectors allow the simultaneous infusion of IV medications and other intermittent medications (known as a *piggyback delivery*) without the use of needles. Technology is advancing and moving away from use of the traditional stylet. Many examples of these devices are on the market. Each institution must evaluate products to determine its own needs based on Occupational Safety and Health Administration (OSHA) guidelines and the institution's policies and procedures.

Peripherally Inserted Central Catheter or Peripheral- Midline Catheter Access Lines. Patients who need moderate- to long-term parenteral therapy often receive a peripherally inserted central catheter (PICC or PIC line) or a peripheral-midline catheter. These catheters are also used for patients with limited peripheral access who require IV antibiotics, blood, vasopressors, or parenteral nutrition. For these devices to be used, the median cephalic, basilic, and cephalic veins must be patent and undamaged. Typically insertion of these catheters is performed by specialized nurses who are trained in the use of them as well as in the use of ultrasonography (which is used to visualize the vein to be cannulized).

If these veins are damaged, then central venous access via the subclavian or internal jugular vein, or surgical placement of an implanted port or a vascular access device, must be considered as an alternative. Table 4-7 compares peripherally inserted central and peripheral-midline catheters.

The provider prescribes the line and the solution to be infused. Insertion of either catheter requires sterile technique. The size of the catheter lumen chosen is based on the type of solution, the patient's body size, and the vein to be used. The patient's consent is obtained before use of these catheters. Use of the dominant arm is recommended as the site for inserting the cannula into the superior vena cava to ensure adequate arm movement, which encourages blood flow and reduces the risk of dependent edema or emboli formation. Contraindications to arm choice include prior mastectomy, pacemaker placement, hemiparesis, and dialysis shunt. Review each institution's policy regarding PICC lines for further contraindications.

Teaching the Patient

Except in emergency situations, a patient should be prepared in advance for an IV infusion. The venipuncture, the expected length of infusion, and activity restrictions are explained. Then, the patient should have an opportunity to ask questions and express concerns. For example, some patients believe that they will die if small bubbles in the tubing enter their veins. After acknowledging this fear, the nurse can explain that usually only relatively large volumes of air administered rapidly are dangerous.

Preparing the IV Site

Before preparing the skin, the nurse should ask the patient whether he or she is allergic to latex or iodine, products commonly used in preparing for IV therapy. Excessive hair at the selected site may be removed by clipping to increase the visibility of the veins and to facilitate insertion of the cannula and adherence of dressings to the IV insertion site. Shaving should not be performed due to increased risk of infection.

Because infection can be a major complication of IV therapy, the IV device, the fluid, the container, and the tubing must be sterile. The insertion site is scrubbed with a sterile pad soaked in 10% povidone–iodine (Betadine) or chlorhexidine gluconate solution for 30 seconds, working in a circular motion from the center of the area to the periphery and allowing the area to air dry for approximately 2 minutes. The site should not be wiped with 70% alcohol because the alcohol negates the effect of the disinfecting solution. (Alcohol pledgets are used for 30 seconds instead, only if the patient is allergic to iodine.) The nurse must perform hand hygiene and put on gloves. Gloves (nonsterile, disposable) must be worn during the venipuncture procedure because of the likelihood of coming into contact with the patient's blood.

TABLE 4-7 Comparison of Peripherally Inserted Central and Peripheral-Midline Catheters

	Peripherally Inserted Central Catheter (PICC)	Peripheral-Midline Catheter
Indications	Parenteral nutrition; IV fluid replacement; administration of chemotherapy agents, analgesics, and antibiotics; removal of blood specimens	Parenteral nutrition; IV fluid replacement; administration of analgesics and antibiotics (no solution or medications with a pH less than 5 or greater than 9 or osmolarity greater than 500 mOsm/L); removal of blood specimens
Features	Single- and double-lumen catheters available 40–60 cm long; gauge variable (16–24 gauge)	Single- and double-lumen catheters available 7.5–20 cm long; gauge variable (16–24 gauge). Can increase two gauges in size as it softens
Material	Radiopaque, polymer (polyurethane), Silastic materials. Flexible.	Silicone, polyurethane, and their derivatives; available impregnated with heparin to ↓ thrombogenicity (radiopaque or clear, with radiopaque strip)
Insertion sites	Venipuncture performed in the antecubital fossa, above or below it into the basilic, cephalic, or axillary veins of the dominant arm. The median basilic is the ideal insertion site.	Venipuncture performed 1½ in above or below the antecubital fossa through the cephalic, basilic, or median cubital vein.
Catheter placement	The tip of the catheter lies in the superior vena cava. The catheter is placed via the basilic or cephalic vein at the antecubital fossa.	Between the antecubital area and the head of the clavicle (tip in axilla region). The tip terminates in the proximal portion of the extremity below the axilla and proximal to central veins and is advanced 3–10 in
Insertion method	Through-the-needle technique, with or without a guide wire, breakaway needle with introducer or cannula with introducer (peel-away sheath). (A peripherally inserted central catheter can also be used as a midline catheter.)	No separate guide wire or introducer is needed. Stiff catheter is passed using the catheter advancement tab.
	Insertion can be accomplished at the bedside using sterile technique. Arm to be used should be positioned in abduction to 90-degree angle. Consent is required	Insertion can be accomplished at the bedside using sterile technique. Arm to be used should be positioned in abduction to 45-degree angle. Consent is required
	Catheter may stay in place for up to 12 months or as long as required without complications	Catheter may stay in place for 2–4 weeks
Potential complications	Malposition, pneumothorax, hemothorax, hydrothorax, arrhythmias, nerve or tendon damage, respiratory distress, catheter embolism, thrombophlebitis, or catheter occlusion. Compared with centrally placed catheters, venipuncture in the antecubital space reduces risk of insertion complications	Thrombosis, phlebitis, air embolism, infection, vascular perforation, bleeding, catheter transection, occlusion
Contraindications	Dermatitis, cellulitis, burns, high fluid volume infusions, rapid bolus injections, hemodialysis, and venous thrombosis. No clamping of this catheter or splinting of the arm permitted. No blood pressure or tourniquets to be used on extremity where PICC is inserted.	Dermatitis, cellulitis, burns, high fluid volume infusions, rapid bolus injection, hemodialysis, and venous thrombosis. No blood pressure or tourniquet to be used on extremity where midline catheter is placed
Catheter maintenance	Sterile dressing changes according to agency policy and procedures. Generally, dressing is changed every 2–3 days or when wet, soiled, or nonocclusive. Line is flushed every shift with 3 mL normal saline followed by 3 mL of heparin (100 U/mL) per lumen. The nurse follows institutional policy for flushing catheter	Sterile dressing changes according to agency policy and procedures. Generally, dressing is changed every 2–3 days or when wet, soiled, or nonocclusive. Line is flushed after each infusion or every shift with 5–10 mL normal saline followed by 1 mL of heparin (100 U/mL). Catheter must be anchored securely to prevent its dislodgment. The nurse follows institutional policy for flushing catheter

Postplacement	Chest x-ray needed to confirm placement of catheter tip	Chest x-ray to assess placement may be obtained if unable to flush catheter, if no free flow blood return, if difficulty with catheter advancement, or if guide wire is difficult to remove or bent on removal
Assessment	Daily measurement of arm circumference (4 in above insertion site) and length of exposed catheter	Daily measurement of arm circumference (4 in above insertion site) and length of exposed catheter
Removal	Catheter should be removed when no longer indicated for use, if contaminated, or if complications occur	Catheter should be removed when no longer indicated for use, if contaminated, or if complications occur
	Arm is abducted during removal. Patient should be in a dorsal recumbent position with head of bed flat and should perform the Valsalva maneuver while catheter is withdrawn	Arm is abducted during removal
	Pressure is applied on removal with a sterile dressing and antiseptic ointment to site. Dressing is changed every 24 hours until epithelialization occurs	Pressure is applied on removal with a sterile dressing and antiseptic ointment to site. Dressing is changed every 24 hours until epithelialization occurs
Advantages	Reduces cost and avoids repeated venipunctures compared with centrally placed catheters. Decreases incidence of catheter-related infections	Reduces cost and avoids repeated venipunctures compared with centrally placed catheters. Decreases incidence of catheter-related infections

Performing Venipuncture

IV therapy initiation is a specialized nursing skill. Institutional policies and procedures determine whether all nurses must be certified to perform venipuncture. A nurse certified in IV therapy or an IV team can be consulted to assist with initiating IV therapy. Refer to each institution's guidelines on venipuncture for specific policies regarding this skill.

Understanding Factors Affecting Flow

The flow of an IV infusion is governed by the same principles that govern fluid movement in general. Flow is directly proportional to the height on the infusion. Raising the infusion bag may improve sluggish flow. The clamp on IV tubing regulates the flow by changing the tubing diameter. In addition, the flow is faster through large-gauge rather than small-gauge cannulas. Issues such as length of IV tubing and viscosity of the fluid being infused may also affect the flow rate.

Monitoring Flow

Because so many factors influence gravity flow, a solution does not necessarily continue to run at the speed originally set. Therefore, the nurse monitors IV infusions frequently to make sure that the fluid is flowing at the intended rate. The IV container should be marked with tape to indicate at a glance whether the correct amount has infused. The flow rate is calculated when the solution is originally started and then monitored at least hourly. To calculate the flow rate, the nurse determines the number of drops delivered per milliliter; this varies with equipment and is usually printed on the administration set packaging. In an effort to decrease the amount of medication errors, it has become standard for all intermittent IV infusions to be given with an electronic infusion device.

A variety of electronic infusion devices are available to assist in IV fluid delivery. These devices allow more accurate administration of fluids and medications than is possible with routine gravity-flow setups. A pump is a positive-pressure device that uses pressure to infuse

fluid at a pressure of 10 psi; newer models use a pressure of 5 psi. The pressure exerted by the pump overrides vascular resistance (increased tubing length, low height of the IV container).

Volumetric pumps calculate the volume delivered by measuring the volume in a reservoir that is part of the set and is calibrated in milliliters per hour (mL/hr). A controller is an infusion assist device that relies on gravity for infusion; the volume is calibrated in drops (gtt) per minute. A controller uses a drop sensor to monitor the flow. Factors essential for the safe use of pumps include alarms to signify the presence of air in the IV line or an occlusion. The standard for the accurate delivery of fluid or medication via an electronic IV infusion pump is plus or minus 5%. The manufacturer's directions must be read carefully before use of any infusion pump or controller because there are many variations in available models. Use of these devices does not eliminate the need for the nurse to monitor the infusion and the patient frequently; however, it does limit the amount of bedside drug calculations and medication administration errors.

Flushing of a vascular device is performed to ensure patency and to prevent the mixing of incompatible medications or solutions. This procedure should be carried out at established intervals, according to hospital policy and procedure, especially for intermittently used catheters. Most manufacturers and researchers suggest the use of saline for flushing. The volume of the flush solution should be at least twice the volume capacity of the catheter. The catheter should be clamped before the syringe is completely empty and withdrawn to prevent reflux of blood into the lumen, which could cause catheter clotting and infiltration.

Discontinuing an Infusion

The removal of an IV catheter is associated with two possible dangers: bleeding and catheter embolism. To prevent excessive bleeding, a dry, sterile pressure dressing should be held over the site as the catheter is removed. Firm pressure is applied until hemostasis occurs.

If a plastic IV catheter is severed, the patient is at risk for catheter embolism. To detect this complication when the catheter is removed, the nurse compares the expected length of the catheter with its actual length. Plastic catheters should be withdrawn carefully and their length measured to make certain that no fragment has broken off in the vein.

Great care must be exercised when using scissors around the dressing site. If the catheter clearly has been severed, the nurse can attempt to occlude the vein above the site by applying a tourniquet to prevent the catheter from entering the central circulation (until surgical removal is possible). However, as always, it is better to prevent a potentially fatal problem than to deal with it after it has occurred. Fortunately, catheter embolism can be prevented easily by following simple rules:

- Avoid using scissors near the catheter.
- Avoid withdrawing the catheter through the insertion needle.
- Follow the manufacturer's guidelines carefully (e.g., cover the needle point with the bevel shield to prevent severance of the catheter).

Managing Systemic Complications

IV therapy predisposes the patient to numerous hazards, including both local and systemic complications. Systemic complications occur less frequently but are usually more serious than are local complications. They include circulatory overload, air embolism, febrile reaction, and infection.

Overloading the circulatory system with excessive IV fluids causes increased blood pressure and CVP. Signs and symptoms of fluid overload include moist crackles on auscultation of the lungs, edema, weight gain, dyspnea, and respirations that are shallow and have an increased rate. Possible causes include rapid infusion of an IV solution or hepatic, cardiac, or kidney disease. The risk of fluid overload and subsequent pulmonary edema is especially increased in elderly patients with cardiac disease; this is referred to as *circulatory overload.*

The treatment for circulatory overload is decreasing the IV rate, monitoring vital signs frequently, assessing breath sounds, and placing the patient in a high Fowler position. The provider is contacted immediately. This complication can be avoided by using an infusion pump for infusions and by carefully monitoring all infusions. Complications of circulatory overload include heart failure and pulmonary edema.

The risk of air embolism is rare but ever-present. It is most often associated with cannulation of central veins. Manifestations of air embolism include dyspnea and cyanosis; hypotension; weak, rapid pulse; loss of consciousness; and chest, shoulder, and low back pain. Treatment calls for immediately clamping the cannula and replacing a leaking or open infusion system, placing the patient on the left side in the Trendelenburg position, assessing vital signs and breath sounds, and administering oxygen. Air embolism can be prevented by using a Luer Lock adapter on all lines, filling all tubing completely with solution, and using an air detection alarm on an IV pump. Complications of air embolism include shock and death. The amount of air necessary to induce death in humans is not known; however, the rate of entry is probably as important as the actual volume of air.

Pyrogenic substances in either the infusion solution or the IV administration set can induce a febrile reaction and septicemia. Signs and symptoms include an abrupt temperature elevation shortly after the infusion is started, backache, headache, increased pulse and respiratory rate, nausea and vomiting, diarrhea, chills and shaking, and general malaise. In severe septicemia, vascular collapse and septic shock may occur. Causes of septicemia include contamination of the IV product or a break in aseptic technique, especially in immunocompromised patients. Treatment is symptomatic and includes culturing of the IV cannula, tubing, or solution if it is suspect as well as establishing a new IV site for medication or fluid administration. See Chapter 54 for a discussion of septic shock.

Infection ranges in severity from local involvement of the insertion site to systemic dissemination of organisms through the bloodstream, as in septicemia. Measures to prevent infection are essential at the time the IV line is inserted and throughout the entire infusion. Prevention includes the following:

- Careful hand hygiene before every contact with any part of the infusion system or the patient
- Examining the IV containers for cracks, leaks, or cloudiness; these findings may indicate a contaminated solution
- Using strict aseptic technique

- Firmly anchoring the IV cannula to prevent to-and-fro motion
- Inspecting the IV site daily and replacing a soiled or wet dressing with a dry sterile dressing (antimicrobial agents that should be used for site care may include 2% tincture of iodine, 10% povidone–iodine, alcohol, or chlorhexidine gluconate, used alone or in combination per the institution's policy)
- Disinfecting injection/access ports with antimicrobial solution before use
- Removing the IV cannula at the first sign of local inflammation, contamination, or complication
- Replacing the peripheral IV cannula every 72 hours, or as indicated
- Replacing the IV cannula inserted during emergency conditions (with questionable asepsis) as soon as possible
- Using a 0.2-&b.mu;m air-eliminating and bacteria/particulate retentive filter with non–lipid-containing solutions that require filtration. The filter can be added to the proximal or distal end of the administration set. If added to the proximal end between the fluid container and the tubing spike, the filter ensures sterility and particulate removal from the infusate container and prevents inadvertent infusion of air. If added to the distal end of the administration set, it filters air particles and contaminants introduced from add-on devices, secondary administration sets, or interruptions to the primary system. The nurse would choose where to place the filter depending on whether the administration set is on a dedicated line.
- Replacing the solution bag and administration set in accordance with agency policy and procedure
- Infusing or discarding medication or solution within 24 hours of its addition to an administration set
- Changing primary and secondary continuous administration sets every 96 hours, or immediately if contamination is suspected (Ling et al., 2016)
- Changing primary administration sets containing lipid-based solutions every 24 hours, or immediately if contamination is suspected (Ling et al., 2016).

Managing Local Complications

Local complications of IV therapy include infiltration and extravasation, phlebitis, thrombophlebitis, hematoma, and clotting of the needle.

Infiltration is the unintentional administration of a nonvesicant solution or medication into surrounding tissue. This can occur when the IV cannula dislodges or perforates the wall of the vein. Infiltration is characterized by edema around the insertion site, leakage of IV fluid from the insertion site, discomfort and coolness in the area of infiltration, and a significant decrease in the flow rate. When the solution is particularly irritating, sloughing of tissue may result. Close monitoring of the insertion site is necessary to detect infiltration before it becomes severe.

Infiltration is usually easily recognized if the insertion area is larger than the same site of the opposite extremity; however, it is not always so obvious. A common misconception is that a backflow of blood into the tubing proves that the catheter is properly placed within the vein. However, if the catheter tip has pierced the wall of the vessel, IV fluid will seep

into tissues as well as flow into the vein. Although blood return occurs, infiltration has occurred as well. A more reliable means of confirming infiltration is to apply a tourniquet above (or proximal to) the infusion site and tighten it enough to restrict venous flow. If the infusion continues to drip despite the venous obstruction, infiltration is present.

As soon as the nurse notes infiltration, the infusion should be stopped, the IV discontinued, and a sterile dressing applied to the site after careful inspection to determine the extent of infiltration. The infiltration of any amount of blood product, irritant, or vesicant is considered the most severe.

The IV infusion should be started in a new site or proximal to the infiltration if the same extremity must be used again. A warm compress may be applied to the site if small volumes of noncaustic solutions have infiltrated over a long period or if the solution was isotonic with a normal pH; the affected extremity should be elevated to promote the absorption of fluid. If the infiltration is recent and the solution was hypertonic or had an increased pH, a cold compress may be applied to the area. Infiltration can be detected and treated early by inspecting the site every hour for redness, pain, edema, coolness at the site, and IV fluid leaking from the IV site. Using the appropriate size and type of cannula for the vein prevents this complication.

Extravasation is similar to infiltration with an inadvertent administration of vesicant or irritant solution or medication into the surrounding tissue. Medications such as dopamine, calcium preparations, and chemotherapeutic agents can cause pain, burning, and redness at the site. Blistering, inflammation, and necrosis of tissues can occur. The extent of tissue damage is determined by the concentration of the medication, the quantity that extravasated, the location of the infusion site, the tissue response, and the duration of the process of extravasation.

The infusion must be stopped and the provider notified promptly. The agency's protocol to treat extravasation is initiated; the protocol may indicate specific treatments, including antidotes specific to the medication that extravasated, and may indicate whether the IV line should remain in place or be removed before treatment. The protocol often specifies infiltration of the infusion site with an antidote prescribed after assessment by the provider, removal of the cannula, and application of warm compresses to sites of extravasation from vinca alkaloids or cold compresses to sites of extravasation from alkylating and antibiotic vesicants (Al-Benna, O'Boyle, & Holley, 2013). The affected extremity should not be used for further cannula placement. Thorough neurovascular assessments of the affected extremity must be performed frequently.

Reviewing the institution's IV policy and procedures, incompatibility charts and checking with the pharmacist before administering any IV medication, whether given peripherally or centrally, is a prudent way to determine incompatibilities and vesicant potential to prevent extravasation. Careful, frequent monitoring of the IV site, avoiding insertion of IV devices in areas of flexion, securing the IV line, and using the smallest catheter possible that accommodates the vein help minimize the incidence and severity of this complication. In addition, when vesicant medication is administered by IV push, it should be given through a side port of an infusing IV solution to dilute the medication and decrease the severity of tissue damage if extravasation occurs.

Signs of phlebitis and infiltration may be assessed using a scale such as the Infusion Nurses Society (INS) infiltration scale (Ray-Barruel, Polit, Murfield, & Rickard, 2014). The scale ranges from 0, or no edema, to 4, which includes pitting edema, moderate to

severe pain at the site, or circulatory impairment. Extravasation should always be rated as a grade 4 on the infiltration scale.

Phlebitis is defined as inflammation of a vein, which can be categorized as chemical, mechanical, or bacterial; however, two or more of these types of irritation often occur simultaneously. Chemical phlebitis can be caused by an irritating medication or solution (increased pH or high osmolality of a solution), rapid infusion rates, and medication incompatibilities. Mechanical phlebitis results from long periods of cannulation, catheters in flexed areas, catheter gauges larger than the vein lumen, and poorly secured catheters. Bacterial phlebitis can develop from poor hand hygiene, lack of aseptic technique, failure to check all equipment before use, and failure to recognize early signs and symptoms of phlebitis. Other factors include poor venipuncture technique, catheter in place for a prolonged period, and failure to adequately secure the catheter. Phlebitis is characterized by a reddened, warm area around the insertion site or along the path of the vein, pain or tenderness at the site or along the vein, and swelling. The likelihood of phlebitis increases with the length of time the IV line is in place, the composition of the fluid or medication infused (especially its pH and tonicity), the size and site of the cannula inserted, ineffective filtration, inadequate anchoring of the line, and the introduction of microorganisms at the time of insertion. Treatment consists of discontinuing the IV and restarting it in another site as well as applying a warm, moist compress to the affected site. Phlebitis can be prevented by using aseptic technique during insertion, using the appropriate-size cannula or needle for the vein, considering the composition of fluids and medications when selecting a site, observing the site hourly for any complications, anchoring the cannula or needle well, and changing the IV site according to agency policy and procedures.

Thrombophlebitis refers to the presence of a clot plus inflammation in the vein. It is evidenced by localized pain, redness, warmth, and swelling around the insertion site or along the path of the vein, immobility of the extremity because of discomfort and swelling, sluggish flow rate, fever, malaise, and leukocytosis.

Treatment includes discontinuing the IV infusion; applying a cold compress first, to decrease the flow of blood and increase platelet aggregation, followed by a warm compress; elevating the extremity; and restarting the line in the opposite extremity. If the patient has signs and symptoms of thrombophlebitis, the IV line should not be flushed (although flushing may be indicated in the absence of phlebitis to ensure cannula patency and to prevent mixing of incompatible medications and solutions). The catheter must be removed promptly. In some circumstances, the catheter tip may be sent to the laboratory for culture, and it should be removed and placed in a sterile container prior to sending to the lab. Thrombophlebitis can be prevented by avoiding trauma to the vein at the time the IV is inserted, observing the site every hour, and checking medication additives for compatibility.

A hematoma results when blood leaks into tissues surrounding the IV insertion site. Leakage can result if the opposite vein wall is perforated during venipuncture, the needle slips out of the vein, or insufficient pressure is applied to the site after removal of the needle or cannula. The signs of a hematoma include ecchymosis, immediate swelling at the site, and leakage of blood at the insertion site.

Treatment includes removing the needle or cannula and applying light pressure with a sterile, dry dressing; applying ice for 24 hours to the site to avoid extension of the hematoma; elevating the extremity; assessing the extremity for any circulatory, neurologic, or motor dysfunction; and restarting the line in the other extremity if indicated. A

hematoma can be prevented by carefully inserting the needle and by using diligent care with patients who have a bleeding disorder, are taking anticoagulant medication, or have advanced liver disease.

Blood clots may form in the IV line as a result of kinked IV tubing, a very slow infusion rate, an empty IV bag, or failure to flush the IV line after intermittent medication or solution administrations. The signs are decreased flow rate and blood backflow into the IV tubing. If blood clots in the IV line, the infusion must be discontinued and restarted in another site with a new cannula and administration set. The tubing should not be irrigated or milked. Neither the infusion rate nor the solution container should be raised, and the clot should not be aspirated from the tubing. Clotting of the needle or cannula may be prevented by not allowing the IV solution bag to run dry, taping the tubing to prevent kinking and maintain patency, maintaining an adequate flow rate, and flushing the line after intermittent medication or other solution administration. In some cases, a specially trained nurse or provider may inject a thrombolytic agent.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 28-year-old man with a history of diabetes mellitus has an open fracture of the tibia as the result of a motorcycle crash. In the emergency department, his temperature is 103°F. His laboratory test results are as follows: blood glucose, 450 mg/dL; BUN, 35 mg/dL; sodium, 140 mEq/L; potassium, 4.1 mEq/L; pH, 7.1; PCO_2, 10 mm Hg; and HCO_3^-, 12 mEq/L. His urine ketones are 3+. What fluid and electrolyte or acid–base disorders is the patient experiencing? What IV fluids would you anticipate being prescribed? Give the rationale for their use. What treatments would address the patient's fluid and electrolyte or acid–base disorders?

2. A 30-year-old woman comes to the emergency department with nausea, confusion, dehydration, and oliguria. Her mother reports that she has been depressed after losing her job as a bank executive. An empty bottle of aspirin was found in her bathroom sink. Her laboratory values are as follows: pH, 7.35; $PaCO_2$, 16 mm Hg; PaO_2, 98 mm Hg; and HCO_3^-, 15 mEq/L. What acid–base disorder does this patient have? What treatments and relevant nursing actions related to the underlying disorder and its treatment should the nurse anticipate?

3. A 58-year-old woman is vomiting bright red blood. She is hypotensive. Her pulse rate is 108 bpm, and her pulse is weak and thready. Her ABG results are as follows: pH, 7.34; $PaCO_2$, 35 mm Hg; PaO_2, 69 mm Hg; and HCO_3^-, 20 mEq/L. Her hemoglobin is 4 g/dL. How do you interpret the patient's blood gas values? What treatment would you anticipate?

NCLEX-Style Review Questions

1. A nurse is analyzing her patient's ABG values. Which result is inconsistent with the

diagnosis of respiratory acidosis?

a. pH 7.3
b. $PaCO_2$ 50
c. Hyperventilation ($PaCO_2$ 25)
d. Hypoventilation ($PaCO_2$ 60)

2. A patient is diagnosed with SIADH. What disturbance should the nurse be aware of related to this diagnosis?

a. Excess water loss
b. Dilutional hyponatremia
c. Serum sodium level of 148 mg/dL
d. Decreased urine osmolality

3. A nurse working on a trauma unit is initiating IV fluids for a patient. For what condition would the nurse administer normal saline?

a. Renal impairment
b. Pulmonary edema
c. Burns
d. Heart failure

4. When entering a patient's room, the nurse notices blood clots in the IV line. What is the most appropriate nursing intervention at this time?

a. Milk the tubing.
b. Discontinue the infusion.
c. Irrigate the tubing and catheter.
d. Aspirate the clot from the tubing.

5. What does the nurse expect to see on the ECG reading when serum potassium levels rise to greater than 6 mEq/L?

a. Peaked, widened T waves
b. ST-segment elevation
c. Lengthened QT interval
d. ST-segment depression

CHAPTER 5

Perioperative Nursing

Joann Preece

Learning Objectives

After reading this chapter, you will be able to:

1. Define the three phases of perioperative nursing.
2. Describe a comprehensive preoperative assessment to identify surgical risk factors.
3. Identify legal and ethical considerations related to informed consent.
4. Describe the immediate preoperative preparation, and intraoperative and postoperative management of the surgical patient.
5. Identify the nurse's role in patient safety and regulatory compliance in the perioperative setting.
6. Describe the principles of surgical asepsis.
7. Identify adverse effects of surgery and anesthesia.
8. Describe types of anesthetic approaches and the implications for nursing care in the perioperative setting.
9. Describe perioperative nursing measures that decrease the risk for complications.

Surgery, whether elective or emergent, is a stressful, complex event. The special field known as perioperative and perianesthesia nursing includes a wide variety of nursing functions associated with the patient's surgical experience during the perioperative period.

INTRODUCTION

Phases

Perioperative and perianesthesia nursing addresses the nursing roles relevant to the three phases of the surgical experience: preoperative, intraoperative, and postoperative. Each phase begins and ends at a particular point in the sequence of events that constitutes the surgical experience, and each includes a wide range of activities that the nurse performs using the nursing process and based on the standards of practice (American Society of Perianesthesia Nurses [ASPAN], 2015). Box 5-1 represents nursing activities characteristic of the three perioperative phases of care.

Surgical Settings

Today, as a result of advances in surgical techniques and instrumentation, as well as in anesthesia, the number of surgeries, imaging studies, and diagnostic tests performed outside of hospitals is growing rapidly. These procedures are primarily moving to ambulatory surgery centers (ASCs), which provide outpatient surgical services not requiring an overnight stay, independent diagnostic and testing facilities, and health providers' offices. Innovation in medical technology and surgical techniques, along with preferences of multiple players in the health care system, has driven the migration of care to nonhospital settings. Less invasive surgical techniques and advances in anesthesia have made it possible for more procedures to be performed in outpatient settings, where recovery time is limited. As a result, today, many patients arrive at the hospital on the morning of surgery and go home after recovering from the anesthesia in the postanesthesia care unit (PACU). Often, surgical patients who require hospital stays are trauma patients, acutely ill patients, and/or patients undergoing major surgery.

Although each setting (ambulatory, outpatient, or inpatient) offers its own unique advantages for the delivery of patient care, they all require comprehensive preoperative nursing assessment and nursing interventions, and a sound knowledge of all aspects of perioperative and perianesthesia nursing.

Surgical Classifications

A surgical procedure may be diagnostic (e.g., biopsy, exploratory laparotomy), curative (e.g., excision of a tumor or an inflamed appendix), or reparative (e.g., multiple wound repair). It may be reconstructive or cosmetic (e.g., mammoplasty or a facelift) or palliative (e.g., to relieve pain or correct a problem—for instance, a gastrostomy tube may be inserted to compensate for the inability to swallow food). Surgery may also be classified according to the degree of urgency involved (Table 5-1).

BOX 5-1 Examples of Nursing Activities in the Perioperative Phases of Care

Preoperative Phase

Preadmission Testing

1. Initiates initial preoperative health history and physical assessment
2. Initiates teaching appropriate to patient's needs
3. Involves family in interview
4. Verifies completion of preoperative testing
5. Verifies understanding of surgeon-specific preoperative orders (e.g., bowel preparation, preoperative shower)
6. Discharge planning—assesses patient's need for postoperative transportation and care

Admission to Surgical Center or Unit

1. Verification of patient identification and expected procedure
2. Completes preoperative assessment
3. Assesses patient's status, including nutritional status and baseline level of pain
4. Assesses for risks for postoperative complications
5. Assesses for and manages perioperative nomothermia
6. Reports unexpected findings or any deviations from normal
7. Verifies that operative consent and all appropriate documents have been signed
8. Coordinates patient teaching with other nursing staff and reinforces previous teaching
9. Explains phases in perioperative period and expectations; answers patient's and family's questions
10. Develops a plan of care
11. Removes and secures prosthesis, dentures, glasses, jewelry
12. Ensures interpreter is present if patient requires
13. Encourages patient to void immediately pre-op
14. Establishes IV line
15. Obtains pre-op blood glucose or pregnancy testing as ordered
16. Administers medications if prescribed, reminds patient not to get OOB after

premedicated
17. Takes measures to ensure patient's comfort
18. Provides psychological support
19. Communicates patient's emotional status to other appropriate members of the health care team

Intraoperative Phase

Maintenance of Safety

1. Maintains aseptic, controlled environment
2. Effectively manages human resources, equipment, and supplies for individualized patient care
3. Transfers patient to operating room bed or table
4. Safely positions the patient:
   a. Confirms functional alignment and secures patient to operating room table
   b. Initiates pressure ulcer reduction and skin injury processes
   c. Ensures appropriate exposure of surgical site
5. Applies grounding device to patient
6. Ensures that the sponge, needle, and instrument counts are correct
7. Ensures that the final verification (time out) is conducted and documented
8. Completes intraoperative documentation
9. Maintains an environment to support patient's body temperature as per procedural protocol

Psychological Support (Before Induction and when Patient is Conscious)

1. Provides emotional support to patient
2. Stands near or touches patient during procedures and induction
3. Continues to assess patient's emotional status

Postoperative Phase

Transfer of Patient to Postanesthesia Care Unit

1. Communicates intraoperative information:
   a. Identifies patient by name
   b. States type of surgery performed
   c. Identifies type of anesthetic used
   d. Reports patient's response to surgical procedure and anesthesia
   e. Describes intraoperative factors (e.g., insertion of drains or catheters; administration of blood, analgesic agents, or other medications during surgery; occurrence of unexpected events)
   f. Describes physical limitations
   g. Reports patient's preoperative level of consciousness
   h. Communicates necessary equipment needs

i. Communicates presence of family and/or significant others

Postoperative Assessment Recovery Area

1. Determines patient's immediate response to surgical intervention
2. Integrates data received at transfer of care
3. Monitors patient's physiologic status
4. Assesses patient's pain level and administers appropriate pain relief measures
5. Maintains patient's safety (airway, circulation, prevention of injury)
6. Administers medications, fluid, and blood component therapy, if prescribed
7. Provides oral fluids if prescribed for ambulatory surgery patient
8. Assesses patient's readiness for transfer to in-hospital unit or for discharge home based on institutional policy

Surgical Unit

1. Continues close monitoring of patient's physical and psychological response to surgical intervention
2. Assesses patient's pain level and administers appropriate pain relief measures
3. Provides teaching to patient during immediate recovery period
4. Assists patient in recovery and preparation for discharge home
5. Determines patient's psychological status
6. Assists with discharge planning

Home or Clinic

1. Provides follow-up care during office or clinic visit or by telephone contact
2. Reinforces previous teaching and answers patient's and family's questions about surgery and follow-up care
3. Assesses patient's response to surgery and anesthesia and their effects on body image and function
4. Determines family's perception of surgery and its outcome

TABLE 5-1 Categories of Surgery Based on Urgency

Classification	Indications for Surgery	Examples
I. Emergent—Patient requires immediate attention; disorder may be life-threatening	Without delay	Severe bleeding Bladder or intestinal obstruction Fractured skull Gunshot or stab wounds Extensive burns
II. Urgent—Patient requires prompt attention	Within 24–30 hours	Acute gallbladder infection Kidney or ureteral stones
III. Required—Patient needs to have surgery	Plan within a few weeks or months	Prostatic hyperplasia without bladder obstruction Thyroid disorders Cataracts
IV. Elective—Patient should have surgery	Failure to have surgery not catastrophic	Repair of scars Simple hernia
V. Optional—Decision rests with patient	Personal preference	Cosmetic surgery

Emergency Surgery

Emergency surgeries are unplanned and occur with little time for preparation of the patient or the perioperative team. The unpredictable nature of trauma and emergency surgery poses unique challenges to the nurse throughout the perioperative period. All of the factors that affect patients preparing to undergo surgery apply to these patients, usually in a very condensed time frame. There may be only one preoperative assessment, and it may take place at the same time as resuscitation in the emergency department. For the unconscious patient, informed consent and essential information, such as pertinent past medical history and allergies, need to be obtained from a family member, if one is available. A quick visual survey of the patient is essential to identify all sites of injury if the emergency surgery is due to trauma. The patient, who may have undergone a very frightening experience, may need extra support, including an explanation of the surgery.

Special Populations

Patients Who are Elderly

Advances in nutrition, public health, education, and social services have produced a major change in human longevity in industrialized societies, and elderly patients now account for more than one third of all hospital care days in the United States. Patients 65 years of age and older have surgery at a rate two to three times that of younger patients and tend to have longer hospital stays (Sieber & Pauldine, 2015). Although the decision to operate lies within the purview of the physician, perioperative nurses should be aware of the surgery's implications. Surgical intervention should be tailored to the patient's symptoms, overall functional and health status, and predicted benefit of the intervention. Important factors that need to be evaluated are (1) disease course versus life expectancy, (2) state of independence, (3) personal motivation, and (4) surgical risk factors versus nonoperative management (Rothrock, 2014).

Preoperative pain assessment and teaching are important in the elderly patient. The older person undergoing surgery may have a combination of chronic illnesses and health issues in addition to the specific one for which surgery is indicated. Elderly people frequently do not report symptoms, perhaps because they fear a serious illness may be diagnosed or because they accept such symptoms as part of the aging process. Subtle clues alert the nurse to underlying problems. A complete pain assessment and review of the patient's medical history will assist with identifying the risk for postoperative complications. Delirium is a common but often undiagnosed complication in the elderly following a major operation.

Health care staff must remember that the hazards of surgery for the aged are proportional to the number and severity of coexisting health problems and the nature and duration of the operative procedure. The underlying principle that guides the preoperative assessment, surgical care, and postoperative care is that the aged patient has less physiologic reserve (the ability of an organ to return to normal after a disturbance in its equilibrium) than does a younger patient. Refer to Table 5-2 for the implications of aging on operative course. The nurse plans interventions based upon the patient's medical history, clinical presentation, and knowledge of the physiologic impact of aging. For example, arthritis is common in older people and may affect mobility, making it difficult for the patient to turn from one side to the other or ambulate without discomfort. The elderly patient has less subcutaneous fat, poor skin turgor, and tissue fragility. Aging-related changes in the musculoskeletal system accentuate bony prominences and decrease range of motion. These changes, along with limitations imposed by chronic pain, make positioning one of the most important considerations for this population of surgical patients. Protective measures include adequate padding for tender areas, moving the patient slowly, and protecting bony prominences from prolonged pressure. Precautions are taken when moving an elderly person because of the fragility of skin, and a lightweight cotton blanket is an appropriate cover when an elderly patient is moved to and from the operating room (OR) because of temperature sensitivity.

TABLE 5-2 GERONTOLOGIC CONSIDERATIONS / Age-Related Changes and Impact on Operative Course

Structural or Functional Change	Impact
Increased incidence of coexisting disease	Higher risks from anesthesia and surgery than younger adult patients
Aging heart and blood vessels	Decreased ability to respond to stress
Reduced cardiac output and limited cardiac reserve	Increased vulnerability to changes in circulating volume and blood oxygen levels; in addition, excessive or rapid administration of IV solutions can cause pulmonary edema.
Decreased ability to compensate for hypoxia	Increased risk of cerebral ischemia, thrombosis, embolism, infarction, and anoxia
Decrease in the percentage of lean body tissue and a steady increase in fatty tissue (from 20 to 90 years of age).	Anesthetic agents that have an affinity for fatty tissue concentrate in body fat and the brain. The elderly patient needs fewer and smaller amounts of anesthetic agents to produce anesthesia and eliminates the anesthetic agent over a longer period of time, compared with a younger patient.
If malnourished or has low plasma protein levels (hypoalbuminemia)	With decreased plasma proteins, more of the anesthetic agent remains free or unbound, resulting in more potent action.
Reduced liver size and potential for reduced kidney function	Decreases the rate at which the liver can inactivate many anesthetic agents, and decreased kidney function slows the elimination of waste products and anesthetics
Impaired ability to increase metabolic rate and impaired thermoregulatory mechanisms	Increased susceptibility to hypothermia
Bone loss (25% in women, 12% in men)	Increased risk of musculoskeletal problems postoperatively
Loss of collagen and muscle; thinning, sagging skin	Increased risk of skin complications
Impaired vision or hearing and reduced tactile sensitivity	Increased potential for communication issues, increased risk of skin complications
Increased tooth loss and periodontal disease, increased incidence of dental devices (dentures, partial plates, crowns)	Increased risk of airway occlusion due to dental device dislodgement

In addition, many elderly people have experienced personal illnesses and possibly life-threatening illnesses of friends and family. Such experiences may result in fears about the surgery and about the future. By providing an opportunity for the patient to express these fears, the nurse enables the patient to gain some peace of mind.

Because the elderly patient may face greater risks during the perioperative period, the following factors are critical: (1) skillful preoperative assessment and treatment, (2) skillful anesthesia and surgery, and (3) meticulous and competent postoperative and postanesthesia management. In addition, the nurse should incorporate pain management information and pain communication skills when teaching the elderly patient how to obtain greater postoperative pain relief.

Patients Who are Obese

Like age, obesity increases the risk and severity of complications associated with surgery. During surgery, fatty tissues are especially susceptible to infection. In addition, obesity increases technical and mechanical problems related to surgery. Therefore, dehiscence (wound separation) and wound infections are more common. Moreover, the obese patient

may be more difficult to care for because of the added weight. The patient tends to have shallow respirations when supine, which increases the risk of hypoventilation and postoperative pulmonary complications. It has been estimated that for each 30 lb of excess weight, about 25 additional miles of blood vessels are needed, and this places increased demands on the heart. Thus, nursing management includes careful assessment of the cardiopulmonary status of obese patients and thorough wound assessments.

Patients with Disabilities

Special considerations for patients with mental or physical disabilities include the need for appropriate assistive devices, modifications in preoperative teaching, and additional assistance with and attention to positioning or transferring. Assistive devices include hearing aids, eyeglasses, braces, prostheses, and other devices. People who are hearing-impaired may need a sign interpreter or some alternative communication system perioperatively. If the patient relies on signing or speech (lip) reading, and his or her eyeglasses or contact lenses are removed or the health care staff wears surgical masks, an alternative method of communication will be needed. These needs must be identified during the preoperative evaluation and clearly communicated to the appropriate personnel. Specific strategies for accommodating the patient's needs must be identified in advance. Ensuring the security of assistive devices is important, because these devices are expensive and can be misplaced easily.

Most patients are directed to move from the stretcher to the OR table and back again. In addition to being unable to see or hear instructions, the patient with a disability may be unable to move without special devices or a great deal of assistance. The patient with a disability that affects body position (e.g., cerebral palsy, post-polio syndrome, and other neuromuscular disorders) may need special positioning during surgery to prevent pain and injury. Moreover, these patients may be unable to sense whether their extremities are positioned incorrectly.

Patients with respiratory problems related to a disability (e.g., multiple sclerosis, muscular dystrophy) may experience pulmonary difficulties unless the problems are made known to the anesthesia provider, who can make adjustments. These factors need to be identified clearly in the preoperative period and communicated to the appropriate personnel.

PREOPERATIVE NURSING

The preoperative phase begins when the decision to proceed with surgical intervention is made, and ends with the transfer of the patient onto the OR table. The nursing roles during this phase focus on assessing the patient and developing a plan of care. This process is performed utilizing diverse modalities. Telephone interviews, face-to-face assessments and computer-aided tools are used to review the physical, psychological, sociocultural, and spiritual needs of the patient. Preadmission units work collaboratively with anesthesia providers to interview and assess the patient to identify potential or actual problems that may occur. The goals of preoperative assessment are to reduce the patient's surgical and anesthetic perioperative morbidity or mortality. Medical history, laboratory values, and diagnostic tests help practitioners evaluate the patient. Preadmission nurses actively participate in pre-op education to prepare the patient and family to take an active role in their experience.

Informed Consent

The surgical experience, except in extreme emergencies, begins after a patient has consented to a recommended surgical procedure. Voluntary and written informed consent from the patient is necessary before nonemergent surgery can be performed. The Department of Health and Human Services, Centers for Medicare and Medicaid Services (CMS), believes that a patient or his or her representative (as allowed under state law) has the right to make informed decisions regarding the patient's care. The guidelines further indicate that, for the surgical patient, a properly executed informed consent form for the operation must be in the patient's chart prior to surgery, except in emergencies. The primary purpose of the informed consent process is to ensure that the patient, or the patient's representative, is provided information necessary to enable him or her to evaluate the proposed surgery before agreeing to it (Centers for Medicare and Medicaid Services, 2017; Waisel, 2015). A written consent protects the patient from unsanctioned surgery and protects the surgeon from claims of an unauthorized operation (The Joint Commission, 2016b). It is normally the responsibility of the performing surgeon to obtain the informed surgical consent, which should consist of the following four basic elements:

1. The physician documents that the patient or surrogate has decision-making capacity, which is distinct from the legal concept of competency as determined by courts. Adults are presumed to be legally competent unless declared otherwise by a court (Waisel, 2015, p. 258).
2. The surgeon discloses to the patient details regarding the diagnosis and treatment options sufficiently for the patient to make an informed choice.
3. The patient demonstrates understanding of the disclosed information.
4. The patient freely authorizes a specific treatment plan without undue influence (Waisel, 2015).

Informed consent is necessary in the following circumstances:

- Invasive procedures, such as a surgical incision, a biopsy, a cystoscopy, or paracentesis
- Procedures requiring sedation and/or anesthesia
- A nonsurgical procedure, such as an arteriography, that carries more than slight risk to the patient
- Procedures involving radiation

If the patient has doubts and has not had the opportunity to investigate alternative treatments, a second opinion may be requested. No patient should be urged or coerced to give informed consent. Refusing to undergo a surgical procedure is a person's legal right and privilege.

The consent process can be improved by providing audiovisual materials to supplement discussion, by ensuring that the wording of the consent form is understandable, and by using other strategies and resources as needed to help the patient understand its content. It is required to have the consent available in multiple languages or have a trained medical interpreter available for non–English-speaking patients. In many cases, it is required to have

alternative forms of communication (e.g., Braille, large print, sign interpreter) for the elderly and disabled.

Preoperative Health Assessment

Before any surgical treatment is initiated, a health history is obtained, a physical examination is performed during which vital signs are noted, and a database is established for future comparisons. Preoperative blood tests, x-rays, and other diagnostic tests are obtained as needed.

The goal in the preoperative period is for the patient to have as many positive health factors as possible. Many risk factors may lead to complications (Box 5-2). Every attempt is made to stabilize those conditions that otherwise hinder recovery.

Nutritional and Fluid Status

Optimal nutrition is an essential factor in promoting healing and resisting infection and other surgical complications. Assessment of a patient's nutritional status identifies factors that can affect the patient's surgical course, such as obesity, under nutrition, weight loss, malnutrition, deficiencies in specific nutrients, metabolic abnormalities, and the effects of medications on nutrition. Nutritional needs may be determined by measurement of body mass index (BMI) and waist circumference (U.S. Department of Health and Human Services, 2015). A BMI of 18.5 to 24.9 is normal; less than 18.5 is underweight, greater than 25 is overweight, greater than 30 is obese, and 40 and greater is extreme obesity. A waist circumference measurement of greater than 40 in in men and 35 in in women is associated with increased cardiac risk.

If possible, any nutritional deficiency, such as malnutrition, should be corrected before surgery to provide adequate protein for tissue repair. The nutrients needed for wound healing are summarized in Table 5-3. Dehydration, hypovolemia, and electrolyte imbalances can also lead to significant problems in patients with comorbid medical conditions or in patients who are elderly. The severity of fluid and electrolyte imbalances is often difficult to determine. Mild volume deficits may be treated during surgery; however, additional time may be needed to correct pronounced fluid and electrolyte deficits to promote the best possible preoperative condition.

BOX 5-2 Risk Factors for Surgical Complications

- Hypovolemia
- Dehydration or electrolyte imbalance
- Nutritional deficits
- Extremes of age (very young, very old)
- Extremes of weight (emaciation, obesity)
- Infection and sepsis
- Toxic conditions
- Immunologic abnormalities
- Pregnancy (because of diminished maternal physiologic reserve)
- Cerebrovascular disease
- Pulmonary disease:

    - Obstructive disease
    - Restrictive disorder
    - Respiratory infection
- Renal or urinary tract disease:
    - Decreased renal function
    - Urinary tract infection
    - Obstruction
- Cardiovascular disease:
    - Coronary artery disease or previous myocardial infarction
    - Cardiac failure
    - Arrhythmias
    - Hypertension
    - Prosthetic heart valve
    - Thromboembolism
    - Hemorrhagic disorders
- Endocrine dysfunction:
    - Diabetes mellitus
    - Adrenal disorders
    - Thyroid malfunction
- Hepatic disease:
    - Cirrhosis
    - Hepatitis
    - Pre-existing mental or physical disability

Drug or Alcohol Use

People who abuse drugs or alcohol frequently deny or attempt to hide it. In such situations, the nurse who is obtaining the patient's health history needs to ask frank questions with patience, care, and a nonjudgmental attitude. Because acutely intoxicated people are at higher risk for potential injury, surgery is postponed if possible. If emergency surgery is required, local, spinal, or regional block anesthesia is used for minor surgery. Otherwise, to prevent vomiting and potential aspiration, a nasogastric tube is inserted before general anesthesia is administered.

TABLE 5-3 Nutrients Important for Wound Healing

Nutrient	Rationale for Increased Need
Protein	To allow collagen deposition and wound healing to occur; clotting factor production; white blood cell (WBC) production and migration; cell-mediated phagocytosis; fibroblast proliferation; granulation tissue formation, neovascularization
Arginine (amino acid)	To provide necessary substrate for collagen synthesis and nitric oxide (crucial for wound healing) at wound site To increase wound strength and collagen deposition To stimulate T-cell response To support a variety of essential reactions of intermediary metabolism
Carbohydrates and fats	To be a primary source of energy in the body and, consequently, in the wound-healing process To meet the demand for increased essential fatty acids needed for cellular function after an injury To spare protein Fibroblast proliferation is sensitive to glucose deficiencies.
Water	To maintain homeostasis
Vitamin C	To support capillary formation, tissue synthesis, and wound healing through collagen formation To allow for antibody formation, WBC production; deficiency is associated with abnormal scar tissue formation
Vitamin B complex	To influence host resistance, indirectly supporting wound healing
Vitamin E	An antioxidant responsible for normal fat metabolism and collagen synthesis
Vitamin A	Increases inflammatory response in wounds, reduces anti-inflammatory effects of corticosteroids on wound healing; is essential for epidermal proliferation, reepithelialization, and epithelium maintenance
Vitamin K	Important for normal blood clotting To help avoid impaired intestinal synthesis associated with the use of antibiotics
Magnesium	Essential cofactor for many enzymes that are involved in the process of protein synthesis and wound repair
Copper	Responsible for collagen cross-linking and erythropoiesis
Zinc	A cofactor for collagen formation, also metabolizes protein, liberates vitamin A from storage in the liver, interacts with platelets in blood clotting, and assists in immune function

The person with a history of chronic alcoholism often suffers from malnutrition and other systemic problems that increase surgical risk. Alcohol withdrawal syndrome or delirium tremens (DTs) may be anticipated between 48 and 72 hours after alcohol withdrawal and is associated with a significant mortality rate when it occurs postoperatively.

Nursing Alert

The nurse is aware that DTs usually appear within 72 hours of withdrawal and is often preceded by tremulousness, anxiety, and insomnia; progressing to tachycardia, diaphoresis, anorexia, agitation, headache, and gastrointestinal distress. Late symptoms include visual hallucinations, delirium or seizures (Ferri, 2016). Many institutions use the Clinical Institute Withdrawal Assessment-Alcohol (CIWA-A) scale to measure the severity of alcohol withdrawal. The CIWA-A scale consists of 10 symptoms, and treatment is either a fixed-dose regimen or individualized benzodiazepine administration dose.

Respiratory Status

The goal for surgical patients is optimal respiratory function. Because adequate ventilation is potentially compromised during all phases of surgical treatment, surgery is usually postponed if the patient has a respiratory infection. Patients with underlying respiratory disease (e.g., asthma, chronic obstructive pulmonary disease [COPD]) are assessed carefully

for current threats to their pulmonary status. Patients should be evaluated for conditions such as respiratory infection and neuromuscular diseases, such as Parkinson disease, which may affect respiratory function.

The use of tobacco is an important risk factor but one that usually cannot be influenced. Even among smokers who have not developed chronic lung disease, smoking is associated with significant changes in lung function. While cessation for 2 days prior to surgery is recommended, a prospective study by Warner, Divertie, & Tinker (1984) revealed that smoking cessation for up to 8 weeks was necessary to reduce the rate of postoperative pulmonary complications. However, the ideal duration of cessation of smoking before surgery remains unclear. What it known is that, within 12 hours of quitting smoking, the patient would experience a decrease in carbon monoxide levels; improved oxygen delivery; lower nicotine levels, which improves vasodilatation; and a decrease in toxic substances that impair wound healing (Stoelting, Hines, & Marschall, 2012).

Cardiovascular Status

The goal in preparing any patient for surgery is to ensure a well-functioning cardiovascular system to meet the oxygen, fluid, and nutritional needs of the perioperative period. If the patient has uncontrolled hypertension, surgery may be postponed until the blood pressure is stabilized. At times, surgical treatment can be modified to meet the cardiac tolerance of the patient. For example, in a patient with obstruction of the descending colon and coronary artery disease, a temporary simple colostomy may be performed rather than a more extensive colon resection that would require a prolonged period of anesthesia.

Hepatic and Kidney Function

The presurgical goal is optimal function of the liver and urinary systems, so that medications, anesthetic agents, body wastes, and toxins are adequately processed and removed from the body.

The liver is important in the biotransformation of anesthetic compounds. Therefore, any disorder of the liver has an effect on how anesthetic agents are metabolized. The limited ability of a failing liver increases the perioperative risks and presents significant challenges. Increased morbidity and mortality is associated with varying degrees of liver insufficiency; thus, it is important to quantify and grade preoperative liver dysfunction using various serum liver function tests (Kaufman & Roccaforte, 2013). Because the kidneys are involved in excreting anesthetic medications and their metabolites, and because acid–base status and metabolism are also important considerations in anesthesia administration, surgery is contraindicated if a patient has acute nephritis, acute kidney injury with oliguria or anuria, or other acute kidney problems. The exception is surgery that is performed as a life-saving measure or that is necessary to improve urinary function, as in the case of an obstructive uropathy.

Endocrine Function

Diabetes is the most common endocrinopathy and has both acute and chronic disease manifestations. Because of this and other factors, patients with diabetes are more likely to require surgery. The majority of patients with diabetes develop disease in more than one

body system, thus a thorough assessment of major organ disease (cardiac, renal, peripheral vascular) must be identified and managed carefully during the perioperative period. The patient with diabetes who is undergoing surgery is at risk for hypoglycemia and hyperglycemia. Hypoglycemia may develop during anesthesia or postoperatively from inadequate carbohydrates or excessive administration of insulin. Hyperglycemia, which can increase the risk for surgical wound infection, and fluid and electrolyte loss, may result from the stress of surgery because it triggers increased release of catecholamines. An increase in catecholamines contributes to an elevation in the blood glucose level. Previously, blood sugar was tightly controlled with intensive insulin therapy—this practice is no longer recommended routinely. Surgical patients with type 1 diabetes are also at risk for developing ketoacidosis. Refer to Chapter 30 for details on management of patients with diabetes.

Patients who have received corticosteroids are at risk of adrenal insufficiency. Therefore, the use of corticosteroids for any purpose during the preceding year must be reported to the anesthesia provider and surgeon. The patient is monitored for signs of adrenal insufficiency, which frequently presents with hyponatremia, hypoglycemia, hyperkalemia, and complaints of weakness and fatigue.

Patients with uncontrolled thyroid disorders are at risk for thyrotoxicosis (with hyperthyroid disorders) or respiratory failure (with hypothyroid disorders). Therefore, the patient is assessed for a history of these disorders. Refer to Chapter 31 for further discussion of endocrine disorders.

Immune Function

The nurse determines the presence of allergies. It is especially important to identify and document any sensitivity to medications and past adverse reactions to these agents. The nurse asks the patient to identify any substances that precipitated previous allergic reactions, including medications, herbal supplements, blood transfusions, contrast agents, latex, and food products, and to describe the signs and symptoms produced by these substances. A sample latex allergy screening questionnaire is shown in Figure 5-1.

Immunosuppression is common with corticosteroid therapy, kidney transplantation, radiation therapy, chemotherapy, and disorders affecting the immune system, such as AIDS and leukemia. The mildest symptoms or slightest temperature elevation must be investigated. Because patients who are immunosuppressed are highly susceptible to infection, the health care team should take great care to ensure strict asepsis.

Medication Use

A medication history is obtained from each patient because of the possible effects of medications on the patient's perioperative course, including the possibility of drug interactions. Any medication the patient is using or has used in the past is documented, including the frequency with which the medication is used. Potent medications have an effect on physiologic functions; interactions of such medications with anesthetic agents can cause serious problems, such as arterial hypotension and circulatory collapse.

The potential effects of prior medication therapy are evaluated by the anesthesia provider, who considers the length of time the patient has used the medication, the physical condition of the patient, and the nature of the proposed surgery. Medications that cause

particular concern are listed in Table 5-4.

Ask the patient the following questions. Check "Yes" or "No" in the box.	YES	NO
1. Has a doctor ever told you that you are allergic to latex?		
2. Do you have on-the-job exposure to latex?		
3. Were you born with problems involving your spinal cord?		
4. Have you ever had allergies, asthma, hay fever, eczema, or problems with rashes?		
5. Have you ever had respiratory distress, rapid heart rate, or swelling?		
6. Have you ever had swelling, itching, hives, or other symptoms after contact with a balloon?		
7. Have you ever had swelling, itching, hives, or other symptoms after a dental examination or procedure?		
8. Have you ever had swelling, itching, hives, or other symptoms following a vaginal or rectal examination or after contact with a diaphragm or condom?		
9. Have you ever had swelling, itching, hives, or other symptoms during or within 1 hour after wearing rubber gloves?		
10. Have you ever had a rash on your hands that lasted longer than 1 week?		
11. Have you ever had swelling, itching, hives, runny nose, eye irritation, wheezing, or asthma after contact with any latex or rubber product?		
12. Have you ever had swelling, itching, hives, or other symptoms after being examined by someone wearing rubber or latex gloves?		
13. Are you allergic to bananas, avocados, kiwi, or chestnuts?		
14. Have you ever had an unexplained anaphylactic episode?

In addition, many patients take self-prescribed or over-the-counter (OTC) medications. Aspirin is a common OTC medication that inhibits platelet aggregation; therefore, it is prudent to stop aspirin at least 7 to 10 days before surgery if possible, especially for surgeries in which excess bleeding would cause significant complications, such as brain or spinal cord surgeries. Because of the effects of aspirin or other OTC medications and possible interactions with prescribed medications and anesthetic agents, it is important to ask a patient about their use. The information is noted in the patient's chart and conveyed to the anesthesia provider and surgeon.

The use of herbal medications is widespread among patients; because of their potential effects on coagulation and potentially lethal interactions with other medications, the nurse must ask surgical patients specifically about the use of these agents, document their use, and inform the surgical team and anesthesia provider. Decisions should be made by the surgical team about the discontinuation of herbal medications prior to surgery. Currently, there are no studies demonstrating specific adverse interactions between herbals and anesthetic drugs; however, some have been implicated to be related to pharmacokinetic and pharmacodynamic interactions (Wijeysundera & Sweitzer, 2015).

Psychosocial Factors

All patients have some type of emotional reaction before any surgical procedure, be it obvious or hidden, normal or abnormal. For example, preoperative anxiety may be an anticipatory response to an experience the patient views as a threat to his or her customary role in life, body integrity, or life itself. Psychological distress directly influences body functioning. In addition to providing anticipatory guidance about what the patient will experience during the operative procedure, the nurse provides opportunities for the patient to ask questions, so that concerns can be addressed.

Most patients who are about to undergo surgery have fears, including fear of the unknown, of death, of anesthesia, of pain, or of cancer. Concerns about loss of work time, loss of job, increased responsibilities or burden on family members, and the threat of permanent incapacity further contribute to the emotional strain created by the prospect of surgery. Less obvious concerns may occur because of previous experiences with the health care system and people the patient has known with the same condition.

People express fear in different ways. For example, some patients may repeatedly ask many questions, even though answers were given previously. Others may withdraw, deliberately avoiding communication, perhaps by reading, watching television, or talking about trivialities. Assessing the patient's readiness to learn and determining the best approach to maximize comprehension provides the basis for preoperative patient education. Consequently, the nurse must be empathetic, listen well, and provide information that helps alleviate concerns.

An important outcome of the psychosocial assessment is the determination of the extent and role of the patient's support network. The value and reliability of all available support systems are assessed. Other information, such as usual level of functioning and typical daily activities, may assist in the patient's care and rehabilitation plans.

Spiritual and Cultural Beliefs

Spiritual beliefs play an important role in how people cope with fear and anxiety. Regardless of the patient's religious affiliation, spiritual beliefs can be as therapeutic as medication. Every attempt must be made to help the patient obtain the spiritual support that he or she requests. Faith has great sustaining power. Therefore, the beliefs of each patient should be respected and supported. In addition, the nurse needs to communicate and document if the patient declines blood transfusions for religious reasons (Jehovah's Witnesses), as this information needs to be clearly identified in the preoperative period. Some nurses avoid the subject of a clergy visit lest the suggestion alarm the patient. Asking whether the patient's spiritual advisor knows about the impending surgery is a caring, nonthreatening approach.

TABLE 5-4 Examples of Medications with the Potential to Affect the Surgical Experience

Agent (Generic and Trade Example)	Effect of Interaction with Anesthetics
Corticosteroids Prednisone (Deltasone)	Cardiovascular collapse can occur if discontinued suddenly. Therefore, a bolus of corticosteroid may be administered intravenously immediately before and after surgery.
Diuretics Hydrochlorothiazide (HydroDIURIL)	During anesthesia, may cause excessive respiratory depression resulting from an associated electrolyte imbalance
Phenothiazines Chlorpromazine (Thorazine)	May increase the hypotensive action of anesthetics
Tranquilizers Diazepam (Valium)	May cause anxiety, tension, and even seizures if withdrawn suddenly
Insulin	Interaction between anesthetics and insulin must be considered when a patient with diabetes is undergoing surgery. IV insulin may need to be administered to keep the blood glucose within the normal range.
Antibiotics Erythromycin (Ery-Tab)	When combined with a curariform muscle relaxant, nerve transmission is interrupted and apnea from respiratory paralysis may result.
Anticoagulants Warfarin (Coumadin)	Can increase the risk of bleeding during the intraoperative and postoperative periods; should be discontinued in anticipation of elective surgery. The surgeon will determine how long before the elective surgery the patient should stop taking an anticoagulant, depending on the type of planned procedure and the medical condition of the patient.
Antiseizure Medications	IV administration of medication may be needed to keep the patient seizure-free in the intraoperative and postoperative periods.
Monoamine Oxidase (MAO) Inhibitors Phenelzine sulfate (Nardil)	May increase the hypotensive action of anesthetics
Thyroid Hormone Levothyroxine sodium (Levothroid)	IV administration may be needed during the postoperative period to maintain thyroid levels.

Showing respect for a patient's cultural values and beliefs facilitates rapport and trust. Some areas of assessment include identifying the ethnic group to which the patient relates and the customs and beliefs the patient holds about illness and health care providers. For example, patients from some cultural groups are unaccustomed to expressing feelings openly. Nurses need to consider this pattern of communication when assessing pain. Nurses should familiarize themselves with these cultural similarities and differences (see Box

1-3 in Chapter 1) and, recently, the Joint Commission has developed standards of cultural competency for health care workers (The Joint Commission, 2016a).

Perhaps the most valuable skill at the nurse's disposal is listening carefully to the patient, especially when obtaining the history. Invaluable information and insights may be gained through effective communication and interviewing skills. An unhurried, understanding, and caring nurse promotes confidence on the part of the patient.

Presence of Genetic Disorders

In the preoperative period, attention needs to be paid to patients with various genetic disorders (listed below) since surgical outcomes may be altered related to complications with anesthesia.

- Malignant hyperthermia (MH) (discussed on page 130)
- Central core disease (CCD), is a genetic disorder that presents in the neonatal period or infancy with muscle weakness and hypotonia and mild facial weakness. This condition increases the risk of developing MH.
- Duchenne muscular dystrophy and Becker dystrophy are two types of muscular dystrophies associated with risk of developing MH.
- Hyperkalemic periodic paralysis is a genetic disorder that causes episodes of extreme muscle weakness and occasionally hyperkalemia. It is also associated with MH.
- King–Denborough syndrome, a rare genetic disorder associated with musculoskeletal abnormalities, is associated with MH.

Preoperative Nursing Management

Providing Preoperative Teaching

Preoperative education is important for improved patient outcomes. Each patient is taught as an individual, with consideration for any unique concerns or learning needs. Preoperative teaching is initiated as soon as possible, includes different modalities (verbal, written, electronic, return demonstration), and should be tailored to the needs of the patient. It should start in the surgeon's office or at the time of Pre-Admission Testing (PAT), continue until the patient arrives in the OR, and extend to and through discharge.

Timing and Technique

It is best to begin teaching early, when the patient and family may be less anxious and can make adjustments or prepare for the postoperative period more effectively. The ideal timing for preoperative teaching is not on the day of surgery but during the preadmission visit, when diagnostic tests are performed. At this time, the nurse or resource person answers questions and provides important patient teaching. During this visit, the patient can meet and ask questions of the perioperative nurse and health care team members, view audiovisual resources, receive written materials, and be given the telephone number to call as questions arise closer to the date of surgery. Many institutions provide access to websites where patients can view and review written instructions, communicate electronically, and ask questions with caregivers.

Teaching should go beyond descriptions of the procedure and should include explanations of the sensations the patient will experience. For example, telling the patient only that preoperative medication will cause relaxation before the operation is not as effective as also noting that the medication may result in lightheadedness and drowsiness. Knowing what to expect will help the patient anticipate these reactions and, thus, attain a higher degree of relaxation than might otherwise be expected. Knowing ahead of time about the possible need for a ventilator, drainage tubes, or other types of equipment helps decrease anxiety in the postoperative period. In addition, preoperative teaching includes instruction in the breathing and leg exercises used to prevent postoperative complications such as pneumonia and deep vein thrombosis (DVT). These exercises may be performed in the hospital or at home. The nurse should guide the patient through the experience and allow ample time for questions. For some patients, overly detailed descriptions increase anxiety; the nurse should be sensitive to this and provide as much detail as necessary to ensure patient preparation.

Deep Breathing, Coughing, and Incentive Spirometry 

One goal of preoperative nursing care is to teach the patient how to promote optimal lung expansion and consequent blood oxygenation after anesthesia. The patient assumes a sitting position to enhance lung expansion. The nurse then demonstrates how to take a deep, slow breath and how to exhale slowly (see Box 11-7 in Chapter 11). After practicing deep breathing several times, the patient is instructed to breathe deeply, exhale through the

mouth, take a short breath, and cough deeply (see Box 5-3). The nurse also demonstrates how to use an incentive spirometer, a device that provides measurement and feedback related to breathing effectiveness. In addition to enhancing respiration, these exercises may help the patient relax.

If a thoracic or abdominal incision is anticipated, the nurse demonstrates how to splint the incision to minimize pressure and control pain. The patient should put the palms of both hands together, interlacing the fingers snugly. Placing the hands across the incisional site acts as an effective splint when coughing. In addition, the patient is informed that medications are available to relieve pain and should be taken regularly for pain relief, so that effective deep breathing and coughing exercises can be performed. The goal in promoting coughing is to mobilize secretions, so that they can be removed. Deep breathing before coughing stimulates the cough reflex. If the patient does not cough effectively, atelectasis (collapse of the alveoli), pneumonia, or other lung complications may occur.

Promoting Mobility

The goals of promoting mobility postoperatively are to improve circulation, prevent venous stasis, and promote optimal respiratory function. The nurse explains the rationale for frequent position changes after surgery and then shows the patient how to turn from side to side and how to assume the lateral position without causing pain or disrupting IV lines, drainage tubes, or other equipment. The nurse uses proper body mechanics when turning the patient and instructs the patient to do the same. Whenever the patient is positioned, his or her body needs to be properly aligned.

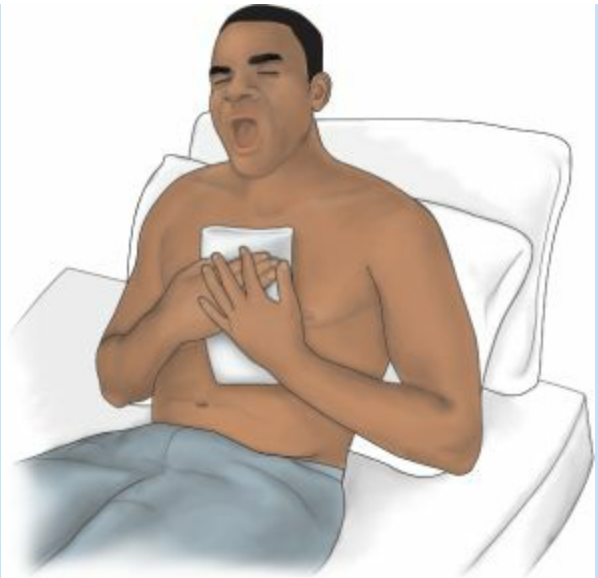
In addition, some patients require instruction about special positions that are required after surgery (e.g., abduction or elevation of an extremity). The importance of maintaining as much mobility as possible despite restrictions is discussed. Reviewing the process before surgery is helpful, because the patient may be too uncomfortable or drowsy after surgery to absorb new information.

BOX 5-3 Patient Education

Preoperative Instructions to Prevent Postoperative Complications

Coughing

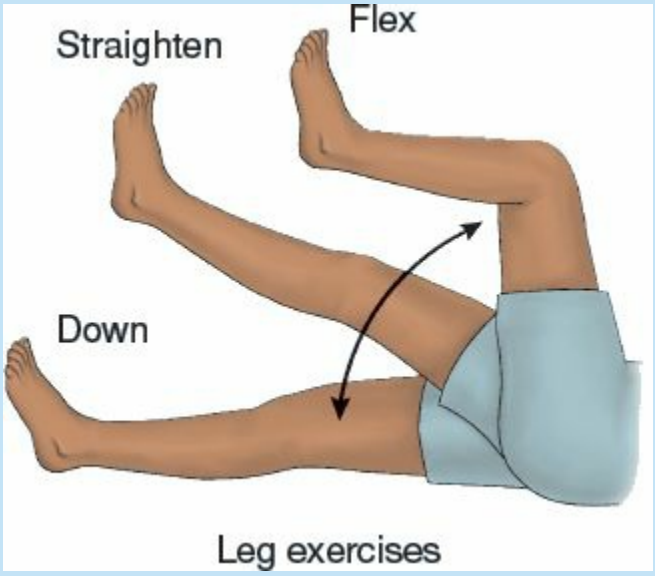
1. Lean forward slightly from a sitting position in bed, interlace your fingers together, and place your hands across the incisional site to act as a splint-like support when coughing.



Splinting of chest when coughing

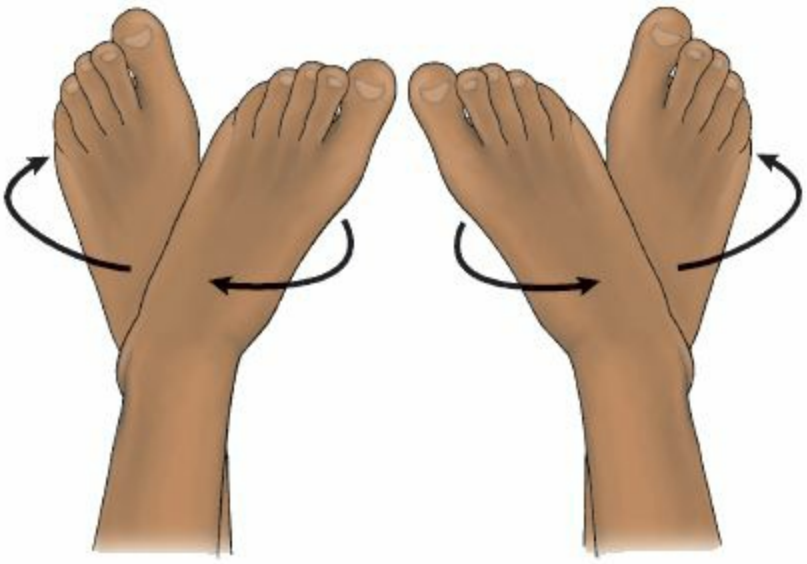
Leg Exercises

1. Lie in a semi-Fowler position and perform the following simple exercises to improve circulation.
2. Bend your knee and raise your foot—hold it a few seconds, then extend the leg and lower it to the bed.



Leg exercises

3. Do this five times with one leg, and then repeat with the other leg.
4. Then trace circles with the feet by bending them down, in toward each other, up, and then out.
5. Repeat these movements five times.



Foot exercises

Turning to the Side

1. Turn on your side with the uppermost leg flexed most and supported on a pillow.
2. Grasp the side rail as an aid to maneuver to the side.
3. Practice coughing while on your side.

Getting Out of Bed

1. Turn on your side.
2. Push yourself up with one hand as you swing your legs out of bed.

Exercise of the extremities includes extension and flexion of the knee and hip joints (similar to bicycle riding while lying on the side). The foot is rotated as though tracing the largest possible circle with the great toe (see Box 5-3). The elbow and shoulder are also put through their range of motion. At first, the patient is assisted and reminded to perform these exercises. Later, the patient is encouraged to do them independently. Muscle tone is maintained so that ambulation will be easier.

Pain Management

The nurse is guided by the recommendations of the Joint Commission that the "hospital uses methods to assess pain that are consistent with the patient's age, conditions, and ability to understand" (www.jc.org, 2015). A pain assessment should include differentiation between acute and chronic pain. A pain intensity scale should be introduced and explained to the patient to promote more effective postoperative pain management.

Once a patient answers yes to whether he or she has pain, the nurse should perform a comprehensive pain assessment and select an appropriate pain assessment scale (see Chapter 7).

Patients are informed that medications will be administered to relieve pain and maintain

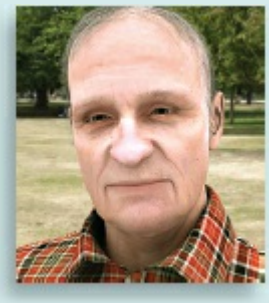
comfort without compromising the cardiopulmonary and neurologic status. Anticipated methods of administration of analgesic agents for inpatients include patient-controlled analgesia (PCA), epidural catheter bolus or infusion, peripheral nerve blockades, or patient-controlled epidural analgesia (PCEA). A patient who is expected to go home likely will receive local anesthetic and oral analgesic agents. These methods are discussed with the patient before surgery, and the patient's interest and willingness to use them are assessed.

Instruction for Patients Undergoing Ambulatory Surgery

Preoperative education for the same-day or ambulatory surgical patient comprises all the material presented above as well as collaborative planning with the patient and family for discharge and follow-up home care. The major difference in outpatient preoperative education is the teaching environment.

Preoperative teaching content may be presented in a group class, on a videotape, at PAT, or by telephone in conjunction with the preoperative interview. In addition to answering questions and describing what to expect, the nurse tells the patient when and where to report, what to bring (insurance card, copayment, and list of medications and allergies), what to leave at home (jewelry, watch, medications, contact lenses), and what to wear (loose-fitting, comfortable clothes; flat shoes). During the final preoperative telephone call, teaching is completed or reinforced as needed, and last-minute instructions are given. The patient is reminded not to eat or drink as directed.

Unfolding Patient Stories: Vernon Watkins • Part 1



Vernon Watkins, a 69-year-old male, came to the emergency department with severe abdominal pain, and a bowel perforation was diagnosed. He is being prepared for surgery. Significant medical history includes controlled hypertension and smoking for 50 years. What preoperative education should the nurse discuss with Mr. Watkins prior to his emergent surgery? (Vernon Watkins' story continues in Chapter 49.)

Care for Vernon and other patients in a realistic virtual environment: vSim for Nursing for (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in (thepoint.lww.com/DocuCareEHR).

Managing Nutrition and Fluids

The major purpose of withholding food and fluid before surgery is to prevent aspiration. Until recently, fluid and food were restricted preoperatively overnight and often longer.

However, the American Society of Anesthesiologists (ASA) reviewed this practice and has made new recommendations for people undergoing elective surgery who are otherwise healthy.

The American Society of Anesthesiologists published practice guidelines pertaining to preoperative fasting in nonlaboring individuals undergoing elective procedures. The recommended fasting period after consuming clear fluids for all patients is 2 hours. In general, the volume of liquid ingested is less important than the type of liquid ingested (e.g., clear liquids vs. milk products) (Wijeysundera & Sweitzer, 2015, p. 1147).

Preparing the Bowel

Enemas are not commonly prescribed preoperatively unless the patient is undergoing abdominal or pelvic surgery. In this case, a cleansing enema or laxative may be prescribed the evening before surgery and may be repeated the morning of surgery. The goals of this preparation are to allow satisfactory visualization of the surgical site and to prevent trauma to the intestine or contamination of the peritoneum by feces. Unless the condition of the patient presents some contraindication, the toilet or bedside commode, rather than the bedpan, is used for evacuating the enema if the patient is hospitalized during this time. In addition, antibiotics may be prescribed to reduce intestinal flora.

Preparing the Skin

The goal of preoperative skin preparation is to decrease bacteria without injuring the skin. If the surgery is not performed as an emergency, the patient may be instructed to use a soap containing a detergent-germicide to cleanse the skin area for several days before surgery to reduce the number of skin organisms; this preparation may be carried out at home.

In general, hair is not removed preoperatively unless the hair at or around the incision site is likely to interfere with the operation. If hair must be removed, electric clippers are used for safe hair removal immediately before the operation.

Providing Immediate Preoperative Care

The patient changes into a hospital gown that is tied loosely and opens in the back. The patient with long hair may braid it, remove hairpins, and cover the head completely with a disposable bouffant cap.

The mouth is inspected, and dentures or plates are removed. If left in the mouth, these items could easily fall to the back of the throat during induction of anesthesia and cause respiratory obstruction.

Jewelry is not worn to the OR; wedding rings and jewelry of body piercings should be removed to prevent injury (The Association of PeriOperative Registered Nurses [AORN], 2015). If a patient objects to removing a ring, some institutions allow the ring to be securely fastened to the finger with tape. All articles of value, including assistive devices, dentures, glasses, and prosthetic devices, are given to family members or are labeled clearly with the patient's name and stored in a safe and secure place according to the institution's policy.

All patients (except those with urologic disorders) should void immediately before going to the OR to promote continence during low abdominal surgery and to make abdominal

organs more accessible. Urinary catheterization is performed in the OR as necessary.

Maintaining the Preoperative Record

Since the release of the World Health Organization's Surgical Safety Checklist in 2008, surgical safety checklists have been used to foster an environment of teamwork and communication while ensuring that staff members consistently adhere to safety standards (Fig. 5-2). The nurse completes the preoperative assessment and plan of care, as well as the portion of the universal protocol/safety checklist that focuses on patient identification, correct documents, and patient understanding of the surgical procedure. The surgical site should be marked by the surgeon during this phase if the surgery involves laterality, and the marking is documented by the admitting nurse. The completed chart (with the preoperative checklist and verification form) accompanies the patient to the OR with the most recent history and physical (within the past 30 days), anesthetic assessment, and surgical consent form attached, along with all laboratory reports and nurses' records per hospital policy. Any unusual last-minute observations that may have a bearing on anesthesia or surgery are noted prominently at the front of the chart. Many institutions document these preoperative requirements electronically. To support this process, institutions are required to ensure that a standard hand-off process is in place to communicate critical and pertinent information to the next caregiver.

Administering Preanesthetic Medication

The rare use of preanesthetic medication is a minimal dose with ambulatory or outpatient surgery. If prescribed, it is usually administered in the preoperative holding area. If a preanesthetic medication is administered, the patient is kept in bed with the side rails raised, because the medication can cause lightheadedness or drowsiness. During this time, the nurse observes the patient for any untoward reaction to the medications. The immediate surroundings are kept quiet to promote relaxation.

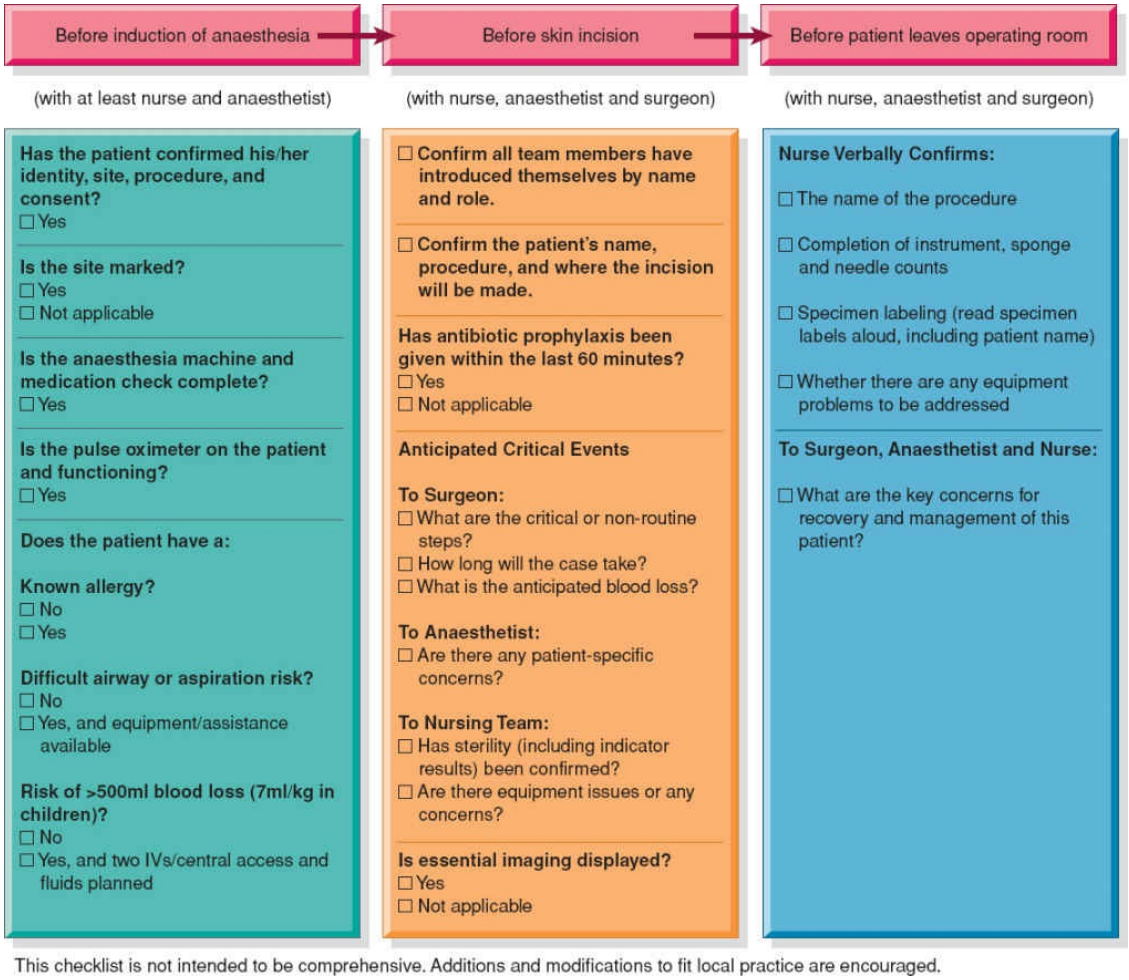


FIGURE 5-2 Surgical safety checklist. Based on the WHO Surgical Safety Checklist, http://whqlibdoc.who.int/publications/2009/9789241598590_eng_Checklist.pdf. (© World Health Organization (WHO), 2008. All rights reserved.)

Nursing Alert

Protecting patients from injury is one of the major roles of the perioperative nurse. Specific nursing interventions to decrease the risk of falling after the premedication is administered are to raise the side rails of the bed, provide the call light if available, and remind the patient that out of bed (OOB) activity is not permitted due to potential medication side effects such as dizziness.

Transporting the Patient to the Presurgical Area

Patient safety in the preoperative area is a priority. Use of a process to verify patient identification, the surgical procedure, and the surgical site is imperative to maximize patient safety. This process should be performed at the time of admission in the presurgical unit and during all hand-offs from caregiver to caregiver. This allows for prompt intervention if any discrepancies are identified.

Attending to Family Needs

Most hospitals and ASCs have a waiting room where family members and significant others can wait while the patient is undergoing surgery. This room may be equipped with

comfortable chairs, television, telephones, and facilities for light refreshment. Volunteers may remain with the family, offer them coffee, and keep them informed of the patient's progress. After surgery, the surgeon should meet the family in the waiting room or call the family and discuss the outcome.

The family and significant others should never judge the seriousness of an operation by the length of time the patient is in the OR. A patient may be in surgery much longer than the actual operating time for several reasons:

- Patients are routinely transported well in advance of the actual operating time.
- The anesthesia provider often makes additional preparations that may take 30 to 60 minutes.
- Patient positioning may take up to 45 minutes prior to procedure start time.
- The surgeon may take longer than expected with the preceding case, which delays the start of the next surgical procedure.

After surgery, the patient is taken to the PACU to ensure safe emergence from anesthesia. Family members and significant others waiting to see the patient after surgery should be informed that the patient may have certain equipment or devices (e.g., IV lines, indwelling urinary catheter, nasogastric tube, oxygen lines, monitoring equipment, blood transfusion lines) in place when he or she returns from surgery. Many hospitals now adopt the model of patient- and family-centered care and allow visitations in the PACU for short periods after the patient is stabilized and made comfortable. In ambulatory surgery and pediatric settings, family members are brought in early in the recovery process and are integral to the preparation for discharge. When the patient returns to the room, the nurse provides explanations regarding the frequent postoperative observations that will be made. However, it is the responsibility of the surgeon, not the nurse, to relay the surgical findings and the prognosis, even when the findings are favorable.

INTRAOPERATIVE NURSING

The intraoperative phase begins when the patient is transferred onto the OR table and ends with admission to the PACU. In this phase, the scope of nursing activities includes:

- providing for the patient's safety
- maintaining an aseptic environment
- ensuring proper function of equipment
- providing the surgeon with specific instruments and supplies for the surgical field
- completing appropriate documentation
- providing emotional support during induction of general anesthesia
- assisting in positioning the patient on the OR table using appropriate principles of body alignment
- acting as scrub nurse, circulating nurse, or registered nurse first assistant (RNFA)

The intraoperative experience has undergone many changes that make it safer and less disturbing to patients. However, even with these advances, anesthesia and surgery place the patient at risk for several complications or adverse events. Consciousness or full awareness, mobility, protective biologic functions, and personal control are totally or partially relinquished by the patient when entering the OR. Staff from the departments of anesthesia, nursing, and surgery work collaboratively to implement professional standards of care, to control iatrogenic (adverse condition in a patient resulting from treatment) and individual risks, to prevent complications, and to promote high-quality patient outcomes.

The Surgical Team

The surgical team includes the circulating nurse (also known as the circulator), scrub person (scrub role), RNFA, surgeon, and anesthesia providers. Table 5-5 summarizes the roles of each member. Every member of the surgical team verifies the patient's name, procedure, and surgical site using objective documentation and data before beginning the surgery, as mandated by the Joint Commission. This is referred to as the "time out" or final pause and must be performed prior to incision, preferably with the patient involved; if patient's surgical site was marked, the mark should be visible.

TABLE 5-5 The Surgical Team

Team Member	Responsibilities
Circulating Nurse (Circulator)	Using the nursing process to develop individualized plans of care Checking and managing the OR conditions (ensuring cleanliness, proper temperature, humidity, lighting, safe function of equipment, and the availability of supplies and materials) Continually assessing the patient for signs of injury and implementing appropriate interventions Verifying consent and ensuring documentation is correct Coordinating the team Monitoring aseptic practices to avoid breaks in technique while coordinating the movement of related personnel (medical, x-ray, and laboratory) Implementing fire safety precautions and accounting for all surgical counts in collaboration with scrub person Ensuring that the second verification of the surgical procedure and site takes place and is documented Managing specimens
Scrub person	Performing a surgical hand scrub Setting up the sterile tables Preparing sutures, ligatures, and special equipment (e.g., laparoscope) Anticipating the instruments and supplies that will be required, such as sponges, drains, and other equipment As the surgical incision is closed, counting all needles, sponges, and instruments with the nurse to be sure they are accounted for and not retained as a foreign body within the patient's body
Registered nurse first assistant (RNFA)	Handling tissue Providing exposure at the operative field Suturing Maintaining hemostasis
Surgeon (he or she is a licensed physician, osteopath, oral surgeon, or podiatrist who is specially trained and qualified)	Performing the surgical procedure Heading the surgical team
Anesthesia Provider—Anesthesiologist (a physician specifically trained in the art and science of anesthesiology) and anesthetist (a qualified health care professional who administers anesthetics; most are certified registered nurse anesthetists [CRNAs])	Assessing the patient before surgery Selecting the anesthesia and administering it Intubating the patient if necessary Managing any technical problems related to the administration of the anesthetic agent Supervising the patient's condition throughout the surgical procedure

The Surgical Environment

The surgical environment is known for its stark appearance and cool temperature. The surgical suite is behind double doors, and access is limited to authorized personnel. To provide the best possible conditions for surgery, the OR is situated in a location that is central to all supporting services (e.g., pathology, x-ray, laboratory). The OR has special air filtration devices to screen out contaminating particles, dust, and pollutants.

Maintaining the Environment

Most of the Joint Commission's 2015 National Patient Safety Goals pertain to the perioperative areas (see Box 5-4). External precautions include adhering to principles of surgical asepsis, and strict control of the OR environment is required, including traffic pattern restrictions. Policies governing this environment address such issues as the health of the staff; the cleanliness of the rooms; the sterility of equipment and surfaces; processes for scrubbing, gowning, and gloving; and OR attire.

BOX 5-4 Primary National Patient Safety Goals for 2015

- Identify patients correctly
- Improve staff communication
- Use medicines safely
- Use alarms safely
- Prevent infection
- Identify patient safety risks
- Prevent mistakes in surgery

From http://www.jointcommission.org/assets/1/6/2015_HAP_NPSG_ER.pdf.

Preventing Surgical Fire

Fire is a risk to both patients and personnel in the operating room due to the three elements of the fire triangle that are necessary for a fire: fuel, oxidizer, and ignition source (AORN, 2015; Norton, Gorgone, & Belanger, 2014). Although rare, the possibility of surgical fires can result in devastating disfigurement, serious injury, and death. Fires can occur at any time in the OR; for example, surgical drapes provide an opportunity for oxygen to concentrate; a stray spark could more easily ignite a fire. To evaluate safety in the facility, electrical hazards, emergency exit clearances, and storage of equipment and anesthetic gases are monitored periodically by official agencies, such as the state department of health and the Joint Commission. All operating room personnel must be familiar with and educated about fire prevention and how to respond in the event that a fire should occur in the operating room. A fire risk assessment should be completed and communicated to the surgical team prior to the start of a procedure (AORN, 2015).

Donning Proper Attire

To help decrease microbes, the surgical area is divided into three zones: the unrestricted zone, where street clothes are allowed; the semirestricted zone, where attire consists of scrub clothes and caps; and the restricted zone, where scrub clothes, shoe covers, caps, and masks are worn. The surgeons and other surgical team members wear additional sterile clothing and protective devices during the operation.

The Association of Perioperative Registered Nurses, formerly known as the Association of Operating Room Nurses (still abbreviated as AORN), recommends specific practices for personnel wearing surgical attire to promote a high level of cleanliness in a particular practice setting (AORN, 2015). Shirts and waist drawstrings should be tucked inside the pants to prevent accidental contact with sterile areas and to contain skin shedding. Wet or soiled garments should be changed.

Masks are worn at all times in the restricted zone of the OR. High-filtration masks decrease the risk of postoperative wound infection by containing and filtering microorganisms from the oropharynx and nasopharynx. Masks should fit tightly, should cover the nose and mouth completely, and should not interfere with breathing, speech, or vision. Masks must be adjusted to prevent venting from the sides. Disposable masks have a filtration efficiency exceeding 95%. Masks are changed between patients and should not be worn outside the surgical department. The mask must be either on or off; it must not be allowed to hang around the neck.

Headgear should cover the hair completely (head and neckline, including beard), so that single strands of hair, bobby pins, clips, and particles of dandruff or dust do not fall on the sterile field.

Shoes should be comfortable and supportive. Shoe covers are worn when it is reasonably anticipated that spills or splashes will occur or if shoes are worn outside of the Operating Room Suite. Shoe covers should be changed when they become wet, torn, or soiled (AORN, 2015).

Barriers such as scrub attire and masks do not entirely protect the patient from microorganisms. Upper respiratory tract infections, sore throats, and skin infections in staff and patients are sources of pathogens and must be reported.

Because artificial fingernails harbor microorganisms and can cause nosocomial infections, a ban on artificial nails by OR personnel is supported by the Centers for Disease Control and Prevention (CDC), AORN, and the Association of Professionals in Infection Control. Short, natural fingernails are encouraged.

Using Environmental Controls

In addition to the protocols described previously, surgical asepsis requires meticulous cleaning and maintenance of the OR environment. Floors and horizontal surfaces are cleaned frequently with detergent, soap, and water or a detergent germicide. Sterilizing equipment is inspected regularly to ensure optimal operation and performance.

All equipment that comes into direct contact with the patient must be sterile. Sterilized linens, drapes, and solutions are used. Instruments are cleaned and sterilized in Central Sterile Services (CSS). Individually wrapped sterile items are used when additional individual items are needed.

Airborne bacteria are a concern. To decrease the amount of bacteria in the air, standard

OR ventilation provides 15 air exchanges per hour, at least three of which are fresh air (CDC, 2015). A temperature of 20° to 24°C (68° to 73°F), humidity between 30% and 60%, and positive pressure relative to adjacent areas are maintained. Staff members shed skin scales, resulting in about 1,000 bacteria-carrying particles (or colony-forming units [CFUs]) per cubic foot per minute. With the standard air exchanges, air counts of bacteria are reduced to 50 to 150 CFUs per cubic foot per minute. Unnecessary personnel and physical movement may be restricted to minimize bacteria in the air and achieve an OR infection rate no greater than 3% to 5% in clean, infection-prone surgery.

Some ORs have laminar airflow units. These units provide 400 to 500 air exchanges per hour (CDC, 2015). The goal for a laminar airflow–equipped OR is an infection rate of less than 1%. An OR equipped with this unit is frequently used for total joint replacement or organ transplant surgery. Constant surveillance and conscientious technique in carrying out aseptic practices are necessary to reduce the risk of contamination and infection.

Health Hazards Associated with the Surgical Environment

Safety issues in the OR include exposure to blood and body fluids, latex and adhesive substances, radiation, toxic agents, and laser plumes. Internal monitoring of the OR includes the analysis of surface swipe samples and air samples for infectious and toxic agents. In addition, policies and procedures have been established for minimizing exposure to body fluids and reducing the dangers associated with lasers and radiation.

An additional hazard is the unintentional leaving of an object in a person during a surgical procedure. The risk that foreign objects may be left in a person increases in the following situations: when the procedure is performed on an emergency basis, when there is an unplanned change in the procedure, and when the patient has a high BMI. Many complications can occur from the retention of an object, and the patient is subjected to the risk of an additional surgical procedure.

Exposure to Blood and Body Fluids

OR attire has changed dramatically since the advent of HIV/AIDS. Double-gloving is routine in trauma and other types of surgery where sharp bone fragments are present. Goggles, or a wrap-around face shield, are worn to protect against splashing when the surgical wound is irrigated or when bone drilling is performed. In hospitals where numerous total joint procedures are performed, a complete face shield may be used. This shield provides full-barrier protection from bone fragments and splashes. Ventilation is accomplished through an accompanying hood with a separate air-filtration system.

Latex Allergy

The AORN has recommended standards of care for the patient with latex allergy (AORN, 2015). These recommendations include early identification of patients with latex allergies, preparation of a latex allergy supply cart, and maintenance of latex allergy precautions throughout the perioperative period. Because of the increased number of patients with latex allergies, most products are latex free. For safety, manufacturers and hospital material managers need to take responsibility for identifying the latex content in items used by patients and health care personnel. Additional discussion of latex allergy can be found in Chapter 38.

Laser Risks

The AORN has recommended practices for laser safety. While lasers are in use, warning signs must be posted clearly to alert personnel. Safety precautions are implemented to reduce the possibility of exposing the eyes and skin to laser beams, to prevent inhalation of the laser plume (smoke and particulate matter), and to protect the patient and personnel from fire and electrical hazards. Several types of lasers are available for clinical use; perioperative personnel should be familiar with the unique features, specific operation, and safety measures for each type of laser used in the practice setting.

All personnel wear special protective goggles, specific to the type of laser used in the procedure (ANSI, 2014).

Whether protection is needed to avoid the laser plume and the effects of its inhalation is controversial. Smoke evacuators are used in some procedures to remove the laser plume from the operative field. In recent years, this technology has been used to protect the surgical team from the potential hazards associated with the generalized smoke plume generated by standard electrocautery units.

The Surgical Experience

During the surgical procedure, the patient will need sedation, anesthesia, or some combination of these. In addition, strict surgical asepsis is maintained.

Anesthesia and Sedation

Anesthesia today is very safe, and although anesthesia-related morbidity and mortality is difficult to quantify, more recent studies estimate anesthesia-related death rate in the United States to be less than 1 per 10,000 anesthetics (Barash et al., 2013). When the patient arrives in the OR, the anesthesia provider reassesses the patient's physical condition immediately prior to initiating anesthesia. For the patient, the anesthesia experience consists of having an IV line inserted, if it was not inserted earlier; receiving a sedating agent prior to induction with an anesthetic agent; losing consciousness; being intubated, if indicated; and then receiving a combination of anesthetic agents. Typically, the experience is a smooth one, and the patient has no recall of the events. The main types of anesthesia are general anesthesia, regional anesthesia, moderate sedation, monitored anesthesia care, and local anesthesia.

During surgery, the anesthesia provider monitors the patient's blood pressure, pulse, and respirations as well as the electrocardiogram (ECG), blood oxygen saturation level, tidal volume, blood gas levels, blood pH, alveolar gas concentrations, and body temperature. Monitoring by electroencephalography (measure of brain waves) is sometimes required. Levels of anesthetics in the body also can be determined; a mass spectrometer can provide instant readouts of critical concentration levels on display terminals. This information helps personnel assess the patient's ability to breathe unassisted or the need for mechanical assistance if ventilation is poor and the patient is not breathing well independently. Even with the availability of automatic monitoring equipment, the anesthesia provider and/or nurse must remain in close contact with the patient to observe any significant physiologic changes immediately.

General Anesthesia

Anesthesia is a state of narcosis (severe central nervous system [CNS] depression produced by pharmacologic agents), analgesia, relaxation, and reflex loss. Patients under general anesthesia are not arousable, not even to painful stimuli. They lose the ability to maintain ventilatory function and require assistance in maintaining a patent airway. Cardiovascular function may be impaired as well.

General anesthesia consists of four stages, each associated with specific clinical manifestations (Box 5-5) (Rothrock, 2014).

BOX 5-5 Stages of General Anesthesia

- *Stage I: Beginning anesthesia.* As the patient breathes in the anesthetic mixture, warmth, dizziness, and a feeling of detachment may be experienced. The patient may have a ringing, roaring, or buzzing in the ears and, although still conscious, may

sense an inability to move the extremities easily. During this stage, noises are exaggerated; even low voices or minor sounds seem loud and unreal. For this reason, unnecessary noises and motions are avoided when anesthesia begins.

- *Stage II: Excitement.* The excitement stage, characterized variously by struggling, shouting, talking, singing, laughing, or crying, is often avoided if the anesthetic is administered smoothly and quickly. Because of the possibility of uncontrolled movements of the patient during this stage, the anesthesia provider must always be assisted by someone ready to help restrain the patient. The patient should not be touched except for purposes of restraint, but restraints should not be applied over the operative site.
- *Stage III: Surgical anesthesia.* Surgical anesthesia is reached by continued administration of the anesthetic vapor or gas. The patient is unconscious and lies quietly on the table. With proper administration of the anesthetic, this stage may be maintained for hours in one of several planes, ranging from light (1) to deep (4), depending on the depth of anesthesia needed.
- *Stage IV: Medullary depression.* This stage is reached when too much anesthesia has been administered. Cyanosis develops and, without prompt intervention, death follows rapidly. If this stage develops, the anesthetic is discontinued immediately and respiratory and circulatory support is initiated to prevent death. Stimulants, although rarely used, may be administered; narcotic antagonists can be used if the overdosage is due to opioids.

When opioid agents (narcotics) and neuromuscular blockers (relaxants) are administered, several of the stages are absent. During smooth administration of an anesthetic, there is no sharp division between stages I, II, and III, and there is no stage IV. The patient passes gradually from one stage to another, and it is through close observation of the signs exhibited by the patient that an anesthesia provider controls the situation. The responses of the pupils, the blood pressure, and the respiratory and cardiac rates are among the most reliable guides to the patient's condition.

Anesthetic agents used in general anesthesia are inhaled or administered by IV (Fig. 5-3). Anesthetics produce anesthesia because they are delivered to the brain at a high partial pressure that enables them to cross the blood–brain barrier. Relatively large amounts of anesthetic must be administered during induction and the early maintenance phases because the anesthetic is recirculated and deposited in body tissues. As these sites become saturated, smaller amounts of the anesthetic agent are required to maintain anesthesia because equilibrium or near equilibrium has been achieved among brain, blood, and other tissues.

Any condition that diminishes peripheral blood flow, such as vasoconstriction or shock, may reduce the amount of anesthetic required. Conversely, when peripheral blood flow is unusually high, as in a muscularly active or apprehensive patient, induction is slower, and greater quantities of anesthetic are required because the brain receives a smaller quantity of anesthetic.

Inhaled Administration. Inhalation anesthetics are commonly used for the provision of general anesthesia. With the addition of a volatile (readily vaporized) anesthetic to inspired oxygen, a state of unconsciousness and amnesia can be established. When combined with additional medications (e.g., opioids and benzodiazepines), further sedation/hypnosis and amnesia are established. They are considered easy to administer, inexpensive, and reliable in terms of ability to monitor their effects with both clinical signs and end-tidal concentrations (Perouansky, Pearce, & Hemmings, 2015). In addition, they are important in situations where there is a lack of venous access and anticipated airway difficulty.

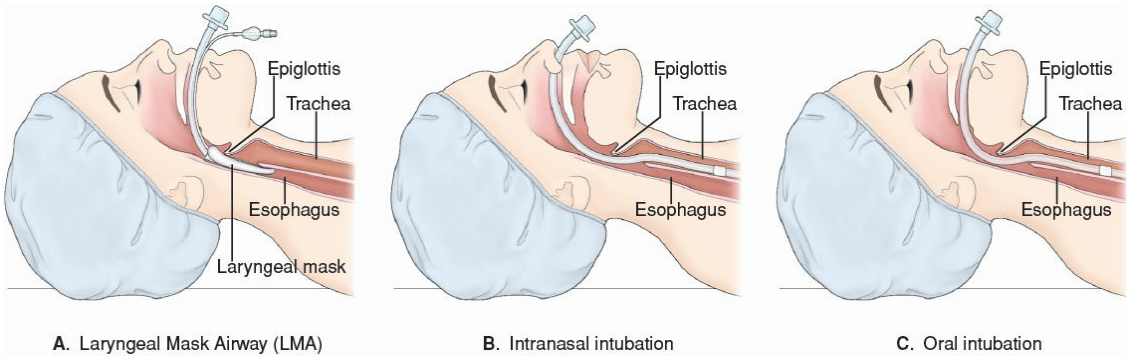

FIGURE 5-3 Anesthetic delivery methods: (A) laryngeal mask airway (LMA), (B) nasal endotracheal catheter (in position with cuff inflated), and (C) oral endotracheal intubation (tube is in position with cuff inflated).

Intravenous Administration. General anesthesia can be produced by the IV administration of various substances, such as barbiturates, benzodiazepines, nonbarbiturate hypnotics, dissociative agents, and opioid agents. Table 5-6 lists commonly used IV anesthetic and analgesic agents, including IV medications used as muscle relaxants in the intraoperative period. These medications may be administered to induce (initiate) or maintain anesthesia. Although they are often used in combination with inhalation anesthetics, they may be used alone. They may also be used to produce moderate sedation.

An advantage of IV anesthesia is that the onset of anesthesia is pleasant; there is none of the buzzing, roaring, or dizziness known to follow administration of an inhalation anesthetic. For this reason, induction of anesthesia usually begins with an IV agent and often is preferred by patients who have experienced various methods. The duration of action is brief, and the patient awakens with little nausea or vomiting.

The IV anesthetic agents are nonexplosive, require little equipment, and are easy to administer. The low incidence of postoperative nausea and vomiting (PONV) makes the method useful in eye surgery because in this setting vomiting would increase intraocular pressure and endanger vision in the operated eye. IV anesthesia is useful for short procedures but is used less often for the longer procedures of abdominal surgery. It is not indicated for children, who have small veins, or for those who require intubation because of their susceptibility to respiratory obstruction.

A disadvantage of an IV anesthetic such as thiopental (Pentothal) is its powerful respiratory depressant effect. It must be administered by a skilled anesthesia provider and only when some method of oxygen administration is available immediately in case of difficulty. Sneezing, coughing, and laryngospasm are sometimes noted with its use.

TABLE 5-6 Commonly Used Intravenous Medications

Medication	Common Usage	Advantages	Disadvantages	Comments
Opioid Analgesics				
Morphine sulfate (MS)	Perioperative pain; premedication	Inexpensive; duration of action 4–5 hours; euphoria; good cardiovascular stability	Nausea and vomiting; histamine release; respiratory depression; postural ↓ BP and ↓ SVR	Used intrathecally and epidurally for postoperative pain; elimination half-life 90 minutes
Alfentanil (Alfenta)	Surgical analgesia in ambulatory patients	Duration of action 0.5 hour; used as bolus or infusion		Potency: 750 μg = 10-mg morphine sulfate; elimination half-life 1.6 hours
Fentanyl (Sublimaze)	Surgical analgesia: epidural infusion for postoperative analgesia; add to SAB	Good cardiovascular stability; duration of action 0.5 hour		Most commonly used opioid; potency: 100 μg = 10-mg morphine sulfate; elimination half-life 3.6 hours
Remifentanil (Ultiva)	IV infusion for surgical analgesia; small boluses for brief, intense pain	Easily titratable; metabolized by blood and tissue esterases; very short duration; good cardiovascular stability	New; expensive; requires mixing; may cause muscle rigidity	Potency: 25 μg = 10-mg morphine sulfate; 20–30 times the potency of alfentanil; elimination half-life 3–10 minutes
Sufentanil (Sufenta)	Surgical analgesia	Good cardiovascular stability; duration of action 0.5 hour; prolonged analgesia	Prolonged respiratory depression	Potency: 15 μg = 10-mg morphine sulfate; elimination half-life 2.7 hours
Nondepolarizing Muscle Relaxants—Intermediate Onset and Duration				
Rocuronium (Zemuron)	Intubation; maintenance of relaxation	Rapid onset (dose dependent); elimination via kidney and liver	Vagolytic; may ↑ HR	Duration similar to atracurium and vecuronium
Vecuronium (Norcuron)	Intubation; maintenance of relaxation	No significant cardiovascular or cumulative effects; no histamine release	Requires mixing	Mostly eliminated in bile, some in urine
Etomidate (Amidate)	Induction	Good cardiovascular stability; fast, smooth induction and recovery	May cause pain with injection and myotonic movements	May cause adrenal suppression
Diazepam (Valium, Dizac)	Amnesia; hypnotic; preoperative medication	Good sedation	Prolonged duration	Residual effects for 20–90 hours; increased effect with alcohol
Ketamine (Ketalar)	Induction, occasional maintenance (IV or IM)	Short acting; patient maintains airway; good in small children and burn patients	Large doses may cause hallucinations and respiratory depression	Need darkened, quiet room for recovery; often used in trauma cases
Midazolam (Versed)	Hypnotic; anxiolytic; sedation; often used as adjunct to induction	Excellent amnesia; water-soluble (no pain with IV injection); short acting	Slower induction than thiopental	Often used for amnesia with insertion of invasive monitors or regional anesthesia
Propofol (Diprivan)	Induction and maintenance; sedation with regional anesthesia or MAC	Rapid onset; awakening in 4–8 minutes	May cause pain when injected	Short elimination half-life (34–64 minutes)
Sodium methohexital (Brevital)	Induction	Ultrashort-acting barbiturate	May cause hiccups	Can be given rectally
Thiopental sodium (Pentothal)	Induction	Induction	May cause laryngospasm; can be given rectally	Large doses may cause apnea and cardiovascular depression

BP, blood pressure; HR, heart rate; IM, intramuscular; IV, intravenous; MAC, monitored anesthesia care; SAB, subarachnoid block; SVR, stroke volume ratio.

IV neuromuscular blockers (muscle relaxants) block the transmission of nerve impulses

at the neuromuscular junction of skeletal muscles. Muscle relaxants are used to relax muscles in abdominal and thoracic surgery, relax eye muscles in certain types of eye surgery, facilitate endotracheal intubation, treat laryngospasm, and assist in mechanical ventilation.

Local Anesthesia

Local anesthesia is used to block nerves in the peripheral nervous system and CNS. Local anesthesia provides anesthesia and analgesia by blocking the transmission of pain sensation along nerve fibers. The degree of blockage depends on both drug concentration and volume.

Local anesthesia can be used alone or in conjunction with other types of anesthesia. Usually it is administered by the surgeon to a specific area of the body by topical application or local infiltration. In most cases, the patient will be monitored by a nurse. To ensure safety and quality of care, the AORN has developed recommended practices for nurses who monitor patients receiving local anesthesia (AORN, 2015). The nurse should also monitor the quantity of medication administered since toxic reactions are dose related (AORN, 2015).

Regional Anesthesia. Regional anesthesia is a form of local anesthesia in which an anesthetic agent is injected around nerves, so that the area supplied by these nerves is anesthetized. The most common techniques are spinal, epidural, and peripheral nerve blocks. Regional anesthesia is an attractive anesthetic option for many types of operative procedures and can provide excellent postoperative pain management in selected patients (Berde & Strichartz, 2015). The effect depends on the type of nerve involved. A local anesthetic blocks motor nerves least readily and sympathetic nerves most readily. An anesthetic cannot be regarded as having worn off until all three systems (motor, sensory, and autonomic) are no longer affected.

The patient receiving regional anesthesia is awake and aware of his or her surroundings unless medications are given to produce mild sedation or to relieve anxiety. The nurse must avoid careless conversation, unnecessary noise, and unpleasant odors; these may be noticed by the patient in the OR and may contribute to a negative response to the surgical experience. A quiet environment is therapeutic. The diagnosis must not be stated aloud if the patient is not to know it at this time.

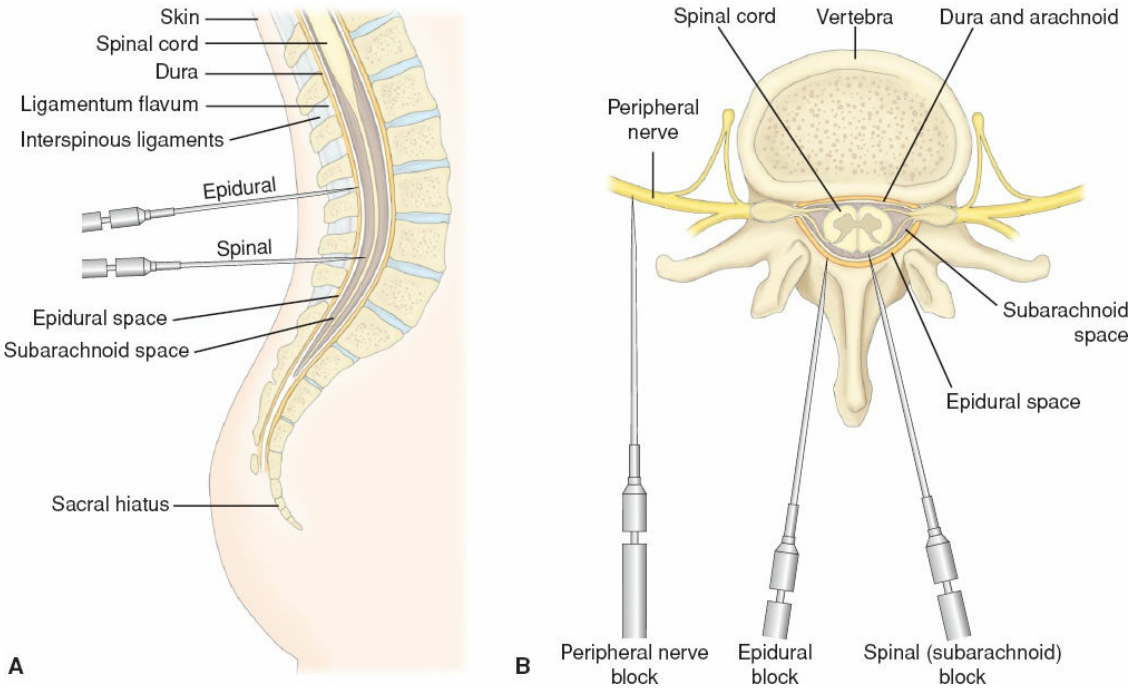

FIGURE 5-4 (A) Injection sites for spinal and epidural anesthesia. (B) Cross-section of injection sites for peripheral nerve, epidural, and spinal blocks.

Spinal Anesthesia. Spinal anesthesia is an extensive conduction nerve block that is produced when a local anesthetic is introduced into the subarachnoid space at the lumbar level, usually between L4 and L5 (Fig. 5-4). It produces anesthesia of the lower extremities, perineum, and lower abdomen. For the lumbar puncture procedure, the patient usually lies on the side in a knee-to-chest position. Sterile technique is used as a spinal puncture is made and the medication is injected through the needle. As soon as the injection has been made, the patient is positioned on his or her back. If a relatively high level of block is sought, the head and shoulders are lowered.

A few minutes after induction of a spinal anesthetic, anesthesia and paralysis affect the toes and perineum and then gradually the legs and abdomen. If the anesthetic reaches the upper thoracic and cervical spinal cord in high concentrations, a temporary partial or complete respiratory paralysis results. Paralysis of the respiratory muscles is managed by mechanical ventilation until the effects of the anesthetic on the cranial and thoracic nerves have worn off.

Nausea, vomiting, and pain may occur during surgery when spinal anesthesia is used. As a rule, these reactions result from manipulation of various structures, particularly those within the abdominal cavity. The simultaneous IV administration of a weak solution of thiopental and inhalation of nitrous oxide may prevent such reactions.

Headache may be an after-effect of spinal anesthesia. Several factors are related to the incidence of headache: the size of the spinal needle used, the leakage of fluid from the subarachnoid space through the puncture site, and the patient's hydration status. Measures that increase cerebrospinal pressure are helpful in relieving headache. These include maintaining a quiet environment, keeping the patient lying flat, and keeping the patient well hydrated.

In continuous spinal anesthesia, the tip of a plastic catheter remains in the subarachnoid space during the surgical procedure, so that more anesthetic may be injected as needed.

This technique allows greater control of the dosage, but there is greater potential for postanesthetic headache because of the large-gauge needle used.

Epidural Anesthesia. Epidural anesthesia, a commonly used conduction block, is achieved by injecting a local anesthetic into the epidural space that surrounds the dura mater of the spinal cord (refer to Fig. 5-4). In contrast, spinal anesthesia involves injection through the dura mater into the subarachnoid space surrounding the spinal cord. Epidural anesthesia blocks sensory, motor, and autonomic functions; it differs from spinal anesthesia by the site of the injection and the amount of anesthetic agent used. Epidural doses are much higher because the epidural anesthetic does not make direct contact with the spinal cord or nerve roots.

Epidural anesthetics, if placed correctly, can cause less hypotension and less hemodynamic changes. However, since the needle used for epidural anesthesia is much larger (17 to 18 gauge) than that used in spinal anesthesia (22 to 24 gauge), the severity of the headache with inadvertent puncture of the dura is much greater. Another disadvantage is the greater technical challenge of introducing the anesthetic into the epidural rather than the subarachnoid space. If inadvertent puncture of the dura occurs during epidural anesthesia and the anesthetic travels toward the head, high spinal anesthesia can result; this can produce severe hypotension and respiratory depression and arrest. Treatment of these complications includes airway support, IV fluids, and use of vasopressors.

Peripheral Nerve Blocks. Blockade of the brachial plexus (arm), lumbar plexus, and specific peripheral nerves is an effective means of providing surgical anesthesia and postoperative analgesia for many surgical procedures involving the upper and lower extremities. The advantages of peripheral nerve block (PNB) include reduced physiologic stress in comparison to spinal or epidural anesthesia, avoidance of airway manipulation and the potential complications associated with endotracheal intubation, and avoidance of potential side effects associated with general anesthesia. All patients undergoing PNB should receive a full perioperative evaluation under the assumption that general anesthesia could be used if the block is inadequate (Berde & Strichartz, 2015). Examples of common local conduction blocks are:

- Brachial plexus block, which produces anesthesia of the arm
- Paravertebral anesthesia, which produces anesthesia of the nerves supplying the chest, abdominal wall, and extremities
- Transsacral (caudal) block, which produces anesthesia of the perineum and, occasionally, the lower abdomen
- Femoral nerve block, which produces anesthesia of the nerves supplying the leg.

Moderate Sedation/Analgesia and Monitored Anesthesia Care

It is important to distinguish between moderate sedation/analgesia and monitored anesthesia care. *Moderate sedation/analgesia* is a term used by the ASA in their practice guidelines for sedation and analgesia by nonanesthesiologists. *Monitored anesthesia care* implies the potential for a level of sedation deeper than what provided by sedation/analgesia and is always administered by an anesthesiologist (ASPAN, 2015). Moderate sedation/analgesia, previously referred to as *conscious sedation,* and monitored anesthesia

are forms of anesthesia that involve the IV administration of sedatives and/or analgesic medications to reduce patient anxiety and control pain during diagnostic or therapeutic procedures. It is being used increasingly for specific short-term surgical procedures in hospitals and ambulatory care centers (Rothrock, 2014). The goal is to depress a patient's level of consciousness (LOC) to a moderate level to enable surgical, diagnostic, or therapeutic procedures to be performed while ensuring the patient's comfort during and cooperation with the procedures. Moderate sedation and monitored analgesia allow the patient to maintain a patent airway, retain protective airway reflexes, respond to verbal and physical stimuli, and recover more rapidly postprocedure.

Moderate sedation can be administered by an anesthesiologist, anesthetist, or other specially trained and credentialed physician or nurse. The patient receiving moderate sedation is never left alone and is closely monitored by a physician or nurse who is knowledgeable and skilled in detecting arrhythmias, administering oxygen, and performing resuscitation. The continual assessment of the patient's vital signs, LOC, and cardiac and respiratory function is an essential component of moderate sedation. Pulse oximetry, ECG monitor, and frequent measurement of vital signs are used to monitor the patient. The regulations for use and administration of moderate sedation differ from state to state, and its administration is addressed in standards issued by the Joint Commission and by institutional policies and nursing specialty organizations, including the AORN (2015).

Surgical Asepsis

Surgical asepsis prevents the contamination of surgical wounds. The patient's natural skin flora or a previously existing infection may cause postoperative wound infection. Rigorous adherence to the principles of surgical asepsis by OR personnel is basic to preventing surgical site infections (SSIs).

Traditionally, the surgeon, surgical assistants, and nurses prepared themselves by scrubbing their hands and arms with antiseptic soap and water, but this traditional practice is being challenged by research investigating the optimal length of time to scrub and the best preparation to use. Many institutions have now introduced a scrubless process for cleaning the hands prior to surgery. Box 5-6 provides guidelines for maintaining surgical asepsis.

Intraoperative Nursing Management

The major goals for care of the patient during surgery are to reduce his or her anxiety, keep the patient free of perioperative injury related to positioning, avoid threats to safety, maintain patient dignity, and avoid complications associated with operative events.

Reducing Anxiety

The OR environment can seem cold, stark, and frightening to the patient, who may be feeling isolated and apprehensive. Introductions, addressing the patient by name warmly and frequently, verifying details, providing explanations, and encouraging and answering questions convey a sense of professionalism and friendliness that can help the patient feel secure. When discussing what the patient can expect in surgery, the nurse uses basic communication skills, such as touch and eye contact, to reduce anxiety. Attention to physical comfort (warm blankets, position changes) helps the patient feel more comfortable. Telling the patient who else will be present in the OR, how long the procedure is expected to take, and other details helps the patient prepare for the experience and gain a sense of control.

BOX 5-6 Basic Guidelines for Maintaining Surgical Asepsis

All practitioners involved in the intraoperative phase have a responsibility to provide and maintain a safe environment. Adherence to aseptic practice is part of this responsibility. Here are the basic principles of aseptic technique:

- All materials in contact with the surgical wound or used within the sterile field must be sterile. Sterile surfaces or articles may touch other sterile surfaces or articles and remain sterile; contact with unsterile objects at any point renders a sterile area contaminated.
- Gowns of the surgical team are considered sterile in front from the chest to the level of the sterile field. The sleeves are also considered sterile from 2 in above the elbow to the stockinette cuff.
- Sterile drapes are used to create a sterile field. Only the top surface of a draped table is considered sterile. During draping of a table or patient, the sterile drape is held well above the surface to be covered and is positioned from front to back.
- Items are dispensed to a sterile field by methods that preserve the sterility of the items and the integrity of the sterile field. After a sterile package is opened, the edges are considered unsterile. Sterile supplies, including solutions, are delivered to a sterile field or handed to a scrubbed person in such a way that the sterility of the object or fluid remains intact.

- The movements of the surgical team are from sterile to sterile areas and from unsterile to unsterile areas. Scrubbed persons and sterile items contact only sterile areas; circulating nurses and unsterile items contact only unsterile areas.
- Movement around a sterile field must not cause contamination of the field. Sterile areas must be kept in view during movement around the area. At least a 1-foot distance from the sterile field must be maintained to prevent inadvertent contamination.
- Whenever a sterile barrier is breached, the area must be considered contaminated. A tear or puncture of the drape permitting access to an unsterile surface underneath renders the area unsterile. Such a drape must be replaced.
- Every sterile field is constantly monitored and maintained. Items of doubtful sterility are considered unsterile. Sterile fields are prepared as close as possible to the time of use.

Preventing Intraoperative Positioning Injury

The patient's position on the operating table depends on the surgical procedure to be performed as well as on the patient's physical condition (Fig. 5-5). The potential for transient discomfort or permanent injury is present because many positions are awkward. Hyperextending joints, compressing arteries, or pressing on nerves and bony prominences usually results in discomfort simply because the position must be sustained for a long period of time (Rothrock, 2014). Factors to consider include the following:

- The patient should be in as comfortable a position as possible, whether conscious or unconscious.
- The operative field must be exposed adequately.
- An awkward position, undue pressure on a body part, or use of stirrups or traction should not obstruct the vascular supply.
- Respiration should not be impeded by pressure of arms on the chest or by a gown that constricts the neck or chest.
- Nerves must be protected from undue pressure. Improper positioning of the arms, hands, legs, or feet can cause serious injury or paralysis. Shoulder braces must be well padded to prevent irreparable nerve injury, especially when the Trendelenburg position (head down) is necessary. The postoperative complication of compartment syndrome is associated with intraoperative positioning (AORN, 2015). Refer to Chapter 42 for information related to clinical manifestations of compartment syndrome.
- Precautions for patient safety must be observed, particularly with thin, elderly, or obese patients as well as those with a physical deformity.
- The patient may need light restraint before induction in case of excitement.

The usual position for surgery, called the dorsal recumbent position, is flat on the back. One arm is positioned at the side of the table, with the hand placed palm down; the other is carefully positioned on an arm board to facilitate IV infusion of fluids, blood, or

medications. This position is used for most abdominal surgeries except for surgery of the gallbladder or pelvis (see Fig. 5-5A).

The Trendelenburg position usually is used for surgery on the lower abdomen and pelvis to obtain good exposure by displacing the intestines into the upper abdomen. In this position, the head and upper body are lowered. The patient is held in position by padded shoulder braces (see Fig. 5-5B).

The lithotomy position is used for nearly all perineal, rectal, and vaginal surgical procedures (see Fig. 5-5C). The patient is positioned on the back with the legs and thighs flexed. The position is maintained by placing the feet in stirrups.

The Sims' or lateral position is used for renal surgery. The patient is placed on the nonoperative side with an air pillow or beanbag 12.5 to 15 cm (5 to 6 in) thick under the loin, or on a table with a kidney or back lift (see Fig. 5-5D).

Other procedures, such as neurosurgery or abdominothoracic surgery, may require unique positioning and supplemental apparatus, depending on the operative approach.

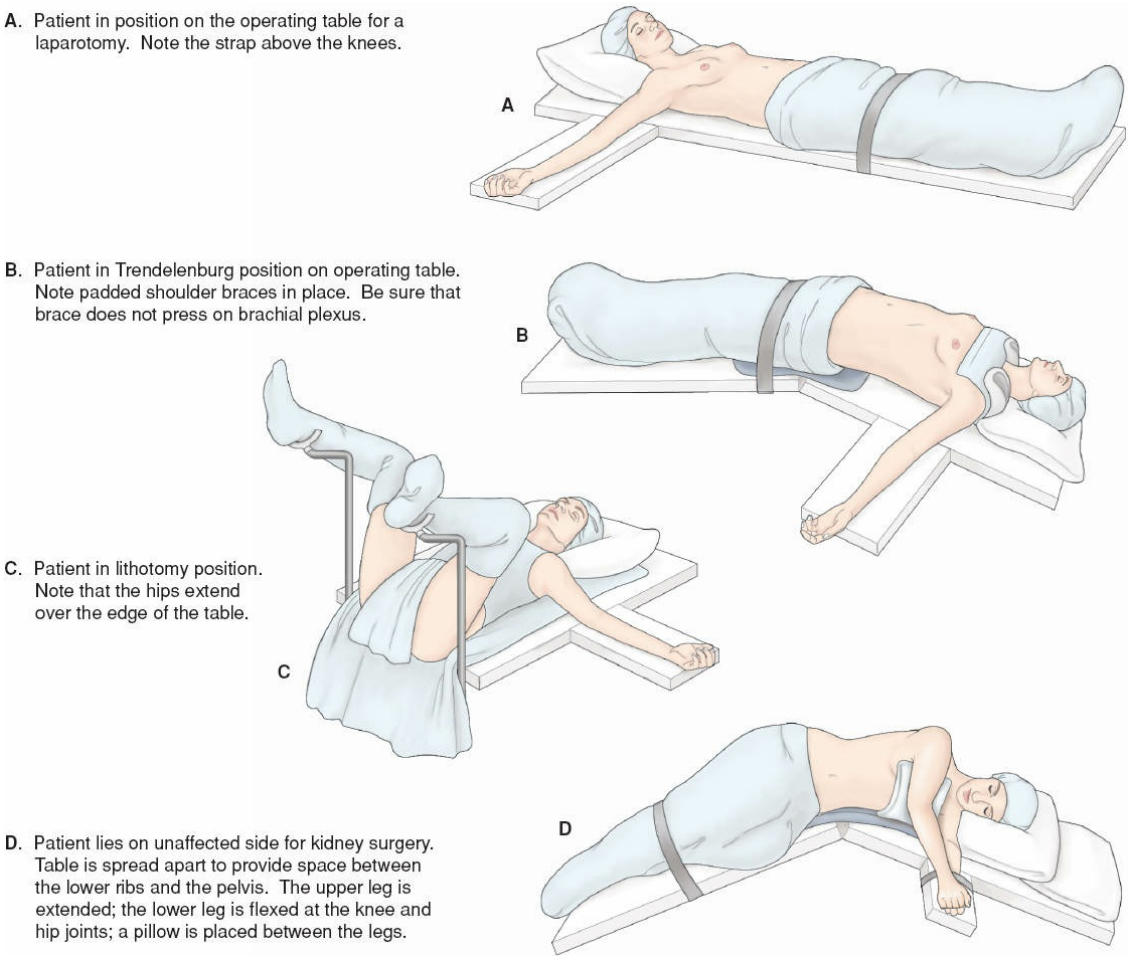

FIGURE 5-5 Positions on the operating table. Captions call attention to safety and comfort features. All surgical patients wear caps to cover the hair completely.

Protecting the Patient from Injury

A variety of activities are used to address the diverse patient safety issues that arise in the OR. The nurse protects the patient from injury by providing a safe environment. Verifying information, checking the chart for completeness, and maintaining surgical asepsis and an optimal environment are critical nursing responsibilities. Verifying that all required documentation is completed is one of the first functions of the intraoperative nurse. The patient is identified, and the planned surgical procedure, correct surgical site, and type of anesthesia are verified. It is important to review the patient's record for the following:

- Correct informed surgical consent, with patient's and surgeon's signatures
- Completed records for health history and physical examination
- Results of diagnostic studies
- Allergies (including latex)

In addition to checking that all necessary patient data are complete, the perioperative nurse obtains the necessary equipment specific to the procedure. The need for nonroutine medications, blood components, instruments, and other equipment and supplies is assessed, and the readiness of the room, completeness of physical setup, and completeness of instrument, suture, and dressing setups are determined. Any aspects of the OR

environment that may negatively affect the patient are identified. These include physical features, such as room temperature and humidity; electrical hazards; potential contaminants (dust, blood, and discharge on floor or surfaces, uncovered hair, faulty attire of personnel, jewelry worn by personnel); and unnecessary traffic. The circulating nurse also sets up and maintains suction equipment in working order, sets up invasive monitoring equipment, assists with insertion of vascular access and monitoring devices (arterial, Swan-Ganz, central venous pressure, IV lines), and initiates appropriate physical comfort measures for the patient.

Preventing physical injury includes using safety straps and side rails and not leaving the sedated patient unattended. Transferring the patient from the stretcher to the OR table requires safe transferring practices. Other safety measures include properly positioning the grounding pad under the patient to prevent electrical burns and shock, removing excess antiseptic solution from the patient's skin, and promptly and completely draping exposed areas after the sterile field has been created to decrease the risk for hypothermia.

The importance of nursing measures to prevent "never events" in surgery such as prevention of retained foreign objects, wrong site surgery, and pressure ulcers cannot be overemphasized. The Joint Commission and the AORN have developed guidelines that should be implemented in each facility to prevent these from occurring. There are also technologic devices that can support the safe counting of surgical instruments and supplies to prevent retention of foreign objects. The unintended retention of foreign objects (URFOs)—also called retained surgical items (RSIs)—after invasive procedures can cause death, and surviving patients may sustain both physical and emotional harm, depending on the type of object retained and the length of time it is retained (Joint Commission, 2013). The risk of URFOs increases during certain surgical conditions (Box 5-7).

Nursing measures to prevent injury from excessive blood loss include blood conservation using equipment such as a cell-saver (a device for recirculating the patient's own blood cells) and administration of blood products. Few patients undergoing an elective procedure require blood transfusion, but those undergoing higher-risk procedures (such as orthopedic or cardiac surgeries) may require an intraoperative transfusion. The circulating nurse anticipates this need, checks that blood has been cross-matched and held in reserve, and is prepared to support the anesthesia provider with administration when needed.

BOX 5-7 Risk Factors for Unintended Retention of Foreign Objects (URFOs)

- The absence of policies and procedures
- Failure to comply with existing policies and procedures
- Problems with hierarchy and intimidation
- Failure in communication with physicians
- Failure of staff to communicate relevant patient information
- Inadequate or incomplete education of staff

From The Joint Commission, 2016.

Serving as Patient Advocate

Because the patient undergoing general anesthesia or moderate sedation experiences

temporary sensory/perceptual alteration or loss, he or she has an increased need for protection and advocacy. Patient advocacy in the OR entails maintaining the patient's physical and emotional comfort, privacy, rights, and dignity. Patients, whether conscious or unconscious, should not be subjected to excess noise, inappropriate conversation, or, most of all, derogatory comments. As surprising as this sounds, banter in the OR occasionally includes jokes about the patient's physical appearance, job, personal history, and so forth. Cases have been reported in which seemingly deeply anesthetized patients recalled the entire surgical experience, including disparaging personal remarks made by OR personnel. As an advocate, the nurse never engages in this conversation and discourages others from doing so. Other advocacy activities include minimizing the clinical, dehumanizing aspects of being a surgical patient by making sure the patient is treated as a person, respecting cultural and spiritual values, providing physical privacy, and maintaining confidentiality.

Monitoring and Managing Potential Complications

It is the responsibility of the surgeon, anesthesia provider, and the circulating nurse to monitor and manage complications. Important nursing functions include being alert to and reporting changes in vital signs and symptoms of nausea and vomiting, anaphylaxis, hypoxia, hypothermia, MH, or disseminated intravascular coagulation (DIC) and assisting with the management of those complications. Each of these complications will be discussed shortly. It is the responsibility of all members of the health care team to maintain asepsis.

Nausea and Vomiting

Nausea and vomiting, or regurgitation, may affect patients during the intraoperative period. If gagging occurs, the patient is turned to the side, the head of the table is lowered, and a basin is provided to collect the vomitus. Suction is used to remove saliva and vomited gastric contents. The advent of new anesthetics has reduced the incidence; however, there is no single way to prevent nausea and vomiting. An interdisciplinary approach involving the surgeon, anesthesia provider, and nurse is best.

In some cases, the anesthesia provider administers antiemetics preoperatively or intraoperatively to counteract possible aspiration. If the patient aspirates vomitus, it will trigger an asthma-like attack with severe bronchial spasms and wheezing. Pneumonitis and pulmonary edema can subsequently develop, leading to extreme hypoxia. Increasing medical attention is being paid to silent regurgitation of gastric contents (not related to preoperative fasting times), which occurs more frequently than previously realized. The volume and acidity of the aspirate determine the extent of damage to the lungs.

Anaphylaxis

Anaphylaxis is an acute life-threatening allergic reaction to a specific antigen or hapten (a small molecule that can cause an immune response when bound to a protein) resulting in urticaria (hives), pruritus (itching), or angioedema (swelling beneath the skin rather than on the surface), and quickly deteriorating to vascular collapse, shock, and respiratory distress. Any time the patient comes into contact with a foreign substance, there is the potential for an anaphylactic reaction. Because medications are the most common cause of anaphylaxis, intraoperative nurses must be aware of the type and method of anesthesia used as well as the specific agents. An anaphylactic reaction can occur in response to many

medications, latex, or other substances. Chapter 38 provides additional detail on anaphylaxis.

Hypoxia and Other Respiratory Complications

Inadequate ventilation, occlusion of the airway, inadvertent intubation of the esophagus, and hypoxia are significant potential complications associated with general anesthesia. Many factors can contribute to inadequate ventilation. Respiratory depression caused by anesthetic agents, aspiration of respiratory tract secretions or vomitus, and the patient's position on the operating table can compromise the exchange of gases. Anatomic variation can make the trachea difficult to visualize and result in the artificial airway being inserted into the esophagus rather than into the trachea. In addition to these dangers, asphyxia can occur from foreign bodies in the mouth, spasm of the vocal cords, relaxation of the tongue, or aspiration of vomitus, saliva, or blood. Brain damage from hypoxia occurs within minutes; therefore, vigilant monitoring of the patient's oxygenation status is a primary function of the anesthesia provider and the circulating nurse. Peripheral perfusion is checked frequently, and pulse oximetry values are monitored continuously.

Hypothermia

During anesthesia, the patient's temperature may fall. This condition is called *hypothermia* and is indicated by a core body temperature that is lower than normal (36.6°C [98.0°F] or less). Inadvertent hypothermia may occur as a result of a low temperature in the OR, infusion of cold fluids, inhalation of cold gases, open body wounds or cavities, decreased muscle activity, advanced age, or the pharmaceutical agents used (e.g., vasodilators, phenothiazines, general anesthetics). Also hypothermia may be induced intentionally in selected surgical procedures (e.g., cardiac surgeries requiring cardiopulmonary bypass) to reduce the patient's metabolic rate and energy demands.

Preventing unintentional hypothermia is a major objective. If hypothermia occurs, the goal of intervention is to minimize or reverse the physiologic process. If hypothermia is intentional, the goal is safe return to normal body temperature. Environmental temperature in the OR can be set temporarily at 25° to 26.6°C (78° to 80°F). IV and irrigating fluids are warmed to 37°C (98.6°F). Wet gowns and drapes are removed promptly and replaced with dry materials because wet linens promote heat loss. Whatever methods are used to rewarm the patient, warming must be accomplished gradually, not rapidly. Conscientious monitoring is required for core temperature, urinary output, ECG, blood pressure, arterial blood gas (ABG) levels, and serum electrolyte levels.

Nursing Alert
Shivering is associated with hypothermia. The nurse is aware that shivering can increase oxygen demand by 300% to 400%, thus supplemental oxygen should be administered, and oxygen saturation monitoring should be continuous.

Malignant Hyperthermia

MH is a rare inherited muscle disorder that is chemically induced by anesthetic agents (Rothrock, 2014). At one time, mortality rates exceeded 80%. Since the introduction of dantrolene sodium in 1979, the development of genetics testing, and early detection and

treatment with specific protocols, fatalities have been reduced to approximately less than 10% (Zhou, Bose, Allen, & Pessah, 2015). Identification of patients at risk for MH is imperative. Susceptible people include those with strong and bulky muscles, familial genetic mutations as described earlier, first-degree relatives of persons who have been diagnosed or suspected of MH, and an unexplained death of a family member during surgery that was accompanied by a febrile response.

During anesthesia, potent agents such as inhalation anesthetics (halothane, enflurane) and muscle relaxants (succinylcholine) may trigger the symptoms of MH (refer to Table 5-5 for list of anesthetic agents). Stress and some medications, such as sympathomimetics (epinephrine), theophylline, aminophylline, anticholinergics (atropine), and cardiac glycosides (digitalis), can induce or intensify such a reaction. The pathophysiology is related to a hypermetabolic condition in skeletal muscle cells that involves altered mechanisms of calcium function at the cellular level. This disruption of calcium causes clinical symptoms of hypermetabolism, which, in turn, increases muscle contraction (rigidity). The sustained muscle contraction causes hyperthermia (fever may exceed 110°F) and subsequent damage to the CNS.

The skeletal muscle cells, when depleted of their source of cellular energy (adenosine triphosphate [ATP]), break down and release the muscle cell contents, including myoglobin (a protein released from muscle when injury occurs), creatine phosphokinase (CPK), and potassium into the systemic circulation. The resulting hyperkalemia has a dramatic effect on the heart, causing ventricular arrhythmias. The muscle pigment myoglobin has an affinity for the kidneys, resulting in potential for kidney failure (refer to Chapter 42, Box 42-7 for details). If untreated, cardiac arrest, kidney failure, blood coagulation problems, internal hemorrhage, brain injury, liver failure, and death can result.

The initial symptoms of MH are related to cardiovascular and musculoskeletal activity. Tachycardia (heart rate >150 bpm) is often the earliest sign. In addition to the tachycardia, sympathetic nervous stimulation leads to ventricular arrhythmia, hypotension, decreased cardiac output, oliguria (less than 400 mL), and, later, cardiac arrest. With the abnormal transport of calcium, rigidity or tetanus-like movements occur, often in the jaw. The rise in temperature is actually a late sign that develops rapidly; body temperature can increase 1° to 2°C (2° to 4°F) every 5 minutes (Rothrock, 2014). The core body temperature can reach or exceed 42°C (104°F) in a very short time and must be properly monitored and recorded during surgery. Clinical signs of patients with MH include: hypercarbia (elevated carbon dioxide in blood), sinus tachycardia, rapidly increasing temperature, elevated temperature, masseter muscle spasm, also known as masseter muscle spasm after succinylcholine administration (the muscle covering the side of the jaw nearest the ear, responsible for mastication [chewing]), generalized muscular rigidity, tachypnea (increased respiratory rate), profuse diaphoresis, cola-colored urine, cyanosis, skin mottling, ventricular tachycardia, excessive bleeding, unstable blood pressure, and ventricular fibrillation (Zhou et al., 2015). The entire health team is alert for the presence of any of the aforementioned signs.

Recognizing symptoms early and discontinuing anesthesia promptly are imperative. The immediate response is the discontinuation of the triggering agent and hyperventilation of the patient with 100% oxygen and immediate administration of at least 2.5 mg/kg of dantrolene sodium intravenously (Zhou et al., 2015). Additional incremental doses may be required until the signs of MH are controlled. Because dantrolene is available in 20-mg

multidose vials that must be reconstituted with 50 mL of sterile water only, it is expected that at least two nurses will be reconstituting the drug during the crisis. If the patient is hyperthermic, active cooling is initiated with iced saline administration, lavage of the stomach, bladder, rectum, and open body cavities if appropriate with iced saline, use of a hypothermia blanket, and use of ice packs. It is essential to monitor the patient's temperature to assess treatment efficacy and avoidance of hypothermia. Antiarrhythmic medications, such as amiodorone, are expected for management of ventricular arrhythmias; infusion by IV glucose and insulin, as well as calcium chloride, is anticipated for the hyperkalemia. Sodium bicarbonate may be administered to treat the metabolic acidosis based upon ABG analysis. In addition, diuretics may be administered to assist with the clearance of filtered myoglobin into the urine; hourly urine output and color of urine are observed closely (Zhou et al., 2015).

Goals of treatment are to decrease metabolism, reverse metabolic and respiratory acidosis, correct arrhythmias, decrease body temperature, provide oxygen and nutrition to tissues, and correct electrolyte imbalance. The Malignant Hyperthermia Association of the United States (MHAUS) publishes a treatment protocol that should be posted in the OR and be readily available on an MH cart. Although MH is uncommon, all providers must identify patients at risk, recognize the signs and symptoms, have the appropriate medication and equipment available, and be knowledgeable about the protocol to follow. This preparation may be life-saving for the patient.

Disseminated Intravascular Coagulation

DIC is a dynamic systemic disorder that results in widespread hemorrhage and microthrombosis with ischemia. It can be a side effect of MH or a precursor to the development of MH. The mortality rate can exceed 80%, and clinical manifestations may be bleeding from mucous membranes, venipuncture sites, and the GI and urinary tracts. Bleeding can range from minimal occult internal bleeding to profuse hemorrhage from all orifices. It is important that all providers are alert for the subtle cues of developing DIC. Refer to Chapter 20 for complete details of DIC.

POSTOPERATIVE NURSING

The postoperative phase begins when the patient is transferred to the PACU and report is given by the anesthesia provider and circulating nurse to the perianesthesia nurse. The postoperative phase ends when the patient is discharged from all phases of postoperative care. The scope of nursing care in this phase covers a wide range of activities, including maintaining the patient's airway, monitoring vital signs, assessing the effects of the anesthetic agents, assessing the patient for complications, and providing comfort and pain relief. Nursing activities also focus on promoting the patient's recovery and initiating the teaching, follow-up care, and referrals essential for recovery and rehabilitation after discharge.

Nursing Management During Postanesthesia Care

Postanesthesia care in some hospitals and ambulatory surgical centers is divided into two phases. In phase I PACU, which is the immediate recovery phase, intensive nursing care is provided. In phase II PACU, the patient is prepared for self-care or care in the hospital, an extended-care setting, or discharge. Recliners rather than stretchers or beds are standard in many phase II units. In facilities without separate phases, the patient remains in the PACU and may be discharged home directly from this unit (ASPAN, 2015).

The nursing management objectives for the nurse in the PACU are to provide care until the patient has recovered from the effects of anesthesia (e.g., until resumption of motor and sensory functions), is oriented or returns to baseline cognition, has stable vital signs and adequate pain control, and shows no evidence of hemorrhage or other complications. All PACU nurses have special skills, including strong assessment skills. The PACU nurse provides frequent monitoring (every 15 minutes) of the patient's pulse, ECG, respiratory rate, blood pressure, and pulse oximeter value (blood oxygen level). In some cases, the end-tidal carbon dioxide ($ETCO_2$) level is monitored as well. The patient's airway may become obstructed because of the latent effects of recent anesthesia, and the PACU nurse must be prepared to assist in reintubation and in handling other emergencies that may occur. Nurses in PACUs must also possess excellent patient teaching skills.

Admitting the Patient to the PACU

Transferring the postoperative patient from the OR to the PACU is the responsibility of the anesthesia provider. During transport from the OR to the PACU, the anesthesia provider remains at the head of the stretcher (to maintain the airway), and a surgical team member remains at the opposite end. Transporting the patient involves special consideration of the incision site, potential vascular changes, and exposure. The surgical incision is considered every time the postoperative patient is moved; many wounds are closed under considerable tension, and every effort is made to prevent further strain on the incision. The patient is positioned so that he or she is not lying on or obstructing drains or drainage tubes. Serious orthostatic hypotension may occur when a patient is moved too quickly from one position to another (e.g., from a lithotomy position to a horizontal position or from a lateral to a supine position), so the patient must be moved slowly and carefully. As soon as the patient is placed on the stretcher or bed, the soiled gown is removed and replaced with a dry gown. The patient is covered with lightweight blankets and warmed. Three side rails may be raised to prevent falls.

Assessing the Patient

The cornerstones of nursing care in the PACU are frequent, skilled assessments of the blood oxygen saturation level, pulse rate and regularity, depth and nature of respirations, skin color, LOC, and ability to respond to commands. The nurse performs a baseline assessment and then checks the surgical site for drainage or hemorrhage and makes sure that all drainage tubes and monitoring lines are connected and functioning. The nurse checks any IV fluids or medications currently infusing and verifies dosage and rate.

After the initial assessment, the patient's vital signs and general physical status are

assessed at least every 15 minutes. Patency of the airway and respiratory function are always evaluated first, followed by assessment of cardiovascular function, the condition of the surgical site, and function of the CNS. Any surgical procedure has the potential for injury due to disrupted neurovascular integrity resulting from prolonged awkward positioning in the OR, manipulation of tissues, inadvertent severing of nerves, or tight bandages. Any orthopedic surgery or surgery involving the extremities carries a risk of peripheral nerve damage. Vascular surgeries, such as replacing sections of diseased peripheral arteries or inserting an arteriovenous graft, put the patient at risk for thrombus formation at the surgical site and subsequent ischemia of tissues distal to the thrombus. Assessment of *circulation, sensation, and mobility* (CSM) includes having the patient move the hand or foot distal to the surgical site through a full range of motion, assessing all surfaces for intact sensation, and assessing peripheral pulses and capillary refill (Rothrock, 2014). Refer to Table 40-3, Assessing for Peripheral Nerve Function for specific nerve monitoring on page 1180. The nurse must be aware of any pertinent information from the patient's history that may be significant (e.g., patient is deaf or hard of hearing, has a history of seizures, has diabetes, is allergic to certain medications or to latex, etc.).

Maintaining a Patent Airway

The primary objective in the immediate postoperative period is to maintain pulmonary ventilation and, thus, prevent hypoxemia (reduced oxygen in the blood) and hypercapnia (excess carbon dioxide in the blood). Both can occur if the airway is obstructed and ventilation is reduced (hypoventilation). Besides checking the provider's orders for and administering supplemental oxygen, the nurse assesses respiratory rate and depth, ease of respirations, oxygen saturation, and breath sounds.

Patients who have experienced prolonged anesthesia usually are unconscious, with all muscles relaxed. This relaxation extends to the muscles of the pharynx. When the patient lies on his or her back, the lower jaw and the tongue fall backward and the air passages become obstructed (Fig. 5-6). This is called *hypopharyngeal obstruction.*

Nursing Alert
Signs of hypopharyngeal occlusion include choking; noisy and irregular respirations; decreased oxygen saturation; and within minutes, a blue, dusky color (cyanosis) of the skin. Because movement of the thorax and the diaphragm does not necessarily indicate that the patient is breathing, the nurse needs to place the palm of her hand at the patient's nose and mouth to feel the exhaled breath.

The anesthesia provider may leave a hard rubber or plastic airway in the patient's mouth or nares to maintain a patent airway. Such a device should not be removed until signs such as gagging indicate that reflex action is returning. Alternatively, the patient may enter the PACU with an endotracheal tube still in place and may require continued mechanical ventilation. The nurse assists in initiating the use of the ventilator and in the weaning and extubation processes. Some patients, particularly those who have had extensive or lengthy surgical procedures, may be transferred from the OR directly to the intensive care unit

(ICU) or from the PACU to the ICU while still intubated and receiving mechanical ventilation.

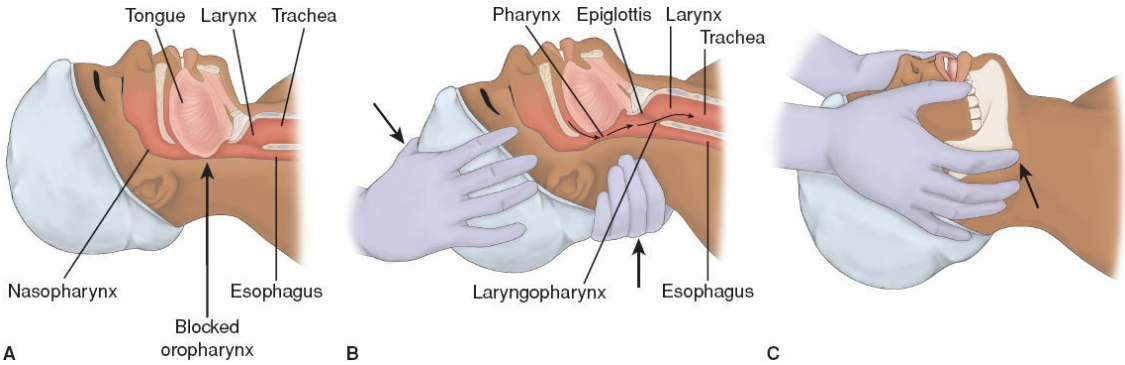

FIGURE 5-6 (A) A hypopharyngeal obstruction occurs when neck flexion permits the chin to drop toward the chest; obstruction almost always occurs when the head is in the midposition. (B) Tilting the head back to stretch the anterior neck structure lifts the base of the tongue off the posterior pharyngeal wall. The direction of the arrows indicates the pressure of the hands. (C) Opening the mouth is necessary to correct valve-like obstruction of the nasal passage during expiration, which occurs in about 30% of unconscious patients. Open the patient's mouth (separate lips and teeth) and move the lower jaw forward, so that the lower teeth are in front of the upper teeth. To regain backward tilt of the neck, lift with both hands at the ascending rami of the mandible.

Respiratory difficulty also can result from excessive secretion of mucus or aspiration of vomitus. Placing the patient on his or her side in the recovery position will allow the fluid to escape from the mouth. The head of the bed is elevated 15 to 30 degrees unless contraindicated, and the patient is closely monitored to maintain the airway as well as to minimize the risk of aspiration. If vomiting occurs, the patient is turned to the side to prevent aspiration, and the vomitus is collected in the emesis basin. Mucus or vomitus obstructing the pharynx or the trachea is suctioned with a pharyngeal suction tip or a nasal catheter introduced into the nasopharynx or oropharynx. Caution is necessary in suctioning the throat of a patient who has had a tonsillectomy or other oral or laryngeal surgery because of risk of bleeding and discomfort.

Maintaining Cardiovascular Stability

To monitor cardiovascular stability, the nurse assesses the patient's mental status; vital signs; cardiac rhythm; skin temperature, color, and moisture; and urine output. Central venous pressure, pulmonary artery pressure, and arterial lines are monitored if the patient's condition requires such assessment. The nurse also assesses the patency of all IV lines. The primary cardiovascular complications seen in the PACU include hypotension and shock, hemorrhage, hypertension, and arrhythmias.

Hypotension and Shock

Hypotension can result from blood loss, hypoventilation, position changes, pooling of blood in the extremities, or side effects of medications and anesthetics. The most common cause is loss of circulating volume through blood and plasma loss. If the amount of blood loss exceeds 500 mL (especially if the loss is rapid), replacement is usually indicated.

Fluid loss is a significant potential problem for surgical patients, owing to their

preoperative NPO status, evaporation of fluid intraoperatively, and significant shifting of sodium-rich fluid from the intravascular space to the extracellular space because of inflammatory process, trauma, or infection. The fluid lost from the blood stream sequesters in the tissues or "third spaces," which may be noted by the presence of edema. It is important for the nurse to understand that, although the patient may clinically present with edema (often associated with fluid volume excess), a hypovolemia exists intravascularly that can progress to shock if fluids are not managed adequately. In addition, the nurse considers fluid loss related to evaporation in the OR. For example, it is estimated that, with surgery involving an open abdomen, insensible fluid losses can reach 500 to 1,000 mL/hr (Rothrock, 2014). When evaluating the patient's fluid volume status, the nurse considers fluid loss from the nasogastric tube, urinary output, drains, estimated blood loss (EBL), and evaporation.

Shock, one of the most serious postoperative complications, can result from hypovolemia and decreased intravascular volume. The types of shock are classified as hypovolemic, cardiogenic, neurogenic, anaphylactic, and septic. See Chapter 54 for more information on shock.

Hemorrhage

Hemorrhage is an uncommon yet serious complication of surgery that can result in death. It can present insidiously or emergently at any time in the immediate postoperative period or up to several days after surgery (Table 5-7). When blood loss is extreme, the patient is apprehensive, restless, agitated and thirsty; the skin is cold, moist, and pale. The pulse rate increases, the temperature falls, hypotension is seen with a narrowed pulse pressure (difference between systolic and diastolic pressure; normal pulse pressure is approximately 40 mm Hg), and respirations are rapid and deep, often of the gasping type spoken of as "air hunger." Capillary refill is prolonged (normal is less than 2 seconds), and there is diminished urine output. If hemorrhage progresses untreated, cardiac output decreases, arterial and venous blood pressure and hemoglobin levels fall rapidly, the lips and the conjunctivae become pale, and the patient grows weaker and obtunded but remains conscious until near death.

TABLE 5-7 Classifications of Hemorrhage

Classification	Defining Characteristic
Time Frame	
Primary	Hemorrhage occurs at the time of surgery.
Intermediary	Hemorrhage occurs during the first few hours after surgery when the rise of blood pressure to its normal level dislodges insecure clots from untied vessels.
Secondary	Hemorrhage may occur some time after surgery if a suture slips because a blood vessel was not tied securely, became infected, or was eroded by a drainage tube.
Type of Vessel	
Capillary	Hemorrhage is characterized by a slow, general ooze.
Venous	Darkly colored blood bubbles out quickly.
Arterial	Blood is bright red and appears in spurts with each heartbeat.
Visibility	
Evident	Hemorrhage is on the surface and can be seen.
Concealed	Hemorrhage is in a body cavity and cannot be seen.

Nursing Alert

The term obtunded comes from the root word, obtund, which means "dulled or less sharp" and is used to describe a patient who presents with less than full alertness (altered LOC). Rather than use terms like stuporous or obtunded, it is beneficial to

describe the behavior in detail rather than use a broad term.

The initial therapeutic measures are to transfusing blood or blood products and determining the cause of hemorrhage. The surgical site and incision should always be inspected for bleeding. If bleeding is evident, a sterile gauze pad and a pressure dressing are applied to reinforce the original surgical dressing, and the site of the bleeding is elevated to heart level if possible. The patient is placed in the shock position (flat on back; legs elevated at a 20-degree angle; knees kept straight). If hemorrhage is suspected but cannot be visualized, the patient may be taken back to the OR for emergency exploration of the surgical site.

In addition, the nurse should be aware of any special considerations related to blood loss replacement. Certain patients may decline blood transfusions for religious or cultural reasons and may identify this request on their advance directives or living will.

Nursing Alert
Always wear gloves when handling blood. To prevent warming of the blood, administration should begin within 30 minutes of retrieving the blood. If this is not possible, the blood should be returned to the blood bank. Baseline vital signs are obtained. Normal saline injection (0.9% sodium chloride) is used to initiate a transfusion of red blood cells (RBCs), whole blood, platelets, or leukocytes. Hypotonic or hypertonic solutions are never used because hemolysis of the RBCs occurs. No medications or other solutions except 0.9% sodium chloride should be added to or infused simultaneously through the same blood set. Refer to Chapter 20 for more details on blood transfusion.

Nursing Alert
Hemoglobin levels of 7 to 9 g/dL are generally tolerated by most asymptomatic patients. Symptomatic patients with cardiac, pulmonary, or cerebrovascular disease may require RBC transfusions to achieve higher hemoglobin levels (Rosen, 2015). The nurse understands that the transfusion of 1 unit of packed RBCs should increase the hemoglobin level by 1 g/dL and the hematocrit by 3%.

Hypertension and Arrhythmias

Hypertension is common in the immediate postoperative period secondary to sympathetic nervous system stimulation from pain, hypoxia, or bladder distention. Arrhythmias are associated with electrolyte imbalance, altered respiratory function, pain, hypothermia, stress, and anesthetic agents. Both hypertension and arrhythmias are managed by treating the underlying causes.

Relieving Pain and Anxiety

IV opioid analgesics are administered judiciously and often in the PACU. IV opioids provide immediate pain relief and are short acting, thus minimizing the potential for drug interactions or prolonged respiratory depression while there are anesthetics still active in the patient's system. The PACU nurse monitors the patient's physiologic status, manages pain, and provides psychological support in an effort to relieve the patient's fears and concerns.

The nurse checks the medical record for special needs and concerns of the patient. When the patient's condition permits, a close member of the family may visit in the PACU. This often decreases the family's anxiety and makes the patient feel more secure.

Controlling Nausea and Vomiting

Postoperative and postdischarge nausea and vomiting (PONV/PDNV) is one of the most commonly occurring postoperative complications, frequently resulting in prolonged postoperative stay, unanticipated admission, and increased health care costs. Health care providers have yet to reach consensus regarding an evidence-based multidisciplinary, multimodel treatment approach to PONV/PDNV. The nurse should intervene at the patient's first report of nausea to control the problem rather than wait for it to progress to vomiting.

Many medications are available to control nausea and vomiting without oversedating the patient; they are commonly administered during surgery, as well as in the PACU. Medications such as metoclopramide (Reglan), prochlorperazine (Compazine), promethazine (Phenergan), dimenhydrinate (Dramamine), hydroxyzine (Vistaril, Atarax), and scopolamine (Transderm-Scop) are commonly prescribed (Rothrock, 2014). Although it is costly, ondansetron (Zofran) is frequently used as an effective antiemetic with few side effects.

ASPAN has developed a practice guideline for nurses to treat this postoperative complication (ASPAN, 2015). It includes the identification of risk factors (e.g., for adults undergoing general inhaled anesthesia, risks include female gender, being a nonsmoker, history of PONV or motion sickness, and the use of postoperative intravenous opioids (Apfel, 2015). Recommended treatments can range from no prophylaxis treatment to several antiemetic combinations for patients at higher risk (ASPAN, 2014).

Preparing for Discharge from the PACU

A patient remains in the PACU until fully recovered from the anesthetic agent. Indicators of recovery include stable blood pressure, adequate respiratory function, adequate oxygen saturation level compared with baseline, and spontaneous movement or movement on command. Discharge criteria should be developed collaboratively with the anesthesia department using the standards below (ASPAN, 2015):

- Stable vital signs
- Return to baseline LOC
- Uncompromised pulmonary function and adequate airway
- Pulse oximetry readings indicating adequate blood oxygen saturation
- Intake and output
- Nausea and vomiting absent or under control
- Pain level
- Sensory and motor function
- Condition of surgical site

Many hospitals use a scoring system (e.g., Aldrete score) to determine the patient's general condition and readiness for transfer from the PACU. Throughout the recovery

period, the patient's physical signs are observed and evaluated by means of a scoring system based on a set of objective criteria (Aldrete & Wright, 1992; Theodora, 2015) that includes consciousness, activity, breathing, pulse oximetry, and circulation. The patient is assessed at regular intervals (e.g., every 15 minutes), and a total score is calculated and recorded on the assessment record. Patients remain in the PACU until their condition improves or they can be transferred safely to an ICU or surgical unit, or discharged (depending on their preoperative baseline score).

The patient is discharged from the phase I PACU by the anesthesia provider to the critical care unit, the medical-surgical unit, the phase II PACU, or home with a responsible family member.

Nursing Management of Direct Discharge Home

To ensure patient safety and recovery, expert patient teaching and discharge planning are necessary when a patient undergoes same-day or ambulatory surgery. Because anesthetics cloud memory for concurrent events, verbal and written instructions should be given to both the patient and the adult who will be accompanying the patient home. Alternative formats (e.g., large print, Braille) of instructions or use of a sign interpreter may be required to ensure patient and family understanding. A translator may be required if the patient and family members do not understand English.

The patient and caregiver (e.g., family member or friend) are informed about expected outcomes and immediate, anticipated postoperative changes. The nurse provides written instructions about wound care, activity and dietary recommendations, medications, and follow-up visits to the surgeon. The patient's caregiver at home is provided with verbal and written instructions about what to look for and about the actions to take if complications occur. Prescriptions and medication reconciliation are given to the patient and/or caregiver. The nurse's or surgeon's telephone number is provided, and the patient and caregiver are encouraged to call with questions and to schedule follow-up appointments.

Nursing Alert

Medication reconciliation is the process of creating the most accurate list possible of all medications a patient is taking—including drug name, dosage, frequency, and route—and comparing that list against the provider's admission, transfer, and/or discharge orders, with the goal of providing correct medications to the patient at all transition points within the hospital (Institute for Healthcare Improvement [IHI], 2016).

Although recovery time varies depending on the type and extent of surgery and the patient's overall condition, instructions usually advise limited activity for 24 to 48 hours. During this time, the patient should not drive a vehicle, drink alcoholic beverages, or perform tasks that require energy or skill. Fluids may be consumed as desired, and smaller-than-normal amounts may be eaten at mealtime. Patients are cautioned not to make important decisions at this time, because the medications, anesthesia, and surgery may affect their decision-making ability.

Nursing Management of the Hospitalized Postoperative Patient

Given the complexities of patient care treatment and management, multisystem disease, and workplace demands, it is important that the traditional "nurse-to-nurse" patient hand-off now be a comprehensive, thorough, and sophisticated account of patient information focusing on patient safety (AORN, 2015). Hand-off communication must also allow opportunity for questions to be answered. The *SBAR* format is an increasingly popular approach to the standardization of relaying of this crucial information. SBAR is a mnemonic for:

Situation (What is happening at the present time?)
Background (What are the circumstances leading up to this situation?)
Assessment (What do I think the problem is?)
Recommendation (What should we do to correct the problem?) (IHI, 2017).

Whatever approach is used in each institution, it is essential that the method is used by all staff members during all hand-offs across all phases of surgical patient care.

Receiving the Patient in the Clinical Unit

The patient's room is readied by assembling the necessary equipment and supplies: IV pole, drainage receptacle holder, suction equipment, oxygen, emesis basin, tissues, disposable pads, blankets, and postoperative documentation. When the call comes to the unit about the patient's transfer from the PACU, the need for any additional items should be communicated. The PACU nurse reports data about the patient to the receiving nurse. The report includes relevant demographic data, medical diagnosis, procedure performed, type of anesthesia, comorbid conditions, allergies, unexpected intraoperative events, EBL, types and amounts of fluids received, medications administered for pain, types of IV fluids or medications infused, whether the patient has voided, and information that the patient and family have received about the patient's condition. Usually, the surgeon speaks to the family after surgery and relays the general condition of the patient. The receiving nurse reviews the postoperative orders, admits the patient to the unit, performs an initial assessment, and attends to the patient's immediate needs.

Providing Care for the First 24 Hours After Surgery

During the first 24 hours after surgery, nursing care of the hospitalized patient on the general medical-surgical unit involves continuing to help the patient recover from the effects of anesthesia, frequently assessing the patient's physiologic status, monitoring for complications, managing pain, and implementing measures designed to achieve the long-range goals of independence with self-care, successful management of the therapeutic regimen, discharge to home, and full recovery. In the initial hours after admission to the clinical unit, primary concerns include adequate ventilation, hemodynamic stability, incisional pain, surgical site integrity, nausea and vomiting, neurologic status, and spontaneous voiding. The pulse rate, blood pressure, respiration rate, and oxygen saturation are recorded per institutional policy. Typically, vital signs are recorded frequently until

stable and then regularly until the patient is discharged. Frequency of vital sign measurements will depend upon the nature of the operation and the clinical course. Thereafter, vital signs are measured less frequently if they remain stable.

Typically, patients begin to return to their usual state of health several hours after surgery or after waking up the next morning. Although pain may still be intense, many patients feel more alert, less nauseous, and less anxious. They have begun their breathing and leg exercises, and many will have dangled their legs over the edge of the bed, stood, and ambulated a few feet or been assisted out of bed to the chair at least once. Many will have tolerated a light meal and had IV fluids discontinued. The focus of care shifts from intense physiologic management and symptomatic relief of the adverse effects of anesthesia to regaining independence with self-care and preparing for discharge (all discussed in the following nursing process section).

NURSING PROCESS

The Hospitalized Patient Recovering from Surgery

ASSESSMENT

Assessment of the hospitalized postoperative patient includes monitoring vital signs, completing a review of the systems, and observing for potential postoperative complications on arrival of the patient to the clinical unit and at regular intervals thereafter.

Respiratory status is important, because pulmonary complications are among the most frequent and serious problems encountered by the surgical patient. The nurse observes for airway patency, watching for laryngeal edema, which is often heralded by inspiratory stridor. The quality of respirations, including depth, rate, and sound, are assessed regularly. Chest auscultation verifies that breath sounds are normal (or abnormal) bilaterally, and the findings are documented as a baseline for later comparisons. Pulse oximetry is assessed to monitor respiratory status. Often, because of the effects of analgesic and anesthetic medications, respirations are slow. Shallow and rapid respirations may be caused by pain, constricting dressings, gastric dilation, abdominal distention, or obesity. Noisy breathing may be due to obstruction by secretions or the tongue.

The nurse assesses the patient's pain level using a verbal or visual analog scale and assesses the characteristics of the pain. The patient's appearance, pulse, respirations, blood pressure, skin color (adequate or cyanotic), and skin temperature (cold and clammy, warm and moist, or warm and dry) are clues to cardiovascular function. When the patient

arrives in the clinical unit, the surgical site is observed for bleeding, type and integrity of dressings, and functioning of all tubes and drains.

The nurse also assesses the patient's mental status and LOC, speech, and orientation, and compares them with the preoperative baseline. Although a change in mental status or postoperative restlessness may be related to anxiety, pain, or medications, it may also be a symptom of oxygen deficit, hypoglycemia, or hemorrhage. These serious causes must be investigated and excluded before other causes are pursued.

General discomfort resulting from lying in one position on the operating table, the surgeon's handling of tissues, the body's reaction to anesthesia, and anxiety are also common causes of restlessness. These discomforts may be relieved by administering the prescribed analgesics, changing the patient's position frequently, and assessing and alleviating the cause of anxiety. Drainage-soaked bandages may cause discomfort. The nurse reinforces or changes the dressing completely, as prescribed by the provider, which may make the patient more comfortable. The bladder is assessed for distention, because urinary retention can also cause restlessness.

DIAGNOSIS

Major nursing diagnoses may include the following:

- Risk for ineffective airway clearance related to depressed respiratory function, pain, and bed rest
- Acute pain related to surgical incision
- Decreased cardiac output related to shock or hemorrhage
- Risk for activity intolerance related to generalized weakness secondary to surgery
- Impaired skin integrity related to surgical incision and drains
- Ineffective thermoregulation related to surgical environment and anesthetic agents
- Risk for imbalanced nutrition, less than body requirements related to decreased intake and increased need for nutrients secondary to surgery
- Risk for constipation related to effects of medications, surgery, dietary change, and immobility
- Impaired urinary elimination related to urinary retention
- Risk for injury related to surgical procedure/positioning or anesthetic agents
- Anxiety related to surgical procedure
- Risk for ineffective self-health management of therapeutic regimen related to wound care, dietary restrictions, activity recommendations, medications, follow-up care, or signs and symptoms of complications

PLANNING

The major goals for the patient include optimal respiratory function, relief of pain, optimal cardiovascular function, increased activity tolerance, unimpaired wound healing, maintenance of body temperature, and maintenance of nutritional balance. Further goals

include resumption of usual pattern of bowel and bladder elimination, identification of any perioperative positioning injury, acquisition of sufficient knowledge to manage self-care after discharge, and absence of complications.

NURSING INTERVENTIONS

PROMOTING RESPIRATORY FUNCTION

Increasing age, smoking, COPD, long duration of surgery, and incisional site (chest and upper abdomen), as well as comorbidities, such as heart failure, arrhythmias, diabetes mellitus, and patients with swallowing disorders, are associated with an increased risk for postoperative pulmonary complications. Respiratory depressive effects of opioid medications, decreased lung expansion secondary to pain, operative position that may have limited maximum respiratory function, impaired mucociliary clearance of secretions, and decreased mobility combine to put the patient at risk for common respiratory complications, particularly atelectasis (alveolar collapse; incomplete expansion of the alveoli), pneumonia, and hypoxemia (Rothrock, 2014). Atelectasis remains a risk for the patient who is not moving well or ambulating, who is not performing deep breathing or coughing out retained secretions, or who is not using an incentive spirometer. Signs and symptoms include decreased breath sounds over the affected area, crackles, and cough. Pneumonia is characterized by chills and fever, tachycardia, and tachypnea. Cough may or may not be present and may or may not be productive. Risk factors for postoperative pneumonia are patients with COPD, impaired cough, and acute bronchitis or lower airway infections.

The types of hypoxemia that can affect postoperative patients are subacute and episodic. Subacute hypoxemia is a constant low level of oxygen saturation, although breathing appears normal. Episodic hypoxemia develops suddenly, and the patient may be at risk for cerebral dysfunction, myocardial ischemia, and cardiac arrest. Risk for hypoxemia is present in patients who have undergone major surgery (particularly thoracic or abdominal), are obese, or have pre-existing pulmonary problems. Hypoxemia can be detected by pulse oximetry, which measures blood oxygen saturation. Factors that may affect the accuracy of pulse oximetry readings include cold extremities, tremors, atrial fibrillation, and acrylic nails. Current research reveals that different colored nail polish demonstrated altered pulse oximetry readings in healthy subjects (Hakverdioğ lu Yönt, Akin Korhan, & Dizer, 2014), thus it seems reasonable that nail polish should be removed prior to SpO_2 (peripheral capillary oxygen saturation) determination to ensure accurate readings.

Preventive measures and timely recognition of signs and symptoms help avert pulmonary complications. Strategies to prevent respiratory complications include use of an incentive spirometer and deep-breathing exercises, and sitting in an upright position that is unrestricted, thus allowing for maximum pulmonary expansion. Mobilization of patients is an important nursing intervention that will assist in maximizing lung expansion and improving circulation, thus facilitating gas exchange while additionally

decreasing the risk of DVT (Rothrock, 2014). Crackles indicate static pulmonary secretions that need to be mobilized by coughing retained secretions and deep-breathing exercises. When a mucus plug obstructs one of the bronchi entirely, the pulmonary tissue beyond the plug collapses, and massive atelectasis results. Thus, coughing is also encouraged to dislodge mucus plugs.

Nursing Alert
It is important to consider that coughing is a forced expiratory maneuver, thus the nurse should encourage the patient to use the incentive spirometer or take deep breaths after coughing to re-expand alveoli. A common recommendation for use of the incentive spirometer is 10 deep breaths every hour while awake.

To clear secretions and prevent pneumonia, the nurse encourages the patient to turn frequently (every 2 hours) and take deep breaths hourly. These pulmonary exercises should begin as soon as the patient arrives on the clinical unit and continue until the patient is discharged. Even if he or she is not fully awake from anesthesia, the patient can be asked to take several deep breaths. This helps expel residual anesthetic agents, mobilize secretions, and prevent alveolar collapse (atelectasis). Careful splinting of abdominal or thoracic incision sites helps the patient overcome the fear that the exertion of coughing might open the incision. Analgesic agents are administered to permit more effective coughing, and oxygen is administered as prescribed to prevent or relieve hypoxia. To encourage lung expansion, the patient is encouraged to yawn or take sustained maximal inspirations to create a negative intrathoracic pressure and expand lung volume to total capacity.

Nursing Alert
Coughing is contraindicated in patients who have head injuries or who have undergone intracranial surgery (because of the risk for increasing intracranial pressure), as well as in patients who have undergone eye surgery (because of the risk for increasing intraocular pressure) or plastic surgery (because of the risk for increasing tension on delicate tissues).

RELIEVING PAIN

Most patients experience some pain after a surgical procedure. Many factors (motivational, affective, cognitive, and emotional) influence the pain experience. The degree and severity of postoperative pain and the patient's tolerance for pain depend on the incision site, the nature of the surgical procedure, the extent of surgical trauma, the type of anesthetic agent, and how the agent was administered. The Agency for Healthcare Research and Policy reports that the most reliable indicator of the existence and intensity of pain is the patient's self-report. Therefore it is important to complete a thorough preoperative pain evaluation and develop pain goals for the surgical patient. This preparation, which includes information such as what to expect, how the pain will be

managed, how to report, and reassurance, can contribute to reducing anxiety and, possibly, the level of postoperative pain experienced. Refer to Chapter 7 for details on patient-controlled analgesia (PCA) and epidural infusions.

For pain that is difficult to control, a subcutaneous pain management system may be used. This is a silicone catheter that is inserted at the site of the affected area. The catheter is attached to a pump that delivers a continuous amount of local anesthetic at a specific amount determined and prescribed by the provider.

Complete absence of pain in the area of the surgical incision may not occur for a few weeks, depending on the site and nature of the surgery, but the intensity of postoperative pain gradually subsides on subsequent days. However, pain control continues to be an important concern for the patient and the nurse. Effective pain management allows the patient to participate in care, perform deep-breathing and leg exercises, and tolerate activity. Poor pain control contributes to postoperative complications and increased length of stay. The nurse continues to assess the pain level, the effectiveness of analgesic agents, and factors that influence pain tolerance (e.g., energy level, stress level, cultural background, meaning of pain to the patient). The nurse explains that taking an analgesic agent before the pain becomes intense is more effective and offers medication to the patient at appropriate intervals rather than waiting for the patient to request it.

Nonpharmacologic pain relief measures, such as imagery, music, relaxation, massage, application of heat or cold (if prescribed), and distraction, are discussed in Chapter 7.

PROMOTING CARDIAC OUTPUT

If signs and symptoms of shock or hemorrhage occur, treatment and nursing care are implemented as described previously in the discussion of care in the PACU.

Although most patients do not hemorrhage or go into shock, changes in circulating volume, the stress of surgery, and the effects of medications and preoperative preparations all affect cardiovascular function. IV fluid replacement is standard for up to 24 hours after surgery or until the patient is stable and tolerating oral fluids. Close monitoring is indicated to detect and correct conditions such as fluid volume deficit, altered tissue perfusion, and decreased cardiac output, all of which can increase the patient's discomfort, place him or her at risk of complications, and prolong the hospital stay. Some patients are at risk of fluid volume excess secondary to existing cardiovascular or renal disease, advanced age, or the release of adrenocorticotropic hormone and antidiuretic hormone as a result of the stress of surgery (Rothrock, 2014). Consequently, fluid replacement must be managed carefully, and intake and output records must be accurate.

Nursing management includes assessing the patency of the IV lines and ensuring that the correct fluids are administered at the prescribed rate. Intake and output, including emesis and output from wound drainage systems, are recorded separately and totaled to determine fluid balance. If the patient has an indwelling urinary catheter, hourly outputs are monitored, and rates of less than 30 mL/hr (0.5–1 mL/kg/hr) are reported; if the patient is voiding, an output of less than 240 mL per 8-hour shift is reported. Levels of electrolytes, hemoglobin, and hematocrit are monitored. Decreased hemoglobin and

hematocrit levels can indicate blood loss or dilution of circulating volume by IV fluids. Recall that the fluid changes associated with surgery cause fluid extravasation into the tissues. This "third spaced" fluid usually returns to the intravascular space by postop day (POD) 2 or 3. At this time period, the nurse assesses for evidence of fluid volume excess. If hemodilution is contributing to the decreased hemoglobin and hematocrit levels, the nurse expects that, as the stress response abates and fluids are mobilized and excreted, the hemoglobin and hematocrit will rise.

Venous stasis from dehydration, immobility, and pressure on leg veins during surgery put the patient at risk for DVT. Leg exercises and frequent position changes are initiated early in the postoperative period to stimulate circulation. Patients should avoid positions that compromise venous return, such as raising the bed's knee gatch, placing a pillow under the knees, sitting for long periods, and dangling the legs with pressure at the back of the knees. Venous return is promoted by elastic compression stockings, sequential compression devices (SCDs), and early ambulation. Early ambulation has a significant effect on recovery and the prevention of complications and can begin, in many instances, on the evening of surgery. Postoperative activity orders are checked before the patient is assisted in getting out of bed. Sitting up at the edge of the bed for a few minutes may be all that the patient who has undergone a major surgical procedure can tolerate at first.

ENCOURAGING ACTIVITY

Most surgical patients are encouraged to be out of bed as soon as possible. Early ambulation reduces the incidence of postoperative complications, such as atelectasis, hypostatic pneumonia, GI discomfort, and circulatory problems. Ambulation improves ventilation and reduces the stasis of bronchial secretions in the lungs. It also reduces postoperative abdominal distention by increasing GI tract and abdominal wall tone and stimulating peristalsis. Early ambulation prevents stasis of blood by increasing the rate of circulation in the extremities; as a result, thrombophlebitis or phlebothrombosis occurs less frequently. Often pain is decreased when early ambulation is possible, and the hospital stay is shorter and less costly, a further advantage to the patient and the hospital.

Despite the advantages of early ambulation, patients may be reluctant to get out of bed on the evening of surgery. Reminding them of the importance of early mobility in preventing complications may help patients overcome their fears. When a patient gets out of bed for the first time, orthostatic hypotension, also called postural hypotension, is a concern. Orthostatic hypotension is an abnormal drop in blood pressure that occurs as the patient changes from a supine to a standing position. It is common after surgery because of changes in circulating blood volume and bed rest. Approximately 500 to 700 mL of blood momentarily shifts to the lower body when changing position to standing from supine, resulting in decreased venous return and arterial pressure. Signs and symptoms include an increase in heart rate of 15 beats per minute (bpm) with a decrease in systolic pressure of 20 mm Hg or a 10 mm Hg decrease in diastolic pressure with position change (typically within 3 minutes). Patients often also complain of weakness, dizziness, leg buckling, and visual blurring. Older adults are at increased risk for

orthostatic hypotension secondary to age-related changes in vascular tone. Refer to Chapter 12 for details on assessing for orthostatic hypotension.

To assist the postoperative patient in getting out of bed for the first time after surgery, the nurse:

- Helps the patient move gradually from the lying position to the sitting position by raising the head of the bed, and encourages the patient to splint the incision when applicable. It may be easier for postoperative patients with abdominal incisions to roll on their side first with the head of the bed elevated. Once the patient is on his side, the nurse has the patient move his feet off the side of the bed and push off his elbow into a sitting position.
- Positions the patient completely upright (sitting) and turned, so that both legs are hanging over the edge of the bed. The nurse allows the patient to sit for a few minutes and assesses for dizziness and vital sign changes if indicated. If patient is asymptomatic, the nurse asks the patient to push down with his arms on the mattress and stand up.
- Helps the patient stand beside the bed

After becoming accustomed to the upright position, the patient may start to walk. The nurse should be at the patient's side to give physical support and encouragement. Care must be taken not to tire the patient; the extent of the first few periods of ambulation varies with the type of surgical procedure and the patient's physical condition and age.

Whether or not the patient can ambulate early in the postoperative period, bed exercises are encouraged to improve circulation. Unless contraindicated by the operative event, bed exercises consist of the following:

- Arm exercises (full range of motion, with specific attention to abduction and external rotation of the shoulder)
- Hand and finger exercises
- Foot exercises to prevent DVT, foot drop, and toe deformities, and to aid in maintaining good circulation
- Leg flexion and leg-lifting exercises to prepare the patient for ambulation
- Abdominal and gluteal contraction exercises

TABLE 5-8 Phases of Wound Healing

Phase	Duration	Events
Inflammatory (also called lag or exudative phase)	1–4 days	Blood clot forms Wound becomes edematous Debris of damaged tissue and blood clot are phagocytosed
Proliferative (also called fibroblastic or connective tissue phase)	5–20 days	Collagen produced Granulation tissue forms Wound tensile strength increases
Maturation (also called differentiation, resorptive, remodeling, or plateau phase)	21 days to months or even years	Fibroblasts leave wound Tensile strength increases Collagen fibers reorganize and tighten to reduce scar size

Hampered by pain, dressings, IV lines, or drains, many patients cannot engage in activity without assistance. Prolonged inactivity may lead to pressure ulcers, DVT, atelectasis, constipation, anorexia, and malaise. Helping the patient increase his or her activity level on the first postoperative day is an important nursing function. One way to increase the patient's activity is to have the patient perform as much routine hygiene care as possible. Setting up the patient to bathe with a bedside wash basin or, if possible, assisting the patient to the bathroom to sit in a chair at the sink not only gets the patient moving but also helps restore a sense of self-control and prepares the patient for discharge.

To be discharged safely to home, patients need to be able to ambulate a functional distance (e.g., length of the house or apartment), get in and out of bed unassisted, and be independent with toileting. Patients can be asked to perform as much as they can and then to call for assistance. The patient and the nurse can collaborate on a schedule for progressive activity that includes ambulating in the room and hallway and sitting out of bed in the chair. Assessing the patient's vital signs and oxygen saturation before, during, and after a scheduled activity helps the nurse and patient determine the rate of progression. By providing physical support, the nurse maintains the patient's safety; by communicating a positive attitude about the patient's ability to perform the activity, the nurse promotes the patient's confidence. The nurse should make sure the patient continues to perform bed exercises, wears pneumatic compression or elastic compression stockings when in bed, and rests as needed. If the patient has had orthopedic surgery of the lower extremities or will require a mobility aid (i.e., walker, crutches) at home, a physical therapist may be involved the first time the patient gets out of bed to teach him or her to ambulate safely or to use the mobility aid correctly. If patients are required to climb steps at home, their ability to do so must be assessed before discharge.

PROMOTING WOUND HEALING

Ongoing assessment of the surgical site involves inspection for approximation of wound edges, integrity of sutures or staples, redness, discoloration, warmth, swelling, unusual tenderness, or drainage. The area around the wound should also be inspected for a reaction to tape or trauma from tight bandages.

Principles of Wound Healing

With shorter hospital stays, much of the healing takes place at home, and both the hospital and home care nurse should be informed about the principles of wound healing. Surgical wound healing occurs in three phases: inflammatory, proliferative, and maturation (Table 5-8). Wounds also heal by different mechanisms, depending on the condition of the wound. These mechanisms are first-, second-, and third-intention wound healing (Fig. 5-7) (Rothrock, 2014).

First-Intention Healing. Wounds made aseptically with a minimum of tissue destruction that are properly closed will heal with little tissue reaction by first intention (primary union). When wounds heal by first-intention healing, granulation tissue is not visible

and scar formation is minimal. Postoperatively, many of these wounds are covered with a dry sterile dressing. If a cyanoacrylate tissue adhesive (LiquiBand®) was used to close the incision without sutures, a dressing is contraindicated.

Second-Intention Healing. Second-intention healing (granulation) occurs in infected wounds (abscess) or in wounds in which the edges have not been approximated. When an abscess is incised, it collapses partly, but the dead and dying cells forming its walls are still being released into the cavity. For this reason, drainage tubes or gauze packing is inserted into the abscess pocket to allow drainage to escape easily. Gradually, the necrotic material disintegrates and escapes, and the abscess cavity fills with a red, soft, sensitive tissue that bleeds easily. This tissue is composed of minute, thin-walled capillaries and buds that later form connective tissue. These buds, called granulations, enlarge until they fill the area left by the destroyed tissue. Healing is complete when skin cells (epithelium) grow over these granulations. This method of repair is called healing by granulation, and it takes place whenever pus is formed or when loss of tissue has occurred for any reason. When the postoperative wound is to be allowed to heal by secondary intention, it is usually packed with saline-moistened sterile dressings and covered with a dry sterile dressing.

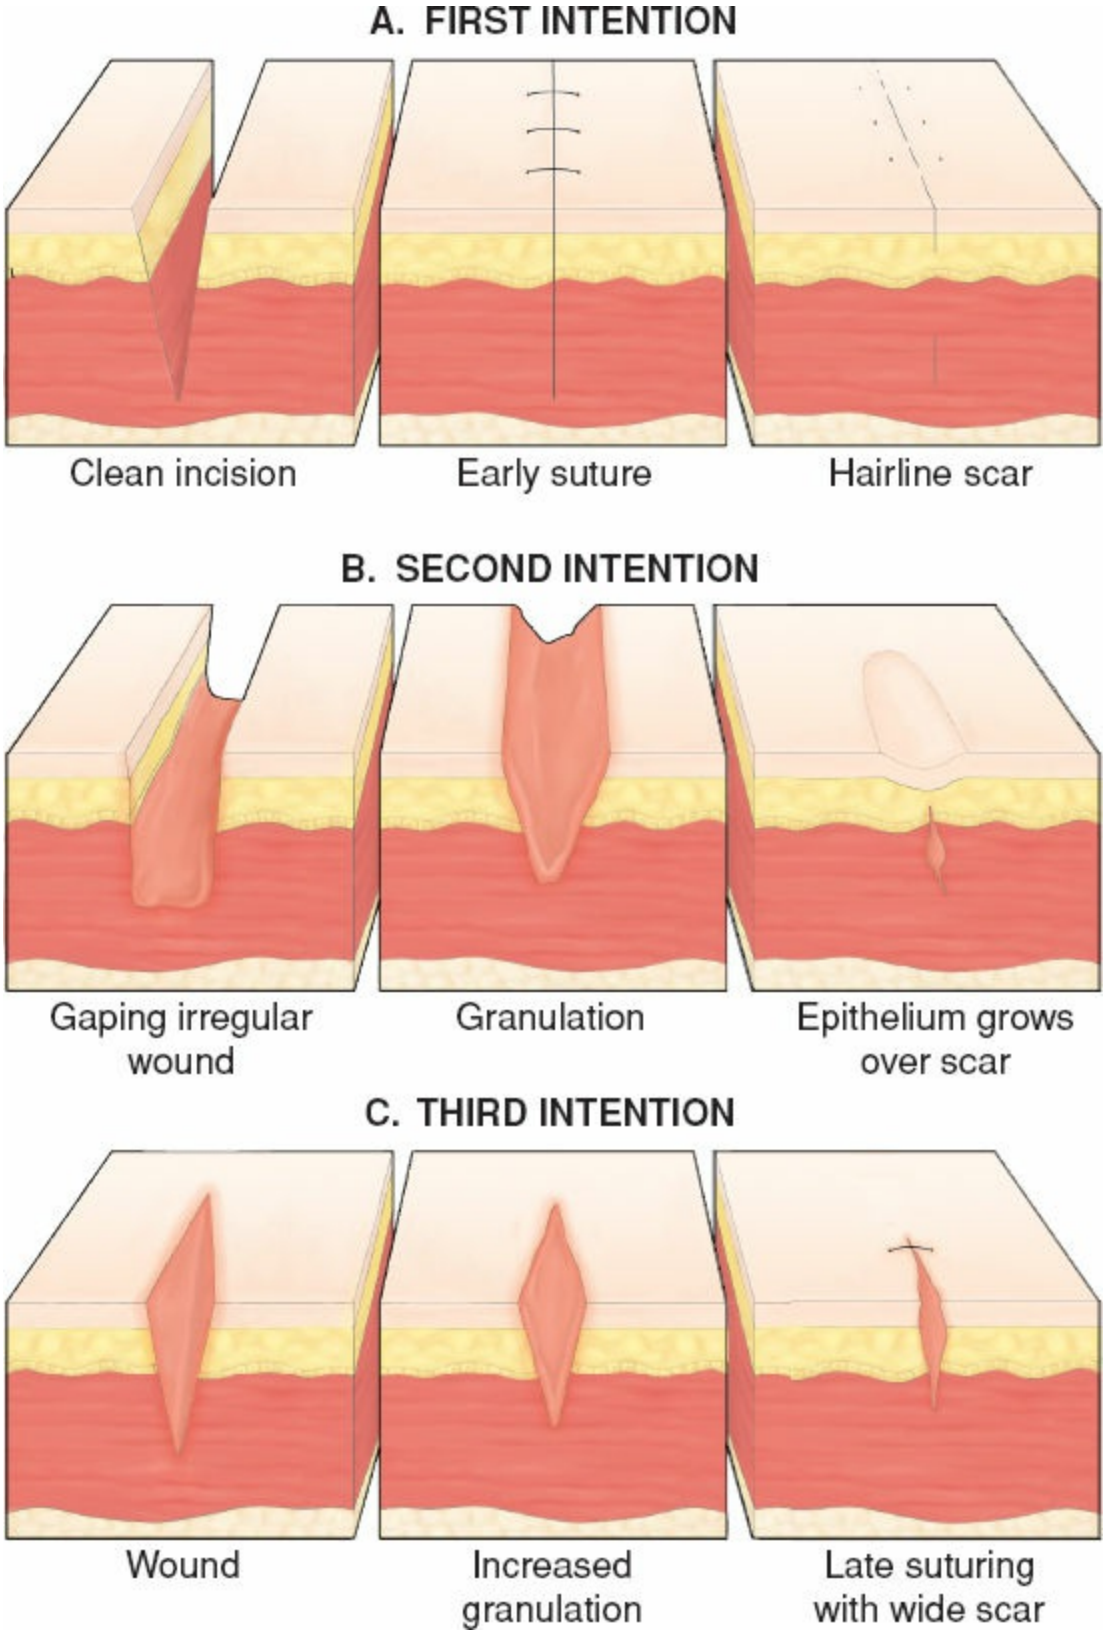

FIGURE 5-7 Types of wound healing: first-intention healing, second-intention healing, and third-intention healing.

Third-Intention Healing. Third-intention healing (secondary suture) is used for deep wounds that either have not been sutured early or break down and are resutured later,

thus bringing together two opposing granulation surfaces. This results in a deeper and wider scar. These wounds are also packed postoperatively with moist gauze and covered with a dry sterile dressing.

Alternatively, wound vacuum-assisted closure (VAC) may be used in the management of open wounds (Fig. 5-8). It applies subatmospheric pressure to the wound surface and consists of a foam dressing, semiocclusive adhesive cover, fluid collection system, and suction pump. The wound VAC, also known as negative pressure therapy, has been shown to speed up the development of granulation tissue. Contraindications include wounds with necrotic tissue; malignancy within the wound; exposed arteries, veins, or vascular grafts; and untreated osteomyelitis (Adams, Heffernan, & Cioffi, 2013). Vacuum dressings, if used, are usually replaced within 24 to 72 hours (Rosen, 2015).

As a wound heals, many factors, such as adequate nutrition, cleanliness, rest, and position determine how quickly healing occurs. Specific nursing assessments and interventions that address these factors and help promote wound healing are presented in Table 5-9. Management of surgical drains and dressings is discussed in more detail below.

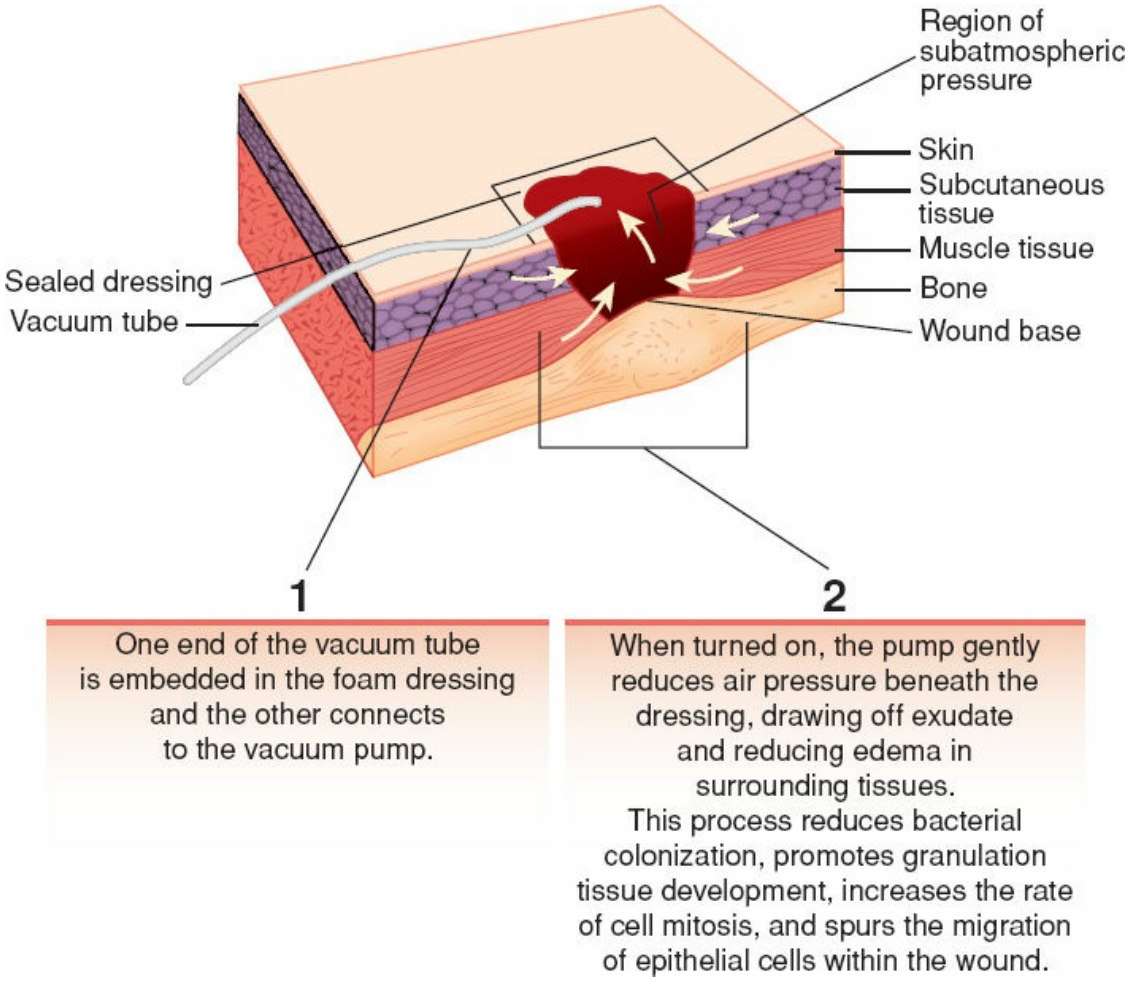

FIGURE 5-8 Wound vacuum-assisted closure (VAC).

TABLE 5-9 Factors Affecting Wound Healing

Factors	Rationale	Nursing Interventions
Age of patient	The older the patient, the less resilient the tissues.	Handle all tissues gently.
Handling of tissues	Rough handling causes injury and delayed healing.	Handle tissues carefully and evenly.
Hemorrhage	Accumulation of blood creates dead spaces as well as dead cells that must be removed. The area becomes a growth medium for organisms.	Monitor vital signs. Observe incision site for evidence of bleeding and infection.
Hypovolemia	Insufficient blood volume leads to vasoconstriction and reduced oxygen and nutrients available for wound healing.	Monitor for volume-deficit (circulatory impairment). Correct by fluid replacement as prescribed.
Patient overactivity	Prevents approximation of wound edges; resting favors healing.	Use measures to keep wound edges approximated: taping, bandaging, splints. Encourage rest.
Immunosuppressed state	Patient is more vulnerable to bacterial and viral invasion; defense mechanisms are impaired.	Provide maximum protection to prevent infection. Restrict visitors with colds; institute mandatory hand hygiene by all staff.
Local Factors		
Edema	Reduces blood supply by exerting increased interstitial pressure on vessels	Elevate part; apply cool compresses.
Inadequate dressing technique		Follow guidelines for proper dressing technique.
Too small	Permits bacterial invasion and contamination	
Too tight	Reduces blood supply carrying nutrients and oxygen	
Nutritional deficits	Protein–calorie depletion may occur. Insulin secretion may be inhibited, causing blood glucose to rise.	Correct deficits; this may require parenteral nutritional therapy. Monitor blood glucose levels. Administer vitamin supplements as prescribed.
Foreign bodies	Foreign bodies retard healing.	Keep wounds free of dressing threads and talcum powder from gloves.
Oxygen deficit (tissue oxygenation insufficient)	Insufficient oxygen may be due to inadequate lung and cardiovascular function as well as localized vasoconstriction.	Encourage deep breathing, turning, controlled coughing, and supplemental oxygen as prescribed.
Drainage accumulation	Accumulated secretions hamper healing process.	Monitor closed drainage systems for proper functioning. Institute measures to remove accumulated secretions.
Medications		
Corticosteroids	May mask presence of infection by impairing normal inflammatory response	Be aware of action and effect of medications patient is receiving.
Anticoagulants	May cause hemorrhage	
Broad-spectrum and specific antibiotics	Effective if administered immediately before surgery for specific pathology or bacterial contamination. If administered after wound is closed, ineffective because of intravascular coagulation.	
Systemic Disorders		
Hemorrhagic shock Acidosis Hypoxia Kidney failure Hepatic disease Sepsis Smoking Immunodeficiency diseases; chemotherapy; radiation Poor nutrition Obesity Diabetes	These depress cell functions that directly affect wound healing.	Be familiar with the nature of the specific disorder. Administer prescribed treatment. Cultures may be indicated to determine appropriate antibiotic.
Wound Stressors		
Vomiting Valsalva maneuver Heavy coughing Straining	Produce tension on wounds, particularly of the torso	Encourage frequent turning and ambulation and administer antiemetic medications as prescribed. Assist patient in splinting incision.

Managing Drains

Wound drains are tubes that exit the peri-incisional area, either into a portable wound suction device (closed) or into the dressings (open). The principle involved is to allow the escape of blood and serous fluids that could otherwise serve as a culture medium for bacteria. In portable wound suction, the use of gentle, constant suction enhances drainage of these fluids and collapses the skin flaps against the underlying tissue, thus removing "dead space." Types of wound drains include the Penrose, Hemovac, and Jackson-Pratt drains (Fig. 5-9). Output from wound drainage systems and all new drainage is recorded. The amount of bloody drainage on the surgical dressing is assessed frequently. Spots of drainage on the dressings are outlined with a pen, and the date and time of the outline are recorded on the dressing, so that increased drainage can be seen easily. A certain amount of bloody drainage in a wound drainage system or on the dressing is expected, but excessive amounts should be reported to the surgeon. Increasing amounts of fresh blood on the dressing should be reported immediately. Some wounds are irrigated heavily before closure in the OR, and open drains exiting the wound may be embedded in the dressings. These wounds may drain large amounts of blood-tinged fluid that saturate the dressing. The dressing can be reinforced with sterile gauze bandages; the time at which they were reinforced should be documented. If drainage continues, the surgeon should be notified, so that the dressing can be changed. Multiple similar drains are numbered or otherwise labeled (e.g., left lower quadrant, left upper quadrant), so that output measurements can be recorded reliably and consistently. Careful positioning and safeguarding that any drains are secure can prevent the dislodgment of nasogastric tubes, chest tubes, and the drains themselves.

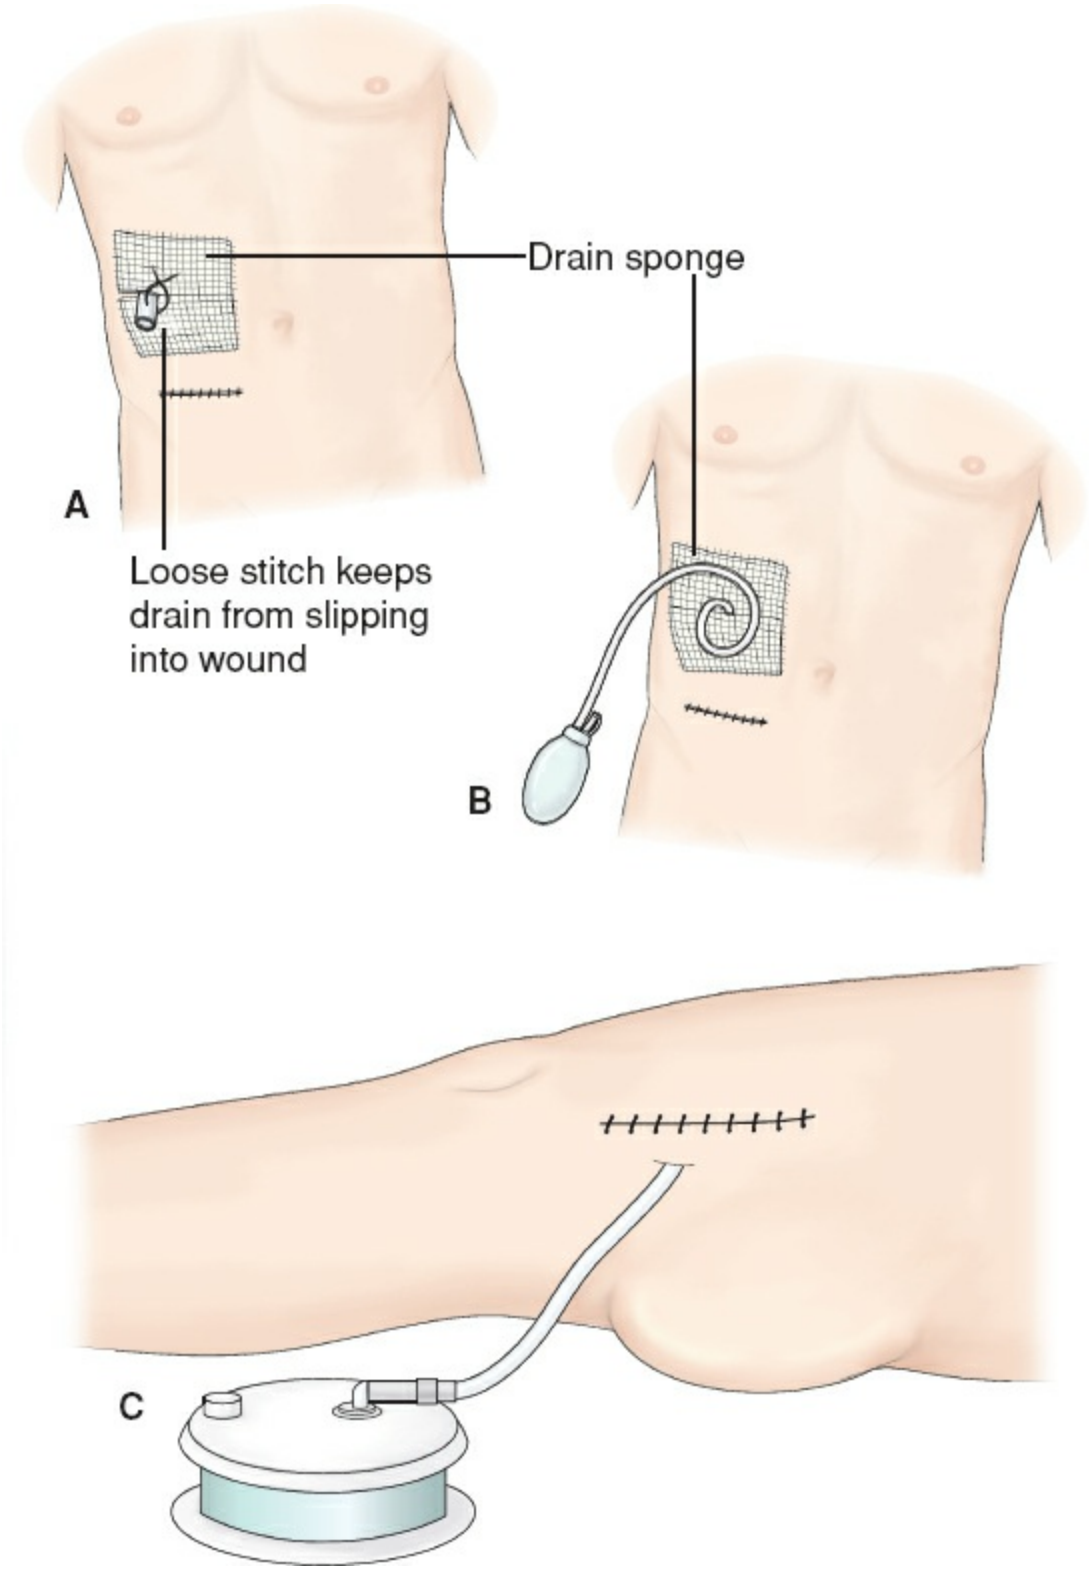

FIGURE 5-9 Types of surgical drains: (A) Penrose, (B) Jackson-Pratt, (C) Hemovac.

Changing the Dressing

Although the first postoperative dressing is usually changed by a member of the surgical team, subsequent dressing changes in the immediate postoperative period are usually performed by the nurse. A dressing is applied to a wound for one or more of the following

reasons: (1) to provide a proper environment for wound healing; (2) to absorb drainage; (3) to splint or immobilize the wound; (4) to protect the wound and new epithelial tissue from mechanical injury; (5) to protect the wound from bacterial contamination and from soiling by feces, vomitus, and urine; (6) to promote hemostasis, as in a pressure dressing; and (7) to provide mental and physical comfort for the patient.

The patient is told that the dressing is to be changed and that changing the dressing is a simple procedure associated with little discomfort. The dressing change is performed at a suitable time (e.g., not at mealtimes or when visitors are present). Privacy is provided, and the patient is not unduly exposed. The nurse should avoid referring to the incision as a scar, because the term may have negative connotations for the patient. Assurance is given that the incision will shrink as it heals and that the redness will fade.

The nurse carries out hand hygiene before and after the dressing change and wears disposable gloves for the dressing change itself. The tape or adhesive portion of the dressing is removed by pulling it parallel with the skin surface and in the direction of hair growth, rather than at right angles. Nonirritating solvents aid in removing adhesive painlessly and quickly. The old dressing is removed and then deposited in a container designated for disposal of biomedical waste. In accordance with standard precautions, dressings are never touched by ungloved hands because of the danger of transmitting pathogenic organisms.

Nursing Alert

There is a dearth of research regarding the influence of sterile or aseptic versus clean gloves and SSIs related to wound care. Therefore the nurse will perform dressing changes depending upon institutional policy. However, the nurse should consider the patient's immune status and depth of a wound when selecting dressing technique of sterile versus clean technique. In addition, use of gloves does not preclude meticulous hand hygiene (Leonard, 2016).

If the patient is sensitive to adhesive tape, the dressing may be held in place with hypoallergenic tape. Many tapes are porous to permit ventilation and prevent skin maceration. The correct way to apply tape is to place the tape at the center of the dressing and then press the tape down on both sides, applying tension evenly, away from the midline. The incorrect way to apply tape—to fix one end of the tape to the skin and to pull it tight over the dressing—often wrinkles and pulls the skin in the process. The resulting continuous and forceful traction produces a shearing effect, causing the epidermal layer to slip sideways and become separated from the deeper dermal layers. Some wounds become edematous after having been dressed, causing considerable tension on the tape. If the tape is not flexible, the stretching bandage will also cause a shear injury to the skin. This can result in denuded areas or large blisters and should be avoided. An elastic adhesive bandage (Elastoplast, 3M Microfoam) may be used to hold dressings in place over mobile areas, such as the neck or the extremities, or where pressure is required. Or a tubular band netting (which stretches and holds dressing in place without tape) can

be considered.

While changing the dressing, the nurse has an opportunity to teach the patient how to care for the incision and change the dressings at home. The nurse observes for indicators of the patient's readiness to learn, such as looking at the incision, expressing interest, or assisting in the dressing change.

MAINTAINING NORMAL BODY TEMPERATURE

The patient is still at risk for MH and hypothermia in the postoperative period. Efforts are made to identify MH and to treat it early and promptly.

Patients who have been anesthetized are susceptible to chills and drafts. Attention to hypothermia management, begun in the intraoperative period, extends into the postoperative period to prevent significant nitrogen loss and catabolism. Signs of hypothermia are reported to physician member of the surgical team. The room is maintained at a comfortable temperature, and blankets are provided to prevent chilling. Treatment includes oxygen administration, adequate hydration, and proper nutrition. The patient is also monitored for cardiac arrhythmias. The risk of hypothermia is greater in the elderly and in patients who were in the cool OR environment for a prolonged period.

MANAGING GI FUNCTION AND RESUMING NUTRITION

GI discomfort (nausea, vomiting, hiccups) and resumption of oral intake are issues for both the patient 'and the nurse. Nausea and vomiting are common after anesthesia (Rothrock, 2014). They are more common in women, in obese people (fat cells act as reservoirs for the anesthetic), in patients prone to motion sickness, and in patients who have undergone lengthy surgical procedures. Other causes of postoperative vomiting include an accumulation of fluid in the stomach, inflation of the stomach, and the ingestion of food and fluid before peristalsis resumes.

If vomiting is likely because of the nature of surgery, a nasogastric tube is inserted intraoperatively and remains in place throughout the surgery and the immediate postoperative period. A nasogastric tube (NG tube) also may be inserted before surgery if postoperative distention is anticipated. In addition, an NG tube may be inserted if a patient who has food in the stomach requires emergency surgery. Refer to Chapter 22 for further details on NG tubes.

Hiccups, produced by intermittent spasms of the diaphragm secondary to irritation of the phrenic nerve, can occur after surgery. The irritation may be direct, such as from stimulation of the nerve by a distended stomach, subdiaphragmatic abscess, or abdominal distention; indirect, such as from toxemia or uremia that stimulates the nerve; or reflexive, such as irritation from a drainage tube or obstruction of the intestines. Usually, these occurrences are mild, transitory attacks that cease spontaneously. If hiccups persist, they may produce considerable distress and serious effects such as vomiting, exhaustion, and wound dehiscence. The provider may prescribe phenothiazine medications (e.g., Thorazine) for intractable hiccups (Chang & Lu, 2012).

Once nausea and vomiting have subsided and the patient is fully awake and alert with the nurse having documented resumption of bowel sounds, the nurse should offer the patient something to drink or eat. The sooner the patient can tolerate a usual diet, the more quickly normal GI function will resume. Taking food by mouth stimulates digestive juices and promotes gastric function and intestinal peristalsis. The return to normal dietary intake should proceed at a pace set by the patient. Of course, the nature of the surgery and the type of anesthesia directly affect the rate at which normal gastric activity resumes. Liquids are typically the first substances desired and tolerated by the patient after surgery. Water, juice, and tea may be given in increasing amounts. Cool fluids are tolerated more easily than are those that are ice cold or hot. Soft foods (gelatin, custard, milk, and creamed soups) are added gradually after clear fluids have been tolerated. As soon as the patient tolerates soft foods well, solid food may be given.

Assessment and management of GI function are important after surgery because the GI tract is subject to uncomfortable or potentially life-threatening complications. Any postoperative patient may suffer from abdominal distention, resulting from the accumulation of gas in the intestinal tract. Manipulation of the abdominal organs during surgery may produce a loss of normal peristalsis for 24 to 48 hours, depending on the type and extent of surgery. Even though nothing is given by mouth, swallowed air and GI secretions enter the stomach and intestines; if not propelled by peristalsis, they collect in the intestines, producing distention and causing the patient to complain of fullness or pain in the abdomen. Most often, the gas collects in the colon. Abdominal distention is increased further by immobility, anesthetic agents, and the use of opioid medications.

After major abdominal surgery, distention may be avoided by having the patient turn frequently, exercise, and ambulate as early as possible. This also alleviates distention produced by swallowing air, which is common in anxious patients. An NG tube inserted before surgery may remain in place until full peristaltic activity (indicated by the passage of flatus) has resumed. The nurse can determine when peristaltic bowel sounds return by listening to the abdomen with a stethoscope (normal frequency of bowel sounds are 5 to 34 clicks and gurgles per minute). Bowel sounds are documented so that diet progression can occur.

Paralytic ileus (failure of forward movement of bowel contents; when due to paralysis of the intestinal muscles, also termed postoperative adynamic ileus) and intestinal obstruction are potential postoperative complications that occur more frequently in patients undergoing intestinal or abdominal surgery.

PROMOTING BOWEL FUNCTION

Constipation is common after surgery and can range from a minor to a serious complication. Decreased mobility, decreased oral intake, and opioid analgesics contribute to difficulty having a bowel movement. In addition, irritation and trauma to the bowel during surgery may inhibit intestinal movement for several days. The combined effect of early ambulation, improved dietary intake, and a stool softener (if prescribed) promotes bowel elimination. Until the patient reports return of normal bowel function, the nurse

should assess the abdomen for distention and the presence and frequency of bowel sounds. If the abdomen is not distended and bowel sounds are normal, and if the patient does not have a bowel movement by the second or third postoperative day, the provider should be notified.

MANAGING VOIDING

Urinary retention after surgery can occur for various reasons. Anesthetics, anticholinergic agents, and opioids interfere with the perception of bladder fullness and the urge to void and inhibit the ability to initiate voiding and completely empty the bladder. Abdominal, pelvic, and hip surgery may increase the likelihood of retention secondary to pain. In addition, some patients find it difficult to use the bedpan or urinal in the recumbent position.

Bladder distention and the urge to void should be assessed at the time of the patient's arrival on the unit and frequently thereafter. The patient is expected to void within 6 to 8 hours after surgery (this includes time spent in the PACU). If the patient has an urge to void and cannot, or if the bladder is distended and no urge is felt or the patient cannot void, a portable ultrasound device (bladder scan) should be performed to assess degree of distention and possible need for urinary catheterization. All methods to encourage the patient to void should be tried (e.g., letting water run, applying heat to the perineum). The bedpan should be warm; a cold bedpan causes discomfort and automatic tightening of muscles (including the urethral sphincter). If the patient cannot void on a bedpan, it may be possible to use a commode rather than resorting to catheterization. Male patients are often permitted to sit up or stand beside the bed to use the urinal, but safeguards should be taken to prevent the patient from falling or fainting due to loss of coordination from medications or orthostatic hypotension. If the patient cannot void in the specified time frame and a bladder scan verifies distention, the patient is catheterized and the catheter is removed after the bladder has emptied. Straight intermittent catheterization is preferred over indwelling catheterization, because the risk of infection is increased with an indwelling catheter.

Even if the patient voids, the bladder may not necessarily be empty. The nurse notes the amount of urine voided and uses the bladder scan to assess residual volume. If more than 100 mL of residual urine is seen on the bladder scanner, it is considered diagnostic of urinary retention. If a bladder scan is not available in your institution, the nurse can palpate the suprapubic area for distention or tenderness after the patient urinates to assess for residual urine. Intermittent catheterization may be prescribed every 4 to 6 hours until the patient can void spontaneously and the postvoid residual is less than 100 mL.

MAINTAINING A SAFE ENVIRONMENT

During the immediate postoperative period, the patient recovering from anesthesia should have two side rails up, and the bed should be in the low position. The nurse assesses the patient's LOC and orientation and determines whether the patient needs his or her eyeglasses or hearing aid, because impaired vision, inability to hear postoperative

instructions, or inability to communicate verbally places the patient at risk for injury. All objects the patient may need should be within reach, especially the call light. Any immediate postoperative orders concerning special positioning, equipment, or interventions should be implemented as soon as possible. The patient is instructed to ask for assistance with any activity. Although restraints are occasionally necessary for the disoriented patient, they should be avoided if at all possible. Agency policy on the use of restraints must be consulted and followed.

PROVIDING EMOTIONAL SUPPORT TO THE PATIENT AND FAMILY

Although patients and families are undoubtedly relieved that surgery is over, anxiety levels may remain high in the immediate postoperative period. Many factors contribute to this anxiety: pain, being in an unfamiliar environment, inability to control one's circumstances or care for oneself, fear of the long-term effects of surgery, fear of complications, fatigue, spiritual distress, altered role responsibilities, ineffective coping, and altered body image are all potential reactions to the surgical experience. The nurse helps the patient and family work through their anxieties by providing reassurance and information and by spending time listening to and addressing their concerns. The nurse describes hospital routines and what to expect in the ensuing hours and days until discharge, and explains the purpose of nursing assessments and interventions. Informing patients when they will be able to drink fluids or eat, when they will be getting out of bed, and when tubes and drains will be removed helps them gain a sense of control and participation in recovery and engages them in the plan of care. Acknowledging family members' concerns and accepting and encouraging their participation in the patient's care assists them in feeling that they are helping their loved one. The nurse can modify the environment to enhance rest and relaxation by providing privacy, reducing noise, adjusting lighting, providing enough seating for family members, and encouraging a supportive atmosphere.

MANAGING POTENTIAL COMPLICATIONS

The RN must be alert for the development of additional postoperative complications that include cardiac complications, DVT and pulmonary embolism (PE), hematoma, wound infection, and/or wound dehiscence and evisceration. The following sections detail each of these complications.

Cardiac Complications

A postoperative cardiac complication is a myocardial ischemia/infarction (MI). The nurse is aware that in the postoperative patient, clinical presentation is often subtle. Perioperative MIs are frequently silent or may present with dyspnea, hypotension, or atypical pain. If suspected, the nurse alerts the surgical team; obtains vital signs and oxygen saturation; performs a cardiac, peripheral vascular, and pulmonary assessment, electrocardiogram; and anticipates laboratory work to assess cardiac biomarkers will be obtained. Refer to Table 14-5 for cardiac laboratory tests on page 446.

As a result of excessive IV fluid administration intraoperatively, the nurse is alert for the development of congestive heart failure (CHF), which can present in the immediate postoperative period, or on POD 2 to 3 when fluid shifting causes increased intravascular volume. Daily weights are an important parameter for judging fluid balance. The nurse is aware that when calculating new gain or loss that 500 mL approximates 1 lb or 1,000 mL approximates 1 kg (2.2 lb). In addition, the nurse observes for jugular vein distention, rales, dyspnea, wheezing, cough, and fatigue. Refer to Chapters 14 and 15 for details of care of the patient with MI and CHF.

Deep Vein Thrombosis and Pulmonary Embolism

DVT and other complications, such as PE, are serious potential complications of surgery (Box 5-8). The stress response that is initiated by surgery inhibits the fibrinolytic system, resulting in blood hypercoagulability. Dehydration, low cardiac output, blood pooling in the extremities, and bed rest add to the risk of thrombosis formation. Although all postoperative patients are at some risk, factors such as a history of thrombosis, malignancy, trauma, obesity, indwelling venous catheters, and hormone use (e.g., estrogen) increase the risk. The first symptom of DVT may be swelling of the involved extremity, often accompanied by a low grade fever. The edema is associated with impaired venous flow. Tenderness, which usually occurs later, is produced by inflammation of the vein wall, and firmness may be detected along the involved veins by gently palpating the affected extremity (palpated cord). Refer to Chapter 18 for details on DVT.

BOX 5-8 Risk Factors for Postoperative Deep Vein Thrombosis

- Orthopedic patients having hip surgery, knee reconstruction, and other lower extremity surgery
- Urologic patients having transurethral prostatectomy and older patients having urologic surgery
- General surgical patients older than 40 years of age, those who are obese, those with a malignancy, those who have had prior DVT or PE, and those undergoing extensive, complicated surgical procedures
- Gynecologic (and obstetric) patients older than 40 years of age with added risk factors (varicose veins, previous venous thrombosis, infection, malignancy, obesity)
- Neurosurgical patients, similar to other surgical high-risk groups (in patients with stroke, for instance, the risk of DVT in the paralyzed leg is as high as 75%)

TABLE 5-10 Wound Classification and Associated Surgical Site Infection Risk

Surgical Category	Determinants of Category	Expected Risk of Postsurgical Infection (%)
Clean	Nontraumatic site Uninfected site No inflammation No break in aseptic technique No entry into respiratory, alimentary, genitourinary, or oropharyngeal tracts	1–3
Clean-contaminated	Entry into respiratory, alimentary, genitourinary, or oropharyngeal tracts without unusual contamination Appendectomy Minor break in aseptic technique Mechanical drainage	3–7
Contaminated	Open, newly experienced traumatic wounds Gross spillage from GI tract Major break in aseptic technique Entry into genitourinary or biliary tract when urine or bile is infected	7–16
Dirty	Traumatic wound with delayed repair, devitalized tissue, foreign bodies, or fecal contamination Acute inflammation and purulent drainage encountered during procedure	16–29

Prophylactic treatment for postoperative patients at risk is common practice, until the patient is ambulatory. External pneumatic compression and thigh-high elastic compression stockings can be used alone or in combination with low-dose heparin. The benefits of early ambulation and hourly leg exercises in preventing DVT cannot be overemphasized, and these activities are recommended for all patients, regardless of their risk. It is important to avoid the use of blanket rolls, pillow rolls, or any form of elevation that can constrict vessels under the knees. Even prolonged "dangling" (having the patient sit on the edge of the bed with legs hanging over the side) can be dangerous and is not recommended in susceptible patients because pressure under the knees can impede circulation. Adequate hydration is also encouraged; the patient can be offered juices and water throughout the day to avoid dehydration.

PE from DVT is a postoperative risk for patients owing to immobility, venous stasis, venous trauma, and hypercoagulability. Clinically, symptoms of a PE include sudden onset of shortness of breath, tachypnea, tachycardia, low-grade temperature, chest pain (pleuritic in nature), and apprehension. Patients who have had major orthopedic surgery of a lower extremity, including hip or knee arthroplasty and hip fracture surgeries, as well as major trauma patients, are at high risk for PE. Some form of prophylactic therapy is expected in high-risk patients to reduce the risk of DVT and PE. Refer to Chapter 10 for more details on PE.

Hematoma

At times, concealed bleeding occurs beneath the skin at the surgical site. This hemorrhage usually stops spontaneously but results in clot (hematoma) formation within the wound. If the clot is small, it will be absorbed and need not be treated. If the clot is large, the wound usually bulges somewhat, and healing will be delayed unless the clot is removed. After several sutures are removed by a member of the surgical team, the clot is evacuated and the wound is packed lightly with gauze. Healing occurs usually by granulation, or a

secondary closure may be performed.

Infection (Wound Sepsis)

The creation of a surgical wound disrupts the integrity of the skin and its protective function. Exposure of deep body tissues to pathogens in the environment places the patient at risk for infection of the surgical site, a potentially life-threatening complication. SSI increases hospital length of stay, costs of care, risk for further complications, and readmission to a hospital.

Multiple factors place the patient at risk for wound infection. One risk factor relates to the type of wound. Surgical wounds are classified according to the degree of contamination. Table 5-10 defines the terms used to describe surgical wounds and gives the expected rate of wound infection per category. Other risk factors include both patient-related factors and those associated with the surgical procedure. Factors related to the surgical procedure include the method of preoperative skin preparation, surgical attire of the team, method of sterile draping, duration of surgery, antimicrobial prophylaxis, aseptic technique, factors related to surgical technique, drains or foreign material, OR ventilation, length of procedure, and exogenous microorganisms. Efforts to prevent wound infection are directed at reducing these risks. Current guidelines to prevent SSIs suggest that an appropriate prophylactic antibiotic that is based on current recommendation be administered within 1 hour of surgical incision (2 hours are allowed for the administration of vancomycin and fluoroquinolones) and discontinuation of prophylactic antibiotics within 24 hours after surgery, owing to the link between the development of resistant organisms and excessive use of antibiotics. Discontinuation of the antibiotic is extended to within 48 hours for cardiothoracic procedures for adult patients. The Surgical Care Improvement Project (SCIP) is a national quality partnership of organizations interested in improving surgical care by significantly reducing surgical complications. They provide guidelines for antibiotic therapy throughout the patient's hospitalization (Joint Commission, 2014).

Wound infection may not be evident until at least POD 5. Most patients are discharged before that time, and more than half of wound infections are diagnosed after discharge, highlighting the importance of patient education regarding wound care. Risk factors for wound sepsis include wound contamination, foreign body, faulty suturing technique, devitalized tissue, hematoma, debilitation, dehydration, malnutrition, anemia, advanced age, extreme obesity, shock, length of preoperative hospitalization, duration of surgical procedure, and associated disorders (e.g., diabetes mellitus, immunosuppression). Signs and symptoms of wound infection include increased pulse rate and temperature; an elevated white blood cell count; wound swelling, warmth, tenderness, or discharge; and incisional pain. Local signs may be absent if the infection is deep. Staphylococcus aureus accounts for many postoperative wound infections. Other infections may result from Escherichia coli, Proteus vulgaris, Aerobacter aerogenes, Pseudomonas aeruginosa, and other organisms. Although they are rare, beta-hemolytic streptococcal or clostridial infections can develop rapidly and be deadly. If wound infection due to beta-hemolytic

streptococcus or clostridium occurs, strict infection-control practices are needed to prevent the spread of infection to others. Intensive medical and nursing care is essential if the patient is to survive.

When a wound infection is diagnosed in a surgical incision, the surgeon may remove one or more sutures or staples and, using aseptic precautions, separate the wound edges with a pair of blunt scissors or a hemostat, opening the incision to allow for drainage. Another option is for the patient to be referred to interventional radiology for percutaneous drainage. Antimicrobial therapy and a wound care regimen are also initiated.

Wound Dehiscence and Evisceration

Wound dehiscence (disruption of surgical incision or wound) and evisceration (protrusion of wound contents) are serious surgical complications (Fig. 5-10). Dehiscence and evisceration are especially serious when they involve abdominal incisions or wounds. These complications result from sutures giving way, from infection, or, more frequently, from marked distention or strenuous cough. They may also occur because of increasing age; obesity; poor nutritional status (hypoproteinemia, hypoalbuminemia); steroid use or immunosuppression (cancer); or the presence of diabetes, uremia, or sepsis; or pulmonary or cardiovascular disease in patients undergoing abdominal surgery. Local risk factors include inadequate closure, increased intra-abdominal pressure, and deficient wound healing (Chu & Agarwal, 2015).

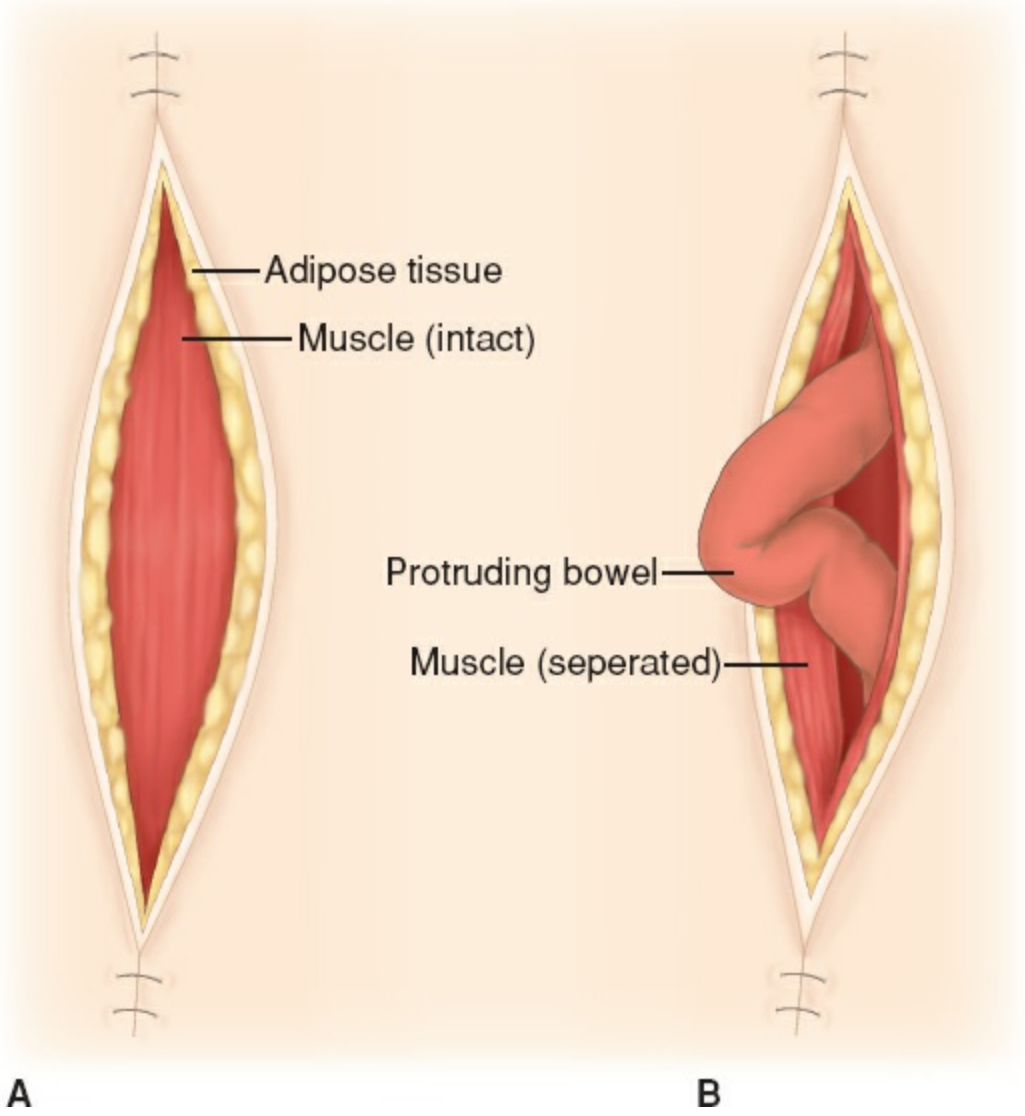

FIGURE 5-10 (A) Wound dehiscence; (B) wound evisceration.

When the wound edges separate slowly, the intestines may protrude gradually or not at all, and the earliest sign may be a gush of bloody (serosanguineous) peritoneal fluid from the wound. When a wound ruptures suddenly, coils of intestine may push out of the abdomen. The patient may report that "something gave way." The evisceration causes pain and may be associated with vomiting.

An abdominal binder, properly applied, is a prophylactic measure against an evisceration and often is used along with the primary dressing, especially in patients with weak or pendulous abdominal walls or when rupture of a wound has occurred. If evisceration occurs, the nurse aseptically covers the abdominal contents with moist saline dressings to prevent drying of the bowel, notifies the surgical team immediately and assesses the patient's vital signs, including oxygen saturation. The patient remains in bed with knees bent to reduce abdominal muscle tension. The patient should be NPO and an IV established for fluid management. After the patient returns from surgery, review splinting of the abdomen and anticipate the use of an abdominal binder.

PROVIDING DISCHARGE TEACHING

Patients have always required detailed discharge instructions to become proficient in special self-care needs after surgery; however, dramatically reduced hospital lengths of stay during the past decade have greatly increased the amount of information needed while reducing the amount of time in which to provide it. Box 5-9 provides patient education about wound care.

BOX 5-9 Patient Education

Wound Care Instructions

Until Sutures are Removed

1. Keep the wound dry and clean:
   - If there is no dressing, ask your nurse or provider if you can bathe or shower.
   - If a dressing or splint is in place, do not remove it unless it is wet or soiled.
   - If wet or soiled, change dressing yourself if you have been taught to do so; otherwise, call your nurse or provider for guidance.
   - If you have been taught, instruction might be as follows:
     - Cleanse area *gently* with sterile normal saline once or twice daily.
     - Cover with a sterile Telfa pad or gauze square large enough to cover the wound.
     - Apply hypoallergenic tape (Dermicel or paper). Adhesive is not recommended because it is difficult to remove without possible injury to the incisional site.
2. Immediately report any of these signs of infection:
   - Increasing redness, swelling, tenderness, pain, or increased warmth around the wound
   - Red streaks in the skin near the wound
   - Pus or discharge, foul odor
   - Chills or temperature higher than 37.7°C (100°F)
3. If soreness or pain causes discomfort, apply a dry cool pack (containing ice or cold water) or take prescribed acetaminophen tablets (2) every 4–6 hours. Avoid using aspirin without direction or instruction because bleeding can occur with its use.
4. Swelling after surgery is common. To help reduce swelling, elevate the affected part to the level of the heart:
   - Hand or arm:
     - Sleep: Elevate arm on pillow at side
     - Sitting: Place arm on pillow on adjacent table
     - Standing: Rest affected hand on opposite shoulder; support elbow with unaffected hand

- Leg or foot:
  - Sitting: Place a pillow on a facing chair; provide support underneath the knee
  - Lying: Place a pillow under affected leg

After Sutures are Removed

Although the wound appears to be healed when sutures are removed, it is still tender and will continue to heal and strengthen for several weeks.

1. Follow recommendations of your provider or nurse regarding extent of activity.
2. Keep the suture line clean; do not rub vigorously; pat dry. Wound edges may look red and may be slightly raised. This is normal.
3. If the site continues to be red, thick, and painful to pressure after 8 weeks, consult the health care provider. (This may be due to excessive collagen formation and should be checked.)

EVALUATION

Expected patient outcomes may include the following:

1. Maintains optimal respiratory function:
   a. Performs deep-breathing exercises
   b. Displays clear breath sounds
   c. Uses incentive spirometer as prescribed
   d. Splints incisional site when coughing to reduce pain
2. Indicates that pain is decreased in intensity or acceptable to patient
3. Increases activity as prescribed:
   a. Alternates periods of rest and activity
   b. Progressively increases ambulation
   c. Resumes normal activities within prescribed time frame
   d. Performs activities related to self-care
4. Wound heals without complication
5. Maintains body temperature within normal limits
6. Resumes oral intake:
   a. Reports absence of nausea and vomiting
   b. Eats at least 75% of usual diet
   c. Is free of abdominal distress and gas pains
   d. Exhibits normal bowel sounds
7. Reports resumption of usual bowel elimination pattern
8. Resumes usual voiding pattern
9. Is free of injury
10. Exhibits decreased anxiety
11. Acquires knowledge and skills necessary to manage therapeutic regimen

12. Experiences no complications

Gerontologic Considerations

Elderly patients recover more slowly, have longer hospital stays, and are at greater risk for the development of postoperative complications. Some of the major threats to recovery include pneumonia, decline in functional ability, exacerbation of comorbid conditions, pressure ulcers, decreased oral intake, GI disturbance, and falls. Expert nursing care can help the older adult avoid these complications or minimize their effects.

Postoperative delirium, characterized by confusion, perceptual and cognitive deficits, altered attention levels, disturbed sleep patterns, and impaired psychomotor skills, is a significant problem for older adults. Causes of delirium are multifactorial (refer to Box 5-10 for causes of delirium). Skilled and frequent assessment of mental status and of all physiologic factors influencing mental status helps the nurse plan care because delirium may be the initial or only early indicator of infection, fluid and electrolyte imbalance, or deterioration of respiratory or hemodynamic status in the elderly patient.

BOX 5-10 Causes of Postoperative Delirium

- Acid–base disturbances
- Age greater than 80 years
- Fluid and electrolyte imbalance
- Dehydration
- History of dementia-like symptoms
- Hypoxia
- Hypercarbia
- Infection (urinary tract, wound, respiratory)
- Medications (anticholinergics, benzodiazepines, central nervous system depressants)
- Unrelieved pain
- Blood loss
- Decreased cardiac output
- Cerebral hypoxia
- Heart failure
- Acute myocardial infarction
- Hypothermia or hyperthermia
- Unfamiliar surroundings and sensory deprivation
- Emergent surgery
- Alcohol withdrawal
- Urinary retention
- Fecal impaction

- Polypharmacy
- Presence of multiple diseases
- Sensory impairments
- High stress or anxiety levels

Recognizing postoperative delirium and identifying and treating its underlying cause are the goals of care. Sometimes postoperative delirium is mistaken for pre-existing dementia or is attributed to age. In addition to monitoring and managing identifiable causes, the nurse implements supportive interventions. Keeping the patient in a well-lit room and close to the nurses' station can help with sensory deprivation. At the same time, distracting and unfamiliar noises should be minimized. Because pain can contribute to postoperative delirium, adequate pain control is essential. The nurse collaborates with the physician or geriatric nurse specialist and the patient to achieve pain relief without oversedation.

The patient is reoriented as often as necessary, and staff should introduce themselves each time they come in contact with the patient. Engaging the patient in conversation and care activities and placing a clock and calendar nearby may improve cognitive function. Physical activity should not be neglected while the patient is confused because physical deterioration can worsen delirium and place the patient at increased risk for other complications. Restraints should be avoided because they also can worsen confusion. If possible, a family member or staff member is asked to stay with the patient instead.

Other problems confronting the elderly postoperative patient, such as pneumonia, altered bowel function, DVT, weakness, and functional decline, often can be prevented by early and progressive ambulation. Ambulation means walking, not just getting out of bed and sitting in a chair. Prolonged sitting positions that promote venous stasis in the lower extremities should be avoided. Assistance with ambulation may be required to keep the patient from bumping into objects and falling. A physical therapy referral may be indicated to promote safe, regular exercise for the older adult.

Urinary incontinence can be prevented by providing easy access to the call bell and the commode and by prompting voiding. Early ambulation and familiarity with the room help the patient to become self-sufficient sooner.

Optimal nutritional status is important for wound healing, return of normal bowel function, and fluid and electrolyte balance. The nurse and patient can consult with the dietitian to plan appealing, high-protein meals that provide sufficient fiber, calories, and vitamins. Nutritional supplements, such as Ensure® or Sustacal, may be recommended. Multivitamins, iron, and vitamin C supplements aid in tissue healing, formation of new RBCs, and overall nutritional status and are commonly prescribed postoperatively.

In addition to monitoring and managing physiologic recovery of the older adult, the nurse identifies and addresses psychosocial needs. The older adult may require much encouragement and support to resume activities, and the pace may be slow. Sensory deficits may require frequent repetition of instructions, and decreased physiologic reserve may necessitate frequent rest periods. The older adult may require extensive discharge planning to coordinate both professional and family care providers, and the nurse, social worker, or nurse case manager may institute the plan for continuing care.

CHAPTER REVIEW

Critical Thinking Exercises

1. An 80-year-old patient with Parkinson disease is scheduled for surgery to replace a fractured hip. Identify the considerations and associated responsibilities of the OR nurse for safe intraoperative care of this patient.

2. A patient develops a temperature of 38°C (100°F) and becomes tachycardic halfway through an abdominal surgery. Five minutes later, the patient's temperature is 42°C (104°F). Describe the protocol you would follow and the medication you would administer for this condition.

3. A male patient is scheduled for major surgery and asks how long before the surgery will he be without food and fluids. What resources would you use to identify the current fasting guidelines? What is the evidence base for the patient's being NPO after midnight as opposed to a 2-hour fast before surgery? Identify the criteria used to evaluate the strength of the evidence for this practice.

NCLEX-Style Review Questions

1. A 70-year-old elderly patient is admitted to the preoperative unit for a liver resection that is scheduled for 6 hours of surgery. What is one of the basic principles that should guide the preoperative nurse's assessment?
   a. Elderly patients do not experience as much preoperative anxiety as younger patients.
   b. The elderly patient has less physiologic reserve than the younger patient.
   c. Elderly patients experience less pain.
   d. Preoperative pain assessment and teaching should occur following the procedure as the elderly patient may not retain the information.

2. A nurse is caring for a postoperative patient who had spinal anesthesia. The patient complains of headache. What action should the nurse take?
   a. Lower the head of the patient's bed.
   b. Keep the patient lying flat, maintain a quiet environment, and keep the patient hydrated.
   c. Encourage the patient to lay on his right side.
   d. Do nothing, as this is a normal response to the spinal anesthesia.

3. When does the postoperative phase begin?
   a. Admission of the patient to the OR
   b. Admission of the patient to the PACU and ending when the patient is discharged to the unit or home
   c. Admission of the patient to the PACU and ending with follow-up evaluation in the clinical setting or home

d. Admission to the PACU

4. A nurse is caring for a postoperative patient on POD 2. The patient had a large upper abdominal incision. While assessing the patient at the beginning of the shift, the nurse noted decreased breath sounds, crackles, and a mild cough. What is the patient most likely experiencing?
   a. Atelectasis
   b. Pneumonia
   c. Acute bronchitis
   d. Hypoxemia

5. Surgical wound healing occurs in:
   a. Two phases: inflammatory and maturation
   b. Three phases: inflammatory, proliferative, and maturation
   c. First-, second-, and third-intention wound healing
   d. First and proliferative phase

CHAPTER 6

Cancer Care

Lisa M. Barbarotta

Learning Objectives

After reading this chapter, you will be able to:

1. Compare the structure and function of the normal cell and the cancer cell.
2. Differentiate between benign and malignant tumors.
3. Identify agents and factors that have been found to be carcinogenic.
4. Describe the significance of health education and preventive care in decreasing the incidence of cancer.
5. Differentiate among the various types of surgical procedures used in cancer treatment, diagnosis, prophylaxis, and palliation.
6. Describe the roles of surgery, radiation therapy, chemotherapy, targeted agents, and immunotherapy in treating cancer.
7. Describe the special nursing needs of patients receiving chemotherapy and immunotherapy.
8. Describe common nursing diagnoses and collaborative problems of patients with cancer.
9. Describe the concept of hospice in providing care for patients with advanced cancer.
10. Discuss the role of the nurse in assessment and management of common oncologic emergencies.

Cancer is not a single disease with a single cause; rather, it is a highly heterogeneous group of diseases with different causes, manifestations, treatments, and prognoses. Cancer nursing, also called oncology nursing, encompasses all age groups and nursing specialties and is carried out in a variety of health care settings, including the home, community, acute care institutions, rehabilitation centers, and hospice. The scope, responsibilities, and goals of oncology nursing are as diverse and complex as those of any nursing specialty. Oncology nurses must be prepared to support patients and families through a wide range of physical, emotional, social, cultural, and spiritual experiences from diagnosis through end of life and survivorship.

EPIDEMIOLOGY OF CANCER

Although cancer affects people of all ages, most cancers occur in people older than 65 years of age. Overall, the incidence of cancer is higher in men than in women and higher in industrialized nations.

In 2016 there were 1.68 million new cancer cases and 595,690 cancer deaths projected in the United States, with cancer being the second leading cause of death (Siegel, Miller, & Jemal, 2016). The most common causes of cancer death include lung and bronchus, prostate, and colorectal cancers in men and lung and bronchus, breast, and colorectal cancer in women (Fig. 6-1) (Siegel et al., 2016). These four cancer types are responsible for 46% of all cancer deaths. Notable trends in the United States include stabilization of the incidence rates for cancer in women and declining rates in men due to decreasing numbers of prostate cancers diagnosed (Siegel et al., 2016).

Over the last 30 years, 5-year survival rates for cancer have increased by 20% in whites and 23% in blacks (Siegel et al., 2016). Progress has been most dramatic for diseases including acute lymphoblastic leukemia (ALL) and chronic myelogenous leukemia (CML) due to the discovery of targeted therapies such as tyrosine kinase inhibitors. Unfortunately, similar advances for lung and pancreatic cancers have been slower to evolve (Siegel et al., 2016).

Cancer incidence and mortality rates vary among racial groups. Black men have the highest overall incidence of cancer and higher mortality rates (Siegel et al., 2016). Higher mortality rates may be a reflection of being diagnosed at an advanced stage of disease. Other factors to account for the disparities include differences in risk factor prevalence, increased incidence of poverty, and less access to high-quality health care (Siegel et al., 2016).

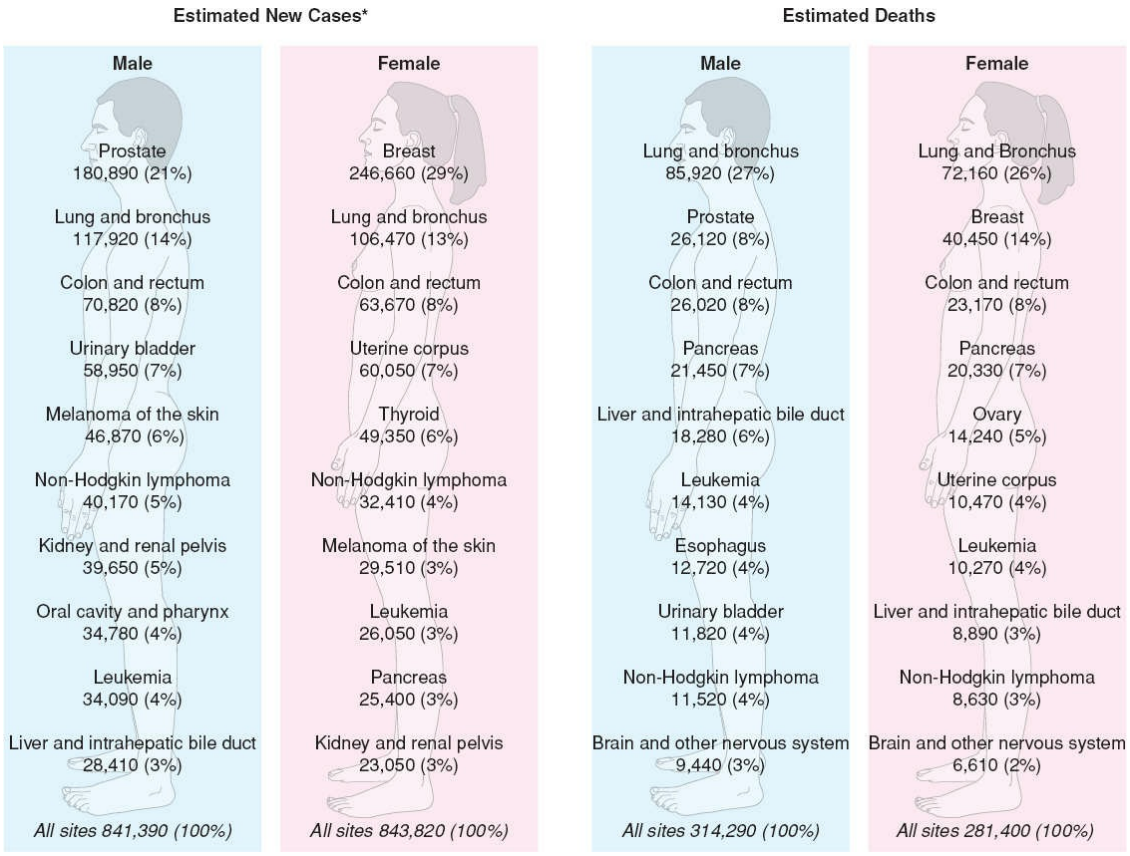

FIGURE 6-1 Ten Leading Cancer Types for the Estimated New Cancer Cases and Deaths by Sex, United States, 2016. *Excludes basal and squamous cell skin cancers and in situ carcinomas except urinary bladder. Estimates rounded to the nearest 10. Adapted from Siegel, R. L., Miller, K. D., & Ahmedin, J. (2016). Cancer statistics, 2016. *CA: Cancer Journal for Clinicians*, *66*, 7–30.

Characteristics of Malignant Cells

The primary difference between malignant (cancerous) and benign cells is that malignant cells have abnormal regulation of growth. Cancer cells continue to grow, even at the expense of their host. They demonstrate uncontrolled cell growth that follows no physiologic demand.

Benign and malignant growths are classified and named by tissue of origin. Benign and malignant cells differ in many cellular growth characteristics, including the method and rate of growth, ability to metastasize or spread, general effects, destruction of tissue, and ability to cause death. These differences are summarized in Table 6-1.

Despite their individual differences, all cancer cells share some common cellular characteristics in relation to the cell membrane, special proteins, the nuclei, chromosomal abnormalities, and the rate of mitosis and growth. Characteristics of cancer cells include:

- Pleomorphism: Cells vary in size and shape
- Polymorphism: Nucleus is enlarged and variable in shape
- Chromosomal mutations including translocations, deletions, amplification, and aneuploidy (abnormal number of chromosomes)
- Production of surface enzymes that aid in invasion and metastasis
- Loss of antigens that label the cell as "self"
- Production of new tumor-associated antigens that label the cell as "nonself"
- Increased rate of anaerobic metabolism
- Loss of contact inhibition, which normally halts cell division once cells are in contact with one another
- Defect in cell recognition and adhesion (cancer cells do not recognize and adhere to each other as normal cells do)
- Loss of control of proliferation
- Increased mitotic index: Tumors have a larger number of cells that are in mitosis
- Abnormal lifespan: Cancer cells tend to live longer than do normal cells

TABLE 6-1 Characteristics of Benign and Malignant Neoplasms

Characteristics	Benign Neoplasms	Malignant Neoplasms
Cell characteristics	Well-differentiated cells that resemble cells in the tissue of origin	Cells are undifferentiated, with anaplasia (loss of differentiation of cells) and atypical structure that often bear little resemblance to cells in the tissue of origin
Mode of growth	Grows by expansion without invading the surrounding tissues; usually encapsulated	Grows by invasion, sending out processes that infiltrate the surrounding tissues
Rate of growth	Usually progressive and slow; may come to a standstill or regress	Variable and depends on level of differentiation; the more undifferentiated the cells, the more rapid the rate of growth
Metastasis	Does not spread by metastasis	Gains access to the blood and lymph channels to metastasize to other areas of the body

Grossman, S., & Porth, C. (2014). *Pathophysiology: Concepts of altered health states* (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

Carcinogenesis

Carcinogenesis, the process in which healthy cells become malignant, is a multi-step process involving both environmental exposure to cancer-causing agents (carcinogens) and random errors in replication of DNA that result in genetic mutations over time (Lemoine, 2014). The end result of these mutations is uncontrolled proliferation of abnormal cells.

Pathophysiology Alert

Although cancer originates from a single mutated cell (monoclonal origin), over time due to subsequent mutations, the tumor cells become heterogeneous in their cellular properties. In addition, cells within different regions of an established tumor may express different genes and different mutations (Harrington, Bristow, Hill, & Tannock, 2013). Understanding the characteristics of the cancer cells assists in developing novel therapies to eliminate it.

The following cellular changes are essential to carcino-genesis:

- loss of sensitivity to growth inhibitory signals
- evasion of apoptosis (programmed cell death)
- limitless replicative potential
- angiogenesis (growth of new blood vessels)
- potential for metastatic/tissue invasion

Cells acquire these properties through genetic and epigenetic alterations (external modifications to DNA that turn genes "on" or "off" but do not change the DNA sequence itself) over time as a result of genomic instability, acquired and inherited mutations, changes in the microenvironment, cell selection, and clonal expansion (Grant, 2013).

Carcinogenesis has been described previously as a three-step process, including tumor initiation, promotion, and progression. *Initiation* involves the interaction between DNA with a reactive chemical species that results in damage. If this damage is not repaired before the next cell division, erroneous DNA replication ensues, resulting in fixed mutations within the genome of individual cells (Grant, 2013). Although initiation is irreversible, not all initiated cells will go on to become a tumor as many of these cells may die by apoptosis. *Promotion* involves the clonal expansion of the initiated cell, in which the initiated cell divides into other cells that now have the same alterations in DNA if not repaired in time (Grant, 2013). Initiated cells may have a selective growth advantage allowing the cells to divide and evade death, resulting in the proliferation and survival of premalignant cells and the formation of benign lesions like polyps. *Progression* is the stage in which benign lesions acquire the ability to proliferate and invade adjacent tissue and establish distant sites of metastasis through the acquisition of additional mutations (Grant, 2013). While this simplistic model has been used over time to understand the multi-step process of carcinogenesis, we now understand that cancer is a complex result of multiple sequential mutations in combination with epigenetic changes and prolonged changes in the cellular

microenvironment (Grant, 2013).

Mutations can be either germ-line mutations or somatic mutations. Germ-line mutations occur in the DNA of sperm or egg cells. These are inheritable mutations that can also be passed on to offspring. Somatic mutations are acquired mutations that occur in nongerm cells and cannot be inherited or passed on. However, any cells that result from division of a cell with a somatic mutation will have that same mutation if the mutation is not corrected before the cell is able to divide (Lemoine, 2014). Mutations can involve an alteration in a single base pair (point mutation) as well as deletions, translocations, or insertions of chromosomes or large parts of DNA. The end results of these mutations are highly variable. Some mutations are silent and do not have any clinical implications. Other mutations, especially those that involve deletions of large amounts of DNA, can be more significant as they result in an inability to make essential proteins needed for cell growth (Lemoine, 2014).

The two most common groups of genes that are mutated are proto-oncogenes, which promote cell proliferation, and tumor suppressor genes, which inhibit cell proliferation (Lemoine, 2014). Oncogenes are the end product of a mutated proto-oncogene and stimulate a cell's ability to move through the cell cycle (called a *gain of function mutation*). Mutations in tumor suppressor genes are referred to as *loss of function mutations* because the normal function of suppressing growth is lost (Harrington et al., 2013). Fusion oncogenes are a result of translocations among normal genes; BCR-ABL and PML–RARα (discussed in Chapter 20) are two examples of fusion oncogenes that stimulate abnormal cell growth (Lemoine, 2014).

The p53 gene (*TP53*) is a tumor suppressor gene that is frequently mutated in more than 50% of human cancers (Grant, 2013). This gene determines whether cells will live or die after their DNA is damaged. Apoptosis is the innate cellular process of programmed cell death. Alterations in *TP53* may decrease apoptotic signals, thus decreasing the body's ability to kill mutated cells, giving rise to a survival advantage for mutant cell populations. Mutant *TP53* is associated with a poor prognosis and may be used to determine response to treatment.

Pathophysiology Alert

Carcinogenesis is the result of both genetic and epigenetic changes. The term epigenetics refers to heritable, reversible changes in gene expression that do not involve changes to the underlying DNA sequence. Epigenetic changes result in a change in phenotype without a change in genotype. Epigenetics are critical to the process of transcription regulation and gene expression (Miozzo, Vaira, & Sirchia, 2015). Epigenetic changes include alterations in DNA methylation, histone modification, changes in chromatin, and noncoding RNA (ncRNA)-associated gene silencing. These changes may result in overexpression or underexpression of genes (Lemoine, 2014; Harrington et al., 2013; Shao, Khokha, & Hill, 2013; Miozzo et al., 2015).

All cells, both healthy and malignant, proliferate by way of the cell cycle (see Fig. 6-2). The cell cycle time is the time required for one cell to divide and reproduce two identical daughter cells. The cell cycle of any cell has four distinct phases, each with a vital underlying function:

1. G_1 phase: RNA and protein synthesis occur
2. S phase: DNA synthesis occurs
3. G_2 phase: Premitotic phase; DNA synthesis is complete, mitotic spindle forms
4. Mitosis: Cell division occurs

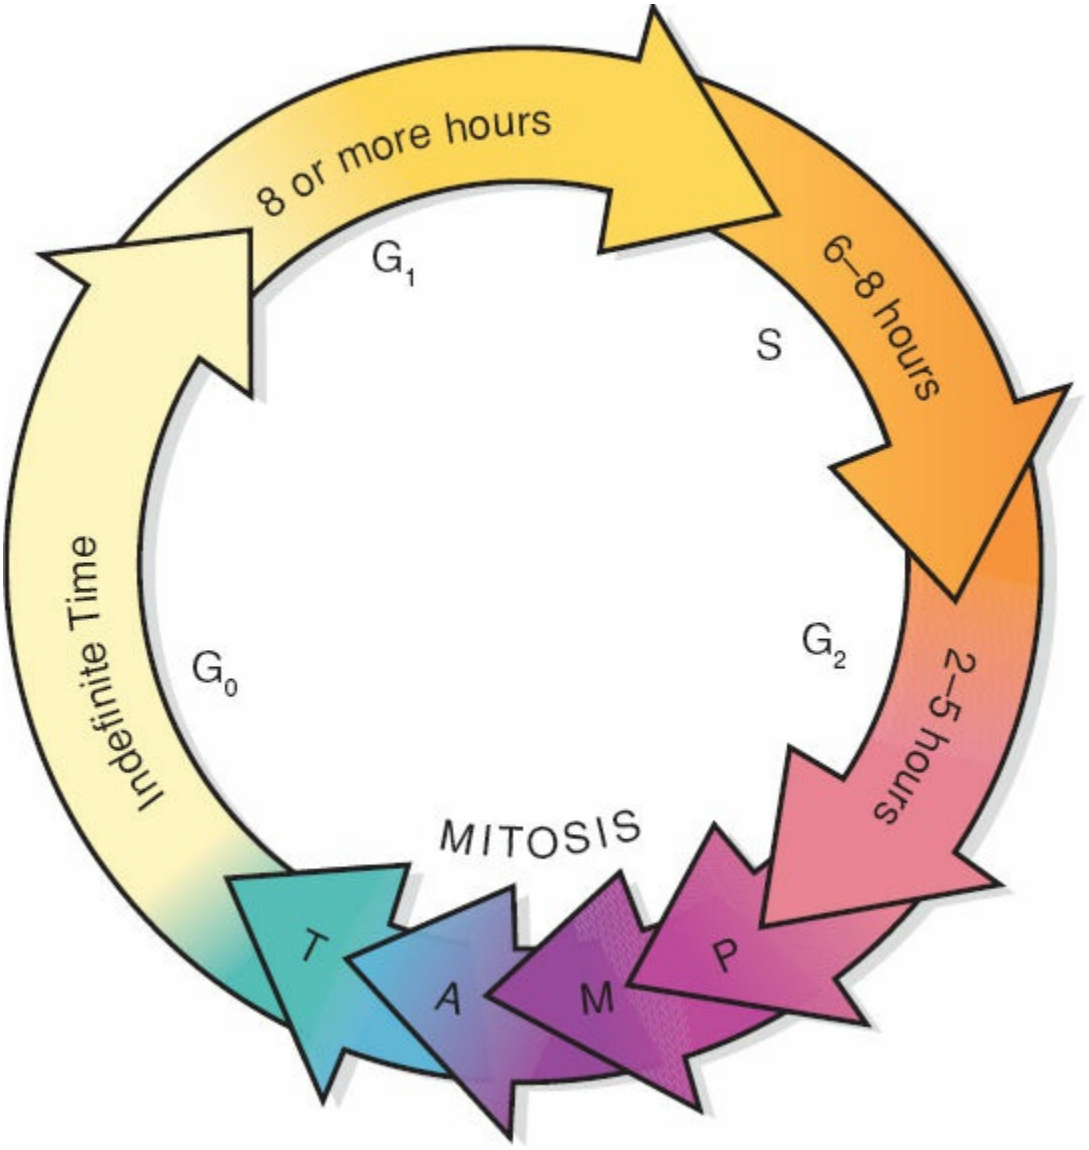

FIGURE 6-2 Phases of the cell cycle extend over the interval between the midpoint of mitosis and the subsequent end point in mitosis in a daughter cell. G_0 is the resting, or dormant, phase of the cell cycle. G_1 is the postmitotic phase during which ribonucleic acid (RNA) and protein syntheses are increased and cell growth occurs. In the S phase, nucleic acids are synthesized and chromosomes are replicated in preparation for cell mitosis. During G_2, RNA and protein synthesis occur as in G_1. P, prophase; M, metaphase; A, anaphase; T, telophase. Redrawn from Porth, C. M. (2002). *Pathophysiology: Concepts of altered health states* (6th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.

The G_0 phase, the resting or dormant phase of cells, can occur after mitosis and during the G_1 phase. In the G_0 phase there are cells that are not actively dividing but have the potential to enter into the cell cycle. Mitosis (cell division) occurs more frequently in malignant cells than in normal cells. As the cells grow and divide, more glucose and oxygen

are needed. If glucose and oxygen are unavailable, malignant cells use anaerobic metabolic channels to produce energy, which makes the cells less dependent on the availability of a constant oxygen supply.

Proliferation through the cell cycle is controlled by a balance of positive and negative signals received from inside and outside of the cell (known as *signal-transduction pathway*) (Harrington et al., 2013). A decrease or increase in the cell's ability to respond to a signal may result in increased proliferation.

Thus, cancer development and progression is a result of a series of mutations over time that destabilize the genome and allow for uncontrolled cell growth. This makes the cells further susceptible to mutations and causes alterations in the surrounding tissue, favoring growth and invasion into surrounding tissue (Harrington et al., 2013).

Metastasis

Tumors also have the capacity to invade and spread from their original site to other organs in the body. This process is known as metastasis. Increasing numbers and types of genetic abnormalities precede tumor progression and metastasis (Shao et al., 2013). The two most common mechanisms of metastasis are via lymphatic channels or blood vessels (Shao et al., 2013).

The most common sites of metastasis include the bones, lungs, liver, and central nervous system (CNS). The site of metastasis is influenced by the availability of a blood supply, cell receptors and genes that may direct the malignant cell to travel to specific sites, and the presence of growth factors essential for metastatic growth that may be elicited only in selected organs.

Angiogenesis

Angiogenesis is the process by which a new blood supply is formed, creating an interface between the tumor and the vascular surface of the host (Rak, 2013). Once a tumor reaches a size of 2 mm^3, this blood supply is necessary for continued growth and facilitation of metastasis. The newly formed blood vessels allow inflow of nutrition, oxygen, growth factors, metabolites, hormones, and regulatory molecules to the tumor and also provide an essential route for metastasis. Angiogenesis also allows the export of metastatic cancer cells, proinflammatory, procoagulant, metabolic, and angiogenesis-regulating substances from the tumor to the vascular system and distant sites (Rak, 2013). The process of angiogenesis is mediated by the release of growth factors and key molecules such as vascular endothelial growth factor (VEGF). These proteins rapidly stimulate formation of new blood vessels. Therapies that target VEGF or its receptors are being used effectively to treat many cancers (Rak, 2013).

Lymphatic Spread

The transport of tumor cells through the lymphatic circulation is the most common mechanism of metastasis. Tumor emboli enter the lymph channels by way of the interstitial fluid, which communicates with lymphatic circulation. Malignant cells also may penetrate lymphatic vessels by invasion. After entering the lymphatic circulation, malignant cells either lodge in the lymph nodes or pass between the lymphatic and venous circulations. Tumors arising in areas of the body with rapid and extensive lymphatic circulation are at high risk for metastasis through lymphatic channels. Breast tumors frequently metastasize in this manner through axillary, clavicular, and thoracic lymph channels.

Hematogenous Spread

Hematogenous spread is the dissemination of malignant cells via the bloodstream and is directly related to the vascularity of the tumor. Malignant cells are able to travel through the bloodstream, attach to endothelium and attract fibrin, platelets, and clotting factors to seal themselves from immune system surveillance. The endothelium retracts, allowing the malignant cells to enter the basement membrane and secrete lysosomal enzymes. These

enzymes destroy surrounding body tissues and thereby allow implantation.

Etiology

Genetic mutations can result from inherited mutations, acquired mutations due to exposure to chemical- or radiation-induced DNA damage, exposure to viruses, and random errors that may occur during DNA synthesis (Harrington et al., 2013). Recent evidence has demonstrated that the environment can also profoundly influence the epigenome: diet, smoking, and alcohol consumption can negatively impact the gene expression profile (Miozzo et al., 2015).

Other factors implicated in carcinogenesis include viruses and bacteria, physical agents, chemical agents, genetic or familial factors, dietary and life style factors, and hormonal agents.

Viruses and Bacteria

Viruses are thought to incorporate themselves into the genetic structure of cells, thus altering future generations of that cell population—perhaps leading to cancer.

The human papillomavirus (HPV) family includes over 170 different types of viruses that infect the mucosa of the anogenital region (anus and genital), upper-respiratory tract, or the skin. HPV16 is a high-risk type of HPV associated with cervical, anogenital, and oral mucosal cancers (Ghittoni, Accardi, Chiocca, & Tommasino, 2015; Hay & Ganley, 2015).

Chronic viral infection with hepatitis C is associated with an increased risk for hepatocellular carcinoma (Mitchell, Lemon, & McGivern, 2015).

A few bacteria are associated with the development of cancer. An example is *Helicobacter pylori (H pylori)* which is linked with gastric ulcers. Because the inner layer of the stomach can also become inflamed and damaged, *H. pylori* can lead to cancer in the lower part of the stomach and is also associated with some types of stomach lymphoma.

Physical Agents

Physical factors associated with carcinogenesis include exposure to sunlight or radiation. Exposure to ionizing radiation can occur with repeated diagnostic x-ray procedures or with radiation therapy used to treat disease. Fortunately, improved x-ray equipment appropriately minimizes the risk to healthy tissue of extensive radiation exposure. Radiation therapy used in disease treatment and exposure to radioactive materials at nuclear weapon manufacturing sites or nuclear power plants is associated with a higher incidence of leukemias; multiple myeloma; and cancers of the lung, bone, breast, thyroid, and other tissues. Background radiation from the natural decay process produces radon that has also been associated with lung cancer.

Chemical Agents

Chemicals can contribute to the initiation, promotion, and progression stages of carcinogenesis either through their ability to damage DNA directly and produce somatic mutations in cells or as a result of an altered microenvironment that provides initiated cells with a growth advantage via metabolic changes, local vascular changes, and/or the ability to evade apoptosis, terminal differentiation, and contact inhibition (Grant, 2013).

Over one third of cancer-related deaths are associated with tobacco use, including cancers of the lung and bronchus, oral cavity and pharynx, larynx, esophagus, stomach, pancreas, kidney and renal pelvis, urinary bladder, and cervix as well as acute myeloid leukemia (Underwood et al., 2015). Incidence rates for tobacco-related cancers have decreased significantly from 152.9 (per 100,000 persons) in 2005 to 145.8 in 2009 (Underwood et al., 2015). In men, death from lung cancer has been reduced by 38% from 1990 to 2014; rates in women have also declined but not as dramatically (Loeb, 2016). Despite these improvements, tobacco continues to account for a large number of cancers in the United States and worldwide (Underwood et al., 2015; Loeb, 2016.)

Alcohol consumption is strongly linked to the development of cancers of the mouth and pharynx, larynx, esophagus, liver, stomach, gallbladder, colon, breast, and lung. An estimated 4% of all cancers can be attributed to daily alcohol consumption; 30% to 40% of cancers of the oral cavity and pharynx and 20% to 50% of esophageal cancers may be attributed to daily alcohol use (Katzke, Kaaks, & Kuhn, 2015). There is a strong synergistic interaction between alcohol consumption and smoking with regard to cancer risk (Katzke et al., 2015).

Many chemical substances found in the workplace have proved to be carcinogens or co-carcinogens. The extensive list of suspected chemical substances continues to grow and includes aromatic amines and aniline dyes; pesticides and formaldehydes; arsenic, soot, and tars; asbestos; benzene; betel nut and lime; cadmium; chromium compounds; nickel and zinc ores; wood dust; beryllium compounds; and polyvinyl chloride.

Genetics or Familial Factors

Observations over time have shown that cancers cluster in some families. This may be due to genetics, shared environments, cultural or lifestyle factors, or chance alone. Obtaining an accurate family history is essential in guiding referrals to genetic counseling and testing for hereditary cancer syndromes, such as hereditary breast and ovarian cancer syndrome (HBOC) and Lynch syndrome. *BRCA1* and *BRCA2* are the genes associated with hereditary breast and ovarian cancer syndrome, and *MLH1, MSH2, MSH6,* and *PMS2* are the genes associated with Lynch syndrome. Lynch syndrome, also known as *hereditary nonpolyposis colorectal cancer (HNPCC)*, is an inherited disorder that increases the risk of developing many other types of cancer, particularly colorectal cancer. Patients who test positive for mutations in these genes need more careful follow-up and surveillance for cancer over their lifespan (Estrada, LeGrazie, McKamie, and Montgomery, 2015). In addition, lifestyle changes to minimize cancer risk may be recommended (Mahon, 2015).

Multigene panel testing, also known as *next-generation gene sequencing*, which tests for germline mutations in a number of genes associated with increased cancer risk, has recently become available to patients. Some of these genetic mutations carry a significantly elevated lifetime cancer risk (greater than 50%), whereas others carry less of a risk (Estrada et al., 2015). For example, mutations in the *MSH2* gene are associated with an 80% lifetime risk for developing colorectal cancer and a 70% chance of developing endometrial cancer (Mahon, 2013b). It is essential to identify individuals or families most likely to benefit from testing and ensure pre- and posttest counseling, preferably done by genetics experts (Mahon, 2013a).

Common errors that may result when nongenetics professionals order genetic tests

include: the wrong genetic test is ordered, genetic test results are misinterpreted, and inappropriate or inadequate genetic counseling leads to psychosocial distress or other negative outcomes (Mahon, 2013b).

The *BRCA1/2* genes account for approximately 25% of hereditary breast cancer cases. However, additional genes have been discovered that may contribute to hereditary breast cancer risk. Next-generation gene sequencing has the potential to detect these other lower penetrance genes that may be responsible for hereditary breast cancer. One commercially available targeted panel that tests for 17 of these genes is called Breast Next™ (Ambry Genetics Laboratories, n.d.).

Approximately 5% of cancers in adults display a familial predisposition. Key indicators of hereditary risk include:

- younger than usual age at time of diagnosis (e.g., colon cancer before age 50);
- multiple family members in one generation with cancer;
- multiple generations with cancer(s) associated with hereditary risk;
- presence of nonmalignant changes associated with hereditary risk (e.g., Dysplastic nevi);
- presence of rare tumors commonly associated with hereditary risk (e.g., medullary thyroid cancer);
- any pattern of cancers associated with a hereditary cancer syndrome (e.g., Lynch syndrome);
- bilateral cancer in a paired organ (e.g., breast cancer in both breasts);
- multiple synchronous cancers (e.g., colon cancer with more than one tumor in the colon); or
- an individual with more than one primary cancer (Mahon, 2015).

Cancers associated with familial inheritance include retinoblastomas; nephroblastomas (kidney tumor); pheochromocytomas (adrenal medulla tumor); malignant neurofibromatosis (tumors of nerve tissue); and breast, ovarian, colorectal, stomach, prostate, and lung cancers.

Dietary and Lifestyle Factors

After tobacco, obesity, diet, and levels of physical activity are the most important modifiable determinants of cancer risk. Poor diet is linked to 25% of cancers. Obesity contributes to as much as 20% of cancer-related deaths (Mahon, 2015). Obesity is also associated with increased risk for cancer, including renal cell cancer; postmenopausal breast cancer; and cancers of the endometrium, pancreas, colon, and esophagus (adenocarcinomas) (Katzke et al., 2015).

Prospective studies have shown that diets with higher intake of fruits, vegetables, and wholegrain foods, and lower intake of red and processed meats and salt, are related to reduced risks of cancer and death and that a healthy diet can improve overall survival after diagnosis of breast and colorectal cancers. There is evidence that high dietary intake of fruit and vegetables may reduce the risk of cancers of the aerodigestive tract (combined organs and tissues of the respiratory tract and the upper part of the digestive tract [lips, mouth, tongue, nose, throat, vocal cords, and part of the esophagus and windpipe]) and dietary fiber protects against colorectal cancer. Red and processed meats increase the risk of

colorectal cancer (Norat et al., 2015).

Dietary substances that appear to increase the risk of cancer include fats, alcohol, salt-cured or smoked meats, and nitrate- and nitrite-containing foods. A high-caloric dietary intake and obesity are associated with an increased cancer risk (Norat et al., 2015).

There is some evidence that exercise, independent of weight, may provide a protective benefit against cancer. A demonstrated inverse association between physical activity and the risk of cancers for which obesity may not be a major risk factor, such as bladder cancer and gastric cancer, may suggest benefits of physical activity beyond preventing obesity (Katzke et al., 2015).

Hormonal Agents

Tumor growth may be promoted by disturbances in hormonal balance, including prolonged exposure to the hormone either by the body's own (endogenous) hormone production or by administration of exogenous hormones. Cancers of the breast and uterus (estrogen dependent) and prostate (androgen dependent) are thought to depend on endogenous hormonal levels for growth.

A lower risk of estrogen and progesterone receptor positive breast cancer is associated with an earlier age at first full-term pregnancy, a higher number of full-term pregnancies, and longer cumulative duration of breast-feeding. Longer duration of breast-feeding is also associated with a decreased risk of hormone receptor negative and HER2 negative (known as *triple negative*) breast cancer (Katzke et al., 2015).

A higher number of full-term pregnancies and longer cumulative lifetime duration of breast-feeding also confer relatively strong protection against ovarian cancer, reducing risk by up to 50% or more (Katzke et al., 2015).

Use of oral contraceptives has been linked to clear reduction in risk of ovarian cancer, with risk reduction of up to 50% depending on duration of use. In addition, oral contraceptive use is associated with up to 40% reductions in risk of endometrial cancer and a more modest (up to around 15%) reduction in risk of colorectal cancer, but a weak (less than 10%) increase in risk of breast cancer (Katzke et al., 2015).

Postmenopausal hormone replacement therapy (HRT), especially combined estrogen-plus-progestin regimens, causes an increase in risk of breast cancer. There is a strong correlation between use of estrogen-only HRT and increased endometrial cancer risk in contrast to the use of combined estrogen-plus-progestin regimens, which may reduce the risk for endometrial cancer (Katzke et al., 2015).

Role of the Immune System

In humans, malignant cells can develop at any time in the life span. However, some evidence indicates that the immune system can detect the development of malignant cells and destroy them before cell growth becomes uncontrolled. When the immune system fails to identify and stop the growth of malignant cells, clinical cancer develops.

An intact immune system has the ability to combat cancer cells in several ways. Usually, the immune system recognizes as foreign certain antigens on the cell membranes of many cancer cells. These antigens, known as *tumor-associated antigens* (also called *tumor cell antigens*), are capable of stimulating both cellular and humoral immune responses.

Along with the macrophages, T lymphocytes are responsible for recognizing tumor-associated antigens. When T lymphocytes, the soldiers of the cellular immune response, recognize tumor antigens, other T lymphocytes that are toxic to the tumor cells are stimulated. These lymphocytes proliferate and are released into the circulation. In addition to possessing cytotoxic (cell-killing) properties, T lymphocytes can stimulate other components of the immune system to rid the body of malignant cells.

A three-phase model has been proposed to describe the role of the immune response during various stages of tumor progression. These stages include elimination, equilibrium, and escape.

During the elimination phase, the immune system recognizes tumor cells and mounts a response against the tumor. During the equilibrium phase, the immune system and the tumor are in dynamic equilibrium, where the combination of the genomic instability of tumor cells and the pressure exerted by the antitumor immune response results in editing of the tumor cell population. The elimination of certain tumor cells by the immune system results in the selection of less immunogenic tumors. During the escape phase, there are too many tumor cells, which overwhelm the immune system and allow the tumor to evade elimination (Nguyen, Lind, & Ohashi, 2013).

The ability to evade the immune response may be, in part, a result of reduced immunogenicity of tumor cells, such as reduced expression of tumor antigens. However, there are many other mechanisms whereby the tumor can evade the immune system (Nguyen et al., 2013).

The failure of the immune system to respond promptly to the malignant cells allows the tumor to grow too large to be managed by normal immune mechanisms. Newer therapies are attempting to restore or stimulate the immune response to treat cancer (discussed later in chapter).

Patients who are immunocompromised have been shown to have an increased incidence of cancer. Organ transplant recipients who receive immunosuppressive therapy to prevent organ rejection have an increased incidence of lymphoma, Kaposi sarcoma, squamous cell cancer of the skin, and cervical and anogenital cancers. Patients with immunodeficiency diseases, such as AIDS, have an increased incidence of Kaposi sarcoma, lymphoma, and rectal and head and neck cancers.

Treatment with certain types of chemotherapy, including alkylating agents and topoisomerase II inhibitors can increase the risk of developing another malignancy over the course of a lifetime. Autoimmune diseases, such as rheumatoid arthritis and Sjögren syndrome, are associated with increased cancer development. Finally, age-related changes,

such as declining organ function, increased incidence of chronic diseases, and diminished immunocompetence, may contribute to an increased incidence of cancer in older people.

PREVENTION

Nurses play a critical role in every level of prevention, including primary prevention, secondary prevention, and tertiary prevention. Primary prevention efforts focus on preventing or delaying onset of cancer. Secondary prevention focuses on the early detection of cancer with the goal of identifying cancer in early stages before symptoms develop. Tertiary prevention includes the management of the disease and prevention of progression to later stages. Nurses must be familiar with current guidelines and recommendations for cancer prevention and screening in order to provide accurate, relevant patient education (Mahon, 2015). A major barrier to adherence to screening standards is lack of a recommendation from a health care provider (Mahon, 2015). Nurses can play a critical role in informing patients about recommended screening tests and provide anticipatory guidance to alleviate any fears patients may have about the tests.

Primary Prevention

As discussed, primary prevention strategies are aimed at preventing or delaying the development of cancer (Mahon, 2015). Nurses play a critical role in educating the community about cancer prevention. Nurses can use their teaching and counseling skills to encourage participation in cancer prevention programs, minimize exposure to known carcinogens, and to adopt healthy lifestyles, including avoiding all forms of tobacco; maintaining a healthy weight; performing regular exercise (150 min/wk); eating a diet rich in fruits and vegetables (at least five servings per day); limiting red meat, high fat, and processed foods; limiting alcohol; using sun protection; getting regular checkups; and being familiar with their own family history and personal cancer risks (Kushi, Doyle, McCullough, 2012; American Cancer Society, 2015). Other primary prevention strategies include immunization against cancer-associated viruses, such as hepatitis and HPV (Mahon, 2015).

For individuals at high risk for cancer, medications or prophylactic surgery may be recommended (Mahon, 2015). Several clinical trials have been conducted to identify medications that may help reduce the incidence of certain types of cancer. For example, a number of studies have demonstrated that daily use of the medication tamoxifen can significantly reduce a woman's lifetime risk of developing breast cancer in high-risk populations (Cuzik et al., 2014).

Secondary Prevention

Nurses must be aware of factors such as race, cultural influences, access to care, provider–patient relationship, level of education, income, and age, which influence the knowledge, attitudes, and beliefs people have about cancer. These factors also may affect the health-promoting behaviors people practice.

Public awareness about health-promoting behaviors can be provided in a variety of ways, including health education and health maintenance programs. Although primary prevention programs may focus on the hazards of tobacco use or the importance of nutrition, secondary prevention programs focus on early detection. Nurses and providers must encourage people to comply with detection efforts as suggested by the American Cancer Society (Table 6-2). Many organizations conduct cancer-screening events that focus on cancers with the highest incidence rates or those that have improved survival rates if diagnosed early, such as breast cancer. These events offer education and examinations, such as mammograms, for minimal or no cost. Often these programs are targeted at people who lack access to health care or cannot afford to participate on their own. In developing these programs, nurses must use strategies that are culturally sensitive to foster participation.

TABLE 6-2 American Cancer Society Recommendations for Early Detection of Cancer in Asymptomatic, Average Risk People

Site	Gender	Age-Specific Evaluation and Frequency
Breast	F	Women ages 40–44 may start annual mammograms if they wish to do so Starting at age 45, mammograms should be done every year, then, Every other year beginning at age 55 Clinical breast examination and self-examination are no longer recommended
Colon/rectum	F/M	Beginning at age 50, one of the following strategies should be used: • Flexible sigmoidoscopy every 5 years*, or • Colonoscopy every 10 years, or • Double-contrast barium enema every 5 years*, or • CT colonography (virtual colonoscopy) every 5 years* • Yearly guaiac-based fecal occult blood test (gFOBT) done via multi-sample take-home test, or • Yearly fecal immunochemical test (FIT) done via multi-sample take-home test, or • Stool DNA test (sDNA) every 3 years* *If test is positive, colonoscopy must be done High-risk patients may be tested on a different schedule.
Prostate	M	Starting at age 50, men should talk to a health care provider about the risks and benefits of testing and then decide about screening. African-American men or those with a father or brother with a history of prostate cancer should have this discussion beginning at age 45. If the decision is made to pursue testing, testing includes a PSA test +/– a digital rectal examination.
Cervix	F	• **Cervical cancer testing should start at age 21.** • **Women between the ages of 21 and 29** should have a Pap test done every 3 years. HPV testing should not be used in this age group unless it's needed after an abnormal Pap test result. • **Women between the ages of 30 and 65** should have a Pap test plus an HPV test (called "cotesting") done every 5 years. This is the preferred approach, but it is also acceptable to have a Pap test alone every 3 years. • **Women over age 65** who have had regular cervical cancer testing in the past 10 years with normal results should not be tested for cervical cancer. Once testing is stopped, it should not be started again. Women with a history of a serious cervical precancer should continue to be tested for at least 20 years after that diagnosis, even if testing goes past age 65. • **A woman who has had her uterus and cervix removed (a total hysterectomy)** for reasons not related to cervical cancer and who has no history of cervical cancer or serious precancer should not be tested. • **All women who have been vaccinated against HPV** should still follow the screening recommendations for their age groups.
Endometrium	F	The American Cancer Society recommends that at the time of menopause, all women should be told about the risks and symptoms of endometrial cancer. Women should report any unexpected vaginal bleeding or spotting to their doctors.
Lung cancer	M/F	For patients: • 55–74 years of age • In good health • Have at least a 30 pack/year smoking history AND are either still smoking or have quit within the last 15 years Screening is done with an annual low-dose CT scan (LDCT) of the chest.
Cancer-related checkups	M/F	For people aged 20 or older who get periodic health examinations, a cancer-related check-up should include health counseling and, depending on a person's age and gender, examinations for cancers of the thyroid, oral cavity, skin, lymph nodes, testes, and ovaries.

(2015); The American Cancer Society Guidelines for the early detection of cancer (2015) available at http://www.cancer.org/healthy/findcancerearly/cancerscreeningguidelines/american-cancer-society-guidelines-for-the-early-detection-of-cancer

Unfolding Patient Stories: Doris Bowman • Part 1

Doris Bowman, a 39-year-old diagnosed with uterine fibroids, dysmenorrhea, and menorrhagia, is scheduled for a total abdominal hysterectomy with bilateral salpingoopherectomy. She has a family history of uterine and ovarian cancer. She asks the nurse what she can do to further reduce her risk for cancer and is also concerned for her family members. What patient and family education should the nurse present on risk reduction strategies, health promotion, and cancer screening? (Doris Bowman's case continues in Chapter 33.)

Care for Doris and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in (thepoint.lww.com/DocuCareEHR).

DIAGNOSIS

A cancer diagnosis is based on an assessment of physiologic and functional changes and results of the diagnostic evaluation.

Diagnostic Evaluation

The diagnostic evaluation is guided by information obtained through a complete history and physical examination. Knowledge of suspicious symptoms and of the behavior of particular types of cancer assists in determining which diagnostic tests are most appropriate. Patients with suspected cancer undergo extensive testing to (1) determine the presence of a tumor and its extent, (2) identify possible spread (metastasis) of disease or invasion of other body tissues, (3) evaluate the function of involved and uninvolved body systems and organs, and (4) obtain tissue and cells for analysis to assist in the evaluation of tumor type, stage, grade, and molecular and genetic changes.

Patients undergoing extensive testing are usually fearful of the procedures and anxious about the possible test results. The nurse can help relieve the patient's fear and anxiety by explaining the tests to be performed, the sensations likely to be experienced, and the patient's role in the test procedures. The nurse encourages the patient and family to voice their fears about the test results, supports the patient and family throughout the test period, and reinforces and clarifies information conveyed by the primary care provider.

Tumor Staging and Grading

A complete diagnostic evaluation includes identifying the stage and grade of the tumor. This is accomplished before treatment begins to provide baseline data for evaluating outcomes of therapy and to maintain a systematic and consistent approach to ongoing diagnosis and treatment. Treatment options and prognosis are based on stage and grade of disease as well as the molecular and genetic profile.

Staging

Staging determines the size of the tumor and the extent of disease. Several systems exist for classifying the disease stage. The TNM system is frequently used for many solid tumor types. In this system, "T" refers to the extent of the primary tumor, "N" refers to lymph node involvement, and "M" refers to the extent of metastasis (Box 6-1) (Shao et al., 2013). A variety of other staging systems are used to describe the extent of cancers that are not well described by the TNM system, such as CNS cancers, hematologic cancers, and malignant melanoma. Staging systems also provide a convenient shorthand notation that condenses lengthy descriptions into manageable terms for comparisons of treatments and prognoses.

BOX 6-1 TNM Classification System

T	The extent of the primary tumor
N	The absence or presence and extent of regional lymph node metastasis
M	The absence or presence of distant metastasis

The use of numerical subsets of the TNM components indicates the progressive extent of the malignant disease.

Primary Tumor (T)

Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1, T2, T3, T4	Increasing size and/or local extent of the primary tumor

Regional Lymph Nodes (N)

Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1, N2, N3	Increasing involvement of regional lymph nodes

Distant Metastasis (M)

Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M	Distant metastasis

From Edge, S., Byrd, D. R., Compton, C. C., Fritz, A. G., Greene, F. L., & Trotti, A. (Eds.). (2010). *AJCC cancer staging manual* (7th ed.). New York: Springer-Verlag.

Grading

Grading refers to the classification of the tumor cells. Grading systems seek to define the type of tissue from which the tumor originated and the degree to which the tumor cells retain the functional and histologic characteristics of the tissue of origin. Samples of cells to be used to establish the grade of a tumor may be obtained through cytology (examination of cells from tissue scrapings, body fluids, secretions, or washings), biopsy, or surgical excision.

This information helps the health care team predict the behavior and prognosis of various tumors. The tumor is assigned a numeric value ranging from I to IV (Box 6-2). Grade I tumors, also known as *well-differentiated tumors,* closely resemble the tissue of origin in structure and function. Tumors that do not clearly resemble the tissue of origin in structure or function are described as *poorly differentiated* or *undifferentiated* and are assigned grade IV. These tumors tend to be more aggressive and less responsive to treatment than are well-differentiated tumors.

Genetic Testing: Precision Medicine

Over the last decade there has been a paradigm shift toward a more personalized approach to cancer treatment. Precision medicine, also called *personalized medicine,* is defined by the National Cancer Institute as "a form of medicine that uses information about a person's genes, proteins, and environment to prevent, diagnose, and treat disease" (National Cancer Institute, 2016).

Precision medicine emerged in oncology with the discovery of molecularly targeted agents based on DNA molecular information of the patients' tumors. While traditional chemotherapy destroys rapidly dividing cells by interfering with DNA replication and cell division, molecularly targeted agents alter the function of specific molecular targets in cell signaling, proliferation, apoptosis, angiogenesis, metabolism, migration, or invasion. Some tumor types share the same targetable molecular alterations (e.g., HER2 overexpression in both breast and gastric cancers) (Le Tourneau et al., 2015).

Molecular profiling of key oncogenic factors has allowed many types of cancers to be more carefully classified. For example, a breast tumor is now defined not just by TNM stage and grade but whether the tumor is estrogen and progesterone receptor positive or negative and whether the tumor expresses HER2. These results allow the provider to recommend treatment targeted to the patient's profile (e.g., tamoxifen or arimidex for estrogen-receptor (ER) positive breast cancer and Herceptin, which targets the HER2 receptor in HER2 positive patients) (Harrington et al., 2013). The advent of readily available, cost-effective tests that identify targetable molecular alterations in a reasonable timeframe has allowed wide integration into oncology practice (Le Tourneau et al., 2015).

BOX 6-2 Grading

GX	Grade cannot be assessed
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated
G4	Undifferentiated

MANAGEMENT

The range of possible treatment goals may include cancer prevention, complete eradication of malignant disease (cure), prolonged survival and prevention of progression (control), or relief of symptoms associated with the disease (palliation).

A number of factors are considered when determining a treatment plan, including the tumor type, stage, and grade; functional or performance status (PS) of the patient; comorbidities; and organ function.

PS is one of the most important factors in determining eligibility for treatments, including clinical trials, and predicting prognosis (West & Jin, 2015). There are two widely used scales for PS. The most commonly used is typically referred to as the Zubrod or ECOG (Eastern Cooperative Oncology Group) scale. The ECOG scale uses a range of 0–4 with 0 being independent and 4 being restricted to bed. The other commonly used scale, the Karnofsky scale, ranges from 10 (moribund) to 100 (fully independent) (West & Jin, 2015).

A variety of approaches, including surgery, radiation therapy, chemotherapy, targeted therapy and immunotherapy, may be used at various times throughout treatment. Understanding the principles of each treatment modality and how they interrelate is important in understanding the rationale and goals of treatment.

The health care team, the patient, and the patient's family must have a clear understanding of the treatment options, goals, and potential impact on quality of life. Open communication and support are vital as the patient and family periodically reassess treatment plans and goals when complications of therapy develop or disease progresses.

Surgery

Surgery is used for a variety of different reasons and at different times during the cancer trajectory. Surgery may be the primary method of treatment, or it may be prophylactic, palliative, or reconstructive. Diagnostic surgery is the definitive method for identifying the cellular characteristics of the tumor that influence all treatment decisions.

Diagnostic Surgery

Diagnostic surgery, such as a biopsy, must be performed to obtain a tissue sample for analysis of cells suspected to be malignant. In most instances, the biopsy is taken from the actual tumor, but in some situations, it is necessary to biopsy lymph nodes near the suspicious tumor. Many cancers metastasize from the primary site to other areas of the body through the lymphatic circulation. Knowing whether adjacent lymph nodes contain tumor cells is critical to staging the cancer and will impact the need for systemic therapies instead of or in addition to surgery, to combat tumor cells that have gone beyond the primary tumor site.

Surgery as Primary Treatment

When surgery is the primary approach in treating cancer, the goal is to remove the entire tumor or as much as is feasible (a procedure sometimes called *debulking*) and any involved surrounding tissue, including regional lymph nodes.

Two common surgical approaches used for treating primary tumors are local and wide excisions:

- A *local excision* is warranted when the mass is small. It includes removal of the mass and a small margin of normal tissue that is easily accessible.
- *Wide* or *radical excisions* (*en bloc dissections*) include removal of the primary tumor, lymph nodes, adjacent involved structures, and surrounding tissues that may be at high risk for tumor spread. This surgical method can result in disfigurement and altered functioning. However, wide excisions are considered if the tumor can be removed completely and the chances of cure or control are good.

Prophylactic Surgery

Prophylactic surgery involves removing nonvital tissues or organs that are likely to develop cancer. Several factors are considered when providers and patients discuss possible prophylactic surgery; these include family history and genetic predisposition, presence or absence of symptoms, potential risks and benefits, ability to detect cancer at an early stage, and the patient's acceptance of the postoperative outcome.

Colectomy (surgical resection of the colon), mastectomy (removal of breast), and oophorectomy (removal of ovary[ies]) are examples of prophylactic surgeries. Recent developments in the ability to identify genetic markers indicative of a predisposition to develop some types of cancer may play a role in decisions concerning prophylactic surgeries. Several factors are considered when deciding to proceed with a prophylactic mastectomy,

including a strong family history of breast cancer; positive results in *BRCA1* or *BRCA2* testing; an abnormal physical finding on breast examination, such as progressive nodularity and cystic disease; a proven history of breast cancer in the opposite breast; abnormal mammography findings; and abnormal biopsy results.

Because the long-term physiologic and psychological effects are unknown, prophylactic surgery is offered selectively to patients with a thorough discussion of potential risks and benefits with patients and families. Preoperative teaching and counseling, as well as long-term follow-up, are provided.

Nursing Alert
BRCA1 (breast cancer 1) and BRCA2 (breast cancer 2) are clinical markers associated with the hereditary development of breast and ovarian cancer. Mutations of the BRCA1 and BRCA2 genes account for most inherited breast cancers. Carriers of BRCA1 (a tumor suppressor gene) mutation have an 85% risk for developing breast cancer and a 45% risk for developing ovarian cancer by age 85 (Fischbach & Dunning, 2014). BRCA2 is also a tumor suppressor gene; mutations in this gene are associated with hereditary breast and ovarian cancer syndrome, and often presents as premenopausal breast cancer, ovarian cancer, and/or male breast cancer (Axilbund & Wiley, 2015). Those who test positive for the mutations should be monitored annually or semi-annually. Discussions with providers may include chemoprevention (e.g., tamoxifen), and consideration of prophylactic surgery (Fischbach & Dunning, 2014).

Palliative Surgery

When cure is not possible, the goals of treatment are to make the patient as comfortable as possible and to improve quality of life as defined by the patient. Palliative surgery is performed in an attempt to relieve complications of cancer, such as ulcerations, obstructions, hemorrhage, pain, and malignant effusions. Honest and informative communication with the patient and family about the risks, benefits, and goals of surgery is essential.

Nursing Management in Cancer Surgery

A multidisciplinary approach to patient care is essential before, during, and after any type of surgery. The effects of surgery on the patient's body image, self-esteem, and functional abilities are addressed. If necessary, a plan for postoperative rehabilitation is made before the surgery is performed.

The nurse must complete a thorough preoperative assessment for factors that may affect the patient undergoing the surgical procedure, including medical history, prior cancer treatments, and any complications associated with those treatments. The nurse targets interventions to minimize the risk of complications (Morgan, 2014). Cardiac risk factors that increase the risk for complications in noncardiac surgery include a history of stroke, heart failure, angina or MI, renal insufficiency, and diabetes (Morgan, 2014). Pre-existing pulmonary disease can increase the risk for postoperative pneumonia and pleural effusions. Patients with cancer may be at increased risk for bleeding (see Chapter 20) and may require additional tests prior to surgery to assess individual bleeding risk. Elective surgery should be

delayed until the patient has an absolute neutrophil count of at least 1,000 cells/mm^3 and a platelet count more than 50 platelets/mm^3 (and more than 100 for any neurosurgery) (Morgan, 2014).

Patients who are undergoing surgery for the diagnosis or treatment of cancer are often anxious about the surgical procedure, possible findings, postoperative limitations, changes in normal body functions, and prognosis. The patient and family require time, support, and assistance to deal with the possible changes and outcomes resulting from the surgery.

The nurse provides education and emotional support by assessing the needs of the patient and family and by discussing their fears and coping mechanisms with them. The nurse encourages the patient and family to take an active role in decision-making when possible. If the patient or family asks about the results of diagnostic testing and surgical procedures, the nurse's response is guided by the information the provider has previously conveyed to the patient and family. The patient and family may also ask the nurse to explain and clarify information that the provider initially gave but that they did not grasp because they were anxious at the time. It is important that the nurse communicate frequently with providers and other members of the health care team to be certain that the information provided is consistent.

After surgery, the nurse assesses the patient's responses to the surgery and monitors the patient for possible complications, such as infection, bleeding, thrombophlebitis, wound dehiscence, fluid and electrolyte imbalance, and organ dysfunction. The nurse also provides for the patient's comfort. Postoperative teaching addresses decreasing the risk for complications, including deep vein thrombosis (DVT) and pneumonia, as well as education on wound care, activity, nutrition, and medication information.

Patients undergoing surgery for cancer require general perioperative nursing care, as described in Chapter 5, along with specific care related to age, organ impairment, nutritional deficits, disorders of coagulation, and altered immunity that may increase the risk of postoperative complications. Combining other treatment methods, such as radiation and chemotherapy, with surgery also contributes to postoperative complications, such as infection, impaired wound healing, altered pulmonary or kidney function, and the development of venous thromboembolism (VTE), also known as DVT. Some cancer types result in an increase in circulating procoagulants, which can significantly increase the risk for DVT. Patients with cancer account for 20% of all DVT cases (Morgan, 2014).

Nursing Alert

Approximately 50% of patients with DVT are asymptomatic. The nurse should inquire about an ache or pain in the calf that is aggravated by standing or walking. In addition, it is important to assess for asymmetry of the limbs as slight swelling may be noted as well as erythema and warmth of the involved extremity. Venous distention in the affected limb that persists despite elevation of the extremity may be noted. Patients may also present with low-grade fever and tachycardia.

Plans for discharge, follow-up and home care, and treatment are initiated as early as possible to ensure continuity of care from hospital to home or from a cancer referral center to the patient's local hospital and health care provider. Patients and families are also encouraged to use community resources, such as the American Cancer Society, for support and information.

Radiation Therapy

In radiation therapy, ionizing radiation is used to interrupt cellular growth. More than half of patients with cancer receive a form of radiation therapy at some point during treatment. Radiation may be used to cure the cancer, as in head and neck, prostate, lung, and bladder cancers. Radiation therapy may also be used to control malignant disease when a tumor cannot be removed surgically or when local nodal metastasis is present, or it can be used prophylactically to prevent leukemic infiltration to the brain (Iwamoto, Haas, & Gosselin, 2012).

Palliative radiation therapy is used to relieve the symptoms of metastatic disease, especially when the cancer has spread to brain, bone, or soft tissue, or to treat oncologic emergencies, such as superior vena cava syndrome (SVCS) or spinal cord compression.

Two types of ionizing radiation—electromagnetic rays (x-rays and gamma rays) and particles (electrons [beta particles], protons, neutrons, and alpha particles)—can lead to tissue disruption. Radiation disrupts malignant cell proliferation through the alteration in DNA structure. Ionizing radiation breaks the strands of the DNA helix, leading to cell death. Ionizing radiation can also ionize constituents of body fluids, especially water, leading to the formation of free radicals and irreversible DNA damage. If the DNA is incapable of repair, the cell may die immediately, or it may initiate apoptosis (Iwamoto et al., 2012).

Cells are most vulnerable to the disruptive effects of radiation during DNA synthesis and mitosis. Therefore, those body tissues that undergo frequent cell division are most sensitive to radiation therapy. These radiosensitive tissues include bone marrow, lymphatic tissue, epithelium of the GI tract, hair cells, and gonads. Slower-growing tissues and tissues at rest are relatively radioresistant (less sensitive to the effects of radiation). Such tissues include muscle, cartilage, and connective tissues.

A radiosensitive tumor is one that can be destroyed by a dose of radiation that still allows for cell regeneration in the normal tissue. Tumors that are well oxygenated also appear to be more sensitive to radiation (Iwamoto et al., 2012). In theory, therefore, radiation therapy may be enhanced if more oxygen can be delivered to tumors. In addition, if the radiation is delivered when most tumor cells are cycling through the cell cycle, the number of cancer cells destroyed (cell kill) is maximal. Certain chemicals, including chemotherapy and some targeted agents (e.g., EGFR inhibitors) act as radiosensitizers and sensitize more hypoxic (oxygen-poor) tumors to the effects of radiation therapy (Iwamoto et al., 2012).

Radiation Delivery

Radiation is delivered to tumor sites by external or internal methods.

External Radiation

If external radiation therapy is used, one of several delivery methods may be chosen, depending on the depth of the tumor. Kilovoltage therapy devices deliver the maximal radiation dose to superficial lesions, such as lesions of the skin and breast. Conversely, linear accelerators and betatron machines produce higher-energy x-rays and deliver their

dosage to deeper structures with less harm to the skin and less scattering of radiation within the body tissues.

Internal Radiation

Internal radiation implantation, or brachytherapy, delivers a high dose of radiation to a localized area. The specific radioisotope for implantation is selected on the basis of its half-life, which is the time it takes for half of its radioactivity to decay. This internal radiation can be implanted by means of needles, seeds, beads, or catheters into body cavities (e.g., vagina, abdomen, pleura) or interstitial compartments (e.g., breast). With internal radiation therapy, the farther the tissue is from the radiation source, the lower the radiation exposure. This spares the noncancerous tissue from the radiation dose and toxicity. Brachytherapy may also be administered orally, as with the isotope iodine-131, which is used to treat thyroid carcinomas.

Intracavitary Radiation. Intracavitary radioisotopes are used frequently to treat gynecologic cancers. In these malignancies, the radioisotopes are inserted into applicators specially positioned in the cervix and vagina, after the position is verified by x-ray. These radioisotopes remain in place for a prescribed time period and then are removed. The patient is maintained on bed rest and carefully log-rolled to prevent displacement of the intracavitary delivery device. The head of the bed must not be elevated greater than 15 degrees due to the risk of perforating the uterus with the appliance. An indwelling urinary catheter is inserted to ensure that the bladder remains empty, which minimizes the exposure of the bladder to radiation. Low-residue diets and antidiarrheal agents, such as diphenoxylate (Lomotil), are provided to prevent bowel movements during therapy that might displace the radioisotopes. Pain management is also a priority for these patients as the presence of the appliance can be painful. Patient-controlled analgesia is a common method used for pain management in this population. Patient are also at risk for atelectasis, pressure ulcers, and DVT due to bed rest so preventative measures, including incentive spirometry, a pressure-relieving mattress, sequential compression devices, and prophylactic anticoagulation, are essential to preventing these complications.

Safety. Because patients receiving internal radiation emit radiation while the implant is in place, contacts with the health care team are guided by principles of *time, distance,* and *shielding* to minimize exposure of personnel to radiation. As the amount of *time* with the patient increases, the nurses' exposure to radiation increases. The goal of nursing care for this population is to deliver safe, efficient care that meets the patients' needs in the shortest amount of time; in general, no more than 30 minutes per 8-hour shift. The *principle of distance* means that the closer you are to the patient, the greater the radiation exposure. When not providing direct care (e.g., when talking with the patient), stand at least 6 feet from the patient to minimize exposure. Organize activities outside the room when possible; for example, preparation of meals and medication. *Shielding* refers to the use of a lead shield to buffer the exposure to radiation. Often, the rooms that patients stay in may be lead-lined, or portable lead shields or aprons may be available to minimize exposure.

Other safety precautions used in caring for a patient receiving brachytherapy include assigning the patient to a private room, posting appropriate notices about radiation safety precautions, having staff members wear dosimeter badges (to track cumulative radiation exposure), ensuring that pregnant staff members are not assigned to the patient's care, prohibiting visits by children or pregnant visitors, limiting visits from others to 30 minutes daily, and seeing that visitors maintain a 6-foot distance from the radiation source.

Nurses must be prepared to respond to a radiation emergency. If the radiation implant becomes dislodged, the nurses' first priority is to ensure the safety of the patient. Metal forceps and a lead-lined container should be available in the room. The nurse can use the forceps to pick up the radiation source and place the source into the lead-lined container. Once the source is contained, the radiation safety officer should be contacted immediately. Then the patient, nurse, and room will be monitored for radioactivity using a Geiger counter. The staff exposed should report to their Occupational Health department for an evaluation. Nurses should refer to their institution's radiation safety committee's guidelines for specific measures.

Radiation Dosage

The radiation dosage is dependent on the sensitivity of the target tissues to radiation and on the tumor size. The lethal tumor dose is defined as the dose that will eradicate 95% of the tumor yet preserve normal tissue. With external radiation, the total radiation dose is delivered over several weeks to allow healthy tissue to repair and to achieve greater cell kill by exposing more cells to the radiation as they begin active cell division. Repeated radiation treatments over time (fractionated doses) also allow for the periphery of the tumor to be reoxygenated repeatedly because tumors shrink from the outside inward. This increases the radiosensitivity of the tumor, thereby increasing tumor cell death.

Toxicity

Toxicity of radiation therapy is localized to the region being irradiated. Toxicity may be increased if concomitant chemotherapy is administered. Acute local reactions occur when normal cells in the treatment area are also destroyed and cellular death exceeds cellular regeneration. Altered skin integrity is a common effect and can include alopecia (hair loss), erythema, and shedding of skin (desquamation). Re-epithelialization occurs after treatments have been completed; healing can take several weeks.

Alterations in oral mucosa secondary to radiation therapy include stomatitis, xerostomia (dryness of the mouth), change and loss of taste, and decreased salivation. The entire GI mucosa may be involved, possibly resulting in esophageal irritation with chest pain and dysphagia. Anorexia, nausea, vomiting, and diarrhea may occur if the stomach or colon is in the irradiated field. Symptoms subside and GI re-epithelialization occurs after treatments have been completed; however, it may take several weeks for stomatitis to resolve. Xerostomia and taste changes may never return to normal.

Bone marrow cells proliferate rapidly, and if sites containing bone marrow (e.g., the iliac crest, sternum) are included in the radiation field, anemia, leukopenia (decreased WBCs), and thrombocytopenia (a decrease in platelets) may result. The patient is then at increased risk for infection and bleeding until blood cell counts return to normal. Chronic anemia may occur commonly due to the cumulative effects of radiation and may be evidenced by

shortness of breath, dizziness, fatigue, decreased oxygen saturation, and decreased activity tolerance.

Acute side effects to radiation therapy can occur within hours to days of receiving the first treatment. Bone marrow suppression, gonadal toxicity, skin changes, salivary changes, and GI side effects, such as nausea, may occur acutely.

Late effects from radiation are seen months to years after therapy even in the absence of acute symptoms. These effects include changes to the pituitary and thyroid glands, lungs, bones, breasts, cartilage, and pancreas (Iwamoto et al., 2012).

Nursing Management in Radiation Therapy

Providing Patient Education

Patients receiving radiation therapy, and their families, often have questions and concerns about its safety. To answer questions and allay fears about the effects of radiation on the tumor and on the patient's normal tissues and organs, the nurse explains the procedure for delivering radiation and describes the equipment, the duration of the procedure (often minutes only), the methods for immobilizing the patient during the procedure, and the sensory experience, including the absence of pain, during the procedure.

If a radioactive implant is used, the nurse informs the patient and family about the restrictions placed on visitors and health care personnel and other radiation precautions. The patient also should understand his or her own role before, during, and after the procedure. Patients with seed implants may be able to return home because the radiation exposure to others is minimal. Information about any precautions, if needed, is provided to the patient and family members to ensure safety. See Chapters 33 and 34 for further discussion of radiation treatment for gynecologic cancers and prostatic cancer, respectively.

Protecting Skin and Oral Mucosa

The nurse regularly assesses the patient's skin, oral mucosa, nutritional status, and general feeling of well-being. As many as 95% of patients receiving radiation experience radiation dermatitis. The nurse must educate the patient on early identification of symptoms and self-care guidelines to minimize further damage (Bauer, Laszewski, & Magnan, 2015).

The skin in the radiation field must be protected from irritation, and the patient is instructed to avoid using ointments, lotions, or powders on the treated area. The patient is instructed to gently cleanse the skin with lukewarm water and a mild, nondeodorant soap using the fingertips or a soft washcloth (no scrubbing) and then gently pat the area dry. If temporary skin markings were applied to facilitate external radiation treatments, warn the patient not to remove the markings. Avoid any perfumed lotion or powder; avoid applying makeup to the treatment field. Emollients such as Aquaphor® may be used as directed by the radiation oncologist to soothe and moisturize irritated skin. However, even approved emollients should not be used up to 4 hours before the treatment time. Lotions and emollients may amplify the effects of the radiation on the skin. Electric razors should be used for shaving, but aftershave products should be avoided. Patients should be instructed to avoid constrictive clothing that may irritate skin. Loose, cotton clothing is usually most comfortable. Other instructions include avoiding sun exposure, wind, extreme temperatures, heating lamps, heating pads, and ice packs to the area being treated—these are all potential sources of thermal injury. Avoid itching skin and avoid applying tape to

radiated areas to minimize trauma to the skin (Iwamoto et al., 2012; Bauer et al., 2015).

Gentle oral hygiene is essential to remove debris, prevent irritation, and promote healing (see Box 6-3 for detailed instructions). If systemic symptoms, such as weakness and fatigue, occur, the patient may need assistance with activities of daily living and personal hygiene (see Nursing Process later in the chapter). In addition, the nurse offers reassurance by explaining that these symptoms are a result of the treatment and do not represent deterioration or progression of the disease.

BOX 6-3 Patient Education

Mouth Care for Patients Receiving Head and Neck Radiation Therapy

- Use a bland mouth rinse (such as salt water or baking soda and water) often. Gently swish and gargle with this before and after meals and at bedtime. You may use it more often as needed to soothe a dry or sore mouth. To make the mouth rinse: Mix 1 teaspoon of baking soda with 16 oz of water; or 1 teaspoon of table salt with 16 oz of water.
- Use fluoride preparations daily as instructed by your dentist. Brush your teeth using a soft-bristled toothbrush three to four times a day. Floss your teeth daily.
- Dentures should be left out if they are irritating to the gums or are poorly fitting.
- Avoid alcoholic beverages, tobacco, highly spiced foods, and commercial mouthwashes containing alcohol.
- Once you begin to experience pain or sensitivity in your mouth, avoid foods and drinks that are too hot or too cold. Room temperature is best. Avoid carbonated drinks such as soda or sparkling water.
- Avoid acidic fruits and juices like tomato, orange, lemon, grapefruit, and pineapple. Avoid rough, crunchy foods such as pretzels, nuts, and chips.
- Inspect your mouth daily and report any changes to your nurse or doctor.
- For a dry mouth, drink 8 oz of water or other noncaffeinated beverage every 2 to 3 hours. Keep a cool mist humidifier running, especially at night.
- Moisturize lips frequently with water-based moisturizer.

Chemotherapy

In chemotherapy, antineoplastic agents are used in an attempt to destroy tumor cells by interfering with cellular functions, including replication. Chemotherapy is used primarily to treat systemic disease rather than localized lesions that are amenable to surgery or radiation. Chemotherapy may be combined with surgery, radiation therapy, or both to reduce tumor size preoperatively (neoadjuvant), to destroy any remaining tumor cells postoperatively (adjuvant), for conditioning therapy prior to stem cell transplant, or to treat hematologic malignancies, such as lymphoma and leukemia (Polovich, Olsen, & LeFebvre, 2014). The goals of chemotherapy (cure, control, palliation) define the medications to be used and the aggressiveness of the treatment plan. Chemotherapy may also be delivered in the setting of a clinical trial (see Box 6-4).

Cell Kill and the Cell Cycle

Each time a tumor is exposed to a chemotherapeutic agent, a percentage of tumor cells (20% to 99%, depending on dosage) are destroyed. Repeated doses of chemotherapy are necessary over a prolonged period to achieve regression of the tumor. Eradication of 100% of the tumor is almost impossible. Instead, the goal of treatment is eradication of enough of the tumor so that the remaining tumor cells can be destroyed by the body's immune system.

BOX 6-4 Investigational Antineoplastic Therapies and Clinical Trials

Evaluation of the effectiveness and toxic potential of promising new modalities for preventing, diagnosing, and treating cancer is accomplished through clinical trials. Before new therapies are approved for clinical use, they are subjected to rigorous and lengthy evaluations to identify beneficial effects, adverse effects, and safety.

- *Phase I* clinical trials determine optimal dosing, scheduling, toxicity, and pharmacokinetics. The goal is to determine a tolerable dose and schedule for drug administration.
- *Phase II* trials determine effectiveness with specific tumor types and further define toxicities. Phase I and II trials often involve small numbers of patients to help guide decisions about the utility of further research on a given agent. Participants in early trials are often those who have not responded to standard forms of treatment. Since the goals of Phase I and II trials are not focused on efficacy and extending survival, patients and families must be fully informed about the experimental nature and goal of the trial.
- *Phase III* clinical trials establish the effectiveness of new medications or procedures as compared with conventional approaches.
- *Phase IV* testing further investigates medications in terms of new uses, dosing schedule, and toxicities.

Nurses may assist in the recruitment, eligibility screening, consent, and education processes for patients who participate in clinical trials. In many cases, nurses are instrumental in monitoring and promoting adherence as well as documenting data describing patients' responses and adverse effects. The physical and emotional needs of patients in clinical trials are addressed in much the same way as those of patients who receive standard forms of cancer treatment.

Adapted from Amir, E. & Tannock, 2013.

Cells that are actively dividing within a tumor are the most sensitive to chemotherapeutic agents. Nondividing cells capable of future proliferation (cells in the G_0 phase, see Fig. 6-2) are the least sensitive to antineoplastic medications and, consequently, are potentially dangerous. However, the nondividing cells must also be destroyed to eradicate a cancer. As dividing cells are killed by chemotherapy, nondividing cells are recruited into the cell cycle to divide, in order to replace the dying cells. Repeated cycles of chemotherapy must be used to kill these newly dividing cells.

Chemotherapy drugs are often given in combination (referred to as a *protocol* or *regimen*). The goal of combination chemotherapy is to overcome drug resistance and take advantage of the synergistic effects of some drugs while minimizing toxicity. As described earlier, tumors are heterogeneous so agents with different mechanisms of action are used in combination to increase the number of cells killed; combination approaches also reduce the risk of drug resistance. Considerations for combination chemotherapy include the use of drugs with different mechanisms of action and different side effect profiles (Polovich et al., 2014).

Classification of Chemotherapeutic Agents

Chemotherapeutic agents may be classified by their relationship to the cell cycle. Certain chemotherapeutic agents that are specific to certain phases of the cell cycle are termed *cell cycle–specific agents.* These agents destroy cells that are actively reproducing by means of the cell cycle; most affect cells in the S phase by interfering with DNA and RNA synthesis. Other agents, such as the vinca or plant alkaloids, are specific to the M phase, where they halt mitotic spindle formation. Chemotherapeutic agents that act independently of the cell cycle phases are termed *cell cycle–nonspecific agents.* These agents usually have a prolonged effect on cells, leading to cellular damage or death. Many treatment plans combine cell cycle–specific and cell cycle–nonspecific agents to increase the number of vulnerable tumor cells killed during a treatment period (Polovich et al., 2014).

Chemotherapeutic agents are also classified by chemical group, each with a different mechanism of action. These include the alkylating agents, nitrosoureas, antimetabolites, antitumor antibiotics, plant alkaloids, hormonal agents, and miscellaneous agents. The classification, mechanism of action, common medications, and common side effects of selected antineoplastic agents are listed in Table 6-3.

Administration of Chemotherapeutic Agents

Chemotherapeutic agents may be administered in the hospital, clinic, or home setting by a

variety of routes including topical, oral, IV, intramuscular, subcutaneous, arterial, intracavitary, and intrathecal routes. Intrathecal chemotherapy is the administration of medication into the cerebrospinal fluid. This can be accomplished through a lumbar puncture or through the placement of an intraventricular catheter with the tip lying in the fourth ventricle of the brain. This route is used to treat or prevent CNS metastasis. The route of administration usually depends on the type of agent; the required dose; and the type, location, and extent of tumor being treated. Guidelines for the administration of chemotherapy have been developed by the Oncology Nursing Society (ONS) (Polovich et al., 2014). The use of oral agents to treat cancer is increasing dramatically. Patient education and consistent monitoring of patient adherence is essential to maximize safety.

TABLE 6-3 Selected Antineoplastic Agents

Drug Class and Examples	Mechanism of Action	Cell Cycle Specificity	Most Common Side Effects
Alkylating Agents			
Altretamine, Bendamustine, Busulfan, carboplatin, chlorambucil, cisplatin, cyclophosphamide, dacarbazine, ifosfamide, melphalan, nitrogen mustard, oxaliplatin, temozolomide, thiotepa	Alter DNA structure by misreading DNA code, initiating breaks in the DNA molecule, cross-linking DNA strands	Cell cycle—nonspecific	Bone marrow suppression, nausea, vomiting, cystitis (cyclophosphamide, ifosfamide), stomatitis, alopecia, gonadal suppression, renal toxicity (cisplatin)
Nitrosoureas			
Carmustine (BCNU), lomustine (CCNU), semustine (methyl CCNU), streptozocin	Similar to the alkylating agents; cross the blood–brain barrier	Cell cycle—nonspecific	Delayed and cumulative myelosuppression, especially thrombocytopenia; nausea, vomiting
Topoisomerase I Inhibitors			
Irinotecan, topotecan	Induce breaks in the DNA strand by binding to enzyme topoisomerase I, preventing cells from dividing	Cell cycle—specific (S phase)	Bone marrow suppression, diarrhea, nausea, vomiting, hepatotoxicity

Antimetabolites			
5-Azacitidine, capecitabine, cladribine, clofarabine, cytarabine, decitabine, floxuridine, fludarabine, 5-fluorouracil (5-FU), gemcitabine, 6-mercaptopurine, methotrexate, nelarabine, pemetrexed, pentostatin, pralatrexate, 6-thioguanine	Interfere with the biosynthesis of metabolites or nucleic acids necessary for RNA and DNA synthesis	Cell cycle—specific (S phase)	Nausea, vomiting, diarrhea, bone marrow suppression, stomatitis, renal toxicity (methotrexate), hepatotoxicity
Antitumor Antibiotics			
Bleomycin, dactinomycin, daunorubicin, doxorubicin, epirubicin, idarubicin, mitomycin, mitoxantrone, valrubicin	Interfere with DNA synthesis by binding DNA; prevent RNA synthesis	Cell cycle—nonspecific	Bone marrow suppression, nausea, vomiting, alopecia, anorexia, cardiac toxicity (doxorubicin, daunorubicin, idarubicin, mitoxantrone)
Mitotic Spindle Poisons			
Plant alkaloids: etoposide, teniposide, vinblastine, vincristine (VCR), vindesine, vinorelbine *Taxanes:* cabazitaxel, docetaxel, paclitaxel	Arrest metaphase by inhibiting mitotic tubular formation (spindle); inhibit DNA and protein synthesis Arrest metaphase by inhibiting tubulin depolymerization	Cell cycle—specific (M phase) Cell cycle—specific (M phase)	Plant alkaloids: Bone marrow suppression (mild with VCR), neuropathies (VCR), stomatitis Taxanes: Alopecia, bone marrow suppression, bradycardia, hypersensitivity reactions, neuropathy
Hormonal Agents			
Androgens and antiandrogens, estrogens and antiestrogens, progestins and antiprogestins, aromatase inhibitors, luteinizing hormone–releasing hormone analogs, steroids	Bind to hormone receptor sites that alter cellular growth; block binding of estrogens to receptor sites (antiestrogens); inhibit RNA synthesis; suppress aromatase of P450 system, which decreases estrogen level	Cell cycle—nonspecific	Hypercalcemia, increased appetite, masculinization, feminization, sodium and fluid retention, nausea, vomiting, hot flashes, vaginal dryness
Miscellaneous Agents			
Arsenic trioxide, Asparaginase, hydroxyurea, mitotane, procarbazine Romidepsin Vorinostat	Unknown or too complex to categorize Inhibit histone deacytelase	Varies	Anorexia, nausea, vomiting, bone marrow suppression, hepatotoxicity, anaphylaxis, hypotension, altered glucose metabolism

Adapted from Polovich et al. (2014).

Dosage

Dosage of antineoplastic agents is based primarily on the patient's total body surface area, previous response to chemotherapy or radiation therapy, function of major organ systems, and PS.

Nursing Alert

Because of the high potential for error related to chemotherapy dosing, the standard expectation is that two nurses verify the chemotherapy doses to ensure accuracy. The Mosteller Equation for calculation of body surface area is the most commonly used formula in the United States:

$$\sqrt{\frac{\text{height (cm)} \times \text{weight (kg)}}{3600}}$$

Infusion-Related Events

Nurses administering chemotherapy must carefully assess the patient for infusion-related events, such as infusion reactions, hypersensitivity, and extravasation. Specific assessments vary based on the medication being administered (see Table 6-3).

Infusion Reaction. Reactions that occur during or shortly after drug infusion are described as infusion reactions. These reactions may be allergic or nonallergic in nature. Infusion reactions can often be anticipated when administering drugs such as monoclonal antibodies. Most infusion reactions are mild (e.g., chills) and, if recognized and treated promptly, should resolve. Initial management is interruption of the infusion and symptom management with antihistamines, antiemetics, steroids, or anxiolytics. In most cases, the infusion can be reinitiated and completed at a slower rate with careful monitoring (Jakel, Carsten, Braskett, & Carino, 2016).

Hypersensitivity. About 5% to 15% of patients receiving chemotherapy and biotherapy agents experience hypersensitivity reactions (HSRs). The risk of hypersensitivity varies based on the type of agent being administered. Platinum- and taxane-containing agents have the most frequent incidence of HSRs (Tham, Cheng, Tay, Alcasabas, & Shek, 2015). Prompt recognition of the symptoms of HSRs and quick intervention are critical roles of oncology nurses who administer these agents. Common symptoms observed in patients experiencing HSRs range from flushing, rash (urticarial), nausea, vomiting, flushing, back pain, shortness of breath, and anxiety or sense of impending doom to bronchospasm and hemodynamic collapse (Jakel et al., 2016). Response to HSRs includes stopping the infusion as soon as symptoms are observed; monitoring vital signs; maintaining a patent airway; administering oxygen as needed; maintaining a patent IV with running normal saline; administering emergency medications such as antihistamines, epinephrine, bronchodilators, and corticosteroids as ordered; and providing emotional support to the patient. In mild reactions, reinitiation of the infusion at a slower rate may be considered. For patients with more severe reactions, additional considerations are required for retreatment, including premedication with steroids and antihistamines (H_1 and H_2 blockers) and, in some cases, desensitization protocols (Tham et al., 2015).

Extravasation. Special care must be taken whenever IV vesicant agents are administered. Vesicants are agents that, if deposited into the subcutaneous tissue (extravasation), cause tissue ulceration and necrosis as well as damage to underlying tendons, nerves, and blood vessels. Although the complete mechanism of tissue destruction is unclear, it is known that the pH of many antineoplastic drugs is responsible for the severe inflammatory reaction as well as the ability of some of these drugs (e.g., anthracyclines) to bind to tissue DNA. Sloughing and ulceration of the tissue may be so severe that skin grafting may be necessary. The full extent of tissue damage may take several weeks to become apparent. Some examples of medications classified as vesicants include actinomycin D, dacarbazine, doxorubicin (Adriamycin), epirubicin, nitrogen mustard, mitomycin, vinblastine,

vincristine, vinorelbine (Kreidieh, Moukadem, & El Saghir, 2016).

Nursing Alert
Prior to administration of any anticancer agent, the nurse must be aware of a drug's vesicant potential. If frequent administration of antineoplastic vesicants is anticipated in a patient with poor veins, or if a vesicant agent requires administration over more than 1 hour, a central venous access device (CVAD) must be inserted to promote safety during medication administration. Complications associated with CVAD use include infection and thrombosis. Educating the patient about all risks associated with vesicant chemotherapy administration is critical.

Irritants are drugs that can cause pain or irritation at the extravasation site and burning sensation during administration but do not cause tissue damage. Examples of irritants include bendamustine or carboplatin (Kreidieh et al., 2016).

Exfoliants are drugs that can cause inflammation and peeling or blistering of the skin without tissue necrosis. Examples of exfoliants include Cisplatin, Docetaxel, Liposomal Doxorubicin, Mitoxantrone, Oxaliplatin, and Paclitaxel (Kreidieh et al., 2016).

Patients must understand the importance of prompt reporting of any signs and symptoms of extravasation. Risk factors for extravasation include small and/or fragile veins, lymphedema, obesity, impaired level of consciousness (LOC), history of multiple venipunctures, poor cannula size selection, and poor vein selection. Extravasation can occur as a result of accidental puncturing of the vein or with movement of the cannula itself due to patient activity or a poorly secured catheter. Prolonged peripheral IV infusions of vesicants carry an increased risk of extravasation, and, therefore, vesicant infusions lasting more than 1 hour should be administered through a CVAD (Figs. 6-3 and 6-4).

Strategies to decrease the risk of extravasation include:

- Appropriate training of nurses following the ONS standards
- Selection of appropriate vascular access location, including avoiding veins in the hand, wrist, or antecubital regions
- Avoiding veins that are small and/or fragile
- Avoiding an extremity with lymphedema or recent venipuncture
- Use of the smallest size of cannula in the largest available vein
- Use of a small bore plastic cannula that is 1.2 to 1.5 cm long
- Use of a clear dressing
- Avoiding the use of a butterfly needle

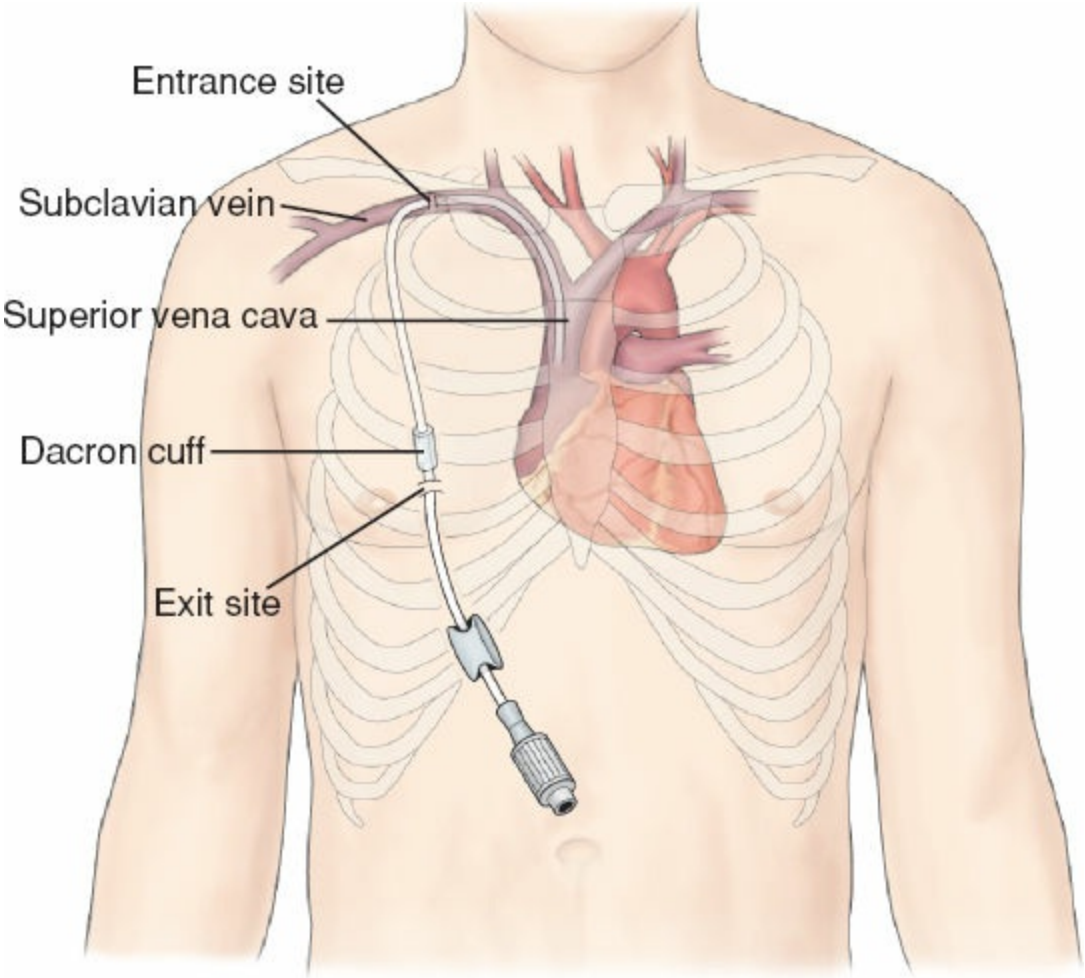

FIGURE 6-3 Central venous access device. The central venous catheter is inserted into the subclavian vein and advanced until its tip lies in the superior vena cava just above the right atrium. The proximal end is then tunneled from the entry site through the subcutaneous tissue of the chest wall and brought out through an exit site on the chest. The Dacron cuff anchors the catheter in place and serves as a barrier to infection.

Nursing Alert

Indications of extravasation during administration of vesicant agents include:

- Absence of blood return from the IV catheter
- Resistance to flow of IV fluid
- Leaking around the insertion site
- Swelling, pain, burning, or redness or blistering at the site, or if using a CVAD, pain in the upper arm, upper back, chest, neck, or jaw
- For some drugs (anthracyclines such as doxorubicin), signs and symptoms of extravasation may continue for weeks after drug administration (Kreidieh et al., 2016).

If any one of the above signs is present, extravasation should be suspected. The medication administration should be stopped immediately. The nurse should attempt to aspirate any residual drug from the IV line. If an antidote is indicated, the nurse should administer it immediately (as ordered). Selection of the neutralizing solution or antidote

depends on the extravasated agent.

Dexrazoxane is approved in the setting of anthracycline extravasation with efficacy rates as high as 98% in preventing tissue damage. Dexrazoxane is administered as a 1- to 2-hour IV infusion for 3 consecutive days. Treatment with dexrazoxane should be initiated within 6 hours of extravasation for best results (Kreidieh et al., 2016).

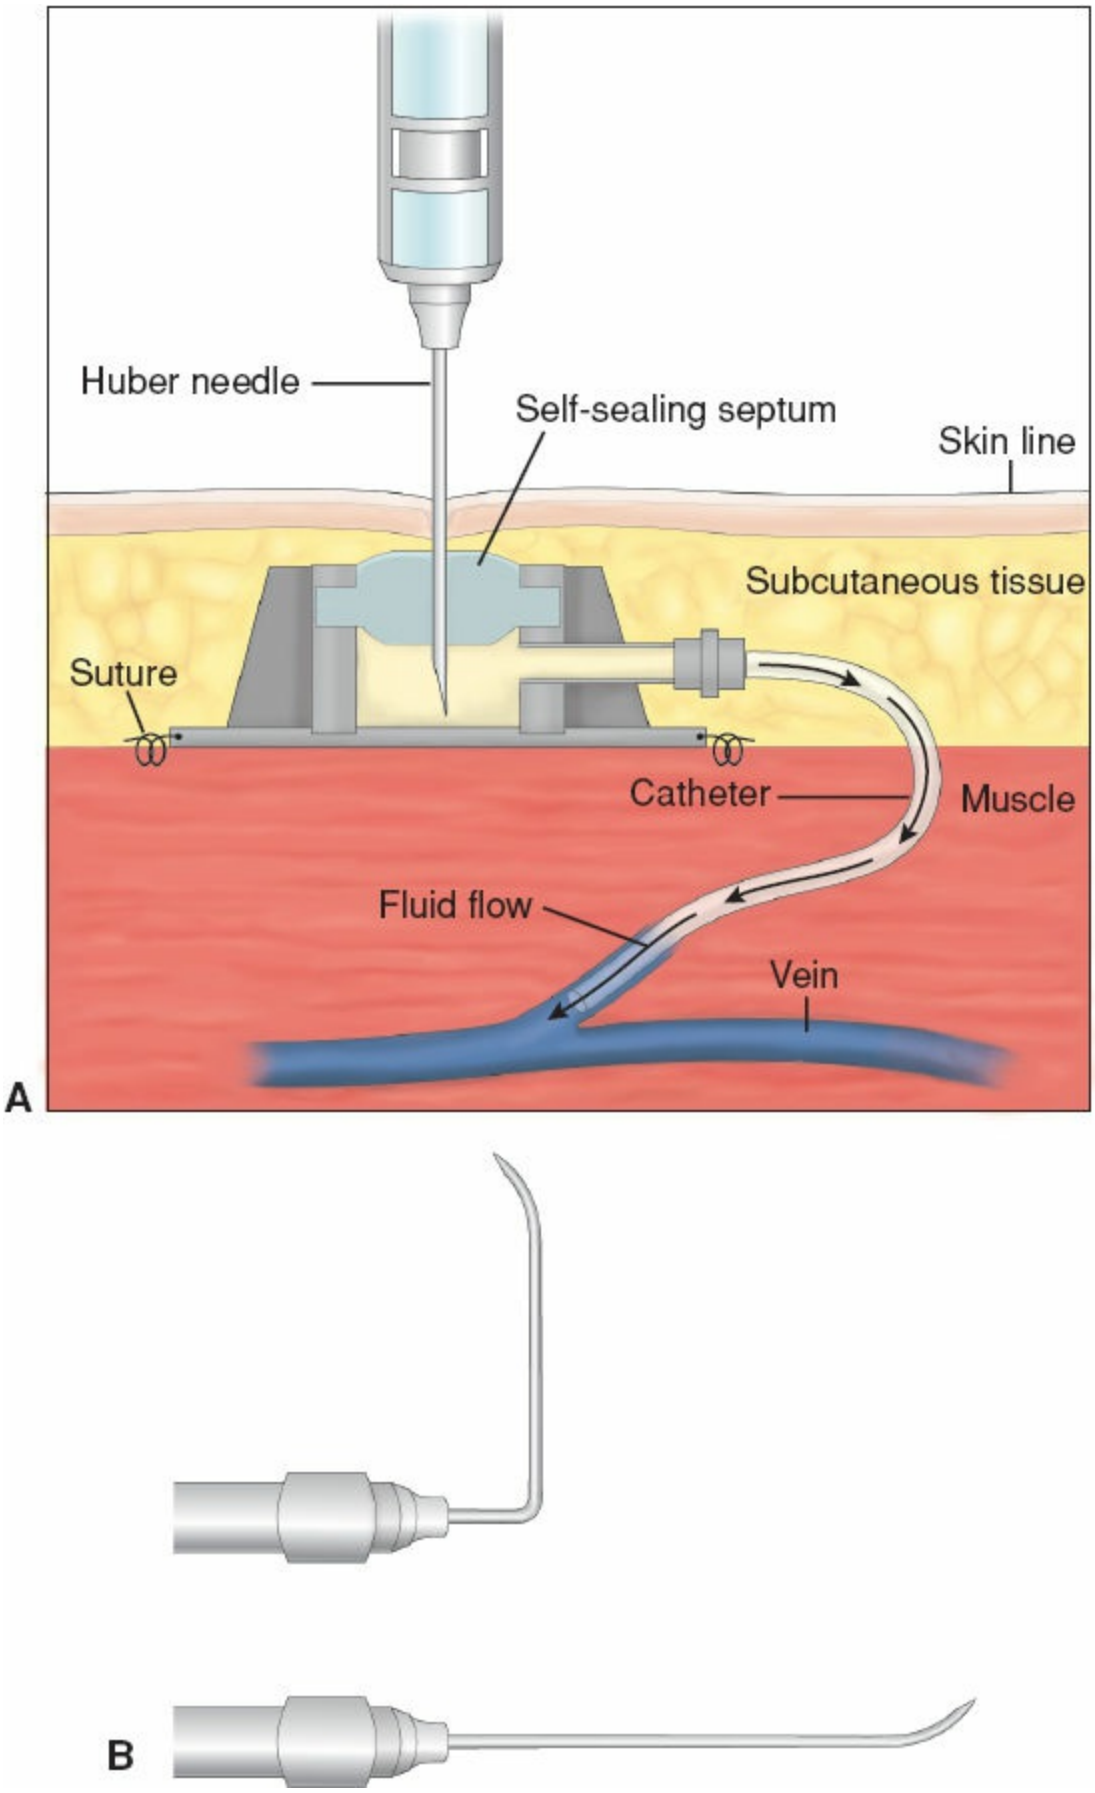

FIGURE 6-4 Implanted vascular access device. (A) A schematic diagram of an implanted vascular

access device used for administration of medications, fluids, blood products, and nutrition. The self-sealing septum permits repeated puncture by Huber needles without damage or leakage. (B) Two Huber needles used to enter the implanted vascular port. The 90-degree needle is used to access the port.

Examples of neutralizing solutions include sodium thiosulfate, hyaluronidase, and sodium bicarbonate. Hyaluronidase is an enzyme administered as a subcutaneous injection into the extravasation site that degrades hyaluronic acid in tissues and promotes diffusion of the extravasated agent. It is recommended for vinca-alkaloids, etoposide and taxanes extravasation with low levels of evidence supporting its use. Sodium thiosulfate is also administered via subcutaneous injection for nitrogen mustard extravasations (Kreidieh et al., 2016). It is essential for nurses to keep up with the research findings related to extravasation and to apply the evidence to clinical practice.

The involved extremity should be elevated for the first 48 hours. Ice is applied to the site (unless the extravasated vesicant is a vinca-alkaloid in which case warm compresses are used) (four times a day for 20 minutes for the first 48 hours), and the patient is educated to avoid further trauma to the site (including heat, constrictive clothing, sunlight) and to report changes in the skin integrity and appearance of the extravasation site to the provider immediately. A plastic surgery consult should be considered within the first 24 hours (Pluschnig et al., 2014). Recommendations and guidelines for managing vesicant extravasation have been issued by individual medication manufacturers, pharmacies, and the ONS, and they differ for each medication.

Protecting Caregivers

Chemotherapy agents are hazardous and have the potential for carcinogenicity, genotoxicity, teratogenicity, reproductive toxicity, and organ toxicity (Redmond, 2016). Nurses involved in handling chemotherapeutic agents may be exposed to low doses of the agents by direct contact, inhalation, or ingestion. Nurses who handle these agents must receive education on safe handling measures to minimize risks of exposure. Exposure is often accidental and can happen during preparation, transport, administration, waste disposal, and spills (Redmond, 2016). Urinalyses of personnel repeatedly exposed to cytotoxic agents have demonstrated the presence of these agents. Although long-term studies of nurses who handle chemotherapeutic agents have not been conducted, chemotherapeutic agents are associated with secondary formation of cancers and chromosomal abnormalities. In addition, nausea, rashes, alopecia, and hearing loss have been reported in health care personnel who have handled chemotherapeutic agents (CDC, 2015). In an effort to minimize the exposure of health care workers to hazardous substances, the Occupational Safety and Health Administration, ONS, hospitals, and other health care agencies have developed specific precautions for health care providers involved in the preparation and administration of chemotherapy (Box 6-5).

Toxicity

Cells with rapid growth rates (e.g., epithelium, bone marrow, hair follicles, sperm) are most susceptible to the effects of chemotherapy.

GI System

Chemotherapy-induced nausea and vomiting (CINV) is a common and feared side effect of chemotherapy and may persist for as long as 24 to 48 hours after its administration. Delayed nausea and vomiting may persist for several days after chemotherapy. Delayed nausea and vomiting is commonly seen with cisplatin, carboplatin, cyclophosphamide, and doxorubicin (Polovich et al., 2014). Anticipatory nausea may be experienced after the first cycle and is caused by classical conditioning; nausea is triggered by taste, odors, sights, thoughts, or anxiety related to a poor initial experience with CINV (Aapro, Jordan, & Fever, 2015). The primary risk factor for CINV is the emetogenic potential of the agents being used (how likely the agents are to cause nausea and vomiting). Patient-specific risk factors include a history of CINV, female sex, under 50 years of age, and history of motion sickness. A history of heavy alcohol use is associated with decreased risk for CINV (Aapro et al., 2015).

BOX 6-5 Safety in Administering Chemotherapy

Safety recommendations from the Occupational Safety and Health Administration (OSHA), Oncology Nursing Society (ONS), hospitals, and other health care agencies for the preparation and handling of antineoplastic agents include the following:

- Use a biologic safety cabinet for the preparation of all chemotherapy agents.
- Wear gloves that have been tested with chemotherapeutic agents when handling antineoplastic drugs and the excretions of patients who received chemotherapy.
- Wear disposable, nonabsorbent long-sleeved gowns with cuffs when preparing and administering chemotherapy agents.
- Use closed-system devices.
- Use Luer-Lok fittings on all IV tubing used to deliver chemotherapy.
- Prime the IV tubing with the diluent, not the medication.
- Work below eye level. Use eye protection if there is a risk of splashing.
- Do not open or crush oral medication.
- Dispose of all equipment used in chemotherapy preparation and administration in appropriate, leak-proof, puncture-proof containers.
- Dispose of all chemotherapy wastes as hazardous materials.

When followed, these precautions greatly minimize the risk of exposure to chemotherapy agents.

The pathophysiology of CINV is not fully understood and is the result of a complex interplay of many different factors. A vagal-dependent pathway is considered a primary mechanism for CINV. A number of important neurotransmitter receptors, including 5-HT3 (palonosetron), NK-1 (aprepitant), and cholecystokinin-1, are located on the terminal ends of the vagal afferents. These receptors lie in close proximity to the enterochromaffin cells located in the gastrointestinal mucosa of the proximal small intestine, which contains a number of local mediators, such as serotonin, substance P, and cholecystokinin. When

patients are treated with cytotoxic drugs that damage the enterochromaffin cells, serotonin is released, activating vagal afferent neurons through interaction with the 5-HT3 receptors. The activation of vagal afferent neurons leads to an emetic response mediated through the chemoreceptor trigger zone within the area postrema (medullary structure in the brain that controls vomiting) (Aapro et al., 2015).

The goal of antiemetics is to prevent CINV. Antiemetic regimens are tailored based on the emetogenicity of the regimen (Polovich et al., 2014). Newer antiemetics have been developed that target 5-HT3 and NK-1 and a combination medication, NEPA, which combines a highly selective NK1RA (netupitant) and the 5-HT3RA (palonosetron) (Jordan, Jahn, & Aapro, 2015). For patients with a high risk of nausea and vomiting who are receiving regimens, a combination of a 5-HT3 antagonist, an NK1 antagonist, and a corticosteroid are given prior to initiation of treatment. NK1 antagonists and long-acting 5-HT3 antagonists are particularly useful in prevention of delayed nausea and vomiting. Patients should also have medication at home for as-needed use for breakthrough nausea and vomiting; options for breakthrough CINV include prochlorperazine, metoclopramide, olanzapine, lorazepam, dronabinol, and ondansetron (for patients who have not received the long-acting medication palonosetron) (Polovich et al., 2014; Jordan et al., 2015). For anticipatory CINV, benzodiazepines are most effective. Nonpharmacologic interventions, such as relaxation, can also be helpful in this setting (Polovich et al., 2014).

Hematopoietic System

Most chemotherapeutic agents cause myelosuppression (depression of bone marrow function), resulting in decreased production of blood cells. Myelosuppression decreases the number of WBCs (leukopenia), red blood cells (RBCs) (anemia), and platelets (thrombocytopenia) and increases the risk of infection and bleeding. Depression of these cells is a common reason for decreasing the dose of the chemotherapeutic agents. Monitoring blood cell counts frequently is essential because it allows strategies to be implemented to protect patients from infection and injury.

Other agents, called colony-stimulating factors (granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF], and erythropoietin [EPO]), can be administered after chemotherapy. G-CSF and GM-CSF stimulate the bone marrow to produce WBCs, including neutrophils, at an accelerated rate, thus decreasing the duration of neutropenia. GCSF decreases the episodes of infection and reduce the need for antibiotics, allowing for timelier cycling of chemotherapy with less need for dose reductions.

Erythropoietin-stimulating agents (ESAs) stimulate RBC production, thus decreasing the symptoms of chronic anemia and reducing the need for blood transfusions. Recent evidence has demonstrated that the use of ESAs in certain malignancies, including head and neck, nonsmall cell lung, lymphoid, cervical, and breast cancers, has resulted in decreased survival rates. Based on this data, the use of ESAs is not recommended in those diseases when the goal is cure (Polovich et al., 2014). Other studies have demonstrated an increase in cardiac events, including cerebrovascular events and myocardial infarction, when hemoglobin (Hgb) targets of greater than 12 mg/dL were used. Specific guidelines are now available to improve the safety of ESA administration, including holding ESAs for Hgb levels greater than 10 mg/dL, assessing the hemoglobin (Hgb) and hematocrit (Hct) prior to each ESA dose, and discontinuing ESA use in patients who do not achieve a significant

benefit within the first 8 weeks of administration.

Reproductive System

Ovarian and testicular function can be affected by chemotherapeutic agents, resulting in possible sterility. Abnormal ovulation, early menopause, or permanent sterility may occur. In men, temporary or permanent azoospermia (absence of spermatozoa) may develop. Reproductive cells may be damaged during treatment, resulting in chromosomal abnormalities in offspring. Banking of sperm is recommended for males of reproductive age before treatments are initiated. Sperm banking requires daily sperm collections for 2 to 3 days in order to collect a sufficient sample. Women should be counseled regarding options for fertility preservation prior to initiating treatment. Embryo cryopreservation is the most well-established method for fertility preservation. Oocyte cryopreservation and cryopreservation of ovarian tissue are considered investigational. Fertility preservation options for women require more time (2 to 6 weeks) and may result in cancer treatment delays, which may impact overall outcomes (Polovich et al., 2014).

Prior to initiating treatment, patients and their partners need to be informed about potential changes in reproductive and sexual function resulting from chemotherapy. They are advised to use reliable methods of birth control while receiving chemotherapy and not to assume that sterility has resulted.

Nursing Management in Chemotherapy

Nurses play an important role in assessing and managing many of the problems experienced by patients undergoing chemotherapy. Chemotherapeutic agents have systemic effects on normal cells as well as malignant ones, which means that these problems are often widespread, affecting many body systems. Nurses must recognize the potential side effects specific to the drug or drug(s) that the patient is receiving and target assessments based on expected side effects. Common side effects seen with chemotherapy include myelosuppression, alopecia, nausea and vomiting, anorexia, and fatigue. The nursing care specific to these side effects is discussed in the nursing process section on page 181.

Targeted Therapies

Recent advances in the fields of molecular biology, biochemistry, immunology, and genetics have led to an improved understanding of cancer development. Traditional therapies such as chemotherapy and radiation are nonspecific, affecting all rapidly dividing cells. As a result, both healthy and malignant cells are subject to harmful systemic effects of treatment. Targeted therapies seek to minimize the negative effects on healthy tissues by disrupting specific cancer cell functions, such as malignant transformation, communication pathways (also called *cell signaling* or *signal transduction*), processes for growth and metastasis, as well as genetic coding. Targeted therapies can be divided into two categories: those with an extracellular target, such as receptors on the surface of the cells (e.g., Monoclonal antibodies or mAbs) and those with an intracellular target (e.g., Tyrosine kinase inhibitors).

Monoclonal antibodies (mAbs) have a specific target that may be unique to the tumor cell or may target proteins that support tumor growth. Monoclonal antibodies may inhibit the binding of growth factors to receptors on the cell surface, which shuts down the subsequent steps necessary for tumor cell division. Monoclonal antibodies also can act directly on the tumor cell to induce death. In addition, mAbs are involved in stimulating antibody-dependent cellular cytotoxicity (ADCC) in which the antibody binds to tumor cell antigen, NK cells recognize the antibody-covered cell, stimulating cytotoxic proteins to be released to destroy the tumor cell (Polovich et al., 2014). Monoclonal antibodies can be conjugated or unconjugated. Unconjugated mAbs kill tumor cells from the direct action of the antibody on the target (e.g., Rituximab, which targets C20; Trastuzumab, which targets HER2; Cetuximab, which targets EGFR). Conjugated mAbs are antibodies attached to antitumor agents (radioisotopes, chemotherapy drugs, toxins). The mAb attaches to its target and releases the antitumor agent into the cell, stimulating cell death (e.g., brentuximab vedotin). Infusion reactions are common with mAbs and require careful monitoring (see section on infusion related events) (Polovich et al., 2014).

Drugs that target intercellular pathways include tyrosine kinase inhibitors, which target the tyrosine kinase receptor and inhibit cell signaling. Examples of tyrosine kinase targets include BCR-ABL, mTOR, and BRAF. Growth factors and growth factor receptors are also targets; examples of growth factors include EGFR and VEGF (Polovich et al., 2014). Many of the drugs targeting these kinases and growth factors are taken orally, and adherence is critical to response. See Tables 6-4 and 6-5 for examples of targeted therapies and approved cytokines.

Immunotherapy

As discussed earlier, the immune system is critical in preventing, controlling, and eliminating cancer. Malignancy develops as a result of multiple mechanisms of immune failure or suppression. Immune therapies, including cytokines, vaccines, and checkpoint inhibitors, were developed in an attempt to restore or stimulate the body's own immune response to treat the cancer.

Cytokines, including interferon (IFN) alpha and interleukin-2 (IL-2), have been in use for many years in the treatment of melanoma. They both have significant side effects, which have limited widespread use. Eight percent of patients treated with IFN experience fever and fatigue. Psychiatric side effects are also common, including depression (45%) with rare reports of suicide. GI side effects include diarrhea, nausea, and anorexia. High-dose IL-2 is associated with capillary leak syndrome leading to hypotension, which may require vasopressor support. Flu-like symptoms are also seen. These patients require expert nursing care and vigilant monitoring (Weber, Yang, Atkins, & Disis, 2015).

Vaccines are used to stimulate the immune system to kill malignant cells. Vaccines are also used to prevent cancer-causing infections (hepatitis, HPV) (Polovich et al., 2014). Sipuleucel-T (Provenge®) is an FDA-approved vaccine for the treatment of advanced prostate cancer. Side effects, including chills, fever, and fatigue, are common in the first 24 hours (Weber et al., 2015).

Three checkpoint inhibitor antibodies are approved for use in the United States, and a number of others are in development: ipilimumab, which blocks CTLA-4; and pembrolizumab and nivolumab, which block PD-1 (Weber et al., 2015). CTLA-4 is a negative regulator of the immune response. Blockade of CTLA-4 using anti CTLA4 antibody, such as ipilimumab, results in T-cell stimulation. PD-1 is a negative regulator of T-cell activity and dampens the immune response when it interacts with PD-L1 and PD-L2. When PD-1 is blocked, signaling pathways necessary for cell growth are inhibited; PD-1 also inhibits effector T-cell activity, so when PD-1 is blocked, effector T cells are able to function (Postow, Callahan, & Wolchok, 2015).

Ipilimumab, a CTLA-4 inhibitor, has demonstrated significant improvements in survival in patients with advanced melanoma (with 18% of patients alive after 2 years compared to 5% in the control group) (Postow et al., 2015). Both nivolumab and pembrolizumab have shown durable response rates in advanced melanoma, renal cell carcinoma, and nonsmall cell lung cancer (Postow et al., 2015). This group of drugs has a unique side effect profile requiring expert care and management. Immune-related adverse events (irAEs) are a result of immune system stimulation and resemble autoimmune disorders, including colitis, pneumonitis, hypophysitis (endocrinopathies), hepatitis, and skin rashes. Skin-related side effects often occur first. Colitis is seen after 4 to 6 weeks; and hepatitis and endocrinopathies occur later, as late as 12 to 24 weeks into treatment (Weber et al., 2015). Prompt initiation of steroids is essential to avoid severe, life-threatening autoimmune effects.

Nursing Management in Immunotherapy

Patients receiving immunotherapy require careful monitoring and thorough patient

education regarding reportable side effects and self-care. The nurse should be familiar with each agent given and its potential effects. Adverse effects, including flu-like symptoms such as fever, chills, myalgia, nausea, and vomiting, as seen with IFN therapy, may not be life threatening. However, the nurse must be aware of the impact of these side effects on the patient's quality of life and should implement supportive care measures, such as NSAIDs for flu-like symptoms and antiemetics for nausea and vomiting to relieve symptoms. Other life-threatening adverse effects (e.g., capillary leak syndrome, pulmonary edema, hypotension) may occur with IL-2 therapy, requiring aggressive fluid resuscitation and, at times, vasopressors (refer to Chapter 54 for details on managing shock). The nurse must work closely with providers to assess and manage potential toxicities of immunotherapy. The specific nursing care required will depend on the agent being administered.

TABLE 6-4 Selected Food and Drug Administration—Approved Targeted Therapies

Monoclonal Antibody	Indication	Target	Selected Side Effects
Alemtuzumab (Campath)	Chronic lymphocytic leukemia	CD52, a marker on cell membrane of lymphocytes, monocytes, and macrophages	Infusion reactions; fever; chills; rash; hives; itching; decreased WBC, platelet, and RBC counts
Bevacizumab (Avastin)	Metastatic colorectal cancer	Vascular endothelial growth factor	Arterial and venous thrombosis, hypertension, hemorrhage, GI perforation, proteinuria, congestive heart failure
Cetuximab (Erbitux)	Metastatic colorectal cancer	Epidermal growth factor	Infusion reactions, fever, chills, rash, hives, itching, acne-like rash, lung inflammation, kidney failure, diarrhea, nausea, abdominal pain, vomiting
Gemtuzumab ozogamicin (Mylotarg)	Acute leukemia	CD33, a marker on cell membrane of leukemic cells	Infusion reactions; fever; chills; weakness; headache; tachycardia; hemorrhage; local skin reaction; rash; stomatitis; decreased platelet, WBC, and RBC counts; increased liver function tests
Ibritumomab-tiuxetan (Zevalin; anti-CD20 B cells)	Non-Hodgkin lymphoma	CD20, a marker on cell membrane of lymphocytes	Decreased platelets, WBC, and RBC counts; weakness; fever; chills
Ofatumumab (anti-CD20 B cells)	Non-Hodgkin lymphoma	CD20, a marker cell membrane of lymphocytes	Infusion reactions, neutropenia, thrombocytopenia, hepatitis B reactivation, intestinal obstruction
Panitumumab (anti-EGFR antibody)	EGFR + metastatic colorectal cancer	Binds to EGFR receptor	Acneform rash, paronychia, dry skin, fissures, fatigue, low magnesium, infusion reactions

Pertuzumab	HER2 + metastatic breast cancer	Targets extracellular domain for HER2	Cardiomyopathy, infusion reactions, peripheral edema, alopecia, rash, diarrhea, myelosuppression
Rituximab (Rituxan; anti-CD20, B cells)	Non-Hodgkin lymphoma	CD20, a marker on cell membrane of lymphocytes	Infusion reactions, fever, chills, back pain, night sweats, infection
Tositumomab (Bexxar; anti-CD20, B cells)	Non-Hodgkin lymphoma	CD20, a marker on cell membrane of lymphocytes	Infusion reactions, fever chills, rash, hives, itching, anemia, thrombocytopenia, decreased WBC count
Trastuzumab (Herceptin)	Breast cancer	HER2, a growth factor protein on cell membrane	Infusion reactions, hypotension, fever, chills, heart failure
Small Molecule Inhibitors	**Indication**	**Target**	**Selected Side Effects**
Axitinib	Advanced renal cell carcinoma	Inhibits VEGF	Hypertension, DVT/PE, bleeding, hypothyroidism, GI perforation, proteinuria, elevated LFTs
Bortezomib	Myeloma	Inhibits proteasome 26S	Peripheral neuropathy, hypotension, nausea, vomiting, diarrhea, constipation, fatigue, myelosuppression, reactivation of herpesvirus
Bosutinib	CML	Inhibits BCR-ABL	Diarrhea, nausea, vomiting, abdominal pain, myelosuppression, LFT elevation, rash, headache
Cabozantinib	Metastatic medullary thyroid cancer	Tyrosine kinase inhibitor	GI perforation, bleeding, DVT/PE, wound complications, hypertension, proteinuria, mucositis, abdominal pain, nausea vomiting, taste changes, myelosuppression
Carfilzomib	Myeloma	Inhibits proteasome 20S	CHF, MI, dyspnea, infusion reactions, myelosuppression, LFT elevation, renal toxicity, fatigue, peripheral edema, peripheral neuropathy, reactivation of herpesvirus
Crizotinib	ALK + NSCLC	Inhibits multiple kinases including ALK	LFT abnormalities, QT prolongation, pneumonitis, nausea, diarrhea, vomiting, edema, anorexia, fatigue, dyspnea, neutropenia
Dasatinib	CML	Inhibits BCR-ABL	Myelosuppression, fluid retention, pleural effusion, diarrhea, nausea, vomiting, bleeding, pulmonary hypertension
Erlotinib	NSCLC	Inhibits tyrosine kinase interfering with EGFR	Rash, diarrhea, anorexia, fatigue, dyspnea, GI bleeding, kidney and liver toxicity, MI, CVA, eye problems
Everolimus	ER + HER2neg breast cancer; metastatic neuroendocrine tumors; renal cell carcinoma	FKBP12 and mTOR	Pneumonitis, infections, mucositis, kidney failure, diarrhea, nausea, vomiting, fatigue, taste changes, headache, cough, dyspnea, myelosuppression, hyperglycemia
Imatinib	CML	BCR-ABL	Nausea, vomiting, myalgias, fluid retention, myelosuppression, hypothyroidism, rash

Lapatinib	Advanced HER2+ breast cancer	EGFR and HER2	Diarrhea, palmar-plantar erythrodysesthesia (hand-foot syndrome), nausea, vomiting, rash, fatigue, QT prolongation, cardiomyopathy, liver and lung toxicity
Nilotinib	CML	BCR ABL	Rash, headache, fatigue, nausea, vomiting, diarrhea, constipation, myelosuppression, liver toxicity, QT prolongation, lipase elevation
Pazopanib	Advanced renal cell carcinoma	VEGF	Liver toxicity, cardiomyopathy, DVT/PE, GI perforation, hypertension, hypothyroidism, proteinuria, infection, myelosuppression, low magnesium and phosphorous, headache, myalgias
Regorafenib	Metastatic colorectal cancer; locally advanced or unresectable gastrointestinal stromal tumors (GIST)	Inhibits multiple kinases	Liver toxicity, bleeding, skin reactions, hypertension, poor wound healing, asthenia, fatigue, anorexia, diarrhea, mucositis, infection, myelosuppression, low calcium/potassium/sodium/phosphorous, proteinuria
Ruxolitinib	Myelofibrosis	JAK1 and JAK2	Myelosuppression, infection
Sorafenib	Unresectable hepatocellular carcinoma and advanced renal cell cancer	Multikinase inhibitor	Palmar plantar erythrodysesthesia (hand-foot syndrome) is erythema, edema, numbness, and desquamation (skin sloughing or peeling) on palms of the hands and soles of the feet (and, occasionally elsewhere), rash, hypertension, MI, mucositis, dyspepsia, elevated lipase, diarrhea, nausea, vomiting, loss of appetite, QT prolongation, low phosphorous, myelosuppression
Sunitinib	GIST Advanced renal cell carcinoma Unresectable pancreatic neuroendocrine tumors	Tyrosine kinase inhibition	Myelosuppression, liver toxicity, decreased LVEF, hypothyroidism, diarrhea, constipation, nausea, vomiting, stomatitis, skin changes, fatigue, hypertension, QT prolongation, impaired wound healing, DVT/PE
Temsirolimus	Advanced renal cell carcinoma	FKBP12, mTOR inhibition	Rash; asthenia; mucositis; nausea; anorexia; myelosuppression; elevated blood sugar, lipids, and cholesterol; elevations in creatinine; low phosphorous; LFT abnormalities; infections

Vandetanib	Unresectable, locally advanced or metastatic medullary thyroid cancer	VEGFR and EGFR inhibition	Skin changes, photosensitivity, QT prolongation, pneumonitis, ischemic cardiovascular events, diarrhea, hypothyroidism, hypertension, fatigue, nausea, anorexia, headache
Vemurafenib	Unresectable melanoma or melanoma with BRAF mutation	BRAF inhibition	Hypersensitivity, skin reactions, QT prolongation, liver toxicity, photosensitivity, eye changes, alopecia, itching, nausea, fatigue, headache, diarrhea
Vismodegib	Metastatic basal cell carcinoma	Hedghog pathway inhibitor	Alopecia, taste changes, weight loss, fatigue, anorexia, nausea, vomiting, arthralgias
Zivaflibercept	Metastatic colorectal carcinoma	VEGF	Bleeding, impaired wound healing, GI perforation, hypertension, arterial thrombolic events, CVA, angina, proteinuria, nephrotic syndrome, myelosuppression, anorexia, diarrhea, fatigue, elevated LFTS

Adapted from Polovich et al. (2014).

The nurse teaches patients self-care and assists in providing for continuing care. Some cytokines, such as IFN, EPO, and G-CSF, can be administered by the patient or family members at home. As needed, the nurse teaches the patient and family how to administer these agents through subcutaneous injections. The nurse also provides instructions about side effects and helps the patient and family identify strategies to manage many of the common side effects of cytokine therapy, such as fatigue, anorexia, and flu-like symptoms.

TABLE 6-5 Selected Side Effects of Food and Drug Administration—Approved Cytokines

Agent Cytokines	Selected Side Effects
Interferon alfa	Flu-like symptoms (fever, chills, weakness, muscle and joint pain, headaches); fatigue; anorexia; mental status changes; depression; irritability; insomnia; rash; pruritus; irritation at the injection site; decreased WBC, RBC, and platelet counts; abnormal liver function values
Interleukin-2	Flu-like symptoms (fever, chills, weakness, muscle and joint pain, headaches); fatigue, anorexia, nausea, vomiting, diarrhea, capillary leak syndrome, edema and fluid retention, hypotension, tachycardia, skin rash, erythema, desquamation
Filgrastim (granulocyte growth factor)	Bone pain, malaise, fever, fatigue, headache, skin rash
Sargramostim (granulocyte-macrophage growth factor)	Allergic/anaphylactic reaction with first dose, bone pain, fever, fatigue, headache, weakness, chills, skin rash, infection
Epoetin alfa (erythrocyte growth factor)	Fever, fatigue, weakness, diarrhea, dizziness, edema, shortness of breath
Oprelvekin (platelet growth factor)	Edema, fever, headache, rash, chills, bone pain, fatigue, nausea, vomiting, abdominal pain, constipation, rhinitis, cough, arrhythmia, skin discoloration, bleeding

Adapted from Polovich et al. (2014).

Patients being treated with checkpoint inhibitor therapies must be monitored carefully over long periods of time for autoimmune-related adverse effects; monitoring should include complete blood counts, liver function tests (LFTs) and metabolic panels, and thyroid function tests. For fatigue and nonspecific syndromes, cortisol should be checked to rule out adrenal insufficiency; and in men, testosterone should be checked as it may be low as a result of pituitary suppression (Weber et al., 2015). Hypothyroidism is also seen and replacement with thyroid hormone may be necessary. Patients must be counseled to report any signs of diarrhea, bloody stool, or abdominal pain promptly as colitis can be life

threatening if untreated. Corticosteroids are the primary treatment, and patients may have to be on steroids for prolonged periods; the nurse should provide education on short- and long-term effects of steroids and the importance of taking steroids with food to minimize stomach upset.

Referral for home care may be indicated to monitor the patient's responses to treatment and to continue to reinforce patient and family teaching. During home visits, the nurse assesses the patient's and family members' technique in administering medications. The nurse collaborates with providers, third-party payers, and pharmaceutical companies to help the patient obtain reimbursement for home administration of these therapies. The nurse also reminds the patient about the importance of keeping follow-up appointments with providers and assesses the patient's need for changes in care.

Hematopoietic Stem Cell Transplantation (HSCT)

Many malignancies exhibit a dose-related response to chemotherapy; by increasing the dose of chemotherapy, the number of malignant cells destroyed is increased. The dose of chemotherapy that is delivered is limited by the toxicity, specifically myelosuppression. The use of bone marrow or stem cells from either the patient (autologous) or from a donor (allogeneic) allows the bone marrow to be "rescued" from the toxic effects of the chemotherapy, therefore allowing higher doses of chemotherapy to be delivered safely (Niess, 2013).

The process of obtaining donor cells has evolved over the years. Traditionally, donor cells were obtained by harvesting large amounts of bone marrow tissue under general anesthesia in the operating room. Currently, a process referred to as *peripheral blood stem cell transplantation* (PBSCT) has gained widespread use. This method of collection uses apheresis methods to collect donor peripheral blood stem cells (PBSCs) for reinfusion. This is a safer and more cost-effective means of collection, rather than the traditional harvesting of marrow.

Types of Stem Cell Transplantation (SCT)

Types of SCT are based on the source of donor cells and include:

- Autologous (from patient)
- Allogeneic (from a donor other than the patient); either a related donor (i.e., family member) or a matched unrelated donor (national bone marrow registry, cord blood registry)
- Syngeneic (from an identical twin)

Autologous hematopoietic SCT, or HSCT, is considered for patients with hematologic malignancies requiring treatment with myeloablative doses of chemotherapy (doses high enough to obliterate marrow function) to achieve cure or prolong survival. Malignancies most commonly treated with autologous transplant include myeloma and lymphoma (Niess, 2013). In autologous transplant, cells are collected from the patient and preserved for reinfusion at a later date. Then the patient is treated with myeloablative chemotherapy and, in some cases, total body irradiation to eradicate any remaining tumor (Polovich et al., 2014). Stem cells are reinfused to "rescue" the marrow from the toxic effects of treatment (Niess, 2013). Until engraftment (repopulation of the marrow with healthy cells) occurs in the bone marrow, there is a high risk of infection, sepsis, and bleeding. Acute toxicities from chemotherapy and radiation therapy may be severe, including mucositis (inflammation and ulceration of the mucous membranes lining the digestive tract), diarrhea, poor appetite, and myelosuppression. No immunosuppressant medications are necessary after autologous bone marrow transplant because the patient does not receive foreign cells. A disadvantage of autologous transplantation is the risk that viable tumor cells may remain despite high-dose chemotherapy.

Allogeneic stem cell transplant is used primarily for disease of the bone marrow, including acute leukemia and aplastic anemia, and depends on the availability of a human leukocyte antigen–matched donor. A patient with one sibling has a 25% chance of having a

matched-sibling donor (Niess, 2013). Prior to transplant, patients and potential donors undergo a thorough clinical assessment to evaluate eligibility (Niess, 2013).

Allogeneic HSCT involves either myeloablative (high-dose) or nonmyeloablative (reduced-intensity) chemotherapy. In myeloablative allogeneic HSCT, the recipient must undergo high doses of chemotherapy and, in some cases, total body irradiation to destroy all existing bone marrow and residual malignant disease. The harvested donor marrow or PBSCs are infused intravenously, similar to a blood transfusion, into the recipient. The infused cells travel to the bone marrow, where the cells mature and proliferate. When the new bone marrow becomes functional, producing RBCs, WBCs, and platelets, engraftment is considered complete (2 to 4 weeks). An advantage of allogeneic HSCT is that the transplanted cells are immunologically intolerant of a patient's malignancy. The donor's healthy immune system is able to recognize the patient's malignancy as foreign and kill any remaining tumor cells. This is referred to as the graft-versus-tumor effect. However, patients can also experience graft versus host disease (GVHD) as a result of the donor's immune system (T cells) recognizing the recipient's tissues as foreign.

In nonmyeloablative allogeneic HSCT, the chemotherapy doses are lower and are aimed at suppressing the recipient's immune system to allow engraftment of donor bone marrow or PBSCs. The lower doses of chemotherapy create less organ toxicity and, thus, can be offered to older patients or those with underlying organ dysfunction, for whom high-dose chemotherapy would be prohibitive. Once the transplanted donor cells begin to grow and reproduce, a process referred to as *engraftment*, a graft-versus-disease effect results in which the donor's healthy immune system keeps the patient's cancer cells from growing.

Before engraftment, patients are at high risk for infection, sepsis, and bleeding. Side effects of the high-dose chemotherapy and total body irradiation can be acute and chronic. Acute side effects include alopecia, hemorrhagic cystitis (inflammation of the bladder), nausea, vomiting, diarrhea, and severe stomatitis. Chronic side effects include sterility, pulmonary dysfunction, cardiac dysfunction, cataracts, and liver disease (McAdams & Burgunder, 2013).

To prevent GVHD, patients receive immunosuppressant drugs, such as cyclosporine (Neoral), tacrolimus (FK 506, Prograf), or sirolimus (Rappamune). In allogeneic transplant recipients, GVHD occurs when the T lymphocytes proliferating from the transplanted donor marrow or PBSCs become activated and mount an immune response against the recipient's tissues (skin, GI tract, liver). T lymphocytes respond in this manner because they view the recipient's tissue as "foreign," immunologically different from what they recognize as "self" in the donor. GVHD may occur acutely (within the first 100 days) or chronically (after 100 days) (Mitchell, 2013).

The first 100 days after allogeneic HSCT are crucial for patients; the immune system and blood-making capacity (hematopoiesis) must recover sufficiently to prevent infection and hemorrhage. Most acute side effects, such as nausea, vomiting, and mucositis, also resolve in the initial 100 days after transplantation. In addition to acute GVHD, patients are also at risk for hepatic venous occlusive disease (VOD) or hepatic sinusoidal obstruction syndrome (HSOS), a vascular injury to the liver caused by high-dose chemotherapy (McAdams & Burgunder, 2013). Incidence of VOD is as high as 30% (Anderson-Rietz & Clancy, 2013). VOD can lead to acute liver failure and death and presents as painful hepatomegaly (enlarged liver), elevated bilirubin levels, ascites, and weight gain in the absence of other causes. Coagulopathy and acute kidney failure can also accompany VOD.

Onset is within the first 20 days posttransplant. There are no standard treatments for VOD; defibrotide has shown promise with response rates of 30% to 60%. Ursodiol has shown some efficacy in the preventative setting and is initiated prior to transplant in some institutions. Fortunately, 70% of patients have resolution of VOD without intervention. Supportive care includes maintaining fluid balance through strict monitoring of I/O and twice-daily weights, pain management, monitoring for signs of bleeding and administering blood products as ordered, and ensuring patient safety (Anderson-Rietz & Clancy, 2013).

Syngeneic transplants use an identical twin as the donor. Syngeneic transplants result in less incidence of GVHD and graft rejection; however, there is also less graft-versus-tumor effect to fight the malignancy. For this reason, even when an identical twin is available for marrow donation, another matched sibling or even an unrelated donor may be the most suitable option to combat an aggressive malignancy (Niess, 2013).

Nursing Management in Stem Cell Transplantation

Providing Care During Treatment

Skilled nursing care is required during all phases of transplant. In the pretransplant phase, the nurse educates the patient about what to expect, pretransplant testing, and finding a donor. When the patient is admitted for high-dose chemotherapy with or without total body irradiation, the nurse educates the patient about expected side effects, expected onset and recovery, and critical self-care measures to decrease the risk of infection. The acute toxicities of nausea, vomiting, diarrhea, mucositis, myelosuppression, and hemorrhagic cystitis require close monitoring and constant attention by the nurse.

Nursing management during the bone marrow or stem cell infusions consists of monitoring the patient's vital signs and blood oxygen saturation; assessing for adverse effects, such as fever, chills, shortness of breath, chest pain, cutaneous reactions (hives), nausea, vomiting, hypotension or hypertension, tachycardia, anxiety, and taste changes; and providing ongoing support and patient teaching.

Throughout the period of bone marrow aplasia (inability to create new cells) until engraftment of the new marrow occurs, the patient is at high risk for death from sepsis and bleeding. The patient requires support with blood products and hematopoietic growth factors. Potential infections may be bacterial, viral, fungal, or protozoan in origin. Renal complications may arise from the nephrotoxic chemotherapy agents used in the conditioning regimen or those used to treat infection (amphotericin B, aminoglycosides). Tumor lysis syndrome (Box 6-6) is an uncommon occurrence with conditioning as most patients do not have a large disease burden at the time of transplant. Acute tubular necrosis is a risk following conditioning therapy.

GVHD requires skillful nursing assessment to detect early effects on the skin, liver, and GI tract, including red maculopapular rash commonly found on the palms of the hands and soles of the feet, elevated LFTs, weight gain, jaundice, right upper quadrant pain, diffuse abdominal pain, early satiety, and diarrhea. Diarrhea resulting from GVHD may be of large volume; therefore, all stools must be measured and monitored for the presence of blood. VOD resulting from the conditioning regimens used in HSCT can result in fluid retention, jaundice, abdominal pain, ascites, tender and enlarged liver, and encephalopathy. Pulmonary complications, such as pulmonary edema, interstitial pneumonia, and other pneumonias, often complicate the recovery after transplant. Immunosuppressive agents,

including cyclosporine, tacrolimus, and rapamycin, require close monitoring of blood levels and kidney function; doses are adjusted based on blood levels. Patients also require education about timing of medication around blood draws and meals, as well as the potential for drug–drug interactions (Mitchell, 2013).

BOX 6-6 Focus on Pathophysiology

Tumor Lysis Syndrome

Malignant cells contain higher intracellular levels of potassium, phosphorous, and nucleic acids than do healthy cells. As the malignant cells are killed by chemotherapy, biotherapy, or corticosteroids, the intracellular contents are released into the bloodstream, leading to hyperkalemia, hyperphosphatemia, and hyperuricemia. The elevation in phosphorous results in an inverse decline in calcium levels. The crystallization of phosphates and uric acid salts in the kidneys can result in acute kidney injury, evidenced by an increase in serum creatinine and acidemia. The treatment plan includes aggressive hydration, administration of medications that block uric acid accumulation (such as Allopurinol) and medications that break uric acid down into a soluble substance that can be excreted through the urine (Rasburicase®), and control of electrolyte disturbances (Porth, 2015). Nursing considerations include strict monitoring of urine output and intake, monitoring of weight changes, and assessment of signs and symptoms of electrolyte disturbances.

Providing Posttransplantation Care

Ongoing nursing assessment and coordination of care in follow-up visits is essential to detect and manage late effects of therapy after HSCT, which occur 100 days or more after the procedure. Late effects include infections (e.g., varicella zoster infection), restrictive pulmonary abnormalities, and recurrent pneumonias. Sterility may result. Chronic GVHD involves the skin, liver, intestine, esophagus, eyes, lungs, joints, and oral and vaginal mucosa. Cataracts may also develop after total body irradiation.

Psychosocial assessments by nursing staff must be ongoing. In addition to the stressors affecting patients at each phase of the transplantation experience, marrow donors and family members also have psychosocial needs that must be addressed.

NURSING PROCESS
The Patient with Cancer

Nurses play a critical role in monitoring for changes over time; identifying problems and alterations in quality of life; and collaborating with patients, families, and members of the multidisciplinary team to optimize patient care. The nursing approach to the most common problems in patients with cancer will be discussed here. A plan of nursing care for a patient with cancer is available online at http://thepoint.lww.com/Honan2e.

ASSESSMENT

Individuals with cancer may experience a range of side effects with varying severity depending on the cancer type, tumor stage, and treatment modalities being used. Assessment of common problems is presented with related interventions below.

DIAGNOSIS

Appropriate nursing diagnoses of the patient with cancer may include:

- Impaired oral mucous membranes
- Impaired skin integrity
- Nausea
- Pain, acute
- Pain, chronic
- Imbalanced nutrition: Less than body requirements
- Fatigue
- Activity intolerance
- Risk for infection
- Risk for bleeding
- Disturbed body image

Based on the assessment data, potential complications include the following:

- Infection and sepsis
- Hemorrhage
- SVCS
- Spinal cord compression
- Hypercalcemia
- Pericardial effusion
- Disseminated intravascular coagulation (DIC)
- Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
- Tumor lysis syndrome

See Table 6-6 for more information on oncologic emergencies.

PLANNING

The major goals for the patient may include relief of fatigue, absence of complications, management of stomatitis, maintenance of nutrition, body image, relief of pain, and effective progression through the grieving process.

NURSING INTERVENTIONS

PREVENTING/MINIMIZING FATIGUE

Cancer-related fatigue is an unusual, distressing, persistent, subjective sense of physical, cognitive, or emotional tiredness related to cancer or cancer treatment and not proportional to recent activity but interfering with usual activity (National Comprehensive Cancer Network [NCCN], 2016a). Fatigue is a prevalent symptom that most patients experience at some point along their cancer experience. Fatigue is a subjective symptom that must be assessed in a systematic way, similarly to pain, relying on the patient's self-report. The nurse should ask the patient to describe the severity of the fatigue. The patient can use a scale of 0 to 10, with 0 being no fatigue and 10 being severe fatigue, or patients can simply state none, mild, moderate, or severe. The nurse should also assess the onset of fatigue as well as aggravating and alleviating factors, including physiologic and psychological stressors that can contribute to fatigue, such as pain, nausea, dyspnea, constipation, fear, and anxiety. The nurse assesses for feelings of weariness, weakness, lack of energy, inability to carry out necessary and valued daily functions, lack of motivation, and inability to concentrate. The patient may become less verbal and may appear pale, with relaxed facial musculature. The nurse helps the patient and family understand that fatigue is an expected side effect of cancer and cancer treatment. Fatigue may be exacerbated by the stress of coping with cancer. It does not always signify that the cancer is advancing or that the treatment is failing.

Nursing strategies are implemented to minimize fatigue or to help the patient cope with existing fatigue. Educational interventions and cognitive behavioral therapies, including providing anticipatory guidance that fatigue is an expected side effect of cancer treatment, have been shown to reduce the severity of cancer-related fatigue (NCCN, 2016a). Helping the patient identify sources of fatigue aids in selecting appropriate and individualized interventions.

Ways to conserve energy are developed to help the patient plan daily activities. Alternating periods of rest and activity are beneficial. Strong evidence exists to support that regular exercise may decrease fatigue and facilitate coping, whereas lack of physical activity and "too much rest" can actually contribute to deconditioning and associated fatigue (Mitchell et al., 2014; NCCN, 2016a). Yoga has also shown to improve cancer-related fatigue (NCCN, 2016a; Sprod et al., 2015). The nurse assists in educating the patient on local resources for exercise and yoga. The nurse also counsels on sleep hygiene, including not staying in bed if the patient is not sleeping; going to bed only when sleepy and at the same time every night; using the bed only for sleep and sexual activity; avoiding daytime napping or, if needed, limiting naps to 30 minutes; avoiding caffeine, nicotine, and alcohol after noon; and using a relaxing routine within 2 hours of going to bed, such

as a warm bath or shower, reading, or listening to music (NCCN, 2016a).

The patient is encouraged to maintain as normal a lifestyle as possible by continuing with activities that he or she values and enjoys. Prioritizing necessary and valued activities can help the patient plan for each day. The patient and family are encouraged to plan to reallocate responsibilities, such as attending to childcare, cleaning, and preparing meals. Patients who are employed full-time may need to reduce the number of hours worked each day or week. The nurse helps the patient and family cope with these changing roles and responsibilities. The nurse also addresses factors that contribute to fatigue, such as poor nutrition, pain, nausea, and depression, and implements pharmacologic and nonpharmacologic strategies to manage these symptoms. The nurse provides nutrition counseling to patients who are not eating enough calories or protein. Small, frequent meals require less energy for digestion. The nurse monitors the patient for deficiencies in serum hemoglobin and hematocrit and administers blood products or ESAs as prescribed. In addition, the nurse monitors the patient for alterations in oxygenation and electrolyte balances. Physical therapy and assistive devices are beneficial for patients with impaired mobility. Studies have evaluated the use of psychostimulants, such as methylphenidate and modafinil, for the treatment of fatigue with mixed results; more data are needed before these interventions can be recommended safely (NCCN, 2016a).

TABLE 6-6 Oncologic Emergencies: Manifestations and Management

Emergency	Diagnostic Approaches and Clinical Manifestations	Medical and Nursing Management

Superior Vena Cava Syndrome (SVCS)
Compression or invasion of the superior vena cava by tumor, enlarged lymph nodes, or intraluminal thrombus that obstructs venous circulation, or drainage of the head, neck, arms, and thorax. Compression of the SVC restricts venous return, decreasing cardiac output. Typically SVCS is associated with bronchogenic cancer but can be associated with other cancers such as lymphoma. Internal occlusion can precipitate SVCS if a central vein catheter becomes occluded. If untreated, SVCS may lead to cerebral anoxia (due to cerebral edema), laryngeal edema, bronchial obstruction, and death.
	Diagnostic
	Diagnosis is confirmed by
	• Clinical findings
	• Chest CT with contrast is preferred test (Shelton, 2013)
	• CXR
	• MRI
	• Biopsy to obtain tissue diagnosis to determine cause is important in initiating treatment.
	
	Clinical
	Gradually or suddenly impaired venous drainage giving rise to:
	• Progressive dyspnea (most common symptom), cough, hoarseness, chest pain, and facial swelling, cyanosis, plethora (redness) of the face, complaints of difficulty buttoning shirt collars
	• Engorged and distended jugular, temporal, and arm veins
	• Dilated thoracic vessels causing prominent venous patterns on the chest wall
	Blood pressure that is falsely elevated in the upper extremities and low in the lower extremities
	Tachycardia
	Late signs: Increased intracranial pressure, associated visual disturbances, headache, dizziness, syncope and altered mental status, irritability, lethargy (Shelton, 2013)
		Medical
		• The goal is control or cure of the underlying malignancy or cause by:
		  • Radiation therapy to shrink tumor size, relieving symptoms
		  • Chemotherapy for chemosensitive cancers (e.g., lymphoma, small cell lung cancer) or when the mediastinum has been irradiated to maximum tolerance
		  • Anticoagulant or thrombolytic therapy for intraluminal thrombosis
		  • Stent placement to restore blood flow
		• Supportive measures such as oxygen therapy, bronchodilators, corticosteroids, diuretics, and anxiolytics (Shelton, 2013)
		
		Nursing
		• Identify patients at risk for SVCS.
		• Monitor and report clinical manifestations of SVCS.
		• Monitor vital signs as well as cardiopulmonary and neurologic status.
		• Facilitate breathing by positioning the patient properly. Assist the patient to maintain an upright position (elevated 45 degrees). This helps to promote comfort and reduce anxiety; it also reduces intracranial pressure.
		• Remove rings and restrictive clothing.
		Assist patient with ADLs to minimize energy expenditures.
		Monitor the patient's fluid volume status: Assess weights and I/Os regularly.
		Ensure that the patient avoids the Valsalva maneuver, which may worsen symptoms, by providing cough suppressants and stool softeners as needed.

Spinal Cord Compression (SCC) Occurs when a malignant disease or a pathologically collapsed vertebrae compresses or displaces the thecal sac that contains the spinal cord, leading to neurologic impairment. The prognosis depends on the severity and rapidity of onset with median of 6 months survival from time of SCC diagnosis. Presenting signs and symptoms depend on the location of compression. 20% of patients present with SCC. About 60% of compressions occur at the thoracic level, 30% in the lumbosacral level, and 10% in the cervical region. Metastatic cancers (breast, lung, kidney, prostate, myeloma, lymphoma) and related bone erosion are associated with spinal cord compression (Pi et al., 2016)	***Diagnostic*** • MRI (preferred test), myelogram, spinal cord x-rays, bone scans, and CT scan • Imaging should include the entire thecal sac as there may be multiple sites of disease involvement (Pi et al., 2016). ***Clinical*** • Percussion tenderness at the level of compression • Abnormal reflexes • Sensory (40–90%) and motor (60–85%) abnormalities • Local or radicular back or neck pain along the dermatomal areas innervated by the affected nerve root (e.g., thoracic radicular pain extends in a band around the chest or abdomen) • Pain exacerbated by movement, supine recumbent position, coughing, sneezing, or the Valsalva maneuver • Back pain is the most common (83–95%) and often the first symptom preceding other symptoms by as much as 2 months. • Neurologic dysfunction, and related motor and sensory deficits (numbness, tingling, feelings of coldness in the affected area, inability to detect vibration, loss of positional sense) • Motor loss ranging from subtle weakness to flaccid paralysis • Bladder and/or bowel dysfunction depending on level of compression (above S2, overflow incontinence; from S3 to S5, flaccid sphincter tone and bowel incontinence). These tend to be late symptoms and match degree of weakness. (Pi et al., 2016)	***Medical*** • Radiation therapy is the initial treatment of choice for those with a radiosensitive tumor type who are not surgical candidates; radiation will reduce tumor size to halt progression. • Corticosteroid therapy at time of presentation to decrease inflammation and swelling at the compression site • Surgery if: patient is medically able to undergo surgical decompression and fixation, direct compression in setting of intraspinal bony fragments unlikely to respond to radiation, an unstable spine where direct fixation and stabilization is the only way to preserve ambulation, impending sphincter dysfunction, lack of response to initial radiation therapy, paraplegia in less than 48 hours, unknown primary tumor type (Pi et al., 2016). • Chemotherapy or hormonal therapy as adjuvant to radiation therapy • *Note:* Despite treatment, patients with poor neurologic function before treatment are less likely to regain complete motor and sensory function; less than 30% of patients who have lost the ability to walk before radiation was started regain the ability to ambulate. Pain management is a priority. ***Nursing*** • Perform ongoing assessment of neurologic status, including motor and sensory function to identify existing and progressing dysfunction (Kaplan, 2013c). • Control pain with pharmacologic and nonpharmacologic measures. • Prevent complications of immobility resulting from pain and decreased function (e.g., skin breakdown, urinary stasis, thrombophlebitis, decreased clearance of pulmonary secretions). • Maintain muscle tone by assisting with range-of-motion exercises in collaboration with physical and occupational therapists. • Institute intermittent urinary catheterization and bowel training programs for patients with bladder or bowel dysfunction. • Maintain safety by assisting the patient with ADLs and ambulation.

Hypercalcemia In patients with cancer, hypercalcemia is a potentially life-threatening metabolic abnormality resulting when the calcium released from the bones exceeds the amount that the kidneys have the ability to excrete or the bones can reabsorb. It may be the result of: • Bone destruction by tumor cells and subsequent release of calcium • Production of prostaglandins and osteoclast-activating factors, which stimulate bone breakdown and calcium release • Tumors that produce parathyroid-like substances that promote calcium release • Overproduction of vitamin D analogues (calcitriol), seen most commonly in hematologic malignancies (Pi et al., 2016) • Most commonly seen in breast cancer, lung cancer, and myeloma (Pi et al., 2016)	***Diagnostic*** Serum calcium level exceeding 11 mg/dL (2.74 mmol/L) Moderate hypercalcemia: 12–14 mg/dL Severe hypercalcemia: greater than 14 mg/dL (Pi et al., 2016) ***Clinical*** Early signs: Fatigue, weakness, lethargy, irritability, cognitive changes, personality changes, confusion, decreased level of responsiveness, hyporeflexia, nausea, vomiting, constipation, anorexia, polyuria (excessive urination), polydipsia (excessive thirst), nocturia, dehydration. Late signs: ataxia, stupor, seizures, coma, arrhythmias, ileus, kidney failure, heart block, cardiac arrest	***Medical*** See Chapters 4 and 31. ***Nursing*** • Identify patients at risk for hypercalcemia and assess for signs and symptoms of hypercalcemia. • Educate patient and family on prevention, including hydration and ambulation/weight-bearing activity. • Teach at-risk patients to recognize and report signs and symptoms of hypercalcemia promptly. • Ensure that patients consume (PO or IV) a total of 3 L of fluid daily unless contraindicated by existing kidney or cardiac disease. • Monitor I/O and daily weight. • Explain the use of dietary and pharmacologic interventions, such as stool softeners and laxatives for constipation. • Discuss antiemetic therapy if nausea and vomiting occur. • Advise patients to maintain nutritional intake without restricting normal calcium intake. • Implement safety measures, including fall and seizure precautions. Promote mobilization by assisting with ambulation and providing active resistive exercises for patients on bed rest; emphasize the importance of mobility in preventing demineralization and breakdown of bones. (Kaplan, 2013b)
Pericardial Effusion and Cardiac Tamponade Cardiac tamponade is an accumulation of fluid in the pericardial space. The fluid compresses the heart and thereby impedes expansion of the ventricles, limiting cardiac filling during diastole. As ventricular volume and cardiac output fall, the heart pump fails, and circulatory collapse develops. With gradual onset, fluid accumulates slowly, and the outer layer of the pericardial space stretches to compensate for rising pressure. Large amounts of fluid accumulate before symptoms of heart failure occur. With rapid onset, pressures rise too quickly for the pericardial space to compensate. Malignancies, particularly from adjacent thoracic tumors (lung, breast, lymphoma), and side effects of cancer treatment are the most common causes of cardiac tamponade. High doses of radiation to fields involving the heart also have been implicated in pericardial fibrosis, pericarditis, and resultant cardiac tamponade. Untreated pericardial effusion and cardiac tamponade lead to circulatory collapse and cardiac arrest (Turner Story, 2013.) Tamponade is associated with late-stage disease and carries a high mortality rate (Turner Story, 2013).	***Diagnostic*** • Electrocardiography (ECG) • Echocardiogram is preferred imaging test (Turner Story, 2013) • In small effusion, chest x-rays show small amounts of fluid in the pericardium; in large effusions, x-ray films disclose "water-bottle" heart (obliteration of vessel contour and cardiac chambers) • CT scans help diagnose pleural effusions and evaluate effect of treatment ***Clinical*** • Fatigue, dyspnea, orthopnea, nonproductive cough, dull or diffuse chest pain • Neck vein distention during inspiration (Kussmaul sign) • Pulsus paradoxus (systolic blood pressure decrease exceeding 10 mm Hg during inspiration; pulse gets stronger on expiration) • Distant heart sounds, rubs and gallops, cardiac dullness • Shifted Point of Maximal Impulse (PMI) • Compensatory tachycardia (heart beats faster to compensate for decreased cardiac output) • Increased venous and vascular pressures • Narrow pulse pressure (the difference between systolic and diastolic blood pressure) • Shortness of breath and tachypnea • Weakness, chest pain, orthopnea, anxiety, diaphoresis, lethargy, and altered consciousness from decreased cerebral perfusion • Low voltage QRS on EKG; electrical alternans	***Medical*** • Pericardiocentesis (the aspiration or withdrawal of pericardial fluid by a large-bore needle inserted into the pericardial space). In malignant effusions, pericardiocentesis provides only temporary relief; fluid usually reaccumulates. Windows or openings in the pericardium can be created surgically as a palliative measure to drain fluid into the pleural space. Catheters may also be placed in the pericardial space, and sclerosing agents (such as doxycycline, talc, bleomycin) are injected to prevent fluid from reaccumulating. • Radiation therapy; antineoplastic agents. In mild effusions, prednisone and diuretic medications may be used. ***Nursing*** • Monitor vital signs, oxygen saturation, cardiac and respiratory examination frequently. • Assess for pulsus paradoxus. • Monitor ECG tracings. • Assess heart and lung sounds, neck vein filling, level of consciousness, respiratory status, and skin color and temperature. • Monitor and record intake and output. • Review laboratory findings (e.g., arterial blood gas and electrolyte levels). • Elevate the head of the patient's bed to ease breathing. • Minimize patient's physical activity to reduce oxygen requirements; administer supplemental oxygen as prescribed. • Provide frequent oral hygiene. • Reposition and encourage the patient to cough, use pursed-lip breathing, and take deep breaths. Assist patient with ADLs to conserve energy. Maintain oxygen saturation greater than 92%. Administer analgesics and anxiolytics as ordered. Assist patients with relaxation techniques (Turner Story, 2013.)

Disseminated Intravascular Coagulation (DIC, also called consumption coagulopathy) Complex disorder of coagulation and fibrinolysis (destruction of clots), which results in thrombosis and bleeding. DIC is most commonly associated with hematologic cancers (leukemia); cancer of prostate, GI tract, and lungs; chemotherapy (methotrexate, prednisone, L-asparaginase, vincristine, and 6-mercaptopurine); and disease processes such as sepsis, hepatic failure, and anaphylaxis.	***Diagnostic*** • Prolonged prothrombin time (PT or protime) • Prolonged international normalized ratio (INR) • Prolonged partial thromboplastin time (PTT) • Prolonged thrombin time (TT) • Decreased fibrinogen level • Decreased platelet level • Decrease in clotting factors • Decreased hemoglobin • Decreased hematocrit • Elevated fibrin split products (or fibrin degradation products) • Elevated D-dimer test • Positive protamine sulfate precipitation test (thrombin activation test)	***Medical*** The underlying cause of DIC must be treated. • Chemotherapy, biologic response modifier therapy, radiation therapy, or surgery is used to treat the underlying cancer. • Antibiotic therapy is used for sepsis. • Anticoagulants, such as heparin or antithrombin III, decrease the stimulation of the coagulation pathways. Anticoagulants must be used with caution in patients who have experienced or are at risk for bleeding.
Blood clots form when normal coagulation mechanisms are triggered. Once activated, the clotting cascade continues to consume clotting factors and platelets faster than the body can replace them, which can result in bleeding. Clots are deposited in the microvasculature, placing the patient at great risk for impaired circulation, tissue hypoxia, and necrosis. In addition, fibrinolysis occurs, breaking down clots and increasing the circulating levels of anticoagulant substances, thereby placing the patient at risk for hemorrhage.	***Clinical*** *Chronic DIC:* Characterized by diffuse thrombosis or subacute bleeding. Few or no observable symptoms or easy bruising, prolonged bleeding from venipuncture and injection sites, bleeding of the gums, and slow GI bleeding *Acute DIC:* life-threatening hemorrhage and infarction; clinical symptoms of this syndrome are varied and depend on the organ system involved in thrombus and infarction or bleeding episodes. Bleeding can occur anywhere.	• Transfusions of fresh-frozen plasma (containing clotting factors) or cryoprecipitate (containing fibrinogen), packed RBCs, and platelets may be used as replacement therapy in patients with evidence of bleeding. • Although controversial, antifibrinolytic agents such as aminocaproic acid (Amicar), which is associated with increased thrombus formation, may be used (Kaplan, 2013a). ***Nursing*** • Monitor vital signs. • Measure and document intake and output. • Assess skin color and temperature; lung, heart, and bowel sounds; level of consciousness; headache; visual disturbances; chest pain; decreased urine output; and abdominal tenderness. • Inspect all body orifices, tube insertion sites, incisions, and bodily excretions for bleeding. • Review laboratory test results. • Minimize physical activity to decrease injury risks and oxygen requirements. • Prevent bleeding; apply pressure to all venipuncture sites, and avoid nonessential invasive procedures; avoid the use of tourniquets; provide electric rather than straight-edged razors; avoid tape on the skin and advise gentle but adequate oral hygiene with use of a soft toothbrush or toothette. • Assist the patient to turn, cough, and take deep breaths every 2 hours. • Reorient the patient, if needed; maintain a safe environment; and provide appropriate patient education and supportive measures.

Syndrome of Inappropriate Secretion of Antidiuretic Hormone (SIADH)

SIADH is a result of the failure in the negative feedback mechanism that normally regulates the release of antidiuretic hormone (ADH). Some malignancies, such as small-cell lung cancer, inappropriately release antidiuretic hormone (ADH). The excessive release of ADH produced by tumor cells or by the abnormal stimulation of the hypothalamic–pituitary network leads to uncontrolled water reabsorption. The most common cause of SIADH is cancer, especially small cell cancer of the lung.

Medications, including antineoplastics—vincristine, vinblastine, cisplatin, and cyclophosphamide—and morphine also stimulate ADH secretion (see Chapters 4 and 31 for details on SIADH).

Diagnostic

- Decreased serum sodium level
- Decreased serum osmolality
- Increased urine osmolality
- Increased urinary sodium level
- Increased urine-specific gravity
- Decreased blood urea nitrogen (BUN), creatinine, and serum albumin levels secondary to dilution
- Abnormal water load test results

Clinical

Mild SIADH: serum sodium 125–134 mEq/L

Signs and symptoms include: increased thirst, anorexia, nausea, fatigue, weakness, headache

Moderate SIADH: Serum sodium levels between 115 and 124 mEq/L (120 mmol/L)

Signs and symptoms include: personality changes, irritability, nausea, anorexia, vomiting, weight gain, oliguria, fatigue, muscular pain (myalgia), headache, lethargy, and confusion

Severe SIADH: Serum sodium levels less than 115 mEq/L

Signs and symptoms include: seizure, abnormal reflexes, delirium, ataxia, papilledema, coma, and death.

Number and severity of symptoms depends on the rate of onset; the faster the onset of SIADH, the more symptomatic the patient may be.

Signs and symptoms of fluid volume overload, including edema, are rare.

Medical

The underlying cause of SIADH must be treated in order to effectively treat SIADH.

Discontinue the offending medication.

Fluid intake limited to 500–1,000 mL/day to increase the serum sodium level. If water restriction alone is not effective in correcting or controlling serum sodium levels, demeclocycline is often prescribed to inhibit ADH secretion and promote water excretion.

If neurologic symptoms are severe, parenteral sodium replacement and diuretic therapy are indicated. Electrolyte levels are monitored carefully to detect secondary magnesium, potassium, and calcium imbalances.

After the symptoms of SIADH are controlled, the underlying cancer is treated. If water excess continues despite treatment, pharmacologic intervention may be indicated. Hypertonic (3%) saline may be administered for a short time (1–3 hours) in an intensive care setting with frequent (q2h) serum sodium levels (Lahoti et al., 2016)

The goal is to increase the serum sodium level slowly. Increasing the serum sodium level too quickly can cause intracellular dehydration, which may result in serious neurologic impairment.

Nursing

Early identification of at-risk patients is essential to promote early intervention.

- Maintain intake and output measurements; assess urine-specific gravity.
- Assess level of consciousness, lung and heart sounds, vital signs, daily weight; also assess for nausea, vomiting, anorexia, edema, fatigue, and lethargy.
- Monitor laboratory test results, including serum electrolyte levels, osmolality, and BUN, creatinine, and urinary sodium levels.
- Minimize the patient's activity; provide appropriate oral hygiene; maintain environmental safety; and restrict fluid intake if necessary.
- Maintain safety: implement fall and seizure precautions for sodium levels below 120 mEq/L.

Tumor Lysis Syndrome (TLS) TLS is a rapidly developing oncologic emergency that results from the rapid release of intracellular contents as a result of radiation- or chemotherapy-induced cell destruction of large or rapidly growing cancers, such as leukemia, lymphoma, and small cell lung cancer. Cancer cells have an abnormally high amount of potassium, phosphate, and nucleic acids. The release of these intracellular contents from the tumor cells leads to electrolyte imbalances—hyperkalemia, hypocalcemia, hyperphosphatemia, and hyperuricemia—because the kidneys can no longer excrete large volumes of the released intracellular metabolites. These metabolic abnormalities may result in life-threatening arrhythmias, seizures, and kidney failure.	***Diagnostic*** Electrolyte imbalances identified by laboratory test results, including: Uric acid greater than 8 mg/dL Phosphorus greater than 4.5 mg/dL Potassium greater than 5.5 mEq/L Calcium less than 7 mg/dL (Pi et al., 2015) ***Clinical*** Clinical manifestations depend on the extent of metabolic abnormalities. • Neurologic: fatigue, weakness, memory loss, altered mental status, muscle cramps, irritability, paresthesias (numbness and tingling), tetany seizures • Cardiac: hypotension, peaked T waves, flattened P waves, widened QRS waves, ST depression, dysrhythmias, cardiac arrest • GI: anorexia, nausea, vomiting, abdominal cramps, diarrhea • Renal: flank pain, oliguria, anuria, kidney failure, hematuria, acidic urine pH	***Medical*** Prevention, early detection, and prompt management are critical in decreasing morbidity and mortality. • To prevent kidney failure and restore electrolyte balance, aggressive hydration (one to two times the daily maintenance requirement) is initiated 48 hours before the initiation of cytotoxic therapy to increase urine volume and eliminate uric acid and electrolytes. Alkalinization of urine is no longer recommended due to lack of clear benefit (Pi et al., 2015). • Following aggressive hydration, diuretic therapy may be used to increase electrolyte excretion (potassium, uric acid). • Allopurinol therapy should be started prior to the initiation of chemotherapy to inhibit the conversion of nucleic acids to uric acid (Pi et al., 2015). Rasburicase therapy may be initiated as prophylaxis or treatment of hyperuricemia. Rasburicase converts uric acid into allantoin, which is a substance that is soluble in urine. • Administration of a cation-exchange resin, such as sodium polystyrene sulfonate (Kayexalate) to treat hyperkalemia by binding and eliminating potassium through the bowel. (Refer to Chapter 4 for treatment of hyperkalemia.) • Administration of hypertonic dextrose and regular insulin temporarily shifts potassium into cells and lowers serum potassium levels. • Administration of phosphate-binding gels, such as aluminum hydroxide, treats hyperphosphatemia by promoting phosphate excretion in the feces. • Hemodialysis is performed when patients have persistently elevated electrolytes with worsening kidney function or in patients with symptomatic electrolyte imbalances or fluid volume overload from TLS management.
		Nursing • Identify at-risk patients. • Institute essential preventive measures as described above. • Assess patient for signs and symptoms of electrolyte imbalances. • Monitor serum electrolyte and uric acid levels. • Assess for evidence of fluid volume overload secondary to aggressive hydration by monitoring I/O and daily weights. • Instruct patients to report symptoms indicating electrolyte disturbances.

MONITORING AND MANAGING INFECTION AND SEPSIS

Monitoring for Infection. For patients in all stages of cancer, the nurse assesses risk factors for infection and observes for clinical signs and symptoms, as infection is the leading cause of death in cancer patients. The nurse monitors laboratory studies to detect early changes in WBC counts. Common sites of infection, such as the oropharynx, skin, perianal area, urinary tract, GI tract, and respiratory tract, are assessed frequently. The typical signs of infection (swelling, redness, drainage, and pain) may not occur in immunosuppressed patients because of a diminished local inflammatory response. Fever or localized tenderness may be the only sign of infection. The nurse also monitors the patient for sepsis, particularly if invasive catheters or venous access devices are in place.

WBC function is often impaired in patients with cancer. There are two types of WBCs: granulocytes (neutrophils, eosinophils, basophils) and agranulocytes (lymphocytes, monocytes, macrophages). The neutrophils, totaling 60% to 70% of the body's total WBCs, play a major role in combating infection by engulfing and destroying microorganisms in a process called *phagocytosis.* Both the total WBC count and the number of neutrophils are important in determining the patient's ability to fight infection. A decrease in circulating WBCs is referred to as *leukopenia. Granulocytopenia* or *neutropenia* is a decrease in neutrophils (see Chapters 19 and 20).

A differential WBC count identifies the relative numbers of WBCs and permits tabulation of the absolute neutrophil count (ANC). The ANC includes the number of polymorphonuclear neutrophils (mature neutrophils, reported as "polys," PMNs, or "segs") and immature forms of neutrophils (reported as bands, metamyelocytes, and "stabs"). The ANC is calculated by the following formula:

$$\text{Total WBC} \times [\%\text{segs} + \%\text{bands}]$$

For example, if the total WBC count is 6,000 cells/mm^3, with segmented neutrophils 25% and bands 25%, the ANC is 3,000 cells/mm^3. That is 6,000 × [0.25 + 0.25] = 6,000 × 0.5 = 3,000.

Neutropenia, an abnormally low ANC, is associated with an increased risk for infection. The risk for infection rises as the ANC decreases and persists. An ANC less than 500 cells/mm^3 reflects a severe risk of infection. Nadir is the lowest ANC after myelosuppressive chemotherapy or radiation therapy. Therapies that suppress bone marrow function are called *myelosuppressive.* Therapies that severely suppress bone marrow function are called *myeloablative.* The nadir is reached, on average, 7 to 10 days following chemotherapy treatment and takes an additional 7 to 14 days to recover. The patient is at increased risk for infection throughout the duration of neutropenia.

Gram-positive bacteria (*Streptococcus* and *Staphylococcus* species) and gram-negative organisms (*Escherichia coli, Klebsiella pneumoniae,* and *Pseudomonas aeruginosa*) are the most frequently isolated causes of infection. Fungal organisms, such as *Candida albicans,* also contribute to the incidence of serious infection. Viral infections in immunocompromised patients are caused most commonly by herpes viruses and respiratory viruses.

Nursing Alert
Normal WBC levels in adults are 4.5 to 10.5 × 10^3 cells/mm^3 or 4,500 to 10,500 cells/mm^3. For African-American adults, normal levels are 3,200 to 10,000 cells/mm^3. A WBC level (count) below 500 or above 30,000 is a critical value.

Managing Patients with Febrile Neutropenia. A fever in a patient with neutropenia is considered an emergency due to the high mortality rate associated with sepsis in neutropenic patients. Hospitalized patients who are neutropenic and become febrile are assessed immediately for infection. Cultures of blood, sputum, urine, stool, catheter, or

wounds are obtained. In addition, a chest x-ray is often included to assess for pulmonary infections. If a patient is at home and develops neutropenic fever, the patient is instructed to notify their health care provider and seek medical attention immediately.

Nursing Alert
Fever is often the only sign of infection in immunocompromised patients. Although fever may be related to a variety of noninfectious conditions, including the underlying cancer, any temperature of 38.3°C (100.9°F) or higher or a sustained temperature of 38.0°C (100.4°F) for 1 hour is reported and addressed promptly (NCCN, 2016b).

Empiric antibiotics are initiated to treat infections immediately after cultures are obtained. The term *empiric antibiotics* refer to the use of broad-spectrum antibiotics used to treat infection before a definitive organism is identified. Often, Gram stains are ordered along with cultures to assist providers in identifying the most appropriate antibiotic. Empiric antibiotics have been employed due to the high incidence of mortality associated with untreated infection in neutropenic patients. Broad-spectrum antibiotic coverage or empiric therapy most often includes a combination of medications to defend the body against the major pathogenic organisms (both gram-positive and gram-negative). It is important for the nurse to administer these medications promptly, immediately after two sets of blood cultures are obtained, according to the prescribed schedule, to achieve adequate blood levels of the medications (NCCN, 2016b).

Minimizing the Risk of Infection in Neutropenic Patients. Strict asepsis is essential when handling IV lines, catheters, and other invasive equipment. Patients are advised to minimize contact with anyone who might be sick and to avoid crowds. Patients with profound immunosuppression, such as allogeneic HSCT recipients or patients with acute leukemia, should be placed in single rooms where the air is filtered. To reduce the risk of foodborne illnesses, patients are educated to avoid raw meat, eggs, or fish; deli meats; unroasted raw nuts or nuts in the shell; miso products; raw grain products; unpasteurized milk products; and soft cheese, cheese with uncooked vegetables, or cheese with mold. Fruits and vegetables must be washed well, eliminating soft fruits such as berries that are difficult to wash.

Hand hygiene and appropriate general hygiene are critical to reduce exposure to potentially harmful bacteria and to eliminate environmental contaminants. Invasive procedures, such as injections, vaginal or rectal examinations, rectal temperatures, and surgery, are avoided. The patient is encouraged to cough and to perform deep-breathing exercises frequently to prevent atelectasis and other respiratory problems. Prophylactic antimicrobial therapy may be used for patients who are expected to be profoundly immunosuppressed and at risk for certain infections, such as patients undergoing autologous or allogeneic stem cell transplant and patients with acute leukemia. The nurse teaches the patient and family to recognize signs and symptoms of infection that should be reported, performs effective hand hygiene, uses antipyretics, maintains skin integrity,

and administers hematopoietic growth factors when indicated.

MONITORING AND MANAGING BLEEDING AND HEMORRHAGE

The nurse assesses the patient with cancer for factors that may contribute to bleeding. Bleeding may result from a reduction in the quantity or quality of platelets, a decrease in clotting factors, or from DIC (see Chapter 20 for details on DIC). Treatment-related factors include bone marrow suppression from radiation, chemotherapy, and other medications that interfere with coagulation and platelet functioning, such as aspirin and other nonsteroidal anti-inflammatory medications, dipyridamole, heparin, or warfarin (Coumadin).

Thrombocytopenia often results from bone marrow depression after certain types of chemotherapy and radiation therapy. Tumor infiltration of the bone marrow can also impair the normal production of platelets. In some cases, platelet destruction is associated with an enlarged spleen (hypersplenism) and abnormal antibody function, which occur with leukemia and lymphoma. Chapter 19 details thrombocytopenia. Refer to Box 19-2 for thrombocytopenia precautions.

Concept Mastery Alert

A nurse can best detect early signs and symptoms of thrombocytopenia by closely observing the client's skin for petechiae and bruising.

The nurse administers platelet transfusions as ordered and monitors for signs of transfusion reaction, including fever, chills, urticaria, and shortness of breath. In limited circumstances, the nurse may administer Interluekin (IL)-11 (Oprelvekin), which has been approved by the U.S. Food and Drug Administration (FDA) to prevent severe thrombocytopenia and to reduce the need for platelet transfusions after myelosuppressive chemotherapy in patients with nonmyeloid malignancies. In some instances, the nurse teaches the patient or family members to administer IL-11 in the home (Wyeth, 2013).

When a hospitalized patient experiences bleeding, the nurse monitors blood pressure and pulse and respiratory rates every 15 to 30 minutes. Serum hemoglobin and hematocrit are monitored carefully for changes indicating blood loss. The nurse tests all urine, stool, and emesis for occult blood. Neurologic assessments are performed to detect changes in orientation and behavior. Headaches reported by the patient or abnormal neurologic findings must be reported to the provider immediately as even subtle signs may indicate an intracranial hemorrhage. The nurse administers fluids and blood products as prescribed to replace any losses.

Nursing Alert

One unit of platelets is approximately 50 to 70 mL; in general, four to six units are pooled for a platelet transfusion and infused according to the patient's tolerance. The platelet transfusion is anticipated to increase the platelet count 5,000 to

10,000/mL per unit.

ASSESSING AND MANAGING STOMATITIS

Mucositis is a common side effect of radiation and some types of chemotherapy that may lead to inflammation and ulceration of any portion of the GI tract from the oral cavity throughout the alimentary canal. One form of mucositis, stomatitis, is an inflammatory response of the oral tissues that is characterized by mild redness (erythema) and edema or, if severe, by painful ulcerations, bleeding, and secondary infection. Stomatitis commonly develops 5 to 14 days after patients receive myelosuppressive chemotherapeutic agents and often coincides with the WBC nadir. As many as 40% of patients receiving standard-dose chemotherapy experience some degree of stomatitis during treatment, and up to 100% of patients receiving high-dose chemotherapy or combination therapy with radiation and chemotherapy for treatment of head and neck cancers may experience stomatitis (Eilers et al., 2014).

As a result of normal everyday wear and tear, the epithelial cells that line the oral cavity undergo rapid turnover and slough off routinely. Until recently, stomatitis was thought to occur because chemotherapy and radiation interfered with this process. Mucositis is now understood as a complex process involving inflammation, tissue damage, cell death, cytokine release, and microbes in the oral cavity (Eilers et al., 2014). Poor oral hygiene, existing dental disease, use of other medications that dry mucous membranes, advanced age, smoking, previous cancer treatment, diminished kidney function, and impaired nutritional status all contribute to morbidity associated with stomatitis. Radiation-induced xerostomia (dry mouth) associated with decreased function of the salivary glands may contribute to stomatitis in patients who have received radiation to the head and neck.

Myelosuppression (bone marrow depression), resulting from underlying disease or its treatment, predisposes the patient to oral bleeding and infection. Severe pain associated with ulcerated oral tissues can significantly interfere with nutritional intake, speech, and a willingness to maintain oral hygiene. Severe stomatitis may cause or prolong hospitalizations. In addition, stomatitis may lead to interruptions in chemotherapy and radiation administration or decreases in the intended dosing until the inflammation subsides. Further, it may significantly reduce the patient's quality of life.

Nurses must perform routine oral assessments in patients at risk for developing stomatitis and in patients with established stomatitis. Standardized oral assessment guides exist to facilitate objective descriptions of the oral mucosa (Eilers et al., 2014). The assessment should include the color and moisture of the lips and oral mucosa; presence of ulcerations; presence of edema of the lips, buccal mucosa, or tongue; and quantity and quality of saliva. The nurse also assesses the level of pain that the patient experiences secondary to stomatitis, alterations in the patient's ability to talk or sleep, and nutritional intake (Polovich et al., 2014).

Although multiple studies on stomatitis have been published, the optimal prevention and treatment approaches have not been identified. Future studies will focus on

addressing the cascade of inflammatory events and release of chemical substances that leads to the cellular and tissue destruction underlying stomatitis. Routine, good oral hygiene, including brushing, flossing, and rinsing, is necessary to minimize the risk of oral complications associated with cancer therapies. Soft-bristled toothbrushes and nonabrasive toothpaste prevent or reduce trauma to the oral mucosa. Oral swabs with sponge-like applicators may be used in place of a toothbrush for painful oral tissues. Flossing may be performed unless it causes pain or bleeding. Oral rinses with saline solution or tap water after meals and at bedtime may be necessary for patients who cannot tolerate tooth brushing. Products that irritate oral tissues or impair healing, such as alcohol-based mouth rinses, are avoided. Foods that are difficult to chew or that are hot or spicy are avoided to minimize further trauma. The patient's lips are lubricated to keep them from becoming dry and cracked. Topical anti-inflammatory and anesthetic agents may be prescribed to promote healing and minimize discomfort. Products that coat or protect oral mucosa are used to promote comfort and prevent further trauma. Patients who experience severe pain and discomfort with stomatitis require systemic analgesics.

Adequate fluid and food intake is encouraged. In some instances, parenteral hydration and nutrition are necessary. Topical or systemic antifungal and antibiotic medications are prescribed to treat local or systemic infections.

Cryotherapy (sucking on ice chips) has demonstrated a reduction in pain incidence and severity in patients being treated with drugs with a short half-life (e.g., bolus 5-fluorouracil, melphalan) (Eilers et al., 2014). Low-level laser therapy has also demonstrated a reduction in prevalence, severity, pain, and duration of mucositis (Eilers et al., 2014; Polovich et al., 2014).

Palifermin, a synthetic form of human keratinocyte growth factor, is an IV medication approved in 2005 by the FDA for treatment of mucositis in patients with hematologic malignancies who are undergoing high-dose chemotherapy or total body radiation prior to HCST. Palifermin appears to promote more rapid replacement of cells in the mouth and GI tract, decreasing the incidence and duration of severe mucositis. It has not yet been tested in other patients with cancer. Careful timing of administration and monitoring are essential for maximum effectiveness and to detect adverse effects (Eilers et al., 2014; Polovich et al., 2014).

CARING FOR PATIENTS WITH NAUSEA AND VOMITING

Nausea is an unpleasant sensation experienced in the back of the throat, epigastrium, or stomach that may result in vomiting. Nausea is one of the most feared side effects of cancer treatment. The potential causes of nausea are numerous, and nurses should not assume that nausea is due to chemotherapy; all potential causes must be considered. Causes of nausea include primary or metastatic tumor involving the CNS; gastroparesis (slowed gastric emptying); obstruction in the GI tract; infection; hypercalcemia; kidney or liver dysfunction; hyponatremia; and side effects of medications including chemotherapy, morphine, and antibiotics. Risk factors for treatment-induced nausea include younger age, female sex, and a history of treatment-induced nausea and vomiting.

Nausea is a subjective phenomenon analogous to pain. Nausea is best assessed by eliciting the patient's self-report. The following components should be assessed: timing of nausea in relation to treatment, perceived meaning of nausea to the patient, onset, frequency, associated symptoms, precipitating and alleviating factors, and previous experiences with nausea. Physical assessment should include signs of sweating, tachycardia, dizziness, pallor, excessive salivation, weakness, gastric distention, abdominal tenderness, and evaluation of bowel sounds. Laboratory values including electrolytes and kidney function should be monitored.

The prevention of chemotherapy-induced nausea and vomiting is a priority (see earlier discussion). For nausea and vomiting unrelated to chemotherapy, medications including serotonin receptor antagonists (e.g., ondansetron), dopamine receptor antagonists (e.g., metoclopramide), phenothiazines (e.g., prochlorperazine), corticosteroids (e.g., dexamethasone), and cannabinoids (e.g., dronabinol) can be used. Antiemetics should be administered around the clock with breakthrough doses as needed. Nonpharmacologic interventions that have proven to be effective in decreasing nausea include relaxation, guided imagery, acupressure, acupuncture, deep breathing, and eliminating odors. Patients should be instructed to avoid reclining within the first 30 minutes after eating. Dietary interventions include eating small, frequent meals and eating bland, chilled foods.

MAINTAINING SKIN INTEGRITY

The nurse assesses the patient with cancer for any skin problems. Maintaining integrity of skin and tissue poses a problem for patients with cancer because of the effects of chemotherapy, radiation therapy, surgery, and invasive procedures carried out for diagnosis and therapy. Targeted therapies are associated with cutaneous toxicity, including skin and nail changes (Shi, Levy, & Choi, 2016). Nail changes can include loss of all or a portion of the nail, transverse ridges across the nail plate (Beau lines), and hyperpigmentation (Polovich et al., 2014). The EGFR inhibitors commonly cause skin rash appearing as acneform eruptions or a papulopustular rash (Polovich et al., 2014). The rash can cause itching and discomfort. Up to 30% of patients experience an infection due to alteration in skin integrity. Treatment of EGFR inhibitor rash includes topical steroids and oral antibiotics (Shi et al., 2016).

As part of the assessment, the nurse identifies which of these predisposing factors is present and assesses the patient for risk factors, including treatment type, nutritional deficits, bowel and bladder incontinence, immobility, immunosuppression, multiple skin folds, and changes related to aging. The nurse notes the presence of skin lesions, ulcers, rashes, or ulcerations secondary to the tumor or the effects of treatment.

Some of the most frequently encountered disturbances of tissue integrity, in addition to stomatitis, include skin and tissue reactions to radiation therapy, alopecia, and metastatic skin lesions. Patients with skin and tissue reactions to radiation therapy require careful skin care to prevent further skin irritation, drying, and damage. The skin over the affected area is handled gently; avoiding rubbing and use of hot or cold water, soaps, powders, lotions, and cosmetics. Patients may avoid tissue injury by wearing loose-fitting, cotton

clothes and avoiding clothes that constrict, irritate, or rub the affected area. If blistering occurs, care is taken not to disrupt the blisters, thus reducing the risk of introducing bacteria. Moisture- and vapor-permeable dressings, such as hydrocolloids and hydrogels, are helpful in promoting healing and reducing pain. Aseptic wound care is indicated to minimize the risk for infection and sepsis. Topical antibiotics, such as 1% silver sulfadiazine cream (Silvadene), may be prescribed for use on areas of moist desquamation (painful, red, moist skin). As many cancer treatments cause photosensitivity, patients must be counseled on sun protection and use of sunscreen (Polovich et al., 2014).

Helping Patients Cope with Alopecia. The nurse notes the presence of alopecia (hair loss), which is another form of tissue disruption common in patients with cancer who receive radiation therapy or chemotherapy. In addition, the nurse assesses the psychological impact of this side effect on the patient and family.

The temporary or permanent thinning or complete loss of hair is a potential adverse effect of various radiation therapies and chemotherapeutic agents. The extent of alopecia depends on the type, dose, and duration of therapy. Combination chemotherapy is more likely to cause complete hair loss than monotherapy. These treatments cause alopecia by damaging stem cells and hair follicles. As a result, the hair is brittle and may fall out or break off at the surface of the scalp. Hair loss may be patchy or total, involve scalp hair and body hair, although loss of body hair is less frequent (Dua, Heiland, Kracen, & Deshields, 2017). Hair loss usually begins 2 to 3 weeks after the initiation of treatment; regrowth begins within 8 weeks after the last treatment and may take up to 6 months for complete regrowth. Some patients who undergo radiation to the head may sustain permanent hair loss. Many health care providers view hair loss as a minor problem when compared with the potentially life-threatening consequences of cancer. However, for many patients, hair loss is a major assault on body image, resulting in depression, anxiety, anger, rejection, and isolation. To patients and families, hair loss can serve as a constant reminder of the challenges cancer places on coping abilities, interpersonal relationships, and sexuality.

Scalp cooling or scalp hypothermia has been studied with mixed results. It is not recommended for patients with hematologic malignancies and should be used in the context of clinical trials in patients with solid tumors (Polovich et al., 2014). Topical minoxidil has demonstrated decreased severity and duration of alopecia but does not prevent it entirely (Polovich et al., 2014).

The nurse provides information about alopecia and supports the patient and family in coping with changes in body image. The patient is advised to use shampoos without detergents, menthol, salicylic acid, alcohol, or heavy perfume to minimize damage; avoiding hair color, perms and bleach, hot rollers or excessive heat, or aggressive hair brushing or combing (Polovich et al., 2014). The patient is encouraged to acquire a wig or hairpiece before hair loss occurs, so that the replacement matches the patient's own hair. Use of attractive scarves and hats may make the patient feel less conspicuous. The nurse can refer the patient to supportive programs, such as "Look Good, Feel Better,"

offered by the American Cancer Society. The scalp should be protected from cold and sun with hats, scarves, wigs, and sunscreen; eye protection (sunglasses) is also important, especially if eyelashes are lost (Polovich et al., 2014). Knowledge that hair usually begins to regrow after therapy is completed may comfort some patients, although patients must be prepared that the color and texture of the new hair may be different.

IMPROVING NUTRITIONAL STATUS

Assessment of the patient's nutritional status is an important nursing role. Impaired nutritional status may contribute to disease progression, decreased survival, immune incompetence, increased incidence of infection, delayed tissue repair, diminished functional ability, decreased capacity to continue antineoplastic therapy, increased length of hospital stay, and impaired psychosocial functioning. Altered nutritional status, weight loss, and cachexia (muscle wasting, emaciation) are complex states and may be secondary to decreased protein and caloric intake, metabolic or mechanical effects of the cancer, systemic disease, side effects of the treatment, or the patient's emotional status.

The nursing assessment of nutritional status includes monitoring the patient's weight and caloric intake consistently. Other information obtained by assessment includes diet history, any episodes of anorexia, changes in appetite, situations and foods that aggravate or relieve anorexia, and medication history. Difficulty in chewing or swallowing is identified, and the presence of nausea, vomiting, or diarrhea is noted. The patient should also be asked about the ability to prepare and obtain food to assist in identifying the need for additional resources.

Clinical and laboratory data useful in assessing nutritional status include anthropometric measurements (triceps skin fold and middle-upper arm circumference), serum protein levels (albumin, prealbumin, and transferrin), serum electrolytes, lymphocyte count, hemoglobin levels, hematocrit, urinary creatinine levels, and serum iron levels.

Nursing Alert

A normal serum albumin is 3.5 to 5.2 g/dL or 35 to 52 g/L and gives the clinician a quick assessment of protein stores. In a seminal study by Seltzer et al. (1979), a sixfold increase in mortality was seen with an albumin level of less than 35 g/L, while additional studies associate serum albumin levels of less than 30 g/L with significant morbidity and mortality regardless of patient age and diagnosis (Jellinge, Henriksen, Hallas, & Brabrand, 2014). However, since albumin is degraded over 14 to 21 days, it is not a good measure for assessing recent nutritional deficits. Prealbumin has a half-life of 2 days and, therefore, is a better measure of response to dietary treatments. The normal reference range for prealbumin in males is 19 to 37 mg/dL, and in females, 17 to 31 mg/dL.

Understanding Cancer-Related Causes of Malnutrition. Most patients with cancer experience some weight loss during their illness. Anorexia, malabsorption, and cachexia are examples of nutritional problems that commonly occur in patients with cancer; special

attention is needed to prevent weight loss and promote nutrition.

Anorexia. Anorexia is defined as an involuntary loss of appetite. Among the many causes of anorexia in patients with cancer is alterations in taste, manifested by increased salty, sour, and metallic taste sensations, and altered responses to sweet and bitter flavors. These changes lead to decreased appetite, decreased nutritional intake, and protein–calorie malnutrition. Taste alterations may result from mineral (e.g., zinc) deficiencies, increases in circulating amino acids and cellular metabolites, or the administration of chemotherapeutic agents. Patients undergoing radiation therapy to the head and neck may experience "mouth blindness" (MacCarthy-Leventhal, 1959) which is a severe impairment of taste. Alterations in the sense of smell also alter taste; this is a common experience of patients with head and neck cancers.

Anorexia may occur because people feel full after eating only a small amount of food. This is referred to as *early satiety.* This sense of fullness occurs secondary to a decrease in digestive enzymes, abnormalities in the metabolism of glucose and triglycerides, and prolonged stimulation of gastric volume receptors, which convey the feeling of being full. Psychological distress (e.g., fear, pain, depression, and isolation) throughout illness may also have a negative impact on appetite. Patients may develop an aversion to food because of nausea and vomiting after treatment.

Cachexia. Cachexia is common in patients with cancer with prevalence ranging from 40% at cancer diagnosis to 70% to 80% in advanced phases of the disease (Alexander, Goldberg, & Korc-Grodzicki, 2016). It is a multifactorial syndrome marked by loss of skeletal muscle mass without loss of fat mass that cannot be entirely reversed by nutritional support alone (Penet & Bhujwalla, 2015). Cachexia is defined as a weight loss of 10% body weight or more within 6 months, a BMI below 20, and any weight loss greater than 2% (Penet & Bhujwalla, 2015; Polovich et al., 2014). Cachexia is characterized by negative protein and energy balance as a result of decreased food intake and abnormal metabolism (Polovich et al., 2014). Cachexia often leads to a decline in functional status, quality of life, and decreased tolerance to treatment. Progressive cachexia suggests a poor prognosis and accounts for 20% of all cancer deaths (Penet & Bhujwalla, 2015). Treatment includes nutritional support and counseling and treatment of the underlying malignancy.

Promoting Nutrition. Whenever possible, every effort is used to maintain adequate nutrition through the oral route. Referral to a registered dietitian is essential as this has been shown to improve calorie intake (Polovich et al., 2014). High calorie/high protein supplements should be encouraged. Food should be prepared in ways that make it appealing. Unpleasant smells are avoided. Family members are included in the plan of care to encourage adequate food intake. The patient's preferences, as well as physiologic and metabolic requirements, are considered when selecting foods. Small, frequent meals are provided with supplements between meals. Patients often tolerate larger amounts of food earlier in the day rather than later, so meals can be planned accordingly. To avoid

early satiety, the patient should avoid drinking fluids while eating. Oral hygiene before mealtime often makes meals more pleasant. It is important to assess and manage pain, nausea, and other symptoms that may interfere with nutrition. Medications, such as corticosteroids, dronabinol, and progestational agents such as megestrol acetate, have been used successfully as appetite stimulants (Alexander et al., 2016). Prokinetic agents, such as metoclopramide, are used to increase gastric emptying in patients with early satiety and delayed gastric emptying.

If adequate nutrition cannot be maintained by oral intake, nutritional support via the enteral route may be necessary. Short-term nutritional supplementation may be provided through a nasogastric tube. However, if nutritional support is needed for longer than several weeks, a gastrostomy or jejunostomy tube may be inserted. The patient and family are taught to administer enteral nutrition in the home.

If malabsorption is a problem, enzyme and vitamin replacement may be instituted. Additional strategies include changing the feeding schedule, using simple diets, and relieving diarrhea. If malabsorption is severe, parenteral nutrition may be necessary. Parenteral nutrition can be administered in several ways: by a long-term venous access device (e.g., right atrial catheter), by an implanted venous port, or by a peripherally inserted central catheter (PICC) (Fig. 6-5). The nurse teaches the patient and family to care for venous access devices and to administer parenteral nutrition when appropriate. Home care nurses may assist with or supervise parenteral nutrition administration in the home.

Interventions to reduce cachexia usually do not prolong survival or improve nutritional status significantly. Optimal management of other symptoms that may be contributing, such as depression, anxiety, nausea or xerostomia, is critical to promoting improved nutritional intake. Further study is needed to assess the effects of nutritional intervention on disease status and the patient's quality of life. Before invasive nutritional strategies are instituted, the nurse should assess the patient carefully and discuss goals of care and options with the patient and family.

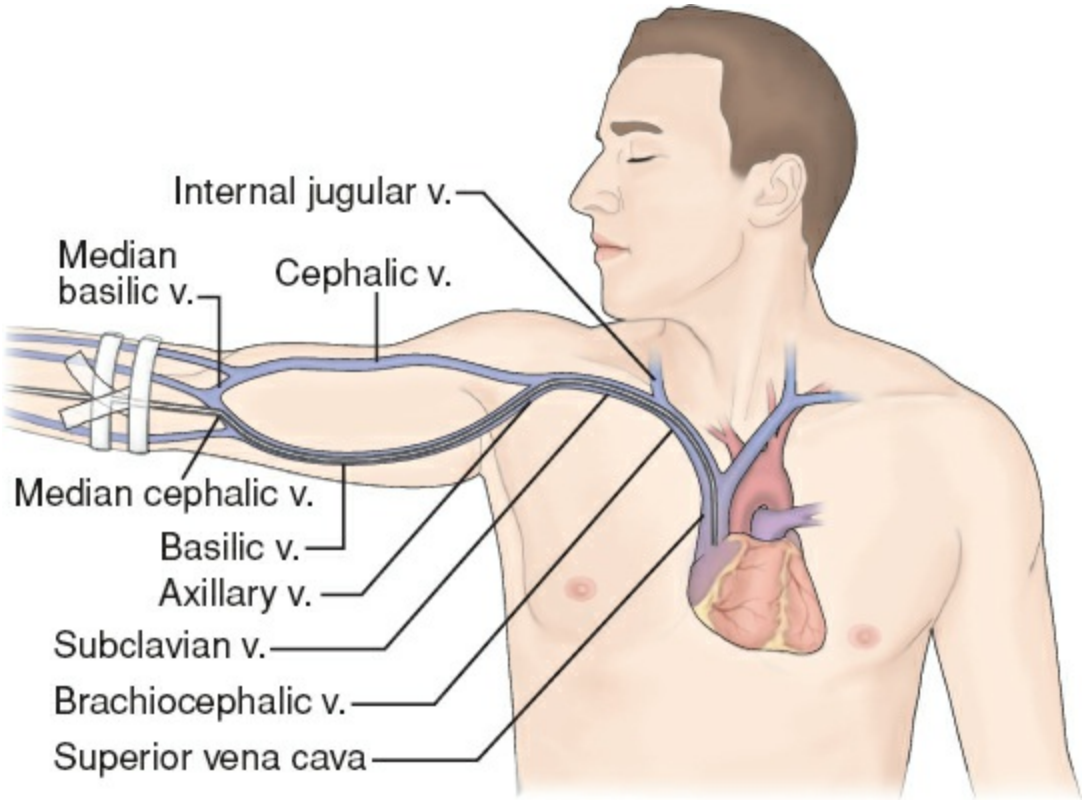

FIGURE 6-5 A peripherally inserted central catheter (PICC) is advanced through the cephalic or basilic vein to the axillary, subclavian, or brachiocephalic vein or the superior vena cava.

RELIEVING PAIN

The nurse assesses the patient with cancer for the source and site of pain. In cancer, pain and discomfort may be related to underlying disease, pressure exerted by the tumor, diagnostic procedures, or the cancer treatment itself. As in any other situation involving pain, cancer pain is affected by both physical and psychosocial influences. A comprehensive pain assessment is completed including onset, duration, location, quality or characteristics, quantity, aggravating and alleviating factors, associated symptoms, and the treatments that the patient has used to relieve pain.

The nurse also assesses those factors that increase the patient's perception of pain, such as fear and apprehension, fatigue, anger, and social isolation. Pain assessment scales (see Chapter 7) are useful for assessing the patient's pain before pain-relieving interventions are instituted and for evaluating the effectiveness of these interventions.

Various pharmacologic and nonpharmacologic options are available for managing cancer pain. No reasonable approaches, even those that may be invasive, should be overlooked because of a poor or terminal prognosis. The nurse helps the patient and family take an active role in managing pain. The nurse provides education and support to correct fears and misconceptions about opioid use. Inadequate pain control leads to suffering, anxiety, fear, immobility, isolation, and depression. The goal, regardless of the patient's disease status, is to maximize quality of life and optimize functional ability by adequately managing pain. Refer to Chapter 7 for details on managing cancer pain.

IMPROVING BODY IMAGE

The nurse identifies potential threats to the patient's body image and assesses the patient's ability to cope with the many assaults to body image that he or she experiences throughout the course of disease and treatment. Entry into the health care system is often accompanied by depersonalization. Threats to self-concept are enormous as the patient faces the realization of illness, disfigurement, possible disability, and possible death. To accommodate treatments or because of the disease, many patients with cancer are forced to alter their lifestyles. Priorities and values change when body image is threatened. Disfiguring surgery, hair loss, cachexia, skin changes, altered communication patterns, and sexual dysfunction are some of the devastating results of cancer and its treatment that threaten the patient's self-esteem and body image.

A positive approach is essential when caring for patients with altered body image. To help the patient retain control and positive self-esteem, it is important to encourage independence and continued participation in self-care and decision-making. The patient is assisted to assume those tasks and participate in those activities that are personally of most value. Any negative feelings that the patient has or threats to body image should be identified and discussed. The nurse serves as a listener and counselor to both the patient and the family. Referral to a support group can provide the patient with additional assistance in coping with the changes resulting from cancer or its treatment. In many cases, cosmetologists can provide ideas about hair or wig styling, makeup, and the use of scarves and other head coverings to help with body image concerns.

Patients who experience alterations in sexuality and sexual function are encouraged to discuss concerns openly with the health care team and with their partners. Alternative forms of sexual expression are explored with patients and their partners to promote positive self-worth and acceptance. Nurses who identify serious physiologic, psychological, or communication difficulties related to sexuality or sexual function are in a key position to help patients and partners seek further counseling if necessary.

TEACHING PATIENTS SELF-CARE

Many patients with cancer return home from acute-care facilities to receive treatment in the home or outpatient area. The shift from the acute-care setting also shifts the responsibility for care to the patient and family. As a result, family members and friends must assume increased involvement in patient care, which requires teaching that enables them to provide quality care. Teaching initially focuses on providing information needed by the patient and family to address the most immediate care needs likely to be encountered at home.

Side effects of treatments and changes in the patient's status that should be reported are reviewed verbally and reinforced with written information. Strategies to deal with side effects of treatment are discussed with the patient and family. Other learning needs are identified based on the priorities conveyed by the patient and family as well as on the complexity of care provided in the home.

Technologic advancements allow home administration of chemotherapy, parenteral

nutrition, blood products, parenteral antibiotics, and parenteral analgesics as well as management of symptoms and care of vascular access devices. Although home care nurses provide care and support for patients receiving this advanced technical care, patients and families need instruction and ongoing support that allow them to feel comfortable and proficient in managing these treatments at home. Follow-up visits and telephone calls from the nurse are often reassuring and increase the patient's and family's comfort in dealing with complex and new aspects of care. Continued contact facilitates evaluation of the patient's progress and assessment of the ongoing needs of the patient and family.

CONTINUING CARE

Referral for home care is often indicated for patients with cancer. The responsibilities of the home care nurse include assessing the home environment, suggesting modifications in the home or in care to help the patient and family address the patient's physical needs, providing physical care, and assessing the psychological and emotional impact of the illness on the patient and family.

Assessing changes in the patient's physical status and reporting relevant changes to the provider help ensure that appropriate and timely modifications in therapy are made. The home care nurse also assesses the adequacy of pain management and the effectiveness of other strategies to prevent or manage the side effects of treatment modalities.

It is necessary to assess the patient's and family's understanding of the treatment plan and management strategies and to reinforce previous teaching. The nurse often facilitates coordination of patient care by maintaining close communication with all involved health care providers. The nurse may make referrals and coordinate available community resources (e.g., local office of the American Cancer Society, home aides, church groups, parish nurses, support groups) to assist patients and caregivers.

EVALUATION

Nurses play an important role in evaluating the expected outcomes for patients with cancer. To maximize beneficial outcomes and intervene in the presence of potential complications, evaluation of the patient's and family's needs are assessed because cancer affects not only the patient but also the family members. In addition, with the shift away from inpatient care, many families are caring for patients at home and should be considered members of the health care team. The nurse can refer the patient and family to a variety of support groups sponsored by the American Cancer Society or available community resources. The nurse also collaborates with a variety of providers (e.g., physical and occupational therapists, wound and ostomy nurses, nutritionists, pharmacists, social workers, psychologists, and clergy or spiritual advisors) to help identify appropriate interventions that support the goal of regaining the highest level of function and independence possible for the patient.

Expected patient outcomes may include the following:

1. Maintains integrity of oral mucous membranes
2. Maintains adequate tissue integrity

3. Maintains adequate nutritional status
4. Achieves relief of pain and discomfort
5. Demonstrates increased activity tolerance and decreased fatigue
6. Exhibits improved body image and self-esteem
7. Progresses through the grieving process
8. Experiences no complications, such as infection, or sepsis, and no episodes of bleeding or hemorrhage

GERONTOLOGIC CONSIDERATIONS

As a result of an increased life expectancy and an increased risk of cancer with age, nurses are providing cancer-related care for growing numbers of elderly patients. More than half of all cancers occur in people older than 65 years of age, and 70% of all cancer deaths with prostate, bladder, colon, uterine, pancreatic, gastric, rectal and lung carcinomas accounting for the majority of cases (Suhag, Sunita, Sarin, & Singh, 2015). Nursing care of this population addresses special needs, including physical, psychosocial, and financial concerns.

Oncology nurses working with the elderly population must understand the normal physiologic changes that occur with aging. These changes include decreased skin elasticity; decreased skeletal mass, structure, and strength; decreased organ function and structure; impaired immune system mechanisms; alterations in neurologic and sensory functions; and altered drug absorption, distribution, metabolism, and elimination. These changes ultimately influence the ability of elderly patients to tolerate cancer treatment. In addition, many elderly patients have other chronic diseases and associated treatments that may limit tolerance to cancer treatments. Polypharmacy is common in the elderly and the growing number of drug–drug interactions with newer anti-cancer therapies must be considered carefully (Thompson & Dale, 2015). Treatment decisions should not be based on age alone; a thorough consideration of the patient's performance status and comorbidities is essential in decision making (Suhag et al., 2015).

Potential chemotherapy-related toxicities, such as renal impairment, myelosuppression, fatigue, and cardiomyopathy, may increase as a result of declining organ function and diminished physiologic reserves. The recovery of normal tissues after radiation therapy may be delayed, and older patients may experience more severe adverse effects, such as mucositis, nausea and vomiting, and myelosuppression. Because of decreased tissue-healing capacity and declining pulmonary and cardiovascular functioning, older patients are slower to recover from surgery. Elderly patients are also at increased risk for complications such as atelectasis, pneumonia, and wound infections.

Access to cancer care for elderly patients may be limited by discriminatory or fatalistic attitudes of health care providers, caregivers, and patients themselves. Issues such as the gradual loss of supportive resources, declining health or loss of a spouse, and unavailability of relatives or friends may result in limited access to care and unmet needs for assistance with activities of daily living. In addition, the economic impact of health care may be difficult for those living on fixed incomes.

Nurses must be aware of the special needs of the aging population. Nurses carefully monitor elderly patients receiving cancer treatments for signs and symptoms of adverse effects. In addition, elderly patients are instructed to report all symptoms to their provider. It is not uncommon for elderly patients to delay reporting symptoms, attributing them to "old age." Many elderly people do not want to report illness for fear of losing their independence or financial security. Sensory losses (e.g., hearing and visual losses) and memory deficits are considered when planning patient education because they may affect the patient's ability to process and retain information. In such cases, the nurse acts as a patient advocate, encouraging independence and identifying resources, such as home care, for support when indicated. Often elderly patients see a number of different doctors and subspecialists; coordination of care becomes critical (Suhag et al., 2015).

END-OF-LIFE CONSIDERATIONS

The needs of patients with terminal illnesses are best met by a comprehensive multidisciplinary program that focuses on quality of life, palliation of symptoms, and provision of psychosocial and spiritual support for patients and families when cure and control of the disease are no longer possible. The concept of hospice, which originated in Great Britain, best addresses these needs. Most important, the focus of care is on the family, not just the patient. Hospice care can be provided in several settings: free-standing, hospital-based, and community- or home-based settings. Research has demonstrated that use of palliative care teams can improve patient care and reduce costs at the end of life (Gebauer, 2015; Nekhlyudov, Levit, Hurria, & Ganz, 2014).

Hospice care is often delivered through coordination of services provided by hospitals and the community. Although physicians, social workers, clergy, dietitians, pharmacists, physical therapists, and volunteers are involved in patient care, nurses are most often the coordinators of hospice activities. It is essential that home care and hospice nurses possess advanced skills in communication, assessing and managing pain, nutrition, dyspnea, bowel dysfunction, and skin impairments.

In addition, hospice programs facilitate clear communication among family members and health care providers. Most patients and families are informed of the prognosis and are encouraged to participate in decisions regarding pursuing or terminating cancer treatment. Through collaboration with other support disciplines, the nurse helps the patient and family cope with changes in role identity, family structure, grief, and loss. Hospice nurses are actively involved in bereavement counseling. In many instances, family support for survivors continues for approximately 1 year.

CHAPTER REVIEW

Critical Thinking Exercises

1. Your patient has been receiving high doses of chemotherapy to treat leukemia. She reports that she wants to stop the chemotherapy because of the oral ulcerations and pain that have developed since she started on the chemotherapy. What would be your response to her? What evidence-based nursing interventions would you implement to relieve the ulcers and her pain? What is the evidence for the interventions that you identified? How strong is that evidence, and what criteria did you use to assess the strength of that evidence?

2. A 74-year-old patient with prostate cancer and metastasis to the bone is to begin a continuous subcutaneous infusion of analgesia through an ambulatory infusion pump to relieve his severe pain. The patient's wife is afraid that he will become addicted, and his adult children state that his pain remains unrelieved. As a home care nurse, what assessments would be of highest priority to you during your initial visit to this patient? What nursing interventions and teaching would be indicated in this situation? How would you modify your interventions if the patient is receiving fentanyl by transdermal

patch and still reporting severe pain?

3. Your 68-year-old patient with lung cancer has been admitted for emergent radiation therapy for the diagnosis of SVCS. Describe the underlying pathology that can lead to the signs and symptoms of SVCS. What patient monitoring will be essential during this patient's course of care? Describe the medical and nursing management strategies that will be used for this patient.

NCLEX-Style Review Questions

1. In assessing the neutropenic patient's understanding of discharge education, which patient statement indicates that the nurse needs to provide further education?
   a. "I should stay away from crowds and people who are sick."
   b. "I should wash my hands carefully after using the bathroom and before eating meals."
   c. "If I have a fever or chills, I should take acetaminophen immediately and recheck my temperature an hour later."
   d. "My WBC count should recover about 14 days after my treatment is completed."

2. A nurse is caring for a patient receiving brachytherapy for cervical cancer. Which of the following statements regarding the nursing care of this patient is true? Select all that apply.
   a. The patient must be maintained on bed rest.
   b. The head of the bed must be elevated more than 30 degrees to decrease the risk of aspiration.
   c. Pain management is a priority.
   d. The patient will have an indwelling urinary catheter.

3. A patient is receiving external beam radiation therapy for head and neck cancer. The patient reports moderate pain to the tongue and buccal mucosa that is interfering with his ability to eat, sleep, and speak. Which of the following interventions would you recommended for this patient? Select all that apply.
   a. Take pain medication 30 minutes before meals.
   b. Avoid acidic, spicy, and sharp foods such as chips.
   c. Keep dentures out when not eating to promote healing.
   d. Rinse the oral mucosa regularly with an alcohol-based solution.

4. A nurse is creating a public health intervention that targets teenagers at risk for skin cancer secondary to sun and tanning bed exposure. Which of the following is an example of primary prevention?
   a. Establishing a van that travels to high schools to perform skin assessments
   b. Establishing a clinic based in the school nurse's office that performs screening examinations for skin cancer
   c. Developing an educational intervention to teach skin self-assessment
   d. Developing a television commercial, to be aired on the music television network,

educating teens on the risks of sun exposure

5. A nurse is caring for a patient with newly diagnosed leukemia who is receiving chemotherapy for the first time. Twenty-four hours after the first dose of chemotherapy, the patient experiences decreased urine output, an abnormal heart rate, and lethargy. Which of the following laboratory results would help support the nurse's suspicion for tumor lysis syndrome?
   a. Serum calcium 13.0 mg/dL, potassium 3.5 mEq/L, magnesium 2.0 mg/dL
   b. Potassium 2.0 mEq/L, phosphorous 3.0 mg/dL, calcium 6.0 mg/dL
   c. Uric acid 4.0 mg/dL, creatinine 3.0
   d. Uric acid 10.0 mg/dL, potassium 5.5 mEq/L, phosphorous 5.0 mg/dL

CHAPTER 7

Pain Management

Linda Honan • Rosalina Madrid

Learning Objectives

After reading this chapter, you will be able to:

1. Compare characteristics of acute pain, chronic (persistent) pain, and cancer pain.
2. Describe the effects of acute and chronic pain.
3. Describe the pathophysiology of pain.
4. Describe factors that can alter the response to pain.
5. Demonstrate appropriate use of pain measurement instruments.
6. Explain the nursing role in multidisciplinary pain management.
7. Identify nonpharmacologic pain relief interventions for selected groups of patients.
8. Develop a plan to prevent and treat the adverse effects of analgesic agents.
9. Use the nursing process as a framework for the care of patients with pain.

Pain has been defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage (Merskey & Bogduk, 1994). It is the most common reason for seeking health care (Cohen & Raja, 2016). It is associated with many disorders, diagnostic tests, and treatments. It disables, distresses more people than any single disease, varies widely in intensity, and spares no age group. Because nurses spend more time with patients in pain than other health care providers, nurses need to understand the pathophysiology of pain, the physiologic and psychological consequences of acute and chronic (persistent) pain, and the methods used to treat pain. Nurses encounter patients in pain in a variety of settings, including acute care, outpatient, and long-term care settings, as well as in the home. Therefore, they must have the knowledge and skills to assess pain, implement pain relief strategies, and evaluate the effectiveness of these strategies, regardless of setting.

TYPES OF PAIN

Pain is categorized according to its duration, location, and etiology. In general, three basic categories of pain are recognized: acute pain, chronic (persistent, nonmalignant) pain, and cancer-related pain.

Acute Pain

Usually of recent onset and commonly associated with a specific injury, trauma, or painful medical procedures, acute pain indicates that damage or injury has occurred. Pain is significant in that it draws attention to a threat and teaches people to avoid similar potentially painful situations. Thus, pain is both a sensation and a warning signal. If no lasting damage occurs and no systemic disease exists, acute pain usually decreases as healing occurs or as the underlying cause is treated. Acute pain can be an isolated one-time incident or recur at regular intervals, such as menstrual cramping, or sporadically, as with angina or migraine headaches. If untreated, acute pain may lead to chronic pain.

Chronic Pain

Chronic pain is a persistent or intermittent pain that lingers beyond the expected healing time (generally over 3 months). It is associated with a variety of degenerative or traumatic conditions, such as arthritis, degenerative disk disease, and intervertebral disk herniation, but often a specific cause or injury for the chronic pain may not be found. It may have a poorly defined onset, and it is often difficult to treat because the cause or origin may be unclear. Although acute pain may be a useful signal that something is wrong, chronic or persistent pain may become a patient's primary disorder with symptoms of refractory pain, functional and psychological impairment, and disability (Dinakar, 2016*).* Medical-surgical nurses care for patients with chronic pain when these patients are admitted to the hospital for management or when they develop other new etiologies.

Cancer-Related Pain

Pain associated with cancer may be acute or chronic. Pain resulting from cancer is so ubiquitous that when cancer patients are asked about the most feared consequences of cancer, pain is reported most frequently. Approximately one third of cancer patients who receive active therapy, and 60% to 90% of patients with advanced disease, experience moderate to severe pain (LeBlanc & Abernethy, 2015). Pain in patients with cancer can be directly associated with the cancer (e.g., bony infiltration with tumor cells or nerve compression), a result of cancer treatment (e.g., surgery or radiation), or unrelated to the cancer (e.g., trauma). However, most pain associated with cancer is a direct result of tumor involvement. Although the pain may be acute, it is characterized more frequently as chronic. As in other situations involving pain, the experience of cancer pain is influenced by both physical and psychosocial factors.

Cancer can cause pain in various ways. Pain may be associated with various cancer treatments. Acute pain is linked with trauma from surgery. Occasionally, chronic pain syndromes, such as postsurgical neuropathies (pain related to nerve tissue injury), occur. Some chemotherapeutic agents cause tissue necrosis, peripheral neuropathies, and stomatitis—all potential sources of pain—whereas radiation therapy can cause pain secondary to skin or organ inflammation.

For some patients with advanced cancer, pain that continues to increase over time may be a sign that the tumor growth has progressed and that death is near. It is vital for the nurse to recognize the progression of symptoms correlating with the disease process so as to provide physical and emotional support to both the patient and loved ones. As patients anticipate the pain and their anxiety increases, pain perception heightens, producing fear and further pain. Chronic cancer pain, then, can be best described as a cycle progressing from pain to anxiety to fear and back to pain.

EFFECTS OF PAIN

Regardless of its nature, pattern, or cause, pain that is inadequately treated has harmful effects beyond the suffering it causes.

Effects of Acute Pain

Unrelieved acute pain can affect the pulmonary, cardiovascular, GI, endocrine, and immune systems. The stress response (neuroendocrine response to stress) that occurs with trauma also occurs with severe pain. The widespread endocrine, immunologic, and inflammatory changes that occur with stress can have significant negative effects. This is particularly harmful in patients whose health is already compromised by age, illness, or injury.

The stress response generally consists of increased metabolic rate and cardiac output, impaired insulin response, increased production of cortisol, and increased retention of fluids. Box 7-1 discusses the physiologic impact of acute pain. The stress response may increase the risk of physiologic disorders (e.g., myocardial infarction, pulmonary infection, thromboembolism, prolonged paralytic ileus). Patients with severe pain and associated stress may be unable to take deep breaths and may experience increased fatigue and decreased mobility. Although these effects may be tolerated by young, healthy people, they may hamper recovery in elderly, debilitated, or critically ill people. Effective pain relief may result in faster recovery and improved outcomes.

Effects of Chronic Pain

Like acute pain, chronic pain also has adverse effects. Suppression of the immune function associated with chronic pain may promote tumor growth. In addition, chronic pain often results in anger, depression, anxiety, fatigue, and disability. Patients may be unable to continue the activities and interpersonal relationships that they had engaged in before the pain began, with resultant impact on their quality of life. Disabilities may range from curtailing participation in physical activities to being unable to take care of personal needs, such as dressing or eating. Regardless of how patients cope with persistent pain, disability can result if the pain persists for an extended period.

BOX 7-1 Physiologic Response to Acute Pain

Endocrine and metabolic response	Activation of sympathetic nervous system and an increase in glucagon secretion, which causes hyperglycemia, increased lipolysis (fat breakdown), accelerated protein breakdown, and nitrogen loss. The stress response presents as hypertension, tachycardia, arrhythmias, myocardial ischemia, protein catabolism, immune system suppression, and impaired renal excretory function.
Pulmonary function	Decreased phrenic nerve activity and diaphragmatic dysfunction manifested as a decrease in functional residual capacity and a decrease in tidal volume.
GI motility	Decreased gastric motility, especially in the colon. The stomach and small intestines recover within 12–24 hours after abdominal surgery; however, the colon is inhibited for at least 48–72 hours.
Cardiovascular	Increased sympathetic tone, which causes an increase in heart rate and blood pressure as well as redistribution of blood to and within various organs. The redistribution predisposes patients to myocardial ischemia in the presence of coronary artery disease and may induce arrhythmias.
Immune system	Decreased responsiveness to antigens, delayed hypersensitivity, natural killer cell activity, and antibody response.

Adapted from Peeters-Asdourian, C., & Akhouri, V. (2004). Acute pain management in the adult. In C. Warfield & Z. Bajwa (Eds.), Principles and practices of pain management (2nd ed.). New York: McGraw-Hill.

Nurses should understand the effects of chronic pain on patients and families and should be knowledgeable about pain relief strategies and appropriate resources to assist effectively with pain management. Chronic pain that has become refractory to conventional treatment modalities can predispose a patient to take large quantities of opioid medications. Health care providers face the challenge of uncontrolled pain despite continued opioid dose increases. In some cases, patients can become hyperalgesic or have opioid-induced hyperalgesia (OIH), which is defined as the state of nociceptive sensitization caused by long-term exposure to opioids. A patient will report more pain or uncontrolled pain despite an increase in opioid dose. It may be hard for the patient to understand that reducing opioids in the state of hyperalgesia will help with the reduction of pain. The general health care provider can seek referral to available pain resources, such as a consult from an existing pain service or an evaluation by a certified pain nurse specialist.

Effects of Cancer Pain

As noted above, cancer pain may have aspects that are both acute and chronic. In addition, patients with cancer often have multiple causes of pain (e.g., direct tumor involvement, tumor invasion of the nerve and hollow viscera) involving multiple sites (bone pain, pain from chemotherapy, radiation, surgery). There can be significant changes in the patient's personality (mood disturbances, anxiety, and depression), lifestyle (lack of confidence in ability to control pain limits actions, decreased social interactions), and functional ability. Given the multidimensional aspects of cancer pain, it follows that a multidimensional plan is needed to manage the challenging aspects of cancer pain effectively.

PATHOPHYSIOLOGY OF PAIN

The processing of noxious stimuli and the resulting perception of pain involve the peripheral nervous system and central nervous system (CNS). Various nerve mechanisms and structures are involved in the transmission of pain to and from the brain, including nociceptors, or pain receptors, and chemical mediators. Nociceptors are free nerve endings found in the skin. These receptors are preferentially sensitive to intense, potentially damaging mechanical, thermal, or chemical stimuli. Although the skin contains the highest density of nociceptors, they also are found in joints, connective tissues, blood vessels, periosteum, skeletal muscle, fascia, tendons, most visceral organs, and the corneas, and have the potential to respond to painful stimuli. When stimulated, nociceptors send signals to local blood vessels, mast cells, hair follicles, and sweat glands, often resulting in clinical findings associated with pain, such as vasomotor, autonomic, and visceral effects.

The nociceptors transmit information about the noxious, distressing, or damaging stimuli to neurons located in the spinal cord or brainstem, and this sensory information is integrated in the thalamus along with higher brain structures generating protective somatic and autonomic reflexes, endocrine actions, emotional responses, learning and memory about the event, and cortical awareness of pain (Westlund, 2014, p. 87).

Peripheral Nervous System Response

A number of algogenic (pain-causing) substances that enhance the sensitivity of nociceptors are released into the extracellular tissue as a result of tissue damage. Histamine, bradykinin, acetylcholine, serotonin (5-HT), calcitonin gene-related peptide (CGRP), and substance P are chemicals that increase the transmission of pain (Barrett, Barman, Boitano, & Brooks, 2016). The injured tissue releases bradykinin and prostaglandins that sensitize or activate nociceptors, which, in turn, release substance P. Substance P acts on mast cells to release histamine and CGRP, which dilates the blood vessels, resulting in edema and an inflammatory process. Serotonin (5-HT) is released from platelets and activates nociceptors. Prostaglandins are chemical substances that are believed to increase the sensitivity of pain receptors by enhancing the pain-provoking effect of bradykinin. It is interesting to note that aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) block the enzyme needed for prostaglandin synthesis, resulting in pain control. At the peripheral nervous system level, two main types of fibers are involved in nociception (the neurologic transmission of pain impulses). The larger, myelinated A delta fibers transmit the initial pain sensation rapidly, at a rate of 12 to 34 m/sec, to the brain (acute pain, or "fast pain"). This type of pain frequently is associated with mechanical or thermal stimuli. The smaller, unmyelinated C fibers transmit impulses at a rate of 0.5 to 2 m/sec (Barrett et al., 2016). This is called "second pain" or "slow-wave pain" due to delayed onset and longer duration. It has dull, aching, diffuse, or burning qualities, which last longer than the initial fast pain. Chronic pain is believed to be associated with C-fiber stimulation.

If there is repeated C-fiber stimulation, there is a heightened response in spinal cord neurons, causing the person to perceive more pain. For this reason, it is important to treat patients with analgesic agents when they first feel pain. Patients require less medication and experience more effective pain relief if analgesia is administered before they become sensitized to the pain.

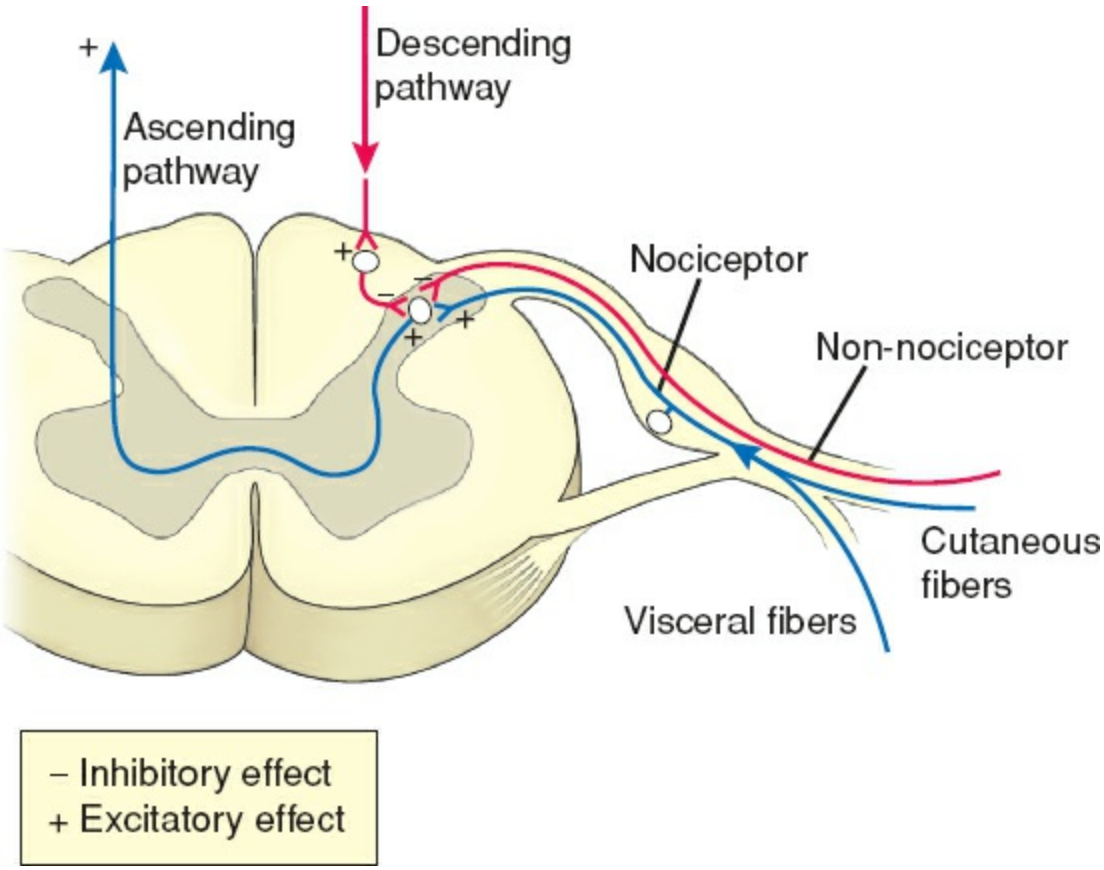

FIGURE 7-1 A schematic representation of aspects of nociceptive system.

Central Nervous System Response

For pain to be consciously perceived, neurons in the ascending system must be activated. Activation occurs as a result of input from the nociceptors. After tissue injury occurs, nociception continues and relays the impulses to the dorsal horn of the spinal cord. Upon entering the spinal cord at the dorsal horn, the pain impulse crosses the spinal cord and passes upward to the brain by the anterolateral pathway to the thalamus. Then the pain signals are transmitted to other areas of the brain and sensory cortex where the conscious experience or perception of pain occurs. Figure 7-1 illustrates pain transmission.

Chemicals that reduce or inhibit the transmission or perception of pain include endorphins, enkephalins, and dynorphins (Porth, 2015). These chemical, morphine-like neurotransmitters are endogenous (produced by the body) and reduce nociceptive transmission.

Just as the ascending system relays signal up to the brain for interpretation, the descending control system is considered inhibitory. It is always somewhat active, and it prevents continuous transmission of painful stimuli, partly through the action of the endorphins. Cognitive processes may stimulate endorphin production in the descending control system. The effectiveness of this system is illustrated by the effects of distraction. The distractions of visitors or a favorite television show may increase activity in the descending control system. Therefore, patients who have visitors or who are engaged in a television program may not report pain because activation of the descending control system results in less noxious or painful information being transmitted to consciousness. In addition, tactile stimulation can modulate pain through a complex process of tactile information being transmitted by large and small fibers throughout the CNS (Porth, 2015).

The neuromatrix theory of pain proposed by Melzack (2001) provides a conceptual framework to examine chronic pain. It proposes in response to injury, inflammation, disease, or chronic stress, the body–self neuromatrix activates perceptual, homeostatic, and behavioral responses. Endocrine, autonomic, immune, and opioid systems contribute to this interactive cognitive interpretation of pain. The pain experience is distinctive to each individual, shaped by sensory, psychosocial, and genetic factors, and modulated by various sensory inputs from the environment and by cognitive events, such as psychological stress (Stanos, Tyburski, & Harden, 2016). Thus, pain occurs in response to a widely distributed neural network in the brain (sensory, affective, and cognitive dimensions) rather than only to the sensory input of injury, inflammation, or pathology.

Nursing Alert

Large internal organs (viscera) have a low density of nociceptors; as a result, typically visceral pain is poorly localized, nauseating, and frequently associated with diaphoresis and autonomic symptoms. Typically, pain originating in these large, internal organs results from intense stimulation of multipurpose receptors that respond to inflammation, stretching, ischemia, dilation, and spasm of the internal organs. An intense response in these fibers can cause severe pain.

FACTORS INFLUENCING PAIN RESPONSE

Several factors, including past experiences with pain, anxiety, culture, age, gender, genetics, and expectations about pain relief, influence a person's experience of pain. These factors may increase or decrease perception of pain, increase or decrease tolerance for pain, and affect responses to pain.

Past Experience

The way a person responds to pain is a result of many separate painful events during a lifetime. The nurse understands that a patient's pain history may provide vital information on how a person has been able to either positively cope and manage their pain as well as what has hindered their physical and emotional well-being. This information will shape the patient's current expectation of pain and or pain management. If pain is relieved promptly and adequately, the person may be less fearful of future pain and better able to tolerate it.

Anxiety and Depression

Although it is commonly believed that anxiety increases pain, this is not necessarily true (see Box 7-2 for common misconceptions about pain). However, anxiety that is associated with pain may increase the patient's perception of pain. For example, the patient who was treated 2 years ago for breast cancer and who now has hip pain may fear that the pain indicates metastasis. In this case, the patient's anxiety may result in increased pain. However, anxiety that is unrelated to the pain (e.g., anxiety about who is taking care of the pets while the patient is in the hospital) may distract the patient and may actually decrease the perception of pain.

BOX 7-2 Common Concerns and Misconceptions About Pain and Analgesia

Patients with chronic pain have a higher tolerance to pain.	Patients with chronic pain have a decreased tolerance to pain associated with decreased endorphins, the effect of neurotransmitters, and physiologic responses. In patients with chronic pain, signals for pain and muscle spasm continue to be transmitted by the nervous system.
Chronic pain is due to psychological disturbance.	When unable to find a physiologic reason for pain, providers often attribute chronic pain to a psychological issue and, in addition, have demonstrated more positive responses to patients when pathology is found.
Chronic pain is caused by stress, and if the stress is relieved, pain abates.	Coping with chronic pain can be stressful which can lead to suffering and depression.
Patients will exaggerate their pain in order to receive increased compensation payments.	No evidence exists that patients report increased pain when seeking compensation or litigation.
Patients in chronic pain demonstrate manipulative behavior.	It is rare for patients with chronic pain to misrepresent their symptoms. Rather, some patients may seek out a variety of providers to obtain relief.
Depression causes chronic pain.	There is a corollary between chronic pain and depression; however, it is more likely that the stress of managing the chronic pain leads to depression.
People get addicted to pain medicine easily.	Research suggests a negligible risk of addiction when patients are prescribed opioids for pain. Misconceptions are related to a lack of knowledge of tolerance, physical dependence, and addiction.
Often patients are noncompliant and to blame for their physical symptoms.	Evidence shows that patients with chronic pain are generally compliant, and, if not, the reasons are attributed to treatment side effects or lack of treatment response.

From Shaw, S., & Lee, A. (2009). Student nurses' misconceptions of adults with chronic nonmalignant pain. *American Society for Pain Management Nursing, 11*(1), 2–14.

Just as anxiety is associated with pain because of concerns and fears about an underlying disease, depression is associated with chronic pain and unrelieved cancer pain. In cases of chronic pain, the incidence of depression is increased with variable rates of 5% to 87% (Stanos et al., 2016) and often is associated with major life changes caused by the limiting effects of persistent pain.

Culture

Beliefs about pain and how to respond to it differ from one culture to the next. Early in childhood, people learn from those around them what responses to pain are acceptable or unacceptable. For example, a child may learn that a sports injury is not expected to hurt as much as a comparable injury caused by a motor vehicle crash. The child also learns what stimuli are expected to be painful and what behavioral responses are acceptable.

Cultural factors must be taken into account to manage pain effectively. Factors that help explain differences in a cultural group include age, gender, education level, and income. In addition, the degree to which patients identify with a culture influences the extent to which they will adopt new health behaviors or rely on traditional health beliefs and practices. A wide range of behaviors may be seen in response to pain, ranging from moaning and complaining about pain and describing pain as "unbearable" to behaving in a quiet, stoic manner rather than expressing the pain verbally. The nurse must respond to the person's perception of pain and assess the person's behavior taking into consideration cultural influences. The nurse who recognizes cultural differences has insight into the impact of pain on the patient and is more accurate in assessing pain and in planning appropriate treatments to relieve pain.

The main issues to consider when caring for patients of a different culture are:

- What does the illness mean to the patient?
- Are there culturally based stigmas related to this illness or pain?
- What is the role of the family in health care decisions?
- Are traditional pain relief remedies used?
- What is the role of stoicism in the patient's culture?
- Are there culturally determined ways of expressing and communicating pain?
- Does the patient have any fears about the pain?
- Has the patient seen or does the patient want to see a traditional healer?

The nurse should avoid stereotyping the patient by culture and should provide individualized care rather than assuming that a patient of a specific culture will exhibit more or less pain. In addition to avoiding stereotyping, health care providers should individualize the amount of medications or therapy according to the information provided by the patient. The nurse should recognize that stereotypes exist and become sensitive to how they negatively affect care; refer to Box 7-2 for common misconceptions.

TABLE 7-1 GERONTOLOGIC CONSIDERATIONS / For Pain Management

Physiologic Changes Influencing Pain Response	Pain Management Interventions
• Higher incidence of chronic illnesses • Increased use of prescription and OTC medications • Sensitivity to medications and increased risk for drug toxicity • Changes in medication absorption and metabolism due to decreased function of the liver, kidney, and GI system • Altered distribution of medications due to changes in body weight, protein stores, and distribution of body fluid • Slowed metabolism of medications • Higher blood levels of medications • Susceptibility to depression of both the nervous and the respiratory systems; hypoxia and hypercarbia can worsen workload on the heart, resulting in myocardial ischemia • Decreased binding of meperidine by plasma proteins, with possible result of twice the levels found in younger patients	• Obtain a careful medication history to identify potential drug interactions. • Administer analgesic agents, keeping a balance between minimal side effects and effective pain relief. • Consider possible need for slightly smaller initial dose of analgesic medication than prescribed for younger patients. • Patient may need prolonged dosing interval for subsequent doses. • Nurse may not administer meperidine because its active neurotoxic metabolite, normeperidine, is more likely to accumulate and cause CNS excitation and seizures. • Refer to clinical practice guidelines for managing persistent pain as needed. • Perform frequent assessments and evaluation of patient responses to pain interventions.

OTC, over the counter.

Age

Age-related changes that impact the assessment and management of pain include physiologic changes in the peripheral and CNS, kidneys, and liver function. Aging brings about a reduction of endorphin and serotonin receptors (Stewart, Schofield, Gooberman-Hill, Mehta, & Reid, 2014). In addition, the speed of processing nociceptive stimuli via A delta and C fiber function decreases, which may result in reduction in reaction time and a susceptibility to injury (Stewart et al., 2014). Kidney and liver function may decrease with aging, and, as a result, if medications are cleared by the kidney or liver, then increased half-lives are seen. Thus to avoid the risk of toxicity, dosages and/or frequency modifications may be necessary for medications. The nurse also recognizes that total body water decreases with aging (approximately 50% vs. 60% for adults), and total body fat generally increases, which translates into higher peak plasma concentrations for water-soluble drugs and prolonged half-lives for lipid-soluble drugs (Stewart et al., 2014, p. 467). Finally, the nurse considers the impact of high rates of polypharmacy among older adults, when administering medications.

Unrelieved pain contributes to the problem of depression as well as poor sleep quality, social relationships, performance of activities of daily living, and symptom management in older adults (Stewart et al., 2014). Older adults deal with pain according to their lifestyle, personality, and cultural background, as do younger adults. Many elderly people are afraid of the side effects related to pain medications, such as constipation, as a result, do not report that they are in pain or ask for medication to relieve pain. Others fail to seek care because they fear that the pain may indicate serious illness or that pain relief will be associated with a loss of independence. Nurses are aware that confusion in the elderly may be a result of untreated and unrelieved pain. In some cases, postoperative confusion clears once the pain is relieved. Pain assessment and the adequate treatment of pain in the elderly should not only be based on the patient's report of pain but age related changes and their implication to treatment. Table 7-1 provides gerontologic considerations related to pain management.

Gender

Women and African Americans are more likely to report pain than are men and whites, respectively; however, because of the highly individualized nature of pain, a "one size fits all" treatment plan for pain is ineffective and potentially harmful (Cohen & Raja, 2016).

PAIN ASSESSMENT

The role of primary health care providers is to assess and relieve pain by administering medications and other treatments. Nurses collaborate with other health care professionals while administering most pain relief interventions, evaluating their effectiveness, and serving as patient advocates when the intervention is ineffective. In addition, nurses serve as educators to patients and families, teaching them to manage the pain relief regimen themselves when appropriate.

The definition of pain forwarded by the International Association for the Study of Pain identified at the beginning of this chapter encompasses the multidimensional nature of pain. An early broad definition of pain by McCaffery is, "whatever the person says it is, existing whenever the experiencing person says it does" (McCaffery & Pasero, 1999, p. 5). This definition emphasizes the highly subjective nature of pain and pain management. Patients are the best authority on the existence of pain. Therefore, validation of the existence of pain is based on the patient's report that it exists.

Pain assessment is one core element of patient care that requires ongoing surveillance. Self-report of pain intensity and distress should be used whenever possible. Regular assessment and documentation of pain assessment help monitor the efficacy of analgesic modalities.

Although it is important to believe patients who report pain, it is equally important to be alert to patients who deny pain in situations where pain would be expected. A nurse who suspects pain in a patient who denies it should explore with the patient the reason for suspecting pain, such as discussing the fact that the disorder or procedure is painful for most people or pointing out that the patient grimaces when moving or avoids movement. It also may be helpful to explore why the patient may be denying pain. Some people deny pain because they fear the treatment that may result if they report or admit pain. Others deny pain for fear of becoming addicted to opioids (previously referred to as narcotics) if these medications are prescribed. The American Pain Foundation developed the Pain Care Bill of Rights, which addresses the importance of pain management (Box 7-3).

The highly subjective nature of pain means that pain assessment and management present challenges for all clinicians. The report of pain is a social transaction; that is, the assessment and management of pain will require the establishment of rapport and trust with the person in pain. In assessing a patient with pain, the nurse reviews the patient's description of the pain and other factors that may influence pain (e.g., previous experience, anxiety, age) as well as the patient's response to pain relief strategies. Documentation of the pain level as rated on a pain scale becomes part of the patient's medical record, as does the record of the pain relief obtained from interventions.

BOX 7-3 Pain Care Bill of Rights

Although not always required by law, these are the rights you should expect and, if necessary, demand, for your pain care.

As a person with pain, you have the right to:

- Have your report of pain taken seriously and be treated with dignity and respect by

doctors, nurses, pharmacists, and other health care professionals.

- Have your pain thoroughly assessed and promptly treated.
- Be informed by your health care provider about what may be causing the pain, possible treatments, and the benefits, risks, and cost of each.
- Participate actively in decisions about how to manage your pain.
- Have your pain reassessed regularly and your treatment adjusted if your pain has not been eased.
- Be referred to a pain specialist if your pain persists.
- Get clear and prompt answers to your questions, take time to make decisions, and refuse a particular type of treatment if you choose.

Courtesy of the American Pain Foundation, 201 N. Charles Street, Suite 710, Baltimore, Maryland, 21201, www.painfoundation.org

Pain assessment includes determining what level of pain relief the acutely ill patient believes is needed to recover quickly or improve function, or what level of relief the chronically or terminally ill patient requires to maintain comfort. Part of a thorough pain assessment is understanding the patient's expectations and misconceptions about pain, which may include the notion that pain is a normal experience, that pain builds character, that pain medication side effects are worse than the pain, and the fear of becoming addicted to opioids. People who understand that pain relief not only contributes to comfort but also hastens recovery are more likely to request or self-administer treatment appropriately.

Nursing Alert

Previously, pain assessment had been referred to as "the fifth vital sign" to emphasize its significance in data collection and to increase the awareness among health care professionals of the importance of the relationship between pain and health. However, research reveals that the routine measurement of pain as the fifth vital sign did not increase the quality of pain management (Alexander, Kruszewski, & Webster, 2012). Since pain is subjective and not an objective sign that can be measured, it is important for nurses to recognize that routine documentation of pain intensity (i.e., rating of 0 to 10), while important to care, is limited in its singular ability to improve the quality of pain management. The intent of this chapter is to present the scope of pain assessment and interventions available for the RN. In addition, it is important for nurses to know that pain assessment and management are mandated by The Joint Commission (2016).

Characteristics of Pain

The factors to consider in a complete pain assessment are the intensity, timing, location, quality, and personal meaning of pain; aggravating and alleviating factors; and pain behaviors. Pain assessment begins by careful patient observation, noting overall posture and presence or absence of overt pain behaviors. In addition, it is essential to ask the patient to describe the specifics of the pain. The words used to describe the pain may point toward the cause. For example, the classic description of chest pain that results from a myocardial infarction includes pressure or squeezing on the chest. A detailed history should follow the initial description of pain.

Intensity

The intensity of pain ranges from none to mild discomfort to excruciating. There is no correlation between reported intensity and the stimulus that produced it. The reported intensity is influenced by the person's pain threshold and pain tolerance. Pain threshold is the smallest stimulus for which a person reports pain, and pain tolerance is the maximum amount of pain a person can tolerate. To understand variations, the nurse can ask about the present pain intensity as well as the least and the worst pain intensity. Various scales and surveys are helpful to patients trying to describe pain intensity; see the later discussion of Instruments for Assessing the Perception of Pain on page 205.

Timing

Sometimes the cause of pain can be determined when its temporal aspects are known. Therefore, the nurse inquires about the onset and duration of pain, the relationship between time and intensity (e.g., at what time is the pain worst), and changes in rhythmic patterns. The patient is asked if the pain began suddenly or increased gradually. Sudden pain that rapidly reaches maximum intensity is indicative of tissue rupture; thus immediate assessment and intervention is necessary. Pain from chronic ischemia gradually increases and becomes intense over a longer time. The chronic (or persistent) pain of arthritis illustrates the usefulness of determining the relationship between time and intensity because people with arthritis usually report that pain is worse in the morning.

Location

The location of pain is best determined by having the patient point to the area of the body involved. Some general assessment forms include drawings of human figures, on which the patient is asked to shade in the area involved. This is especially helpful if the pain radiates (referred pain). The shaded figures are helpful in determining the effectiveness of treatment or change in the location of pain over time.

Nursing Alert

Patients with irritation of a visceral organ frequently complain of pain that is referred—that is, pain is sensed not at that site but a distance away. A factor associated with this finding is that the structure developed from the same embryonic

segment or dermatome. Thus, since the heart and the arm have the same segmental origin, chest pain may be referred to the arm, and since the testicle migrated from where the kidney and ureter also developed, ureter distension may cause testicular pain. In addition, irritation under the diaphragm may be referred to the shoulder. Common sites of pain referral assist the clinician in considering sources for the patient's complaints. See Figure 7-2.

Quality

The nurse asks the patient to describe the pain without offering clues. For example, the nurse asks the patient to describe what the pain feels like. The nurse must give the patient sufficient time to describe the pain and then record all words in the answer. If the patient cannot describe the quality of the pain, the nurse can suggest words such as burning, aching, throbbing, or stabbing. It is important to document the exact words used by the patient to describe the pain and which words were suggested by the nurse conducting the assessment.

Personal Meaning

Pain means different things to different people; as a result, patients experience pain differently. The meaning of the pain experience helps the clinician understand how the patient is affected and assists in planning treatment. It is important to ask how the pain impacts the person's daily life. Some people with pain can continue to work or study, whereas others may be disabled by their pain, which may affect family finances. For some patients, the recurrence of pain may mean worsening of disease, such as the spread of cancer.

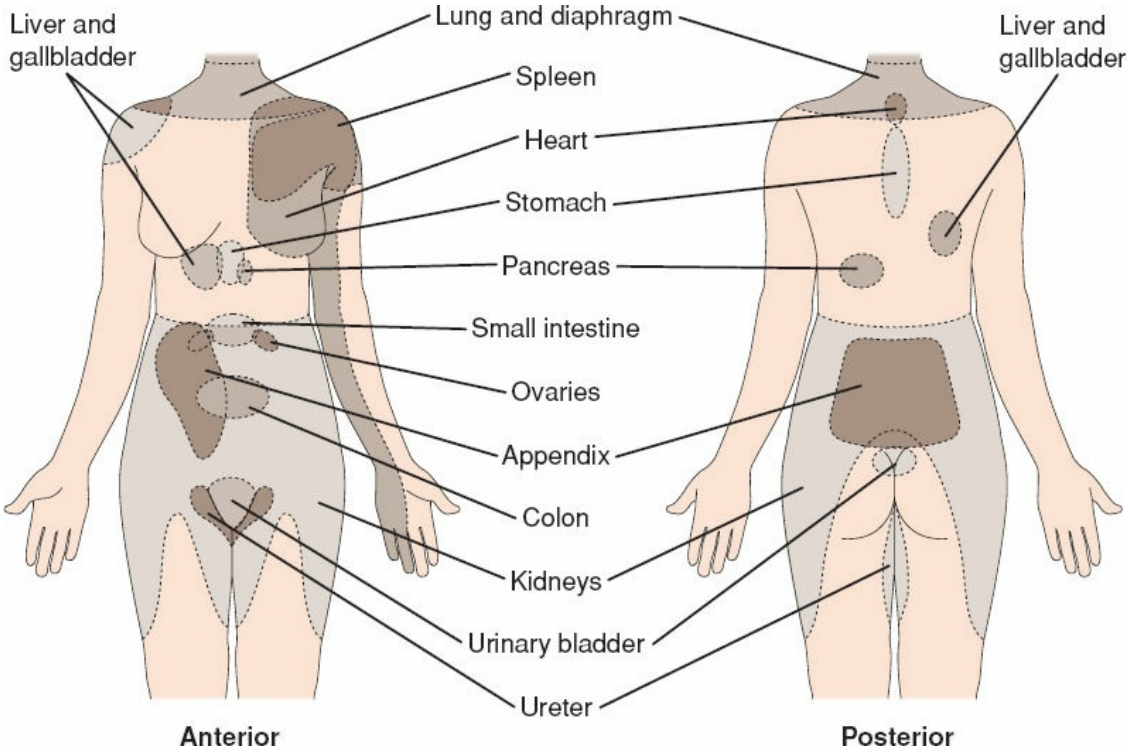

FIGURE 7-2 Referred pain. Certain visceral organs can refer pain to specific cutaneous areas. If all special tests are negative yet the individual continues to feel pain at a specific site, it may be referred

pain. (From Marcia K Anderson, Foundations of Athletic Training.)

Aggravating and Alleviating Factors

The nurse asks the patient what, if anything, makes the pain worse and what makes it better, and asks specifically about the relationship between activity and pain. This helps detect factors associated with pain. For example, in a patient with advanced metastatic cancer, pain with coughing may signal spinal cord compression. The nurse also ascertains whether environmental factors influence pain because they may be modified more easily than other factors. For example, making the room warmer may aid in patient relaxation, which may decrease the person's pain. Finally, the nurse asks the patient whether the pain is influenced by or affects the quality of sleep or anxiety. Both can significantly influence pain intensity and the quality of life.

Knowledge of alleviating factors assists the nurse in developing a treatment plan. Therefore, it is important to ask about the patient's use of medications (prescribed and over-the-counter [OTC]), including amount and frequency. In addition, the nurse asks if herbal remedies, nonpharmacologic interventions, or alternative therapies have been used with success. This information assists the nurse in determining teaching needs.

Pain Behaviors

When experiencing pain, people express pain through many different behaviors. Nonverbal and behavioral expressions of pain can be useful indicators of the quality or intensity of pain. A patient may grimace, cry, rub the affected area, guard the affected area, or immobilize it. Others may moan, groan, grunt, or sigh. Not all patients exhibit the same behaviors, and different meanings may be associated with the same behavior.

Sometimes, in nonverbal patients, pain behaviors are used as a proxy to assess pain. It is unwise to make judgments and formulate treatment plans based on behaviors that may or may not indicate pain. In unconscious patients, pain should be assumed to be present and treated. All patients have a right to adequate pain management.

Physiologic responses to acute pain, such as tachycardia, hypertension, tachypnea, pallor, diaphoresis, mydriasis (pupillary dilatation), hypervigilance, and increased muscle tone, are related to stimulation of the autonomic nervous system. These responses are short-lived as the body adapts to the stress. These physiologic signs could be the result of a change in the patient's condition, such as the onset of hypovolemia. Use of physiologic signs to indicate pain is unreliable. Although it is important to observe for any and all pain behaviors, the absence of these behaviors does not indicate an absence of pain.

Instruments for Assessing the Perception of Pain

Only the patient can describe and assess the individual pain experience accurately. Therefore, a number of pain assessment tools have been developed to assist in the assessment of the patient's perception of pain. Such tools may be used to document the need for intervention, to evaluate the effectiveness of the intervention, and to identify the need for alternative or additional interventions if the initial intervention is ineffective in relieving the pain. For a pain assessment tool to be useful, it must require little effort on the part of the patient, be easy to understand and use, be easily scored, and be sensitive to small changes in the characteristic being measured. Figure 7-3 shows a pain assessment pathway that can be used at the time of assessment to direct clinical decisions for pain management.

Nursing Alert

Pain scores represent an important component of pain management; however, other assessments can add data to your assessment and may include consideration of functional ability, psychological and emotional functioning, satisfaction ratings with their current treatment, and inquiring about any adverse treatment effects.

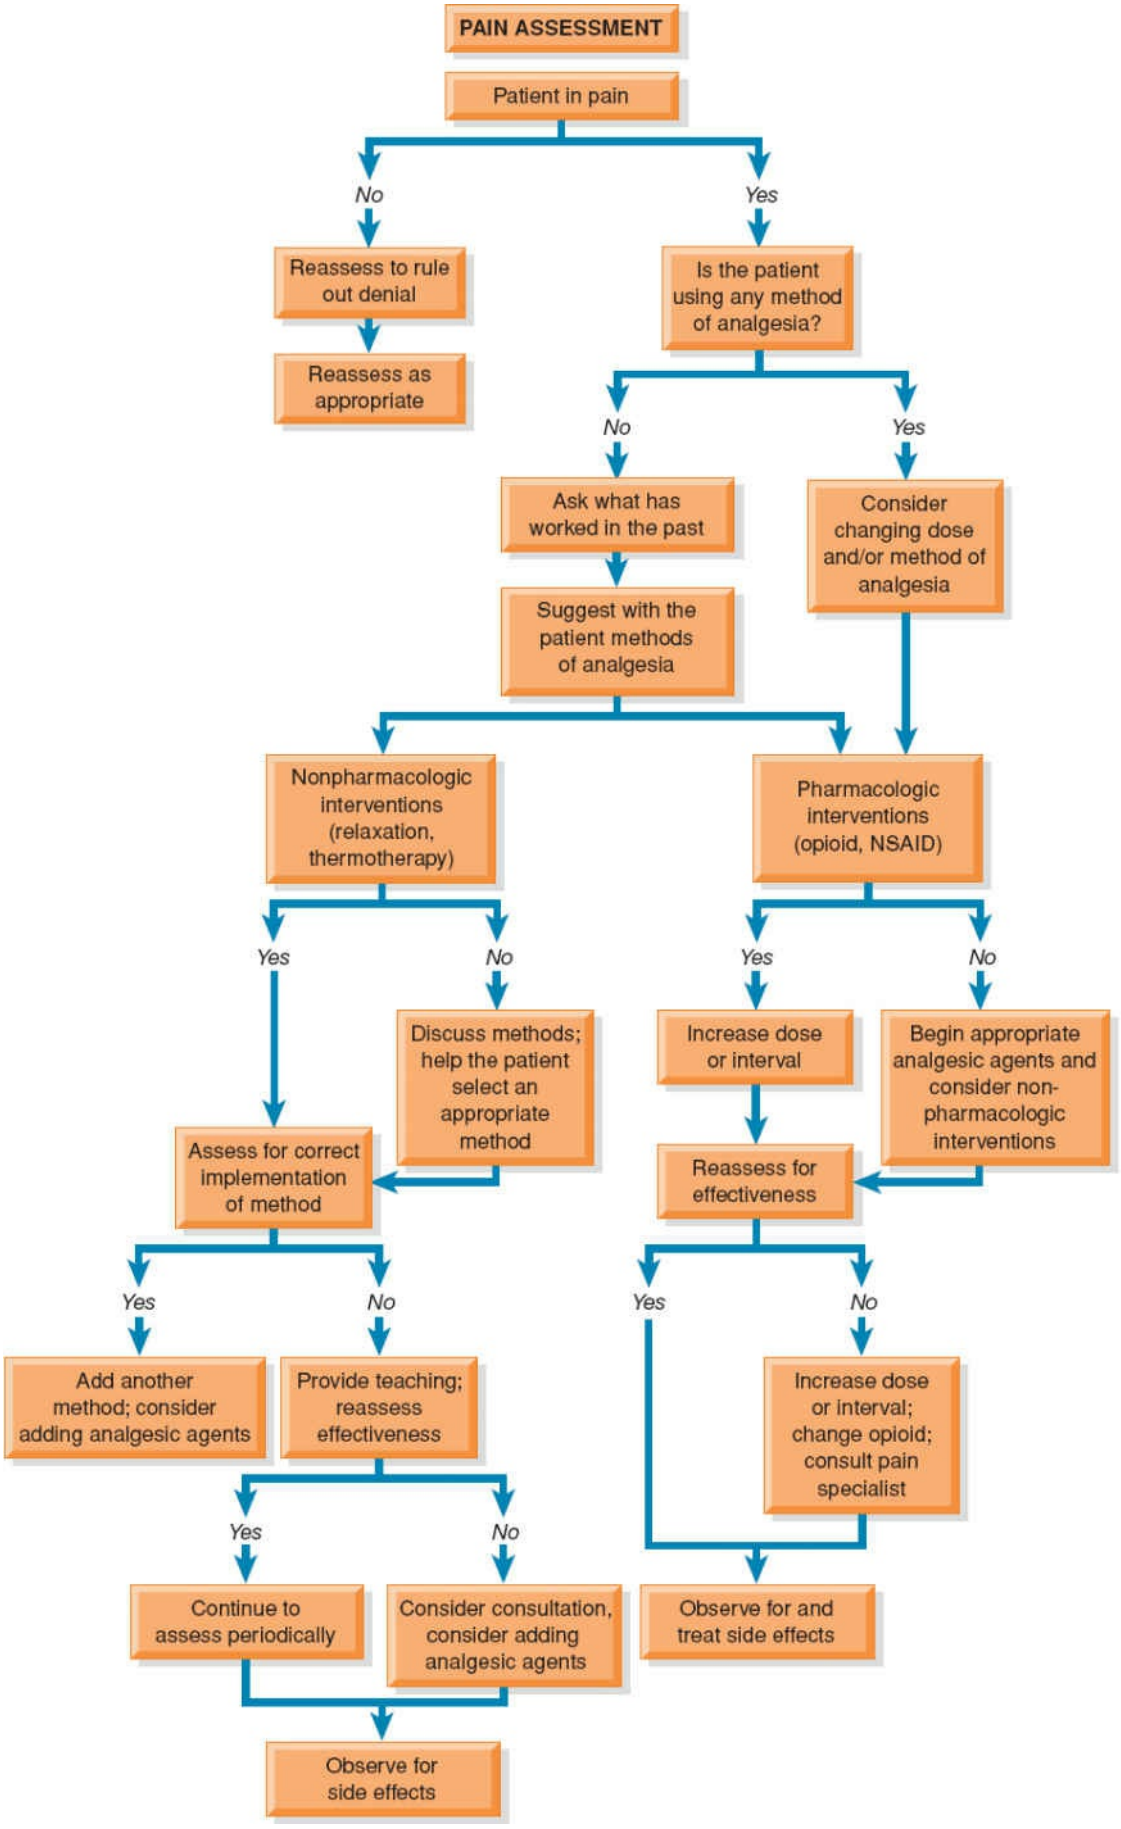
Visual Analogue Scales

Visual analogue scales (VAS) are useful in assessing the intensity of pain (Fig. 7-4). One version of the scale includes a horizontal 10-cm line, with anchors (ends) indicating the extremes of pain. The patient is asked to place a mark indicating where the current pain lies on the line. The left anchor usually represents "none" or "no pain," whereas the right anchor usually represents "severe" or "worst possible pain." To score the results, a ruler is placed along the line, and the distance the patient marked from the left or low end is measured and reported in millimeters or centimeters.

Some patients (e.g., children, elderly patients, visually or cognitively impaired patients) may find it difficult to use an unmarked VAS. In those circumstances, ordinal scales, such as a simple descriptive pain intensity scale or a 0-to-10 numeric pain intensity scale, may be used.

Faces Pain Scale—Revised

The revised faces pain scale uses six facial expressions that range from contented to obvious distress (Fig. 7-5). The patient is asked to point to the face that most closely resembles the experienced pain intensity.



PAIN ASSESSMENT
Patient in pain
No
Yes
Reassess to rule out denial
Reassess as appropriate
Is the patient using any method of analgesia?
No
Yes
Ask what has worked in the past
Suggest with the patient methods of analgesia
Consider changing dose and/or method of analgesia
Nonpharmacologic interventions (relaxation, thermotherapy)
Pharmacologic interventions (opioid, NSAID)
Yes
No
Yes
No
Discuss methods; help the patient select an appropriate method
Assess for correct implementation of method
Increase dose or interval
Begin appropriate analgesic agents and consider non-pharmacologic interventions
Reassess for effectiveness

Guidelines for Using Pain Assessment Scales

Using a written scale to assess pain may not be possible if a person is seriously ill, is in severe pain, or has just returned from surgery. In these cases, the nurse can ask the patient, "On a scale of 0–10, 0 being no pain and 10 being the worse pain that you can ever imagine, how bad is your pain?" For patients who have difficulty with a 0 to 10 scale, a 0 to 5 scale may be tried. Whichever scale is used, it should be used consistently. Most patients usually can respond without difficulty. Ideally, the nurse teaches the patient how to use the pain scale before the pain occurs (e.g., before surgery). The nurse can integrate function into the pain scale and explain "pain that is a 5 or 6" is pain that can interrupt focus or concentration. This means the patient has difficulty reading a book or watching TV because the pain can be disruptive intermittently. Pain that is higher than "7 or 8" may cause the patient to think or focus only on pain. A "pain that is a 9 or 10" can mean the

patient cannot even think clearly or do anything because the pain is the worst pain imaginable. The patient's numerical rating is documented and used to assess the effectiveness of pain relief interventions.

If a particular patient does not speak English or cannot clearly communicate information needed to manage pain, an interpreter/translator and/or caregivers familiar with the person's method of communication should be consulted and a method established for pain assessment. Often, a chart can be constructed with English words on one side and the foreign language on the other. Then the patient can point to the corresponding word to tell the nurse about the pain.

When people with pain are cared for at home by family caregivers or home care nurses, a pain scale may help assess the effectiveness of the interventions if the scale is used before and after the interventions are implemented. Scales that address the location and pattern of pain may be useful in identifying new sources or sites of pain in patients who are chronically or terminally ill and in monitoring changes in the patient's level of pain. For example, a home care nurse who sees a patient only at intervals may benefit from consulting the patient's or family's written record of pain scores to evaluate how effective the pain management strategies have been over time.

Guidelines for Assessing Pain in Patients with Disabilities

Alternative forms of communication may be necessary for people with sensory impairments or other disabilities.

- For people who are blind and who know how to read Braille, pain assessment instruments can be obtained in Braille. In addition, computer software is available that allows written documents to be scanned and converted into Braille. If these programs are not available, agencies that provide services for people who are blind may be able to assist in developing Braille versions.
- For people who are deaf or hard of hearing, outside interpreters (i.e., not family members) should be used. Other useful communication strategies may include sign language, written notes, or pictures. When writing notes on a "magic slate" or making written notes, it is necessary to make every effort to guard the patient's privacy and confidentiality.
- For people with disabilities that result in communication impairment, computer-generated speech may be useful.

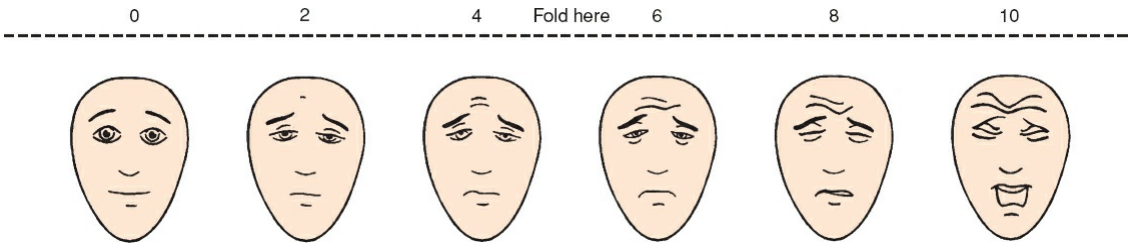

FIGURE 7-5 Faces Pain Scale—Revised. This pain scale is especially suited for helping children describe pain. Instructions for using this scale follow: "These faces show how much something can hurt. This face (*point to left-most face*) shows *no pain.* The faces show more and more pain (*point to each from left to right*) up to this one (*point to right-most face*). It shows *very much pain.* Point to the face that

shows how much you hurt (right now)." Score the chosen face 0, 2, 4, 6, 8, or 10, counting left to right, so 0 = no pain and 10 = very much pain. Do not use words like "happy" or "sad." This scale is intended to measure how children feel inside, not how their face looks. (From *The pediatric pain sourcebook.* Used with permission of the International Association for the Study of Pain and the Pain Research Unit, Sydney Children's Hospital, Randwick NSW 2031, Australia.)

Nursing Alert

For people with cognitive impairment, a triangulated approach may be useful, which includes self-report, caregiver report, and direct observation. For acute pain, behaviors that are suggestive of pain may include sympathetic nerve stimulation (increased heart rate, dilated pupils, diaphoresis, hypertension), grimacing, frowning, changes in sleep patterns and nutritional intake, vocalizations (noisy respirations, moaning), changes in mental status (confusion, irritability), guarding, bracing, and behavioral changes (aggressive, disruptive, social withdrawal) (Stewart et al., 2014). The nurse is aware that chronic pain is usually not associated with autonomic activation that causes the vital sign changes noted above.

THE NURSE'S ROLE IN PAIN MANAGEMENT

The nurse helps relieve pain by administering pain-relieving interventions (including both pharmacologic and nonpharmacologic approaches), assessing the effectiveness of those interventions, monitoring for adverse effects, and serving as an advocate for the patient when the prescribed intervention is ineffective in relieving pain. It is important to assess the patient's medical history and family history for response to analgesics (e.g., codeine). It is also critical to assess the patient's ethnic and racial background. For example, when assessing a patient's lack of response to codeine, it may be appropriate to consider a genetic cause and obtain a prescription for a different opioid. In addition, the nurse provides education to the patient and family to enable them to manage the prescribed intervention themselves when appropriate.

Identifying Goals for Pain Management

Pain is a common reason most people seek care, but the literature indicates a pain reduction of only 30% is typically achieved in treated patients (Tauben & Theodore, 2014). Some patients may expect a cure of their pain, or even substantial pain reduction and, therefore, are likely to be disappointed. It is important to align patient expectations with this reality (Calpin, Imran, & Harmon, 2016). The information the nurse obtains from the pain assessment is used to identify goals for managing pain. These goals are shared and validated with the patient. Other goals may include a decrease in the intensity, duration, or frequency of pain and a decrease in the negative effects of the pain. Therefore, goals might be to decrease time lost from work, to increase the quality of interpersonal relationships, or to improve the quality of sleep.

To determine the goal, a number of factors are considered. The first factor is the severity of the pain as judged by the patient. A patient with chronic pain may report the pain at 8 out of 10 on a daily basis; the patient may want the pain to be more tolerable and strive for a comfort score of 5 out of 10. Each patient is different in what that comfort score may be; therefore, this assessment is important to tailor each treatment plan accordingly. The second factor is the anticipated harmful effects of pain. Patients with other serious health issues are at much greater risk for harmful effects of pain than are young, healthy patients (e.g., elderly patients with unrelieved pain who have contributing comorbidities and are on chronic pain-relieving medications may be at higher risk for falls). The third factor is the anticipated duration of the pain. In patients with pain from a disease such as cancer, the pain may be prolonged, possibly for the remainder of the patient's life. Therefore, interventions will be needed for some time and should not detract from the patient's quality of life. In the acute stages of illness, the patient may be unable to participate actively in relief measures, but when the patient has sufficient mental and physical energy, the patient may learn self-management techniques to relieve the pain. Therefore, as the patient progresses through the stages of recovery, increased patient use of self-management of pain relief measures may be a goal.

Patients who receive palliative care for pain when they are conscious should continue to receive pain treatment when they cannot communicate. It should be assumed that the pain persists even if the patient is unconscious. Family members often can be taught what unique behaviors to look for to assess for pain: a furrowed brow, stiffening of a part of the body, or moaning (refer to Chapter 3 for more details on palliative care). The goals for pain treatment include not simply pain reduction but also improved functional ability, sleep, psychological well-being, and social interaction.

Providing Patient Education

Patient education is extremely important since the patient or family may be responsible for managing the pain at home and preventing or managing side effects. Teaching about pain and strategies to relieve it may reduce the threat of the pain and, thus, the pain itself, in the absence of other relief measures and may enhance the effectiveness of the pain relief measures used.

The nurse also provides information by explaining how pain can be controlled. For example, the patient should be informed that pain should be reported in the early stages. When the patient waits too long to report pain, sensitization may occur, and the pain may become so intense that it is difficult to relieve. Sensitization results from a heightened nervous system response after exposure to a noxious (pain) stimulus. This results in an increased and prolonged pain experience. When health care providers assess and treat pain before it becomes severe, sensitization is diminished or avoided, and less medication is needed.

Providing Physical Care

Patients in pain may be unable to participate in the usual activities of daily living or to perform usual self-care and may need assistance to carry out these activities. Usually patients are more comfortable when physical and self-care needs have been met and efforts have been made to ensure the patient is in as comfortable a position as possible. A fresh gown and change of bed linens, along with efforts to make the person feel refreshed (e.g., brushing teeth, combing hair), often increase the level of comfort and improve the effectiveness of the pain relief measures.

In acute, long-term, and home settings, the nurse who provides physical care to patients also has the opportunity to perform complete assessments and to identify problems that may contribute to the patient's discomfort and pain. Appropriate and gentle physical touch during care may be reassuring and comforting. If transdermal treatments such as fentanyl (an opioid analgesic) patches or IV or epidural catheters are used, the skin around the patch or catheter should be assessed for integrity during physical care.

Managing Anxiety Related to Pain

Anxiety may affect the patient's response to pain. A patient who anticipates pain may become increasingly anxious. Anticipatory guidance about the nature of the impending painful experience and the ways to reduce pain often decreases anxiety. Pain relief measures should be used before pain becomes severe. It is important to explain to all patients that pain relief or control is more successful if such measures begin before the pain becomes unbearable. Administering medications early before an expected painful procedure or activity will lessen pain more effectively and allow the patient to meet goals of care. A patient who experiences nausea after pain medication may feel compelled to pass on subsequent pain medication dosing, causing anxiety and pain to build. Premedicating with antiemetics or other medications is recommended to mitigate the side effects of the pain medications. The nurse is aware that, often, people who experience pain use previously learned strategies; therefore, it is important to teach the patient about measures to relieve pain. This nursing action may lessen the threat of pain and give the patient a sense of control. The patient's anxiety may be reduced by explanations that point out the degree of pain relief that can be expected from each measure. For example, a patient who is informed that an intervention may not eliminate pain completely is less likely to become anxious when a certain amount of pain persists. A positive nurse–patient relationship characterized by trust is essential. Acknowledging to the patient, "I know that you have pain," often has positive impact on the patient's psychological state. Occasionally, patients who fear that no one believes their pain feel relieved to know that the nurse believes that the pain exists.

A patient who is anxious about pain may be less tolerant of the pain, which, in turn, may increase anxiety levels. To prevent the pain and anxiety from escalating, the anxiety-producing cycle must be interrupted. A patient who suffers from an anxiety disorder that is not under control will have an effect on pain perception. Pain intensity is heightened, and the response to pain may cause more undue stress.

PAIN MANAGEMENT STRATEGIES

Reducing pain to a "tolerable or comfort" level is considered the goal of pain management. Looking further, even patients who have described pain relief as adequate often report disturbed sleep and marked distress because of pain. In view of the harmful effects of pain and inadequate pain management, the goal of the nurse is that of relieving pain. Pain management strategies include both pharmacologic and nonpharmacologic approaches. These approaches are selected on the basis of the requirements and goals of particular patients.

Nursing Alert

Analgesic medications are appropriate when patients are in pain. These agents are not considered a last resort to be used only when other pain relief measures fail. Any intervention is most successful if it is initiated before pain sensitization occurs, and usually the greatest success is achieved if several interventions are applied simultaneously. Nonpharmacologic interventions include efforts to create a quiet environment, comfort measures (e.g., back rub, change of position, use of heat or cold compresses), use of relaxation exercises (e.g., focused breathing, visualization, guided imagery), and diversional or distraction activities (Murr & Doenges, 2016).

Pharmacologic Interventions

Pharmacologic management of pain is accomplished in collaboration and communication with health care providers, patients, and, often, families. A physician, nurse practitioner, or physician assistant prescribes specific medications for pain or may insert an IV line for administration of analgesic medications. Alternatively, an anesthesiologist or nurse anesthetist may insert an epidural catheter for administration of such analgesic agents. However, it is the nurse who maintains the analgesia, assesses its effectiveness, and reports whether the intervention is ineffective or produces side effects.

There are three general categories of analgesic agents: opioids, NSAIDs, and adjuvants. These agents work by different mechanisms. Adjunctive agents, such as antidepressant and antiseizure medications, local anesthetics, topical agents, baclofen, and NMDA receptor antagonists also may be used.

Opioid Analgesic Agents

The goal of administering opioids is to relieve pain and improve quality of life; therefore, the route of administration, dose, and frequency of administration are determined on an individual basis. Factors that are considered in determining the route, dose, and frequency of medication include the characteristics of the pain (e.g., its expected duration and severity), the overall status of the patient (e.g., NPO status), the patient's response to analgesic medications, and the patient's report of pain. Opioids can be administered by various routes—oral, IV, subcutaneous, intraspinal, intranasal, buccal mucosa, rectal, and transdermal. Although the oral route is usually preferred for opioid administration, oral opioids must be given frequently enough to be effective. Opioid analgesic agents given orally may provide a more consistent serum level than those given intravenously.

Nursing Alert

The nurse recognizes that the route of administration determines response time to the medication. Intravenous (IV) medications are the most direct route, and responses are expected in the shortest time frame. The nurse also recognizes that when intramuscular (IM) or subcutaneous (SC) routes are selected, there will be variable responses depending on blood flow to the extremity.

If the patient is expected to require opioid analgesic agents at home, the clinician should consider the ability of the patient and family to administer opioids as prescribed at the planning stages and should take steps to ensure that the required medications will be available to the patient. Many pharmacies, especially those in smaller rural areas or inner cities, may be reluctant to stock large amounts of opioids. Therefore, arrangements must be made ahead of time for obtaining these prescription medications.

Side Effects

With the administration of opioids by any route, side effects must be considered and anticipated. Clinicians who take steps to minimize the side effects increase the likelihood that the patient will receive adequate pain relief without interrupting therapy to treat the

effects.

Respiratory Depression and Sedation. Respiratory depression is the most serious adverse effect of opioid analgesic agents administered intravenously, subcutaneously, or by an epidural route. However, respiratory depression is relatively rare because doses administered through these routes are small, and tolerance to respiratory depressant effects increases if the dose is increased slowly. The risk of respiratory depression increases with age and with the concomitant use of other opioids or other CNS depressants.

A patient who receives opioids by any route must be assessed frequently for changes in respiratory status (see Box 7-6). Specific notable changes are shallow respirations, decreasing respiratory rate, hypercarbia (increased carbon dioxide in blood), and decreasing oxygen saturation. Sedation, which may occur with any method of opioid administration, is likely to occur when opioid doses are increased. However, patients often develop tolerance so that, in time, they are no longer sedated by the dose that had caused sedation initially. Increasing the time between doses or reducing the dose temporarily, as prescribed, usually prevents deep sedation from occurring. The institution of a continuous pulse oximetry and or end tidal CO_2 monitoring may be initiated by the nurse for closer monitoring for patients at risk for respiratory depression. Patients at risk for sedation must be monitored closely for changes in respiratory status. Patients are also at risk for problems associated with sedation and immobility. The nurse must initiate strategies to prevent problems, such as skin breakdown.

Nausea and Vomiting. Nausea and vomiting frequently occur with opioid use. Usually these effects can occur immediately or hours after initial administration. Patients, especially postoperative patients, may not think to tell the nurse that they are nauseated, particularly if the nausea is mild. However, a patient receiving opioids should be assessed for nausea and vomiting, which may be triggered by a position change and may be prevented by having the patient change positions slowly. Adequate hydration and the administration of antiemetic agents may also decrease the incidence of nausea. Opioid-induced nausea and vomiting often subside within a few days.

Constipation. Constipation, a common side effect of opioid use, may become so severe that the patient is forced to choose between relief of pain and relief of constipation. This situation can occur in patients after surgery and in patients receiving large doses of opioids to treat cancer-related pain. Preventing constipation must be a high priority in all patients receiving opioids, and an effective bowel program is needed. Whenever a patient receives opioids, a bowel regimen should begin at the same time. Tolerance to this side effect does not occur; rather, constipation persists even with long-term use of opioids.

Several strategies may help prevent and treat opioid-related constipation. Mild laxatives and a high intake of fluid and fiber may be effective in managing mild constipation. Unless contraindicated, a mild laxative and a stool softener should be administered on a regular schedule. However, continued severe constipation often requires the use of a stimulating cathartic agent, such as senna derivatives (Senokot™) or bisacodyl (Dulcolax™). Additional laxatives used include suppositories, enemas, and lactulose, along with diet modification and increased intake of fluid and fiber (Leonard & Baker, 2015). Three medications are approved specifically for opioid-induced constipation: naloxegol, lubiprostone, and

methylnaltrexone. The newest medication, naloxegol, is pegylated naloxone (narcan) molecule with mu-opioid antagonist activity and is effective in countering the gastric peristaltic effects of morphine without a significant effect on analgesia (Leonard & Baker, 2015). However, it is classified as a Schedule II drug under the Controlled Substance Act because of its structural relationship to noroxymorphone, thus it remains to be seen if the increased cost and increased provider visits will limit its use.

Pruritus and Urinary Retention. When asked about drug allergies, patients with previous hospital experience (especially for surgery) may report that they are "allergic" to morphine. This report should be investigated thoroughly. Commonly, this allergy is described as itching only. Pruritus (itching) is a frequent side effect of opioids administered by any route, but it is not an allergic reaction. It can be relieved by administering prescribed antihistamines. Epidural or continuous intravenous administration of opioids also may cause urinary retention. The patient should be monitored and may require urinary catheterization. A weight-based low-dose naloxone infusion may be prescribed to relieve problems of nausea, vomiting, itching, urinary retention, and ileus in patients who are receiving continuous opioids for the relief of acute postoperative pain.

Endocrine Deficiencies. The nurse understands that chronic use of opioids is associated with decreased testosterone levels, leading to hypogonadism, sexual dysfunction, infertility, and accelerated osteoporosis (exact mechanism for osteopenia and osteoporosis is not known). Opioid-induced hypogonadism is treatable with appropriate hormone replacement therapy. Screening should be considered for osteoporosis for patients on chronic opioid medication. Refer to Chapter 41 for details on osteoporosis.

Inadequate Pain Relief

One factor commonly associated with ineffective pain relief is an inadequate dose of opioids. This is most likely to occur when the caregiver underestimates the patient's pain or fails to consider differences in absorption and action after a change in the route of administration. Consequently, the patient receives doses that are too small to be effective and, possibly, too infrequent to relieve pain. For example, if opioid delivery is changed from the IV route to the oral route, the oral dose must be approximately three times greater than that given parenterally to provide relief. Because of differences in absorption of orally administered opioids among individuals, patients must be assessed carefully to ensure that the pain is relieved.

Table 7-2 lists opioids and dosages that are equivalent to morphine; Table 7-3 is an equianalgesic table that providers may use when changing routes of administration (e.g., from IV to oral medications in preparation for patient discharge). These tables serve only as a guide; the doses listed are not necessarily the most appropriate doses for all patients. However, the tables do give clinicians some idea of equivalency.

After administering the first dose of an opioid, the nurse should perform a complete pain assessment to determine the efficacy of that dose. The time, date, patient's pain rating (scale of 0 to 10), analgesic agent, other pain relief measures, side effects, and patient activity are recorded. If the pain has not decreased in 30 minutes (sooner if an IV route is used) and the patient is reasonably alert and has a satisfactory respiratory status, blood pressure, and pulse rate, then some change in analgesia is indicated. In general, calculate the

equianalgesic dose of the new opioid, and then reduce the dose by 50% to avoid potential cross-tolerance (Therapeutic Research Center [TRC], 2012). Cross-tolerance is a phenomenon that occurs when a patient who is tolerant to the effects of a certain pharmaceutical agent also develops a tolerance to another agent. From here, the dose can be adjusted to each individual response. Although extended-release agents come in the same dosage form and contain the same drug, they are not considered therapeutically equivalent because they use different release mechanisms. Patients who need to change brands should be monitored carefully both for overdose and for inadequate pain relief.

Because of the fear of promoting addiction or causing respiratory depression, health care providers tend to prescribe and administer inadequate dosages of opioid agents to treat acute pain or persistent pain, particularly in patients who are terminally ill. Long-term use of opioids can lead to dependence and addiction (Slover, Zieg, & Clopton, 2015). In the past decade there has been a dramatic increase in opioid prescriptions, which is associated with increased abuse, overdose, and accidental deaths. In primary care settings, prevalence of opioid abuse ranged from 0.6% to 8%. In pain clinic settings, prevalence of addiction ranged from 2% to 14% (Chou et al., 2015). Currently, there is a general agreement that opioids are overprescribed; that education regarding management of acute and chronic pain by health care providers is essential; and that efforts must be made to balance between treating patients in pain and mitigating abuse, overdoses, and related deaths (Atkinson, Schatman, & Fudin, 2014).

Genetic factors play a role in the varied responses to NSAIDs and opioids seen in patients. There appears to be a higher incidence of poor drug metabolism among Caucasians and Asian Americans compared with African Americans. The most extensively studied genetic variation related to pain in humans is in the metabolism of codeine. Drug metabolism involves genetically controlled enzyme activity for absorption, distribution, inactivation, and excretion. In studies of both experimental and clinical pain, multiple polymorphisms (DNA proteins with variant alleles) result both in poor metabolism and poor analgesic efficacy, leading to changes in drug absorption, distribution, and elimination (Edmondson, 2017).

TABLE 7-2 Selected Opioid Analgesic Agents Commonly Used for Moderate and Severe Pain in Adults

Name	Starting Dose (milligrams)		Comments	Precautions and Contraindications
	Moderate Pain	Severe Pain		
Morphine	—	30–60 (oral) 10 (parenteral)	Agonist at specific opioid receptors in the CNS to produce analgesia, euphoria, and sedation	Use with caution, especially in elderly patients, very ill patients, and those with respiratory impairment. Major risks include respiratory depression, apnea, circulatory depression, and respiratory arrest, shock, and cardiac arrest. Obtain history of hypersensitivity to opioids. Monitor patient closely. If prescribed in correct dose, oral preparations are effective in treating moderate and severe pain.
Codeine	15–30 (oral)	60 (oral) up to 360/24 hr	Agonist at specific opioid receptors in the CNS to produce analgesia, euphoria, and sedation. Is also an antitussive. 10% of people lack the enzyme needed to make codeine active. Codeine may cause more nausea and constipation per unit of analgesia than other mu-agonist opioids.	Many preparations of codeine and the other opioids in this table are combinations with nonopioid analgesics. Caution must be used in patients with impaired ventilation, bronchial asthma, increased intracranial pressure, or impaired liver function and in elderly and very ill patients.
Oxycodone (OxyContin™)	5 (oral)	10–20 (oral)	Agonist at specific opioid receptors in the CNS to produce analgesia, euphoria, and sedation	Caution must be used in patients with impaired ventilation, bronchial asthma, increased intracranial pressure, or impaired liver function and in elderly and very ill patients.
Meperidine (Demerol™)	50 (oral)	300 (oral) 75 (parenteral)	Agonist at specific opioid receptors in the CNS to produce analgesia, euphoria, and sedation. Shorter acting than morphine. Meperidine is biotransformed to normeperidine, a toxic metabolite.	Normeperidine, a toxic metabolite of meperidine, accumulates with repetitive dosing, causing CNS excitation. High risk for seizures. No longer recommended for the management of pain due to its transformation to a toxic metabolite and poor analgesic properties. Used in the presence of postoperative shivering. Avoided in patients with impaired kidney function who are receiving MAO inhibitors. Is irritating to tissues with repeated intramuscular injections. Should not be used for more than 1 or 2 days.
Hydrocodone (Vicodin™)	5–10 (oral)	—	—	Most preparations are combined with nonopioid analgesics.
Tramadol (Ultram™)	50–100 (oral)	—	Unique mechanism; analgesia results from the synergy of two mechanisms. Maximum dose is 400 mg/day.	Most common side effects are dizziness, nausea, constipation, and somnolence. Lowers seizure threshold.

CNS, central nervous system; MAO, monoamine oxidase.
Adapted from American Pain Society. (2008). *Principles of analgesic use in the treatment of acute pain and chronic cancer pain* (6th ed.). Skokie, I. L., and Karch, A. M. (2013). *Focus on nursing pharmacology*. Philadelphia, PA: Lippincott Williams & Wilkins.

TABLE 7-3 Approximate Dose Equivalents for Opioid Analgesics[a]

Drug	Oral Dose (mg)	Parenteral Dose[b]
Morphine[c]	30	10 mg
Codeine[d]	200	100–120 mg
Fentanyl[e,f]	NA	100 μg or 0.1 mg
Hydrocodone (Vicodin)	30–45	NA
Hydromorphone (Dilaudid)[c]	7.5	1.5 mg
Levorphanol	4	1 mg
Methadone[g,h]	The conversion ratio of methadone is variable. Please refer to specific conversion tables based upon single opioid or multiple opioid regimens.	
Oxycodone (OxyContin)[d]	20	Only available orally (tablet and liquid), not available parenterally
Oxymorphone (Opana, Opana ER, and OpanaIV[c])	10	1 mg
Buprenorphine	NA	0.4 mg

IV, IV; NA, not available.

[a]Published tables vary in the suggested doses that are equianalgesic to morphine. Many of these doses are based on clinical consensus rather than well-controlled trials. Clinical response is the criterion that must be applied for each patient; titration to clinical response is necessary. Because there is not complete cross-tolerance among these drugs, usually it is necessary to use a lower-than-equianalgesic dose when changing drugs and reiterate according to response.

Nursing Alert

Conversion tables available for the transdermal systems should be used only to establish the initial dose of the transdermal fentanyl or buprenorphine when patients switch from oral morphine to the transdermal route of delivery (and not vice versa). If these tables are used inappropriately to determine the dosages of oral morphine for patients who have been receiving transdermal fentanyl or buprenorphine, many patients will not achieve satisfactory analgesia and will require an increase in their opioid dose to treat breakthrough pain.

Nursing Alert

If the conversion table or equation is used incorrectly to calculate a morphine dose, there is a risk of overdose. If a patient requires a change from transdermal fentanyl or buprenorphine back to oral or IV morphine (as in the case of surgery), the patch should be removed and IV morphine administered on an as-needed basis. Before a new patch is applied, the patient should be checked carefully for any older, forgotten patches, which should be removed and discarded. Patches should be replaced every 72 hours.

Opioid Use with Selected Conditions and Medications

A number of factors may influence the safety and effectiveness of opioid administration. Opioid analgesic agents are primarily metabolized by the liver and excreted by the kidney. Therefore, metabolism and excretion of analgesic medications are impaired in patients with liver or kidney disease, increasing the risk of cumulative or toxic effects.

Patients with untreated hypothyroidism are more susceptible to the analgesic effects and side effects of opioids. In contrast, patients with hyperthyroidism may require larger doses for pain relief. Patients with a decreased respiratory reserve from disease or aging may be more susceptible to the depressant effects of opioids and must be monitored carefully for respiratory depression.

Patients who are dehydrated are at increased risk for the hypotensive effects of opioids. Patients who become hypotensive after the administration of an opioid should be kept recumbent and rehydrated unless fluids are contraindicated. Patients who are dehydrated also are more likely to experience nausea and vomiting with opioid use. Rehydration usually relieves these symptoms.

Patients receiving certain other medications, such as monoamine oxidase (MAO) inhibitors, phenothiazines, or tricyclic antidepressants, may have an exaggerated response to the depressant effects of opioids. Patients taking these medications should receive small doses of opioids and must be monitored closely. Continued pain in these patients indicates that a therapeutic level of the analgesic has not been achieved. Patients must be monitored for sedation even if an analgesic effect has not been obtained.

Tolerance and Addiction

There is no maximum safe dosage of opioids, nor is there any easily identifiable therapeutic serum level. Both the maximal safe dosage and the therapeutic serum level are relative and individual.

Tolerance (the need for increasing doses of opioids to achieve the same therapeutic

effect) develops in almost all patients taking opioids for extended periods. Patients requiring opioids over a long term, especially cancer patients, need increasing dosages to relieve pain, although after the first few weeks of therapy, the progressively increasing dosages will no longer be required and the patient can be placed on maintenance dosages. Patients who become tolerant to the analgesic effects of large doses of morphine may obtain pain relief by changing to a different opioid. Symptoms of physical dependence may occur when the opioids are discontinued; dependence often occurs with opioid tolerance and does not indicate an addiction. It is an expected physiologic response that will occur in all people exposed to continuous opioid administration (Slover et al., 2015).

Nursing Alert
Although patients may need increasing levels of opioids, they are not addicted. Physical tolerance usually occurs in the absence of addiction. Tolerance to opioids is common and becomes a problem primarily in terms of delivering or administering the medication.

Addiction is a behavioral pattern of substance use characterized by a compulsion to take the substance (drug or alcohol) primarily to experience its psychic effects. Fear that patients will become addicted or dependent on opioids has contributed to inadequate treatment of pain. This fear is commonly expressed by health care providers as well as patients and results from lack of knowledge about the risk of addiction. Current research suggests that patients with a history of other substance abuse are at higher risk for opioid addiction. About 4% of patients treated for trauma had problems with opiates but showed other indications of addictive behavior that correlated with their increased use (Slover et al., 2015, p. 462). Therefore, patients and health care providers should be discouraged from withholding opioid analgesics for patients in acute pain because of concerns about addiction.

Currently, over 20 million people in the United States are dealing with substance abuse disorders; thus, it is likely that nurses in acute care will encounter patients with a history of addiction seeking care for acute or chronic pain (SAMHSA, 2016). When caring for people with a known history of addiction, nurses should consider that each individual person has the right to be treated for pain. The use of multimodal analgesia is treatment strategy useful for the treatment of pain in patients with a history of addiction; the use of NSAIDs or acetaminophen, gabapentin, or duloxetine regional blocks and local infiltration of anesthetics also should be considered (Slover et al., 2015). If opioids are necessary, the use of long-acting agents is suggested, with collaboration of a multidisciplinary team (Garimella & Cellini, 2013). If prescribed, the opioids should be tapered slowly to prevent withdrawal symptoms; the use of a mutually agreeable pain contract should be considered (Garimella & Cellini, 2013). The use of complementary therapies is also suggested and is described later in the chapter.

Nursing Alert
Patients admitted to the hospital suffering from an acute illness who have a history of substance abuse and are currently on methadone maintenance treatment (MMT) should have their methadone dose continued or an equivalent opioid given to prevent

craving. Also the patient's methadone treatment facility should be consulted. Additional opioids can be prescribed on an as-needed basis if indicated while applying the same monitoring guidelines for potential opioid-induced side effects. Patients can also be taking sublingual buprenorphine for the treatment of both pain and opioid use disorder (Salsitz, 2016).

Nursing Alert
Patients may be monitored during opioid therapy with urine toxicology studies. They should be informed to avoid eating poppy seeds, which can make a urine drug screen (UDS) positive for opiates, depending on where the threshold for opioid screening is set.

NSAIDs

NSAIDs are thought to decrease pain by inhibiting cyclo-oxygenase (COX), the enzyme involved in the production of prostaglandin (which is believed to increase the sensitivity of pain receptors) from traumatized or inflamed tissues. There are two types of COX: COX-1 and COX-2.

COX-1 mediates prostaglandin formation involved in the maintenance of physiologic functions, such as platelet aggregation, which prevents ischemia and promotes mucosal integrity. Inhibition of COX-1 may result in gastric ulceration, bleeding, and kidney damage.

COX-2 mediates prostaglandin formation that results in symptoms of pain, inflammation, and fever. Therefore, inhibition of COX-2 is desirable. Celecoxib (Celebrex™) is an example of a COX-2 inhibitor. There is evidence of increased cardiovascular risk associated with COX-2 inhibitors. Ibuprofen (Advil™, Motrin™), another NSAID, blocks both COX-1 and COX-2. It is effective in relieving mild to moderate pain and has a low incidence of adverse effects. Aspirin, the oldest NSAID, also blocks COX-1 as well as COX-2; however, because it causes frequent and severe side effects, aspirin is used infrequently to treat significant acute or persistent pain.

NSAIDs are very helpful in treating arthritic diseases and may be especially powerful in treating cancer-related bone pain. They have been combined effectively with opioids to treat postoperative and other severe pain. The use of NSAIDs in combination with opioids relieves pain more effectively than the use of opioids alone. In such cases, patients may obtain pain relief with decreased doses of opioids and with fewer side effects. A regimen of a fixed-dose, time-contingent NSAID (e.g., every 6 hours) and a separately administered fluctuating dose of opioid may be effective in managing moderate to severe cancer pain. In more severe pain, the opioid dose is also fixed, with an additional fluctuating dose as needed for breakthrough pain (a sudden increase in pain despite the administration of pain-relieving medications). Most patients tolerate NSAIDs well. However, those with impaired kidney function may require a smaller dose and must be monitored closely for side effects. Patients taking NSAIDs bruise easily because the agents have some anticoagulant effect. Furthermore, NSAIDs may displace other medications, such as warfarin (Coumadin™), from serum proteins and increase their effects. Thus, high doses or prolonged use can irritate the stomach and, in some cases, result in gastric ulcers and GI bleeding as well. For this reason, the use of NSAIDs is dependent on the individual patient's risk factors. If administered, monitoring for GI bleeding is indicated, and

gastroprotective agents should be considered to prevent this complication (Ralston & McInnes, 2014).

Drug Alert!
Cardiovascular risks of NSAIDs: NSAIDs, especially COX-2 inhibitors, should be avoided or used with caution in patients with a cardiac history. The use of COX-2 inhibitors may decrease prostacyclin levels, which may lead to increased thrombotic risk (Dinakar, 2016). In addition, NSAIDs may exacerbate hypertension and heart failure as well as impair kidney function.

Local Anesthetic Agents

Local anesthetics work by blocking nerve conduction when applied directly to the nerve fibers. They can be applied directly to the site of injury (e.g., a topical anesthetic spray for sunburn) or directly to nerve fibers by injection or at the time of surgery. Also they can be administered through an epidural catheter (see later discussion of Intraspinal and Epidural Administration).

Local anesthetic agents have been successful in reducing the pain associated with thoracic or upper abdominal surgery when injected by the surgeon intercostally. Local anesthetic agents are rapidly absorbed into the bloodstream, resulting in decreased availability at the surgical or injury site and an increased anesthetic level in the blood, increasing the risk of toxicity. Therefore, a vasoconstrictive agent (e.g., epinephrine or phenylephrine) is added to the anesthetic agent to decrease its systemic absorption and maintain its concentration at the surgical or injury site.

A topical anesthetic agent known as *eutectic mixture* (emulsion of local anesthetics), or EMLA cream, has been effective in preventing the pain associated with invasive procedures, such as lumbar puncture or the insertion of IV lines. To be effective, EMLA must be applied to the site 60 minutes before the procedure.

A lidocaine 5% patch acts locally by targeting damaged nerves responsible for discharging pain impulses and is approved for limited use. The lidocaine 5% patch provides sufficient medication for anesthetic effect but not enough to cause total sensory block in the area of application so it has a wide margin of safety. The recommended dose is one to three patches at a time applied over the affected area for 12 hours daily.

Topical NSAIDs also have been beneficial in randomized controlled studies for patients with rheumatologic disorders and have demonstrated comparable efficacy for regional pain conditions but with fewer adverse effects than systemic NSAIDs (Cohen & Raja, 2016).

Antidepressant and Antiseizure Medications

Pain of neurologic origin (e.g., causalgia [intense burning pain and sensitivity to the slightest vibration or touch]), tumor impingement on a nerve, postherpetic neuralgia) is difficult to treat and, in general, is not responsive to opioid therapy. If these pain syndromes are accompanied by dysesthesia (burning or cutting pain), then they may be responsive to tricyclic antidepressants or antiseizure agents. When indicated, tricyclic antidepressant agents, such as amitriptyline (Elavil™) or imipramine (Tofranil™), are prescribed in doses considerably smaller than those generally used for depression. Since

antidepressants have the FDA warnings of worsening mood and suicidal ideations, patients should be informed about side effects before beginning this treatment (Dinakar, 2016). Patients also need to know that a therapeutic effect may not occur until they have taken the medication for 4 weeks. Antiseizure medications, such as phenytoin (Dilantin™) or carbamazepine (Tegretol™), may be used in doses lower than those prescribed for seizure disorders. They may be beneficial in patients with neuropathic pain who do not respond to antidepressants; however, they also have the FDA warnings of mood changes, worsening depression, and suicidal ideation, predominantly in adolescents and young adults (Dinakar, 2016, p. 725). Because a variety of medications can be tried, nurses should be familiar with the possible side effects of each and should teach patients and families how to recognize these effects.

Approaches to Using Analgesic Agents

The nurse obtains the patient's medication history (e.g., current, usual, or recent use of prescription or OTC medications or herbal agents), along with a history of health disorders and allergies. Certain medications or conditions may affect the analgesic medication's effectiveness or its metabolism and excretion. Table 7-4 lists adverse interactions of herbal substances or foods with analgesics. Before administering analgesic agents, the nurse should assess the patient's pain status, including the intensity of current pain, changes in pain intensity after the previous dose of medication, and side effects of the medication. Medications are most effective when the dose and interval between doses are individualized to meet the needs of a particular patient.

Balanced Analgesia

Pharmacologic interventions are most effective when a multimodal, or balanced, analgesia approach is used. Multimodal analgesia combines two or more analgesic agents or techniques that act by different mechanisms to provide analgesia with better pain relief and less opioid side effects. Using two or three types of agents simultaneously can maximize pain relief while minimizing the potentially toxic effects of any one agent (Manworren, 2015). When one agent is used alone, it usually must be used in a higher dose to be effective.

Treating Cancer Pain

Different kinds of pain are treated with different medications. Multimodal analgesia is the use of opioids, nonopioid analgesics, and adjuvant agents together to maximize the efficacy and minimize side effects from one analgesic (mainly opioids) (Grisenko, Khelemsky, & Urman, 2014). The World Health Organization advocates a three-step approach to treat cancer pain (Fig. 7-6). Analgesics are administered based on the patient's level of pain. Nonopioid analgesics (e.g., acetaminophen) are used for mild pain; weak opioid analgesics (e.g., codeine) are used for moderate pain; and strong opioid analgesics (e.g., morphine) are used for severe pain. Also adjuvant medications are administered to enhance the effectiveness of analgesics. Examples of adjuvant medications include antidepressants, antiseizure agents, antispasmodics, local anesthetics, radiopharmaceuticals (radioactive agents that may be used to treat painful bone tumors), and corticosteroids. A cancer pain algorithm, developed as a set of analgesic guiding principles, is given in Figure 7-7.

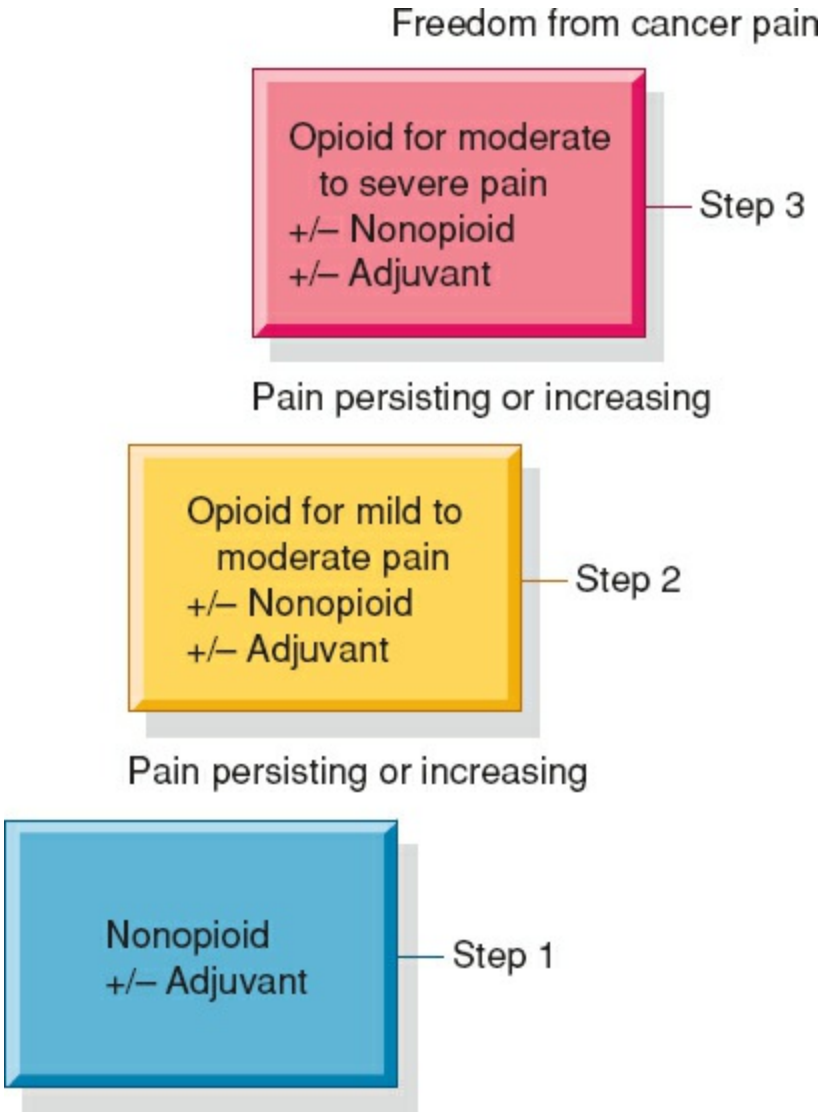

FIGURE 7-6 Adapted from the World Health Organization three-step ladder approach to relieving cancer pain. Various opioid (narcotic) and nonopioid medications may be combined with other medications to control pain.

Preventing and reducing pain help to decrease anxiety and break the pain cycle. This can be accomplished best by administering analgesics on a regularly scheduled basis as prescribed (the preventive, preferred approach to pain management), with additional analgesics administered for breakthrough pain as needed and as prescribed.

Preventive Approach

With the preventive approach, analgesic agents are administered at set intervals so that the medication acts before the pain becomes severe and before the serum opioid level decreases to a subtherapeutic level. For example, a patient takes prescribed morphine or a prescribed NSAID (e.g., ibuprofen) every 4–6 hours rather than waiting until the pain is severe. If the pain is likely to occur around the clock or for a substantial portion of a 24-hour period, a regular around-the-clock schedule of administering analgesia may be indicated. Even if the analgesic is prescribed *pro re nata* (PRN), or "as needed," it can be administered on a preventive basis before the patient is in severe pain as long as the prescribed interval

between doses is observed. The preventive approach reduces the peaks and troughs in the serum level and provides more pain relief with fewer adverse effects.

Smaller doses of medication are needed with the preventive approach because the pain does not escalate to a level of severe intensity. Therefore, a preventive approach may result in the administration of less medication over a 24-hour period, helping prevent tolerance to analgesic agents and decreasing the severity of side effects (e.g., sedation, constipation). Better pain control can be achieved with a preventive approach, reducing the amount of time patients are in pain.

TABLE 7-4 Adverse Interactions of Herbal Substances or Food with Analgesics

Analgesic	Herb, Supplement, or Food	Potential Interaction
NSAID	Bilberry fruit (*Vacciniummyrtillus*)	Potential for increased bleeding if taken with anticoagulants and other antiplatelet drugs; use cautiously if taking medicinal quantities
	Chondroitin	Do not take with anticoagulants; may potentiate bleeding
	German or Hungarian chamomile (*Matricariarecutita*)	Anticoagulants may potentiate effect; use cautiously together
	Dong quai (*Angelica sinensis*)	May increase bleeding time if used with warfarin and other anticoagulant drugs
	Fenugreek (*Trigonellafoenum-graecum*)	May potentiate effects of anticoagulants
	Feverfew (*Tanacetumparthenium*)	May increase bleeding; use cautiously with anticoagulants
	Garlic (*Allium sativum*)	May increase bleeding; use cautiously with anticoagulants
	Ginger (*Zingiberofficinale*)	May increase bleeding; use cautiously with anticoagulants
	Melatonin (N-acetyl-5-methoxytryptamine)	NSAIDs and antidepressants may deplete melatonin
	Pau D'arco (*Tabebuiaimpetiginosa, T. ipe*)	May potentiate effects of anticoagulants; avoid concurrent use
	Red clover (*Trifoliumpratense*)	May increase bleeding; use cautiously with anticoagulants and antiplatelet agents
	Turmeric (*Curcuma longa*)	Avoid using large doses with anticoagulants and NSAIDs; possible additive effect for bleeding
	Willow (*Salix* spp.)	Use cautiously with NSAIDs; may increase likelihood of GI irritation and bleeding due to tannins.
Ibuprofen	St. John wort (*Hypericumperforatum*)	Mean residence time of ibuprofen may be reduced with concurrent use of St. John wort.
Acetaminophen	Watercress	May inhibit the oxidative pathway of acetaminophen metabolism.
Aspirin	Ginkgo (*Ginkgo biloba*)	May increase bleeding tendencies; patients taking aspirin should avoid concurrent use of ginkgo biloba.
	Dan shen (*Salvia miltiorrhiza*)	Avoid concurrent use with sedatives, warfarin, and aspirin.
Opioids (sedatives)	Kava-kava (*Piper methysticum*)	May potentiate action of alcohol, tranquilizers (barbiturates), and antidepressants; may increase sedative effect of anesthetics
	Sarsaparilla (*Smilax* spp.)	May increase elimination of sedatives
	Valerian (*Valeriana officinalis*)	May intensify effects of sedatives
Alfentanil, fentanyl, sufentanil	Grapefruit	Inhibits CYP3A4 and P-glycoprotein; if used in combination with drugs that are metabolized through 3A4 or via P-glycoprotein, may increase in concentration leading to potential adverse effects
	St. John wort (*Hypericumperforatum*)	May increase or decrease cyclic P-450 activity; may affect medications that are metabolized by this pathway

From Drug interactions facts™: Herbal supplements and food. (2008). St. Louis, MO: Wolters Kluwer Health/Facts and Comparisons; Kuhn, M., & Winston, D. (2008). *Herbal therapy & supplements: A scientific and traditional approach*. Philadelphia, PA: Wolters Kluwer Health/Lippincott Williams & Wilkins.

In using the preventive approach, the nurse assesses the patient for sedation before administering the next dose. It is not safe to medicate the patient with opioids repeatedly if the patient is sedated or not in pain.

Individualized Dosage

The dosage and the interval between doses should be based on the patient's requirements rather than on an inflexible standard or routine. As noted earlier, metabolism and absorption of medications are highly variable. Therefore, a certain dose of an opioid medication given at specified intervals may be effective for one patient but ineffective for another.

As in the preventive approach discussed above, the nurse does not wait for the patient to complain of pain and then administer analgesia. To receive pain relief from an opioid analgesic, the serum level of that opioid must be maintained at a minimum therapeutic level (Fig. 7-8). The lower the serum opioid level, the more difficult it is to achieve the therapeutic level with the next dose. If pain is reported to be continuous, then a long-acting or around-the-clock administration of an opioid needs to be considered.

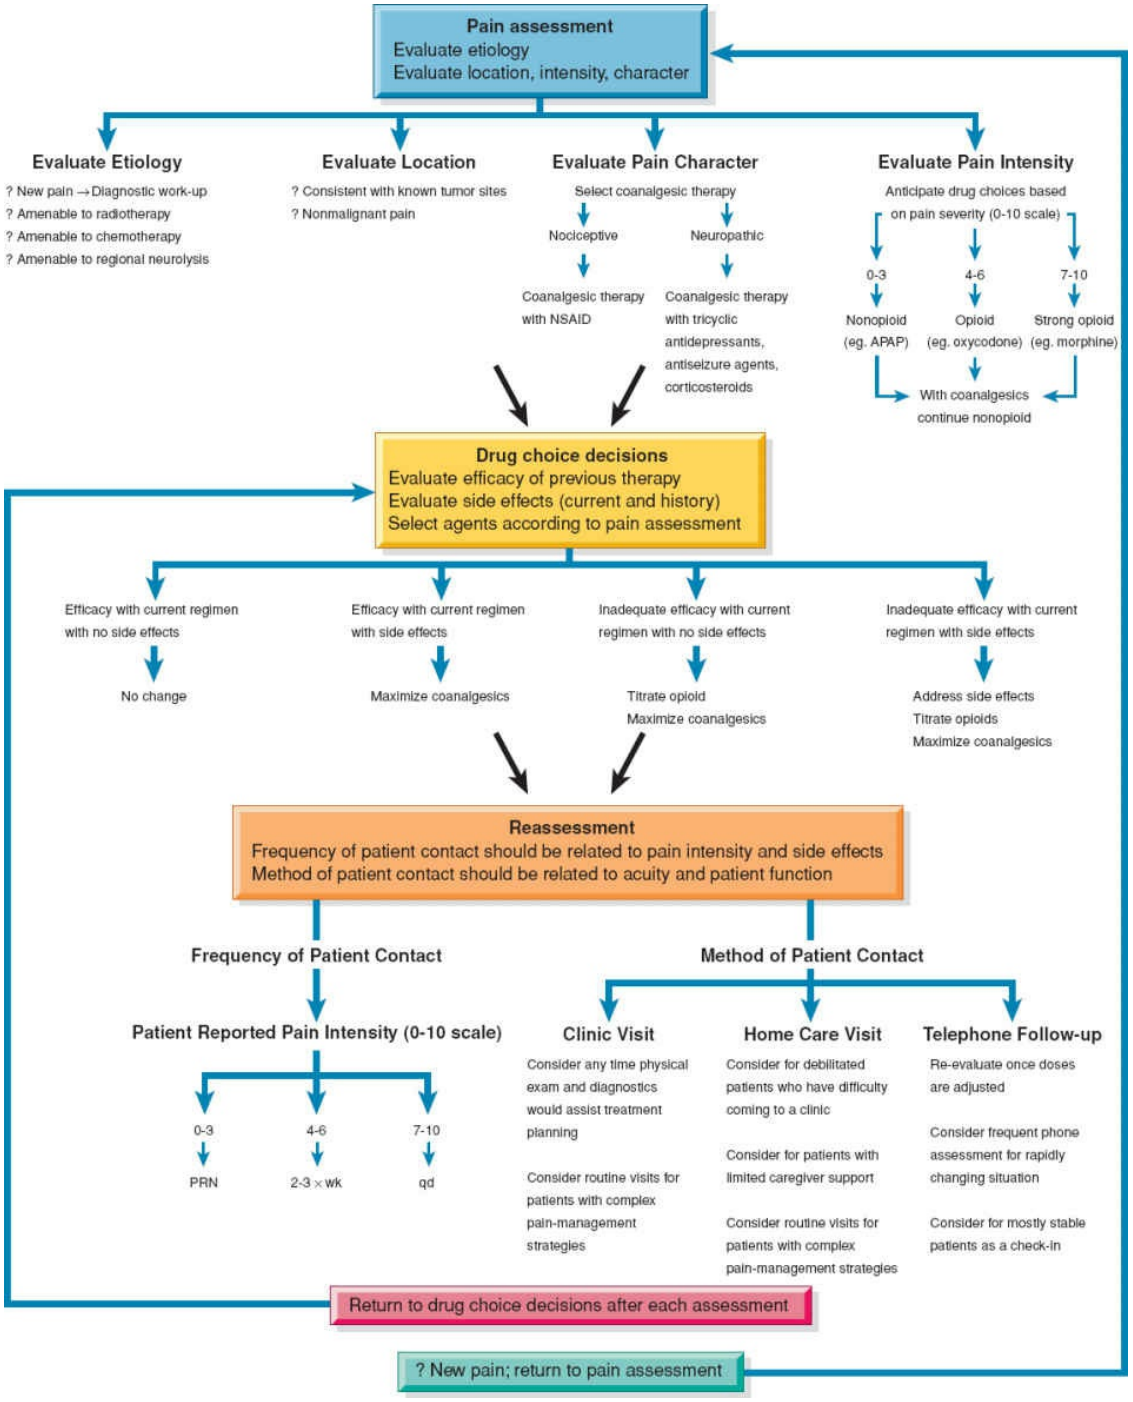

FIGURE 7-7 The cancer pain algorithm (highest-level view) is a decision-tree model for pain treatment that was developed as an interpretation of the AHCPR Guideline for Cancer Pain, 1994. FIGURE 7-8 Relationship of mode of delivery of analgesia to serum analgesic level. *Top:* Intramuscular (IM) and IV patient-controlled analgesia (PCA). *Bottom:* Transdermal (TD) and transmucosal (•) delivery.

Routes of Administration

The route selected for administration of an analgesic agent (Table 7-5) depends on the condition of the individual patient and the desired effect of the medication. Analgesic agents can be administered by parenteral, oral, rectal, transdermal (skin patch), transmucosal, intraspinal, or epidural routes. Each method of administration has advantages and disadvantages. The route chosen should be based on patient need. Box 7-4 discusses the safe use of transdermal fentanyl administration.

Patient-Controlled Analgesia

Used to manage postoperative pain as well as persistent pain in hospitals or home settings, patient-controlled analgesia (PCA) allows patients to control the administration of their own medication within predetermined safety limits.

The PCA pump permits the patient to self-administer a predetermined amount of medication safely and to administer extra medication (demand doses) with episodes of increased pain or painful activities. A PCA pump is electronically controlled by a timing device. A patient experiencing pain can administer small amounts of medication directly into the IV, subcutaneously, or into the epidural catheter by pressing a button. The pump then delivers a preset amount of medication.

The PCA pump also can be programmed to deliver a constant, background infusion of

medication (or basal rate) and still allow the patient to administer additional bolus doses as needed. The nurse also can administer clinician doses, which typically are higher doses than the demand dose. The timer can be programmed to prevent additional doses from being administered until a specified time period has elapsed (lock-out time) and until the first dose has had time to exert its maximal effect. Even if the patient pushes the button multiple times in rapid succession, no additional doses are released. If another dose is required at the end of the delay period, the button must be pushed again for the dose to be delivered. Patients who are controlling their own opioid administration usually become sedated and stop pushing the button before any significant respiratory depression occurs. Nevertheless, assessment of respiratory status remains a major nursing role.

Pain should be brought under control before a PCA is started with the use of intravenous pain medication. Then, after control is achieved, the pump is programmed to deliver small doses of medication at a time. If a patient with severe pain has a low serum level of opioid analgesic, it is difficult to regain control with the small doses available by pump. The patient is instructed not to wait until the pain is severe before pushing the button to obtain a bolus dose. Since the patient can maintain a near-constant level of medication, the periods of severe pain and sedation that occur with the traditional PRN regimen are avoided. If PCA is to be used in the patient's home, the patient and family are taught about the operation of the pump as well as about the side effects of the medication and strategies to manage them.

TABLE 7-5 Administration Routes for Analgesics

Route	Patient Factors	Advantages	Disadvantages
IV	Can be used if patient has had nothing by mouth. Side effects are nausea, vomiting.	Rapid, reliable effect, helps make patient feel more comfortable; may be administered by push or slow push (e.g., over a 5- to 10-minute period); may be administered by continuous infusion with a pump. Continuous infusion provides a steady level of analgesia over 24-hour period.	Short duration; careful calculation of dosage needed. Possible respiratory depression
Intramuscular	Can be used if patient has had nothing by mouth. Side effects are nausea, vomiting.	Limited to emergency setting where no IV access can be obtained or patient preference	Slower entry into bloodstream; slow metabolism. Absorption depends on site selected and amount of body fat.
Subcutaneous	Use if patient is in severe pain or had limited IV sites Use for home pain management	Effective, convenient	Limited to small volume that can be administered at one time into the subcutaneous tissue
Oral	Preferred over parenteral administration if patient can take medication by mouth	Easy, noninvasive, not painful. Severe pain can be relieved with oral opioids if dose is high enough. Gradual dose increase provides additional pain relief without producing respiratory depression or sedation	Increased doses needed as the disease progresses; tolerance may develop to the medication. Change from parenteral to oral route requires equianalgesic dosing to avoid withdrawal reaction and recurrence of pain
Rectal	Use if patient is unable to take medications by any other route. Side effects include bleeding problems.	Prolonged duration of action	Onset of action unclear; delayed absorption compared with other routes of administration
Transdermal	Use for home pain management or hospice care in patients currently taking oral sustained-release opioid.	Consistent opioid serum level; slightly less constipation than oral opioids; less costly than parenteral route	Delay in effect while the dermal layer is saturated. Increased absorption in febrile patients. Require short-acting opioids for breakthrough pain; more expensive than sustained-release opioids
Transmucosal	Use in patients on sustained-release opioid who experience breakthrough pain.	Rapid onset of action nasal sprays allows analgesia to be achieved within 5–10 minutes; significant decreases in pain intensity; high patient satisfaction.	This route promotes rapid absorption and high bioavailability as a result of a highly vascularized oral mucosa entering systemic circulation directly and bypassing the GI tract and first-pass effect in the liver.

Nursing Alert

Family members are cautioned not to push the button for a patient, especially if the patient is asleep, because this overrides some of the safety features of the PCA system.

Intrathecal and Epidural Administration

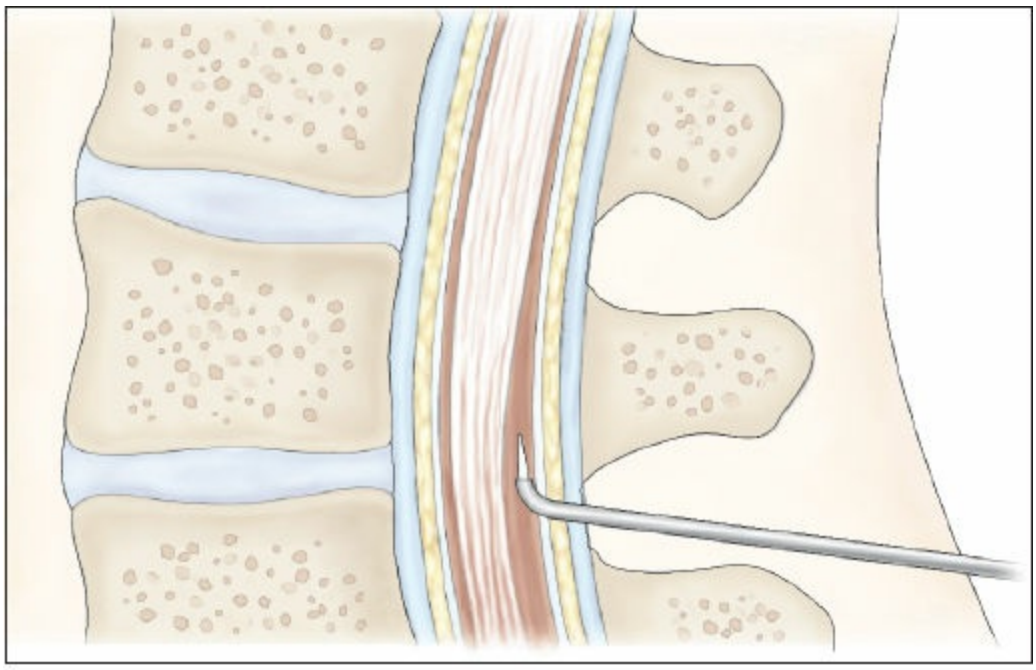
Infusion of opioids or local anesthetic agents into the intrathecal space or epidural space has been used for effective control of pain in postoperative patients and those with chronic pain unrelieved by other methods. A catheter is inserted into the epidural space at the thoracic or lumbar level for administration of opioid or anesthetic agents (Fig. 7-9). With intrathecal administration, medications infuse directly into the subarachnoid space and cerebrospinal fluid, which surrounds the spinal cord. With epidural administration, medication is deposited in the epidural space of the spinal canal and diffuses into the subarachnoid space. It is believed that pain relief from intrathecal administration of opioids is based on the

existence of opioid receptors in the spinal cord.

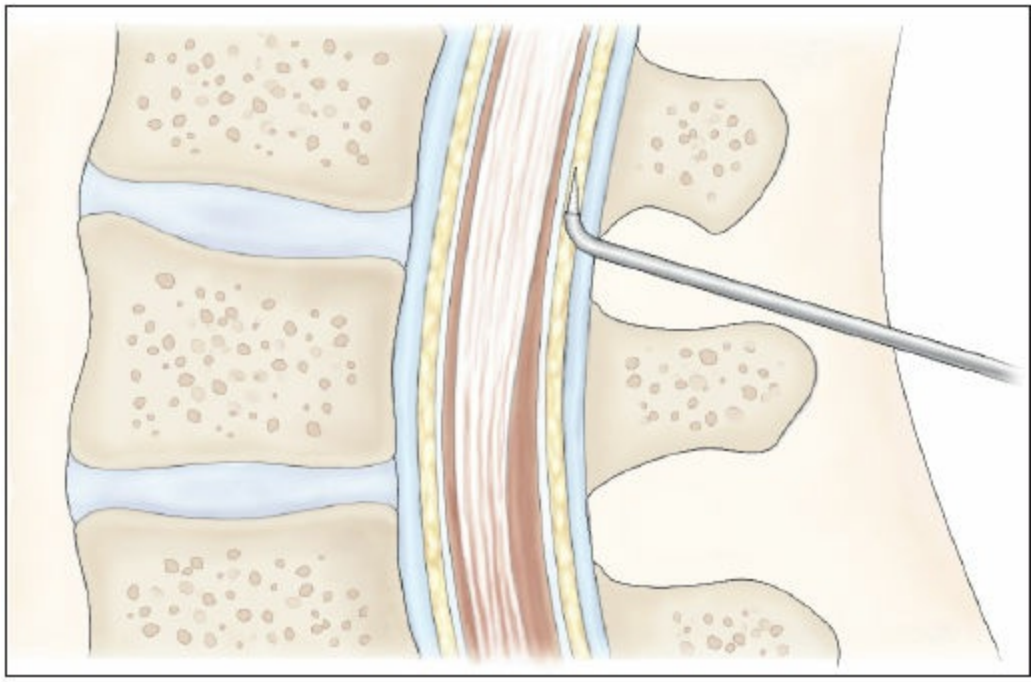
BOX 7-4 Safe Use of Transdermal Fentanyl

The U.S. Food and Drug Administration issued a public health advisory in 2009 about the use of fentanyl skin patches and warned patients and health care providers about the need for the patches to be used as intended. The advisory also included precautions about safe storage and disposal of fentanyl skin patches:

- Fentanyl skin patches are very strong opioids and always should be prescribed at the lowest dose needed for pain relief. They should be used only for patients with chronic pain that is not well controlled with shorter-acting opioids.
- Patients should be cautioned that a sudden and possibly dangerous rise in the level of fentanyl in their blood can occur with use of alcohol or other medications that affect brain function, an increase in body temperature or exposure to heat, or use of other medicines that affect the metabolism of fentanyl.
- Patients should be informed about signs and symptoms of fentanyl overdose (i.e., shallow or difficult breathing; fatigue, extreme sleepiness, or sedation; inability to think, talk, or walk normally; and feeling faint, dizzy, or confused).



A



B

FIGURE 7-9 Placement of intraspinal catheters for administration of analgesic medications: (A) intrathecal route; (B) epidural route.

An epidural anesthetic agent can be administered continuously in low doses, intermittently on a schedule, or on demand as the patient requires it, and it is often combined with the epidural administration of opioids. Typically, an opioid and local anesthetic (0.5% bupivacaine) administered at induction of anesthesia results in good postoperative analgesia for up to 24 hours (Garimella & Cellini, 2013, p. 192). Morphine is the intrathecal drug most commonly used for pain relief. Research reveals no difference

in length of hospital stay and adverse events when comparing PCA versus continuous epidural analgesia (CEA) in patients undergoing abdominal surgery; however, patients achieved better pain control in the first 72 postoperative hours with CEA (Garimella & Cellini, 2013). In addition, epidural analgesia for thoracic surgery provides superior pain control, less sedation, and better pulmonary function than parenteral opiates (Hernandez & Sherwood, 2017, p. 381).

For patients who have persistent, severe pain that fails to respond to other treatments or for those who obtain pain relief only with the risk of serious side effects, medication administered by a long-term intrathecal or epidural catheter may be effective.

Nursing Alert
Epidural catheters inserted for pain control are usually managed by nurses. Baseline information necessary to provide safe and effective pain control includes the level or site of catheter insertion, the medications (e.g., local anesthetic agents, opioids) that have been administered, and the medications anticipated in the future. The infusion rate is increased with caution when anesthetic agents are combined with opioids. Sensory deficits can occur, and patients must be assessed frequently. An infusion with a lower concentration of anesthetic agent allows for administration of a greater concentration of opioid with a lower risk of sensory deficits.

Adverse effects associated with intrathecal administration include spinal headache resulting from loss of spinal fluid when the dura is punctured. The dura must be punctured with the intrathecal route, and dural puncture may occur inadvertently with the epidural route. If dural puncture occurs inadvertently, spinal fluid seeps out of the spinal canal. Headache resulting from spinal fluid loss may be delayed. Therefore, the nurse needs to assess regularly for headache after either type of catheter is placed. If headache develops, the patient should remain flat in bed and should be given large amounts of fluids (provided the medical condition allows), caffeinated drinks and the provider should be notified. An epidural blood patch may be performed to reduce leakage of spinal fluid (typically if the headache does not resolve within 36 hours) (Barr, 2015).

BOX 7-5 Pasero Opioid-Induced Sedation Scale (POSS)

S = Sleep, easy to arouse
Acceptable; no action necessary; may increase opioid dose if needed
1 = Awake and alert
Acceptable; no action necessary; may increase opioid dose if needed
2 = Slightly drowsy, easily aroused
Acceptable; no action necessary; may increase opioid dose if needed
3 = Frequently drowsy, arousable, drifts off to sleep during conversation
Unacceptable; monitor respiratory status and sedation level closely until sedation level is stable at less than 3 and respiratory status is satisfactory; decrease opioid dose 25% to 50% or notify prescriber or anesthesiologist for orders; consider administering a nonsedating, opioid-sparing nonopioid, such as acetaminophen or an NSAID, if

not contraindicated.

4 = Somnolent, minimal or no response to verbal and physical stimulation

Unacceptable; stop opioid; consider administering naloxone; notify prescriber or anesthesiologist; monitor respiratory status and sedation level closely until sedation level is stable at less than 3 and respiratory status is satisfactory.

Pasero Opioid-Induced Sedation Scale (POSS). Copyright 1994, Chris Pasero. Used with permission.

Respiratory depression generally peaks 6 to 12 hours after epidural opioids are administered, but it can occur earlier or up to 24 hours after the first injection. It is important for the nurse to monitor the patient closely during the postoperative period with particular attention to sedation and oxygen saturation. Depending on the lipophilicity (affinity for body fat) of the opioid injected, the time frame for respiratory depression can be short or long. Morphine is hydrophilic (it has an affinity to water), and the time for peak effect is longer than that of fentanyl, which is lipophilic. The nurse must assess and record respiratory status and sedation levels using a sedation scale according to agency policy. The health care provider will need to be notified if the patient has a sedation scale of less than 3 on the Pasero Opioid-Induced Sedation Scale (POSS) (Kobelt, Burke, & Renker, 2014). The POSS evaluates the patient's level of consciousness since sedation precedes respiratory depression (Boxes 7-5 and 7-6 [research brief]). The patient should be easily aroused if slightly drowsy, and should be able to remain awake during conversation. Opioid antagonist agents such as naloxone must be available for IV use if respiratory depression occurs (see Box 7-7).

Cardiovascular effects (hypotension) may result from relaxation of the vasculature in the lower extremities. However, bradycardia, may occur with placement of a high thoracic epidural affecting the cardiac accelerator nerves. Therefore, the nurse should assess frequently for decreases in blood pressure, pulse rate, and urine output.

BOX 7-6 Nursing Research

Bridging the Gap to Evidence-Based Practice

Kobelt, P., Burke, K., & Renker, P. (2014). Evaluation of a standardized sedation assessment for opioid administration in the postanesthesia care unit. *Pain Management Nursing, 3*(15), 672–681.

Purpose

The impact of opioid-related sedation progressing to respiratory depression in the Post Anesthesia Care Unit (PACU) can be extensive; however, there is a paucity of research on the subject of standardized assessment tools to prevent adverse events. The purposes of this study were: (1) to measure the efficacy of a standardized method of assessing sedation and administering opioids for pain management via the Pasero Opioid-Induced Sedation Scale (POSS) with interventions in the PACU; (2) to increase PACU nurses' confidence in assessing sedation associated with opioid administration for pain management and in the quality of care provided in their clinical area; and (3) to facilitate communications between PACU and postoperative clinical unit nurses during patient handoffs regarding safe opioid administration.

Design
A quasi-experimental design was used to evaluate the POSS protocol. Two PACUs and six nursing units receiving postsurgical patients in a Midwestern inner-city hospital served as the setting for this research. Medical records were surveyed for outcome data to evaluate the efficacy of the care protocol in two patient cohorts before and after implementation of the POSS protocol. Nurses completed a written survey to identify changes in satisfaction with nurse-to-nurse communication, perceptions of quality of care, and confidence with opioid administration. The final sample included 842 PACU patients and 67 nurses from the PACU and clinical units.

Findings
The intervention did not significantly change PACU length of stay or amount of administered opioids, and patients were noted to be more alert at time of discharge from the PACU. Nurses reported increased perceptions of quality of care and confidence in opioid administration.

Nursing Implications
The findings from this study support the use of the POSS scale with interventions in the PACU care protocols (see Box 7-7).

BOX 7-7 Opioid Analgesic Orders: General Considerations for the Nurse

A. Opioid analgesic orders or a hospital protocol should include the expectation that a nurse will hold the opioid dose if a patient is sedated excessively. The nurse documents the rationale for holding the dose. The nurse also recognizes that a fall in oxygen saturation can represent a critical level of respiratory depression and the need for immediate intervention to prevent life-threatening hypoxemia.
B. In the event of oversedation or life-threatening respiratory depression, the hospital protocol should include that naloxone should be available for the nurse. In general, 0.1–0.4 mg of naloxone and 9 mL of normal saline are mixed in a syringe, and this dilute solution is administered very slowly (e.g., 1 mL or 0.04 mg over 1 minute) while observing the patient's response (titrate to effect). Patients should be monitored after being recovered with naloxone because the patient can fall back into unresponsiveness as the half-life of naloxone is only about 30 minutes before wearing off.
C. The nurse is aware that naloxone is administered incrementally in order to improve respiratory function but not reverse all analgesia, to avoid recurrence of severe pain.
D. When naloxone is administered in excessive doses, excitement, blood pressure liability, pulmonary edema, ventricular tachycardia and fibrillation, and seizures may be caused in postoperative patients (Vallerand, Sanoski, & Deglin, 2017).

Adapted from Pasero, C., Portenoy, R. K., McCaffery M. (1999). Opioid analgesics. In *Pain: Clinical manual* (2nd ed.). St. Louis, MO: Mosby, p. 267; American Pain Society (APS). (2003). *Principles of analgesic use in the treatment of acute pain and chronic cancer pain* (5th ed.), Glenview, IL: American Pain Society.

Urinary retention and pruritus may develop, and the health care provider may prescribe intravenous infusion of low-dose naloxone to combat these effects. The nurse administers doses that are small enough to reverse the side effects of the opioids without reversing the analgesic effects. Diphenhydramine or low-dose intravenous infusion of naloxone also may be used to relieve opioid-related pruritus.

Precautions must be taken to avoid infection at the catheter site and catheter displacement. The epidural catheter insertion site should be inspected routinely for any signs of infection or drainage. Only medications without preservatives should be administered into the subarachnoid or epidural space because of the potential neurotoxic effects of preservatives.

Nursing Alert

Because of the risk of an epidural hematoma, a general consensus exists that the epidural catheter should not be removed earlier than 12 hours after the last dose of low–molecular-weight heparin (LMWH), and LMWH should not be restarted earlier than 2 hours after catheter removal. The nurse is aware that symptoms of an epidural hematoma include back pain, sensory and motor dysfunction of the lower limbs, and bladder and bowel abnormalities (Hernandez & Sherwood, 2017).

Placebo Effect

A placebo effect occurs when a person responds to the medication or other treatment because of an expectation that the treatment will work rather than because it actually does so. The American Society for Pain Management Nurses contends that placebos (tablets or injections with no active ingredients) should not be used to assess or manage pain in any patient, regardless of age or diagnosis (Arnstein, Broglio, Wuhrman, & Kean, 2011). Furthermore, the group recommends that all health care institutions have policies in place prohibiting the use of placebos for this purpose. Educational programs should be conducted to educate nurses and other health care providers about effective pain management, and ethics committees should assist in developing and disseminating these policies.

Nonpharmacologic Interventions

Analgesic medication is the most powerful tool for pain relief that is available, but it is not the only one. Nonpharmacologic nursing interventions can assist in pain relief, usually with low risk to the patient. Although such measures are not a substitute for medication, they may be all that is necessary or appropriate to relieve episodes of pain lasting only seconds or minutes. In instances of severe pain that lasts for hours or days, combining nonpharmacologic interventions with medications may be the most effective way to relieve pain.

Cutaneous Stimulation and Massage

Massage, which is generalized cutaneous stimulation of the body, often concentrates on the back and shoulders. A massage does not specifically stimulate the nonpain receptors in the same receptor field as the pain receptors, but it may have an impact through the descending control system (see previous discussion). Although the exact mechanism of massage therapy is not known, it is purported to improve local circulation, tone of supportive musculature, joint flexibility, and decrease inflammation (Perlman, 2016). Massage also promotes comfort, improves function, produces muscle relaxation and relieves stress (Perlman, 2016). It has demonstrated potential benefit for neck pain, low back pain, constipation, high blood pressure, lymphedema, stress, depression, and osteoarthritis (Perlman, 2016).

Thermal Therapies

Ice and heat therapies may be effective pain relief strategies in some circumstances; however, their effectiveness and mechanisms of action need further study. Proponents believe that ice and heat stimulate the nonpain receptors in the same receptor field as the injury. Both ice and heat therapy must be applied carefully and monitored closely to avoid injuring the skin. Neither therapy should be applied to areas with impaired circulation or used in patients with impaired sensation.

For greatest effect, ice should be placed on the injury site immediately after injury or surgery. Ice therapy after joint surgery can significantly reduce the amount of analgesic medication required. Ice therapy also may relieve pain if applied later. Care must be taken to assess the skin before treatment and to protect the skin from direct application of the ice. Ice should be applied to an area for no longer than 15 to 20 minutes at a time and should be avoided in patients with compromised circulation (Arthritis Foundation, 2015). Prolonged applications of ice may result in frostbite or nerve injury.

Application of heat increases blood flow to an area and contributes to pain reduction by speeding healing. Both dry and moist heat may provide some analgesia, but their mechanisms of action are not well understood.

Nursing Alert
Heat should not be applied to a painful area that is the site of acute, untreated infection (e.g., mastitis, tooth abscess) because it may cause increased pain with increased blood flow to the site.

Transcutaneous Electrical Nerve Stimulation

Transcutaneous electrical nerve stimulation (TENS) uses a battery-operated unit with electrodes applied to the skin to produce a tingling, vibrating, or buzzing sensation in the area of pain. It has been used in both acute and chronic pain relief and is thought to decrease pain by stimulating the nonpain receptors in the same area as the fibers that transmit the pain. Research studies have demonstrated that low-frequency high-intensity TENS has inhibitory effects on pain perception (Treede, 2016). The mechanism of action of TENS is related to the gate control theory of pain, which was proposed in 1965 and held that the perception of pain can be inhibited by activation of nerves that do not transmit pain signals, thus interrupting the nociceptors signals. This theory explains the effectiveness of cutaneous stimulation when applied in the same area as an injury. Although much has been learned about the complexity of spinal circuitry, the gate control theory model predicted the efficacy of TENS.

Distraction

Distraction helps relieve both acute and chronic pain (Slover et al., 2015; Schreiber et al., 2014). Distraction, which involves focusing the patient's attention on something other than the pain, may be the mechanism responsible for other effective cognitive techniques. Distraction is thought to reduce the perception of pain by stimulating the descending control system, resulting in fewer painful stimuli being transmitted to the brain. The effectiveness of distraction depends on the patient's ability to receive and create sensory input other than pain. Distraction techniques may range from simple activities, such as watching television or listening to music, to highly complex physical and mental exercises. Pain relief generally increases in direct proportion to the patient's active participation, the number of sensory modalities used, and interest in the stimuli. Therefore, the stimulation of sight, sound, and touch is likely to be more effective in reducing pain than is the stimulation of only a single sense.

Visits from family and friends are effective in relieving pain. Watching an action-packed movie on a large screen with "surround sound" through headphones may be effective (provided the patient finds it acceptable). Others may benefit from games and activities (e.g., chess, crossword puzzles) that require concentration. Not all patients obtain pain relief with distraction, especially those in severe pain. Severe pain may prevent patients from concentrating well enough to participate in complex physical or mental activities.

Relaxation Techniques/Meditation

Skeletal muscle relaxation is believed to reduce pain by relaxing tense muscles that contribute to the pain. A simple relaxation technique consists of abdominal breathing at a slow, rhythmic rate. The patient may close both eyes and breathe slowly and comfortably. A constant rhythm can be maintained by counting silently and slowly with each inhalation ("in, two, three") and exhalation ("out, two, three"). When teaching this technique, the nurse may count out loud with the patient at first. Slow, rhythmic breathing may also be used as a distraction technique. Relaxation techniques, as well as other noninvasive pain relief measures, may require practice before the patient becomes skilled in using them. Patients who already know a relaxation technique may need to be reminded to use it to

reduce or prevent increased pain. Almost all people with persistent pain can benefit from some method of relaxation. Meditation has demonstrated impact on lowering of blood pressure and heart rate, increased cerebral blood flow, and decreased levels of hormones associated with stress (Perlman, 2016). Regular relaxation periods may help combat the fatigue and muscle tension that occur with and increase chronic pain.

Guided Imagery

Guided imagery is using one's imagination in a special way to achieve a specific positive effect. Guided imagery for relaxation and pain relief may consist of combining slow, rhythmic breathing with a mental image of relaxation and comfort. The nurse instructs the patient to close the eyes and breathe slowly in and out. With each slowly exhaled breath, the patient imagines muscle tension and discomfort being breathed out, carrying away pain and tension and leaving behind a relaxed and comfortable body. With each inhaled breath, the patient imagines healing energy flowing to the area of discomfort.

If guided imagery is to be effective, it requires a considerable amount of time to explain the technique and time for the patient to practice it. Usually, the patient is asked to practice guided imagery for approximately 5 minutes, three times per day. Several days of practice may be needed before the intensity of pain is reduced. Many patients begin to experience the relaxing effects of guided imagery the first time they try it. Pain relief can continue for hours after the imagery is used. Patients should be informed that guided imagery may work only for some people. Guided imagery should be used only in combination with all other forms of treatment that have demonstrated effectiveness.

Hypnosis

Hypnosis, which has been effective in relieving pain or decreasing the amount of analgesic agents required in patients with acute and chronic pain, may promote pain relief in particularly difficult situations (e.g., burns). The mechanism by which hypnosis acts is unclear. Its effectiveness depends on the hypnotic susceptibility of the individual (Jensen & Patterson, 2014). In some cases, hypnosis may be effective in the first session, with effectiveness increasing in additional sessions. In other cases, hypnosis does not work at all. Usually, hypnosis must be induced by specially skilled people (a psychologist or a nurse with specialized training in hypnosis). Some patients may learn to perform self-hypnosis.

Music Therapy

Music therapy is an inexpensive and effective therapy for the reduction of pain and anxiety in some patient populations. Research has shown that it reduces postoperative pain, fatigue, anxiety, and cumulative opioid consumption (Sin & Chow, 2015). Music therapy was also found to decrease pain in persons with chronic pain (Stanos, Tyburski, & Harden, 2016). More research needs to be done to determine the mechanism by which music exerts its positive effect on pain relief.

Acupuncture

The insertion of the needles is intended to stimulate or improve the balance of the flow of "life energy" or *qi* (pronounced chi), whereas a blockage of flow or imbalance of *qi* is

associated with patient complaints or disease. Although very different from a Western medical view of pathophysiology, acupuncture has been shown to have various physiologic effects on the body, including stimulation of endorphins (Perlman, 2016). Research suggests that acupuncture may be beneficial for pain associated with fibromyalgia, headache, and chronic pain and has been used with varied conditions such as stroke, analgesia during childbirth, and infertility treatment. In addition, stimulation of the acupuncture point at the wrist is potentially effective in reducing postoperative nausea and vomiting (Perlman, 2016).

Movement Therapy

Restoring balance to the body by using physical movement, such as yoga, and tai chi have gained in popularity and have had positive health benefits in patients with low back pain and back-related disabilities. In addition, often tai chi can be practiced even by patients with heart disease or arthritis as well as patients who are at risk of falling (Perlman, 2016).

Alternative Therapies

The National Institutes of Health has established the National Council for Complementary and Alternative Medicine (CAM) to examine the effectiveness of complementary and alternative therapies. The new field of integrative medicine allows for a combination of mainstream medicine and alternative therapies that enhance effectiveness and safety for patients seeking CAM therapies for pain and other disorders. The use of CAM has increased in the United States, and patients with cancer or rheumatologic conditions use CAM at a higher rate than the general population. For example, a study noted that 75% of cancer patients surveyed had used at least one CAM modality, compared to usage in 38% of the general population (Perlman, 2016).

When caring for patients who are using or considering using untested therapies, it is imperative for the nurse not to diminish the patient's hope. This must be weighed against the nurse's responsibility to protect the patient from costly and potentially harmful and dangerous therapies that the patient is not in a position to evaluate scientifically. The nurse encourages the patient to assess the effectiveness of the therapy, continually using standard pain assessment techniques. All use of alternative and complementary therapies needs to be discussed with the patient's health care provider.

Neurologic and Neurosurgical Approaches to Pain Management

In some situations, especially with long-term and severe intractable pain, usual pharmacologic and nonpharmacologic methods of pain relief are ineffective. In those situations, neurologic and neurosurgical approaches to pain management may be considered. *Intractable pain* refers to pain that cannot be relieved satisfactorily by the usual approaches, including medications. Such pain often is the result of malignancy (especially of the cervix, bladder, prostate, and lower bowel), but it may occur in other conditions, such as postherpetic neuralgia, trigeminal neuralgia, spinal cord arachnoiditis, and uncontrollable ischemia and other forms of tissue destruction.

Neurologic and neurosurgical methods available for pain relief include: (1) stimulation procedures (intermittent electrical stimulation of a tract or center to inhibit the transmission of pain impulses), (2) administration of intraspinal opioids (see previous discussion), and (3) interruption of the tracts conducting the pain impulse from the periphery to cerebral integration centers. Stimulation of nerves with minute amounts of electricity is used if other pharmacologic and nonpharmacologic treatments fail to provide adequate relief. These treatments are reversible. If they need to be discontinued, the nervous system continues to function. However, methods that involve interruption of the tracts are destructive or ablative procedures. They are used only after other methods of pain relief have failed because their effects are permanent.

Stimulation Procedures

Electrical stimulation, or neuromodulation, is a method of suppressing pain by applying controlled low-voltage electrical pulses to the different parts of the nervous system. Electrical stimulation is thought to relieve pain by blocking painful stimuli. This pain-modulating technique is administered by many modes. TENS (discussed earlier) and dorsal spinal cord stimulation are the most common types of electrical stimulation used. There are also brain-stimulating techniques in which electrodes are implanted in the periventricular area of the posterior third ventricle, allowing the patient to stimulate this area to produce analgesia.

Spinal cord stimulation is a technique used for the relief of persistent, intractable pain, ischemic pain, spinal stenosis pain, pain from angina, and other neuropathic pain syndromes. A surgically implanted device allows the patient to apply pulsed electrical stimulation to the dorsal aspect of the spinal cord to block pain impulses (the largest accumulation of afferent fibers is found in the dorsal column of the spinal cord (Al-Kaisy et al., 2014). The dorsal column stimulation unit consists of a radiofrequency stimulation transmitter, a transmitter antenna, a radiofrequency receiver, and a stimulation electrode. The battery-powered transmitter and antenna are worn externally; the receiver and electrode are implanted. A laminectomy is performed above the highest level of pain input, and the electrode is placed in the epidural space over the posterior column of the spinal cord. The placement of the stimulating systems varies. A subcutaneous pocket is created over the clavicular area or at some other site for placement of the receiver. The two are connected through a subcutaneous tunnel. As implantable devices carry higher risks than conservative nonoperative approaches, this treatment is generally reserved for patients who

have exhausted more conservative options (Eli, Konrad, & Neimat, 2015).

Deep brain stimulation is performed in patients with special pain problems if there is no response to the usual techniques of pain control. Under local anesthesia, electrodes are introduced through a burr hole in the skull and inserted into a selected site in the brain, depending on the location or type of pain. After the effectiveness of stimulation is confirmed, the implanted electrode is connected to a radiofrequency device or pulse-generator system operated by external telemetry. It is used in patients with neuropathic pain that may be caused by damage or injury from a stroke, chronic cluster headaches, brain or spinal cord injuries, or Parkinson disease.

Interruption of Pain Pathways

Pain-conducting fibers can be interrupted at any point from their origin to the cerebral cortex. In doing so, some part of the nervous system is destroyed, resulting in varying amounts of neurologic deficit and incapacity. For example, a spinal ablation procedure of the dorsal root, which selectively destroys neurons located in the posterolateral spinal cord where sensory fibers enter into the spinal cord, may be used in neuropathic pain, phantom limb pain, and traumatic brachial and lumbosacral plexus avulsion injuries. Studies report 60% of patients demonstrated good pain relief with an average follow-up of 71 months (Eli et al., 2015). Destructive procedures used to interrupt the transmission of pain also include cordotomy, myelotomy, and rhizotomy. A cordotomy is destruction of the lateral spinothalamic tract (which carries pain signals) in the anterolateral part of the spinal cord and is used for intractable unilateral cancer pain (Eli et al., 2015). A percutaneous technique can be used for this procedure, which limits risks. A myelotomy is a neuroablation treatment used for patients with intractable oncologic visceral pain in the abdomen or pelvis. A rhizotomy is an ablative procedures of the sensory and pain fibers of the trigeminal nerve either centrally or peripherally to provide pain relief. These procedures are offered if it is thought that the procedure will result in an improved quality of life. The use of other methods to interrupt pain transmission is reserved for a patient with intractable pain where medical therapy has been exhausted.

Unfolding Patient Stories: Stan Checketts • Part 1

Stan Checketts, a 52-year-old male, is in the emergency department with severe abdominal pain. The provider has ordered buprenorphine 0.3 mg IV push for pain. Explain the assessments performed by the nurse prior to, during, and following the administration of the medication. Also consider nonpharmacologic interventions the

nurse can incorporate to assist with his pain relief. (Stan Checketts' story continues in Chapter 24.)

vSim for Nursing Care for Stan and other patients in a realistic virtual environment: (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

BOX 7-8 Expected Patient Outcomes for the Patient with Pain

Relief of pain, evidenced when the patient rates pain at a lower intensity:

- On a scale of 0–10 after intervention.
- For longer periods.

Correct administration of prescribed analgesic medications, evidenced when the patient or family:

- States correct dose of medication.
- Administers correct dose using correct procedure.
- Identifies side effects of medication.
- Describes actions taken to prevent or correct side effects.

Use of nonpharmacologic pain strategies as recommended, evidenced when the patient:

- Reports practice of nonpharmacologic strategies.
- Describes expected outcomes of nonpharmacologic strategies.

Minimal effects of pain and minimal side effects of interventions, evidenced when the patient:

- Participates in activities important to recovery (e.g., drinking fluids, coughing, ambulating).
- Participates in activities important to self and to family (e.g., family activities, interpersonal relationships, parenting, social interaction, recreation, work).
- Reports adequate sleep and absence of fatigue and constipation.

EVALUATING PAIN MANAGEMENT STRATEGIES

An important aspect of caring for patients in pain is reassessing the pain after the intervention has been implemented. The measure's effectiveness is based on the patient's assessment of pain, as reflected in pain assessment tools. If the intervention was ineffective, the nurse should consider other measures. If these are ineffective, pain relief goals need to be reassessed in collaboration with the primary care provider and or interdisciplinary team. The nurse serves as the patient's advocate in obtaining additional pain relief.

After interventions have had a chance to work, the nurse asks the patient to rate the intensity of pain. The nurse repeats this assessment at appropriate intervals after the intervention and compares the result with the previous rating. These assessments indicate the effectiveness of the pain relief measures and provide a basis for continuing or modifying the plan of care. A plan of nursing care for a patient with pain is available at http://thepoint.lww.com/Honan2e. Expected patient outcomes are given in Box 7-8.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 35-year-old man who is a recovering heroin addict is admitted to the hospital for an emergency appendectomy. During surgery, the appendix ruptures, and the patient remains hospitalized for several days for IV antibiotics. He tells the nurse that he has been "clean" for the past 3 months. He complains of pain (7 on a 0 to 10 scale) and refuses to use the patient-controlled analgesia that is prescribed for him. He states, "I don't want to get hooked again." Describe how you would address pain relief in this patient, and give the rationale for your actions. Who would you consult to help with this patient's pain management?

2. A 48-year-old woman has severe chronic pain associated with cancer metastasis to the bone. She is reluctant to take opioids because she wants to remain alert to enjoy being around her family. Furthermore, she is concerned about having opioids around the house because of the presence of young children in the home. Identify pharmacologic alternatives and nonpharmacologic interventions that might be appropriate. Identify the evidence base and the strength of the evidence for the use of the nonpharmacologic interventions.

NCLEX-Style Review Questions

1. The nurse is managing an epidural catheter for a patient diagnosed with cancer. The patient has developed a spinal headache. Which intervention should be completed at this time?
   a. Increase the dosage of anesthetic.
   b. Place in semi-Fowler position.

c. Continue to monitor the patient.
d. Initiate administration of prescribed fluids.

2. The nurse is caring for an 80-year-old patient following right hip surgery. When administering pain medication to this patient, what is important for the nurse to remember?
   a. Elderly patients have a faster metabolism than their younger counterparts.
   b. Elderly patients have an increased risk for drug toxicity.
   c. Elderly patients have a lower incidence of chronic illness.
   d. Elderly patients infrequently use OTC medications.

3. A patient has a pancreatic tumor and history of alcoholism. The patient receives morphine 2 mg subcutaneously every 3 to 4 hours for treatment of pain associated with the tumor. After 2 days of receiving this dose every 4 hours, the patient tells the nurse that the medication is needed more frequently to control the pain. What is the nurse's best response to this situation?
   a. The patient is becoming addicted to the morphine, and the medication should be administered less frequently than every 4 hours.
   b. A tolerance to the morphine is developing, and the patient should receive the drug every 3 hours.
   c. Administering the morphine every 3 hours will increase the patient's physical dependence on the drug.
   d. Physical dependence should be avoided at all costs, and the drug should continue to be administered every 4 hours.

4. A patient who had abdominal surgery 5 days ago complains of sharp, throbbing abdominal pain that ranks 8 on a scale of 0 (no pain) to 10 (worst pain). The patient's pain rating has averaged at a 3/10 for the first 5 days postoperatively on epidural administration of hydromorphone. However, narcotic administration via epidural catheter was discontinued earlier this morning. Which of the following would be the nurse's first action?
   a. Obtain an order to restart the epidural narcotic administration.
   b. Assess the patient to rule out possible complications secondary to surgery.
   c. Check the patient's chart to determine what additional pain medications can be administered.
   d. Explain to the patient that his pain should not be this severe 5 days postoperatively.

5. What instruction should the nurse stress when teaching the preoperative patient about correct use of the PCA device?
   a. Push the button when you feel the pain beginning rather than waiting until the pain is at its worst.
   b. Push the button every 15 minutes whether you feel pain at that time or not.
   c. Instruct your family or visitors to press the button for you when you are sleeping.

d. Try to go as long as you possibly can before you press the button.

Problems Related to Gas Exchange and Respiratory Function

A 43-year-old 43-year-old patient diagnosed with laryngeal cancer will undergo a total laryngectomy. He is very anxious about how he will deal with his care at home. How can the nurse address his fears?

- Discuss potential complications that may arise following a total laryngectomy.

- Discuss areas to be included in teaching the patient self-care.
- Discuss area support groups for laryngectomy patients.

CHAPTER 8

Nursing Assessment: Respiratory Function

Linda Honan

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the structures and functions of the upper and lower respiratory tracts.
2. Define ventilation, perfusion, diffusion, and shunting.
3. Explain the use of inspection, palpation, percussion, and auscultation for respiratory assessment.
4. Discriminate between normal and abnormal breath sounds.
5. Use assessment parameters appropriate for determining the characteristics and severity of the major symptoms of respiratory dysfunction.
6. Identify the nursing implications of the various procedures used for diagnostic evaluation of respiratory function.

Disorders of the respiratory system are commonly encountered by nurses in every setting from the community to the intensive care unit. Expert assessment skills must be developed and used when caring for patients with acute and chronic respiratory problems. In addition, an understanding of respiratory function and the significance of abnormal diagnostic test results is essential.

ANATOMIC AND PHYSIOLOGIC OVERVIEW

The respiratory system is composed of the upper and lower respiratory tracts, blood vessels, thoracic cage (spine, ribs, and sternum) and respiratory muscles, chiefly the diaphragm (Fig. 8-1). Respiration requires concert of ventilation (movement of air from the atmosphere to the alveoli [the functional unit of the lung]), diffusion (exchange of oxygen [O_2] and carbon dioxide [CO_2] at the alveolar–capillary membrane), and perfusion (blood flow). In addition, innervations of the respiratory system are controlled by the neurologic system (medulla, pons, spinal nerves), muscular system (diaphragm, intercostal muscles), and chemical regulation.

Anatomy of the Upper Respiratory Tract

Upper airway structures consist of the nose, sinuses and nasal passages, pharynx, tonsils and adenoids, and larynx, which warm, humidify, and filter atmospheric air.

Nose

The anterior nares (nostrils) are the external openings of the nasal cavities. The internal portion of the nose is divided into two by a narrow vertical divider, the *septum*, which is richly supplied with sensory nerves and blood vessels. Each nasal cavity is divided into three passageways by the projection of the turbinates (also called conchae), which are highly sensitive. The middle passageway, or meatus, lies under the middle turbinate and contains the ostia (openings) of three of the paranasal sinuses (discussed below) that drain into this area. The nasal cavities are lined with highly vascular ciliated mucous membranes (nasal mucosa). Mucus, secreted continuously by goblet cells, covers the surface of the nasal mucosa and is moved back to the nasopharynx by the action of the cilia (fine hairs).

Nursing Alert
The nurse considers that prolonged obstruction of the ostia (as with a nasotracheal tube or nasogastric [NG] tube) is associated with sinusitis (Bennett, Dolan, & Blaser, 2014). Patients with endotracheal intubation are also at risk for nosocomial sinusitis because of pooling of nasopharyngeal secretions.

Paranasal Sinuses

The paranasal sinuses include four pairs of bony cavities or air spaces that drain into the nasal cavity and lighten the weight of the skull. The sinuses are named by their location: frontal (above the eyebrows), ethmoidal (between the eyes and behind the nose), sphenoidal (behind the ethmoid sinuses), and maxillary (located on the cheeks below the eyes). They serve as a resonating chamber in speech and are a common site of infection.

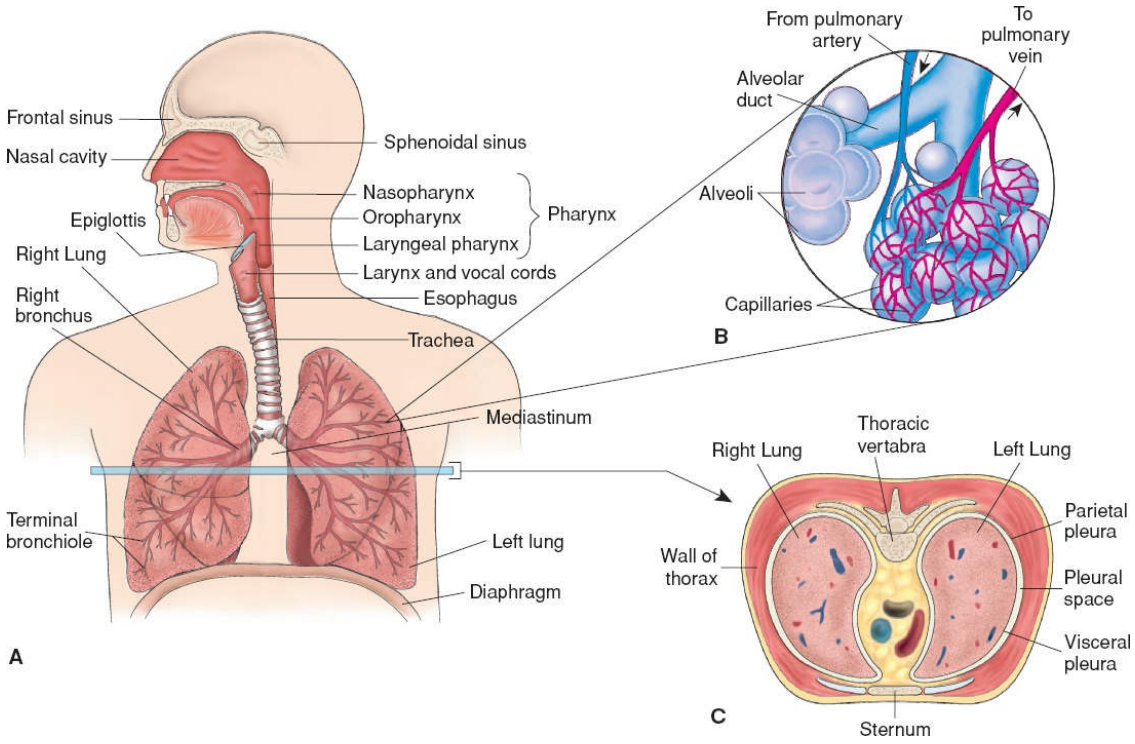

FIGURE 8-1 The respiratory system. A. Upper respiratory structures and the structures of the thorax. B. Alveoli. C. A horizontal cross-section of the lungs.

Pharynx, Tonsils, and Adenoids

The pharynx, or throat, is a tube-like structure that connects the nasal and oral cavities to the larynx and is a passageway for the respiratory and digestive tracts. It is divided into three regions: nasal, oral, and laryngeal. The nasopharynx is located posterior to the nose and above the soft palate. The adenoids, or pharyngeal tonsils, are located in the roof of the nasopharynx. Air entering reaches the nasopharynx, where it contacts sensitive nerves. Some of these nerves detect odors; others provoke sneezing to expel irritating dust. The eustachian tubes are also located here, they connect the middle ear to the nasopharynx and function to drain mucus and equalize pressures. The oropharynx houses the faucial, or palatine, tonsils. The tonsils, the adenoids, and other lymphoid tissue encircle the throat. These structures are important links in the chain of lymph nodes guarding the body from invasion by organisms entering the nose and the throat. The laryngopharynx extends from the hyoid bone to the cricoid cartilage.

Larynx

The larynx, or voice organ, connects the pharynx and the trachea. The major function of the larynx is vocalization. It also protects the lower airway from foreign substances and facilitates coughing. It is frequently referred to as the voice box and consists of the following:

- *Epiglottis:* A valve flap of cartilage (lid-like structure) that covers the entrance to the larynx during swallowing; it is essential to prevent aspiration (inhalation of food or fluid into the lungs)
- *Glottis:* The opening between the vocal cords in the larynx

- *Thyroid cartilage:* The largest of the cartilage structures; it can be felt anteriorly as the "Adam's apple"
- *Cricoid cartilage:* The only complete cartilaginous ring in the larynx (located below the thyroid cartilage)
- *Arytenoid cartilages:* Used in vocal cord movement with the thyroid cartilage
- *Vocal cords:* Ligaments controlled by muscular movements that produce sounds; located in the lumen of the larynx

During expiration, the vocal cords vibrate to produce high or low sounds. High sounds are associated with a taut glottis, whereas low sounds are associated with a more relaxed one. The nurse is alert for the development of stridor, an abnormal, high-pitched sound, as it signifies turbulent airflow through a partially obstructed airway at the level of the supraglottis, glottis, subglottis, and/or trachea. Any obstruction of the glottis area can be fatal.

Nursing Alert

Any artificial airway bypasses the normal protective function of warming, humidifying, and filtering the air. Although, O_2 can be humidified and warmed, it cannot be filtered, thus any artificial airway is a risk factor for infection. In addition, since artificial airways bypass the larynx (responsible for voice), communication is a priority nursing concern. The upper airway also serves as a conduit for air to reach the lungs. The nurse is alert for any obstruction—such as a foreign body; the tongue; swelling secondary to allergic reaction, infection, or trauma; or neurologic impairment in which nerves or muscles may be impaired—that predisposes the patient to airway obstruction.

Anatomy of the Lower Respiratory Tract

The lower respiratory tract consists of the trachea, right and left mainstem bronchi, secondary bronchi, bronchioles, and lungs, and can be further subdivided into the conducting airways and the acinus, where the respiratory bronchioles and alveoli (functional unit of the lung) are located.

Trachea

The trachea, or windpipe, is composed of smooth muscle with C-shaped rings of cartilage at regular intervals. The cartilaginous rings are incomplete on the posterior surface and give firmness to the wall of the trachea, preventing it from collapsing. About 1 in (2.5 cm) in diameter, the trachea extends from the cricoid cartilage of the larynx to the top of the carina (area where the trachea bifurcates or divides). This division into the mainstem bronchi is at the second intercostal space (ICS) anteriorly (at the level of the angle of Louis) (see Fig. 8-2).

Nursing Alert
The angle of Louis is a significant anatomical landmark that has implications for cardiac and pulmonary assessment as well as clinical procedures (i.e., EKG lead placement). Since the angle of Louis relates to the second rib, the nurse understands the ICS directly below this rib is the second ICS. The aortic valve is auscultated at the second ICS right sternal border (SB); the pulmonary valve is heard at the second ICS, left SB. The angle of Louis is also anatomically where the trachea bifurcates into the left and right mainstem bronchus. The angle of Louis is also referred to as the sternal angle or the manubriosternal junction.

Lungs

The lungs are paired elastic structures enclosed in the thoracic cage, which is an airtight chamber with distensible walls (Fig. 8-3). They are divided into lobes by fissures. The lungs are separated into upper and lower lobes by the oblique or major fissures that begin at T3 posteriorly and terminate at the sixth rib in the midclavicular line (MCL) bilaterally. To find T3, the nurse asks the patient to flex the neck forward; the most protruding spinous process is C7. The nurse palpates below this process from here to T1, T2, and T3. An additional horizontal fissure produces the middle lobe of the right lung. It begins anteriorly at approximately the fourth rib at the right SB and extends to the fifth rib in the midaxillary line. It is essential for nurses to understand that the right middle lobe can be auscultated only anteriorally (see later discussion and Box 8-7 on page 248).

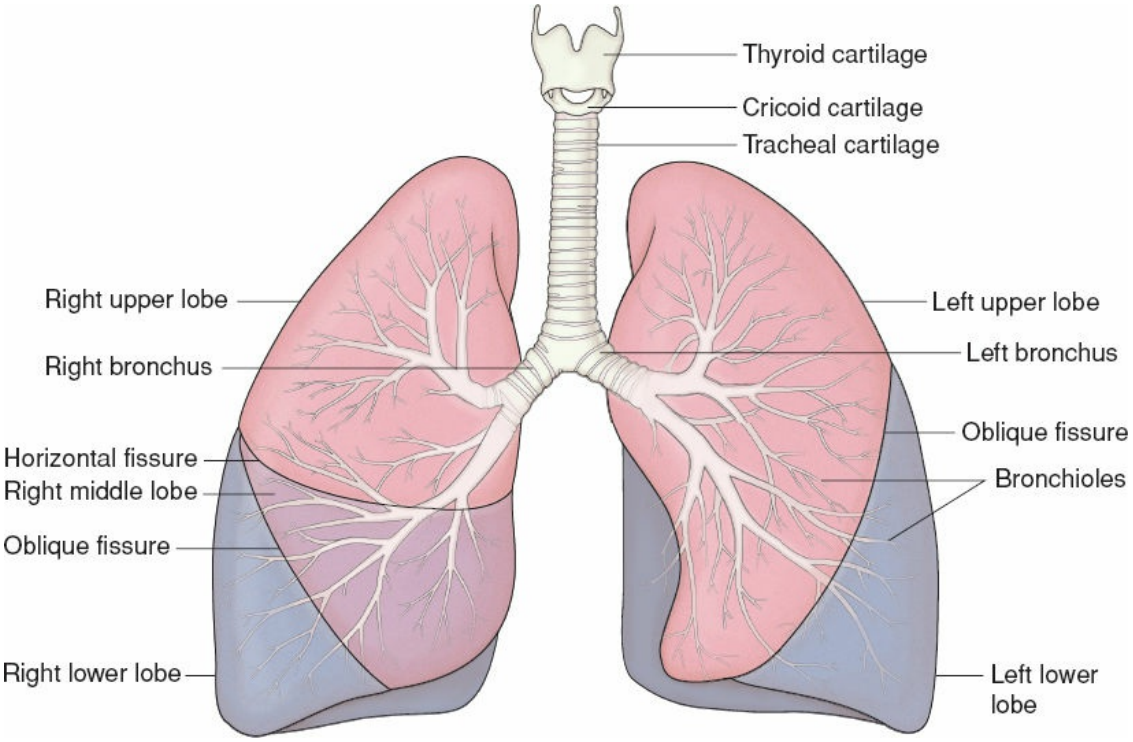

FIGURE 8-2 Anterior view of the lungs. The lungs consist of five lobes. The right lung has three lobes (upper, middle, lower); the left has two (upper and lower). The lobes are further subdivided by fissures. The bronchial tree, another lung structure, inflates with air to fill the lobes.

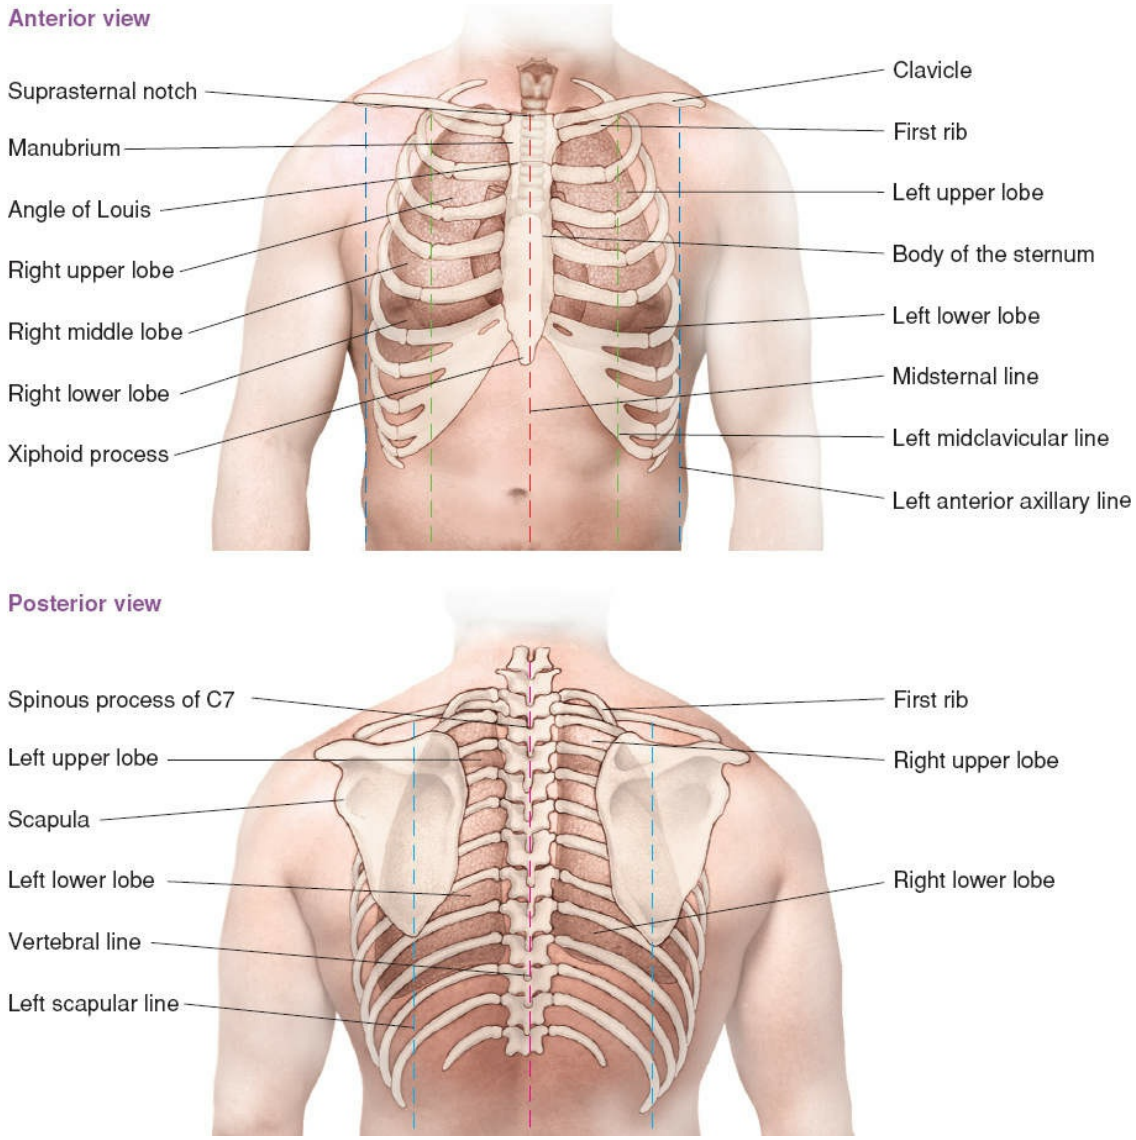

FIGURE 8-3 Landmarks in respiratory assessment.

Bronchi and Bronchioles

The bronchi begin at the carina. The right main bronchus, which provides air to the right lung, is wider, shorter (about 2.5 cm long), and more vertical in direction than the left main bronchus, which supplies the left lung. Because of the anatomical structure, aspiration of material tends to occur in the right lung. The mainstem bronchi divide into five lobar bronchi: three in the right lung and two in the left lung, to correspond with each respective lobe of the lung. The lobar bronchi enter the lung at the hilum (a fissure or opening) along with blood vessels, nerves, and lymphatics. The lobar bronchi branch into segmental bronchi (10 on the right and 8 on the left). They are the structures identified when choosing the most effective postural drainage position for a given patient. The segmental bronchi further subdivide until they branch into bronchioles. Bronchioles have no cartilage in their walls, thus patency depends entirely on the elastic recoil of the surrounding smooth muscle and on the alveolar pressure. The terminal bronchioles then become respiratory bronchioles that have actual alveolar sacs imbedded in their walls, so that gas exchange can occur. Up until this point, the exchange of O_2 and CO_2 has not occurred, thus it is termed

anatomical dead space and is calculated to be 150 mL.

There are characteristics common to most of the conducting airways: the production of mucus, the presence of serous glands that secrete a watery substance containing antibacterial enzymes, and the surfaces are covered with cilia. These cilia create a constant whipping motion that propels mucus and foreign substances away from the lungs toward the larynx, where the patient coughs out the substances.

Alveoli

The lung is made up of about 300 million alveoli (see Fig. 8-1), which are arranged in clusters of 15 to 20. There are three types of alveolar cells. Type I alveolar cells are epithelial cells that form the alveolar walls. Type II alveolar cells are metabolically active. These cells secrete surfactant, a phospholipid that decreases the surface tension in the alveoli and prevents their collapse. Stimulus for surfactant production is thought to be related to maximum deep inspiration sustained for a few seconds or sighing, in which a person's normal tidal volume (normal breath of approximately 500 mL) is increased one to three times what is normal. Type III alveolar cell macrophages are large phagocytic cells that ingest foreign matter (e.g., mucus, bacteria) and act as an important defense mechanism.

Pleura

The lungs and wall of the thorax are lined with a serous membrane called the pleura. The visceral pleura covers the lungs; the parietal pleura lines the thorax. Only the parietal pleura has fibers for pain transmission. The intrapleural space, which lies between these two layers, contains a small amount of pleural fluid (20 to 25 cc) that serves to provide a frictionless surface between the two pleura in response to changes in respiration. The intrapleural space is negative with the average resting interpleural pressure –4 cm H_2O, that is four centimeters of water, below that of atmospheric pressure at rest, and remains so during inspiration and expiration. Refer to Table 8-1 for pleural pressures.

Mediastinum

The mediastinum is in the middle of the thorax, between the pleural sacs. It contains the great vessels of the heart, the heart, esophagus, trachea, thoracic duct, thymus, and lymph nodes, as well as the vagus, cardiac, and phrenic nerves.

TABLE 8-1 Pressures: Atmospheric, Intrapulmonary, and Intrapleural

Pressure	At Rest	Inspiratory	Expiratory
Atmospheric	760	760	760
Intrapulmonary	760	757	763
Intrapleural	756	750	756

Lobes

Each lung is divided into lobes. The left lung consists of an upper and lower lobe, whereas the right lung has an upper, middle, and lower lobe (refer to Fig. 8-2). The upper lobes of the lungs rise 1 in above the inner one third of the clavicle, thus there is always a risk of a pneumothorax (air in the pleural space) when inserting venous catheters in the neck. The base of each lung (when in a neutral position) is at the sixth rib in the MCL, the eighth rib in the midaxillary line (MAL), and the tenth rib posteriorly at rest. With inspiration, the lungs can descend to the eighth rib in the MCL, tenth rib in the MAL, and twelfth rib at the vertebral border. Use Figure 8-3 to find the common landmarks used in respiratory assessment.

Thoracic Cage

The 12 ribs, costal cartilages (cartilages that connect the sternum and the ends of the ribs; termed the *costochondral junction*), manubrium, sternum, xiphoid process, and vertebral column provide the structure that supports and protects the lung. The notch on the top of the manubrium may be referred to as the *suprasternal notch, sternal notch,* or *jugular notch.* Seven ribs and their costal cartilages articulate directly to the body of the sternum, ribs 8 to 10 attach to cartilage of the seventh rib. Ribs 11 and 12 do not have an anterior attachment and are sometimes referred to as 'floating ribs'. Posteriorly, each rib attaches to a vertebra. An important landmark for nurses to use when counting ribs is the angle of Louis, which is where the manubrium (top of sternum, approximately 4 cm long) and the body of the sternum meet at the second rib. This area is also termed the manubriosternal junction and can be palpable as a transverse ridge in most patients. The second costal cartilages articulate with the sternum here at the angle of Louis; the ICS below the angle is the second ICS.

It is important to recognize that any disorder to the bony structure of the thorax affects the ability of the lungs to function. The costal angle (lower parts of the anterior rib cage near the xiphoid process) normally is about 90 degrees.

Respiratory Muscles

Ventilation requires movement of the walls of the thoracic cage and of its floor, the *diaphragm.* The diaphragm is a dome-shaped muscle that, when contracted (during inspiration), pulls the lungs in a downward and forward direction; the abdomen appears to enlarge because the abdominal contents are being compressed by the diaphragm. With inspiration, the diaphragmatic pull elongates the chest cavity, and the external intercostal muscles (located between and along the lower borders of the ribs) contract to raise the ribs, which expands the anteroposterior (AP) diameter. The effect of these movements is to decrease the intrapulmonary pressure (pressure within the lung) to less than atmospheric pressure, which causes air to rush into the lung (see Table 8-1). With expiration, the diaphragm and intercostals recoil, which increases the intrapulmonary pressure over atmospheric pressure so that gases are expelled from the lung. While inspiration is an active process, expiration is passive. In respiratory diseases, such as chronic obstructive pulmonary disease (COPD), the act of breathing becomes work requiring energy.

Additional accessory muscles of inspiration, including the scalene (elevates the first two ribs), sternocleidomastoid (raise the sternum), and the alae nasi (faring of nostrils), which may be called upon to assist with inspiration when exercising, while the abdominal and internal intercostal muscles may be used to increase expiration.

Nursing Alert
The diaphragm is innervated by the phrenic nerve, which exits the spinal column at the level of C3 to C5. Any fracture at or above this level will cause respiratory paralysis.

Neuroanatomy Related to Respiration

The rhythm of breathing is controlled by the medulla oblongata and pons. In addition, central chemoreceptors located in the medulla respond to changes in PCO_2 and pH levels in the cerebrospinal fluid and alter the depth and then the rate of ventilation to correct an imbalance. In addition, peripheral chemoreceptors are located in the aortic arch and the carotid arteries that respond first to changes in PaO_2 (less than 60 mm Hg) and then to $PaCO_2$ and pH by altering the depth and rate of respiration (Porth, 2015). These chemoreceptors no longer respond to $PaCO_2$ or pH in patients with COPD because of the persistently high levels of $PaCO_2$ that exist with this disorder, thus the primary drive to breathe comes from a low O_2 level rather than a high CO_2 level. If O_2 is administered at a high enough rate to raise the PaO_2 to normal, there is a risk of obliterating the hypoxic drive. Therefore low-flow O_2 is administered to a patient with COPD while the nurse carefully assesses for complications.

A final reflex to consider is the Hering–Breuer reflex that prevents overinflation of the lung. It is activated by stretch receptors located within the smooth muscle of large and small airways that inhibit further inspiration. Tidal volumes increased to approximately three times normal (greater than approximately 1,500 mL) are generally required to elicit this reflex in conscious, normally breathing adults (Hall, 2016a).

Function of the Respiratory System

The cells of the body require O_2. Certain vital tissues, such as the brain and the heart, cannot survive for long without a continuous supply. However, as a result of oxidation in the body tissues, CO_2 is produced and must be removed from the cells to prevent the buildup of acid waste products. The respiratory system performs this life-sustaining function of gas exchange.

Respiration

The process of respiration requires gas exchange both in the lungs, termed *external or pulmonary respiration,* and, ultimately, in the tissues, termed *internal or cellular respiration.* External respiration requires three processes: (1) *ventilation,* the act of breathing (inspiration and expiration); (2) *perfusion,* blood flow to the alveoli, so that gases can be exchanged; and (3) *diffusion,* movement of gases from a higher area of concentration to a lower area across the alveolar–capillary membrane. Systemic veins carry venous blood richer in CO_2 and poorer in O_2 than the systemic arteries to the pulmonary circulation. The O_2 concentration in blood within the capillaries of the lungs is lower than in the alveoli. Because of this concentration gradient, O_2 diffuses from the alveoli to the blood. Carbon dioxide, which has a higher concentration in the blood than in the alveoli, diffuses from the blood into the alveoli. The end result is O_2-rich blood leaving the pulmonary veins (the only veins other than the umbilical vein to carry oxygenated blood) to systemic circulation. Internal respiration refers to the process by which O_2 is supplied to, and CO_2 is removed from, the body cells by way of the circulating blood. Cells are in close contact with capillaries, the thin walls of which permit easy passage or exchange of O_2 and CO_2. Oxygen diffuses from the capillaries through the capillary walls to the interstitial fluid. At this point, O_2 diffuses through the membrane of tissue cells, where it is used by mitochondria for cellular respiration. The movement of CO_2 occurs by diffusion in the opposite direction—from cell to blood. These processes are critical for survival.

Ventilation

During inspiration, air flows from the environment into the trachea, bronchi, bronchioles, and alveoli. During expiration, alveolar gas travels the same route in reverse.

Physical factors that govern air flow in and out of the lungs are collectively referred to as the *mechanics of ventilation* and include air pressure variances, resistance to air flow (the narrower the airway, the greater the resistance to flow), and lung compliance (the dispensability of the lung, or how well the lung stretches).

Airway Resistance

Resistance is determined chiefly by the radius or size of the airway through which the air is flowing. Any process that changes the bronchial diameter or width affects airway resistance and alters the rate of air flow for a given pressure gradient during respiration (Box 8-1). With increased resistance, greater-than-normal respiratory effort is required to achieve

normal levels of ventilation.

BOX 8-1 Causes of Increased Airway Resistance

Common phenomena that may alter bronchial diameter, which affects airway resistance, include the following:

- Contraction of bronchial smooth muscle—as in asthma
- Thickening of bronchial mucosa—as in chronic bronchitis
- Obstruction of the airway—by mucus, a tumor, or a foreign body
- Loss of lung elasticity—as in emphysema, which is characterized by connective tissue encircling the airways, thereby keeping them open during both inspiration and expiration

Compliance

Compliance is a measure of the elasticity, expandability, and distensibility of the lungs and thoracic structures. Consider an elastic band: When it is stretched, it easily returns to its normal shape; so too should the lungs. Factors that determine lung compliance are the surface tension of the alveoli (normally low with the presence of surfactant) and the connective tissue (i.e., collagen and elastin) of the lungs.

Compliance is normal (1.0 L/cm H_2O) if the lungs and thorax easily stretch and distend when pressure is applied. High or increased compliance occurs if the lungs have lost their elasticity (cannot return to normal state) and the thorax is overdistended (i.e., in emphysema). Low or decreased compliance occurs if the lungs and thorax are "stiff" (difficult to stretch). Conditions associated with decreased compliance include pneumothorax, hemothorax, pleural effusion, pulmonary edema, atelectasis, pulmonary fibrosis, and acute respiratory distress syndrome (ARDS), all of which are discussed in later chapters in this unit.

Lung Volumes and Capacities

Lung function, which reflects the mechanics of ventilation, is viewed in terms of lung volumes and lung capacities. These terms are described in Table 8-2 and illustrated in Figure 8-4. Three common measurements that the medical-surgical nurse should understand are tidal volume, minute ventilation, and vital capacity. The volume of each breath is referred to as the *tidal volume* and can be measured by a bedside spirometer. If the patient is breathing through an endotracheal tube or tracheostomy, the spirometer is attached directly to it, and the exhaled volume is obtained from the reading on the gauge. In other patients, the spirometer is attached to a face mask or a mouthpiece positioned so that it is airtight, and the exhaled volume is measured.

The tidal volume may vary from breath to breath. To ensure that the measurement is reliable, it is important to measure the volumes of several breaths and to note the range of tidal volumes, together with the average tidal volume. But measurements like respiratory rates and tidal volume alone are unreliable indicators of adequate ventilation because both

can vary widely from breath to breath. However, together the tidal volume and respiratory rate are important because the minute ventilation is useful in detecting respiratory failure.

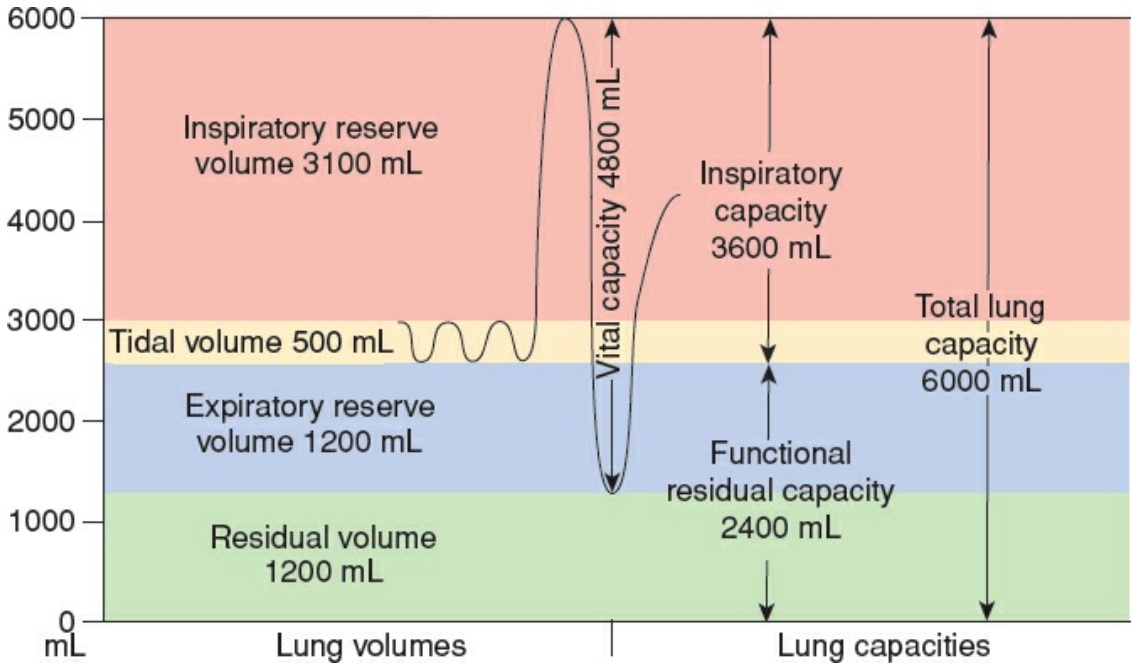

FIGURE 8-4 Spirometry recordings of respiratory volumes (*left*) and diagram of lung capacities (*right*). The tidal volume (TV, *yellow*) is the amount of air inhaled and exhaled during normal breathing; the inspiratory reserve volume (IRV, *pink*) is the maximal amount of air in excess of the tidal volume that can be forcefully inhaled; the maximal expiratory reserve (ERV, *blue*) is the maximal amount of air that can be exhaled in excess of tidal volume; and the residual volume (RV, *green*) is the air that continues to remain in the lung after maximal expiratory effort. The functional residual capacity (FRC) is the sum of the ERV and the RV. The vital capacity is the sum of IRV, TV, and ERV. (From Porth, C. M. (2015). *Essentials of pathophysiology* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

TABLE 8-2 Lung Volumes and Lung Capacities

Term	Symbol	Description	Normal Value[a]	Significance
Lung Volumes				
Tidal volume	VT or TV	The volume of air inhaled and exhaled with each breath	500 mL or 5–10 mL/kg	The tidal volume may not vary, even with severe disease.
Inspiratory reserve volume	IRV	The maximum volume of air that can be inhaled after a normal inhalation	3,100 mL	Inspiratory reserve volume is decreased in obstructive lung disorders.
Expiratory reserve volume	ERV	The maximum volume of air that can be exhaled forcibly after a normal exhalation	1,200 mL	Expiratory reserve volume is decreased with restrictive conditions, such as obesity, ascites, or pregnancy.
Residual volume	RV	The volume of air remaining in the lungs after a maximum exhalation	1,200 mL	Residual volume may be increased with obstructive disease.
Lung Capacities				
Vital capacity	VC	The maximum volume of air exhaled from the point of maximum inspiration VC = TV + IRV + ERV	4,800 mL	A decrease in vital capacity may be found in neuromuscular disease, generalized fatigue, atelectasis, pulmonary edema, and COPD.
Inspiratory capacity	IC	The maximum volume of air inhaled after normal expiration IC = TV + IRV	3,600 mL	A decrease in inspiratory capacity may indicate restrictive disease; may also be decreased in obesity.
Functional residual capacity	FRC	The volume of air remaining in the lungs after a normal expiration FRV = ERV + RV	2,400 mL	Functional residual capacity may be increased with COPD and decreased in ARDS.
Total lung capacity	TLC	The volume of air in the lungs after a maximum inspiration TLC = TV + IRV + ERV + RV	6,000 mL	Total lung capacity may be decreased with restrictive disease (atelectasis, pneumonia) and increased in COPD.

[a]Values for healthy men; women are 20–25% less.
ARDS, acute respiratory distress syndrome; COPD, chronic obstructed pulmonary disease.

Minute ventilation is the volume of air expired per minute. It is equal to the product of the tidal volume in liters multiplied by the respiratory rate or frequency. In practice, the minute ventilation is not calculated but is measured directly using a spirometer. Minute ventilation may be decreased by a variety of conditions that result in hypoventilation. When the minute ventilation falls, alveolar ventilation in the lungs also decreases, and the $PaCO_2$ increases.

Forced vital capacity requires having the patient take in a maximal breath and exhale fully and forcefully. Most patients can exhale at least 80% of their vital capacity in 1 second (forced expiratory volume in 1 second, or FEV_1) and almost all of it in 3 seconds (FEV_3). A reduction in FEV_1 (ability to get the air OUT of the lung) suggests abnormal pulmonary air flow. If the patient's FEV_1 and forced vital capacity are reduced proportionately, maximal lung expansion is restricted in some way. If the reduction in FEV_1 greatly exceeds the reduction in forced vital capacity, the patient may have some degree of airway obstruction. Often forced vital capacity is reduced in COPD because of air trapping, and a decreased FEV is a valuable clue to the severity of the expiratory airway obstruction.

Thus, pulmonary function tests (PFTs) can aid in diagnosing restrictive or obstructive pulmonary disorders. Restrictive disorders are ones that make the lungs stiff; they decrease the total volume of air the lungs can hold. This is typically due to a decrease in the elasticity of the lungs or the inability of the chest wall to expand during inhalation. Examples of restrictive lung diseases are asbestosis, sarcoidosis, and pulmonary fibrosis. Obstructive

disorders cause a narrowing or blockage in exhaled airflow and are commonly associated with COPD (discussed in Chapter 11).

Diffusion and Perfusion

Diffusion is the process by which O_2 and CO_2 are exchanged at the air–blood interface. The alveolar–capillary membrane is ideal for diffusion because of its thinness and large surface area. In the normal, healthy adult, O_2 and CO_2 travel across the alveolar–capillary membrane without difficulty as a result of differences in gas concentrations in the alveoli and capillaries.

Pulmonary perfusion is the actual blood flow through the pulmonary circulation. The blood is pumped into the lungs by the right ventricle (RV) through the pulmonary artery. The pulmonary artery divides into the right and left branches to supply both lungs. These two branches divide further to supply all parts of each lung. Normally, about 2% of the blood pumped by the RV does not perfuse the alveolar capillaries. This "shunted" blood drains into the left side of the heart without participating in alveolar gas exchange.

The pulmonary circulation is considered a low-pressure system because the systolic blood pressure in the pulmonary artery is 20 to 30 mm Hg and the diastolic pressure is 8 to 15 mm Hg. Because of these low pressures, the pulmonary vasculature normally can vary its capacity to accommodate the blood flow it receives. However, pulmonary blood flow is also not consistent. Regardless of body position, the lower (dependent) areas of the lung receive greater blood flow than upper (nondependent) areas (Butterworth, Mackey, & Wasnick, 2013). When a person is in an upright position, the pulmonary artery pressure is not great enough to supply blood to the apex of the lung against the force of gravity. Thus, when a person is upright, the lung may be considered to be divided into three sections: an upper part with poor blood supply, a lower part with maximal blood supply, and a section between the two with an intermediate supply of blood. When a person lying down turns to one side, more blood passes to the dependent lung. Thus, the nurse should consider that the dependent lung, regardless of position, is better perfused.

Perfusion is also influenced by alveolar pressure. The pulmonary capillaries are sandwiched between adjacent alveoli. If the alveolar pressure is sufficiently high, the capillaries are squeezed. Depending on the pressure, some capillaries completely collapse, whereas others only narrow.

Pulmonary artery pressure, gravity, and alveolar pressure determine the patterns of perfusion. In lung disease, these factors vary, and the perfusion of the lung may become very abnormal.

Ventilation and Perfusion Balance and Imbalance

Ventilation is the flow of gas in and out of the lungs (normally at a rate of 4 L/min), and perfusion is the filling of the pulmonary capillaries with blood (normally at a rate of 5 L/min). Thus, the alveolar (ventilation) to capillary (perfusion) ratio is 4:5 or 0.8. Adequate gas exchange depends on an adequate ventilation–perfusion ($\dot{V}/\dot{Q}$) ratio.

$\dot{V}/\dot{Q}$ imbalance occurs as a result of inadequate ventilation, inadequate perfusion, or both. There are four possible $\dot{V}/\dot{Q}$ states in the lung: normal $\dot{V}/\dot{Q}$ ratio, low $\dot{V}/\dot{Q}$ ratio (shunt), high $\dot{V}/\dot{Q}$ ratio (dead space), and absence of ventilation and perfusion (silent unit)

(Box 8-2).

Shunting is the term used to describe conditions in which ventilation is impaired and perfusion is adequate. Normal shunting is about 2%; severe hypoxia results when the amount of shunting exceeds 20%. This can occur secondary to airway obstruction from a variety of causes (mucus plug, atelectasis, infective process, tumor), where blood is bypassing the alveoli without gas exchange. Adequate ventilation but impaired perfusion (as in pulmonary emboli, which is a blood clot in pulmonary vessels) is termed *increased dead space.* In this situation, the alveolus has inadequate perfusion, and gas exchange does not occur. Both conditions result in hypoxia (low levels of cellular O_2). Supplemental O_2 is of use in conditions causing an increase in dead space, as long as the impaired perfusion is not massive; supplemental O_2 may not improve hypoxemia in shunting, however, as the O_2 does not come in contact with alveoli (areas of diffusion).

Physiology Alert

The nurse understands that with low O_2 saturation (especially when it falls below 70% of normal, i.e., below 73 mm Hg PO_2), the adjacent blood vessels constrict, with resulting increased vascular resistance. The lower the O_2 level, the higher the pulmonary vasoconstriction, which, in turn, causes strain on the RV. Recall the RV must push blood through this increased resistance, leading to RV strain. This effect is opposite *to the effect observed in systemic vessels, which dilate rather than constrict in response to low O_2 levels. Although not completely understood, it is thought low O_2 concentration may stimulate the release of vasoconstrictor substances or decrease release of a vasodilator, such as nitric oxide, from the lung tissue (Hall, 2016b).*

Concept Mastery Alert

When ventilation exceeds perfusion (exhibited by a pulmonary embolus), a dead space exists. A low ventilation–perfusion ratio (shunting) exists when ventilation is impaired and perfusion is adequate.

Gas Exchange

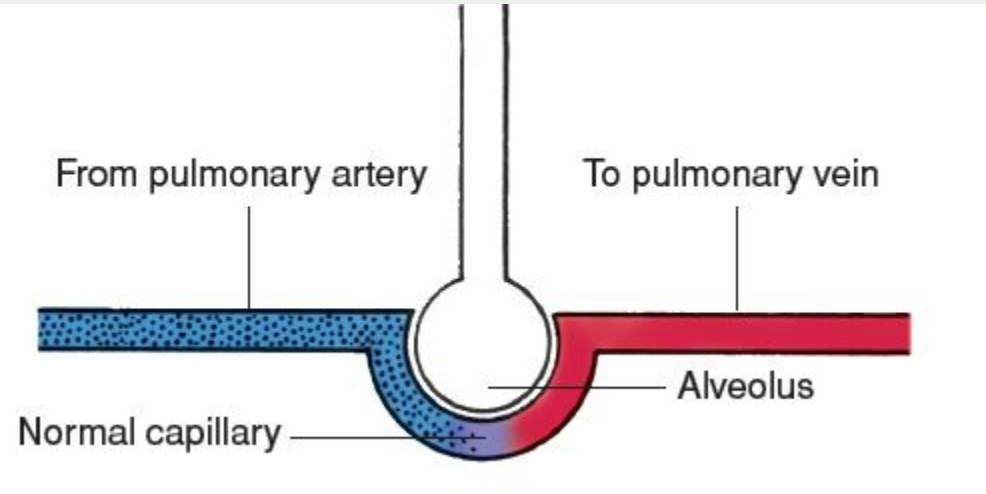
The air we breathe is a gaseous mixture consisting mainly of nitrogen (78.62%) and O_2 (20.84%), with traces of CO_2 (0.04%), water vapor (0.05%), helium, and argon.

Oxygen and CO_2 are transported simultaneously, dissolved in blood, or combined with some of the elements of blood. Oxygen is carried in the blood in two forms: first, as physically dissolved O_2 in the plasma, and second, in combination with the hemoglobin of the red blood cells. Each 100 mL of normal arterial blood carries 0.3 mL of O_2 physically dissolved in the plasma and 20 mL of O_2 in combination with hemoglobin. Thus, much more O_2 is normally transported in combination with hemoglobin (approximately 98%) than is physically dissolved in the blood (2%) (Porth, 2015). Hemoglobin is essential to supply sufficient O_2 to meet tissue demands. Figure 8-5 demonstrates differences in O_2 and CO_2 in venous, arterial, alveolus, and atmosphere.

BOX 8-2 Understanding Ventilation and Perfusion

Normal Ventilation and Perfusion

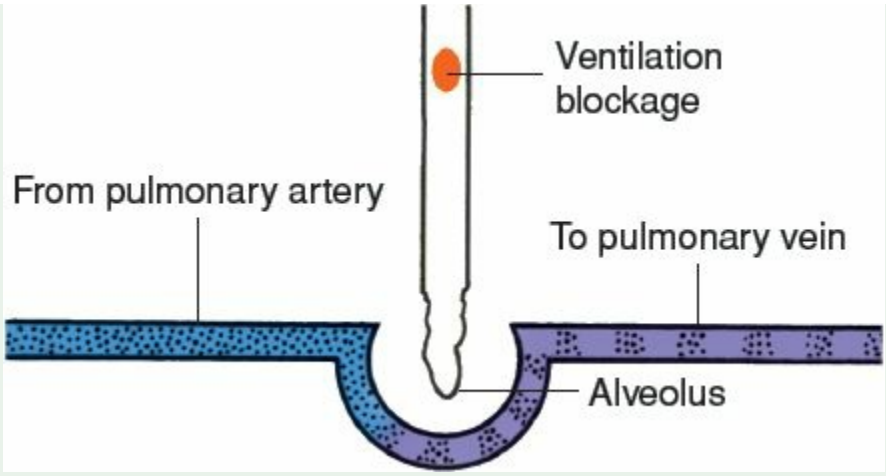
When ventilation and perfusion ($\dot{V}/\dot{Q}$) are matched, unoxygenated blood from the venous system returns to the right side of the heart through the pulmonary arteries to the lung, carrying carbon dioxide (CO_2). The arteries branch into alveolar capillaries. Gas exchange takes place in the alveolar capillaries. Normal ventilation is 4 L/min, and perfusion is normally at a rate of 5 L/min. Thus, the alveolar (ventilation) to capillary (perfusion) ratio is 4:5 or 0.8.



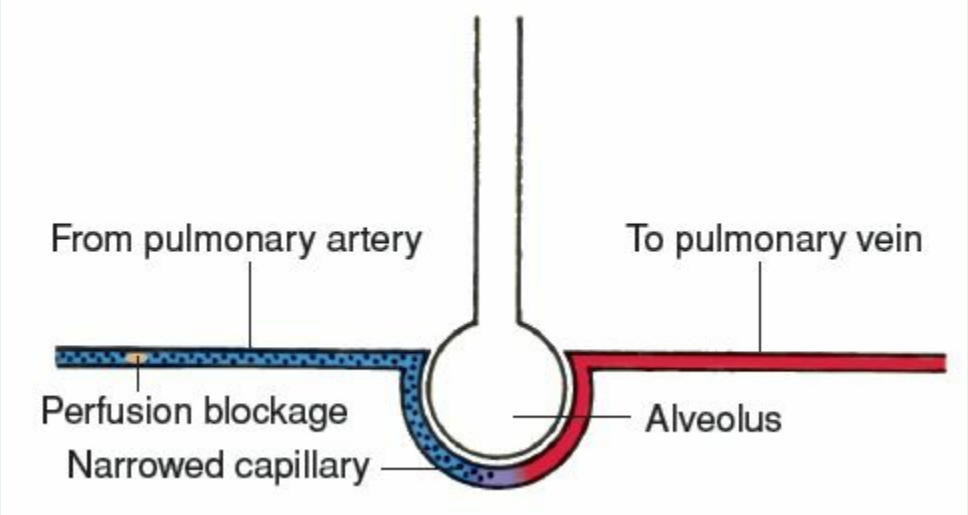
Ventilation and Perfusion Mismatch

Conditions that may produce a $\dot{V}/\dot{Q}$ mismatch include the following:

1. Shunting (reduced ventilation to a lung unit) causes unoxygenated blood to move from the right side of the heart to the left side and into systemic circulation; it may result from obstruction of the distal airways, such as with pneumonia, atelectasis, tumor, or a mucus plug. When the $\dot{V}/\dot{Q}$ ratio is low, pulmonary circulation is adequate, but not enough oxygen (O_2) is available to the alveoli for normal diffusion. To illustrate, assume the ventilation is now 2 L/min versus a perfusion of 5 L/min. The ratio is now 2:5 or reduced to 0.4. A portion of the blood flowing through the pulmonary vessels doesn't become oxygenated.

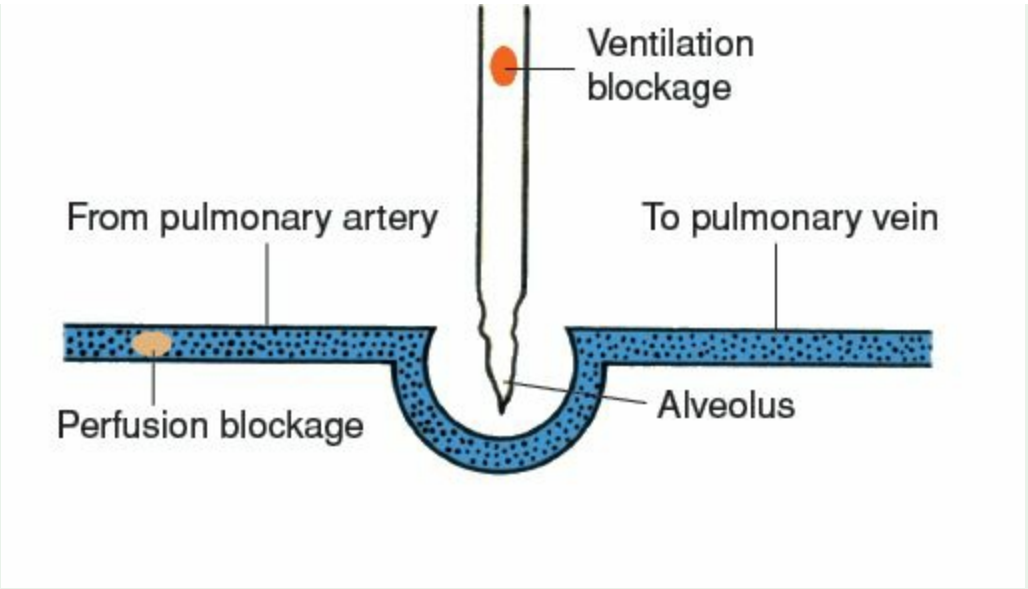


2. Dead-space ventilation (reduced perfusion to a lung unit) occurs when alveoli do not have adequate blood supply for gas exchange to occur, such as with pulmonary emboli (PE) and pulmonary infarction. When the $\dot{V}/\dot{Q}$ ratio is high, as shown here, ventilation is normal, but alveolar perfusion is reduced or absent. Note the narrowed capillary, indicating poor perfusion. This commonly occurs from a perfusion defect, such as PE, or a disorder that decreases cardiac output (cardiogenic shock). In this situation, assume the ventilation is normal at 4 L/min but perfusion is reduced to 3 L/min; thus, the ratio is 4:3 or increased to 1.3.



3. A silent unit (a combination of shunting and dead-space ventilation) occurs when little or no ventilation and perfusion are present, such as in acute respiratory distress syndrome.

The silent unit indicates an absence of ventilation and perfusion to the lung area.



Key to the figures: Blue, blood with CO_2; red, blood rich in O_2; purple, blood with CO_2 and O_2.

Adapted from Hemodynamic monitoring made incredibly visual. (2011). Philadelphia, PA: Lippincott Williams & Wilkins.

Nursing Alert

Hemoglobin rapidly combines reversibly with O_2 (half-time of 0.01 second or less); that is, it allows O_2 to be released quickly to the tissues to satisfy metabolic needs. Some hemoglobin exists in forms such as methemoglobin (commonly seen in drug reaction) or is combined with carbon monoxide (as in smoke inhalation), in which case the hemoglobin cannot bind O_2, resulting in tissue hypoxia and lactic acidosis. Thus, the nurse is aware that O_2 delivery to tissues is dependent upon hemoglobin, O_2 content, and cardiac output. While a healthy heart generally can increase cardiac output to compensate for diseased lungs or a low hemoglobin level, a diseased heart may be unable to. It is important for the nurse to consider that a combination of poor oxygenation, low hemoglobin level, and low cardiac output may be rapidly fatal.

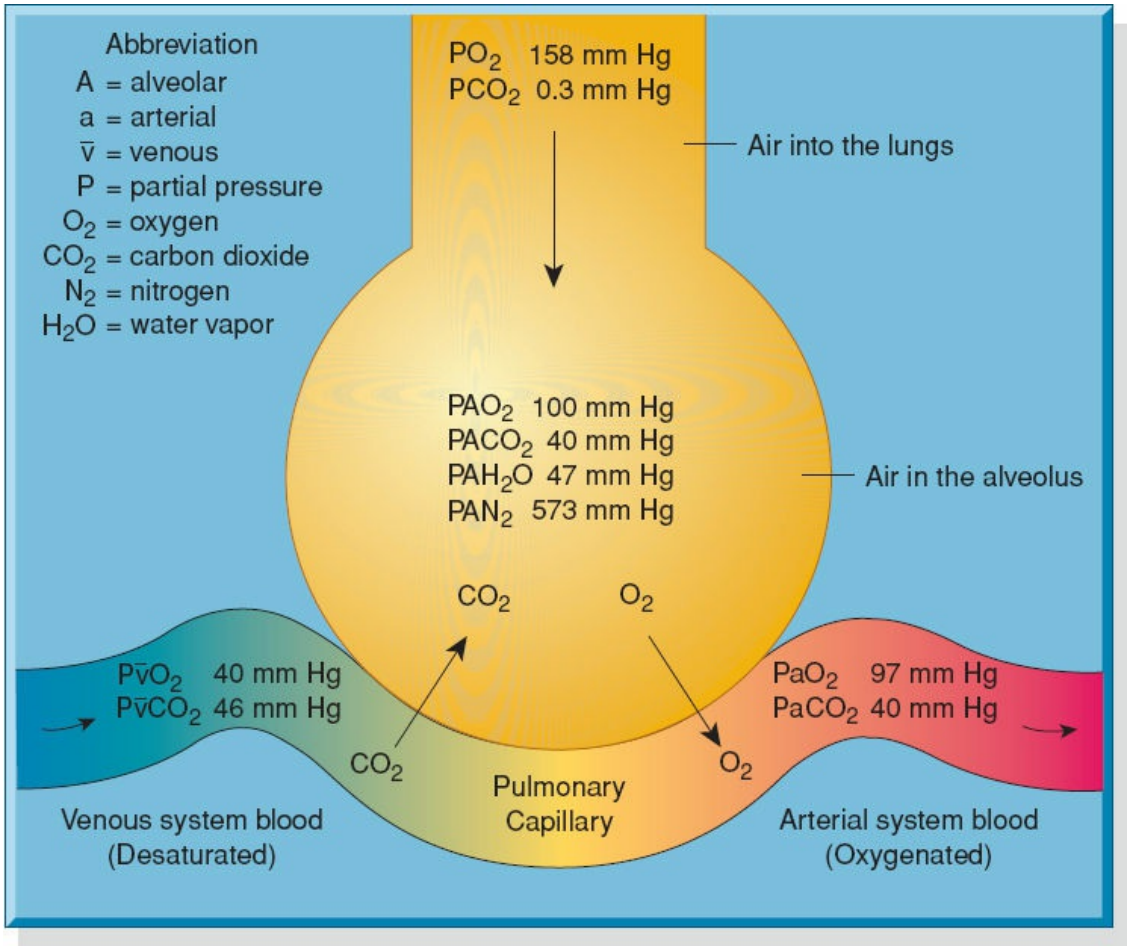


FIGURE 8-5 Changes occur in the partial pressure of gases during respiration. These values vary as a result of the exchange of O_2 and CO_2 as well as the changes that occur in their partial pressures as venous blood flows through the lungs.

Gerontologic Considerations

A gradual decline in respiratory function begins in early to middle adulthood and affects the structure and function of the respiratory system. With aging (age 40 years and above), changes occur in the alveoli that reduce the surface area available for the exchange of O_2 and CO_2. At approximately 50 years of age, the alveoli begin to lose elasticity. A decrease in vital capacity occurs with loss of chest wall mobility, which restricts the tidal flow of air. The amount of respiratory dead space increases with age. These changes result in a decreased diffusion capacity for O_2 with increasing age, producing lower O_2 levels in the arterial circulation. Also, there is degeneration of the bronchial epithelium and mucous glands, which increases the susceptibility to infections (Swartz, 2014a,b). Gerontologic changes in the respiratory system are summarized in Table 8-3.

ASSESSMENT OF THE RESPIRATORY SYSTEM

Health History

The health history focuses on the physical and functional problems of the patient and the effects of these problems on the patient, including his or her ability to carry out activities of daily living (ADLs).

Common Complaints

Common signs and symptoms of respiratory disease are dyspnea (shortness of breath [SOB]), cough, sputum production, chest pain, wheezing, clubbing of the fingers, hemoptysis (coughing up blood), and cyanosis. These clinical manifestations are related to the duration and severity of the disease. In addition to identifying the chief reason why the patient is seeking health care, the nurse tries to determine when the health problem or symptom started, how long it has lasted, if it was relieved at any time, and how relief was obtained. The nurse obtains information about precipitating factors, duration, severity, and any associated factors or symptoms.

Dyspnea

Dyspnea is the subjective experience of "shortness of breath" (Swartz, 2014b). Dyspnea (difficult or labored breathing, breathlessness, SOB) is a symptom common in life-threatening conditions such as pulmonary embolism (PE), pulmonary edema, acute airway obstruction from anaphylaxis or foreign bodies, pneumothorax, pneumonia, myocardial infarction, or cardiac tamponade. Chronic dyspnea (longer than 4 weeks in duration) is associated with COPD, asthma, interstitial lung disease, heart failure, cardiomyopathy, gastroesophageal reflux disease (GERD), or other respiratory diseases (Braithwaite & Perina, 2014; Kraft, 2016; Peters, 2013). It may also be associated with neurologic or neuromuscular disorders (i.e., myasthenia gravis, Guillain–Barré syndrome, muscular dystrophy), renal (failure, acidosis), hepatic (ascites), endocrine (hyperthyroidism), and hematologic (anemia, hemoglobinopathy) diseases that affect respiratory function or physical deconditioning. Dyspnea can also occur after physical exercise in people without disease (Porth, 2015). It is also a symptom at the end of life, associated with anxiety, depression, and fear in patients and helplessness in caregivers (Blinderman & Billings, 2015). If the patient is experiencing severe dyspnea, the nurse may need to modify or abbreviate the questions asked and the timing of the health history to avoid increasing the patient's breathlessness and anxiety.

TABLE 8-3 Age-Related Changes in the Respiratory System

Component	Structural Changes	Functional Changes	History and Physical Findings
Defense mechanisms (respiratory and nonrespiratory)	↓ Number of cilia and ↓ mucus; ↓ thirst response ↓ Cough and gag reflex Loss of surface area of the capillary membrane Lack of a uniform or consistent ventilation and/or blood flow	↓ Protection against foreign particles; may have less moisture within the mucous membranes of the upper and lower respiratory tracts ↓ Protection against aspiration ↓ Antibody response to antigens ↓ Response to hypoxia and hypercapnia (chemoreceptors)	Thickened mucus, cough reflex may be reduced ↑ Infection rate History of respiratory infections, COPD, pneumonia Risk factors: smoking, environmental exposure, TB exposure
Lung	↓ Size of airway ↑ Diameter of alveolar ducts ↑ Collagen of alveolar walls ↑ Thickness of alveolar membranes ↓ Elasticity of alveolar sacs	↑ Airway resistance ↑ Pulmonary compliance ↓ Expiratory flow rate ↓ Oxygen diffusion capacity ↑ Dead space Premature closure of airways ↑ Air trapping ↓ Expiratory flow rates Ventilation–perfusion mismatch ↓ Exercise capacity ↑ Anteroposterior (AP) diameter	Unchanged total lung capacity (TLC) ↑ Residual volume (RV) ↓ Inspiratory reserve volume (IRV) ↓ Expiratory reserve volume (ERV) ↓ Forced vital capacity (FVC) and vital capacity (VC) ↑ Functional residual capacity (FRC) ↓ PaO_2 ↑ CO_2
Chest wall and muscles	Calcification of intercostal cartilages Arthritis of costovertebral joints ↓ Continuity of diaphragm ↓ Muscle mass Muscle atrophy	↑ Rigidity and stiffness of thoracic cage ↓ Respiratory muscle strength ↑ Work of breathing ↓ Capacity for exercise ↓ Peripheral chemosensitivity ↑ Risk for inspiratory muscle fatigue	Barrel chest ↑ AP diameter Shortness of breath ↑ Abdominal and diaphragmatic breathing ↓ Maximum expiratory flow rates
Skeletal changes	↑ dorsal curve of the thoracic spine Osteoclastic activity is greater than osteoblastic activity.	↑AP/lateral chest diameter Enlargement of the cancellous bone spaces and a thinning of the trabeculae	Kyphosis; loss of height; ↑ AP/lateral chest diameter; skeletal changes also contribute to a decrease in vital capacity ↑ Risk of osteoporosis

↑, increased; ↓, decreased.

Clinical Significance. In general, acute diseases of the lungs produce a more severe grade of dyspnea than do chronic diseases. Sudden dyspnea in a healthy person may indicate pneumothorax (air in the pleural space), acute respiratory obstruction, or ARDS. In immobilized patients, sudden dyspnea may denote PE. *Orthopnea* (inability to breathe unless sitting or standing) may be found in patients with heart disease and occasionally in patients with COPD; dyspnea with an expiratory wheeze occurs with COPD. Noisy breathing may result from a narrowing of the airway or localized obstruction of a major bronchus by a tumor or foreign body. The presence of both inspiratory and expiratory wheezing usually signifies asthma if the patient does not have heart failure. Since dyspnea can occur with a variety of disorders, a thorough health history is essential.

The circumstance that produces the dyspnea must be determined; it is important to ask the patient the following questions:

- How much exertion triggers SOB?
- Is there an associated cough?
- Is the SOB related to other symptoms?
- Was the onset of SOB sudden or gradual?
- At what time of day or night does the SOB occur?
- Is the SOB worse when the patient is flat in bed?
- Does the SOB occur at rest? With exercise? Running? Climbing stairs?
- Is the SOB worse while walking? If so, when walking how far? How fast?

- How many level blocks can you walk without becoming short of breath?
- How many level blocks could you walk 6 months ago?
- What makes the SOB worse? What relieves it?

Other issues that are important in the assessment of dyspnea include the following: the patient's rating of the intensity of breathlessness, the effort required to breathe, and the severity of the breathlessness or dyspnea. Patients use a variety of terms and phrases to describe breathlessness, such as "can't get enough air," "hard to breath," "feeling tight," and the nurse needs to clarify what terms are most familiar to the patient and what these terms mean. Several scales are available to assess the severity of dyspnea, including visual analog scales similar to pain scales, where one side denotes no dyspnea and the extreme is maximal dyspnea. These scales can be used to assess changes in the severity of dyspnea over time (Porth, 2015). Box 8-3 illustrates one such scale.

Relief Measures. The management of dyspnea is aimed at identifying and correcting its cause. Relief of the symptom sometimes is achieved by placing the patient at rest with the head elevated (high Fowler position), encouraging the patient to lean forward with arms and upper body supported on a table (orthopneic position), and using pursed-lip breathing (i.e., breathing in through the mouth and exhaling slowly through pursed lips to facilitate exhalation of air). Using a handheld fan (blowing air across the nose and mouth) has demonstrated success in reducing the sensation of breathlessness (Booth, Chin, & Spathis, 2015), and, in some cases, administering O_2 may help (Box 8-4). Strategies that enable patients with chronic or persistent dyspnea to decrease or prevent breathlessness and to cope with it can lead to improved quality of life (Moriyama, Takeshita, Haruta, Hattori, & Ezenwaka, 2015). Medical and nursing intervention may include use of opioids (Blinderman & Billings, 2015), O_2 administration in patients with hypoxemia (low O_2 saturation), pulmonary rehabilitation programs (Kiongera & Houde, 2015), or treatment specific to the cause of the dyspnea (i.e., proton-pump inhibitors [PPIs] for GERD, or angiotensin-converting enzyme [ACE] inhibitor or an angiotensin II receptor blocker [ARB], and a beta blocker for heart failure [HF]). See Chapter 11 for interventions for COPD.

BOX 8-3 Grading Dyspnea

To assess dyspnea as objectively as possible, ask your patient to briefly describe how various activities affect his breathing. Then document his response using this grading system:

- *Grade 0:* Not troubled by breathlessness except with strenuous exercise
- *Grade 1:* Troubled by shortness of breath when hurrying on a level path or walking up a slight hill
- *Grade 2:* Walks more slowly on a level path because of breathlessness than do people of the same age or has to stop to breathe when walking on a level path at his own pace
- *Grade 3:* Stops to breathe after walking about 100 yards (91 m) on a level path

- *Grade 4:* Too breathless to leave the house or breathless when dressing or undressing

Cough

Although cough is a reflex that protects the lungs from the accumulation of secretions or the inhalation of foreign bodies, it can also be a symptom of a number of disorders of the pulmonary system, or it can be suppressed in other disorders. It is the most common reason for seeking heath care in the United States (Kraft, 2016).

Involuntary coughing can be initiated by a variety of nerve receptors in the oropharynx, larynx, and tracheobronchial tree that can be stimulated by irritation (airborne irritants such as smoke, smog, perfume, powders, or dust), excess secretions, or a foreign body. These signals are transmitted to the vagus nerve and to the cough center (medulla).

A persistent and frequent cough can be exhausting and have significant impact on the patient's lifestyle and sense of well-being. Coughs can be significant enough to cause incontinence, vomiting, rib fractures, pain, and syncope. They may indicate serious pulmonary disease, but they may be caused by a variety of other problems, including cardiac disease, medications (e.g., amiodarone, ACE inhibitors), smoking, postnasal drip, pertussis, and GERD (Kraft, 2016).

It is important to consider that the cough reflex may be impaired by weakness or paralysis of the respiratory or abdominal muscles. Risk factors include prolonged inactivity, surgery, the presence of an NG tube (may prevent closure of the glottis), or depressed function of the medullary centers in the brain (e.g., anesthesia, drugs that depress the cough center, brain disorders) predisposing the patient to pulmonary problems (Porth, 2015).

Clinical Significance. To help determine the cause of the cough, the nurse needs the patient to describe the characteristics of the cough. A dry, irritative cough is a feature of an upper respiratory tract infection of viral origin, or a side effect of ACE inhibitor therapy. Laryngotracheitis causes an irritative, high-pitched cough. Tracheal lesions produce a brassy cough. Pertussis has a characteristic long, strident inspiratory noise (a whoop) before the cough. A hacking cough may be suggestive of pneumonia. A severe or changing cough may indicate bronchogenic carcinoma. Pleuritic chest pain that accompanies coughing may indicate pleural or chest wall (musculoskeletal) involvement.

BOX 8-4 Nursing Research

Bridging the Gap to Evidence-Based Practice

Incentive spirometry (IS) for prevention of postoperative pulmonary complications in upper abdominal surgery

Nascimento, P., Módolo, N., Andrade, S., Guimarães, M., Braz, L., & Dib, R. (2014). *The Cochrane Database of Systemic Reviews.* 2:CD006058. Doi: 10.1002/14651858.CD006058.pub3.

Purpose

Since upper abdominal surgical procedures are associated with a high risk of

postoperative pulmonary complications, the authors assessed the effect of incentive spirometry compared to no therapy or physiotherapy, including coughing and deep breathing, on all-cause postoperative pulmonary complications and mortality in adult patients admitted to a hospital for upper abdominal surgery.

Design
Meta-analysis of 12 studies was originally proposed, however this was decreased to 8 studies because of problems with the methodologic quality of the included studies. A total of 1,160 participants are reported below.

Findings
Four trials (152 patients) compared the effects of IS with no respiratory treatment. No statistically significant difference between the participants receiving IS and those who had no respiratory treatment for clinical complications (relative risk [RR] 0.59, 95% confidence interval [CI] 0.30 to 1.18). Two trials (194 patients) compared incentive spirometry with deep breathing exercises (DBE). No statistically significant differences between the participants receiving IS and those receiving DBE in the meta-analysis for respiratory failure (RR 0.67, 95% CI 0.04 to 10.50). Two trials (946 patients) compared IS with other chest physiotherapy. No statistically significant differences between the participants receiving IS and those receiving physiotherapy in the risk of developing a pulmonary condition or the type of complication. There was no evidence that IS is effective in the prevention of pulmonary complications.

Nursing Implications
It is important for nurses to be aware of current research findings. In this study, the evidence suggests there is a lack of effectiveness of incentive spirometry for prevention of postoperative pulmonary complications in patients after upper abdominal surgery. However, this review underlines the urgent need to conduct well-designed trials in this field. It seems prudent that for patients who are at risk for pulmonary complications, nurses should continue to educate patients regarding the use of IS, encourage them to use it hourly, and consider the minimal cost and noninvasive nature of IS therapy. Finally, nurses should participate in research studies that evaluate the efficacy of IS in well-designed studies.

The time of coughing is also noted. Coughing at night may herald the onset of left-sided heart failure or bronchial asthma. A cough in the morning with sputum production may indicate bronchitis. A cough that worsens when the patient is supine suggests postnasal drip (sinusitis) or reflux (spill-over of gastric contents into the larynx). Coughing after food intake may indicate aspiration of material into the tracheobronchial tree. A cough of recent onset is usually from a viral or upper respiratory tract infection. Duration is also a factor; a cough is considered acute if present for less than 3 weeks, persistent if between 3 and 8 weeks, and chronic if greater than 8 weeks.

Nursing Alert
Coughs are not localized only to a pulmonary problem. For example, chronic cough is the only symptom in 75% of patients with GERD. Eight common conditions associated with 98% of cases of chronic cough are: postnasal drip; asthma; GERD; chronic bronchitis; eosinophilic bronchitis, bronchiectasis; use of ACE inhibitors, and postinfectious cough (Kraft, 2016).

Relief Measures. Treatment depends on the cause of the cough. Treatment may include cautious use of cough suppressants because, while they may relieve the cough, they do not address the etiology of the cough. Other treatments are antihistamines, decongestants, or nasal corticosteroids if the etiology of the cough is postnasal drip; or H_2-blockers or PPIs when cough is associated with GERD. If the cough is a result of irritation, smoking cessation strategies are indicated. Drinking warm beverages may relieve cough caused by throat irritation.

Sputum Production

A patient who coughs long enough almost invariably produces sputum. Sputum production is the reaction of the lungs to any constantly recurring irritant. It also may be associated with a nasal discharge. The amount of sputum a person produces daily varies widely with mean values of 200 mL to over 500 mL (Santini, Cavallesco, & Grossi, 2015). Sputum production is unnoticed and sputum is swallowed, thus any complaint of sputum needs to be investigated. To help quantify the amount of sputum production, patients are asked to describe the volume of sputum production in terms of teaspoon (~5 mL) to cupful (~240 mL); however, this is difficult to calculate because of how much sputum may have been swallowed by the patient.

Clinical Significance. The nature of the sputum is indicative of the causal condition. A profuse amount of purulent sputum (thick and yellow or green) is a common sign of bacterial infection, lung abscess, or bronchiectasis. A small amount of purulent sputum is associated with acute bronchitis, pneumonia during resolution, small tuberculous cavities, or lung abscess. Sputum that looks like currant jelly is associated with *Klebsiella pneumoniae* or *Streptococcus pneumoniae.* Purulent rust-colored sputum suggests *pneumococcal pneumonia.* Thin, mucoid sputum frequently results from viral bronchitis. A gradual increase of sputum over time may indicate the presence of chronic bronchitis or bronchiectasis. Pink-tinged mucoid sputum suggests a lung tumor. Expectorated blood-stained sputum tends to be a complaint of patients with bronchogenic carcinoma, PE, and TB (Raftery, Lim, & Ostor, 2014). Profuse, frothy, white or pink material, often welling up into the throat, may indicate pulmonary edema. Foul-smelling sputum and bad breath point to the presence of a lung abscess, bronchiectasis, or an infection caused by anaerobic organisms (LeBlond, Brown, Suneja, & Szot, 2015b). A musty odor may indicate pseudomonas infection (Alspach, 2013).

Relief Measures. If the sputum is too thick for the patient to expectorate, it is necessary to decrease the sputum's viscosity by increasing its water content through adequate hydration (drinking water) and inhalation of aerosolized solutions, which may be delivered by any

type of nebulizer.

Smoking is contraindicated with excessive sputum production because it interferes with ciliary action, increases bronchial secretions, causes inflammation and hyperplasia of the mucous membranes, and reduces production of surfactant. When a person stops smoking, sputum volume decreases and resistance to bronchial infections increases.

The patient's appetite may decrease because of the odor of the sputum or the taste it leaves in the mouth. The nurse encourages adequate oral hygiene and wise selection of food, measures that stimulate the appetite. Citrus juices at the beginning of the meal may increase palatability, because these juices cleanse the palate of the sputum taste.

Hemoptysis

Hemoptysis is a symptom of both pulmonary and cardiac disorders. The onset of hemoptysis is usually sudden, and it may be intermittent or continuous. Signs, which vary from blood-stained sputum to a large sudden hemorrhage, always merit investigation. Frank bloody sputum (obvious, visible presence of blood) may indicate a pulmonary emboli, bronchogenic carcinoma, or erosion of a bronchial artery by cavitary tuberculosis, whereas blood-stained sputum (streaks of blood) may indicate inflammation in the nose, nasopharynx, gums, larynx, or bronchi, or airway trauma from severe coughing (Kraft, 2016). The amount of blood produced is not always proportional to the seriousness of the cause. If the oropharynx is colonized with *Serratia marcescens*, a red-pigment–producing aerobic gram-negative rod, the sputum can also be red and be confused with hemoptysis (Kraft, p. 589).

Nursing Alert
Blood from the lung is usually bright red, frothy, and mixed with sputum. Initial symptoms include a tickling sensation in the throat, a salty taste, a burning or bubbling sensation in the chest, and perhaps chest pain, in which case the patient tends to splint the bleeding side. The term hemoptysis is reserved for the coughing up of blood arising from a pulmonary hemorrhage. This blood has an alkaline pH (greater than 7.0). If the hemorrhage is in the stomach, the blood is vomited (hematemesis) rather than coughed up. Blood that has been in contact with gastric juice is sometimes so dark that it is referred to as "coffee grounds." This blood generally has an acid pH.

Chest Pain

Chest pain or discomfort may be associated with pulmonary or cardiac disease. Chest pain associated with pulmonary conditions may be sharp, stabbing, and intermittent, or it may be dull, aching, and persistent. The pain usually is felt on the side where the pathologic process is located, but it may be referred elsewhere—for example, to the neck, back, or abdomen.

Clinical Significance. Chest pain may occur with pneumonia, PE with lung infarction, and pleurisy. It also may be a late symptom of bronchogenic carcinoma. In carcinoma, the pain may be dull and persistent because the cancer has invaded the chest wall, mediastinum, or spine.

Lung disease does not always cause thoracic pain because the lungs and the visceral

pleura lack sensory nerves and are insensitive to pain stimuli. However, the parietal pleura has a rich supply of sensory nerves that are stimulated by inflammation and stretching of the membrane. Pleuritic pain from irritation of the parietal pleura is sharp and seems to "catch" on inspiration; patients often describe it as "like the stabbing of a knife." The nurse assesses the quality, intensity, and radiation of pain and identifies and explores precipitating factors and their relationship to the patient's position. In addition, it is important to assess the relationship of pain to the inspiratory and expiratory phases of respiration.

Relief Measures. Analgesic medications may be effective in relieving chest pain, but care must be taken not to depress the respiratory center or a productive cough, if present. Nonsteroidal anti-inflammatory drugs (NSAIDs) achieve this goal and, therefore, are used for pleuritic pain. A regional anesthetic block may be performed to relieve extreme pain. Patients may be more comfortable when they lie on the affected side because this splints the chest wall, limits expansion and contraction of the lung, and reduces the friction between the injured or diseased pleura on that side. Pain associated with cough may be reduced manually by splinting the rib cage.

Wheezing

Wheezing is often the major finding in a patient with bronchoconstriction or airway narrowing. It is heard with or without a stethoscope, depending on its location. Wheezing is a high-pitched, musical sound heard mainly on expiration; however, it may be heard on both inspiration and expiration. Wheezing is associated with a variety of clinical conditions other than asthma. The nurse needs to assess for all possible etiologies (discussed later in this chapter). Oral or inhalant bronchodilator medications reverse wheezing in most instances.

Nursing Alert
If a patient has severe bronchospasm, there may be an absence of wheezing or gas movement. Thus a "quiet" chest is a "scary" chest.

Patient and Family History

The nurse also assesses for risk factors and genetics factors that may contribute to the patient's lung condition (Boxes 8-5 and 8-6).

Social History

The nurse inquires about current or past smoking and calculates pack/year history. This is calculated by the number of packs smoked per day times the number of years the patient has smoked. Thus, 2 packs per day times 20 years equals a 40 pack/year history.

The impact of signs and symptoms on the patient's ability to perform ADLs and to participate in usual work and family activities is assessed. Questions related to sleep–rest patterns should include asking about nocturnal dyspnea (waking up with SOB) or orthopnea as well as quantifying the number of pillows used at night. In addition, psychosocial factors that may affect the patient are explored. These factors include anxiety, role changes, family relationships, financial problems, employment status, and the strategies the patient uses to cope with them. It is also important to ask questions concerning

immunizations, medications, exposure to environmental hazards, use of O_2, hospitalizations, and medical and surgical history.

BOX 8-5 Risk Factors for Respiratory Disease

- Smoking (the single most important contributor to lung disease)
- Exposure to secondhand smoke
- Personal or family history of lung disease
- Genetic makeup
- Allergens and environmental pollutants
- Recreational and occupational exposure

BOX 8-6 Risk Factors for Hypoventilation

- Limited neurologic impulses transmitted from the brain to the respiratory muscles, as in spinal cord trauma, cerebrovascular accidents, tumors, myasthenia gravis, Guillain–Barré syndrome, polio, and drug overdose
- Depressed respiratory centers in the medulla, as with anesthesia, sedation, and drug overdose
- Limited thoracic movement (kyphoscoliosis), limited lung movement (pleural effusion, pneumothorax), or reduced functional lung tissue (chronic pulmonary diseases, severe pulmonary edema)

Many respiratory diseases are chronic and progressively debilitating and disabling. Therefore, ongoing assessment of the patient's physical abilities, psychosocial supports, and quality of life is needed to plan appropriate interventions. It is important that the patient with a respiratory disorder understand the condition and be familiar with necessary self-care interventions. The nurse evaluates these factors over time and provides education as needed.

Physical Assessment

Complete respiratory assessment includes assessment of the integument and upper and lower respiratory structures. The nurse also observes the work of breathing (e.g., nasal flaring, mouth breathing, use of accessory muscles, splinting, etc.).

Assessment of the Integumentary System

Respiratory conditions may have skin and nail manifestations.

Inspection of Color

Cyanosis, a bluish coloring of the skin, is a very late indicator of hypoxia. The presence or absence of cyanosis is determined by the amount of unoxygenated hemoglobin in the blood. Cyanosis appears when there is at least 5 g/dL of unoxygenated hemoglobin (normal hemoglobin is approximately 15 g/dL). Thus, a full one third of the hemoglobin is deoxygenated before cyanosis is observed. In addition, a patient with anemia rarely manifests cyanosis, and a patient with polycythemia may appear cyanotic even if adequately oxygenated. Thus, cyanosis is *not* a reliable sign of hypoxia.

Assessment of cyanosis is affected by room lighting, the patient's skin color, and the distance of the blood vessels from the surface of the skin. Central cyanosis (tongue and lips), often associated with clubbing of the fingers and toes, indicates inadequate oxygenation of blood, whereas peripheral cyanosis (nailbeds) results from vasoconstriction or diminished peripheral blood flow in the distal extremities from a variety of causes and does not necessarily indicate a central systemic problem. In addition, the two may coexist. In people of color, the nurse assesses for central cyanosis by examining for dull, dark color in the buccal mucosa (inside of the cheek) and hard palate (roof of the mouth).

Inspection for Clubbing of the Fingers

Clubbing of the fingers is found in patients with chronic hypoxic conditions, chronic lung and pleural infections, or malignancies of the lung and pleural. It is also associated with cyanotic congenital heart disease, infective endocarditis, and cirrhosis (Tosti, 2016). It is painless, usually bilateral, and may be reversed if the causative factor is removed (Usatine, Smith, Chumley, & Mayeaux, 2013). This finding may be manifested initially as sponginess of the nail bed and loss of the nail bed angle, resulting in a bulbous enlargement of the distal segments of the fingers and toes (see Chapter 51, Box 51-4).

Assessment of Upper Respiratory Structures

For a routine examination of the upper airway, only a simple light source, such as a penlight, is necessary.

Inspection and Palpation of Nose and Sinuses

The nurse inspects the external nose for lesions, asymmetry, or inflammation and then asks the patient to tilt the head backward. Gently pushing the tip of the nose upward, the nurse examines the internal structures of the nose, inspecting the mucosa and septum for color,

swelling, exudate, or bleeding. The nasal mucosa is normally redder than the oral mucosa. It may appear swollen and hyperemic if the patient has a common cold, but in allergic rhinitis, the mucosa appears pale and swollen. Most people have a slight degree of septal deviation, but actual displacement of the cartilage into either the right or left side of the nose may produce nasal obstruction. Such deviation usually causes no symptoms. Observation of nasal flaring and mouth breathing suggests respiratory distress. Next, the nurse may palpate the frontal and maxillary sinuses for tenderness, which suggests inflammation. Using the thumbs, gentle pressure is applied in an upward fashion at the supraorbital ridges (frontal sinuses) and in the cheek area adjacent to the nose (maxillary sinuses) (Fig. 8-6).

Inspection of Pharynx and Mouth

The mouth and pharynx are assessed by asking the patient to open the mouth wide and take a deep breath. Usually, this flattens the posterior tongue and briefly allows a full view of the anterior and posterior pillars, tonsils, uvula, and posterior pharynx (Fig. 8-7). These structures are inspected for color, symmetry, and evidence of exudate, ulceration, or enlargement. If a tongue blade is needed to depress the tongue to visualize the pharynx, it is pressed firmly down on the midpoint of the arched tongue to avoid a gagging reflex (Bickley, 2017).

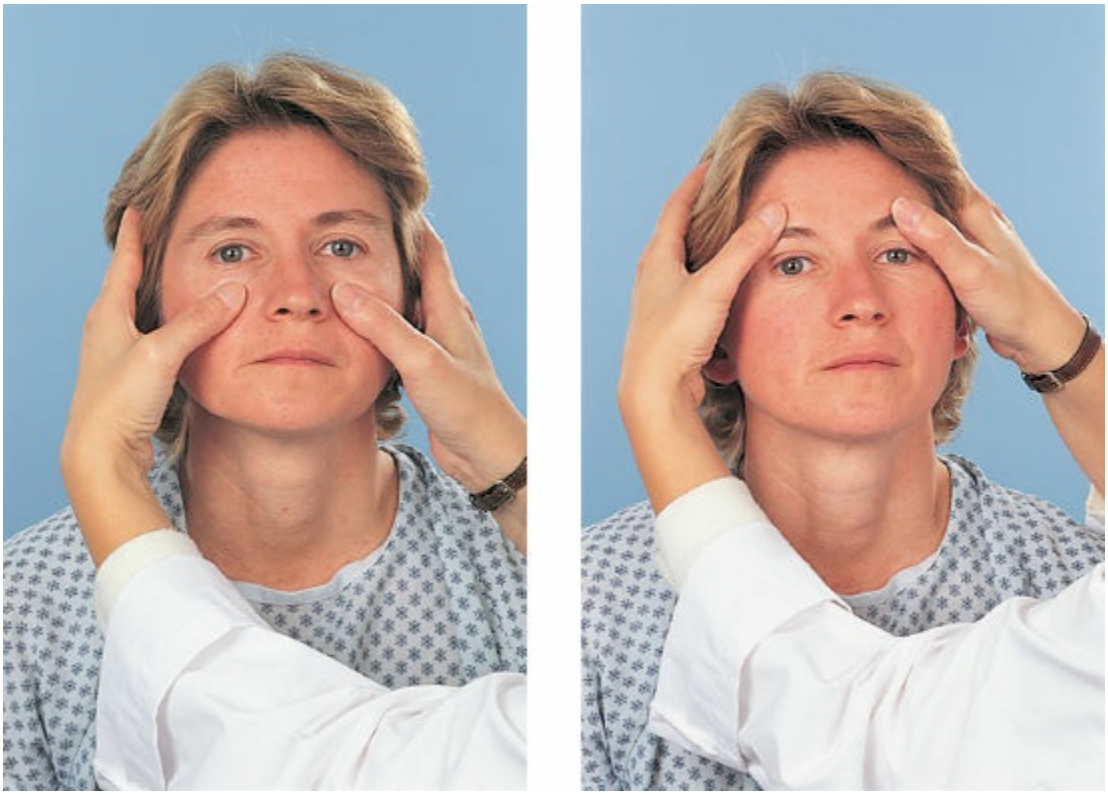

FIGURE 8-6 Technique for palpating the frontal sinuses at left and the maxillary sinuses at right.

Palpation of the Trachea

The position and mobility of the trachea are noted by placing the thumb and index finger of one hand on either side of the trachea just above the sternal notch. The trachea is highly sensitive, and palpating too firmly may trigger a coughing or gagging response. The trachea

is normally in the midline as it enters the thoracic inlet behind the sternum, but it may be deviated by masses in the neck or mediastinum. The trachea may deviate away from a life-threatening tension pneumothorax, and toward an atelectasis or fibrosis of the lung (Mootz & Matuschak, 2015).

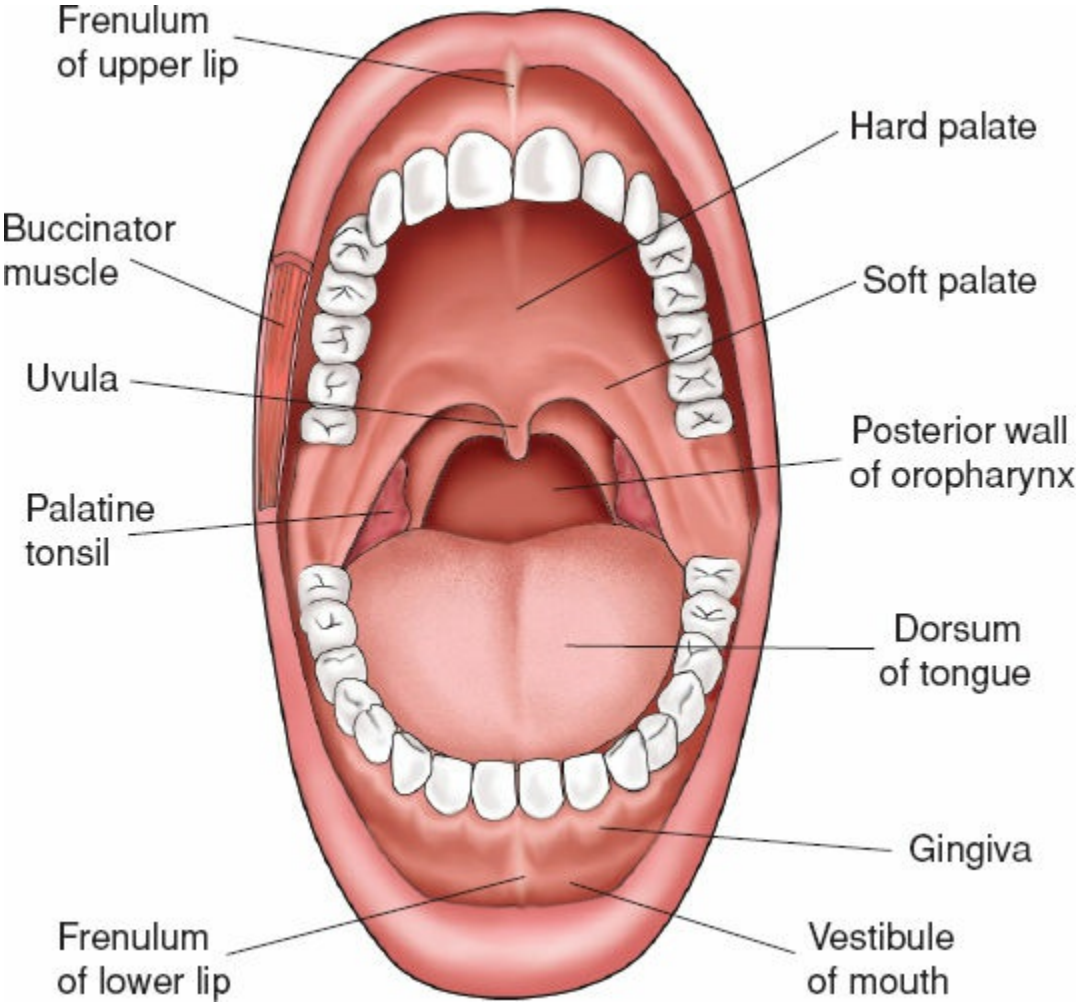

FIGURE 8-7 The pharynx and other oral structures—pillars, tonsils, uvula, hard and soft palates, posterior pharynx, and tongue—are easily seen when the mouth is open.

Physical Assessment of the Lower Respiratory Structures and Breathing

Lower respiratory assessment consists of four areas: inspection, palpation, percussion, and auscultation. The patient should be positioned upright, if possible, to assess the posterior thorax and lungs, and supine to assess the anterior chest and lung with chest exposed.

Thoracic Inspection

The nurse observes the skin over the thorax for color and turgor and for evidence of loss of subcutaneous tissue. In recording or reporting the findings, anatomic landmarks are used as points of reference (Box 8-7). Normally, there is symmetry in chest movement. It is important to note asymmetry, if present. In thin people, it is quite normal to note a slight retraction of the ICSs during quiet breathing. Bulging of the ICSs during expiration implies obstruction of expiratory airflow, as in emphysema. Marked retraction on

inspiration, particularly if asymmetric, implies blockage of a branch of the respiratory tree. Asymmetric bulging of the ICSs, on one side or the other, is created by an increase in pressure within the hemithorax. This may be a result of air trapped under pressure within the pleural cavity, where it is not normally present (pneumothorax), or the pressure of fluid within the pleural space (pleural effusion).

Nursing Alert
Frequently, patients with COPD are found to have cachexia and muscle dysfunction. These patients should be screened for malnutrition and referred to a nutrition practitioner when there is diminished nutritional intake or weight loss (Seres, 2015).

Chest Configuration. Normally, the ratio of the AP diameter to the lateral diameter is 1:2. However, four main deformities of the chest are associated with respiratory disease that alter this relationship: barrel chest, funnel chest (pectus excavatum), pigeon chest (pectus carinatum), and kyphoscoliosis (see Fig. 8-8).

Barrel chest occurs as a result of lung hyperinflation, as in emphysema. There is an increase in the AP diameter of the thorax so that it approximates a 1:1 ratio. In a patient with emphysema, note the costal angle will also be greater than 90 degrees.

Funnel chest or pectus excavatum is a common developmental deformity where there is a depression in the lower portion of the sternum, so that the sternum appears "bowl-like," and the ratio may be less than 1:2. It may be symmetrical or asymmetrical to the midline of the sternum. Refer to a pediatric resource for further details. Most patients are asymptomatic but may have mild restriction on PFTs (Tzelepis & Dennis McCool, 2015) and decreased thoracic volume with aging; thus, medical-surgical nurses should assess these patients' pulmonary function thoroughly and encourage the use of the incentive spirometer (IS).

Pectus carinatum is also a congenital structural abnormality in which the sternum is displaced anteriorly, increasing the AP diameter. For some patients, this deformity is associated with a rigid chest wall in which the AP diameter is almost fixed in full inspiration. In these patients, respiratory efforts are less efficient, and use of IS should be encouraged.

A *kyphoscoliosis* is characterized by elevation of the scapula and a corresponding S-shaped spine. This deformity limits lung expansion within the thorax. It may occur with osteoporosis and other skeletal disorders that affect the thorax.

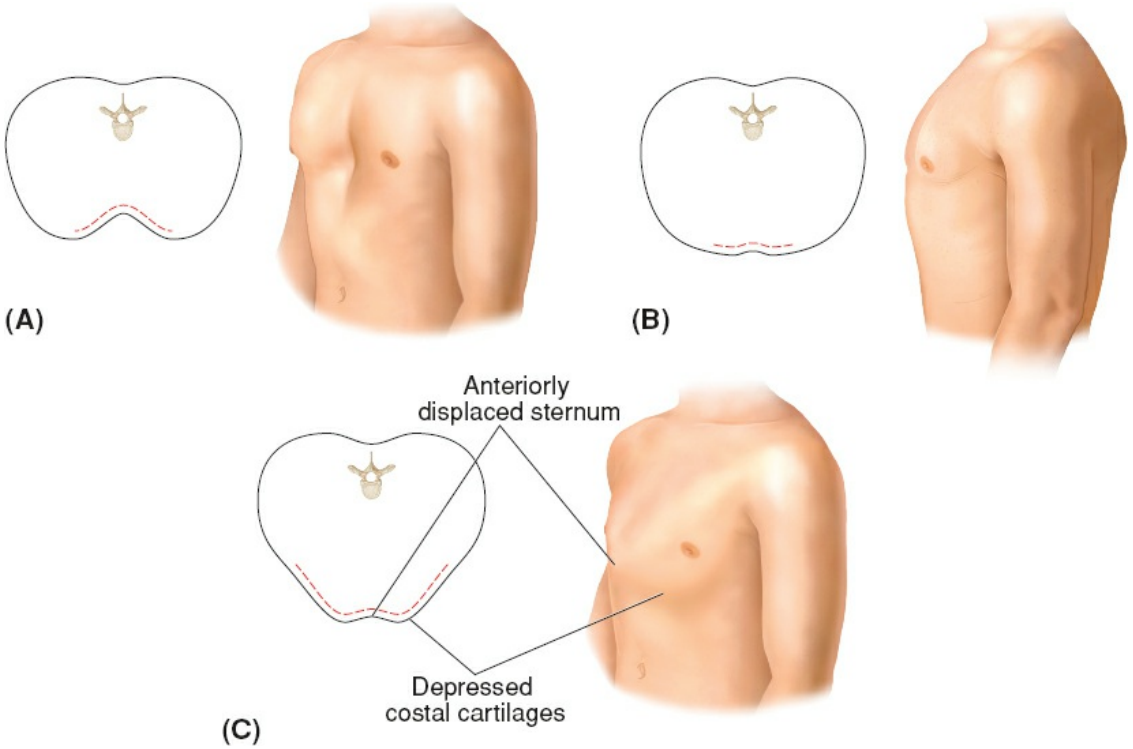

FIGURE 8-8 Deformities of the thoracic wall. (A) Funnel chest (pectus excavatum); (B) Barrel chest; (C) Pigeon chest (pectus carinatum).

BOX 8-7 Locating Thoracic Landmarks

With respect to the thorax, location is defined both horizontally and vertically. With respect to the lungs, location is defined by lobe.

Horizontal Reference Points

Horizontally, thoracic locations are identified according to their proximity to the rib or the intercostal space under the examiner's fingers. On the anterior surface, identification of a specific rib is facilitated by first locating the angle of Louis. This is where the manubrium joins the body of the sternum in the midline. The second rib joins the sternum at this prominent landmark.

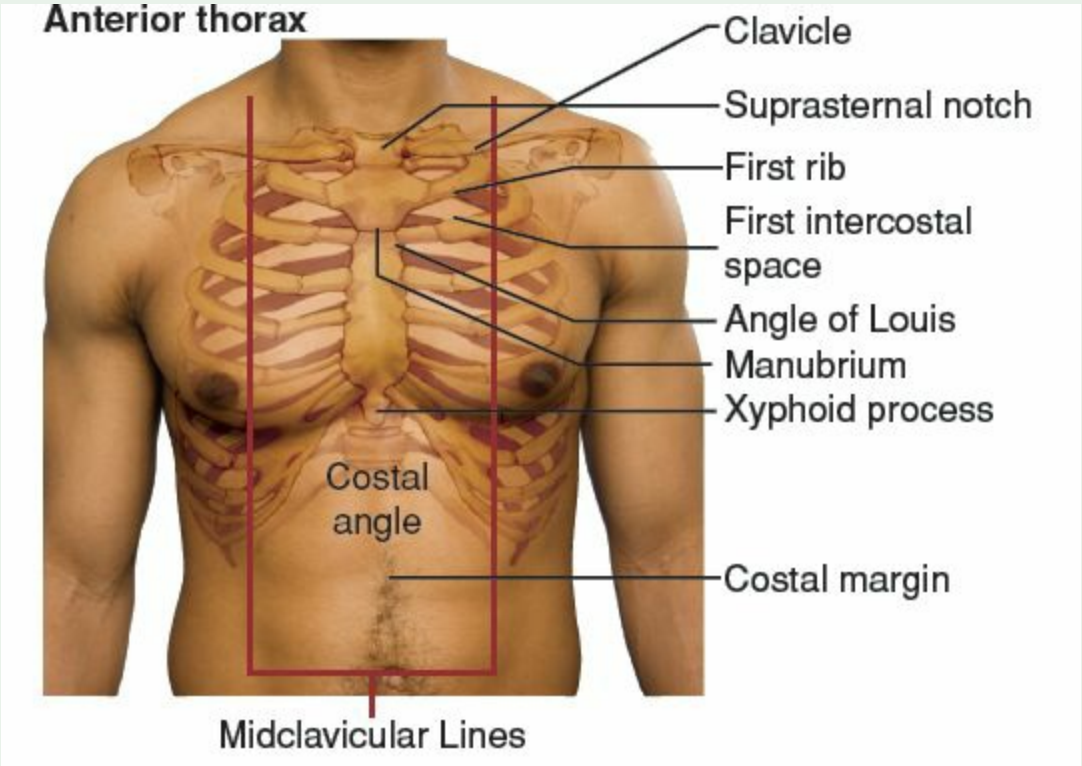
Other ribs may be identified by counting down from the second rib. The intercostal spaces are referred to in terms of the rib immediately above the intercostal space; for example, the fifth intercostal space is directly below the fifth rib.

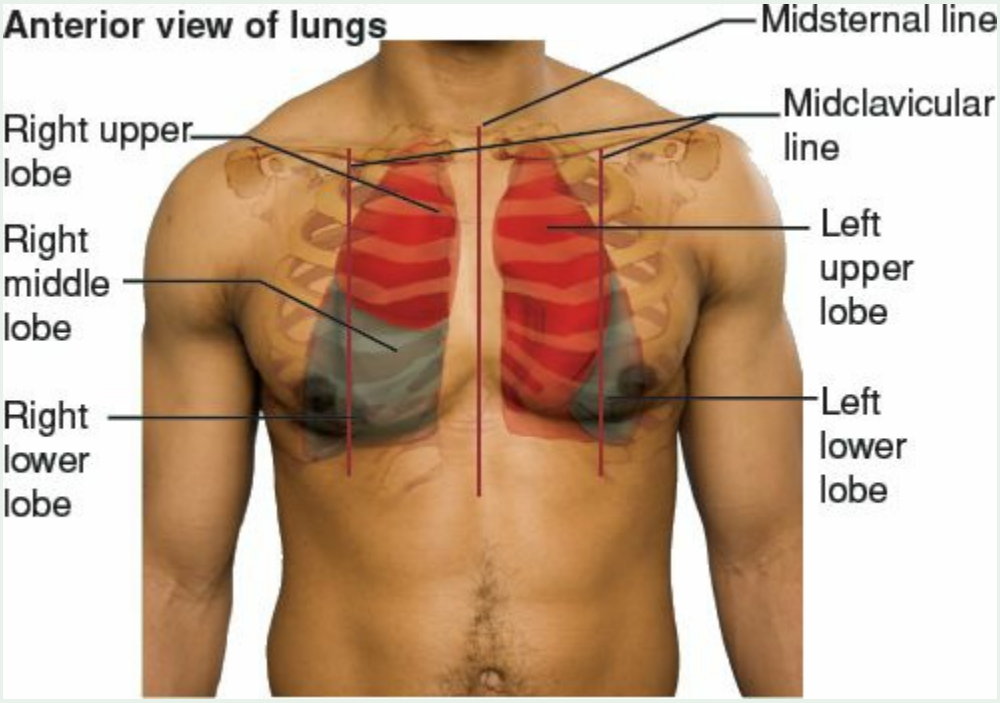
Locating ribs on the posterior surface of the thorax is more difficult. The first step is to identify the spinous process. This is accomplished by finding the seventh cervical vertebra (*vertebra prominens*), which is the most prominent spinous process. When the neck is slightly flexed, the seventh cervical spinous process stands out. Other vertebrae are then identified by counting downward.

Vertical Reference Points

Several imaginary lines are used as vertical referents or landmarks to identify the

location of thoracic findings. The *midsternal line* passes through the center of the sternum. The *midclavicular line* is an imaginary line that descends from the middle of the clavicle. The *point of maximal impulse* of the heart normally lies medial to this line on the left thorax.



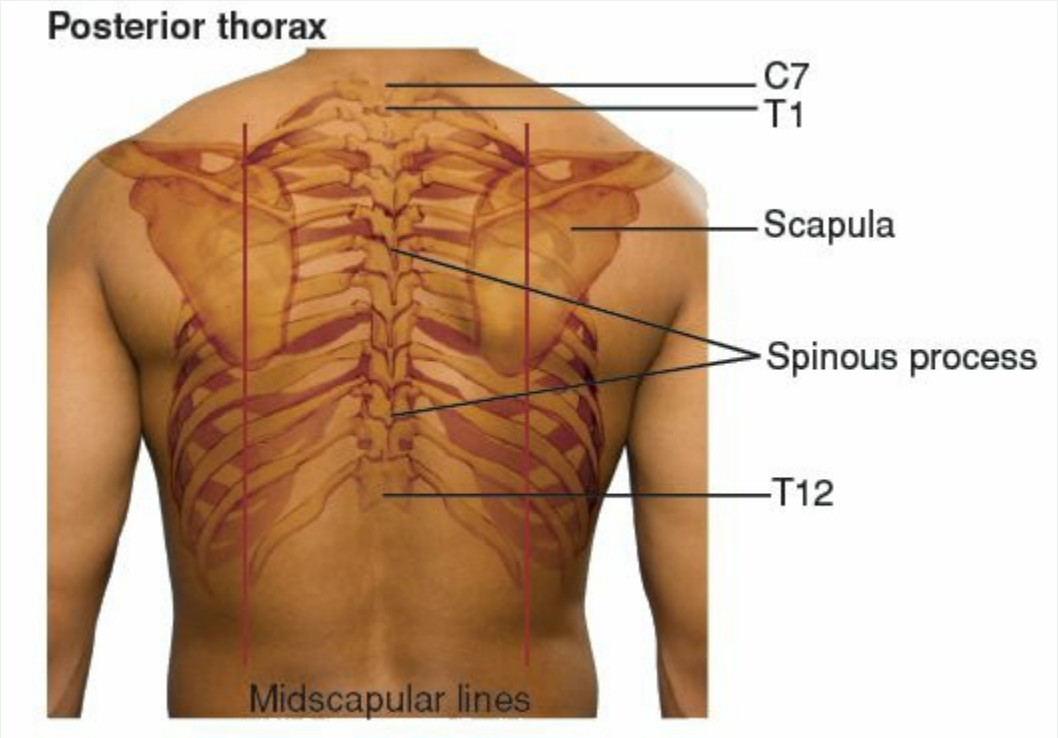


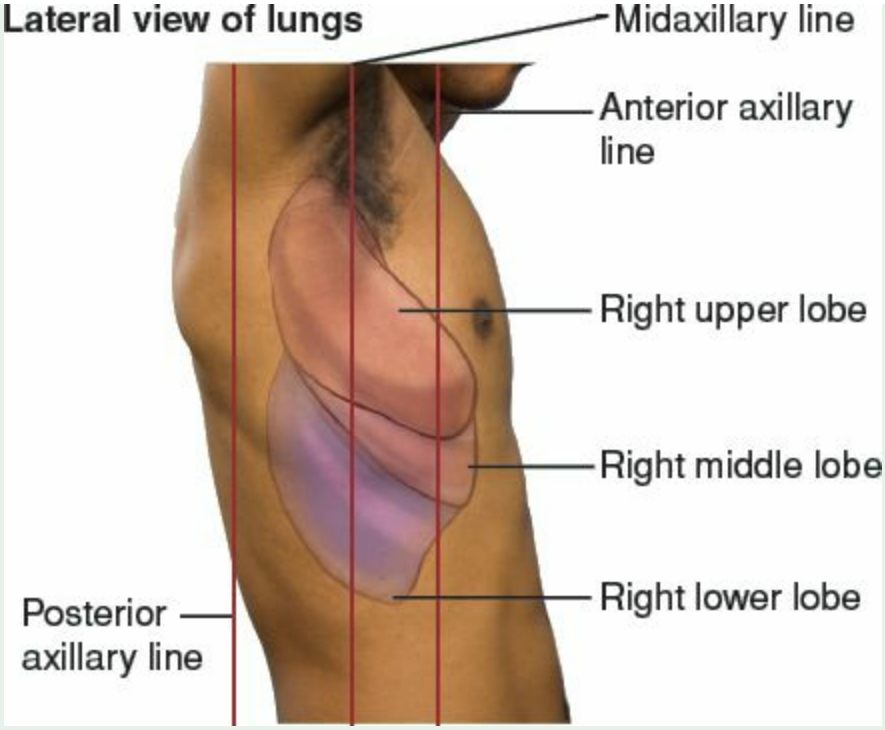
When the arm is abducted from the body at 90 degrees, imaginary vertical lines may be drawn from the anterior axillary fold, from the middle of the axilla, and from the

posterior axillary fold. These lines are called, respectively, the *anterior axillary line,* the *midaxillary line,* and the *posterior axillary line.* A line drawn vertically through the superior and inferior poles of the scapula is called the *scapular line,* and a line drawn down the center of the vertebral column is called the *vertebral line.* Using these landmarks, for example, the nurse communicates findings by referring to an area of dullness extending from the vertebral to the scapular line between the seventh and tenth ribs on the right.

Lobes of the Lungs

The lobes of the lung may be mapped on the surface of the chest wall in the following manner. The fissure that divides the right and left lung into upper and lower lobes posteriorly is termed the oblique fissure. It begins at T3 (spinous process) and obliquely to sixth rib in the midclavicular line (MCL) bilaterally. The right lung is further divided anteriorly by the horizontal fissure, which runs close to the fourth rib at the sternal border (SB) to the fifth rib in the midaxillary line (MAL). There is no presentation of the right middle lobe on the posterior surface of the chest.





In addition, the nurse notes the presence of paradoxical chest movements known as a *flail chest*, which occurs with multiple ipsilateral (same side) rib fractures. In this condition, asymmetrical chest movements are observed; during inspiration, the unstable chest wall collapses inward and then bulges outward with expiration. It is associated with respiratory distress and crepitus (see later discussion). The nurse is aware that early intubation and ventilatory assistance in patients with flail chest reduce mortality compared with delaying intubation until the onset of respiratory failure (Jones, Nelson, & Ma, 2016).

Breathing Patterns and Respiratory Rates. Observing the rate and depth of respiration is a simple but important aspect of assessment. The normal adult who is resting comfortably takes 12 to 20 breaths per minute. Except for occasional sighs, respirations are regular in depth and rhythm. This normal pattern is described as *eupnea.*

Certain patterns of respiration are characteristic of specific disease states. Respiratory rhythms and their deviation from normal are important observations that the nurse reports and documents. The rates and depths of various patterns of respiration are presented in Table 8-4.

Nursing Alert
One should not rely on only visual inspection of the rate and depth of a patient's respiratory excursions to determine the adequacy of ventilation. Respiratory excursions may appear normal or exaggerated due to an increased work of breathing, but actually the patient may be moving only enough air to ventilate the dead space. If there is any question regarding adequacy of ventilation, auscultation or pulse oximetry (or both) should be used for additional assessment of respiratory status.

Thoracic Palpation

The nurse palpates the thorax for tenderness, masses, lesions, respiratory excursion, vocal fremitus, and crepitus.

Respiratory Excursion. Respiratory excursion is an estimation of thoracic range and expansion and may disclose significant information about thoracic movement during breathing. The patient is instructed to inhale deeply while the movement of the nurse's thumbs is observed (placed along the costal margin on the anterior chest wall) during inspiration and expiration. This movement is normally symmetric.

Posterior assessment is performed by placing the thumbs adjacent to the spinal column at the level of the tenth rib (Fig. 8-9). The hands lightly grasp the lateral rib cage. Sliding the thumbs medially about 2.5 cm (1 in) raises a small skinfold between the thumbs. The patient is instructed to take a full inspiration and to exhale fully. The nurse observes for normal flattening of the skinfold and feels the symmetric movement of the thorax.

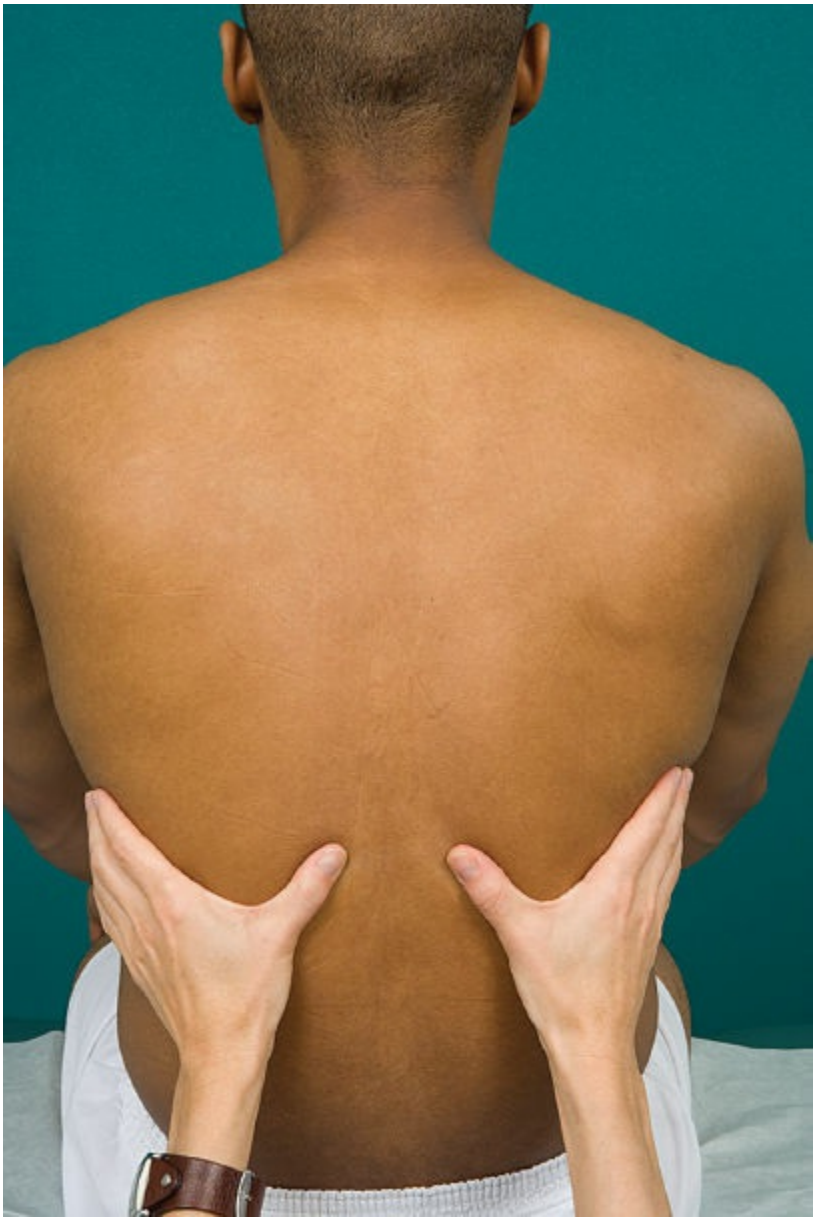


FIGURE 8-9 Method for assessing posterior respiratory excursion. Place both hands posteriorly at the level of T9 or T10. Slide hands medially to pinch a small amount of skin between your thumbs. Observe for symmetry as the patient exhales fully following a deep inspiration.

Asymmetric excursion may be due to a problem in the underlying chest wall, pleura, or lung; causes include pain (fractured ribs, trauma, splinting secondary to pleurisy or incisional pain), fibrosis, consolidation (lobar pneumonia), pleural effusion, or unilateral bronchial obstruction (Bickley, 2013). Equal but diminished expansion is seen in neurologic disease and emphysema.

Tactile Fremitus. The detection of palpable sound vibration transmitted to the chest wall as the patient speaks is called *tactile fremitus.* Normal fremitus is widely varied. It is influenced by thickness of the chest wall, especially with an increase in subcutaneous tissue associated with obesity, and pitch (lower-pitched sounds travel better and produce greater vibration of the chest wall). Fremitus is most pronounced in the second ICS lateral to the sternum and medial to the scapula, the level of the bronchus. Therefore, it is most palpable in the upper thorax, anteriorly and posteriorly.

The patient is asked to repeat "99" or "1, 2, 3" as the nurse's hands move down the patient's thorax comparing vibrations from similar areas (Fig. 8-10). Some clinicians test for fremitus using both hands simultaneously to compare the two sides, whereas others prefer a systematic survey of the chest wall with one hand. The vibrations are detected with the palmar surfaces of the fingers and hands, or the ulnar aspect of the extended hands, on the thorax. Bony areas are not tested.

TABLE 8-4 Rates and Depths of Respiration

	Definition
Eupnea 	Normal, breathing at 12–20 breaths/min
Bradypnea 	Slower than normal rate (<10 breaths/min), with normal depth and regular rhythm; associated with increased intracranial pressure, brain injury, CNS depressants (e.g., opiates, benzodiazepines, barbiturates, alcohol), and drug overdose
Tachypnea 	Rapid, shallow breathing >24 breaths/min; commonly seen in patients with a number of causes including metabolic acidosis, septicemia, severe pain, and rib fracture
Hypoventilation 	Decreased depth of breathing; associated with decreased medullary respiratory center drive, weakness of the respiratory muscles from a variety of neurologic disorders (e.g., myasthenia gravis, amyotrophic lateral sclerosis, Guillain–Barré)
Hyperventilation 	Increased rate and depth of breathing (called *Kussmaul respiration* if caused by diabetic ketoacidosis); associated with severe acidosis of diabetic or renal origin and hypoxemia
Apnea 	Period of cessation of breathing. Time duration varies; apnea may occur briefly during other breathing disorders, such as with sleep apnea. Life-threatening if sustained.
Cheyne–Stokes 	Regular cycle in which the rate and depth of breathing increase and then decrease until apnea (usually about 20 seconds) occurs. It may be seen during the sleep of normal children and the aged, also associated with heart failure and damage to the respiratory center (drug-induced, tumor, trauma).
Biot respiration 	Periods of normal breathing (3–4 breaths) followed by a varying period of apnea (usually 10–60 seconds). Uncommon, but associated with some central nervous system disorders, meningitis.

Air does not conduct sound well, but a solid substance such as a tumor, or fluid that increases the density of the lung, such as occurs in pneumonia, does. Therefore, an increase in solid tissue of the normally air-filled lung enhances fremitus, and an increase in air of the lung impedes sound. Patients with emphysema, which results in trapping of air, exhibit almost no tactile fremitus. A patient with consolidation of a lobe of the lung from pneumonia has increased tactile fremitus over that lobe. Air in the pleural space does not conduct sound; thus, a pneumothorax will have absent fremitus (Bickley, 2013). In the case of pleural effusion, decreased fremitus is noted at the effusion; however, the lung above the effusion may reveal increased fremitus as the fluid has increased the density of the lung.

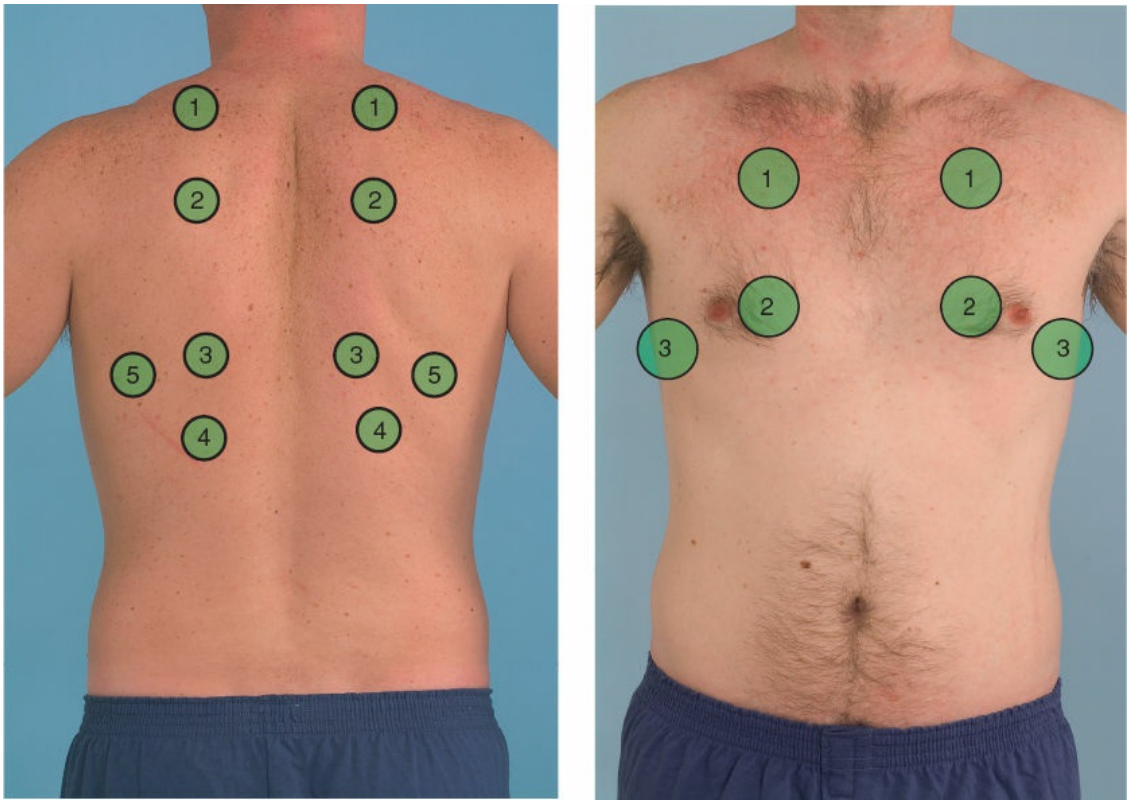

FIGURE 8-10 The palpation sequence for tactile fremitus.

Crepitus. Crepitus or subcutaneous emphysema is indicated by the presence of air bubbles in the subcutaneous tissues or underlying muscle; upon palpation, the sensation of bubbles under the fingers can be felt and, occasionally, crackling can be heard. Crepitus is not painful. The gas bubbles move with palpation. It is associated with pneumothorax, trauma (e.g., fractured rib piercing the lung), surgical wounds, or gas gangrene.

Thoracic Percussion

Percussion sets the chest wall and underlying structures in motion, producing audible and tactile vibrations. It helps to determine whether underlying tissues are filled with air, fluid, or solid material and is used to estimate diaphragmatic excursion. If possible, the patient is positioned in a sitting position with the head flexed forward and the arms crossed in front of the chest touching the patient's shoulders, which exposes more lung area for assessment by separating the scapulae widely. The nurse maintains a position to the side of the patient in order to comfortably and firmly hyperextend the middle finger of the nondominant hand (pleximeter finger) in the ICSs, being careful to avoid contact with any other finger on the chest wall as sound will be dampened. Bony structures (scapulae or ribs) are not percussed. While the middle finger is positioned firmly against the chest wall in the ICS, the middle finger of the opposite hand strikes the pleximeter finger in a quick and sharp manner. The striking finger aims for the distal interphalangeal joint (below the nail and above the distal joint). The term to describe the sound heard over a normal lung is resonant. Normally dullness is heard over bone, thus if this sound is noted over lung tissue, it is associated with consolidation, such as from pneumonia or a tumor. Hyperresonant sounds, which are louder and lower-pitched sounds, are associated with COPD or pneumothorax. It takes practice to develop comfort striking the finger with a quick, sharp

but relaxed wrist motion and training to distinguish dullness, resonance, and hyperresonance (Bickley, 2013). The sound will penetrate only 5 to 7 cm, thus any density below this depth will not be discovered. The nurse proceeds down the posterior thorax, percussing symmetric areas at intervals of 5 to 6 cm (2 to 2.5 in) (Fig. 8-11). Dullness over the lung occurs when air-filled lung tissue is replaced by fluid or solid tissue.

Diaphragmatic Excursion. The normal resonance of the lung stops at the diaphragm. The position of the diaphragm is different during inspiration and expiration. Initially, the nurse determines the change from resonance (normal lung) to dullness (structures below the diaphragm) during normal breathing. Posteriorly, the lung normally ends at the tenth ICS with quiet respiration, and the diaphragm is generally two interspaces below this level. The point on the midscapular line at which the percussion changes from resonance to dullness is marked with a pen. An additional area medial or lateral to this area should be assessed to confirm the change to dullness. Then the patient is instructed to inhale fully and hold it while the nurse again percusses downward from the marked area to the new level of dullness of the diaphragm. With deep inspiration, the diaphragm descends. This point is also marked. The distance between the two markings indicates the range of motion of the diaphragm. The new position for the transition between resonance and dullness is 5 to 6 cm lower in healthy adults as their diaphragms descend with deeper breaths (LeBlond et al., 2015a). Decreased diaphragmatic excursion may occur with pleural effusion, a paralyzed hemidiaphragm, and emphysema.

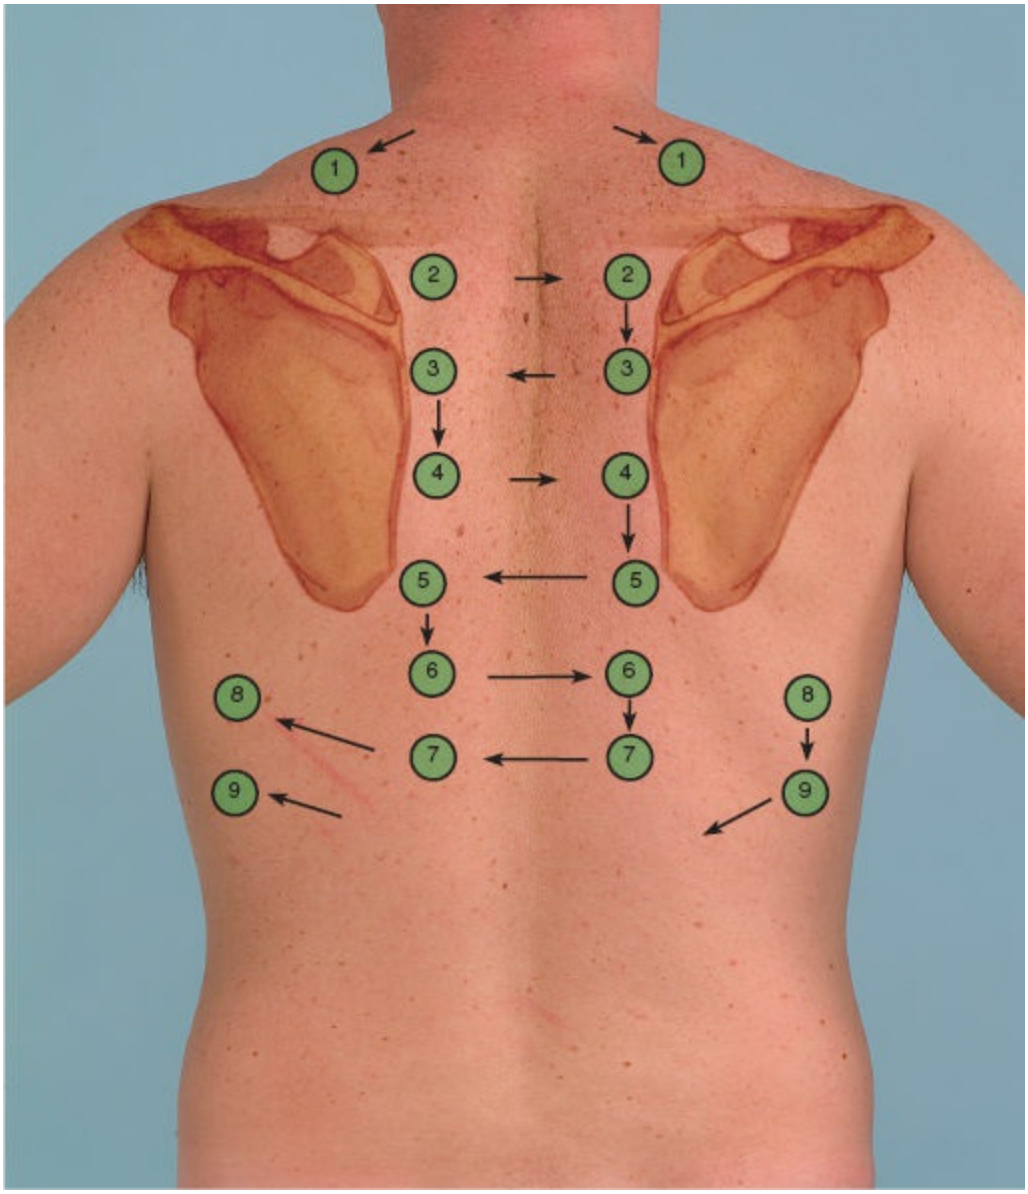

FIGURE 8-11 Percussion of the posterior thorax. With the patient in a sitting position, symmetric areas of the lungs are percussed at 5-cm intervals. This progression starts at the apex of each lung and concludes with percussion of each lateral chest wall.

Thoracic Auscultation

Auscultation is useful in assessing the flow of air through the bronchial tree and in evaluating the presence of fluid or solid obstruction in the lung. The nurse auscultates for normal breath sounds, adventitious sounds, and voice sounds.

Examination includes auscultation of the anterior, posterior, and lateral thorax and is performed as follows. The nurse places the diaphragm of the stethoscope firmly against the chest wall as the patient breathes slowly and deeply through the mouth. Corresponding areas of the chest are auscultated in a systematic fashion from the apices to the bases and along MALs. The sequence of auscultation and the positioning of the patient are similar to those used for percussion. Often it is necessary to listen to two full inspirations and

expirations at each anatomic location for valid interpretation of the sound heard. Repeated deep breaths may result in symptoms of hyperventilation (e.g., light-headedness); this is avoided by having the patient rest and breathe normally periodically during the examination.

Breath Sounds. The diaphragm of the stethoscope is used to assess for lung sounds. Normal breath sounds are distinguished by their location over a specific area of the lung and are identified as bronchial (tubular), which may possibly be heard over the manubrium; bronchovesicular, which are heard at the first and second ICS, at approximately the angle of Louis anteriorly and between the scapula posteriorly; and vesicular (dominant sound over the remaining lung) breath sounds. In bronchial breath sounds, the inspiration phase is shorter than expiration; in bronchovesicular sounds, inspiration and expiration phases are equal; and with vesicular sounds, inspiration is longer than expiration.

The location, quality, and intensity of breath sounds are determined during auscultation. As the nurse moves down the chest wall, the sounds decrease. When airflow is decreased by fluid (pleural effusion) or tissue (obesity), breath sounds may be diminished or absent. For example, the breath sounds of the patient with emphysema are faint or often completely inaudible. Bronchial and bronchovesicular sounds that are audible anywhere except over the main bronchus in the lungs signify pathology, usually indicating consolidation in the lung (e.g., pneumonia). This finding requires further evaluation.

Adventitious Sounds. An abnormal condition that affects the bronchial tree and alveoli may produce adventitious (additional or abnormal) sounds that are superimposed over usual breath sounds. Adventitious sounds are divided into two categories: discrete, noncontinuous sounds (crackles), and continuous musical sounds (wheezes) (Table 8-5). The duration of the sound is the important distinction to make in identifying the sound as noncontinuous or continuous.

Crackles (formerly referred to as *rales*) are discrete, noncontinuous sounds that result from delayed reopening of deflated airways. Crackles may or may not be cleared by coughing. They reflect underlying inflammation or congestion and often are present in such conditions as pneumonia, bronchitis, heart failure, bronchiectasis, atelectasis, and pulmonary fibrosis. Usually crackles are heard on inspiration, but they also may be heard on expiration.

Pleural friction rubs are specific examples of crackles. Friction rubs result from inflammation of the pleural surfaces that induces a crackling, grating sound usually heard in inspiration and expiration (late in inspiration and early in expiration) (Grippi, Senior, & Callen, 2015). The sound can be enhanced by applying pressure to the chest wall with the diaphragm of the stethoscope. Pleural fluid can accumulate in the pleural space because of transudation of fluid from the pleural and pulmonary vessels (increased venous hydrostatic pressure, decreased oncotic pressure, capillary leak), increased production of pleural fluid (inflamed pleura or pleural neoplasm), decreased pleural absorption of fluid (lymphatic obstruction, systemic venous hypertension), or by bleeding into the pleural space (LeBlond, Brown, Suneja, & Szot, 2015b). Pleural fluid dampens vibrations from the bronchotrachea so vocal fremitus, breath sounds, and whispered and spoken voice are decreased (see below), and dullness is noted on percussion in the area of fluid accumulation.

TABLE 8-5 Abnormal (Adventitious) Breath Sounds

Breath Sound	Description	Etiology
Crackles		
Crackles in general	Soft, high-pitched, discontinuous popping sounds that occur during inspiration; sounds like several hairs rubbing together between the thumb and index finger	Secondary to fluid in the airways or alveoli or to opening of collapsed alveoli; When present in patients without lung disease, crackles (formerly termed rales) are specific for heart failure.
Coarse crackles	Discontinuous popping sounds heard in early inspiration; harsh, louder, lower-pitched moist sound originating in the large bronchi	Associated with obstructive pulmonary disease, asthma
Fine crackles	Discontinuous popping sounds heard in late inspiration; originates in the alveoli	Associated with interstitial pneumonia, restrictive pulmonary disease (e.g., fibrosis), atelectasis, congestive heart failure (CHF). In CHF, crackles may be heard widely over both lung fields (typically beginning at the bases) and may be accompanied by expiratory wheezing (cardiac asthma). Fine crackles in early inspiration are associated with bronchitis or pneumonia.
Wheezes		
Wheezes in general	Usually heard on expiration but may be heard on inspiration or both phases	Associated with turbulent airflow and small airway vibration in which there is partial obstruction, commonly seen with COPD, asthma, and bronchitis
Rhonchi	Deep, low-pitched rumbling sounds heard primarily during expiration; caused by air moving through narrowed tracheobronchial passages	Secretions within the larger airways that clear or change significantly after an effective cough; heard in a wide variety of pathologies, any of which cause increased secretions (e.g., cystic fibrosis, pneumonia, bronchitis or emphysema)
Stridor	Loud, rough, continuous, high-pitched sound that is pronounced during inspiration; it indicates proximal airway obstruction.	Turbulent air flowing through a narrowed trachea or larynx; loudest over the trachea. Commonly a medical emergency that needs to be recognized early. Diagnoses include epiglottitis, vocal cord dysfunction, croup, and airway edema (which could be secondary to trauma or an allergic reaction)
Friction Rubs		
Pleural friction rub	Harsh, crackling sound, like two pieces of leather being rubbed together. Heard during inspiration alone or during both inspiration and expiration. May subside when patient holds breath. Coughing will not clear sound. Auscultate in the region where patient complains of pleuritic pain.	Secondary to inflammation and loss of lubricating pleural fluid

Rhonchi are low-pitched gurgling sounds produced by secretions within the larger airways. They clear or change significantly after an effective cough.

Wheezes are associated with bronchial wall oscillation and changes in airway diameter. Although usually heard on expiration, wheezes may be heard on inspiration, or both phases. They are commonly heard in patients with asthma, chronic bronchitis, or bronchiectasis. *Stridor*, a high-pitched, harsh inspiratory wheeze associated with partial obstruction of the larynx or trachea, demands immediate attention (Bickley, 2013).

Voice Sounds. The sound heard through the stethoscope as the patient speaks is known as *vocal resonance*. The vibrations produced in the larynx are transmitted to the chest wall as they pass through the bronchi and alveolar tissue. During the process, the sounds are diminished in intensity and altered so that syllables are not distinguishable. Voice sounds are usually assessed by having the patient repeat "99" or "eee" while the nurse listens with the stethoscope in corresponding areas of the chest, from the apices to the bases.

TABLE 8-6 Assessment Findings in Common Respiratory Disorders

Disorder	Tactile Fremitus	Percussion	Auscultation
Consolidation (e.g., pneumonia)	Increased	Dull	Bronchial breath sounds, crackles, bronchophony, egophony, whispered pectoriloquy
Bronchitis	Normal	Resonant	Normal to decreased breath sounds, wheezes
Emphysema	Decreased	Hyperresonant	Decreased intensity of breath sounds, usually with prolonged expiration
Asthma (severe attack)	Normal to decreased	Resonant	Wheezes
Pulmonary edema	Normal	Resonant	Crackles at lung bases, possibly wheezes
Pleural effusion	Absent	Dull	Decreased to absent breath sounds, bronchial breath sounds and bronchophony, egophony, and whispered pectoriloquy above the effusion over the area of compressed lung
Pneumothorax	Decreased	Hyperresonant	Absent breath sounds
Atelectasis	Absent	Dull (if large)	Decreased to absent breath sounds, fine crackles

Bronchophony describes vocal resonance that is more intense and clearer than normal. *Egophony* describes voice sounds that are distorted. It is best appreciated by having the patient repeat the letter E. The distortion produced by consolidation transforms the sound into a clearly heard "A" rather than "E." Bronchophony and egophony have precisely the same significance as bronchial breathing with an increase in tactile fremitus. When an abnormality is detected, it should be confirmed using more than one assessment method. A change in tactile fremitus is more subtle and can be missed, but bronchial breathing and bronchophony can be noted loudly and clearly.

Whispered pectoriloquy is a very subtle finding, which is heard only in the presence of rather dense consolidation of the lungs. Transmission of the high-frequency components of sound is so enhanced by the consolidated tissue that even whispered words are heard, a circumstance not noted in normal physiology. The significance is the same as that of bronchophony (Bickley, 2013).

The physical findings for the most common respiratory diseases are summarized in Table 8-6.

Diagnostic Evaluation

A wide range of diagnostic studies, described in the following sections, may be performed to aid in diagnosing or monitoring patients with a variety of respiratory conditions.

Pulmonary Function Tests

PFTs are used routinely in patients with chronic respiratory disorders. These tests are performed to assess respiratory function and to determine the extent of dysfunction. PFTs are useful in screening patients for major surgery, monitoring the course of a patient with an established respiratory disease, and assessing the response to therapy. They are useful as screening tests in potentially hazardous industries, such as coal mining and those that involve exposure to asbestos and other noxious fumes, dusts, or gases.

PFTs generally are performed by a technician using a spirometer that has a volume-collecting device attached to a recorder that demonstrates volume and time simultaneously. A number of tests are carried out because no single measurement provides a complete picture of pulmonary function.

PFT results are interpreted on the basis of the degree of deviation from normal, taking into consideration the patient's height, weight, age, and gender. Because there is a wide range of normal values, PFTs may not detect early localized changes.

Patients with respiratory disorders may be taught how to measure their peak flow rate (which reflects maximal expiratory flow) at home using a spirometer to monitor progress of therapy, assess effect of alteration of medications, and use as a guide for when to notify the health care provider.

Arterial Blood Gas Studies

Measurements of blood pH and of arterial O_2 and CO_2 tensions are obtained when managing patients with respiratory problems and adjusting O_2 therapy as needed. The arterial O_2 tension (PaO_2) indicates the degree of oxygenation of the blood, and the arterial CO_2 tension ($PaCO_2$) indicates the adequacy of alveolar ventilation (i.e., how effectively CO_2 is exhaled from the body). Arterial blood gas (ABG) studies aid in assessing the ability of the lungs to provide adequate O_2 and remove CO_2 as well as the ability of the kidneys to reabsorb or excrete bicarbonate ions to maintain normal body pH. ABG levels are obtained through an arterial puncture at the radial, brachial, or femoral artery or through an indwelling arterial catheter. Before obtaining an ABG from the radial artery, it is necessary to test the patency of the ulnar artery by performing the Allen test (refer to Chapter 12 for details).

Pulse Oximetry

Pulse oximetry is a noninvasive method of continuously monitoring the O_2 saturation of hemoglobin (SaO_2). When O_2 saturation is measured with pulse oximetry, it is referred to as SpO_2. Although pulse oximetry does not replace ABG measurement, it is an effective tool to monitor for subtle or sudden changes in O_2 saturation as this measurement is

available in real time.

A probe or sensor is attached to a well-perfused fingertip (Fig. 8-12), forehead, earlobe, or bridge of the nose. The sensor detects changes in O_2 saturation levels by monitoring light signals generated by the oximeter and reflected by blood pulsing through the tissue at the probe. Normal SpO_2 values are 95% to 100%. Values of less than 90% imply inadequate oxygenation, and further evaluation is needed. SpO_2 values obtained by pulse oximetry are unreliable in cardiac arrest and shock (decreased pulsatile force of blood), if dyes (i.e., methylene blue) or vasoconstrictor medications have been used or if the patient has severe anemia or a high carbon monoxide level (smoke inhalation and carbon monoxide poisoning). Furthermore, they are not reliable detectors of hypoventilation or rising CO_2 which leads to respiratory acidosis.

End Tidal CO_2

End-tidal CO_2 ($ETCO_2$) is a continuous recording of the concentration of CO_2 at the end of expiration. An $ETCO_2$ monitor may be a separate monitor or part of the patient's bedside hemodynamic monitoring system. Because end-tidal gas is primarily alveolar gas and is virtually identical to $PaCO_2$ (arterial partial pressure of CO_2), $ETCO_2$ is used clinically as an estimate of $PaCO_2$. In addition, it is used to (1) ensure that airway adjuncts (such as endotracheal tubes) are placed correctly in the trachea (and not in the esophagus) of a mechanically ventilated patient, (2) assess the effectiveness of interventions related to mechanical ventilation, neuromuscular blockade used with mechanical ventilation, and changing body positioning, and (3) assess the adequacy of chest compressions during cardiopulmonary resuscitation. Normally, $ETCO_2$ is 2 to 5 mm Hg lower than arterial CO_2 pressure so the typical range is 30 to 40 mm Hg versus 35 to 45 mm Hg for arterial CO_2. An early sign of malignant hyperthermia is a rapidly rising $ETCO_2$ especially if it is unresponsive to hyperventilation (refer to Chapter 5). The nurse should notify the provider of an increase or decrease in readings of 10% (Walsh, 2015).

Sputum Studies

Sputum is obtained for analysis to identify pathogenic organisms and to determine whether malignant cells are present. It also may be used to assess for hypersensitivity states (in which there is an increase in eosinophils). In general, sputum cultures are used in diagnosis, for drug sensitivity testing, and to guide treatment.

A

B

FIGURE 8-12 Measuring blood oxygenation with pulse oximetry reduces the need for invasive procedures, such as drawing blood for analysis of O_2 levels. A. Self-contained digital fingertip pulse oximeter, which incorporates the sensor and display into one unit. B. Table top model with sensor attached. Memory permits tracking heart rate and O_2 saturation over time.

Expectoration is the usual method for collecting a sputum specimen. The patient is instructed to clear the nose and throat and rinse the mouth to decrease contamination of the sputum. After taking a few deep breaths, the patient coughs forcefully on exhalation (rather than spits), using the diaphragm, and expectorates into a sterile container. An early morning specimen is best for collection; 2 to 3 mL is generally a sufficient amount (Fischbach & Dunning, 2015).

If the sputum cannot be raised spontaneously, respiratory therapy personnel may assist the patient in obtaining an "aerosol-induced" specimen with an ultrasonic nebulizer until a strong cough reflex is initiated. The specimen is labeled as being aerosol induced. Other methods of collecting sputum specimens include chest physiotherapy, nasotracheal or tracheal suctioning, and bronchoscopy.

Nursing Alert

A sputum specimen is sealed in a sterile container and placed in a leak-proof biohazard bag. The specimen is sent as soon as possible to the laboratory after being labeled properly. Usually sputum specimens are not refrigerated. Allowing the specimen to stand for several hours in a warm room results in the overgrowth of contaminant organisms and may make it difficult to identify the pathogenic organisms (especially Mycobacterium tuberculosis).

Imaging Studies

Imaging studies, including x-rays, computed tomography (CT), magnetic resonance imaging (MRI), contrast studies, and radioisotope diagnostic scans may be part of any diagnostic workup, ranging from a determination of the extent of infection in sinusitis to tumor growth in cancer.

Chest X-Ray

Normal pulmonary tissue is radiolucent; therefore, densities produced by fluid, tumors, foreign bodies, and other pathologic conditions can be detected by x-ray examination. The routine chest x-ray consists of two views—the posteroanterior projection and the lateral projection. Usually chest x-rays are taken after full inspiration (a deep breath) because the lungs are best visualized when they are well aerated. Also, the diaphragm is at its lowest level, and the largest expanse of lung is visible.

Computed Tomography

CT is an imaging method in which the lungs are scanned in successive layers by a narrow-beam x-ray. The images produced provide a cross-sectional view of the chest. CT can distinguish fine tissue density. They may be used to define pulmonary nodules and small tumors adjacent to pleural surfaces that are not visible on routine chest x-rays as well as to

demonstrate mediastinal abnormalities and hilar adenopathy, which are difficult to visualize with other techniques. Contrast agents are useful when evaluating the mediastinum and its contents. Computed tomography pulmonary angiography (CTPA), which is the injection of contrast media directly into a vein or artery via a needle and/or catheter, has become the standard imaging technique for diagnosing PE (Solaiman & Bartholomew, 2013).

Magnetic Resonance Imaging

MRI is similar to CT except that with MRI, magnetic fields and radiofrequency signals are used instead of a narrow-beam x-ray. MRI yields a much more detailed diagnostic image than CT. MRI is used to characterize pulmonary nodules, to help stage bronchogenic carcinoma (assessment of chest wall invasion), and to evaluate inflammatory activity in interstitial lung disease, acute PE, and chronic thrombolytic pulmonary hypertension.

Positron Emission Tomography

Positron emission tomography (PET) imaging involves the combined use of positron-emitting radionuclides and emission CT. PET generates high-resolution images of body function and metabolism, thus PET provides physiologic, anatomic, and biochemical data. PET images include glucose metabolism, O_2 utilization, blood flow, and tissue perfusion. Clinical PET is useful for aiding in diagnosis of many disease states, primarily in oncology, neurology, and cardiology.

Nursing Alert

Nurses must assess patient allergy to iodine contrast media before diagnostic studies; the nurse asks about iodine-containing substances (e.g., seafood, cabbage, kale, raw leafy vegetables, turnips, iodized salt) and documents findings in the patient record. The risk for subsequent reactions increases three to four times after the first reaction; however, subsequent reactions will not necessarily be more severe than the first (Fischbach & Dunning, 2015).

Fluoroscopic Studies

Fluoroscopy is used to assist with invasive procedures, such as a chest needle biopsy or transbronchial biopsy, that are performed to identify lesions. It also may be used to study the movement of the chest wall, mediastinum, heart, and diaphragm; to detect diaphragm paralysis; and to locate lung masses.

Pulmonary Angiography

Pulmonary angiography remains the reference standard for which most studies are compared in the diagnosis of PE despite these factors: (1) it is not universally available, (2) it is invasive, and (3) it is costly (Solaiman & Bartholomew, 2013). It involves the rapid injection of a radiopaque agent into the vasculature of the lungs for radiographic study of the pulmonary vessels. It is not without complications; morbidity of 5% and mortality of 0.5% were reported (Solaiman & Bartholomew, 2013). Due to introduction of CTPA, pulmonary angiography is used infrequently.

Radioisotope Diagnostic Procedures (Lung Scans)

Several types of lung scans—ventilation/perfusion (V/Q) scan, gallium scan, and PET—are used to assess normal lung functioning, pulmonary vascular supply, and gas exchange.

A V/Q lung scan is performed by injecting a radioactive agent into a peripheral vein and then obtaining a scan of the chest to detect radiation. The isotope particles pass through the right side of the heart and are distributed into the lungs in proportion to the regional blood flow, making it possible to trace and measure blood perfusion through the lung. This procedure is used clinically to measure the integrity of the pulmonary vessels relative to blood flow and to evaluate blood flow abnormalities, as seen in pulmonary emboli. The imaging time is 20 to 40 minutes, during which the patient lies under the camera with a mask fitted over the nose and mouth. This is followed by the ventilation component of the scan. The patient takes a deep breath of a mixture of O_2 and radioactive gas, which diffuses throughout the lungs. A scan is performed to detect ventilation abnormalities in patients who have regional differences in ventilation. Ventilation without perfusion is seen with pulmonary emboli. V/Q scanning has been replaced by CTPA and currently is considered a second-line modality in the diagnosis of PE. However, V/Q scan remains a valuable tool in the diagnosis of acute PE in patients with a normal chest x-ray or patients who cannot undergo CTPA (contrast allergy, renal insufficiency, or pregnancy) (Solaiman & Bartholomew, 2013).

A gallium scan is a radioisotope lung scan used to detect inflammatory conditions, abscesses, adhesions, and the presence, location, and size of tumors. It is used to stage bronchogenic cancer and document tumor regression after chemotherapy or radiation. Gallium is injected intravenously, and scans are taken at intervals (e.g., 6, 24, and 48 hours) to evaluate gallium uptake by the pulmonary tissues. Although gallium is radioactive, the risk of radiation exposure is lower than x-ray or CT scan.

Endoscopic Procedures

Bronchoscopy

Bronchoscopy is the direct inspection and examination of the larynx, trachea, and bronchi for diagnosis of infectious, inflammatory, and malignant disease of the chest through a flexible or rigid fiberoptic bronchoscope (Fig. 8-13).

Therapeutic bronchoscopy is used to (1) remove foreign bodies from the tracheobronchial tree, (2) perform difficult endotracheal intubations, (3) remove secretions obstructing the tracheobronchial tree when the patient cannot clear them, (4) diagnose lung infection, inflammation, and interstitial diseases, (5) destroy and excise lesions, (6) place endobronchial radiation therapy (brachytherapy) and laser therapy of obstructive airway lesions, (7) stent obstructing endobronchial lesions, and (8) dilate stenotic airways.

Possible complications of bronchoscopy include a reaction to the local anesthetic, infection, aspiration, bronchospasm, hypoxemia (low blood O_2 level), pneumothorax, bleeding, and perforation.

Before the procedure, a signed consent form is obtained from the patient. Food and fluids are withheld for 8 hours before the test to reduce the risk of aspiration when the cough reflex is blocked by anesthesia. The nurse explains the procedure to the patient to reduce fear and decrease anxiety and administers preoperative medications if required.

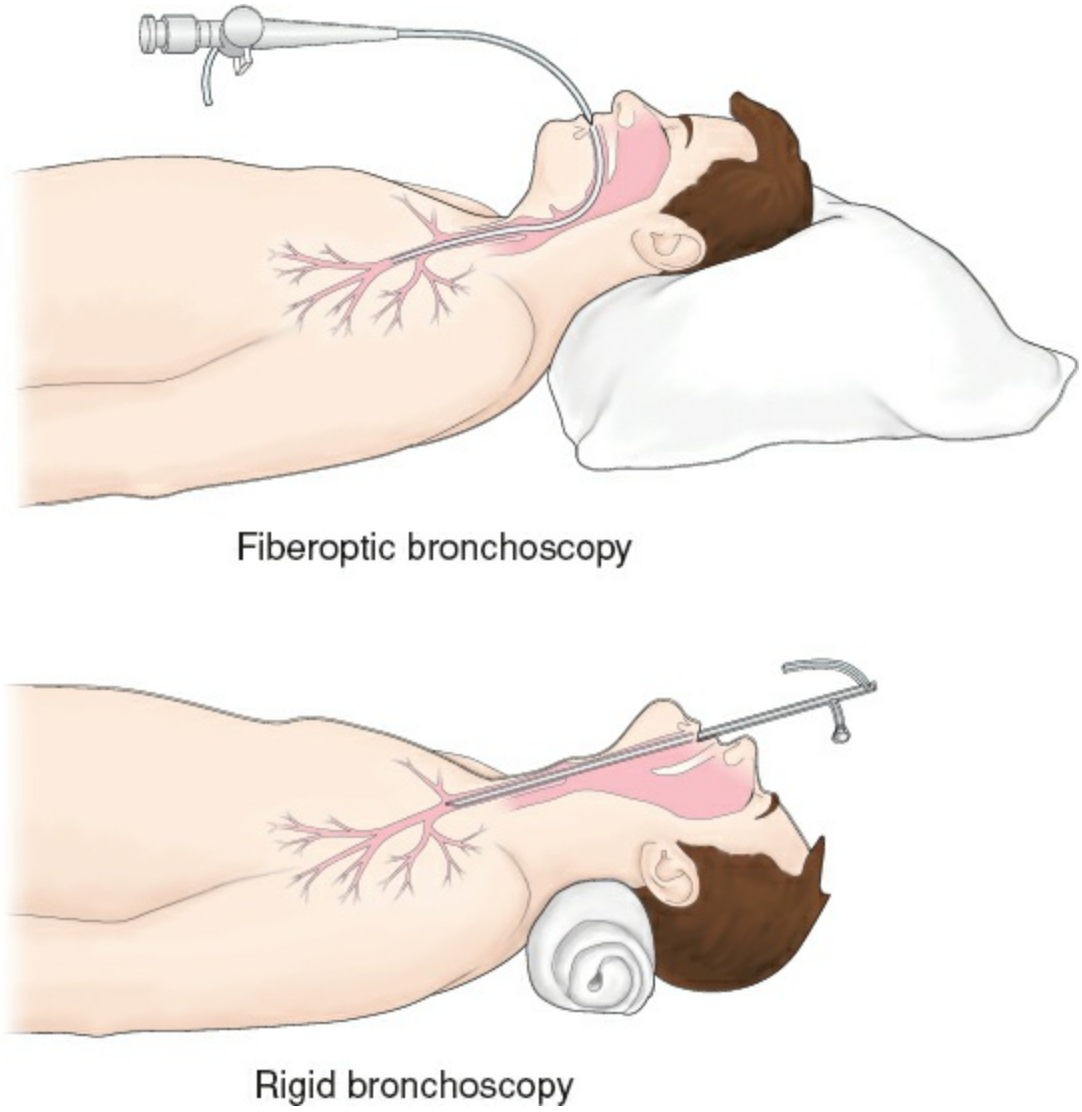

FIGURE 8-13 Endoscopic bronchoscopy permits visualization of bronchial structures. The bronchoscope is advanced into bronchial structures orally. Bronchoscopy permits the provider not only to diagnose but also to treat various lung problems.

The patient must remove dentures and other oral prostheses. Usually the examination is performed under local anesthesia or moderate sedation. A topical anesthetic such as lidocaine (Xylocaine) may be sprayed on the pharynx or dropped on the epiglottis and vocal cords and into the trachea to suppress the cough reflex and minimize discomfort. Sedatives or opioids are administered intravenously as prescribed to provide moderate sedation. Resuscitative and suctioning equipment should be available.

After the procedure, it is important that the patient takes nothing by mouth until the cough reflex returns, because the preoperative sedation and local anesthesia impair the protective laryngeal reflex and swallowing for several hours. The patient is instructed to spit out saliva rather than swallow it until the gag reflex returns. Once the patient demonstrates a cough reflex, the nurse may offer ice chips and, eventually, fluids. The nurse also monitors the patient's respiratory status and observes for hypoxia, hypotension, tachycardia, arrhythmias, hemoptysis, subcutaneous air or crepitus, stridor, or dyspnea. Any abnormality is reported promptly. The patient is not discharged from the recovery area until adequate cough reflex and respiratory status are present. The nurse instructs the

patient and family caregivers to report any SOB or bleeding immediately.

Nursing Alert
Anesthesia can temporarily impair the pharyngeal reflex (ninth, tenth, CN), which is responsible for the gag reflex and swallowing; to prevent aspiration, before refeeding the patient, the nurse must reassess return of this reflex (refer to Chapter 43 for details on assessment).

Thoracentesis

A thoracentesis (aspiration of fluid or air from the pleural space) is performed on patients with various clinical problems. As a diagnostic or therapeutic procedure, thoracentesis may be used for removal of fluid and air from the pleural cavity, aspiration of pleural fluid for analysis, pleural biopsy, or instillation of medication into the pleural space. Care of the patient undergoing thoracentesis is discussed in Box 8-8 on pages 258–259. A needle biopsy of the pleura may be performed at the same time. Studies of pleural fluid include: gram stain culture and sensitivity, acid-fast staining and culture, differential cell count, cytology, pH, specific gravity, total protein, and lactic dehydrogenase.

BOX 8-8 GUIDELINES FOR NURSING CARE

Assisting the Patient Undergoing Thoracentesis

Equipment

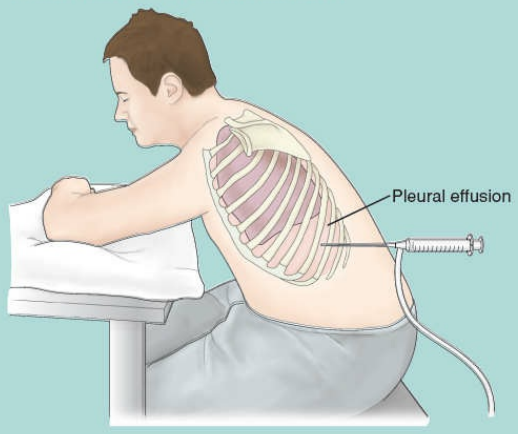
- Thoracentesis tray
- Local anesthetic
- Sterile gloves
- Sterile collection bottles
- Germicide solution

Implementation

ACTIONS	RATIONALE
1. Ascertain in advance that a chest x-ray and ultrasound (if available) has been ordered and completed and the consent form has been signed. The nurse also anticipates that coagulation studies are evaluated and any coagulopathy corrected before the procedure.	1. Posteroanterior and lateral decubitus chest x-ray films are obtained before the procedure and ultrasound if available to determine optimal site for thoracentesis When thoracentesis is performed under ultrasound guidance, it has a lower rate of complications than when it is performed without ultrasound guidance, including a decrease in post-procedure pneumothorax, less accidental organ puncture, and improved site selection. If fluid is loculated (isolated in a pocket of pleural fluid), ultrasound scans are performed to help select the best site for needle aspiration. Correction of coagulopathy may be necessary to decrease the bleeding risk with this procedure.
2. Assess the patient for allergy to the local anesthetic to be used.	2. If the patient is allergic to the anesthetic prescribed initially, then assessment findings provide an opportunity to use a safer anesthetic.
3. Administer sedation if prescribed.	3. Sedation enables the patient to cooperate with the procedure and promotes relaxation.
4. Inform the patient about the nature of the procedure and: a. The importance of remaining immobile b. Pressure sensations to be experienced c. That minimal discomfort is anticipated after the procedure	4. An explanation helps to orient the patient to the procedure, provides anticipatory guidance, and provides an opportunity to ask questions and verbalize anxiety.
5. Position the patient comfortably with adequate supports. If possible, place the patient upright or in one of the following positions: a. Sitting on the edge of the bed with the feet supported and arms and head on a padded over-the-bed table b. Straddling a chair with arms and head resting on the back of the chair c. Lying on the unaffected side with the head of the bed elevated 30–45 degrees if unable to assume a sitting position	5. The upright position facilitates the removal of fluid that usually localizes at the base of the thorax. A position of comfort helps the patient to relax.
6. Support and reassure the patient during the procedure: a. Prepare the patient for the cold sensation of skin germicide solution and for a pressure sensation from infiltration of local anesthetic agent. b. Encourage the patient to refrain from coughing.	6. Sudden and unexpected movement, such as coughing, by the patient can traumatize the visceral pleura and lung.
7. Expose the entire chest. The site for aspiration is visualized by chest x-ray and percussion. If fluid is in the pleural cavity, the thoracentesis site is determined by the chest x-ray, ultrasound scanning, and physical findings, with attention to the site of maximal dullness on percussion.	7. If air is in the pleural cavity, the thoracentesis site is usually in the second or third intercostal space in the midclavicular line because air rises in the thorax.
8. The procedure is performed under aseptic conditions. After the skin is cleansed, the provider uses a small-caliber needle to inject a local anesthetic slowly into the intercostal space.	8. An intradermal wheal is raised slowly; rapid injection causes pain. The parietal pleura is very sensitive and should be well-infiltrated with anesthetic before the physician passes the thoracentesis needle through it.
9. The provider advances the thoracentesis needle with the syringe attached. When the pleural space is reached, suction may be applied with the syringe: a. A 20-mL syringe with a three-way stopcock is attached to the needle (one end of the adapter is attached to the needle and the other to the tubing leading to a receptacle that receives the fluid being aspirated). b. If a considerable quantity of fluid is removed, the needle is held in place on the chest wall with a small hemostat. c. The nurse should anticipate that no more than 1 L will be removed from the chest. Amounts greater than 1 to 1.5 L can result in re-expansion pulmonary edema (Longo et al., 2013).	9. Use of thoracentesis needle allows proper insertion: a. When a large quantity of fluid is withdrawn, a three-way stopcock serves to keep air from entering the pleural cavity. b. The hemostat steadies the needle on the chest wall. Sudden pleuritic chest pain or shoulder pain may indicate that the needle point is irritating the visceral or the diaphragmatic pleura. c. To prevent re-expansion pulmonary edema.

10. After the needle is withdrawn, pressure is applied over the puncture site and a small, airtight, sterile dressing is fixed in place.
11. Advise the patient that he or she will be on bed rest and a chest x-ray will be obtained after thoracentesis.
12. Record the total amount of fluid withdrawn from the procedure and document the nature of the fluid, its color, and its viscosity. If indicated, prepare samples of fluid for laboratory evaluation. A specimen container with formalin may be needed for a pleural biopsy.
13. Monitor the patient at intervals for increasing respiratory rate; increased dyspnea, asymmetry in respiratory movement; faintness; vertigo; tightness in chest; uncontrollable cough; blood-tinged, frothy mucus; a rapid pulse; and signs of hypoxemia.

10. Pressure helps to stop bleeding, and the airtight dressing protects the site and prevents air from entering the pleural cavity.
11. A chest x-ray verifies that there is no pneumothorax.
12. The fluid may be clear, serous, bloody, purulent, etc.
13. Pneumothorax, tension pneumothorax, subcutaneous emphysema, and pyrogenic infection are complications of a thoracentesis. Pulmonary edema or cardiac distress can occur after a sudden shift in mediastinal contents when large amounts of fluid are aspirated.



CHAPTER REVIEW

Critical Thinking Exercises

1. A man with a long history of smoking (60 pack/year) is scheduled for surgery to remove a nonfunctioning kidney. In preparation for surgery, he is scheduled for PFTs, which he refuses to have because he says his breathing has nothing to do with his kidney problem or his scheduled kidney surgery. How would you respond to his statement? What impact does his 60 pack/year history of cigarette smoking have on your preoperative, intraoperative, and postoperative assessment?

2. When obtaining a health history from a 55-year-old patient who is seeking health care because of a persistent cough and extreme fatigue, you note that she is able to speak only in short sentences before having to stop to catch her breath. What specific information about signs and symptoms would you obtain during the health history? How would you modify your physical examination based on your observations? What initial laboratory tests would you anticipate will be ordered for this patient?

NCLEX-Style Review Questions

1. Before an ABG is drawn from the patient's radial artery, what test should be performed?
   a. Doppler flow test

b. Allen test
c. Babinski test
d. Ankle Brachial Index (ABI)

2. A patient has a chronic cough with thick sputum. He undergoes a bronchoscopy for diagnostic purposes. Following the bronchoscopy, which action by the nurse is most appropriate?
   a. Encourage fluid intake to promote elimination of contrast media.
   b. Monitor hemoglobin and hematocrit to evaluate blood loss.
   c. Check vital signs every 15 minutes for 4 hours.
   d. Keep NPO until the gag reflex returns.

3. A patient is admitted to the ICU after falling from a roof and sustaining fractures of the first three ribs on the right side. The patient is dyspneic, and crepitus (subcutaneous emphysema) can be palpated. Auscultation reveals decreased breath sounds on the right. The chest x-ray reveals a pneumothorax. Upon percussion, what does the nurse expect to hear?
   a. Dullness on the right
   b. Resonance on the right
   c. Tympany on the right
   d. Hyperresonance on the right

4. The finding of normal breath sounds on the right chest and diminished, distant breath sounds on the left chest of a newly intubated patient is probably due to which of the following?
   a. A left pneumothorax
   b. A right hemothorax
   c. Intubation of the right mainstem bronchus
   d. A malfunctioning mechanical ventilator

5. A patient presents to the emergency room with pulmonary edema. The nurse expects to hear what adventitious sound?
   a. Decreased breath sounds
   b. Inspiratory and expiratory wheezing
   c. Crackles
   d. Friction rub

CHAPTER 9

Nursing Management: Patients with Upper Respiratory Tract Disorders

Jancee Pust-Marcone

Learning Objectives

After reading this chapter, you will be able to:

1. Compare and contrast the upper respiratory tract infections with regard to cause, incidence, clinical manifestations, management, and the significance of preventive health care.
2. Use the nursing process as a framework for care of patients with upper airway infection.
3. Describe the nursing management of the patient with obstructive sleep apnea.
4. Describe the nursing management for patients receiving continuous positive-pressure (CPAP) or bi-level (BiPAP) breathing.
5. Describe nursing management of the patient with epistaxis.
6. Describe nursing management of patients undergoing laryngectomy.
7. Describe the nursing care for a patient with an endotracheal tube or a tracheostomy.
8. Demonstrate the procedure of tracheal suctioning.

Many upper airway disorders are relatively minor, and their effects are limited to mild and temporary discomfort for the patient. Others may be acute, severe, and life-threatening and may require permanent alterations in breathing and speaking. The nurse must have expert assessment skills, an understanding of the wide variety of disorders that may affect the upper airway, and an awareness of the impact of these alterations on patients.

UPPER AIRWAY INFECTIONS

Upper airway infections, also known as upper respiratory tract infections (URIs), are the most common cause of illness, and affect most people on occasion. There are many causative organisms, and people are susceptible throughout their lives.

Some infections are acute, with symptoms that last several days, while others are chronic, with symptoms that last a long time or recur. Patients with these conditions seldom require hospitalization. URIs affect the nasal cavity; ethmoidal air cells; and frontal, maxillary, and sphenoid sinuses (see Fig. 9-1), as well as the larynx and trachea. About 90% of upper respiratory disorders stem from a viral infection of the upper respiratory passages and subsequent mucous membrane inflammation.

RHINITIS

Rhinitis is a group of disorders characterized by inflammation and irritation of the mucous membranes of the nose as well as ocular symptoms. Rhinitis may be acute or chronic, nonallergic or allergic (see Chapter 38 for information about allergic rhinitis).

Viral rhinitis is the most frequent viral infection in the general population and is referred to as the "common cold." It affects between 10% and 30% of adults and 40% of children (Borish, 2016).

Pathophysiology

Nonallergic rhinitis may be caused by a variety of factors, including environmental factors such as changes in temperature or humidity, odors, or foods; infection; age; systemic disease; illegal drugs (e.g., cocaine); over-the-counter (OTC) and prescribed nasal decongestants; and the presence of a foreign body.

The most common cause of nonallergic rhinitis is the common cold. Colds are believed to be caused by as many as 200 different viruses. Rhinoviruses are the most likely causative organisms and are believed to cause more than 40% of colds. Other viruses implicated in the common cold include coronavirus, adenovirus, respiratory syncytial virus (RSV), influenza virus, and parainfluenza virus. Each virus may have multiple strains. Because of this diversity of causes, development of a vaccine is almost impossible. Immunity after recovery is variable and depends on many factors, including a person's natural host resistance and the specific virus that caused the cold. Drug-induced rhinitis is associated with use of antihypertensive agents, oral contraceptives, and chronic use of nasal decongestants. Other causes of rhinitis are identified in Table 9-1. Figure 9-2 shows the pathologic processes involved in rhinitis and sinusitis.

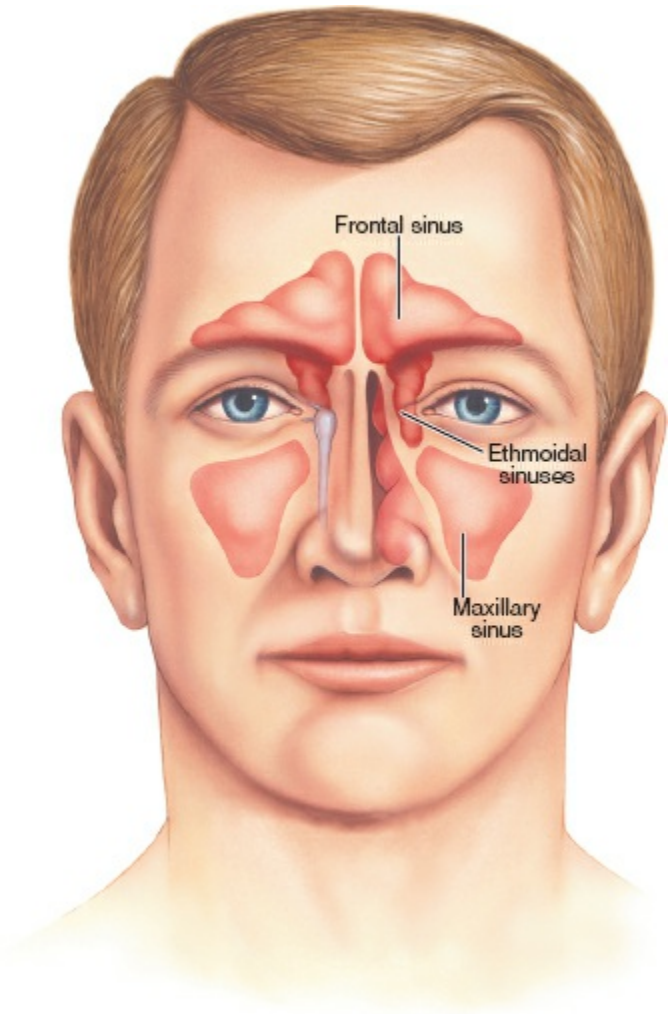

FIGURE 9-1 Sinuses are air-filled cavities in your head. This image details the: sphenoid sinuses; frontal sinuses; ethmoid sinuses. (From Anatomical Chart Company.)

Risk Factors

Colds are highly contagious because virus is shed for about 2 days before the symptoms appear and during the first part of the symptomatic phase. Adults in the United States average two to four colds each year mostly between September and May (American Lung Association, 2015). Adult women are more susceptible than adult men. Viral rhinitis can occur at any time of the year, but three time periods account for the epidemics in the United States: in September, just after the opening of school; in late January; and toward the end of April. Contrary to popular belief, cold temperatures and exposure to cold, rainy weather do not increase the incidence or severity of the common cold.

Clinical Manifestations and Assessment

The signs and symptoms of nonallergic rhinitis include rhinorrhea (excessive nasal drainage, runny nose); nasal congestion; nasal discharge (purulent with bacterial rhinitis); sneezing; and pruritus of the nose, roof of the mouth, throat, eyes, and ears (Borish, 2016). Headache may occur particularly if sinusitis is also present. In addition to the above symptoms, viral rhinitis may present with sore throat, general malaise, low-grade fever, chills, and muscle aches. As the illness progresses, cough usually appears. In some people, the virus exacerbates herpes simplex, commonly called a "cold sore."

TABLE 9-1 Causes of Rhinitis

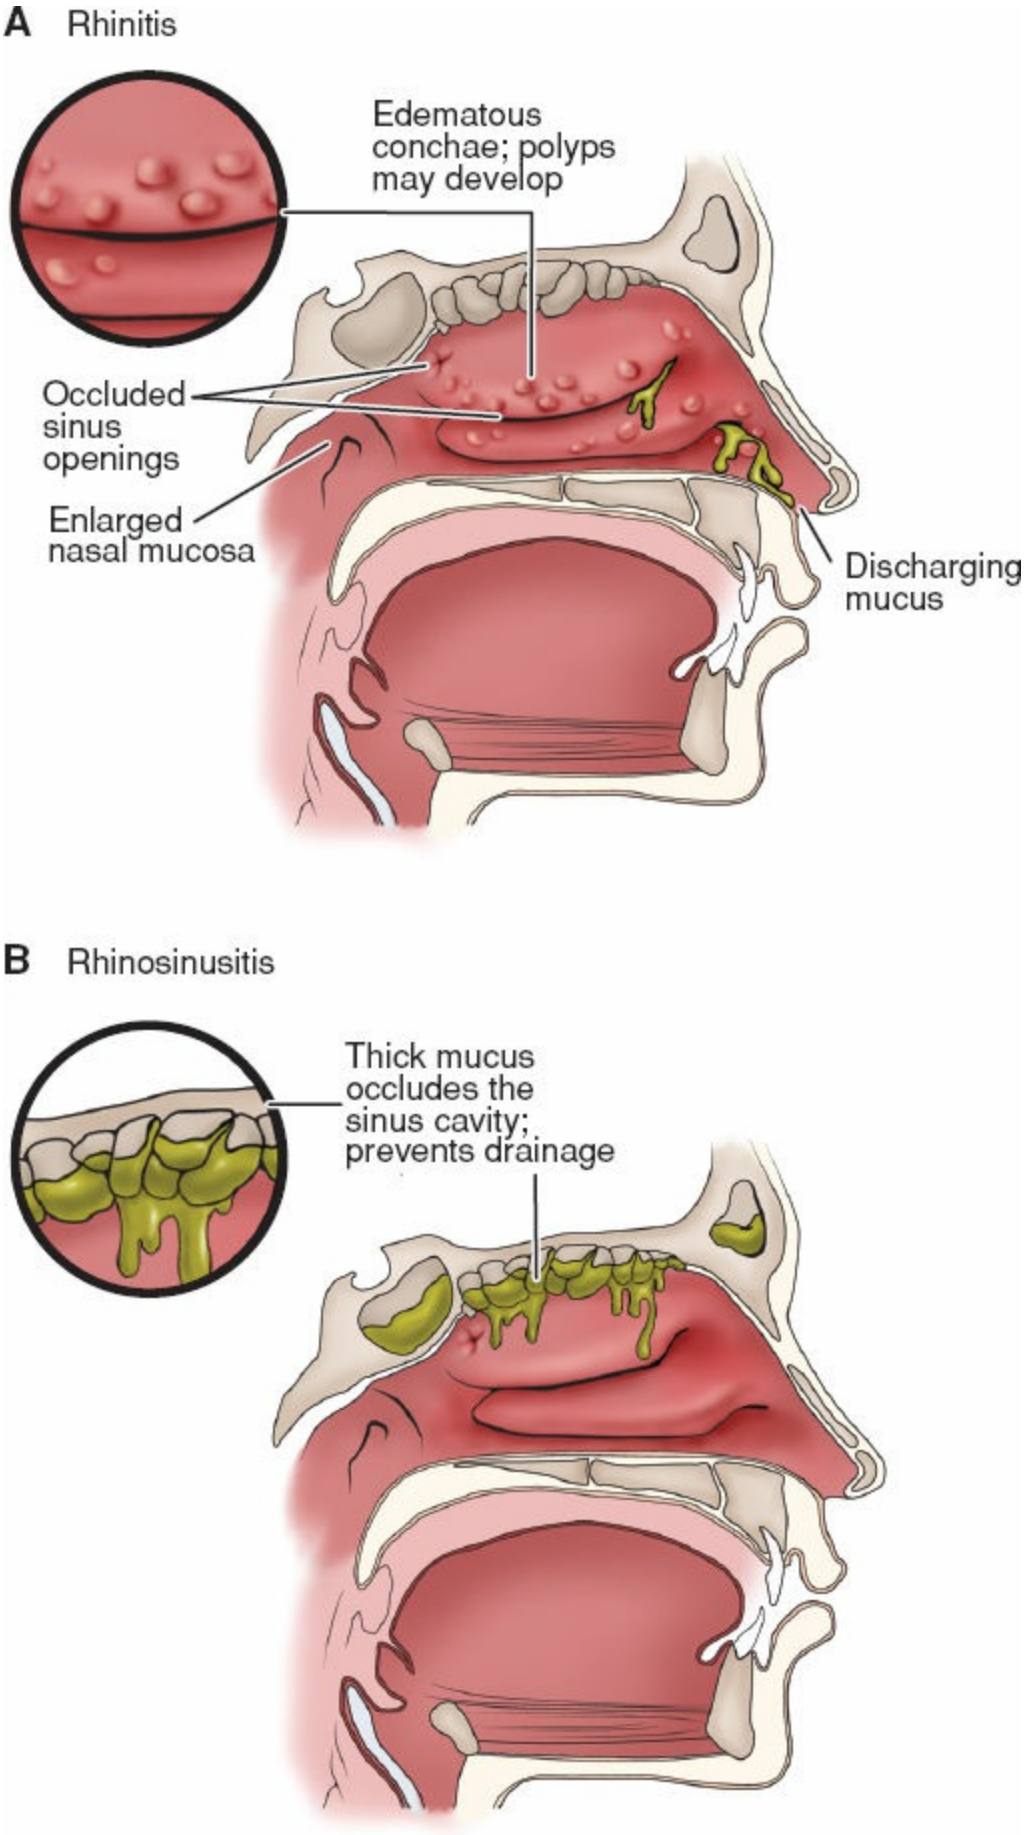
Category	Causes
Allergic	Seasonal (pollens) Perennial (dust/mold)
Vasomotor	Idiopathic Abuse of nasal decongestants (rhinitis medicamentosa) Drugs (reserpine, prazosin, cocaine abuse) Psychological stimulation (anger, sexual arousal) Irritants (smoke, air pollution, exhaust fumes, cocaine)
Mechanical	Tumor Deviated septum Crusting Hypertrophied turbinates Foreign body Cerebrospinal fluid leak
Chronic inflammatory	Polyps (in cystic fibrosis) Sarcoidosis Wegener granulomatosis Midline granuloma
Infectious	Acute viral infection Acute or chronic sinusitis Rare nasal infections (syphilis, tuberculosis)
Hormonal	Pregnancy Hypothyroidism Use of oral contraceptives Hypothyroidism

Adapted from Carr, M. M. Differential diagnosis of rhinitis. Retrieved from http//icarus.med.utoronto.ca/carr/manual/ddxrhinitis.html.

The symptoms of viral rhinitis may last from 1 to 2 weeks.

Medical and Nursing Management

Management consists of symptomatic therapy. Medication therapy for allergic and nonallergic rhinitis focuses on symptom relief. The choice of medications depends on the symptoms, adverse reactions, adherence factors, risk of drug interactions, and cost to the patient. Acetaminophen or nonsteroidal anti-inflammatory agents (NSAIDs), such as aspirin or ibuprofen, relieve the aches, pains, and fever.



A Rhinitis
Edematous conchae; polyps may develop
Occluded sinus openings
Enlarged nasal mucosa
Discharging mucus
B Rhinosinusitis
Thick mucus occludes the sinus cavity; prevents drainage

FIGURE 9-2 Pathophysiologic processes in rhinitis and rhinosinusitis. Although pathophysiologic processes are similar in rhinitis and sinusitis, they affect different structures. In rhinitis (A), the mucous membranes lining the nasal passages become inflamed, congested, and edematous. The swollen nasal conchae block the sinus openings, and mucus is discharged from the nostrils. Rhinosinusitis (B) is also marked by inflammation and congestion, with thickened mucous secretions filling the sinus cavities and occluding the openings.

The four major categories of medications used to manage cold symptoms are antihistamines, decongestants, antitussives, and expectorants. Antihistamines remain the most common treatment and are administered for sneezing, nasal congestion, pruritus, and rhinorrhea. The most common adverse effects of antihistamines are sedation, dry mouth, GI upset, and cardiac arrhythmias. Antihistamines have been show to aggravate certain conditions and should be used with caution in patients with asthma, urinary retention, hypertension, open-angle glaucoma, and prostatic hypertrophy. Topical nasal decongestants should be used with caution. Topical therapy delivers medication directly to the nasal mucosa, but its overuse can produce *rhinitis medicamentosa* (an increase in the severity or duration of rhinitis that results from prolonged use of decongestant nasal spray) or rebound rhinitis (Borish, 2016). Oral decongestant agents may be used for congestive nasal obstruction. Use of saline nasal spray can act as a mild decongestant and can liquefy mucus to prevent crusting. Expectorants are available without a prescription and are used to promote removal of secretions. Several antiviral medications are available by prescription. Antimicrobial agents (antibiotics) should not be used because they do not affect the virus or reduce the incidence of bacterial complications, and they have been implicated in development of organisms resistant to therapy.

Herbal medicines (e.g., echinacea, zinc lozenges, zinc nasal spray) are used frequently to treat the common cold; however, evidence regarding their effectiveness in shortening the symptomatic phase is questionable (American Lung Association, 2015). The inhalation of steam or heated, humidified air has been a mainstay of home remedies for common cold sufferers, but the value of this therapy has not been demonstrated.

If symptoms suggest a bacterial infection, an antimicrobial agent will be used. Other treatment measures include adequate fluid intake, adequate rest, prevention of chilling, and warm saltwater gargles to soothe the sore throat. Patients with nasal septal deformities or nasal polyps may be referred to an ear, nose, and throat (ENT) specialist.

RHINOSINUSITIS

Rhinosinusitis, formerly called *sinusitis*, is an inflammatory process involving the paranasal sinuses and nasal cavity (Rosenfeld et al., 2015). The clinical practice guideline for adult rhinosinusitis released by the American Academy of Otolaryngology–Head and Neck Surgery Foundation recommends use of the term *rhinosinusitis* because sinusitis is almost always accompanied by inflammation of the nasal mucosa (Peters et al., 2014; Rosenfeld et al., 2015). Rhinosinusitis affects 1 in 8 Americans, about 31 million people in the United States, and accounts for billions of dollars in direct health care costs (Peters et al., 2014; Rosenfeld et al., 2015). Uncomplicated rhinosinusitis does not extend beyond the paranasal sinuses and nasal cavity. Rhinosinusitis is classified by duration of symptoms as acute (less than 4 weeks), subacute (4 to 12 weeks), and chronic (more than 12 weeks) with or without acute exacerbations (Peters et al., 2014; Rosenfeld et al., 2015). Rhinosinusitis can be further classified as an acute bacterial rhinosinusitis (ABRS) or acute viral rhinosinusitis (AVRS) (Rosenfeld et al., 2015). Recurrent acute rhinosinusitis is characterized by three or more acute episodes of ABRS per year without symptoms of rhinosinusitis between episodes (Peters et al., 2014; Rosenfeld et al., 2015). Chronic rhinosinusitis (CRS) is defined as an inflammation of the nose and the paranasal sinuses characterized by two or more symptoms, one of which should be either nasal blockage or discharge, and/or facial pain and/or reduced smell. CRS affects 2% to 16% of the U.S. population (Halawi, Smith, & Chandra, 2013). It occurs more often in women than men and accounts for almost 20 million visits to providers' offices annually. In about 29% to 36% of patients, CRS is accompanied by nasal polyps.

Pathophysiology

Acute rhinosinusitis usually follows a viral URI or cold, such as an unresolved viral or bacterial infection, or an exacerbation of allergic rhinitis. Nasal congestion, caused by inflammation, edema, and transudation of fluid secondary to URI, leads to obstruction of the sinus cavities (see Fig. 9-2). This provides an excellent medium for bacterial growth.

CRS occurs with episodes of prolonged inflammation and with repeated or inadequate treatment of acute infections. Irreversible damage to the mucosa may occur, and symptoms last for longer than 3 months.

Bacterial organisms account for more than 60% of the cases of acute rhinosinusitis. *Streptococcus pneumoniae, Haemophilus influenzae,* and, less commonly, *Staphylococcus aureus* and *Moraxella catarrhalis* (Papadakis, McPhee, & Rabow, 2015; Rosenfeld et al., 2015) are implicated. Other organisms that are occasionally isolated include *Chlamydia pneumoniae, Streptococcus pyogenes,* viruses, and fungi (*Aspergillus fumigatus*). Immunodeficiency should be considered in patients with CRS or acute recurrent rhinosinusitis. Acute fulminant/invasive sinusitis is a life-threatening illness and is commonly attributed to *Aspergillus.*

Risk Factors

Some people are more prone to rhinosinusitis because of chronic inflammation of the nasal passages due to exposure to environmental hazards such as paint, sawdust, and chemicals. If sinus drainage is obstructed by a deviated septum or by hypertrophied turbinates, spurs, or nasal polyps or tumors, sinus infection may persist as a smoldering (persistent) secondary infection or progress to an acute suppurative process (causing purulent discharge). Other conditions that can block the normal flow of sinus secretions include abnormal structures of the nose, enlarged adenoids, diving and swimming, tooth infection, trauma to the nose, tumors, and the pressure of foreign objects. Immunocompromised patients are at increased risk for the development of fungal sinusitis. Fungal sinusitis in immunocompromised patients can be divided into three categories: (1) fungus ball, (2) chronic erosive (noninvasive) sinusitis, and (3) allergic fungal sinusitis. *A. fumigatus* is the most common organism associated with fungal sinusitis. The fungus ball is usually a brown or greenish-black material with the consistency of peanut butter or cottage cheese.

Clinical Manifestations and Assessment

Symptoms of ABRS include purulent nasal drainage accompanied by nasal obstruction or a combination of facial pain, pressure, or a sense of fullness (referred to collectively as facial pain–pressure–fullness), or both (Rosenfeld et al., 2015). The facial pain–pressure–fullness may involve the anterior face or the periorbital region. The patient may also report cloudy or colored nasal discharge, congestion, blockage, or stuffiness, as well as a localized or diffuse headache. The occurrence of symptoms for 10 days or more after the initial onset of upper respiratory symptoms indicates ABRS.

The symptoms of AVRS are similar to those of ABRS with the exceptions of the duration of symptoms. Symptoms of AVRS occur for less than 10 days after the onset of upper respiratory symptoms and do not worsen (Rosenfeld et al., 2015).

Clinical manifestations of CRS are similar to ABRS and include mucopurulent drainage, nasal obstruction, cough, chronic hoarseness, chronic headaches in the periorbital area, facial pain or pressure, and hyposmia (decreased sense of smell) (Adriaensen & Fokkens, 2013). As a result of chronic nasal congestion, the patient is usually required to breathe through the mouth. Snoring, sore throat, and, in some situations, adenoidal hypertrophy may also occur. In general, these symptoms are most pronounced on awakening in the morning.

To diagnose the rhinosinusitis, a careful history and physical examination are performed. It is essential to obtain any history of comorbid conditions, including asthma, and history of tobacco use. A history of fever, fatigue, previous episodes and treatments, and previous response to therapies are also obtained.

The head and neck, particularly the nose, ears, teeth, sinuses, pharynx, and chest, are examined. The physical assessment includes examination of the external nose for evidence of anatomical abnormality. Nasal mucous membranes are assessed for erythema, pallor, atrophy, edema, crusting, discharge, polyps, erosions, and septal perforations or deviations. There may be tenderness to palpation over the infected sinus area.

Diagnostic imaging (x-ray, computed tomography [CT], magnetic resonance imaging [MRI]) is not recommended for the diagnosis of acute rhinosinusitis if the patient meets clinical diagnostic criteria (Adriaensen & Fokkens, 2013; Rosenfeld et al., 2015). Diagnostic testing may be required to rule out other local or systemic disorders, such as tumor, fistula, and allergy for the patient with CRS. Nasal endoscopy may be indicated to rule out underlying diseases, tumors, and sinus mycetomas (fungus balls).

Medical and Nursing Management

Treatment of acute and chronic rhinosinusitis depends on the cause. The goals of treatment of acute rhinosinusitis are to treat the infection, shrink the nasal mucosa, and relieve pain.

General measures include adequate hydration, steam inhalation for 20 to 30 minutes three times per day if possible, saline irrigation (Adriaensen & Fokkens, 2013), and saline nose drops. Patients are instructed to sleep with the head of the bed elevated and to avoid exposure to cigarette smoke and fumes. Patients are cautioned to avoid caffeine and alcohol, which can lead to dehydration.

Treatment of acute and chronic rhinosinusitis typically involves nasal saline lavage and decongestants. Decongestants or nasal saline spray can improve patency of the ostiomeatal unit (area where the frontal and maxillary sinuses normally drain into the nasal cavity) and improve drainage of the sinuses. Topical decongestants are used only in adults and should not be used for longer than 3 or 4 days. Oral decongestants must be used cautiously in patients with hypertension. OTC antihistamines and prescription antihistamines are used if an allergic component is suspected. Heated mist and saline irrigation also may be effective for opening blocked passages. If the patient continues to have symptoms after 7 to 10 days, the sinuses may need to be irrigated (Prokopakis, Vlastos, Pan, & Ferguson, 2013).

Observation without the use of antibiotics is an option for some patients with uncomplicated ABRS (mild pain, temperature of less than 38.3°C [101°F]). Follow-up is essential. Studies suggest that most patients will improve spontaneously, and antibiotics should be reserved for those with prolonged symptoms (Rosenfeld et al., 2015). When ABRS is confirmed, antibiotic therapy is prescribed. The recommended first-line drug for both children and adults is amoxicillin-clavulanate. Doxycycline may be used as an alternative for patients who cannot tolerate amoxicillin-clavulanate. For patients with a penicillin allergy, doxycycline or a respiratory fluoroquinolone such as levofloxacin or moxifloxacin is recommended (Murr, 2016; Teeters, Boles, Ethier, Jenkins, & Curtis, 2013). Prescribed medications may be required for a period of 3 to 4 weeks for CRS and recurrent acute rhinosinusitis.

For patients with concomitant asthma, leukotriene inhibitors may be used. Leukotriene inhibitors block the binding of *leukotrienes,* which are inflammatory mediators. If allergies are a possible cause of CRS, oral antihistamines or nasal corticosteroids may be prescribed (Borish, 2016; Adriaensen & Fokkens, 2013). The use of intranasal inhalations has been associated with a significant improvement of symptoms of CRS and a reduction in nasal bacteria (Dunn, Dion, & McMains, 2013; Huang & Govindaraj, 2013; Rosenfeld et al., 2015). Intranasal corticosteroids have been shown to produce complete or marked improvement in acute symptoms of CRS, with or without the presence of nasal polyps (Manes & Batra, 2013; Rosenfeld et al., 2015).

If standard medical therapy fails to treat CRS and symptoms persist, endoscopic sinus surgery (ESS) may be indicated to correct structural deformities that obstruct the ostia (openings) of the sinuses (Borish, 2016; Settipane, Peters, & Chandra, 2013). Patients undergoing ESS report a reduction of symptoms including headache, nasal obstruction, fatigue, body pains, and hyposmia (Settipane et al., 2013). Excising and cauterizing nasal polyps, correcting a deviated septum, incising and draining the sinuses, aerating the sinuses, and removing tumors are some of the specific procedures performed. If sinusitis is caused

by a fungal infection, surgery is required to excise both the fungus ball and necrotic tissue and drain the sinuses. Antimicrobial agents are administered before and after surgery. Some patients with severe chronic sinusitis obtain relief only by relocating to a dry climate.

Complications

If untreated, acute rhinosinusitis may lead to severe complications. Local complications include osteomyelitis and mucocele (cyst of the paranasal sinuses). Osteomyelitis requires prolonged antibiotic therapy and, at times, removal of necrotic bone. Intracranial complications are rare but include cavernous sinus thrombosis, meningitis, brain abscess, ischemic brain infarction, and severe orbital cellulites (Papadakis et al., 2015; Ocampo & Grammer, 2013). Complications of CRS, although uncommon, include severe orbital cellulitis, subperiosteal abscess, cavernous sinus thrombosis, meningitis, encephalitis, and ischemic infarction. CRS can also lead to intracranial infection.

PHARYNGITIS

Acute pharyngitis is a sudden inflammation of the pharynx involving the back portion of the tongue, soft palate, and tonsils. Chronic pharyngitis is a persistent inflammation of the pharynx.

Pathophysiology

Most cases of acute pharyngitis are caused by viral infection. Responsible viruses include the adenovirus, influenza virus, Epstein–Barr virus, and herpes simplex virus. Bacterial organisms account for the remainder of the cases. Ten percent of adults with pharyngitis have group A beta-hemolytic streptococcus, more commonly known as group A streptococcus (GAS), streptococcal pharynigitis or "strep throat". Other bacterial organisms found in acute pharyngitis include *Mycoplasma pneumoniae, Neisseria gonorrhoeae,* and *H. influenzae* type B.

Risk Factors

Acute pharyngitis is more common in patients less than 25 years of age (usually between 5 and 15 years). Chronic pharyngitis is common in adults who work or live in dusty surroundings, use their voice to excess, suffer from chronic cough, or habitually use alcohol and tobacco.

Clinical Manifestations and Assessment

The signs and symptoms of acute pharyngitis include a fiery-red pharyngeal membrane and tonsils, lymphoid follicles that are swollen and flecked with white-purple exudate, enlarged and tender cervical lymph nodes, and no cough (Fig. 9-3). Creamy exudates may be present in the tonsillar pillars. A fever greater than 100.4°F (38°C), malaise, and sore throat also may be present. Patients with GAS pharyngitis may exhibit vomiting, anorexia, and a scarlatina-form rash with urticaria known as *scarlet fever.*

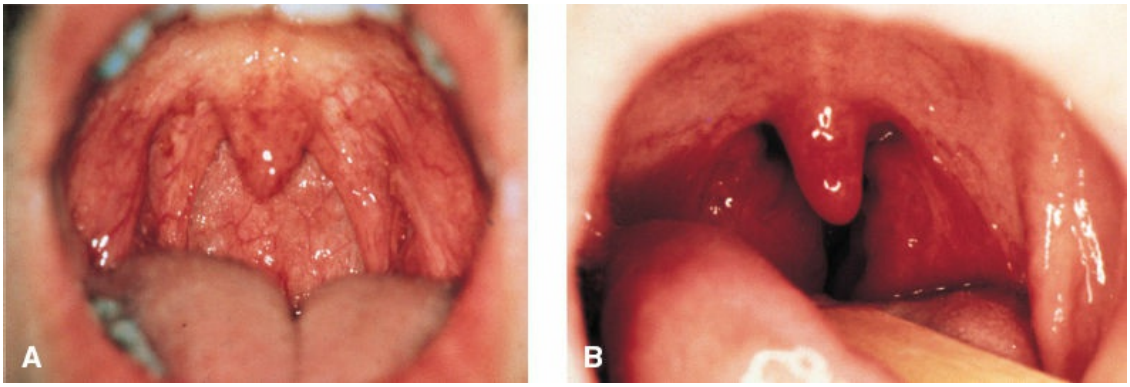


FIGURE 9-3 Pharyngitis, inflammation without exudate. A. Redness and vascularity of the pillars and uvula are mild to moderate. B. Redness is diffuse and intense. Each patient would probably complain of a sore throat. (From Bickley, L. S., & Szilagyi, P. G. (2013). *Bates' guide to physical examination and history taking* (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Patients with chronic pharyngitis complain of a constant sense of irritation or fullness in the throat, mucus that collects in the throat and can be expelled by coughing, and difficulty swallowing. A sore throat that is worse with swallowing in the absence of pharyngitis suggests the possibility of thyroiditis and should be referred for evaluation.

Accurate diagnosis of pharyngitis is essential to determine the causative organism and to initiate treatment early. Rapid antigen detection testing (RADT) strep test and strep culture (sometimes referred to as STCX) should be used and require proper collection technique because improper collection reduces the accuracy of the test (Borchardt, 2013).

Medical and Nursing Management

Viral pharyngitis is treated with supportive measures. Antibiotics will have no effect on the organism.

If a bacterial cause is suggested or demonstrated, penicillin is usually the treatment of choice in the treatment of acute pharyngitis (Spinks, Glasziou, & Del Mar, 2013). Nasal congestion may be relieved by short-term use of nasal sprays or medications containing ephedrine sulfate or phenylephrine hydrochloride. For a patient with a history of allergy, one of the antihistamine decongestant medications is prescribed orally every 4 to 6 hours. Aspirin or acetaminophen is recommended for its anti-inflammatory and analgesic properties.

Treatment of chronic pharyngitis is based on relieving symptoms, avoiding exposure to irritants, and correcting any upper respiratory, pulmonary, or cardiac condition that might cause a chronic cough. For adults with chronic pharyngitis, tonsillectomy is an effective option.

Complications

Uncomplicated viral infections usually subside promptly, within 3 to 10 days after the onset. However, pharyngitis caused by more virulent bacteria, such as GAS, is a more severe illness. If left untreated, the complications can be severe and life-threatening. Complications include rhinosinusitis, otitis media, peritonsillar abscess, mastoiditis, and cervical adenitis. In rare cases, the infection may lead to bacteremia, pneumonia, meningitis, rheumatic fever, rheumatic heart disease or glomerulonephritis. Acute poststreptococcal glomerulonephritis (APSGN) is a complication that follows roughly 10 days after the onset of streptococcal infection and results in temporary kidney failure. APSGN is characterized by the rapid onset of gross hematuria, edema (leading to respiratory distress and pulmonary edema), and hypertension, and is usually preceded by an episode of group A streptococcal (GAS) pharyngitis or pyoderma (skin infection with pustules) (Borchardt, 2013).

LARYNGITIS

Laryngitis is inflammation of the larynx.

Pathophysiology

Laryngitis often occurs as a result of voice abuse or exposure to dust, chemicals, smoke, and other pollutants, or as part of a URI. It also may be caused by infection involving the vocal cords. Laryngitis is also associated with gastroesophageal reflux.

Laryngitis is very often caused by the same pathogens that cause the common cold and pharyngitis: a virus. Laryngitis is often associated with allergic rhinitis or pharyngitis. The onset of infection may be associated with exposure to sudden temperature changes, dietary deficiencies, malnutrition, or an immunosuppressed state. Viral laryngitis is common in the winter and is easily transmitted to others.

Clinical Manifestations and Assessment

Signs of acute laryngitis include hoarseness or aphonia (complete loss of voice) and severe cough. Other signs of acute laryngitis include sudden onset aggravated by cold dry wind. The throat feels worse in the morning and improves when the patient is indoors in a warmer climate. At times, the patient presents with a dry cough and a dry, sore throat that worsens in the evening hours. If allergies are present, the uvula will be visibly edematous. Many patients also complain of a "tickle" in the throat that is made worse by cold air or cold liquids. Chronic laryngitis is marked by persistent hoarseness.

Medical and Nursing Management

Management of acute or chronic laryngitis includes resting the voice, avoiding irritants (including smoking), getting enough rest drinking additional fluids, and inhaling cool steam or an aerosol. Decongestants should be avoided due to their drying effects. In addition, alcohol and caffeine should be avoided because of their diuretic effects (Fort, 2016). The majority of patients recover with conservative treatment; however, laryngitis tends to be more severe in elderly patients and may be complicated by pneumonia.

If laryngitis is part of a more extensive respiratory infection caused by a bacterial organism, or if it is severe, appropriate antibacterial therapy is instituted. For chronic laryngitis, the use of topical corticosteroids may be given by inhalation. These preparations have few systemic or long-lasting effects and may reduce local inflammatory reactions. Treatment for reflux laryngitis typically involves use of proton pump inhibitors given once daily.

NURSING PROCESS

The Patient with Upper Airway Infection

ASSESSMENT

A health history may reveal signs and symptoms of headache, sore throat, pain around the eyes and on either side of the nose, difficulty in swallowing, cough, hoarseness, fever, stuffiness, and generalized discomfort and fatigue. Determining when the symptoms began, what precipitated them, what (if anything) relieves them, and what aggravates them is part of the assessment. Inspection may reveal swelling, lesions, or asymmetry of the nose, as well as bleeding or discharge. The nurse inspects the nasal mucosa for abnormal findings such as increased redness, swelling, exudate, and nasal polyps, which may develop in chronic rhinitis. The mucosa of the nasal turbinates may also be swollen (boggy) and pale, bluish-gray. The nurse palpates the frontal and maxillary sinuses for tenderness, which suggests inflammation, and then inspects the throat by having the patient open the mouth wide and take a deep breath. The tonsils and pharynx are inspected for abnormal findings such as redness, asymmetry, or evidence of drainage, ulceration, or enlargement. The nurse also palpates the trachea to determine the midline position in the neck and to detect any masses or deformities. The neck lymph nodes are palpated for enlargement and tenderness.

DIAGNOSIS

Appropriate nursing diagnoses may include:

- Ineffective airway clearance related to excessive mucus production secondary to retained secretions and inflammation.
- Acute pain related to upper airway irritation secondary to an infection.
- Impaired verbal communication related to physiologic changes and upper airway irritation secondary to infection, swelling, hoarseness, or loss of speech.
- Deficient fluid volume related to decreased fluid intake and increased fluid loss secondary to diaphoresis associated with a fever.
- Deficient knowledge regarding prevention of URIs, treatment regimen, surgical procedure, or postoperative care.

PLANNING

The major goals for the patient may include maintenance of a patent airway, relief of pain, maintenance of effective means of communication, normal hydration, knowledge of how to prevent upper airway infections, and absence of complications.

NURSING INTERVENTIONS

MAINTAINING A PATENT AIRWAY

An accumulation of secretions can block the airway in patients with URI. As a result, changes in the respiratory pattern occur, and the work of breathing increases to compensate for the blockage. The nurse can implement several measures to loosen thick secretions or to keep the secretions moist so that they can be expectorated easily. Increasing fluid intake helps thin the mucus. Use of room vaporizers or steam inhalation also loosens secretions and reduces inflammation of the mucous membranes. To enhance drainage from the sinuses, the nurse instructs the patient about the best position to assume; this depends on the location of the infection or inflammation.

PROMOTING COMFORT

URIs usually produce localized discomfort. The nurse encourages the patient to take analgesics as prescribed. Other helpful measures include topical anesthetic agents for symptomatic relief of herpes simplex blisters and sore throats, hot packs to relieve the congestion of rhinosinusitis and promote drainage, and warm-water gargles or irrigations to relieve the pain of a sore throat. The benefits of this treatment depend on the degree of heat that is applied. The nurse encourages rest to relieve the generalized discomfort and fever that accompany many upper URIs.

PROMOTING COMMUNICATION

URIs may result in hoarseness or loss of speech. The nurse instructs the patient to refrain from speaking as much as possible. Additional strain on the vocal cords may delay full return of the voice. The nurse encourages the patient and family to use alternative forms

of communication, such as a memo pad.

ENCOURAGING FLUID INTAKE

In URIs, the work of breathing and the respiratory rate increase as inflammation and secretions develop. This may increase insensible fluid loss. Fever further increases the metabolic rate, diaphoresis, and fluid loss. Sore throat, malaise, and fever may interfere with a patient's willingness to eat and drink. The nurse provides a list of easily ingested foods to increase caloric intake during the acute phase of illness. These include soups, pudding, yogurt, cottage cheese, high-protein drinks, and popsicles. The nurse encourages the patient to drink 2 to 3 L of fluid per day during the acute stage of airway infection, unless contraindicated, to thin the secretions and promote drainage. Liquids (hot or cold) may be soothing, depending on the disorder. In severe situations, IV fluids may be needed.

PREVENTING INFECTION

Prevention of most URIs is difficult because of the many potential causes. But because most URIs are transmitted by hand-to-hand contact, the nurse teaches the patient and family techniques to minimize the spread of infection to others, including frequent handwashing. The nurse advises the patient to avoid exposure to people who are at risk for serious illness including elderly adults, immunosuppressed people, and those with chronic health problems. The nurse may advise elderly patients and those at increased risk from a respiratory infection to consider an annual influenza and pneumococcal vaccine as recommended by the primary care provider (PCP). A follow-up appointment with the PCP may be indicated for patients with compromised health status to ensure that the respiratory infection has resolved.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Because most patients with URIs are managed at home, patients and their families must be instructed to monitor for signs and symptoms and to seek immediate medical care if the patient's condition does not improve or if the patient's physical status appears to be worsening. Symptoms that require further attention include persistent or high fever, increasing shortness of breath, confusion, and increasing weakness and malaise. Potential complications include sepsis, meningitis or brain abscess, and peritonsillar abscess, otitis media, or rhinosinusitis.

Sepsis and meningitis may occur in patients with compromised immune status or in those with an overwhelming bacterial infection. The nurse explains to the patient that fever, severe headache, and nuchal rigidity (stiffness of the neck/inability to bend the neck) are signs of potential complications. The patient with sepsis requires expert care to treat the infection, stabilize vital signs, and prevent or treat septicemia and shock. Deterioration of the patient's condition necessitates intensive care measures (e.g., hemodynamic monitoring and administration of vasoactive medications, IV fluids, nutritional support, corticosteroids) to monitor the patient's status and to support the

patient's vital signs. High doses of antibiotics may be administered to treat the causative organism. The nurse's role is to monitor the patient's vital signs, hemodynamic status, and laboratory values; administer needed treatment; alleviate the patient's physical discomfort; and provide explanations, teaching, and emotional support to the patient and family. Refer to Chapter 54 for management of septic shock.

The patient and family are instructed about the signs and symptoms of otitis media and rhinosinusitis (periorbital edema, severe facial pain on palpation) and about the importance of follow-up with the PCP to ensure adequate evaluation and treatment of these conditions.

Potential for airway compromise is possible in severe pharyngitis. Symptoms that require provider referral include dyspnea, drooling, inability to swallow, and inability to fully open the mouth. The skin should be examined for possible rash because acute pharyngitis may precede some other communicable diseases (e.g., rubella). For the patient with laryngitis, the signs and symptoms that require contacting the health care provider include loss of voice with sore throat that makes swallowing saliva difficult, hemoptysis, and noisy respirations.

EVALUATION

Expected outcomes include:

1. Maintains a patent airway by managing secretions:
    a. Reports decreased congestion.
    b. Assumes best position to facilitate drainage of secretions.
    c. Uses self-care measures appropriately and consistently to manage secretions during the acute phase of illness.
2. Reports relief of pain and discomfort using pain intensity scale:
    a. Uses comfort measures: Analgesics, hot packs, gargles, rest.
    b. Demonstrates adequate oral hygiene.
    c. Free of pain in ears, sinuses, and throat.
3. Demonstrates ability to communicate needs, wants, level of comfort.
4. Maintains adequate fluid and nutrition intake.
5. Utilizes strategies to prevent upper airway infections:
    a. Demonstrates hand hygiene technique.
    b. Identifies the value of the influenza and pneumococcal vaccines.
6. Absence of complications:
    a. No signs of sepsis: Fever, hypotension, deterioration of cognitive status.
    b. Vital signs and hemodynamic status normal.
    c. No evidence of neurologic involvement.
    d. No signs of development of brain abscess.
    e. Resolution of URI without development of otitis media or rhinosinusitis.

OBSTRUCTION AND TRAUMA OF THE UPPER RESPIRATORY AIRWAY

OBSTRUCTION DURING SLEEP

Obstructive sleep apnea syndrome (OSA) is a disorder characterized by recurrent episodes of upper airway obstruction and a reduction in ventilation. It is defined as cessation of breathing (apnea) during sleep, usually caused by repetitive upper airway obstruction. It interferes with the person's ability to obtain adequate rest and, ultimately, can affect memory, learning, and decision-making (Carlucci, Smith, & Corbridge, 2013). As many as 18 million Americans suffer from sleep apnea (Jordan, McSharry, & Malhotra, 2014).

Various definitions of OSA—also referred to as obstructive sleep apnea/hypopnea syndrome (OSAHS) or upper respiratory resistance syndrome (UARS)—exist, leading to overestimation of the prevalence of this syndrome.

Pathophysiology

OSA is a disorder characterized by recurrent episodes of upper airway obstruction, causing a reduction in ventilation followed by frequent arousals and periodic oxyhemoglobin desaturations during sleep (Jordan et al., 2014). OSA is defined as the presence of at least five obstructive events (apneas and hypopneas [slow or shallow breathing]) per hour during sleep (Jordan et al., 2014; Paiva & Attarian, 2014). Repetitive apneic events result in hypoxia and hypercapnia, which trigger a sympathetic response (increased heart rate and increased tone and contractility of smooth muscle). An obstruction may be caused by mechanical factors such as a reduced diameter of the upper airway or dynamic changes in the upper airway during sleep.

Patients with OSA have a higher prevalence of hypertension and an increased risk of myocardial infarction, stroke, and death (Basner, 2016; Jordan et al., 2014). Patients with underlying cardiovascular disease may find the nocturnal hypoxemia may predispose them to arrhythmias. Patients who have a diagnosis of heart failure and who have untreated OSA are at increased risk of death (Pavia & Attarian, 2014; Jordan et al., 2014). OSA can also increase insulin resistance and other metabolic changes that can increase the risk of vascular disease (Drager, Togeiro, Polotsky, & Lorenzi-Filho, 2013). OSA is more prevalent in people with coronary artery disease, congestive heart failure, metabolic syndrome, and type 2 diabetes, suggesting that screening for OSA is indicated in patients with these pathologies (Carlucci et al., 2013).

Risk Factors

Sleep apnea is more prevalent in men, especially those who are older and overweight (Jordan et al., 2014). However, postmenopausal and obese women are at increased risk of developing OSA as well (Basner, 2016). The major risk factor for OSA is obesity around the neck that narrows and compresses the upper airway. The elderly have a higher prevalence of OSA (Jordan et al., 2014). Other associated factors include alteration in the upper airway, such as structural changes (e.g., tonsillar hypertrophy, abnormal posterior positioning of one or both jaws, excessive fat deposits in the lateral walls of the pharynx, and craniofacial structural abnormalities) that contribute to the collapsibility of the airway and increase the risk of sleep apnea (Pavia & Attarian, 2014).

Clinical Manifestations and Assessment

OSA is characterized by frequent and loud snoring with breathing cessation for 10 seconds or longer, for at least five episodes per hour, followed by awakening abruptly with a loud snort as the blood oxygen level drops. Classic signs and symptoms of OSA are presented in Box 9-1. Symptoms typically progress with increases in weight and aging as well as during the transition to menopause (Jordan et al., 2014).

Several screening tools/questionnaires are available to assess the frequency and severity of symptoms (Jordan et al., 2014). The diagnosis of sleep apnea is based on clinical symptoms plus polysomnographic findings (sleep study). This overnight sleep study measures multiple physiologic signals related to sleep (electroencephalogram [EEG], electrocardiogram [ECG], and airflow), in order to gauge oxyhemoglobin saturation, brain activity, eye movement, thoracic muscle activity, body position, respiratory rate, heart rate, cardiac arrhythmias, chest impedance, and airflow (Jordan et al., 2014).

Medical Management

Treatments are varied but include weight loss and avoidance of alcohol and hypnotic medications initially (Papadakis et al., 2015; Pavia & Attarian, 2014). Weight loss reduces the number of apneas and hypopneas per hour of total sleep time as measured by the apnea–hypopnea index (AHI) (Carlucci et al., 2013; Baby, Aronow, & Chandy, 2013). Oral appliances designed to reposition the mandible or tongue may be useful in select patients. These devices are not very beneficial in the elderly patient as full dentition is required (Baby et al., 2013; Jordan et al., 2014).

BOX 9-1 Focused Assessment

Obstructive Sleep Apnea (OSA)

Be alert for the following signs and symptoms:

- Excessive daytime sleepiness
- Frequent nocturnal awakening
- Insomnia
- Loud snoring
- Morning headaches
- Intellectual deterioration
- Personality changes, irritability
- Impotence
- Systemic hypertension
- Arrhythmias
- Pulmonary hypertension, cor pulmonale
- Polycythemia
- Enuresis

Noninvasive Positive-Pressure Ventilation

In more severe cases of OSA involving hypoxemia with severe carbon dioxide retention (hypercapnia), the treatment includes continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) therapy with supplemental oxygen (Carlucci et al., 2013). Patients are considered candidates for noninvasive ventilation if they have acute or chronic respiratory failure, acute pulmonary edema, chronic obstructive pulmonary disease (COPD), chronic heart failure, or OSA. The device also may be used at home to improve tissue oxygenation and to rest the respiratory muscles while the patient sleeps at night.

CPAP provides positive pressure to the airways throughout the respiratory cycle, preventing collapse (Basner, 2016; Baby et al., 2013; Jordan et al., 2014). A CPAP delivery system is comprised of an air pump that is connected to a nasal, oral, or combined mask by

a flexible tube. The air pump extracts external filtered air to deliver the pressurized airflow that can be adjusted (Basner, 2016; Baby et al., 2013). The leak-proof mask keeps the alveoli open, thereby preventing respiratory failure. CPAP is the most effective treatment for OSA because the positive pressure acts as a splint, keeping the upper airway and trachea open during sleep. To use CPAP, the patient must be breathing independently (Baby et al., 2013; Carlucci et al., 2013).

BiPAP ventilation offers independent control of inspiratory and expiratory pressures while providing pressure-support ventilation. It delivers two levels of positive airway pressure via a nasal or oral mask, nasal pillow, or mouthpiece with a tight seal and a portable ventilator. Each inspiration can be initiated either by the patient or by the machine (programmed backup rate). The backup rate ensures that the patient will receive a set number of breaths per minute. BiPAP is most often used for patients who require ventilatory assistance at night, such as those with severe COPD or sleep apnea. Tolerance is variable; BiPAP usually is most successful with highly motivated patients (Baby et al., 2013).

Problems with CPAP or BiPAP therapy are common. Commonly reported adverse effects of CPAP include skin irritations, pain, rash, or breakdown at the mask contact points (usually the bridge of the nose). Dryness or irritation of the nasal and pharyngeal membranes, nasal congestion, and eye irritation from leakage from the mask are also reported (Basner, 2016; Baby et al., 2013; Hu, Yu, & Tsao, 2013). Gastrointestinal bloating secondary to air swallowing is another common side effect (Basner, 2016). Proper fitting of the mask should allow for therapy to continue. Although these treatments are effective in managing OSA, patient compliance with treatment continues to be a major concern (Carlucci et al., 2013). Nursing research on the factors (physical, psychological, and social) influencing the use and nonuse of CPAP therapy is described in Box 9-2.

Surgical Management

Surgical procedures (e.g., tonsillectomy or uvulopalatopharyngoplasty [termed UPPP, the surgical resection of pharyngeal soft tissue and uvula]) may be performed to correct the obstruction should the airway be in jeopardy or the patient has been unsuccessful with CPAP therapy. Effective in about 50% of patients, UPPP is more effective in eliminating snoring than in eliminating apnea (Baby et al., 2013). UPPP has been shown to reduce the AHI by 50% (Pavia & Attarian, 2014). Nasal septoplasty may be performed for anatomic nasal septal deformities. Tracheostomy relieves upper airway obstruction but has many adverse effects, including speech difficulties and increased risk of infections. These procedures, as well as other maxillofacial surgeries, are reserved for patients with life-threatening arrhythmias or severe disabilities who have not responded to conventional therapy (Baby et al., 2013; Papadakis et al., 2015).

Pharmacologic Therapy

Although medications are not generally recommended for OSA, modafinil (Provigil) has been shown to reduce daytime sleepiness (Jordan et al., 2014). Protriptyline (Triptil), Theophylline (Aminophylline), and estrogen therapy are not recommended for treating OSA (Baby et al., 2013). Patients must understand that medications are not a substitute for CPAP or BiPAP therapy. Administration of low-flow nasal oxygen at night can help relieve

hypoxemia in some patients but has little effect on the frequency or severity of apnea. Further study on the effectiveness of pharmacologic therapy is needed.

Nursing Management

The patient with OSA may not recognize the potential consequences of the disorder. The nurse explains the disorder and relates symptoms (daytime sleepiness, morning headaches, heartburn, insomnia, snoring) to the underlying disorder. The nurse also instructs the patient and family about treatments, including weight loss, avoiding alcohol and sedative medications, and the correct and safe use of prescribed therapies such as CPAP, BiPAP, and oxygen therapy.

EPISTAXIS (NOSEBLEED)

Epistaxis, a hemorrhage from the nose, is caused by the rupture of tiny, distended vessels in the mucous membrane of any area of the nose. Most commonly, the site is the anterior septum, where three major blood vessels enter the nasal cavity. Several risk factors may be associated with epistaxis and are described in Box 9-3.

BOX 9-2 Nursing Research

Bridging the Gap to Evidence-Based Practice

Is Inconsistent Pretreatment Bedtime Related to CPAP Nonadherence?

Sawyer, A. M., King, T. S., Sawyer, D. A., & Rizzo, A. (2014). *Research in Nursing & Health*, 37(6), 504–511.

Purpose

Continuous positive airway pressure (CPAP) is the treatment of choice for patients with obstructive sleep apnea (OSA). Lack of adherence to continuous positive airway pressure therapy (CPAP) is a well-recognized limitation to the effectiveness of treatment of OSA. Patterns of CPAP use are established early in the treatment period, generally during the first week of home therapy. These patterns have been shown to be consistent with long-term CPAP outcomes. It is important to determine predictors of CPAP nonadherence prior to treatment initiation to minimize noncompliance. Multiple factors have been examined as related to CPAP compliance, including patient characteristics, titration method, sleep quality, disease and symptom severity, and psychological and psychosocial factors. Some important insights into CPAP adherence have emerged, but challenges still surround CPAP nonadherence.

Design

In a prospective longitudinal study conducted at two clinical sleep centers in the United States, the authors examined whether inconsistent self-reported bedtime before initiation of CPAP treatment, operationalized as bedtime variability, was (1) different among those adherent (more than 4 hours a night) and nonadherent to CPAP treatment at 1 week and 1 month; and/or (2) related to 1-week and 1-month CPAP use when other variables were accounted for. Participants were recruited from those referred to the sleep centers for CPAP titration polysomnogram (PSG). Patients who responded to an invitation to participate in the study were contacted and screened. Inclusion criteria for the study were (1) newly diagnosed OSA with AHI of at least five events/hour on in-laboratory PSG; (2) referral to CPAP titration PSG; and (3) able to speak and read English. Exclusion criteria were (1) supplemental oxygen or bilevel positive airway pressure required during titration PSG; (2) newly diagnosed psychiatric disorder within 6 months; and (3) medical contraindications to using CPAP for treatment of OSA. A total of 102 patients were enrolled with a final complete data collection from 79 patients.

Data collection included an 18-item, self-reported demographic questionnaire; a diagnostic PSG; and a 1-week sleep diary completed after PSG but before CPAP

titration PSG. Participants completed the diary by recording date; day of the week; whether it was a work day, vacation day, and/or weekend day; time to bed; and time of terminal awakening. The independent variable, pretreatment bedtime variability (inconsistency in time of going to bed to initiate sleep), was derived from sleep diary recordings. Objective CPAP use data were collected from the internal microprocessor on standard CPAP devices after 1 month of home CPAP treatment. The CPAP use data were hours per night at effective pressure for at least 20 minutes. Nonadherence was defined as less than 4 hours per night of CPAP use.

Findings

The study sample (N = 79) were predominantly white non-Hispanic, college-educated, obese, and employed full-time, with slightly more males than females. Most (68%) had been referred. The majority had severe OSA. Participants' CPAP use averaged 4.6 hours per night (SD 2.5) at 1 week, with 27 participants (34.2%) below the minimal adherence level of 4 hours per night. The sample averaged 4.3 hours per night (SD 2.4) of CPAP at 1 month, with 31 (39.2%) below the 4-hour minimum for adherence. Hours of CPAP use per night were significantly different between CPAP adherents and nonadherents at both time points. There were no differences between 1-month CPAP adherents and nonadherents on any baseline characteristic except marital status.

Mean pretreatment bedtime variability was 63.1 minutes (SD 38.04; median 55.93, IQR 38.17). Pretreatment bedtime variability was not statistically different between CPAP adherents and nonadherents at 1 week and did not predict CPAP nonadherence at 1 week. The 31 participants who were nonadherent at 1 month had significantly greater variability in pretreatment bedtime. Men who were nonadherent to CPAP had greater bedtime variability than did adherent men; while for female participants, the difference in bedtime variability between nonadherent and adherents was not statistically significant. Educational level was examined as potential modifiers for the effect of bedtime variability. Lower educational levels were associated with an increased bedtime variability and CPAP nonadherence.

These results suggest that pretreatment bedtime variability, or inconsistency in time of going to bed to initiate sleep, is an important and modifiable predictor of 1-month CPAP nonadherence, especially among men and those with little completed education. More than 75 minutes of bedtime variability conferred significantly more statistical risk for CPAP nonadherence than having less than 75 minutes of bedtime variability. These findings provide preliminary evidence to support the inclusion of sleep schedule stabilization, or minimizing bedtime inconsistency, in future interventions aimed at reducing CPAP nonadherence.

Nursing Implications

Strategies for patient education, assessment, and management of therapies to treat disorders of sleep related to OSA can be strengthened as the variables leading to adherence or nonadherence to CPAP therapy are studied and reported in the literature.

Incorporating knowledge and behavioral changes, including incorporating scheduled repetitive behaviors around bedtime, can lead to increase in adherence to CPAP treatment.

BOX 9-3 Risk Factors for Epistaxis

- Local infections/inflammation (vestibulitis, rhinitis, rhinosinusitis, sinusitis, nasal polyps)
- Systemic infections (scarlet fever, malaria)
- Drying of nasal mucous membranes (cold, dry environment); overuse of decongestant nasal sprays
- Structural deformities (deviated septum, chronic perforations)
- Nasal inhalation of illicit drugs (e.g., cocaine), irritants
- Trauma (digital trauma as in picking the nose; blunt trauma; fracture; forceful nose-blowing)
- Nasal or facial surgery
- Arteriosclerosis
- Hypertension
- Tumor (sinus or nasopharynx)
- Coagulopathy (thrombocytopenia, hemophilia, von Willebrand disease)
- Drugs: Use of aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), warfarin
- Liver disease
- Osler–Weber–Rendu (hereditary hemorrhagic telangiectasia)
- Foreign bodies in the nasal cavity

Medical Management

Management of epistaxis depends on its cause and the location of the bleeding site. Initial treatment includes applying direct pressure. The patient sits upright with the head tilted forward to prevent swallowing and aspiration of blood and is directed to pinch the soft outer portion of the nose against the midline septum for 5 or 10 minutes continuously. If this measure is unsuccessful, the nose must be examined using good illumination and suction to determine the site of bleeding (Murr, 2016). Cotton applicators soaked in a vasoconstricting solution (i.e., epinephrine, ephedrine, cocaine) may be inserted into the nose to reduce the blood flow. Visible bleeding sites may be cauterized with silver nitrate or electrocautery (high-frequency electrical current). A supplemental patch of Surgicel or Gelfoam may be used (Papadakis et al., 2015). If the origin of the bleeding cannot be identified, the nose may be packed with gauze impregnated with petroleum jelly or antibiotic ointment. The packing may remain in place for 48 hours or up to 5 or 6 days if necessary to control bleeding. Antibiotics may be prescribed because of the risk of iatrogenic sinusitis and toxic shock syndrome.

Nursing Management

The nurse monitors the patient's vital signs, assists in the control of bleeding, and provides tissues and an emesis basin to allow the patient to expectorate any excess blood. The nurse continuously assesses the patient's airway and breathing, as well as vital signs. On rare occasions, a patient with significant hemorrhage requires IV infusions of crystalloid solutions (normal saline) as well as cardiac and pulse oximetry monitoring.

Once the bleeding is controlled, the nurse instructs the patient to avoid vigorous exercise for several days and to avoid hot or spicy foods and tobacco, as they may cause vasodilation and an increased risk of rebleeding. Discharge teaching includes reviewing ways to prevent epistaxis: avoiding forceful nose-blowing, straining, high altitudes, and nasal trauma. Adequate humidification may prevent drying of the nasal passages. The nurse instructs the patient how to apply direct pressure to the nose in case of a recurrent nosebleed. If recurrent bleeding cannot be stopped, the patient is instructed to seek additional medical attention.

NASAL OBSTRUCTION

The passage of air through the nostrils is frequently obstructed by a deviation of the nasal septum, hypertrophy of the turbinate bones, or the presence of nasal polyps. Chronic nasal congestion forces the patient to breathe through the mouth, producing dryness of the oral mucosa and other problems including persistent dry, cracked lips. Patients with chronic nasal congestion often suffer from sleep deprivation due to difficulty maintaining an adequate airway while lying flat during sleep.

Medical Management

The treatment of nasal obstruction requires the removal of the obstruction, followed by measures to treat chronic infection. Measures to reduce or alleviate nasal obstruction include nonsurgical as well as surgical techniques. Commonly used medications include nasal corticosteroids. Treatment with nasal corticosteroids for 1 to 3 months is beneficial in treatment of small polyps, avoiding surgical intervention. Additional medications may include antibiotics for the treatment of underlying infection or antihistamines for management of allergies. Hypertrophied turbinates may be treated by applying an astringent agent to shrink them. A more aggressive approach in treating nasal obstruction caused by turbinate hypertrophy involves surgical reduction of the hypertrophy, a procedure known as functional rhinoplasty.

Nursing Management

Most of these surgical procedures are performed on an outpatient basis. Postoperatively, the nurse elevates the head of the bed to promote drainage and to alleviate discomfort from edema. Frequent oral hygiene is encouraged to overcome dryness caused by breathing through the mouth. Before discharge, the patient is instructed to avoid blowing the nose with force during the postoperative recovery period. The patient is also instructed about the signs and symptoms of bleeding and infection and when to contact the provider.

FRACTURES OF THE NOSE

Nasal fracture is the most common fracture involving the face. Fractures of the nose usually result from a direct assault. Nasal fractures may affect the ascending process of the maxilla and the septum. The torn mucous membrane results in a nosebleed. In a series of complications, the patient could ultimately experience a hematoma, infection, abscess, and a vascular/septic necrosis. However, as a rule, serious consequences usually do not occur.

Clinical Manifestations and Assessment

The signs and symptoms of a nasal fracture are pain, bleeding from the nose externally and internally into the pharynx, swelling of the soft tissues adjacent to the nose, periorbital ecchymosis, nasal obstruction, and deformity. The patient's nose may have an asymmetric appearance that may not be obvious until the edema subsides.

The nose is examined internally to rule out the possibility that the injury may be complicated by a fracture of the nasal septum and a submucosal septal hematoma (Papadakis et al., 2015). Clear fluid draining from either nostril suggests a fracture of the cribriform plate with leakage of cerebrospinal fluid (CSF). Because CSF contains glucose, it can readily be differentiated from nasal mucus by means of a dipstick. Refer to Chapter 45 for details of CSF leaks.

Nursing Alert
If CSF is suspected, the patient is instructed not to cough or blow the nose. If the patient has to sneeze, do so with an open mouth. The head of bed should be elevated, and nothing should be inserted into the nares. The primary concern of CSF rhinorrhea (leakage of CSF via the nares) is the complication of meningitis.

Careful inspection or palpation discloses any deviations of the bone or disruptions of the nasal cartilages. An x-ray may reveal displacement of the fractured bones and may help rule out extension of the fracture into the skull.

Medical Management

Any bleeding is controlled with the use of packing. For the patient who has sustained traumatic force to break the nose or any facial bone, the possibility of a cervical spine fracture must be considered. If suspected, stabilize the cervical spine and log roll the patient if turning is required. Uncomplicated nasal fractures may be treated initially with analgesic agents, use of ice to reduce swelling, and ENT follow-up.

Treatment of nasal fractures is aimed at restoring nasal function and returning the aesthetic appearance of the nose to baseline. Reduction of the fracture is performed as soon as possible. If edema is too severe to reduce the fraction immediately, reduction is performed within 3 to 7 days. Fractures that heal but are misaligned may require surgical intervention, such as rhinoplasty, to reshape the external appearance of the nose. In patients who develop a septal hematoma, the provider will drain the hematoma through a small incision. Antibiotic coverage is expected after septal hematoma evacuation. A septal hematoma that is not drained can lead to permanent deformity of the nose.

Nursing Management

Immediately after the fracture, the nurse applies ice and encourages the patient to keep the head elevated. The nurse instructs the patient to apply ice packs to the nose for 20 minutes, four times each day, to decrease swelling. The packing inserted to stop the bleeding may be uncomfortable and unpleasant, and obstruction of the nasal passages by the packing forces the patient to breathe through the mouth. This, in turn, causes the oral mucous membranes to become dry. Mouth rinses help to moisten the mucous membranes and to reduce the odor and taste of dried blood in the oropharynx and nasopharynx. Use of analgesic agents, such as acetaminophen, is preferred initially over NSAIDs, such as ibuprofen or naproxen, in the first 2 days to avoid increasing the risk of bleeding. The nurse reminds the patient to avoid sports activities, especially contact sports, for 6 weeks.

LARYNGEAL OBSTRUCTION

Obstruction of the larynx caused by edema is a serious, often fatal, condition. The larynx contains a narrow space between the vocal cords (glottis), through which air must pass. Swelling of the laryngeal mucous membranes may close off the opening tightly, leading to life-threatening hypoxia or suffocation.

Pathophysiology

Edema of the glottis occurs rarely in patients with acute laryngitis, occasionally in patients with urticaria, and more frequently in patients with severe inflammation of the throat, as in scarlet fever. It is an occasional but usually preventable cause of death in severe anaphylaxis (angioedema). Hereditary angioedema (HAE) is also characterized by episodes of life-threatening laryngeal edema. Laryngeal edema in people with HAE can occur at any age, although young adults are at greatest risk. Laryngospasm, a severe form of airway obstruction, may be triggered by mechanical stimulation of the larynx or by cord irritation due to aspiration of oral secretions, blood, or vomitus (Lavery & Craig, 2014).

Risk Factors

Risk factors for laryngeal obstruction are provided in Box 9-4. Foreign bodies frequently are aspirated into the pharynx, the larynx, or the trachea.

BOX 9-4 Risk Factors for Laryngeal Obstruction

- History of allergies that may result in anaphylaxis
- Inhalation/ingestion of foreign body (balloon fragments, chewing gum, drug packets)
- Heavy alcohol consumption or tobacco use (causing a tumor)
- Family history of airway problems (suggests angioedema)
- Use of ACE inhibitors
- Recent throat pain or fever (suggests infectious process)
- History of surgery or previous tracheostomy (suggests possible subglottic stenosis)

Clinical Manifestations and Assessment

The foreign objects obstruct the air passages and cause difficulty in breathing, hoarseness, and stridor, which may lead to asphyxia; and later, the obstructing objects may be drawn farther down, entering the bronchi or a bronchial branch and causing symptoms of irritation, such as a croupy cough, expectoration of blood or mucus, or labored breathing. The patient may demonstrate lowered oxygen saturation; however, normal oxygen saturation should not be interpreted as a sign that the obstruction is not significant. Use of accessory muscles to maximize airflow may occur and is often manifested by retractions in the neck or abdomen during inspirations. Patients who demonstrate these symptoms may need ventilatory support (i.e., mechanical ventilation or positive-pressure ventilation).

A thorough history can be very useful to the health care team in diagnosing and treating the patient with a laryngeal obstruction. The nurse obtains a history from the patient or family about alcohol or tobacco consumption, current medications, family history of airway problems, recent infections, pain or fever, dental pain or poor dentition, and any previous surgeries or trauma. Emergency measures to secure the patient's airway should not be delayed to obtain a history or perform tests. The patient's clinical presentation and x-ray findings confirm the diagnosis of laryngeal obstruction.

Medical and Nursing Management

Medical management is based on the initial evaluation of the patient and the need to ensure a patent airway. If the airway is obstructed by a foreign body and signs of asphyxia are apparent, immediate treatment is necessary. Frequently, if the foreign body has lodged in the pharynx and can be visualized, the finger can dislodge it. If the obstruction is in the larynx or the trachea, the clinician or other rescuer tries the subdiaphragmatic abdominal thrust (Heimlich) maneuver. If all efforts are unsuccessful, an immediate tracheotomy is necessary. If the obstruction is caused by edema resulting from an allergic reaction, treatment may include administration of subcutaneous epinephrine and a corticosteroid (see Chapter 38). Continuous pulse oximetry is essential. Box 9-5 describes nursing management of an upper airway obstruction.

CANCER OF THE LARYNX

Cancer of the larynx is a malignant tumor in and around the larynx (voice box). Squamous cell carcinoma is the most common form of cancer of the larynx (95%). Approximately 55% of patients with laryngeal cancer present with involved lymph nodes at the time of diagnosis (DeVita, Lawrence, & Rosenberg, 2014).

Carcinogens associated with laryngeal cancer include tobacco (smoke, smokeless) and alcohol and their combined effects. Occupational or environmental exposure to asbestos, wood dust, coal dust, steel dust, cement dust, tar products, leather, formaldehyde, and iron compounds and fumes have also been implicated. Other contributing factors include straining the voice, chronic laryngitis, nutritional deficiencies (riboflavin), family predisposition, and a weakened immune system.

Metastatic disease from the true vocal cords is very rare because they are devoid of lymph nodes. The prognosis for patients who have small laryngeal cancers without evidence of spread to the lymph nodes is about 75% to 95%. Recurrence occurs usually within the first 2 to 3 years after diagnosis. The presence of disease after 5 years is very often secondary to a new primary malignancy.

Risk Factors

Cancer of the larynx occurs more frequently in men than in women, and it is most common in people between the ages of 60 and 70 years (American Cancer Society, 2015). The incidence of laryngeal cancer continues to decline, but the incidence in women versus men continues to increase. The disease is also about 50% more common among African Americans than among Caucasian Americans.

Clinical Manifestations and Assessment

Hoarseness of more than 2 weeks' duration occurs in the patient with cancer in the glottic area because the tumor impedes the action of the vocal cords during speech. The voice may sound harsh, raspy, and lower in pitch. Affected voice sounds are not early signs of subglottic or supraglottic cancer. The patient may complain of a persistent cough or sore throat and pain and burning in the throat, especially when consuming hot liquids or citrus juices. A lump may be felt in the neck. Later symptoms include dysphagia, dyspnea (difficulty breathing), unilateral nasal obstruction or discharge, persistent hoarseness, persistent ulceration, and foul breath. Cervical lymph adenopathy, unintentional weight loss, a general debilitated state, and pain radiating to the ear may occur with metastasis.

An initial assessment includes a complete history and physical examination of the head and neck. An indirect laryngoscopy, using a flexible endoscope, is initially performed by the otolaryngologist to visually evaluate the pharynx, larynx, and possible tumor. Mobility of the vocal cords is assessed; if normal movement is limited, the growth may affect muscle, other tissue, and even the airway. The neck and the thyroid gland are palpated for enlarged lymph nodes or thyroid gland.

BOX 9-5 Management of Upper Airway Obstruction

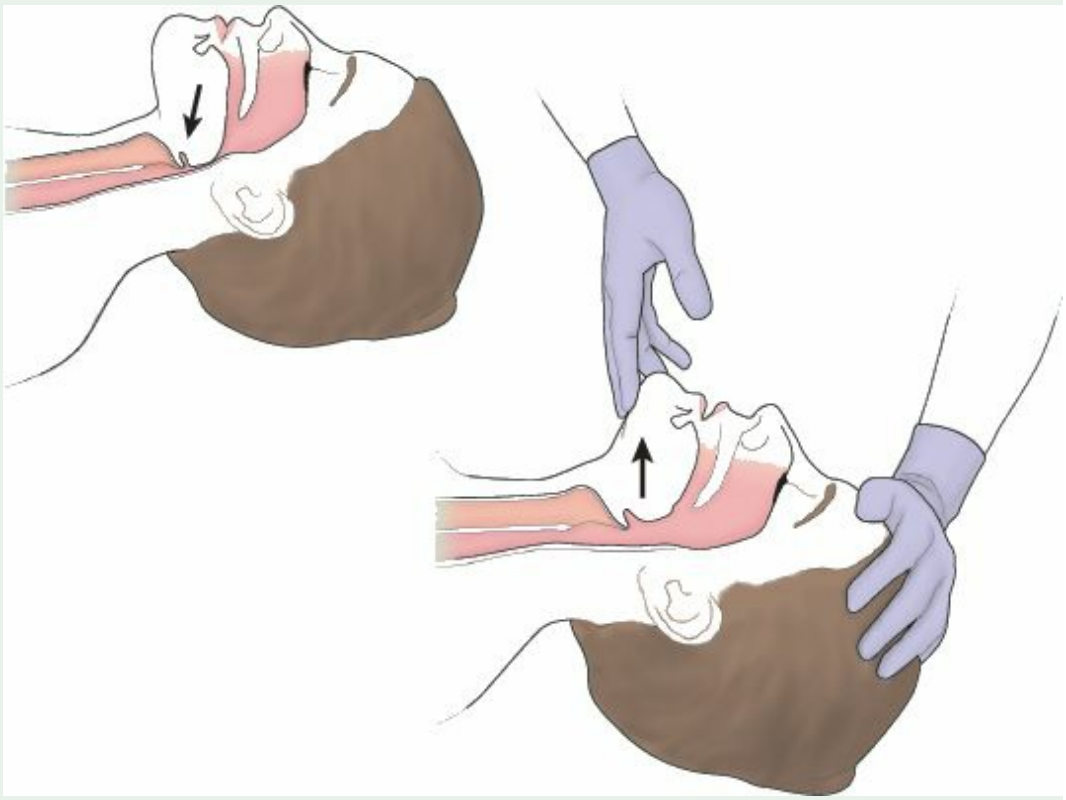
Adequate ventilation is dependent on free movement of air through the upper and lower airways. Maintaining a patent (open) airway is achieved through meticulous airway management, whether in an emergency situation, such as airway obstruction, or in long-term management, as in caring for a patient with an endotracheal or a tracheostomy tube. The patient with an altered level of consciousness from any cause is at risk for upper airway obstruction because of loss of the protective reflexes (cough and swallowing) and loss of the tone of the pharyngeal muscles, which causes the tongue to fall back and block the airway.

The nurse makes rapid observations to assess for signs and symptoms of upper airway obstruction: assessing the patient's level of consciousness (LOC), inspecting the chest for movement and use or retraction of accessory muscles, and noting skin color and any obvious signs of deformity or obstruction of the airway (trauma, food, teeth, tongue, vomitus). The nurse should palpate the trachea for midline location and look for any specific areas of tenderness, fracture, or subcutaneous emphysema (crepitus). Auscultation is performed to assess for audible air movement, stridor (inspiratory crowing sound), or wheezing (high-pitched musical sound) that may be present over the lower trachea and bilaterally in all lobes. As soon as an upper airway obstruction is identified, the nurse takes the following emergency measures:

Clearing the Airway

- Hyperextend the patient's neck by placing one hand on the forehead and placing the fingers of the other hand underneath the jaw and lifting upward and forward. This action pulls the tongue away from the back of the pharynx. Note that this position

is used only if the cervical spine is free of injury. Assess the patient by observing the chest and listening and feeling for the movement of air.

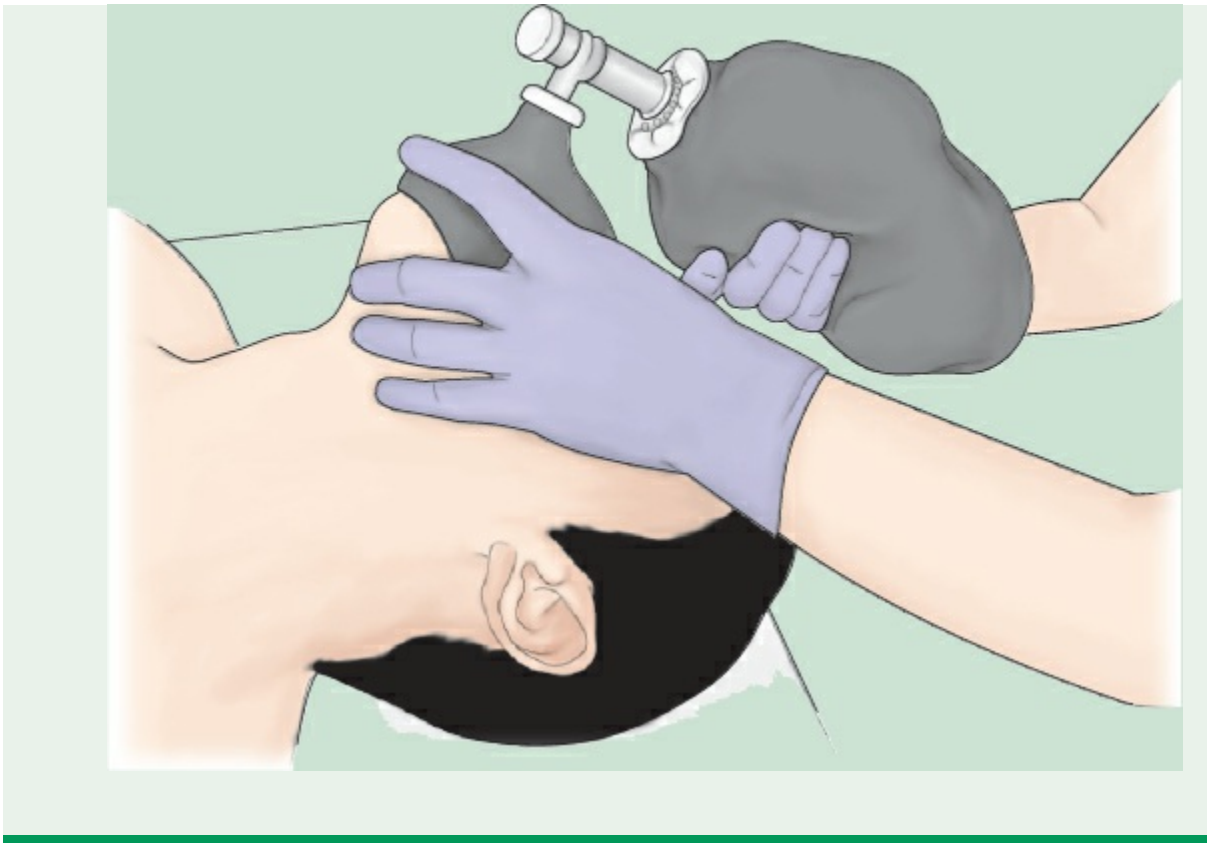


- Use a cross-finger technique to open the mouth and observe for obvious obstructions, such as secretions, blood clots, or food particles.
- If no passage of air is detected, apply five quick sharp abdominal thrusts just below the xiphoid process to expel the obstruction. Repeat this procedure until the obstruction is expelled.

- After the obstruction is expelled, roll the patient as a unit onto the side for recovery.
- When the obstruction is relieved, if the patient can breathe spontaneously but not cough, swallow, or gag, insert an oral or nasopharyngeal airway.

Bag and Mask Resuscitation

- Use a resuscitation bag and mask if assisted ventilation is required.
- Apply the mask to the patient's face and create a seal by pressing the thumb of the nondominant hand on the bridge of the nose and the index finger on the chin. Using the rest of the fingers on that hand, pull on the chin and the angle of the mandible to maintain the head in extension. Use the dominant hand to inflate the lungs by squeezing the bag to its full volume.



Diagnostic procedures that may be utilized include endoscopy, optical imaging, and CT scans. A direct laryngoscopic examination performed under local or general anesthesia may be required to evaluate all areas of the larynx. Direct visualization and palpation of the vocal folds may yield a more accurate diagnosis.

CT and MRI are used to assess regional adenopathy and soft tissue and to help stage and determine the extent of a tumor. MRI is also helpful in posttreatment follow-up to detect a recurrence. Positron emission tomography (PET) scanning may also be used to detect recurrence of a laryngeal tumor after treatment.

Medical Management

The goals of treatment of laryngeal cancer include cure; preservation of safe, effective swallowing; preservation of useful voice; and avoidance of permanent tracheostomy (Papadakis et al., 2015). Treatment options include surgery, radiation therapy, and chemotherapy. The prognosis depends on a variety of factors: tumor stage, the patient's gender and age, and pathologic features of the tumor, including the grade and depth of infiltration. The treatment plan also depends on whether this is an initial diagnosis or a recurrence.

Surgery and radiation therapy are both effective methods in the early stages of cancer of the larynx. Chemotherapy traditionally has been used for recurrence or metastatic disease. It has also been used more recently in conjunction with radiation therapy, to avoid a total laryngectomy, or preoperatively, to shrink a tumor before surgery.

Surgical Management

Surgical management depends largely on the stage of the disease. Complete removal of the larynx (total laryngectomy) can provide the desired cure, but it also leaves the patient with significant loss of the natural voice and the need to breathe through a stoma created in the lower neck. The stoma is a permanent opening into the trachea. Several different procedures are available that can offer voice-sparing results while achieving a positive cure rate for the patient who has an early laryngeal carcinoma. These procedures include vocal cord stripping and cordectomy. Vocal cord stripping involves removal of the mucosa of the edge of the cord using an operating microscope. It is used to treat dysplasia, hyperkeratosis, and leukoplakia and is often the curative treatment for this classification of lesions. A cordectomy is an excision of the vocal cord performed via transoral laser and is used for confined lesions involving the middle third of the vocal cord. The probability of poor voice quality is related to the extent of tissue removed.

These partial resections are increasingly common surgical procedures, using total laryngectomy as salvage therapy for recurrences (Tomeh & Holsinger, 2014; Lewis, 2012). Several different types of laryngectomy are considered for patients with more extensive involvement. These include partial laryngectomy, supraglottic laryngectomy, hemilaryngectomy, or total laryngectomy.

- *Partial laryngectomy* (laryngofissure–thyrotomy): A portion of the larynx is removed, along with one vocal cord and the tumor; all other structures remain. The airway remains intact, and the patient is expected to have no difficulty swallowing. The voice quality may change, or the patient may sound hoarse. It is associated with a high cure rate.
- *Supraglottic laryngectomy:* A voice-sparing operation; the hyoid bone, glottis, and false cords are removed. The true vocal cords, cricoid cartilage, and trachea remain intact. A tracheostomy is left in place until the glottic airway is established. Postoperative irradiation may be indicated. The quality of the voice may change.
- *Hemilaryngectomy:* The thyroid cartilage of the larynx is split in the midline of the neck, and the portion of the vocal cord (one true cord and one false cord) is removed with the

tumor. Some change may occur in the voice quality. The voice may be rough, raspy, and hoarse and have limited projection. The airway and swallowing remain intact.

- *Total laryngectomy:* A complete removal of the larynx, including the hyoid bone, epiglottis, cricoid cartilage, and two or three rings of the trachea. The tongue, pharyngeal walls, and trachea are preserved. This procedure is performed for advanced laryngeal cancer and results in permanent loss of the voice and a change in the airway.

Surgery for laryngeal cancer is more difficult when the lesion involves the midline structures or both vocal cords. With or without neck dissection, a total laryngectomy requires a permanent tracheal stoma (Fig. 9-4) because the larynx that provides the protective sphincter is no longer present. The tracheal stoma prevents the aspiration of food and fluid into the lower respiratory tract. The patient will have no voice but will have normal swallowing. A total laryngectomy changes the manner in which airflow is used for breathing and speaking, as depicted in Figure 9-5. Patients who have this procedure require alternatives to normal speech.

Complications that may occur include a salivary leak, wound infection from the development of a pharyngocutaneous fistula, stomal stenosis, and dysphagia secondary to pharyngeal and cervical esophageal stricture. Advances in surgical techniques for treating laryngeal cancer may minimize the cosmetic and functional deficits previously seen with total laryngectomy. Some microlaryngeal surgery can be performed endoscopically. Many patients who have undergone a total laryngectomy report a good quality of life overall (Singer et al., 2013).

Radiation Therapy

The goal of radiation therapy is to eradicate the cancer and preserve the function of the larynx. The decision to use radiation therapy is based on several factors, including the staging of the tumor and the patient's overall health status, lifestyle (including occupation), and personal preference. Early-stage vocal cord tumors are treated initially with irradiation. One of the benefits of radiation therapy is that patients retain a near-normal voice. A few develop chondritis (inflammation of the cartilage) or stenosis; a small number may require laryngectomy later. Radiation therapy may also be used preoperatively to reduce the tumor size. Radiation therapy is combined with surgery in advanced laryngeal cancer as adjunctive therapy to surgery or chemotherapy and as a palliative measure.

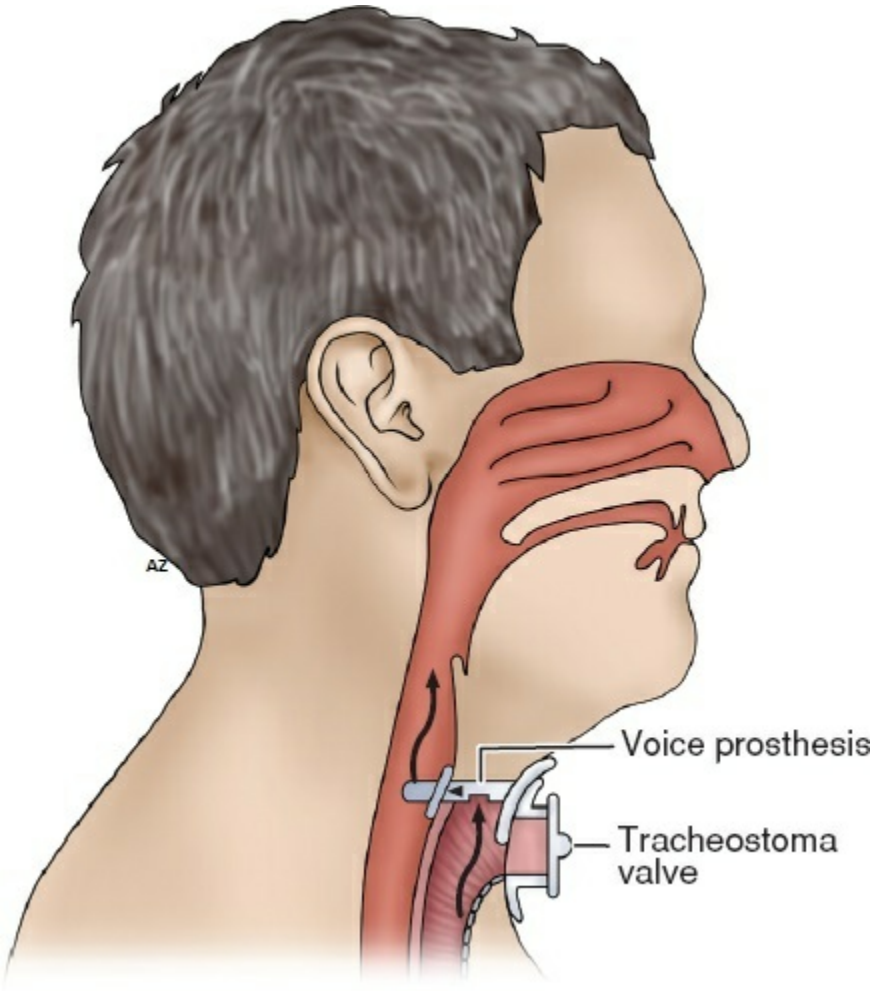

FIGURE 9-5 Schematic representation of tracheoesophageal puncture speech (TEP). Air travels from the lung through a puncture in the posterior wall of the trachea into the esophagus and out the mouth. A voice prosthesis is fitted over the puncture site.

Advances in research and treatment of these tumors with surgery, chemotherapy, and radiation therapy have improved outcomes and decreased incidence of posttreatment morbidities (DeVita et al., 2014). Complications from radiation therapy are a result of

external radiation to the head and neck area, which may also include the parotid gland, which is responsible for mucus production. Symptoms may include acute mucositis, ulceration of the mucous membranes, pain, xerostomia (dry mouth), loss of taste, dysphasia, fatigue, and skin reactions. Complications occurring later may include laryngeal necrosis, edema, and fibrosis.

Speech Therapy

The patient who undergoes a laryngectomy faces potentially complex and frustrating communication problems. These are related to alterations in communication methods, perceived voice quality, and perceptions of quality of life related to communication, disfigurement, and socialization. To minimize anxiety and frustration for the patient and family, the nurse discusses the loss or alteration of speech with the patient and family before surgery, and the speech therapist conducts a preoperative evaluation. The nurse discusses with the patient and family those methods of communication that will be available in the immediate postoperative period. These include writing, lip speaking, and communication or word boards. A system of communication is established with the patient, family, nurse, and provider, and is implemented consistently after surgery.

In addition, a long-term postoperative communication plan for alaryngeal communication is developed. The three most common techniques of alaryngeal communication are esophageal speech, artificial larynx (electrolarynx), and tracheoesophageal puncture.

With esophageal speech, patients compress air into the esophagus and expel it, setting off a vibration of the pharyngeal esophageal segment. The technique can be taught once the patient begins oral feedings after surgery. The patient learns to belch and use this action to transform simple explosions of air from the esophagus to sound for speech purposes. The speech therapist continues to work with the patient to make speech intelligible. The success rate is low.

With the electrolarynx, a battery-powered apparatus projects sound into the oral cavity. When the mouth forms words (articulation), the sounds from the electrolarynx become audible words. The voice that is produced sounds mechanical, and some words may be difficult to understand. The advantage is that the patient is able to communicate with relative ease while working to become proficient at either esophageal or tracheoesophageal puncture speech.

With tracheoesophageal puncture, a valve is placed in the tracheal stoma to divert air into the esophagus and out the mouth. Once the puncture is surgically created and has healed, a voice prosthesis (Blom-Singer) is fitted over the puncture site. A speech therapist teaches the patient how to produce sounds. Moving the tongue and lips to form the sound into words produces speech. To prevent airway obstruction, the prosthesis is removed and cleaned when mucus builds up (see Fig. 9-5). This method most resembles normal speech and is easily learned.

The success of these various approaches to preserve or restore speech varies. In studies that evaluated the effectiveness of these methods, the electrolarynx was used more often than the other methods of speaking, and tracheoesophageal speech was preferred over esophageal speech (DeVita et al., 2014; Pereira da Silva, Feliciano, Vaz Freitas, Esteves, & Almeida E Sousa, 2015; Vilaseca et al., 2013).

Nursing Alert

The ability to speak intelligibly after total laryngectomy increases with time and speech rehabilitation, although it has been reported that some patients are never able to speak intelligibly—if at all—following surgery (Singer et al., 2013).

Nursing Management

Teaching the Patient Preoperatively

The nurse reinforces information related to diagnosis and treatment options given to the patient and family by the provider and clarifies any misconceptions. Informational materials (written and audiovisual) about the surgery are given to the patient and family for review and reinforcement. If a complete laryngectomy is planned, the patient must understand that the natural voice will be lost but that special training can provide a means for communicating. The patient needs to know that temporarily communication will be possible by writing or by using a special communication board. The patient's ability to sing, laugh, and whistle will be lost.

The nurse reviews equipment and treatments for postoperative care with the patient and family, teaches important coughing and deep-breathing exercises, and assists the patient to perform return demonstrations. The nurse clarifies the patient's role in the postoperative and rehabilitation periods.

Reducing Anxiety and Depression

Patients undergoing surgery for laryngeal cancer may have many fears. These fears may relate to the diagnosis of cancer and the possibility of permanent loss of the voice and disfigurement. The nurse provides the patient and family with opportunities to ask questions, verbalize feelings, and discuss perceptions. The nurse should address any questions and misconceptions the patient and family have. During the preoperative or postoperative period, a visit from someone who has had a laryngectomy may reassure the patient that people are available to assist with rehabilitation.

In the immediate postoperative period, the nurse spends time with the patient, focusing on building trust and reducing the patient's anxiety. Clear instructions and explanations are given to the patient and family in a calm, reassuring manner before and during each contact with the patient. The nurse seeks to learn from the patient what activities promote feelings of comfort and assists the patient in such activities (e.g., listening to music, reading). Relaxation techniques, such as guided imagery and meditation, are often helpful.

Maintaining a Patent Airway

The nurse promotes a patent airway by positioning the patient in the semi-Fowler or Fowler position after recovery from anesthesia. This position decreases surgical edema and promotes lung expansion. Observing the patient for restlessness, labored breathing, apprehension, and increased pulse rate helps to identify possible respiratory or circulatory problems. The nurse assesses the patient's lung sounds and reports changes that may indicate impending complications. Medications that depress respiration, particularly opioids, should be used cautiously. Adequate use of analgesic medications is essential for pain relief, as postoperative pain can result in shallow breathing and an ineffective cough. The nurse encourages the patient to turn, cough, and take deep breaths. If needed, suctioning may be performed to remove secretions, but the nurse must avoid disruption of suture lines. The nurse also encourages and assists the patient with early ambulation to

prevent atelectasis, pneumonia, and deep vein thrombosis. Pulse oximetry is used to monitor the patient's oxygen saturation level.

If a total laryngectomy was performed, a laryngectomy tube may not be used; in others, it is used temporarily; and in many, it is used permanently. The laryngectomy tube, which is shorter than a tracheostomy tube but has a larger diameter, is the patient's only airway. The care of this tube is the same as for a tracheostomy tube (see discussion later in the chapter). If a tracheostomy tube without an inner cannula is used, humidification and suctioning of this tube are essential to prevent formation of mucous plugs.

Frequently, the patient coughs up large amounts of mucus through this opening. Because air passes directly into the trachea without being warmed and moistened by the upper respiratory mucosa, the tracheobronchial tree compensates by secreting excessive amounts of mucus. The patient will have frequent coughing episodes and may develop a brassy-sounding, mucus-producing cough. The nurse reassures the patient that these problems will diminish in time, as the tracheobronchial mucosa adapts to the altered physiology.

After the patient coughs, the tracheostomy opening must be wiped clean and clear of mucus. A simple gauze dressing, washcloth, or even paper towel (because of its size and absorbency) worn below the tracheostomy may serve as a barrier to protect the clothing from the copious mucus that the patient may expel initially.

One of the most important factors in decreasing cough, mucus production, and crusting around the stoma is adequate humidification of the environment. Mechanical humidifiers and aerosol generators (nebulizers) increase the humidity and are important for the patient's comfort. The laryngectomy tube may be removed when the stoma is well healed, within 3 to 6 weeks after surgery. The nurse teaches the patient how to clean and change the tube and remove secretions.

Wound drains, inserted during surgery, may be in place to assist in removal of fluid and air from the surgical site. Suction also may be used, but cautiously, to avoid trauma to the surgical site and incision. The nurse observes, measures, and records drainage. When drainage is less than 30 mL/day for 2 consecutive days, a member of the surgical team usually removes the drains.

Promoting Alternative Communication Methods

Establishing an effective means of communication is the primary goal in the rehabilitation of the patient with a laryngectomy. To understand and anticipate the patient's postoperative needs, the nurse works with the patient, speech therapist, and family to encourage use of alternative communication methods. These means of communication are established preoperatively and must be used consistently by all personnel who come in contact with the patient. The patient is unable to use an intercom system. A call bell or hand bell must be placed within easy reach of the patient. A reusable writing board often is used for communication so the nurse documents which hand the patient uses for writing so that the opposite arm can be used for IV infusions. To ensure the patient's privacy, the nurse discards any old notes used for communication. If the patient cannot write, a picture–word–phrase board or hand signals can be used. Writing everything or communicating through gestures can be very time-consuming and frustrating. The patient must be given adequate time to communicate his or her needs. The patient may become

impatient and angry when not understood.

Promoting Adequate Nutrition and Hydration

Postoperatively, the patient may not be permitted to eat or drink for several days. Alternative sources of nutrition and hydration include IV fluids, enteral feedings through a nasogastric or gastrostomy tube, and parenteral nutrition.

When the patient is ready to start oral feedings, a speech therapist or radiologist may conduct a swallow study to evaluate the patient's risk for aspiration. Once the patient is cleared for oral feedings, the nurse explains that thick liquids will be used first because they are easy to swallow. Different swallowing maneuvers are attempted with various food consistencies. Once the patient is cleared for food intake, the nurse stays with the patient during initial oral feedings and keeps a suction setup at the bedside for needed suctioning. The nurse observes the patient for any difficulty swallowing, particularly when eating resumes, and reports its occurrence to the provider.

The nurse instructs the patient to avoid sweet foods, which increase salivation and suppress the appetite. Solid foods are introduced as tolerated. The patient is instructed to rinse the mouth with warm water or mouthwash after oral feedings and to brush the teeth frequently.

Because taste and smell are so closely related, taste sensations are altered for a while after surgery because inhaled air passes directly into the trachea, bypassing the nose and the olfactory end organs. Over time, the patient usually accommodates to this change and olfactory sensation adapts, often with return of interest in eating. The patient's weight and laboratory data are monitored to ensure that nutritional and fluid intake are adequate. Skin turgor and vital signs are assessed for signs of decreased fluid volume.

Promoting Positive Body Image and Self-Esteem

Disfiguring surgery and an altered communication pattern are a threat to a patient's body image and self-esteem. The reaction of family members and friends is a major concern for the patient. The nurse encourages the patient to express feelings about the changes brought about by surgery, particularly feelings related to fear, anger, depression, and isolation. Encouraging use of previous effective coping strategies may be helpful. Referral to a support group, such as the International Association of Laryngectomees (IAL) and I Can Cope (the American Cancer Society), may help the patient and family deal with the changes in their lives. In addition to its work through support groups, the IAL encourages an exchange of ideas and methods for teaching and learning alaryngeal methods of communication.

Promoting Self-Care

A positive approach is important when caring for the patient and includes promotion of self-care activities. The patient and family should begin participating in self-care activities as soon as possible. The nurse assesses the patient's readiness for decision-making and encourages the patient to participate actively in performing care. The nurse needs to support the patient and the family, especially when explaining the tubes, dressings, and drains that are in place postoperatively.

Monitoring and Managing Potential Complications

The potential complications after laryngectomy include respiratory distress and hypoxia, hemorrhage, infection, wound breakdown, aspiration, and tracheostomal stenosis.

Respiratory Distress and Hypoxia

The nurse monitors the patient for signs and symptoms of respiratory distress and hypoxia, particularly restlessness, irritation, agitation, confusion, tachypnea, use of accessory muscles, and decreased oxygen saturation on pulse oximetry (SpO_2). Any change in respiratory status requires immediate intervention. Hypoxia may cause restlessness and an initial rise in blood pressure; this is followed by hypotension and somnolence. Cyanosis is a late sign of hypoxia. Obstruction needs to be ruled out immediately by suctioning and by having the patient cough and breathe deeply. Hypoxia and airway obstruction, if not immediately treated, are life-threatening.

Other nursing measures include repositioning of the patient to ensure an open airway and administering oxygen as prescribed. Oxygen should be used with caution in patients with chronic obstructive pulmonary disease.

Nursing Alert

Adequate oxygenation is important in the management of hypoxia and should never be withheld. Key in the care of patients with COPD on supplemental oxygen is monitoring and assessment, with the goal of achieving and maintaining an oxygen saturation of greater than or equal to 90%. Pulse oximetry is helpful in assessing response to therapy. The nurse considers patency of the airway, protective reflexes, inspired oxygen concentration, and respiratory drive when assessing adequacy of the airway.

The nurse should always be prepared for possible intubation and mechanical ventilation. The nurse must be knowledgeable about the hospital's emergency code protocols and skilled in use of emergency equipment. The nurse must remain with the patient at all times during respiratory distress. The emergency call bell and telephone should be used to initiate a code, call for further assistance, and summon the provider immediately if nursing measures do not improve the patient's respiratory status.

Nursing Alert

After a total laryngectomy, it is advisable to have a properly sized replacement laryngectomy tube and an appropriately sized replacement cuffed tracheostomy tube at the bedside should the treatment of the patient's respiratory distress require placement on a mechanical ventilator. If the patient suffers a respiratory arrest, the nurse is aware that the naso/oro pharynx is now distinct from the tracheal bronchial tree, meaning the patient CAN NOT be intubated orally. The airway must be managed via a laryngectomy tube or tracheostomy tube, allowing for rescue breathing via mouth-to-neck or bag-valve mask with supplemental oxygen delivery.

Hemorrhage

Bleeding from the drains at the surgical site or with tracheal suctioning may signal the occurrence of hemorrhage. The nurse promptly notifies the surgeon of any active bleeding from the surgical site, drains, and trachea. Rupture of the carotid artery is especially dangerous. Should this occur, the nurse must apply direct pressure over the artery, summon assistance, and provide emotional support to the patient until the vessel is ligated. The nurse monitors vital signs for increased pulse rate, decreased blood pressure, and rapid deep respirations, as well as restlessness and delayed capillary refill. Cold, clammy, pale skin may indicate active bleeding. IV fluids and blood components may be administered and other measures implemented to prevent or treat hemorrhagic shock.

Infection

The nurse monitors the patient for signs of postoperative infection. These include an increase in temperature and pulse, a change in the type of wound drainage, and increased areas of redness or tenderness at the surgical site. Other signs include purulent drainage, odor, and increased wound drainage. The nurse monitors the patient's white blood cell (WBC) count. An elevation in WBCs (leukocytosis) may indicate the body's effort to combat infection. In elderly patients, infection can be present without an increase in the patient's WBC count. WBCs will be suppressed in the patient with decreased immune function (e.g., patients with HIV infection or those receiving chemotherapy or radiation therapy); this predisposes the patient to a severe infection and sepsis. Antimicrobial (antibiotic) medications must be administered as scheduled. All suspicious drainage is cultured, and the patient may be placed in isolation as indicated. The nurse reports any significant change in the patient's status to the surgeon.

Wound Breakdown

Wound breakdown caused by infection, poor wound healing, development of a fistula, radiation therapy, or tumor growth can create a life-threatening emergency. The carotid artery, which is close to the stoma, may rupture from erosion if the wound does not heal properly. The nurse observes the stoma area for wound breakdown, hematoma, and bleeding and reports this to the surgeon. If wound breakdown occurs, the patient must be monitored carefully and identified as being at high risk for carotid hemorrhage.

Aspiration

The patient who has undergone a laryngectomy is at risk for aspiration and aspiration pneumonia due to depressed cough, the sedating effects of anesthetic and analgesic medications, alteration in the airway, impaired swallowing, and the administration of tube feedings. The nurse assesses for the presence of nausea and administers antiemetic medications as prescribed. The nurse keeps a suction setup available in the hospital and instructs the family to do so at home for use if needed. Patients receiving tube feedings are positioned with the head of the bed at 30 degrees or higher during feedings and for 30 to 45 minutes after tube feedings. For patients with a nasogastric or gastrostomy tube, the placement of the tube must be checked before each feeding. High residual volumes may indicate delayed gastric emptying and can lead to reflux and aspiration. Risks for aspiration include a low level of consciousness, heavy sedation, low head-of-bed elevation, and vomiting. Gastric residual volumes (GRVs) have not been shown to be correlated with pneumonia, regurgitation, or aspiration (McClave et al., 2016). The American Society of Parenteral and Enteral Nutrition and the Society of Critical Care Medicine continue to suggest that GRVs of 250 to 500 mL appear to be tolerated and do not increase the risk of regurgitation, aspiration, or pneumonia (McClave et al., 2016). Because individual procedures vary widely and uncertainty exists regarding the assessment and treatment for high residual volumes, it is important to follow institutional procedures (McClave et al., 2016). Residual volumes from the small bowel are usually less than 10 mL; however, limited research is available to suggest a volume that might contribute to aspiration risk. If intestinal residual volumes are similar to GRVs, the nurse should be suspicious for dislocation of the distal portion of the intestinal tube upward into the stomach (Preiser et al., 2015). Refer to Chapter 22 for details of gastric and intestinal feedings.

Tracheostomal Stenosis

Tracheostomal stenosis is an abnormal narrowing of the trachea or the tracheostomy stoma. Infection at the stoma site, excessive traction on the tracheostomy tube by the connecting tubing, and persistent high tracheostomy cuff pressure are risk factors for tracheostomal stenosis. Cuff pressures should be below 25 cm H_2O (18 mm Hg) (Morris, Whitmer, & McIntosh, 2013). The incidence of this condition varies widely and is often preventable. The nurse assesses the patient's stoma for signs and symptoms of infection and immediately reports any evidence of this to the provider. Tracheostomy care is performed routinely. The nurse assesses the connecting tubing (e.g., ventilation tubing) and secures the tubing to avoid excessive traction on the patient's tracheostomy. The nurse ensures that, for the patient who is breathing independently (without ventilator), the tracheostomy cuff is deflated (for a patient with a cuffed tube).

Nursing Alert
An inflated tracheostomy cuff will not prevent aspiration. The decision to administer medications or food in a patient with a tracheostomy should be made as a team, which should include a formal swallowing evaluation and consideration of the patient's medical and psychological status (Morris et al., 2013).

Teaching Patients Self-Care

In preparing the patient to go home, the nurse assesses the patient's readiness to learn and the level of knowledge about self-care management. The patient will need to learn a variety of self-care behaviors, including tracheostomy and stoma care (described later in the chapter), wound care, and oral hygiene. The nurse also instructs the patient about the need for adequate dietary intake, safe hygiene, and recreational activities.

Special precautions are needed in the shower to prevent water from entering the stoma. Wearing a loose-fitting plastic bib over the tracheostomy or simply holding a hand over the opening is effective. Swimming is not recommended because a person with a laryngectomy can drown without submerging his or her face. Hair sprays, loose hair, and powder should not get near the stoma, because they can block or irritate the trachea and possibly cause infection.

The nurse teaches the patient and caregiver the signs and symptoms of infection and identifies indications that require contacting the provider after discharge. The nurse teaches the patient and family to wash their hands before and after caring for the tracheostomy, to use tissue to remove mucus, and to dispose of soiled dressings and equipment properly. If the patient's surgery included cervical lymph node dissection, the nurse teaches the patient exercises for strengthening the shoulder and neck muscles.

Recreation and exercise are important for the patient's well-being and quality of life, and all but very strenuous exercise can be enjoyed safely. Avoidance of strenuous exercise and fatigue is important because the patient will have more difficulty speaking when tired, which can be discouraging. Additional safety points to address include the need for the patient to wear or carry medical identification—such as a bracelet or card—to alert medical personnel to the special requirements for resuscitation should this need arise. If

resuscitation is needed, direct mouth-to-stoma ventilation should be performed. For home emergency situations, prerecorded emergency messages for police, the fire department, or other rescue services can be kept near the phone to be used quickly.

The nurse instructs and encourages the patient to perform oral care on a regular basis to prevent halitosis and infection. Brushing the teeth or dentures and rinsing the mouth several times a day will assist in maintaining proper oral hygiene. If the patient is receiving radiation therapy, synthetic saliva may be required because of decreased saliva production. The nurse instructs the patient to drink water or sugar-free liquids throughout the day and to use a humidifier at home.

It is important that the person who has had a laryngectomy have regular physical examinations and seek advice concerning any problems related to recovery and rehabilitation. The patient is also reminded to participate in health promotion activities and health screening as well as about the importance of keeping scheduled appointments with the provider, speech therapist, and other health care providers.

ARTIFICIAL AIRWAYS

The patient with an airway disorder such as a laryngeal obstruction or cancer may require the use of a temporary or, in some cases, a permanent artificial airway. Two types of artificial airways that may be used include an endotracheal tube (ETT) or a tracheostomy tube. General recommendations are to favor a tracheostomy tube rather than ETT if the patient will be intubated for 21 days or greater, and to favor the ETT over a tracheostomy if support will be required for 10 days or less (Morris et al., 2013). To provide for adequate ventilation, mechanical ventilation may be required to ensure adequate oxygenation.

ETT and tracheostomy tubes have several disadvantages. The tubes cause discomfort, the cough reflex is depressed because closure of the glottis is hindered, and secretions tend to become thicker because the warming and humidifying effect of the upper respiratory tract has been bypassed. The swallowing reflexes are depressed because of prolonged disuse and the mechanical trauma produced by the endotracheal or tracheostomy tube, thus increasing the risk of aspiration. In addition, ulceration and stricture of the larynx or trachea may develop. Of great concern to the patient is the inability to talk and to communicate needs.

ENDOTRACHEAL INTUBATION

Endotracheal intubation is a temporary means of providing an airway for patients who cannot maintain an adequate airway on their own (e.g., comatose patients, patients with upper airway obstruction), for patients needing mechanical ventilation, and for suctioning secretions from the pulmonary tree.

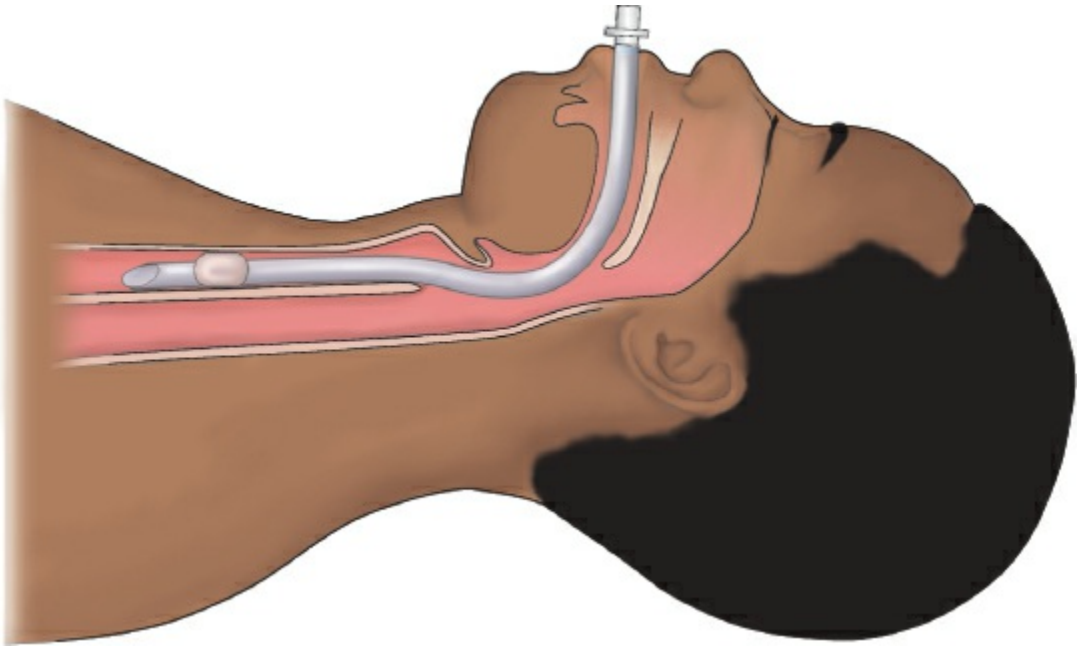

FIGURE 9-6 Endotracheal tube in place. The tube has been inserted using the oral route. The cuff has been inflated to maintain the tube's position and to minimize the risk of aspiration.

Nursing Alert

For any patient with an artificial airway, a self-inflating bag-valve mask device or Ambu bag must be at the bedside as well as suction catheters and suctions source.

Endotracheal intubation involves passing an ETT through the mouth or nose into the trachea (Fig. 9-6) with the aid of a laryngoscope or illuminated glidescope by specifically trained personnel. It is the method of choice in emergency care. Once the tube is inserted, a cuff is inflated to prevent air from leaking around the outer part of the tube, to minimize the possibility of subsequent aspiration, and to prevent movement of the tube.

The nurse should be aware that complications could occur from pressure exerted by the cuff on the wall of the trachea. Low cuff pressure can increase the risk for aspiration pneumonia. High cuff pressure can cause tracheal bleeding, ischemia, and pressure necrosis. Routine deflation of the cuff is not recommended because of the increased risk for aspiration and hypoxia. The cuff must be deflated before the ETT is removed. Tracheobronchial secretions are suctioned through the tube (see description in Tracheostomy section). Warmed, humidified oxygen should always be introduced through the tube, whether the patient is breathing spontaneously or is receiving ventilatory support. Endotracheal intubation should be used until a time when it is prudent to consider a

tracheostomy to decrease oropharyngeal irritation and trauma to the tracheal lining, to reduce the incidence of vocal cord paralysis (secondary to laryngeal nerve damage), and to decrease the work of breathing.

Unintentional or premature removal of the tube is a potentially life-threatening complication of endotracheal intubation that is a frequent problem in intensive care units and occurs mainly during nursing care or by the patient.

TRACHEOSTOMY

A tracheotomy is a surgical procedure in which an opening is made into the trachea. The indwelling tube inserted into the trachea is called a tracheostomy tube. A tracheostomy may be either temporary or permanent.

A tracheostomy is used to bypass an upper airway obstruction, to allow removal of tracheobronchial secretions, to permit the long-term use of mechanical ventilation, to prevent aspiration of oral or gastric secretions in the unconscious or paralyzed patient (by closing off the trachea from the esophagus), and to replace an ETT. Many disease processes and emergency conditions make a tracheostomy necessary, including total laryngectomy.

Procedure

A surgical opening is made between the second and third tracheal rings. After the trachea is exposed, an obturator guides insertion of the cuffed tracheostomy tube by creating a pathway for the tracheostomy tube. The obturator is removed immediately after the tracheostomy tube is in place. This procedure can be done in the Operating Room or is increasingly being done percutaneously as a bedside procedure in the ICU (Morris et al., 2013). A spare tracheostomy tube (cuffed) and the obturator should be available in the room in case of accidental dislodgement of the tracheostomy tube. The cuff is inflated to occlude the space between the tracheal walls and the tube, to permit effective mechanical ventilation, and to decrease the risk of aspiration. The tracheostomy tube is held in place by twill tape or a cloth neckband with velcro band fasteners placed around the patient's neck. Usually a square of sterile gauze is placed between the tube and the skin to absorb drainage and reduce the risk for infection (Morris et al., 2013). The nurse should refer to institutional protocols regarding tracheostomy management.

Tube Types

Types of tracheostomy tubes include (Fig. 9-7):

- *Cuffed tracheostomy tube*: This is required when placing a patient on a ventilator because the balloon prevents air from being diverted out to the upper airway (Fig. 9-7A).
- *Fenestrated tube*: This tube allows some air flow up to the larynx, which allows for vocalization (Fig. 9-7B).
- *Uncuffed (cuffless) tube*: This tube does not permit ventilator management but will allow talking if the airway is not edematous and the patient covers or "buttons" the end of the tube. This allows air to flow from the nose and mouth past the larynx and vocalization (Fig. 9-7C).

Nursing Alert
In an emergency, if an Ambu bag or ventilator was used on a cuffless tube, then the nurse needs to understand that air will follow the path of least resistance, out the nose and mouth rather than into the lungs. Therefore, any patient who has a cuffless tracheostomy must have the exact size tracheostomy tube at the bedside with a cuff. In an emergency, the provider will change the cuffless tube to a cuffed tube and inflate the balloon, allowing for ventilation with an Ambu bag or ventilator.

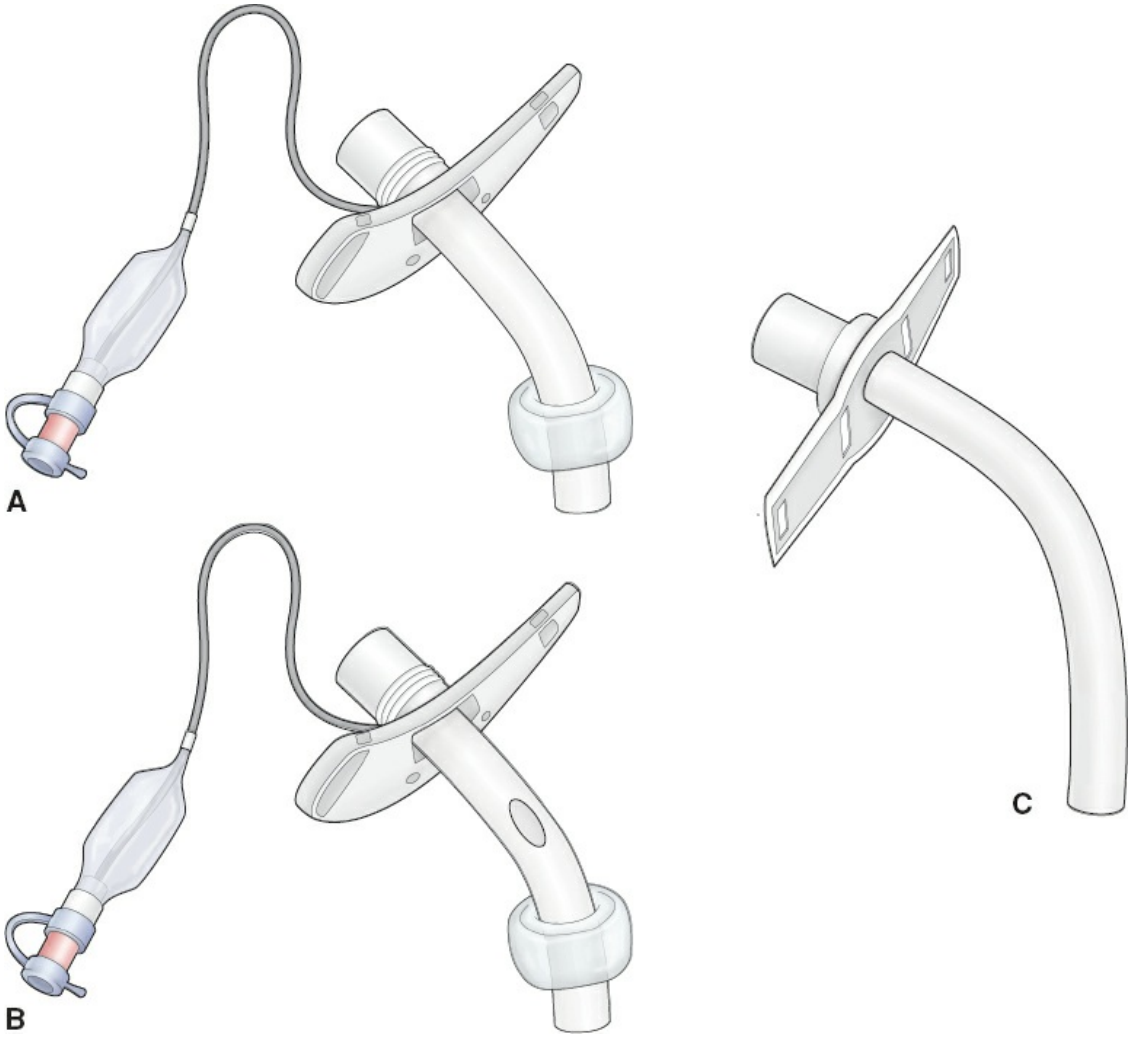

FIGURE 9-7 Tracheostomy tubes. A. Cuffed tracheostomy tube; used for patients on mechanical ventilation. B. Cuffed fenestrated tube; allows the patient to talk. C. Uncuffed tracheostomy tube; not used for adult patients on mechanical ventilation; often used for permanent tracheostomy patients who are not ventilator dependent.

BOX 9-6 Preventing Complications Associated with Endotracheal and Tracheostomy Tubes

- Administer adequate warmed humidity.
- Maintain cuff pressure at appropriate level.
- Suction as needed per assessment findings.
- Maintain skin integrity. Change tape and dressing as needed or per protocol.
- Auscultate lung sounds.
- Monitor for signs and symptoms of infection, including temperature and white blood cell count.
- Administer prescribed oxygen and monitor oxygen saturation.
- Monitor for cyanosis.
- Maintain adequate hydration of the patient.

- Use sterile technique when suctioning and performing tracheostomy care.

Complications

Complications may occur early or late in the course of tracheostomy tube management. Early complications include bleeding, pneumothorax, air embolism, aspiration, subcutaneous or mediastinal emphysema, recurrent laryngeal nerve damage, and posterior tracheal wall penetration. Long-term complications include airway obstruction from accumulation of secretions or protrusion of the cuff over the opening of the tube, infection, rupture of the innominate artery, dysphagia, tracheoesophageal fistula, tracheal dilation, and tracheal ischemia and necrosis. Tracheal stenosis may develop after the tube is removed. Box 9-6 provides information about preventing complications.

Nursing Management

The patient with an artificial airway requires continuous monitoring and assessment. The airway must be kept patent by proper suctioning of secretions. After the vital signs are stable, the patient is placed in a semi-Fowler position to facilitate ventilation, promote drainage, minimize edema, and prevent strain on the suture lines. Analgesia and sedative agents must be administered with caution because of the risk of suppressing the cough reflex.

Major objectives of nursing care are to alleviate the patient's apprehension, provide an effective means of communication, and prevent infection. The nurse keeps paper and pencil or a reusable writing board and the call light within the patient's reach at all times to ensure a means of communication. The care of the patient with a tracheostomy tube is summarized in Box 9-7.

For the patient with a tracheostomy tube, a Passy-Muir Valve (PMV) allows the patient to speak. The devise is a positive-closure, one-way speaking valve. The PMV opens upon inspiration to allow the patient to inspire through the tracheostomy tube and then closes after inspiration, redirecting the exhaled air around the tube, through the vocal cords, and out of the mouth. The tracheostomy cuff must be deflated completely before the PMV is placed.

BOX 9-7 GUIDELINES FOR NURSING CARE

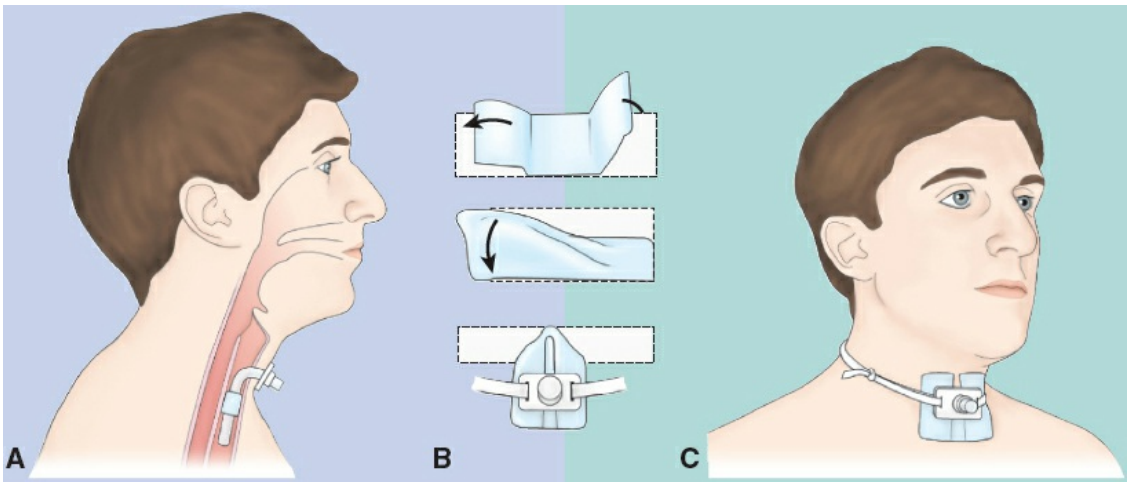
Providing Care for a Patient with a Tracheostomy Tube

Equipment

- Sterile gloves
- Goggles, mask, or face shield
- Sterile cotton-tipped applicators
- Disposable inner cannula, size for patient
- Sterile dressing
- Twill tape or commercially prepared tracheostomy holder
- Normal saline solution or sterile water

Implementation

ACTIONS	RATIONALE
1. Gather the needed equipment.	1. Everything needed to care for a tracheostomy should be readily on hand for the most effective care.
2. Provide patient and family instruction on the key points for tracheostomy care; inspect the tracheostomy dressing for moisture or drainage.	2. The tracheostomy dressing is changed as needed to keep the skin clean and dry. To prevent potential breakdown, moist or soiled dressings should not remain on the skin.
3. Perform hand hygiene.	3. Hand hygiene reduces bacteria on hands.
4. Explain procedure to patient and family.	4. A patient with a tracheostomy is apprehensive and requires ongoing assurance and support.
5. Put on clean gloves; remove and discard the soiled dressing in an appropriate container. Discard gloves.	5. Observing body substance isolation reduces cross-contamination from soiled dressings. Having necessary supplies and equipment readily available allows the procedure to be completed efficiently.
6. Prepare sterile supplies, including normal saline solution or sterile water, cotton-tipped applicators, dressing, and tape.	6. Sterile equipment minimizes transmission of surface flora to the sterile respiratory tract.
7. Put on sterile gloves. (Some providers approve clean technique for long-term tracheostomy patients in the home.)	7. Clean technique may be used in the home because of decreased exposure to potential pathogens.
8. Cleanse the wound and the plate of the tracheostomy tube with sterile cotton-tipped applicators moistened with sterile saline solution.	8. Rinsing prevents retention of residue.
9. Soak inner cannula in peroxide or sterile saline; rinse with saline solution; inspect to be sure all dried secretions have been removed. Dry and reinsert inner cannula or replace with a new disposable inner cannula.	9. Soaking loosens and removes secretions from the inner lumen of the tracheostomy tube. Retained secretions could harbor bacteria, leading to infection. Some plastic tracheostomy tubes may be damaged by using peroxide.
10. Place clean twill tape in position to secure the tracheostomy tube by inserting one end of the tape through the side opening of the outer cannula. Take the tape around the back of the patient's neck and thread it through the opposite opening of the outer cannula. Bring both ends around, so that they meet on one side of the neck. Tighten the tape until only two fingers can be inserted comfortably under it. Secure with a knot. **For a new tracheostomy, two people should assist with tape changes.** Remove soiled twill tape after the new tape is in place. In place of twill tape, a commercially prepared tracheostomy tube holder may be used.	10. This taping technique provides a double thickness of tape around the neck, which is needed because the tracheostomy tube can be dislodged by movement or by a forceful cough if left unsecured. However, it cannot be so tight that it causes constriction of the jugular vein. Therefore, changing ties should always be a two-person task. A dislodged tracheostomy tube is difficult to reinsert, and respiratory distress may occur. Dislodgement of a new tracheostomy is a medical emergency.
11. Remove old tapes and discard in a waste container after the new tape is in place.	11. Tapes with old secretions may harbor bacteria.
12. Although some long-term tracheostomies with healed stomas may not require a dressing, other tracheostomies do. Use a sterile tracheostomy dressing, fitting it securely under the twill tape and flange of tracheostomy tube, so that the incision is covered, as shown below. A sterile precut "drain" sponge may be available also.	12. Healed tracheostomies with minimal secretions do not need a dressing. Dressings that will shred are not used around a tracheostomy because of the risk that pieces of material, lint, or thread may get into the tube and eventually into the trachea, causing obstruction or abscess formation.
13. Dispose of all used equipment in waste receptacle, remove and discard gloves, and perform hand hygiene.	13. Disposing of all used equipment, cleaning agents, and gloves prevents the spread of contaminants/bacteria. Performing hand hygiene prevents the spread of infection.



(A) The cuff of the tracheostomy tube fits smoothly and snugly in the trachea in a way that promotes

circulation but seals off the escape of secretions and air surrounding the tube. (B) For a dressing change, a specially designed drain sponge or a 4 × 4-in gauze pad may be folded (cutting would promote shredding, placing the patient at risk for aspiration) around the tracheostomy tube and (C) stabilized by slipping the neck tape ties through the neck plate slots of the tracheostomy tube. The ties may be fastened to the side of the neck to eliminate the discomfort of lying on the knot.

Suctioning the Tracheal Tube (Tracheostomy or Endotracheal Tube)

When a tracheostomy or ETT is in place, it is necessary to suction the patient's secretions because of the decreased effectiveness of the cough mechanism. Tracheal suctioning is performed when adventitious breath sounds are detected or whenever secretions are obviously present. Unnecessary suctioning can initiate bronchospasm and cause mechanical trauma to the tracheal mucosa.

All equipment that comes into direct contact with the patient's lower airway must be sterile to prevent pulmonary and systemic infections. The procedure for suctioning a tracheostomy is presented in Box 9-8. Recent research analysis suggests using minimally invasive endotracheal suctioning, in which the suction catheter is inserted to the length of the ETT or tracheostomy tube only. The suction catheter is inserted to the carina and then retracted 1 to 2 cm before suctioning is performed; an alternative option is to measure the length of the suction catheter estimated by measuring an identical ETT (Maggiore et al., 2013; Morris et al., 2013; Schrieber, 2015). However, deep suctioning may be necessary in patients with large amounts of secretions in the lower airways, since minimally invasive suctioning removes secretions from central airways only. Deep suctioning may lead to episodes of bradycardia. As research data are analyzed, best practice related to suctioning practices will be established.

In mechanically ventilated patients, an inline suction catheter may be used to allow rapid suction when needed and to minimize cross-contamination by airborne pathogens. An inline suction device allows the patient to be suctioned without being disconnected from the ventilator circuit.

BOX 9-8 GUIDELINES FOR NURSING CARE

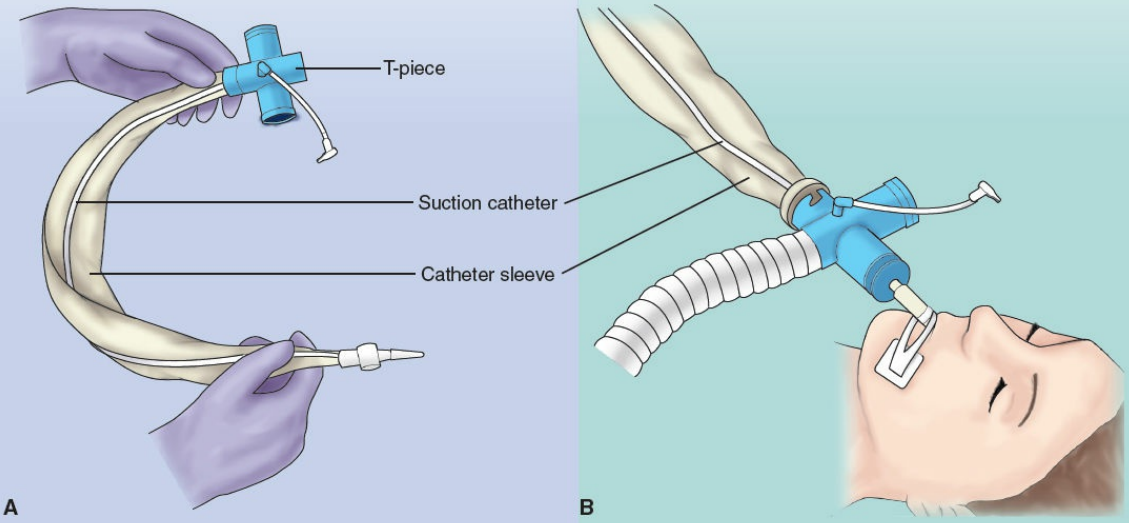
Performing Tracheal Suction

Equipment

- Suction catheters, may be available in a commercially prepared kit
- Gloves (sterile and nonsterile), mask, and goggles. Additional PPE as required.
- Basin for sterile normal saline solution for irrigation
- Manual resuscitation bag with supplemental oxygen
- Portable or wall suction unit with tubing

Implementation

ACTIONS	RATIONALE
1. Explain the procedure to the patient before beginning and offer reassurance during suctioning. Unless contraindicated, elevate the head of the patient's bed; semi-Fowler position is preferred.	1. Patients are apprehensive and require ongoing assurance and support. Elevation of bed maximizes diaphragmatic excursion.
2. Perform hand hygiene. Put on nonsterile gloves, goggles, gown, and mask.	2. Hand hygiene reduces transmission of microorganisms and body secretions; donning PPE follows standard precautions.
3. Secure the end of the suction tubing to the suction device. Place the open end within reach in preparation for connecting to the suction catheter. Turn on suction source (pressure should not exceed 150 mm Hg).	3. High vacuum pressures are associated with mucosal injury.
4. To perform open-suction technique: Open-suction catheter kit on a clean surface, using the inside of the wrapping as a sterile field. Suction catheter should be less than half of the internal lumen of the endotracheal tube or tracheostomy.	4. If the catheter is too small, it will not adequately remove secretions, and if it is too large, it will obstruct airflow around the catheter during insertion. To calculate the catheter size needed, note the interior diameter (ID) of the tracheostomy tube, divide by two, and then multiply by three to obtain the French size. For example, a size 8 tracheostomy tube would accommodate a 12-French suction catheter.
Set up a sterile solution container. Fill basin with approximately 100 mL of sterile normal saline or water. Be careful not to touch the inside of the container. Don sterile gloves.	This maintains sterility and follows standard precautions.
Pick up suction catheter; avoid touching nonsterile surfaces. With the nondominant hand, pick up the connecting tubing. Secure the suction catheter to the suction tubing.	This maintains catheter security. The dominant hand should not come in contact with the connecting tubing. Wrapping the sterile catheter around the sterile dominant hand helps to prevent inadvertent contamination of the catheter.
Check equipment for proper functioning by suctioning a small amount of sterile saline solution from the container.	Ensures equipment function.
To perform closed-suction technique: Connect the suction tubing to the closed system suction port, according to the manufacturer's guidelines. The sterile suction catheter is in a clear plastic sleeve (see illustration). This system allows the patient to remain connected to the ventilator during suctioning.	



Closed airway suction system. **(A)** Closed tracheal suction system. **(B)** Closed system connected by a T-piece to the endotracheal tube and ventilator.

5. Follow institution guidelines related to hyperoxygenating the patient's lungs before suctioning. In general, for the nonventilator-dependent patient, humidified oxygen via a tracheostomy mask is placed over the tracheostomy for several deep breaths before suctioning, or if on a ventilator, preoxygenate the patient with 100% oxygen for at least 30 seconds prior to and after suctioning. OR Increase the baseline faction of inspired oxygen (FIO_2) level on the mechanical ventilator. Disconnect the ventilator or gas delivery tubing from the end of the endotracheal or tracheostomy tube, attach the manual resuscitation bag (MRB) to the tube with the nondominant hand, and administer five to six breaths. Attach a PEEP valve to the MRB for patients on more than 5 cm H_2O PEEP (refer to Chapter 55). Verify 100% oxygen delivery capabilities of MRB.	5. Routine use of hyperinflation is not recommended due to the risk of barotrauma (damage to the lung from rapid or excessive pressure changes) from large volumes, high peak pressures, and patient discomfort. Hyperoxygenation with 100% oxygen is used to prevent a decrease in arterial oxygen levels during the suctioning procedures. Press the suction hyperoxygenation button on the ventilator with the nondominant hand. Using this added valve increases the amount of air left in the lungs at the end of exhalation, increasing functional residual capacity.
6. With the suction off, gently and quickly insert the catheter with the dominant hand into the artificial airway to the extent of the tracheostomy or ETT (not to pass beyond the tip of the tubes), which can be measured. Other researchers suggest passing the catheter to the carina (strong cough reflex or where resistance is felt), then pull back 1–2 cm before suctioning is performed; this is termed *minimally invasive suctioning*. Deeper suctioning may be necessary in patients with large amounts of secretions in the lower airways since minimally invasive suctioning removes secretions from central airways only.	6. Suction should be applied only as needed to remove secretions and for as short a time as possible to minimize decreases in arterial oxygen levels.
7. Place the nondominant thumb over the control vent of the suction catheter and apply continuous or intermittent suction. Rotate the catheter 360 degrees between the dominant thumb and forefinger as you withdraw the catheter in the sterile catheter sleeve (closed-suction technique) or out of the open airway (open-suction technique). The suctioning procedure should take no more than 15 seconds, waiting at least 1 minute between suctioning events.	7. Tracheal damage from suctioning is similar with intermittent or continuous suction. Decreases in arterial oxygen levels during suctioning can be kept to a minimum with brief suction periods.
8. After suctioning, hyperoxgenate the patient for at least 1 minute as described earlier. Inflate the patient's lungs for several breaths. Assess oxygen saturation and evidence of bradycardia and arrhythmias (particularly if deep suctioning was required).	8. Arterial oxygen desaturation and cardiopulmonary complications increase with each successive pass.
9. Repeat steps until the airway is clear.	
10. Rinse catheter by suctioning a few milliliters of sterile saline solution from the basin between suction attempts.	10. Removes the buildup of secretions in the connecting tubing and/or the inline suction catheter.
11. When the lower airway has been adequately cleared of secretions, suction the nasal or oropharyngeal cavity.	11. Prevents contamination of the lower airways with upper airway organisms.
12. Rinse suction tubing.	12. Removes contaminates from tubing
13. Discard catheter, gloves, and basin appropriately. If using the open-suction technique, wrap the catheter around the dominant hand. Pull glove off inside out. Catheter remains in the glove. Pull other glove off in the same manner. Discard both gloves, and turn off suction device.	13. Reduces transmission of microorganisms. Solutions and catheters that come in direct contact with the lower airways during suctioning must be kept sterile to decrease the risk of nosocomial pneumonia.
14. Perform hand hygiene.	

Nursing Alert

Evidence-based research reveals that the routine instillation of normal saline prior to endotracheal suctioning increases the risk of infections and patient discomfort, and therefore is not recommended. Research indicates no evidence to support the claims of improving secretion clearance (Caparros & Forbes, 2015; Dawson, 2014).

Managing the Cuff

For the patient being supported with a mechanical ventilator, the cuff on the endotracheal or tracheostomy tube must be inflated. The pressure within the cuff should be the lowest possible pressure that allows delivery of adequate tidal volumes. Cuff pressure must be monitored at least every 8 hours by attaching a handheld pressure gauge to the pilot balloon of the tube or by using the minimal leak volume or minimal occlusion volume technique. Usually the pressure is maintained at less than 25 cm H_2O to prevent injury; when cuff pressure exceeds capillary perfusion pressure, necrosis of the tracheal wall, ischemia and stenosis can occur.

CHAPTER REVIEW

Critical Thinking Exercises

1. A 55-year-old woman is brought to the emergency department by her husband, who tells you that her nose has been bleeding for more than 3 hours. The patient reports that she takes one aspirin a day (325 mg), has a history of atrial fibrillation, and takes medication for hypertension. What immediate action would you take to care for this patient? What are the risk factors for epistaxis in this patient? What medical treatment would you anticipate for her? What nursing measures would you provide for this patient? How would you modify your discharge instructions if the patient lived alone? What strategies would you recommend to the patient and her husband to stop a nosebleed if it occurs again at home? What is the evidence for your recommendations? How will you determine the strength of the evidence on which your recommendations are based?

2. You are caring for a 78-year-old patient on a medical-surgical nursing unit. He has recently been diagnosed with cancer of the larynx and is scheduled for a total laryngectomy in the morning. What patient education is needed before this patient's surgery? Discuss nursing management of the patient's airway in the immediate postoperative period. What critical elements would you include in teaching the patient how to care for his tracheostomy? What community resources would you provide or arrange for this patient once he is discharged? What modifications in teaching and care would be necessary if this man had one-sided weakness secondary to an earlier stroke?

3. A 65-year-old man is referred for home care after a total laryngectomy performed to treat cancer of the larynx. As the home health nurse, you are responsible for providing continued patient education regarding tracheostomy care and gastric tube feedings. The overall plan is for the patient to begin oral feedings; however, both the patient and his wife believe that he is not ready to begin to eat. What are your priorities in terms of assessment of this patient? What are your recommendations to the patient regarding fear, anxiety, communication, and nutrition? What additional medical and support services will the patient need to assist him in his recovery? How would your care differ if this patient lived alone?

NCLEX-Style Review Questions

1. The nurse is providing preoperative teaching for the patient who is to undergo a total laryngectomy. Which nursing intervention is most important?
   a. Having the patient restrict food and fluids
   b. Teaching the care required for the tracheostomy tube
   c. Assessing the patient's ability to communicate postoperatively
   d. Demonstrating cough and deep-breathing exercises

2. A patient who has just had a total laryngectomy for cancer is being discharged. Which statement indicates the patient needs further teaching on care of the tracheostomy?
   a. "I must avoid getting any objects in the stoma."
   b. "I can take a shower when I get home."
   c. "I can learn to speak with an electric larynx."
   d. "I need to clean around the stoma every day."

3. Which statement indicates further teaching is required for the patient diagnosed with obstructive sleep apnea (OSA)?
   a. "The CPAP machine will help me be more awake during the day."
   b. "If I exercise and lose weight, I may not need to use CPAP."
   c. "I will use the CPAP machine only when I really need to sleep well."
   d. "The CPAP helps to keep my airway open when I sleep."

4. The nurse assesses the patient with acute pharyngitis for what signs and symptoms that indicate a complication of GAS pharyngitis?
   a. Pain and spasm of the lower leg muscles
   b. Gross hematuria, edema, and hypertension
   c. Reduced visual fields, blurred vision
   d. Insomnia, heartburn, and abdominal distension

5. A patient will be going home with a tracheal stoma. What information does the nurse include in the discharge teaching for this patient?
   a. Water sports are permitted.
   b. Wear a medical identification bracelet.
   c. Mouth-to-mouth ventilation should be performed in an emergency.
   d. Fifteen minutes of strenuous exercise will improve overall strength.

CHAPTER 10

Nursing Management: Patients with Chest and Lower Respiratory Tract Disorders

Laura Kierol Andrews

Learning Objectives

After reading this chapter, you will be able to:

1. Identify patients at risk for atelectasis and describe nursing interventions related to its prevention and management.
2. Compare the various pulmonary infections with regard to causes, clinical manifestations, nursing management, complications, and prevention.
3. Use the nursing process as a framework for care of the patient with pneumonia.
4. Describe the nursing management for patients receiving oxygen therapy, mini-nebulizer therapy, incentive spirometry, chest physiotherapy, and breathing retraining.
5. Relate pleurisy, pleural effusion, and empyema to pulmonary infection.
6. Relate the therapeutic management techniques of acute respiratory distress syndrome (ARDS) to the underlying pathophysiology of the syndrome.
7. Describe risk factors and measures appropriate for prevention and management of pulmonary embolism (PE).
8. Describe risk factors for the development of occupational lung disease.
9. Discuss the modes of therapy and related nursing management for patients with lung cancer.
10. Describe the complications of chest trauma and their clinical manifestations and nursing management.
11. Describe nursing measures to prevent aspiration.
12. Explain the principles of chest drainage and the nursing responsibilities related to the care of the patient with a chest drainage system.

It is common for patients in medical and surgical areas to have lower respiratory tract conditions. The care of these patients requires judicious assessment and management skills as these conditions are often serious and life-threatening and have a significant impact on activities of daily living and quality of life.

ATELECTASIS

Atelectasis is the collapse of alveoli, leading to the loss of lung volume. It is classified by its cause (absorptive, obstructive, or compressive) and can affect subsegmental, segmental, lobar, or whole lung areas. The diagnosis of atelectasis is based on both clinical and radiologic findings.

Pathophysiology

Absorptive atelectasis occurs by surfactant inactivation or when less than normal levels of inhaled nitrogen (*nitrogen wash-out*) are present in the alveoli. The most common condition that causes an inactivation of surfactant is acute respiratory distress syndrome (ARDS), in which pulmonary edema fluid dilutes and/or reduces surfactant production. The loss of surfactant causes a reduction in alveoli surface tension and leads to their collapse. Nitrogen wash-out is a condition that occurs when high levels of inhaled oxygen (FiO_2 greater than 60%) lessen the amount of nitrogen gas needed to stent open alveoli. In addition, the use of some general anesthetics can cause an absorptive atelectasis.

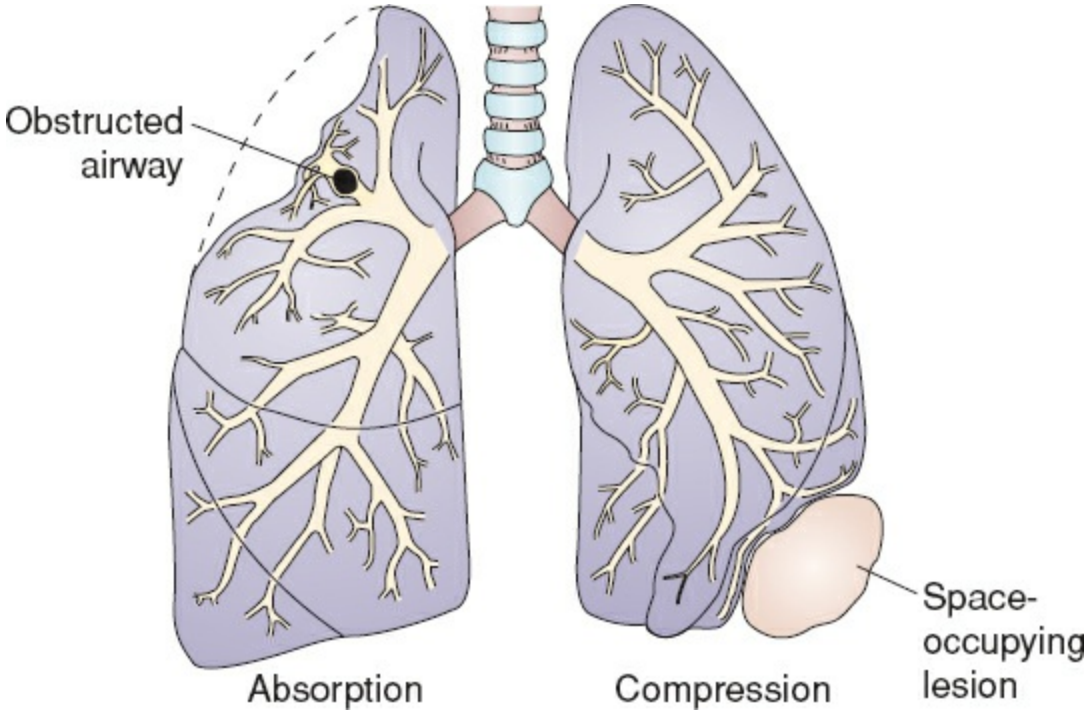

FIGURE 10-1 Atelectasis caused by airway obstruction and absorption of air from the involved lung area (*left*) and by compression of the lung tissue (*right*). (From Grossman, S., & Porth, C. M. (2014). *Pathophysiology: Concepts of altered health states* (9th ed.). Philadelphia, PA: Lippincott Williams & Wilkins.)

Compressive atelectasis occurs as a result of external forces compressing pleural and/or lung tissues. Common causes of this type of atelectasis are pleural effusions, lung tumors, pneumothoraces (air in the pleural space), hemothoraces (blood in the pleural space), and abdominal distention.

Obstructive atelectasis occurs when there is a mechanical obstruction of airways (secretions, mucous plugs, airway tumors, peribronchial lymph node enlargement, foreign bodies) or from low-tidal-volume breathing (which results in hypoventilation of alveoli and then absorption of alveolar gases), causing lung tissue collapse (Fig. 10-1).

Each type of atelectasis can cause a mismatching of lung ventilation in relation to perfusion that results in deoxygenated blood reaching systemic circulation and lowering oxygen supply to tissues. The most common cause of atelectasis is the obstruction of

airways by secretions, mucus, foreign bodies, bronchial tumors, and oxygen toxicity.

Risk Factors

Postoperative patients, especially those who undergo abdominal and/or thoracic procedures, are at risk to develop atelectasis due to anesthetic- and/or narcotic-induced hypoventilation, incisional pain, abdominal distention, and immobility, all of which impair the ability to breathe deeply (expand lung volume) and cough (expel secretions). Additional risk factors for developing atelectasis include chronic lung disease, morbid obesity, tobacco use, anesthesia time greater than 4 hours, prior cerebrovascular accident (CVA), lung cancer, pleural effusions, and nasogastric tube placement.

Clinical Manifestations and Assessment

Signs and symptoms include dyspnea, cough, leukocytosis, diminished breath sounds, and sputum production. Fever is often cited as a clinical sign of atelectasis, but there is no correlation between the severity of atelectasis on chest radiology and the presence of fever. However, atelectasis should be suspected in postoperative patients with low-grade temperature (O'Donnell, 2016). Physical examination findings relate to the severity of collapse. For a small atelectatic area, findings include crackles, decreased breath sounds, and decreased tactile fremitus over the affected lung area(s). For a large atelectatic area, findings include tracheal deviation toward the atelectatic area, decreased fremitus, bronchial breath sounds, egophony (secondary to lobar or lung collapse), and asymmetry of the chest.

If obstruction by an airway tumor or foreign body is the cause, wheezing and stridor can occur. Patients with acute atelectasis or atelectasis involving large areas, such as segments, lobes, or whole lung areas, can develop significant respiratory distress manifested by dyspnea, tachycardia, tachypnea, anxiety, restlessness, pleural pain, and hypoxemia. They may also have paroxysmal breathing, retractions, and use of accessory muscles. Chronic atelectasis has manifestations similar to those of acute atelectasis, and chronic patients are at risk of developing a postobstructive pneumonia.

Atelectasis is diagnosed by radiologic studies such as chest x-ray, computed tomography (CT) scanning, or ultrasound. Radiologic findings of atelectasis may reveal opacity or patchy infiltrates underlying the affected tissue. Larger areas of collapse can reveal shifting of the heart border, hilar vessels, and hemidiaphragm toward the affected sections. Ultrasound can detect several lung pathologies, is portable, and does not expose patients to radiation (Dietrich et al., 2015).

Hypoxemia can be detected by arterial blood gas (ABG) analysis, which shows a decreased PaO_2 and oxygen saturation. Noninvasive pulse oximetry (POX) can be used to detect hypoxemia (SpO_2 less than 90%), but ABGs are the gold standard.

Medical and Nursing Management

The prevention of atelectasis is the primary management goal in at-risk patients (Box 10-1). Patients need to be educated and able to perform maneuvers that can improve ventilation and remove secretions. Immobile patients should be turned frequently, and all patients should be ambulated as soon as possible to improve lung expansion and mobilization of secretions. Lung volume expansion maneuvers, such as controlled deep breathing, coughing exercises, and use of incentive spirometry (IS), should be initiated early in the postoperative period. Patients who have asthma, chronic obstructive pulmonary disease (COPD), lung cancer, and thoracic or abdominal surgeries are at very high risk for developing atelectasis. These patients require additional interventions to prevent atelectasis. The use of aerosolized (nebulized) bronchodilators and/or mucolytics, followed by chest physiotherapy (CPT) (chest percussion and postural drainage), may be instituted.

BOX 10-1 Health Promotion

Preventing Atelectasis

- Change patient's position frequently, especially from supine to upright position, to promote ventilation and prevent secretions from accumulating.
- Encourage early mobilization from bed to chair, followed by early ambulation.
- Encourage appropriate deep breathing and coughing to mobilize secretions and prevent them from accumulating.
- Teach/reinforce appropriate technique for incentive spirometry.
- Administer prescribed opioids and sedatives judiciously to prevent respiratory depression.
- Perform postural drainage and chest percussion, if indicated.
- Institute suctioning to remove tracheobronchial secretions, if indicated.

Incentive Spirometry

Incentive spirometry (IS) is a method of deep breathing that provides visual feedback to encourage the patient to inhale slowly and deeply via a handheld spirometer. This prevents or reduces atelectasis by stimulating alveolar cells to secrete surfactant, which decreases the surface tension in the alveoli and improves inspiratory muscle performance. The use of IS is discussed in Box 10-2.

Nursing Alert

Surfactant, which decreases the surface tension in the alveoli, thus reducing their risk of collapse, needs to be replaced continuously. One stimulus for replacement is maximum deep inhalation that is sustained for a few seconds. Adults sigh or deep breath at one and a half to two times their normal tidal volume (~500 mL) six to eight times every hour. Any etiology that results in monotonous hypoventilation will lead to atelectasis. IS

encourages the patient to sigh or deep breath. The IS is typically graduated to 1.5 L and allows the user to see the depth of their breath by the rise of the three balls inside. Coughing is a forced expiratory maneuver that can "squeeze" alveoli. If coughing is needed to expel secretions, the nurse should follow the coughing maneuvers with the use of IS to re-expand the alveoli and encourage surfactant replacement. Assisting a patient to splint incisions will help improve the efficacy of coughing.

Nebulizer Therapy

Nebulizer therapy dispenses aerosolized medications to a patient's lungs via handheld or face mask devices. The medication is inhaled with a flow of compressed air or oxygen, producing a visible mist. The patient breaths through the mouth, taking slow, deep breaths, and then holds the breath for a few seconds. The patient is encouraged to cough during the treatment, which assists in increasing intrathoracic pressure and promoting secretion expectoration. Antibiotics, bronchodilators, and mucolytic medications can be nebulized.

BOX 10-2 Patient Education

Using an Incentive Spirometer

The inhalation of air, in a slow and controlled manner, helps inflate the lungs. The marker within the spirometer will measure the depth of each breath.

- Assume an upright position if possible (sitting or semi-Fowler's).
- Breathe using your diaphragm.
- Place mouthpiece firmly in the mouth, to breathe in deeply and slowly, holding each breath in for 3–4 seconds and exhaling slowly.
- Repeat 6–10 times per session.
- Use spirometer every hour while awake (keep it within reach).
- Try coughing, with splinting of incision, after each use.

Chest Physiotherapy

Chest physiotherapy (CPT), with or without nebulizer medications, also can be used to prevent or treat atelectasis, bronchial obstructions, and pneumonias. CPT includes postural drainage, chest percussion, vibration, and breathing retraining. The goals of CPT are to remove bronchial secretions, improve ventilation, and increase the efficiency of the respiratory muscles. In addition, teaching the patient effective coughing technique is an important part of CPT.

Postural drainage uses specific positions that allow gravity to aid in the removal of pulmonary secretions. Patients who lie supine will have secretions accumulate in the posterior lung sections, whereas upright patients will pool secretions in their lower lobes. By having the patient change positions (Fig. 10-2), secretions can drain from the affected bronchioles into the bronchi and trachea and then be removed by coughing or suctioning. Postural drainage is usually performed two to four times daily, prior to meals (to prevent

nausea, vomiting, or aspiration) and at bedtime. Prescribed nebulizer therapy should be given prior to postural drainage to dilate the bronchioles, reduce bronchospasm, and thin secretions. The patient is instructed to remain in each position for 10 to 15 minutes, inhaling slowly through the nose and exhaling slowly through pursed lips. If the patient cannot tolerate a position, the nurse modifies it for comfort. When changing positions, the patient should be instructed to deep breath and cough out secretions, or the nurse may have to suction if the patient is unable to cough.

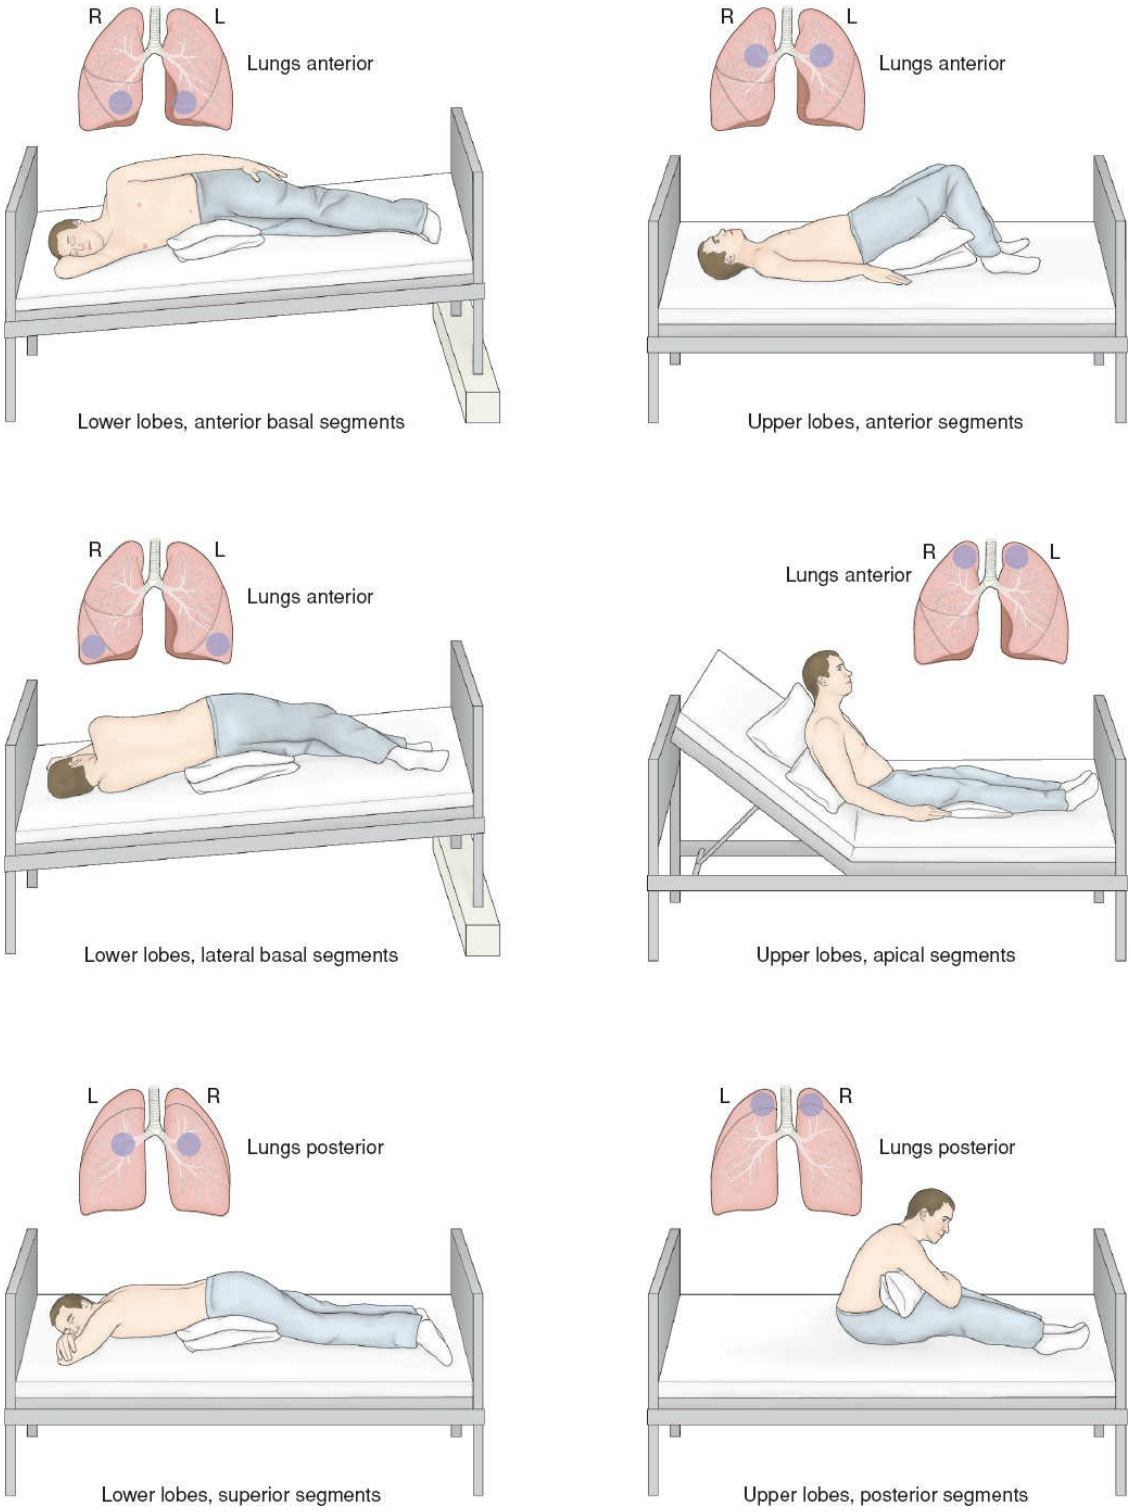

FIGURE 10-2 Positions used in lung drainage.

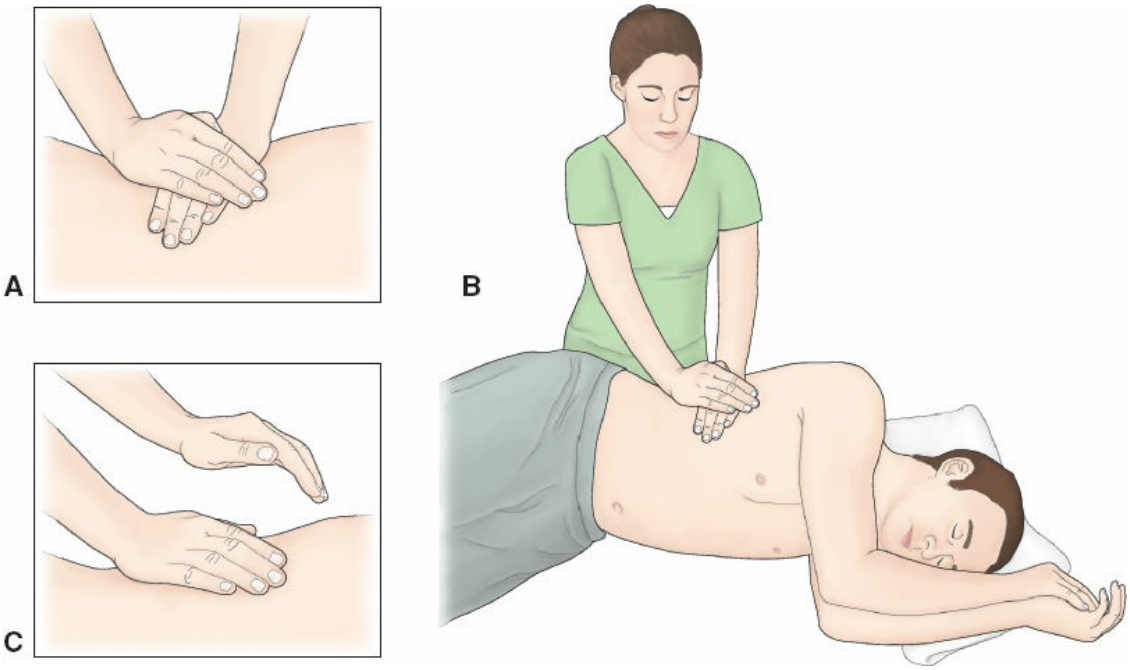

FIGURE 10-3 Percussion and vibration. A. Proper hand position for vibration. B. Proper technique for vibration. The wrists and elbows remain stiff; the vibrating motion is produced by the shoulder muscles. C. Proper hand position for percussion.

Chest percussion and vibration can be used in each position to loosen secretions (Fig. 10-3). Percussion is performed by the nurse or respiratory therapist by rapidly "clapping" their cupped hands over the affected lung lobe. This is done for 1 to 2 minutes in each postural area. Commercial percussion vests and beds are also available for use. Vibration is performed either manually or with a mechanical device. The nurse places his or her hands over the affected area and rapidly contracts the arms and shoulders while the patient exhales. This maneuver is done for 5 to 10 breaths over each lung area.

Other Treatments

If the cause of atelectasis is bronchial obstruction from secretions, the secretions must be removed by forceful coughing or suctioning to allow air to reenter that portion of the lung. Mucolytic agents such as acetylcysteine (Mucomyst) or dornase alfa (Pulmozyme) can be added to loosen and thin tenacious mucus. If intensive pulmonary toilet maneuvers and nebulizers fail to remove the obstructive mucus, a bronchoscopy can be performed. A bronchoscopy can also be used to remove foreign bodies from airways. Patients with airways tumors also may undergo biopsy for diagnostic purposes, cryotherapy (cold therapy), or laser therapy via bronchoscopy. Additional therapies for these patients include airway stents or radiation and chemotherapy.

If the cause of atelectasis is compression of lung tissue, the goal is to decrease or remove the compression. Large pleural effusions that collapse lung tissue can be removed by thoracentesis (removal of fluid by needle aspiration) or chest tube insertion (thoracostomy). A hemothorax or pneumothorax usually is treated by inserting a chest tube to drain the blood or air that is collapsing the lung. No matter what the cause of atelectasis, in patients with significant hypoxemia, intubation and mechanical ventilation with positive end-expiratory pressure (PEEP) may be necessary to provide adequate

ventilation and oxygenation.

Complications

Usually mild atelectasis can be managed with lung expansion maneuvers, CPT, and mobilization of the patient, but in some cases patients can develop severe hypoxia, respiratory distress, or pneumonia. Mortality is highest in patients who require intubation and mechanical intubation, especially for more than 48 hours. Complications also can occur from treatments used to treat atelectasis, such as bronchoscopy, thoracentesis, and thoracostomy, all of which place the patient at risk for infection, bleeding, and pneumothorax.

RESPIRATORY INFECTIONS

PNEUMONIA

Pneumonia is the infection of the lower respiratory tract caused by a variety of microorganisms, including bacteria, viruses, fungi, protozoa, and parasites. Pneumonia is common, affecting 1% of the population. Pneumonia causes more than 1.25 million hospitalizations annually and is associated with considerable mortality and morbidity (Mandell et al., 2007; Musher, 2016). It is the most common infectious cause of death and the eighth leading cause of death in the United States (Centers for Disease Control and Prevention [CDC], 2016c).

Classifications

Pneumonia may be classified in a wide variety of ways, including by its microbiologic cause, host condition, and host setting. Currently, the most common classifications for pneumonia are community-acquired pneumonia (CAP), hospital-acquired (nosocomial) pneumonia (HAP), ventilator-associated pneumonia (VAP), health care–associated pneumonia (HCAP), and pneumonia in an immunocompromised patient.

Community-Acquired Pneumonia

CAP occurs either in the community-dwelling person or within the first 48 hours after hospitalization or institutionalization. Most cases of CAP occur in the winter and early spring months, and prevalence rates are higher in men and in African Americans. Each year approximately 12% to 57% of CAP patients require hospitalization; these patients have a mortality rate of 1% to 36% (Lee et al., 2014; McLaughlin, Johnson, Kagan, & Baer, 2015). The need for hospitalization for CAP depends on the severity of the pneumonia, which is assessed by factors such as

- altered mental status,
- azotemia (higher than normal blood levels of urea or other nitrogen-containing compounds),
- respiratory rate greater than or equal to 30 breaths per minute (BPM),
- low blood pressure (BP) (systolic BP less than 90 or diastolic BP less than 60),
- tachycardia (HR greater than 125 bpm),
- high fever (temperature greater than 104°F) or afebrile,
- age of 65 years or older, arterial pH <7.35, and
- poor oxygenation (PaO_2 less than 70 mm Hg if less than 50 years old, PaO_2 less than 60 mm Hg if over 50 years old), or an inability to reliably take medications (Ferri, 2016; Musher, 2016).

In addition, people of advanced age with at least one comorbid disorder are at higher risk for needing hospitalization (Lee et al., 2014). The most common causative microbe of CAP is the gram-positive *Streptococcus pneumoniae* (pneumococcus); however, that causative agent is identified definitively in less than 30% of CAP cases. Other causative agents are *Haemophilus influenzae, Staphylococcus aureus, Legionella* spp., and viruses.

Hospital-Acquired and Ventilator-Associated Pneumonia

HAP is defined as the onset of pneumonia symptoms more than 48 hours after admission in patients who had no evidence of infection at the time of hospitalization. HAP is the second most common nosocomial infection but carries the highest mortality rate (33% to 50%). VAP is a type of HAP that is associated with endotracheal intubation and mechanical ventilation; it is defined as pneumonia that develops in patients who have been receiving mechanical ventilation for at least 48 hours (Montravers, Harpan, & Guivarch, 2016). It is reported that HAP accounts for 25% of intensive care unit infections and

causes increased length of stay, leading to greater costs of care (Musher, 2016). VAP carries a mortality rate of 20% to 50%, and can be even higher when lung infection is caused by high-risk pathogens (Chastre & Luyt, 2016).

HAP occurs when at least one of three conditions exists: host defenses are impaired, microorganisms reach the lower respiratory tract (usually by microaspiration of oropharyngeal microorganisms), or a highly virulent organism is present. Certain factors may predispose patients to HAP because of impaired host defenses (e.g., severe acute or chronic illness), a variety of comorbid conditions, supine positioning, aspiration, altered mental status, malnutrition, prolonged hospitalization, hypotension, and metabolic disorders. Hospitalized patients are also exposed to potential bacteria from other sources (e.g., transmission of pathogens from health care workers' hands, respiratory devices, and water reservoirs that are contaminated). Numerous intervention-related factors also may play a role in the development of HAP (e.g., therapeutic agents that cause central nervous system [CNS] depression with hypoventilation, endotracheal intubation, or inappropriate use of antibiotics). Alterations in the gastric pH due to illness and medications can disrupt the stomach lining, exposing patients to enteric bacteria. The mortality of HAP is related to the virulence of the organisms, their resistance to antibiotics, and the patient's underlying condition. The common organisms responsible for HAP and VAP include gram-negative bacilli and gram-positive cocci. Gram-negative organisms include *Pseudomonas aeruginosa, Escherichia coli, Klebsiella pneumoniae, Acinetobacter* spp., *Serratia* spp., *Stenotrophomonas maltophilia,* and *H. influenzae.* Gram-positive organisms include *S. aureus* (MSSA and MRSA) and *Streptococcus pneumoniae.* Viruses or fungi are less common causative agents, except in the immunocompromised patient.

Health Care–Associated Pneumonia

HCAP occurs in nonhospitalized patients who have had extensive health care contact, as defined as one of the following: resident of a nursing home or other type of long-term care facility, acute care hospitalization for 2 or more days within the last 90 days, intravenous antibiotic therapy, wound care, or chemotherapy, or attended a hospital or hemodialysis clinic within the last 30 days (Barbier, Andremont, Wolff, & Bouadma, 2013; Sopena, Hera, Casas, et al., 2014). Causative microorganisms are similar to those listed for HAP and VAP.

Pneumonia in the Immunocompromised Hosts

Pneumonia in the immunocompromised hosts includes *Pneumocystis* pneumonia (PCP), fungal pneumonias, and *Mycobacterium tuberculosis.* Pneumonia in the immunocompromised hosts occurs with use of corticosteroids or other immunosuppressive agents, chemotherapy, nutritional depletion, use of broad-spectrum antimicrobial agents, acquired immune deficiency syndrome (AIDS), genetic immune disorders, and long-term life-support technology (mechanical ventilation). In addition, increasing numbers of patients with impaired defenses develop HAP from gram-negative bacilli, which poses difficulty in providing coverage. In addition, the combination of an immunocompromised patient and some gram-negative bacilli impacts the incidence of mortality.

Pneumonia in immunocompromised hosts may be caused by the organisms also observed in CAP or HAP. PCP is rarely observed in immunocompetent hosts and is often

an initial AIDS-defining complication. Whether patients are immunocompromised or immunocompetent, the clinical presentation of pneumonia is similar, but PCP has a subtle onset, with progressive dyspnea, fever, and a nonproductive cough. Refer to Chapter 37 for more information about PCP and HIV.

Pathophysiology

Pneumonia can arise from several vectors: from normal flora present in patients whose resistance has been altered; aspiration of flora present in the nasopharynx or oropharynx; the inhalation of airborne microorganisms from other persons (sneezing, coughing, or talking); contaminated water sources or respiratory equipment; or blood-borne organisms that enter the pulmonary circulation (hematogenous spread) and become trapped in the pulmonary capillary beds.

Normal host defenses (cough, ciliary clearance, and alveolar macrophages) and intact upper airway defense mechanisms usually prevent potentially infectious particles from reaching the sterile lower respiratory tract.

Once the microorganisms reach the lower airways and alveoli, their presence activates an inflammatory response that begins with the migration of white blood cells (WBCs) (mainly neutrophils), plasma fluid, and immune complexes into the alveoli, filling the normally air-filled spaces with exudative liquids and cellular debris. This causes alveolar edema and lung tissue consolidation. Additional damage can occur when some microorganisms release toxins that further damage respiratory cells. Alveolar and bronchial tissues become swollen and infiltrated with WBCs, causing consolidation of lung tissue that can be seen on x-ray. The damage caused by toxins and inflammatory mediators and immune complexes interferes with the diffusion of oxygen and carbon dioxide, leading to clinical manifestations of the pneumonia. A mismatch between ventilation and perfusion occurs in the affected area of the lung, and poorly oxygenated blood returns from the pulmonary vasculature to the heart, resulting in arterial hypoxemia.

Risk Factors

Risk factors for pneumonia are summarized in Box 10-3. Patients with comorbid diseases such as COPD, heart failure, diabetes, and chronic liver or kidney disease have higher mortality rates than do those without comorbid diseases.

BOX 10-3 Risk Factors for Pneumonia

Community-Acquired Pneumonia (CAP)

- Smoking
- Alcohol abuse
- Pre-existing hypoxemia
- Acidosis
- Toxic inhalations
- Pulmonary edema
- Altered mental status (e.g., seizure, CVA)
- Presence of comorbid conditions, including chronic respiratory (COPD, asthma) and cardiovascular diseases (HF), cerebrovascular disease, Parkinson disease, epilepsy, dementia, dysphagia, HIV, or chronic kidney or liver disease
- Malnutrition; underweight
- Immunosuppressive therapies
- Poor dental hygiene
- Age older than 65 years
- Intravenous drug abuse
- Regular contact with children
- 10 or more people living in a household
- Previous episodes of pneumonia
- Working and environmental conditions (contact with dust and sudden changes of temperature)

Hospital-Acquired Pneumonia (HAP) and Ventilator-Associated Pneumonia (VAP)

- Debilitation
- Malnutrition
- Altered mental status
- Previous exposure to antibiotics (within the last 90 days)
- Hospital stays of 5 days or longer
- High rates of antibiotic resistance (hospital or unit-specific)
- Immunosuppressive therapies or diseases
- Prolonged (greater than 48 hours) intubation or a tracheostomy
- Male gender

Health Care–Acquired Pneumonia (HCAP)

- Hospitalization for 2 or more days in the last 3 months
- Chronic dialysis within the last month
- Home wound care within 30 days
- Recent home IV therapy (antibiotic, chemotherapy)
- Resident of a skilled nursing or extended-care facility
- Family member with drug-resistant microorganism

Clinical Manifestations and Assessment

Pneumonia varies in its signs and symptoms depending on the causal organism and the presence of underlying disease; however, it is not possible to diagnose a specific type of pneumonia by clinical manifestations alone. The classic clinical manifestations of pneumonia are fever, cough (productive or nonproductive), dyspnea, and leukocytosis (elevated WBCs). Patients can also present with rigors (shaking chills), pleuritic chest pain, tachypnea, use of accessory muscles, tachycardia, fatigue, and anorexia. Some patients initially exhibit an upper respiratory tract infection (nasal congestion, sore throat), and the onset of symptoms of pneumonia is gradual and nonspecific. Then the predominant symptoms may be headache, low-grade fever, pleuritic pain, myalgia (muscle pain), rash, and pharyngitis.

Physical examinations findings may reveal bronchial breath sounds over consolidated lung areas, crackles, increased tactile fremitus (vocal vibration detected on palpation), percussion dullness, egophony, and whispered pectoriloquy (whispered sounds are easily auscultated through the chest wall). These changes occur because sound is transmitted better through solid or dense tissue (consolidation) than through normal air-filled tissue. Purulent sputum or slight changes in respiratory symptoms may be the only sign of pneumonia in patients with COPD. It may be difficult to determine whether an increase in symptoms is an exacerbation or an infectious process.

The diagnosis of pneumonia is made by history (particularly of a recent respiratory tract infection), physical examination, chest x-ray, blood culture (bloodstream invasion, called *bacteremia*, occurs frequently), sputum examination (Gram stain and culture), and rapid bacterial antigen testing of urine or oropharyngeal swabs. A urine test may be ordered when pneumococcal pneumonia is suspected since the enzyme-linked immunosorbent assay (ELISA) can detect pneumococcal cell wall or capsular polysaccharide in the urine of 60% to 80% of patients with bacteremic pneumococcal pneumonia (Musher, 2016). In addition, a urinary antigen test can be obtained to assess for *Legionella pneumophila* if suspected.

The sputum sample is obtained by having patients do the following: (1) rinse the mouth with water to minimize contamination by normal oral flora, (2) breathe deeply several times, (3) cough deeply, and (4) expectorate the raised sputum into a sterile container. The best time to collect the sputum culture is in the morning because the sputum is more concentrated and less likely to be contaminated with saliva and nasopharyngeal secretions. More invasive procedures may be used to collect sputum specimens (nasotracheal or orotracheal suctioning or bronchioalveolar lavage via bronchoscopy).

Nursing Alert

Since timely initiation of antibiotic treatment is important, the nurse understands that a STAT sputum Gram stain may be obtained. The Gram stain will inform the provider whether the organisms are gram-positive (thick cell walls) or gram-negative (thin cell walls). Since results are available rapidly, the provider can prescribe an antibiotic with efficacy to the identified bacteria (positive, negative) and fungi (yeasts, molds), but not viruses. Thus the nurse understands the difference between empiric coverage and culture documented.

Culture documented will name the specific organism and antibiotics that are sensitive or resistant to the specified organism.

Chest x-ray findings associated with pneumonia vary depending upon microbial causes, but a new pulmonary infiltrate or consolidation is often seen within 48 hours of onset of symptoms. Infiltrates can involve segments or lobes, or be multilobar.

Unfolding Patient Stories: Kenneth Bronson • Part 1

Kenneth Bronson, a 27-year-old male, has a history of fatigue, high fever, and a productive cough for a week and arrives in the emergency department with difficulty breathing. A chest x-ray reveals a right lower lobe pneumonia. What are the clinical manifestations and assessment findings associated with a right lower lobe pneumonia that the nurse should investigate when evaluating the patient? (Kenneth Bronson's case continues in Chapter 17.)

Care for Kenneth and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in (thepoint.lww.com/DocuCareEHR).

Medical and Nursing Management

Pharmacologic Therapy

The treatment of pneumonia includes administration of the appropriate antibiotic. The choice of antibiotic is determined by the classification of pneumonia (i.e., CAP vs. HAP), results of Gram stains, culture sensitivities, antigen testing, and patient's comorbid conditions. Initial treatment for CAP is empiric unless sputum culture and sensitivity results are available. Empiric therapy for non-CAP is usually initiated with a broad-spectrum IV antibiotic and may be monotherapy or combination therapy. The choice of antibiotics is based on assessment of risk of multidrug resistance (MDR) pathogens and early versus late onset of HAP or VAP symptoms (Table 10-1). Once the microbacterial cultures and sensitivities are available, therapy should be narrowed to avoid emergence of drug-resistant pathogens. Box 10-4 depicts the risk factors for developing MDR pathogens.

Prompt administration of antibiotics in patients is a key treatment measure. If specific pathogens responsible for the pneumonia are identified, more specific, less broad-spectrum agents should be used. The recommended duration of treatment for CAP is a minimum of 5 days. Patients should be afebrile for at least 2 days before antibiotics are discontinued. Patients with nosocomial pneumonias are treated for 7 to 10 days, as long as the patient is showing signs of clinical improvement. Emerging data are demonstrating that shorter durations of antibiotic use are producing good clinical responses and fewer emergences of MDR pathogens (Montravers, Harpan, & Guivarch, 2016).

TABLE 10-1 Empiric Antibiotic Therapy for Hospital-Acquired, Ventilator-Associated, or Health Care–Acquired Pneumonia

Type	Drugs
Early onset (less than 5 days), with no risk factors for multi drug-resistant pathogens	Ampicillin-sulbactam OR Ceftriaxone OR Levofloxacin, moxifloxacin, or ciprofloxacin OR ertapenem
Late onset (5 days or more) or risk factors for multidrug-resistant pathogens	Cefepime or ceftazidime OR Imipenem or meropenem OR Piperacillin-tazobactam AND Ciprofloxacin or levofloxacin OR amikacin, gentamicin or tobramycin AND Linezolid or vancomycin (MRSA)

Data from American Thoracic Society & Infectious Disease Society of America. (2005). Guidelines for management of adults with hospital-acquired ventilator associated, and healthcare-associated pneumonia. *American Journal of Respiratory and Critical Care Medicine*, *171*, 388–416; Musher, D. (2016). Overview of pneumonia. In L. Goldman & A. Schafter (Eds.), *Goldman-Cecil medicine* (25th ed.). New York: Elsevier, Saunders.

Antibiotics are ineffective in viral pneumonia, and their use may be associated with adverse effects (superinfections, MDR pathogens). Patients who develop pneumonia or who are at risk for influenza can be treated with antiviral agents. The CDC (2015b, 2016c) recommends initiating antiviral therapy for persons with suspected/confirmed influenza

who are severely ill or hospitalized, or are at risk for complications.

Oxygen Inhalation Therapy

Oxygen inhalation therapy is the administration of oxygen at a concentration greater that that found in the environmental atmosphere. At sea level, the concentration of oxygen in room air is 21% and has a relative humidity of 50% under normal circumstances; the lungs contribute about 250 mL of H_2O per day to maximally saturate inspired air. The goal of using oxygen therapy is to prevent or correct tissue hypoxia, which is decreased oxygen supply to the tissues (Box 10-5). Hypoxia is often confused with hypoxemia. Hypoxemia is a decrease in the arterial oxygen content or arterial oxygen tension (partial pressure of oxygen, PaO_2) and is measured by ABG or POX. Hypoxemia is defined as a PaO_2 level of less than 60 mm Hg and/or a POX level of less than 90%. When administering oxygen to a patient, a nurse must keep in mind that oxygen transport to the tissues is dependent not only on the arterial oxygen content but also on cardiac output, hemoglobin concentration, and metabolic requirements.

BOX 10-4 Risk Factors for the Development of Multidrug-Resistant Pathogens

- Antibiotic use in preceding 90 days
- Current hospitalization 5 days or longer
- Immunocompromised (by disease or therapies)
- Increased frequency of drug resistance in the community or hospital unit
- Presence of risk factors for HCAP

Indications for Oxygen Therapy

The use of oxygen to *treat* patients with hypoxia is based on clinical indicators such as subjective information (dyspnea, chest pain), ABG analysis, POX, and physical examination findings. A change in respiratory rate or pattern (bradypnea, tachypnea, Cheyne–Stokes breathing), change in mental status (agitation, anxiety, disorientation, confusion, lethargy, coma), change in BP, change in heart rate (bradycardia or tachycardia), development of arrhythmias, cyanosis (late sign), diaphoresis, or cool extremities are signs of hypoxia. The development of these signs and symptoms depends on how suddenly the hypoxia develops. Acute onset tends to show signs of neurologic and cardiovascular impairment, while with chronic onset, patients complain of fatigue, drowsiness, dyspnea on exertion (DOE), and inattentiveness.

The administration of oxygen to *prevent* hypoxemia in high-risk patients who do not have clinical indicators of hypoxia is common in hospitals. High-risk patients are those who are at risk of rapidly developing hypoxemia or who will not tolerate even mild hypoxemia. Patients with pneumonia, PE, suspected myocardial injury or infarction, and head trauma or injury are just a few examples.

BOX 10-5 Types of Hypoxia

Hypoxia can occur from either severe pulmonary disease (inadequate oxygen supply) or from extrapulmonary disease (inadequate oxygen delivery) affecting gas exchange at the cellular level. The four general types of hypoxia are hypoxemic hypoxia, circulatory hypoxia, anemic hypoxia, and histotoxic hypoxia.

Hypoxemic Hypoxia

Hypoxemic hypoxia is a decreased oxygen level in the blood resulting in decreased oxygen diffusion into the tissues. It may be caused by hypoventilation, high altitudes, ventilation–perfusion mismatch (as in pulmonary embolism), shunts in which the alveoli are collapsed and cannot provide oxygen to the blood (commonly caused by atelectasis), and pulmonary diffusion defects. It is corrected by increasing alveolar ventilation or providing supplemental oxygen.

Circulatory Hypoxia

Circulatory hypoxia results from inadequate capillary circulation. It may be caused by decreased cardiac output, local vascular obstruction, low-flow states such as shock, or cardiac arrest. Although tissue partial pressure of oxygen (PO_2) is reduced, arterial oxygen (PaO_2) remains normal. Circulatory hypoxia is corrected by identifying and treating the underlying cause.

Anemic Hypoxia

Anemic hypoxia is a result of decreased effective hemoglobin concentration, which causes a decrease in the oxygen-carrying capacity of the blood. It is rarely accompanied by hypoxemia. Carbon monoxide poisoning, because it reduces the oxygen-carrying capacity of hemoglobin, produces similar effects but is not strictly anemic hypoxia because hemoglobin levels may be normal.

Histotoxic Hypoxia

Histotoxic hypoxia occurs when a toxic substance, such as cyanide, interferes with the ability of tissues to use available oxygen.

Methods of Oxygen Administration

Oxygen is dispensed from a cylinder or a piped-in system, and a flow meter regulates the flow of oxygen in liters per minute. When oxygen is used at flow rates greater than or equal to 4 L/min, it should be moistened by passing it through a humidification system to prevent it from drying the mucous membranes of the respiratory tract (Tokarczyk, Greenberg, & Vender, 2013). A variety of oxygen delivery systems is available (Table 10-2). Each system and oxygen flow rate is designed to provide a specific fraction of inspired oxygen (FiO_2) or percentage of oxygen. The appropriate form of oxygen therapy is best determined by ABG levels, which indicate the patient's oxygenation status, and/or POX.

Oxygen delivery systems are classified as low-flow or high-flow delivery systems. Low-

flow systems contribute partially to the inspired gas the patient breathes, which means that the patient breathes some room air along with the oxygen. These systems do not provide a constant or known concentration of inspired oxygen. The amount of inspired oxygen changes as the patient's breathing changes. Examples of low-flow systems include nasal cannula, simple mask, partial-rebreather, and nonrebreather masks. In contrast, high-flow systems provide the total amount of inspired air. A specific percentage of oxygen is delivered independent of the patient's breathing. High-flow systems are indicated for patients who require a constant and precise amount of oxygen. Examples of such systems include transtracheal catheters, Venturi masks, aerosol masks, tracheostomy collars, and face tents.

Concept Mastery Alert

For patients fitted with partial rebreathing masks, the masks should always be filled, whether the patient is inhaling or exhaling.

A nasal cannula is used when the patient requires a low to medium concentration of oxygen for which precise accuracy is not essential. This method is relatively simple and allows the patient to move about in bed, talk, cough, and eat without interrupting oxygen flow. Flow rates in excess of 6 to 8 L/min may lead to swallowing of air or may cause irritation and drying of the nasal and pharyngeal mucosa. When oxygen is administered via cannula, the percentage of oxygen reaching the lungs varies with the depth and rate of respirations, particularly if the nasal mucosa is swollen or if the patient is a mouth breather.

Nursing Alert
The nurse is aware that patients with nasal cannula often develop irritation and erythema on their ears and cheeks due to pressure of the cannula tubing. Gauze or protective devices that pad the pressure points may be used around the cheeks and ears during prolonged use.

Oxygen masks come in several forms (Fig. 10-4). Each is used for different purposes. *Simple masks* are used to administer low to moderate concentrations of oxygen. The body of the mask itself gathers and stores oxygen between breaths. The patient exhales directly through openings or ports in the body of the mask. If oxygen flow ceases, the patient can draw air in through these openings around the mask edges. Although widely used, these masks cannot be used for controlled oxygen concentrations and must be adjusted for proper fit. They should not press too tightly against the skin because this can cause a sense of claustrophobia as well as skin breakdown; adjustable elastic bands are provided to ensure comfort and security.

TABLE 10-2 Oxygen Administration Devices

Device	Suggested Flow Rate (L/min)	O_2 Percentage Setting	Advantages	Disadvantages
Low-Flow Systems				
Cannula	1–2 3–5 6	23–30 30–40 42	Lightweight, comfortable, inexpensive, continuous use with meals and activity	Nasal mucosal drying, variable FiO_2
Oropharyngeal catheter	1–6	23–42	Inexpensive, does not require a tracheostomy	Nasal mucosa irritation; catheter should be changed frequently to alternate nostril
Mask, simple	6–8	40–60	Simple to use, inexpensive	Poor fitting, variable FiO_2, must remove to eat
Mask, partial rebreather	8–11	50–75	Moderate O_2 concentration	Warm, poorly fitting, must remove to eat
Mask, nonrebreather	12	80–100	High O_2 concentration	Poorly fitting
High-Flow Systems				
Transtracheal catheter	¼–4	60–100	More comfortable, concealed by clothing, less oxygen liters per minute needed than nasal cannula	Requires frequent and regular cleaning, requires surgical intervention
Mask, Venturi	4–6 6–8	24, 26, 28 30, 35, 40, 50	Provides low levels of supplemental O_2 Precise FiO_2, additional humidity available	Must remove to eat
Mask, aerosol	8–10	30–100	Good humidity, accurate FiO_2	Uncomfortable for some
Tracheostomy collar	8–10	30–100	Good humidity, comfortable, fairly accurate FiO_2	
Face tent	8–10	30–100	Good humidity, fairly accurate FiO_2	Bulky and cumbersome
Oxygen-Conserving Devices				
Pulse dose (or demand)	10–40 mL/breath		Deliver O_2 only on inspiration, conserve 50–75% of O_2 used	Must carefully evaluate function individually

Partial-rebreathing masks have a reservoir bag that *must remain inflated during both inspiration and expiration*. The nurse adjusts the oxygen flow to ensure that the bag does not collapse during inhalation. A high concentration of oxygen can be delivered because both the mask and the bag serve as reservoirs for oxygen. Oxygen enters the mask through small-bore tubing that connects at the junction of the mask and bag. As the patient inhales, gas is drawn from the mask, from the bag, and potentially from room air through the exhalation ports. As the patient exhales, the first third of the exhalation fills the reservoir bag. This is mainly dead space and does not participate in gas exchange in the lungs. Therefore, it has a high oxygen concentration. The remainder of the exhaled gas is vented through the exhalation ports. The actual percentage of oxygen delivered is influenced by the patient's ventilatory pattern.

Nonrebreathing masks are similar in design to partial-rebreathing masks except that they have additional valves. A one-way valve located between the reservoir bag and the base of the mask allows gas from the reservoir bag to enter the mask on inhalation but prevents gas in the mask from flowing back into the reservoir bag during exhalation. One-way valves located at the exhalation ports prevent room air from entering the mask during inhalation. They also allow the patient's exhaled gases to exit the mask on exhalation. As with the partial-rebreathing mask, *it is important to adjust the oxygen flow so that the reservoir bag does not completely collapse on inspiration*. In theory, if the nonrebreathing mask fits the patient snugly, and both side exhalation ports have one-way valves, it is possible for the patient to receive 100% oxygen, making the nonrebreathing mask a high-flow oxygen system.

However, because it is difficult to get an exact fit from the mask on every patient, and some nonrebreathing masks have only one one-way exhalation valve, it is almost impossible to ensure 100% oxygen delivery, thus making it a low-flow oxygen system.

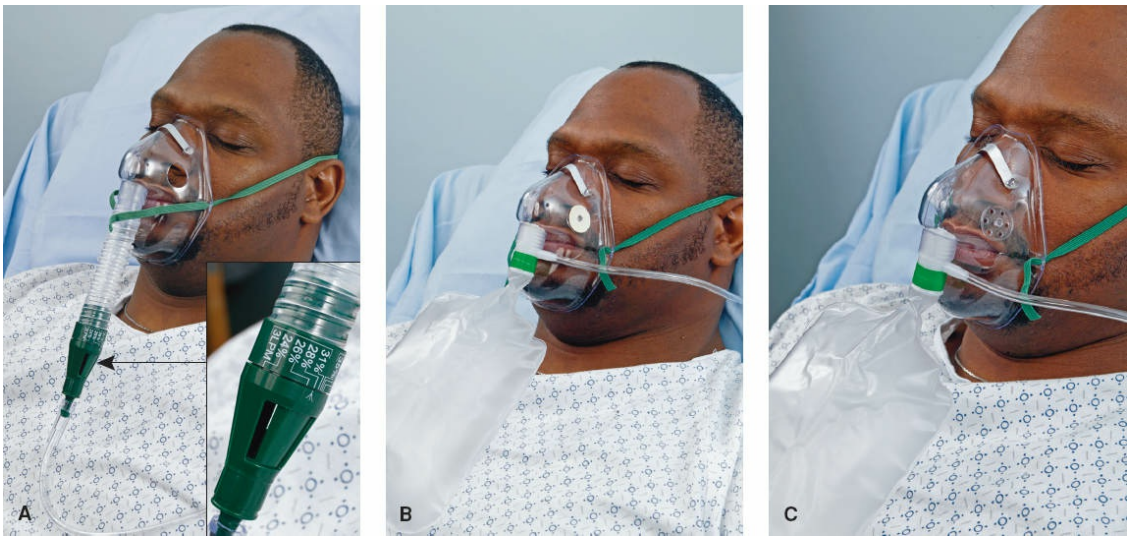

FIGURE 10-4 Types of oxygen masks used to deliver varying concentrations of oxygen. A. Venturi mask. B. Nonrebreather. C. Partial rebreather.

The *Venturi mask* is the most reliable and accurate method for delivering precise concentrations of oxygen through noninvasive means. The mask is constructed in a way that allows a constant flow of room air blended with a fixed flow of oxygen. It is used primarily for patients with COPD because it can accurately provide appropriate levels of supplemental oxygen, thus avoiding the risk of suppressing the hypoxic drive (refer to Chapter 11 for further details).

Nursing Alert
The nurse is aware that patients with severe COPD characteristically have a chronically elevated $PaCO_2$, a normal pH, an elevated HCO_3, and a PaO_2 level that usually is less than 60 mm Hg. As a result, the chemoreceptors in the aortic and carotid bodies are desensitized to the ventilatory stimulation from an increased $PaCO_2$ level but instead remain sensitive to PaO_2. Thus the goal of oxygen therapy is to raise the oxygen level to the patient's chronic baseline level (or a POX of 88% to 92%), not above it.

The Venturi mask uses the Bernoulli principle of air entrainment (trapping the air like a vacuum), which provides a high air flow with controlled oxygen enrichment. For each liter of oxygen that passes through a jet orifice, a fixed proportion of room air is entrained. A precise volume of oxygen can be delivered by varying the size of the jet orifice and adjusting the flow of oxygen. Excess gas leaves the mask through the two exhalation ports, carrying with it the exhaled carbon dioxide. This method allows a constant oxygen concentration to be inhaled regardless of the depth or rate of respiration.

The mask should fit snugly enough to prevent oxygen from flowing into the patient's eyes. The nurse checks the patient's skin for irritation. It is necessary to remove the mask so that the patient can eat, drink, and take medications, at which time supplemental oxygen is

provided through a nasal cannula.

The nurse must understand how to convert percentage of oxygen with a mask to liters per minute for a nasal cannula (Box 10-6).

The *transtracheal oxygen catheter* is inserted directly into the trachea and is indicated for patients with chronic oxygen therapy needs. These catheters are more comfortable, less dependent on breathing patterns, and less obvious than other oxygen delivery methods. Because no oxygen is lost into the surrounding environment, the patient achieves adequate oxygenation at lower rates, making this method less expensive and more efficient.

BOX 10-6 Approximate FiO_2 of Nasal Cannula Flow Rates

Each liter (L) of flow is approximately an addition of 4% FiO_2

- 1 L/min = 24% FiO_2
- 2 L/min = 28% FiO_2
- 3 L/min = 32% FiO_2
- 4 L/min = 36% FiO_2
- 5 L/min = 40% FiO_2
- 6 L/min = 44% FiO_2

Tokrczyk et al. (2013).

Other oxygen devices include *aerosol masks, tracheostomy collars*, and *face tents*, all of which are used with aerosol devices (nebulizers) that can be adjusted for oxygen concentrations from 27% to 100% (0.27 to 1.00). If the gas mixture flow falls below patient demand, room air is pulled in, diluting the concentration. The aerosol mist delivered by the nebulizer must be available for the patient during the entire inspiratory phase. The nurse notifies the respiratory therapist if the nebulizer is not functioning properly.

Hyperbaric oxygen therapy is the administration of oxygen at pressures greater than 1 atmosphere. As a result, the amount of oxygen dissolved in plasma is increased, which increases oxygen levels in the tissues. During therapy, the patient is placed in a small (single patient use) or large (multiple patient use) cylindrical chamber. Hyperbaric oxygen therapy is used to treat conditions such as air embolism, carbon monoxide poisoning, gangrene, tissue necrosis, and hemorrhage. Potential side effects include ear trauma, CNS disorders, and oxygen toxicity.

Complications

Oxygen, like other medications, should be administered with caution and a careful assessment of patient response. A high concentration of oxygen is contraindicated in the patient with COPD because it may worsen alveolar ventilation by decreasing the patient's ventilatory drive, leading to further respiratory decompensation.

When oxygen is metabolized, it produces free radicals that can cause cellular damage. This side effect of oxygen therapy is called *oxygen toxicity*. Although healthy lungs may be

able to tolerate FiO_2 levels of less than 60%, when lungs are damaged FiO_2 over 50% may result in a toxic alveolar O_2 concentration and absorptive atelectasis (Tokrczyk et al., 2013). Toxic levels of oxygen are reached when FiO_2 levels are greater than 50% for longer than 48 hours (Marino, 2014). Signs and symptoms of oxygen toxicity include chest pain, paresthesias, dyspnea, restlessness, fatigue, malaise, progressive respiratory distress, atelectasis, pulmonary infiltrates, and fibrosis. The prevention of oxygen toxicity is achieved by using the lowest level of oxygen needed clinically. If a patient remains hypoxemic on toxic levels of oxygen, additional measures should be instituted, such as intubation and mechanical ventilation.

Oxygen supports combustion; therefore, its use is a fire hazard. No smoking or open flames should be allowed near oxygen use. In addition, the risk of cross-contamination of oxygen supplies (mask, tubing, cannulas) should be addressed and equipment changed per infection control policy.

Supportive Care

Supportive care for pneumonia includes hydration to combat insensible fluid losses from fever and tachypnea. Antipyretics may be used to treat headache, aches, and fever. Warm, moist inhalations are helpful in relieving bronchial irritation.

Additional therapies must be considered for the hospitalized pneumonia patient. Nutritional assessment and support, deep vein thrombosis prophylaxis, nebulized bronchodilators or mucolytics, and comfort care measures should be individualized for each patient.

Gerontologic Considerations 

Pneumonia in elderly patients may occur as a primary diagnosis or as a complication of a chronic disease process. Pulmonary infections in older people frequently are difficult to treat and result in a higher mortality rate than in younger people. General deterioration, weakness, abdominal symptoms, incontinence, anorexia, confusion, tachycardia, and tachypnea may signal the onset of pneumonia. The diagnosis of pneumonia may be missed because the classic symptoms of cough, chest pain, and sputum production may be absent or masked in elderly patients. Fever as a symptom can be missed as well because 30% to 40% of older patients are afebrile. Also, the presence of some signs may be misleading. Abnormal breath sounds, for example, may be caused by atelectasis that occurs as a result of decreased mobility, decreased lung volumes, or other respiratory function changes. It may be necessary to obtain chest x-rays to differentiate chronic heart failure, which is often seen in the elderly, from pneumonia as the cause of clinical signs and symptoms.

Supportive treatment includes hydration (with caution and with frequent assessment because of the risk of fluid overload in the elderly), supplemental oxygen therapy, and assistance with deep breathing, coughing, frequent position changes, and early ambulation. All of these are particularly important in the care of elderly patients with pneumonia. To reduce or prevent serious complications of pneumonia in the elderly, vaccination against pneumococcal and influenza infections is recommended.

Prevention

Pneumococcal disease is more prevalent (three- to fivefold higher) in African-American adults as compared with Caucasians. Pneumococcal vaccination has been demonstrated to prevent pneumonia in otherwise healthy populations by 90%. The vaccine provides specific prevention against pneumococcal pneumonia and other infections caused by *S. pneumoniae* (otitis media, other upper respiratory tract infections). Vaccines should be avoided during the first trimester of pregnancy (CDC, 2016d).

To reduce or prevent serious complications of CAP in high-risk groups, vaccination against pneumococcal infection is advised for persons 2 to 64 years of age with chronic illnesses, those who are immunocompromised or are asplenic (spleen is removed), and for all those 65 years or older. Also smokers or those with asthma between the ages of 19 and 64 should get vaccinated. If vaccine was given prior to age 65, it should be repeated once after 5 years (CDC, 2016d).

NURSING PROCESS

The Patient with Pneumonia

ASSESSMENT

Nursing assessment is critical in detecting pneumonia. Patients with fever, chills, dyspnea, and cough should alert the nurse to the possibility of pneumonia. Respiratory assessment further identifies the clinical manifestations of pneumonia: pleuritic-type pain, fatigue, tachypnea, use of accessory muscles for breathing, tachycardia, coughing, and purulent sputum. The nurse monitors the patient for the following:

- Changes in temperature and pulse
- Amount, odor, consistency, and color of secretions
- Frequency and severity of cough
- Degree of tachypnea or shortness of breath
- Pulse oximetry
- Changes in physical assessment findings (primarily assessed by inspecting and auscultating the chest)
- Changes in the chest x-ray findings
- Changes in WBCs; leukocytosis is seen in *S. pneumoniae, H. influenzae*, and gram-negative bacilli whereas leukopenia may be seen with pneumococcal or gram-negative

bacillary pneumonia (Torres, Menendez, & Wunderink, 2016).

In addition, it is important to assess patients, especially elderly patients, for unusual behavior, altered mental status, dehydration, excessive fatigue, and concomitant heart failure.

DIAGNOSIS

Appropriate nursing diagnoses may include:

- Ineffective airway clearance related to copious tracheobronchial secretions
- Impaired gas exchange
- Activity intolerance related to impaired respiratory function
- Risk for deficient fluid volume related to fever, a rapid respiratory rate, and sepsis
- Imbalanced nutrition: less than body requirements
- Deficient knowledge about the treatment regimen and preventive health measures

Collaborative problems or potential complications that may occur include the following:

- Continuing symptoms after initiation of therapy
- Shock
- Respiratory failure
- Atelectasis
- Pleural effusion
- Confusion
- Superinfection

PLANNING

The major goals may include improved airway patency, rest to conserve energy, maintenance of proper fluid volume, maintenance of adequate nutrition, an understanding of the treatment protocol and preventive measures, and absence of complications.

NURSING INTERVENTIONS

IMPROVING AIRWAY PATENCY

Removing secretions is important because retained secretions interfere with gas exchange and may slow recovery. The nurse encourages hydration (2 to 3 L/day) because adequate hydration thins and loosens pulmonary secretions. Hydration must be achieved more slowly and with careful monitoring in patients with pre-existing conditions, such as heart failure. Humidification may be used to loosen secretions and improve ventilation. A high-humidity face mask (using either compressed air or oxygen) delivers warm, humidified air

to the tracheobronchial tree and helps to liquefy secretion. Coughing can be initiated either voluntarily or by reflex. Lung expansion maneuvers, such as deep breathing with an incentive spirometer, may induce a cough. A directed cough may be necessary to improve airway patency. The nurse encourages the patient to perform an effective, directed cough, which includes correct positioning, a deep inspiratory maneuver, glottic closure, contraction of the expiratory muscles against the closed glottis, sudden glottic opening, and an explosive expiration.

Nursing Alert

In general, the dependent lung is associated with improved perfusion. If the goal is to match ventilation with perfusion, the "good lung down" is a position that will facilitate this. However, any position for a prolonged period of time is associated with stagnation of secretions and pressure on the dependent lung, increasing the risk of atelectasis in the dependent lung. Therefore, the nurse turns the patient at regular intervals. The nurse is aware that when the affected lung is positioned dependently, the oxygen saturation should be assessed to note the impact of this position on oxygen level. In addition, the nurse is aware that in the case of unilateral (one lung) pulmonary hemorrhage or pulmonary abscess, "good lung down" is contraindicated to prevent blood or infected material from draining into the good lung.

CPT is important in loosening and mobilizing secretions. Indications for CPT include sputum retention not responsive to spontaneous or directed cough, a history of pulmonary problems previously treated with CPT, continued evidence of retained secretions (decreased or abnormal breath sounds, change in vital signs), abnormal chest x-ray findings consistent with atelectasis or infiltrates, and deterioration in oxygenation.

The nurse may consult the respiratory therapy department for volume-expansion protocols and secretion-management protocols that help direct the respiratory care of the patient and match the patient's needs with appropriate treatment schedules.

After each position change, the nurse encourages the patient to breathe deeply and cough. If the patient is too weak to cough effectively, the nurse may need to remove the mucus by nasotracheal suctioning. It may take time for secretions to mobilize and move into the central airways for expectoration. Therefore, it is important for the nurse to monitor the patient for cough and sputum production after the completion of CPT.

The nurse also administers and titrates oxygen therapy as prescribed or via protocols. The effectiveness of oxygen therapy is monitored by improvement in clinical signs and symptoms, patient comfort, and adequate oxygenation values as measured by POX or ABG analysis.

PROMOTING REST AND CONSERVING ENERGY

The nurse encourages the debilitated patient to rest and avoid overexertion and possible exacerbation of symptoms. The patient should assume a comfortable position to promote rest and breathing (e.g., semi-Fowler position) and should change positions frequently to enhance secretion clearance as well as ventilation and perfusion in the lungs. It is

important to instruct outpatients not to overexert themselves and to engage in only moderate activity during the initial phases of treatment.

PROMOTING FLUID INTAKE

The respiratory rate of patients with pneumonia increases because of the increased workload imposed by labored breathing and fever. An increased respiratory rate leads to an increase in insensible fluid loss during exhalation and can lead to dehydration. Therefore, it is important to encourage increased fluid intake (at least 2 L/day), unless contraindicated.

MAINTAINING NUTRITION

Many patients with shortness of breath and fatigue have a decreased appetite and consume only fluids. Fluids with electrolytes and protein-supplementation drinks can be prescribed to patients. In addition, IV fluids and nutrients may be administered if necessary.

PROMOTING PATIENTS' KNOWLEDGE

The patient and family are instructed about the cause of pneumonia, management of symptoms of pneumonia, signs and symptoms that should be reported to the health care provider or nurse, and the need for follow-up. The patient also needs information about factors (both patient risk factors and external factors) that may have contributed to development of pneumonia and strategies to promote recovery and prevent recurrence. If the patient is hospitalized, he or she is instructed about the purpose and importance of management strategies that have been implemented and about the importance of adhering to them during and after the hospital stay. Explanations should be given in simple and clear language that the patient can understand. If possible, written instructions and information should be provided, with alternative formats available for patients with hearing or vision loss, if necessary. Because of the severity of symptoms, the patient may require that instructions and explanations be repeated several times.

MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Continuing Symptoms after Initiation of Therapy. The patient is observed for response to antibiotic therapy; patients usually begin to respond to treatment within 24 to 48 hours after antibiotic therapy is initiated. If the patient started taking antibiotics before evaluation by culture and sensitivity of the causative organisms, antibiotics may need to be changed once the results are available. The patient is monitored for changes in physical status (deterioration of condition or resolution of symptoms) and for persistent or recurrent fever, which may be a result of medication allergy (signaled possibly by a rash); medication resistance or slow response (greater than 48 hours) of the susceptible organism to therapy; superinfection; pleural effusion; or pneumonia caused by an unusual organism, such as *P. jiroveci* or *Aspergillus fumigatus.* Failure of the pneumonia to resolve or persistence of symptoms despite improvement on the chest x-ray raises the suspicion of

other underlying disorders, such as lung cancer. As previously described, lung cancers may invade or compress airways, causing an obstructive atelectasis that may lead to pneumonia.

In addition to monitoring for continuing symptoms of pneumonia, the nurse also monitors for other complications, such as shock and multisystem failure and atelectasis, which may develop during the first few days of antibiotic treatment.

Shock and Respiratory Failure. Severe complications of pneumonia include sepsis and septic shock as well as respiratory failure. These complications are encountered primarily in patients who have received nonspecific, inadequate, or delayed treatment in combination with particularly virulent pathogens. These complications are also encountered when the infecting organism is resistant to therapy, when a comorbid disease complicates the pneumonia, or when the patient is immunocompromised.

Severe sepsis is defined as a systemic inflammatory response related to an infection such as pneumonia, with dysfunction or failure of one or more organs (e.g., renal insufficiency, ARDS, or disseminated intravascular coagulation). *Septic shock* occurs when severe sepsis is accompanied by hypotension that is refractory to the infusion of IV fluids. Severe sepsis and septic shock can lead to multiorgan dysfunction and carry a high mortality rate.

If the patient is seriously ill, aggressive therapy may include hemodynamic and ventilator support to combat peripheral vascular collapse, maintain arterial blood pressure, and provide adequate oxygenation. A vasopressor agent may be administered by continuous IV infusion and at a rate adjusted in accordance with the blood pressure response. Corticosteroids may be administered parenterally to combat shock and toxicity in patients who are extremely ill with pneumonia and at apparent risk for death from the infection, or who have adrenal insufficiency. However, whether corticosteroids are beneficial in patients with pneumonia remains uncertain (Musher, 2016). Patients may require endotracheal intubation and mechanical ventilation. Heart failure, cardiac arrhythmias, pericarditis, and myocarditis also are complications of pneumonia that may lead to shock.

The nurse assesses for signs and symptoms of shock and respiratory failure by evaluating the patient's vital signs, POX values, and hemodynamic monitoring parameters. The nurse reports signs of deteriorating patient status and assists in administering IV fluids and medications prescribed to combat shock. Intubation and mechanical ventilation may be required if respiratory failure occurs.

Atelectasis and Pleural Effusion. Atelectasis (from obstruction of a bronchus or small airways by accumulated secretions) may occur at any stage of acute pneumonia. Parapneumonic pleural effusions occur in at least 40% of bacterial pneumonias. A parapneumonic effusion is any pleural effusion associated with bacterial pneumonia, lung abscess, or bronchiectasis. After the pleural effusion is detected on a chest x-ray or CT scan, a thoracentesis may be performed to remove the fluid. The fluid is sent to the laboratory for analysis. There are three stages of parapneumonic pleural effusions based on

pathogenesis: uncomplicated, complicated, and empyema. An empyema occurs when thick, purulent fluid accumulates within the pleural space, often with fibrin development and a loculated (walled-off) area where the infection is located (see later discussion). A chest tube may be inserted to treat pleural infection by establishing proper drainage of the empyema. Sterilization of the empyema cavity usually requires 4 to 6 weeks of antibiotics, but sometimes surgical management is required.

The patient is assessed for atelectasis, and preventive measures are initiated to prevent its development. If pleural effusion develops and thoracentesis is performed to remove fluid, the nurse assists in the procedure and explains it to the patient. After thoracentesis, the nurse monitors the patient for pneumothorax or recurrence of pleural effusion. If a chest tube needs to be inserted, the nurse monitors the patient's respiratory status and assesses functioning of the chest drainage system (see later discussion).

Superinfection. Superinfections may occur with the administration of any antibiotic but are more common with the use of high-dose, broad-spectrum, and multiple antibiotics. Superinfections are the overgrowth of endogenous flora. Common superinfections are oral yeast (thrush) and vaginal candidiasis, and *Clostridium difficile* colitis (pseudomembranous colitis). The patient is monitored for manifestations of superinfection (i.e., white coating of tongue or oral mucosa, vaginal discharge, and diarrhea). These signs are reported, and the nurse assists in implementing therapy to treat superinfection.

Confusion. A patient with pneumonia is assessed for confusion and other more subtle changes in cognitive status. Confusion and changes in cognitive status resulting from pneumonia are poor prognostic signs. Confusion may be related to hypoxemia, fever, dehydration, sleep deprivation, or developing sepsis. Also the patient's underlying comorbid conditions may play a part in the development of confusion. Addressing the underlying factors and ensuring patient safety are important nursing interventions.

PROMOTING HEALTH

The nurse encourages the patient to stop smoking. Smoking inhibits tracheobronchial ciliary action, which is the first line of defense of the lower respiratory tract. Smoking also irritates the mucous cells of the bronchi and inhibits the function of alveolar macrophage (scavenger) cells. The patient is instructed to avoid stress, fatigue, sudden changes in temperature, and excessive alcohol intake, all of which lower resistance to pneumonia. The nurse reviews with the patient the principles of adequate nutrition and rest because one episode of pneumonia may make a patient susceptible to recurring respiratory tract infections.

EVALUATION

Expected patient outcomes may include the following:

1. Demonstrates improved airway patency, as evidenced by adequate oxygenation by

POX or ABG analysis, normal temperature, normal breath sounds, and effective coughing
2. Rests and conserves energy by limiting activities and remaining in bed while symptomatic and then slowly increasing activities
3. Maintains adequate hydration, as evidenced by an adequate fluid intake and urine output as well as normal skin turgor
4. Consumes adequate dietary intake, as evidenced by maintenance or increase in body weight without excess fluid gain
5. States explanation for management strategies
6. Complies with management strategies
7. Exhibits no complications:
   - Exhibits acceptable vital signs, POX, and ABG measurements
   - Reports productive cough that diminishes over time
   - Has absence of signs or symptoms of shock, respiratory failure, or pleural effusion
   - Remains oriented and aware of surroundings
   - Maintains or increases weight
   - Complies with treatment protocol and prevention strategies

PULMONARY TUBERCULOSIS

Tuberculosis (TB) is an infectious disease that primarily affects the lung parenchyma. The primary infectious agent, *M. tuberculosis*, is an acid-fast aerobic bacilli that grows slowly and is sensitive to heat and ultraviolet light. It is a resistant bacterium that can persist in calcified and necrotic lesions and remain able to reinitiate growth.

TB is a worldwide public health problem, and mortality and morbidity rates continue to rise. *M. tuberculosis* infects an estimated one third of the world's population and remains the leading cause of death from infectious disease in the world, although cases in the United States have declined slightly. TB is closely associated with poverty, malnutrition, overcrowding, substandard housing, and inadequate health care (American Thoracic Society, Centers for Disease Control and Prevention, Infectious Disease Society of America [ATS, CDC, & IDSA], 2003; CDC, 2014b, 2014c).

Pathophysiology

TB spreads from person to person by airborne transmission. An infected person releases droplet nuclei (usually particles 1 to 5 &b.mu;m in diameter) through talking, coughing, sneezing, laughing, or singing. Larger droplets settle; smaller droplets remain suspended in the air and are inhaled. Several factors determine the transmission of *M. tuberculosis* and include characteristics of the source case, exposed person, and the exposure; and the virulence of the *M. tuberculosis* strain. Box 10-7 depicts risk factors for tuberculosis.

BOX 10-7 Risk Factors for Tuberculosis (TB)

- Being born in foreign countries with high prevalence of TB
- Being medically underserved and/or with low income. Populations include:
  - Homeless
  - Impoverished
  - Minorities, particularly children under age of 15 years and people between 15 and 44 years
  - Those living in overcrowded, substandard housing
- Being a resident or employee of correction centers, homeless shelters, long-term care facilities
- Being a health care worker caring for high-risk patients
- Being a health care worker performing high-risk activities:
  - Administration of aerosolized medications
  - Sputum-induction procedures, including suctioning and coughing procedures
  - Bronchoscopy
  - Intubations
- Unprotected exposure to TB patients
- Advanced age
- Traveling abroad to work in endemic areas (Southeastern Asia, Africa, Latin America, Caribbean)
- Infants and children exposed to high-risk patients
- Substance abuse (IV/injection drug users and alcoholics)
- Immunocompromise:
  - Human immunodeficiency virus (HIV) infections
  - Malignancies: Head, neck, lung, hematologic
  - Long-term corticosteroid use
  - Immunosuppressive drug therapies
  - Organ transplantation
- Comorbidities:
  - Malnutrition
  - Diabetes

- Silicosis
- Chronic kidney disease
- Gastric or intestinal bypass surgery

TB begins when a susceptible person inhales mycobacteria and the bacteria are transmitted through the airways to the alveoli, where macrophages ingest the bacilli. If the bacilli escape the antimicrobial activities of the macrophages, an infection begins. This stage, called *primary TB*, usually is clinically silent and is due to the chronic inflammatory response that the bacterium provokes. The bacilli may be transported via the lymph system and bloodstream to other parts of the body (kidneys, bones, cerebral cortex) and other areas of the lungs (upper lobes). The spreading of TB via lymphatics and blood is called *miliary TB*. The body's immune system responds by initiating an inflammatory reaction. Phagocytes (neutrophils and macrophages) engulf many of the bacteria, and TB-specific lymphocytes destroy the bacilli along with normal tissue. This tissue reaction results in the accumulation of exudate in the alveoli, causing bronchopneumonia. The initial infection usually occurs 2 to 10 weeks after exposure.

Granulomas, new tissue masses of live and dead bacilli, are surrounded by macrophages, which form a protective wall. Then they are transformed to a fibrous tissue mass, the central portion of which is called a Ghon tubercle. The material (bacteria and macrophages) becomes necrotic, forming a cheesy mass. This mass may become calcified and form a collagenous scar. At this point, the bacteria become dormant, and there is no further progression of active disease.

After initial exposure and infection, active disease may develop because of a compromised or inadequate immune system response. Active disease also may occur with reinfection and activation of dormant bacteria. In this case, the Ghon tubercle ulcerates, releasing the cheesy material into the bronchi. Then the bacteria become airborne, resulting in further spread of the disease. The ulcerated tubercle heals and forms scar tissue. This causes the infected lung to become more inflamed, resulting in further development of bronchopneumonia and tubercle formation.

Unless the process is arrested, it spreads slowly downward to the hilum of the lungs and later extends to adjacent lobes. The process may be prolonged and is characterized by long remissions when the disease is arrested, followed by periods of renewed activity. Approximately 10% of people who are initially infected develop active disease. Some people develop reactivation TB. This type of TB results from a breakdown of the host defenses. It most commonly occurs in the lungs, usually in the apical (upper) or posterior segments of the upper lobes or the superior segments of the lower lobes.

Clinical Manifestations and Assessment

The signs and symptoms of pulmonary TB are insidious. Most patients have a low-grade fever, cough, night sweats, fatigue, and weight loss. Initially the cough is nonproductive but progresses to be mucopurulent. Dyspnea, chest pain, and hemoptysis (bloody sputum) occur as the disease progresses. Both the systemic and the pulmonary symptoms are chronic and may have been present for weeks to months. Elderly patients usually present with less pronounced symptoms than do younger patients. Extrapulmonary disease occurs in up to 16% of cases in the United States. In patients with AIDS, extrapulmonary disease is more prevalent and is manifested by neurologic deficits, bone pain, meningitis symptoms (stiff neck, headache, fever, confusion, and seizures), and urinary tract symptoms (dysuria).

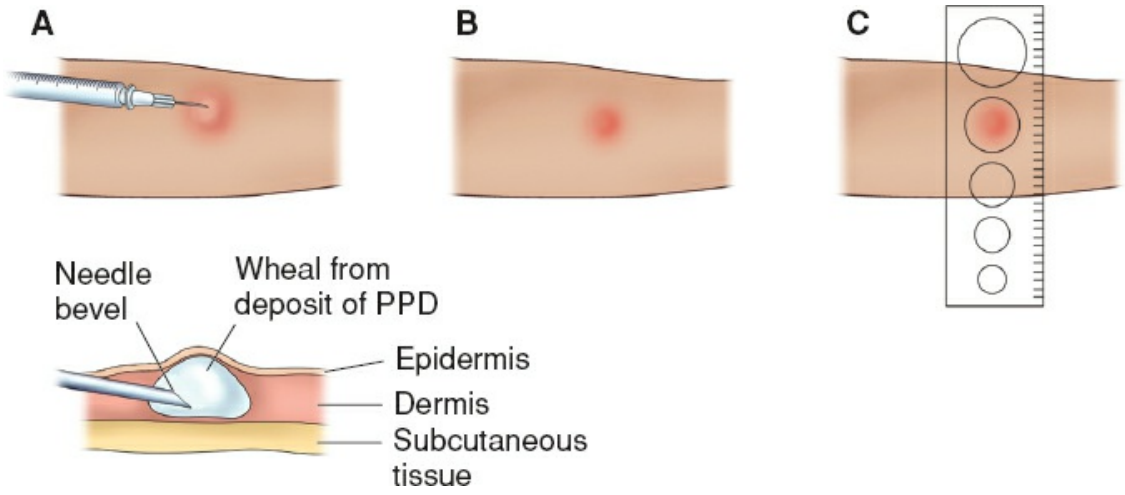

FIGURE 10-5 The Mantoux test for tuberculosis. A. Correct technique for inserting the needle involves depositing the purified protein derivative (PPD) intradermally with the needle bevel facing upward. B. The reaction to the Mantoux test usually consists of a *wheal,* a hive-like, firm welt. C. To determine the extent of the reaction, the wheal is measured using a commercially prepared gauge. Interpretation of the Mantoux test is discussed on this page.

A complete history, physical examination, tuberculin skin test, chest x-ray, AFB smear, and sputum culture are used to diagnose TB. If the patient is infected with TB, the chest x-ray usually reveals lesions in the upper lobes, and the AFB smear contains mycobacteria.

Tuberculin Skin Test

The Mantoux test is used to determine whether a person has been infected with the TB bacillus. The Mantoux test is a standardized procedure and should be performed only by those trained in its administration and reading (Fig. 10-5). Tubercle bacillus extract (tuberculin), purified protein derivative (PPD), is injected into the intradermal layer of the inner aspect of the forearm, approximately 4 in below the elbow. Intermediate-strength PPD, in a tuberculin syringe with a 0.5-in 26- or 27-gauge needle, is used. The needle, with the bevel facing up, is inserted beneath the skin. Then, 0.1 mL of PPD is injected, creating an elevation in the skin, a *wheal* or *bleb.* The site, antigen name, strength, lot number, date, and time of the test are recorded. The test result is read 48 to 72 hours after injection. Tests read after 72 hours tend to underestimate the true size of induration

(hardening).

A reaction occurs when an induration at the injection site is present. After the area is inspected for induration, it is lightly palpated across the injection site, from the area of normal skin to the margins of the induration. The diameter of the induration (not erythema) is measured in millimeters at its widest part, and the size of the induration is documented. Erythema without induration is not considered significant. The size of the induration determines the significance of the reaction. A reaction of 0 to 4 mm is considered not significant; a reaction of 5 mm or greater may be significant in people who are considered to be at risk. An induration of 10 mm or greater is usually considered significant in people who have normal or mildly impaired immunity. A significant reaction indicates past exposure to *M. tuberculosis* or vaccination with Bacille Calmette–Guérin (BCG) vaccine. The BCG vaccine is used in Europe and Latin America but not routinely in the United States.

Nursing Alert

Ambiguity exists in interpretation of the tuberculin skin test (TST) when patients were vaccinated with BCG; however, data reveal that the BCG administered once at birth has little effect on the TST beyond the first year, and by year 10, only 1% of positive TSTs can be attributed to previous BCG administration (Ellner, 2016, p. 2035).

A reaction of 5 mm or greater is defined as positive in patients who are HIV positive or have HIV risk factors and are of unknown HIV status; in those who are close contacts of someone with active TB; and in those who have chest x-ray results consistent with TB. HIV-positive patients are at risk for developing cutaneous anergy from impaired cellular immunity and may have a false-negative reaction to PPD skin testing. These patients may undergo Mantoux-method skin testing with mumps and candida antigens to assess for anergy. A positive test result is an induration of 5 mm or greater, meaning the patient has relatively intact cell-mediated immunity and can mount a reaction to PPD testing (Chapter 37 details anergy further).

A significant (positive) reaction does not necessarily mean that active disease is present in the body. More than 90% of people who are tuberculin-significant reactors do not develop clinical TB. However, all significant reactors are candidates for active TB. In addition, a nonsignificant (negative) skin test does not exclude TB infection or disease because patients who are immunosuppressed cannot develop an immune response that is adequate to produce a positive skin test.

TB Blood Testing

There are two FDA-approved blood tests for the detection of TB by interferon-gamma release assay, the QuantiFERON-TB Gold and the T-spot. A positive test indicates that the person has been infected with TB and further testing is needed to determine latency versus active disease. These blood tests are recommended when a person has received the BCG vaccine or when it is impractical to return for a second visit to read a TST (CDC, 2014b).

Classification

Data from the history, physical examination, TB test, chest x-ray, and microbiologic studies are used to classify TB into one of five classes. A classification scheme provides public health officials with a systematic way to monitor epidemiology and treatment of the disease (ATS & CDC, 2000; WHO, 2014):

- Class 0: No exposure; no infection
- Class 1: Exposure; no evidence of infection
- Class 2: Latent infection; no disease (e.g., positive PPD reaction but no clinical evidence of active TB)
- Class 3: Disease; clinically active
- Class 4: Disease; not clinically active
- Class 5: Suspected disease; diagnosis pending

Gerontologic Considerations 

TB may have atypical manifestations in elderly patients, whose symptoms may include unusual behavior and altered mental status, fever, anorexia, and weight loss. In many elderly patients, the tuberculin skin test produces no reaction (loss of immunologic memory) or delayed reactivity for up to 1 week (recall phenomenon). A second skin test is performed in 1 to 2 weeks.

Medical and Nursing Management

Pharmacologic Therapy

Pulmonary TB is treated primarily with antituberculosis agents, as either active disease treatment or prophylactic treatment for persons exposed and at risk for developing the disease. A prolonged treatment duration is necessary to ensure eradication of the organisms and to prevent relapse. The continuing (since the 1950s) and increasing resistance of *M. tuberculosis* to TB medications is a worldwide concern and challenge in TB therapy. Several types of drug resistance must be considered when planning effective therapy:

- *Primary drug resistance:* Resistance to one of the first-line antituberculosis agents in people who have not had previous treatment
- *Secondary or acquired drug resistance:* Resistance to one or more antituberculosis agents in patients undergoing therapy
- *MDR:* Resistance to two agents, isoniazid (INH) and rifampin. The populations at greatest risk for MDR are those who are HIV positive, institutionalized, or homeless.

The increasing prevalence of drug resistance points out the need to begin TB treatment with three or more medications to ensure completion of therapy and to develop and evaluate new anti-TB medications.

Treatment Regimens

In current TB therapy, four first-line medications are used: INH, rifampin, pyrazinamide, and ethambutol. Combination medications, such as INH and rifampin (Rifamate) or INH, pyrazinamide, and rifampin (Rifater), and other medications administered twice a week (e.g., rifapentine) are available to help improve patient adherence. Capreomycin, ethionamide, para-aminosalicylate sodium, and cycloserine are second-line medications. Additional potentially effective medications include other aminoglycosides, quinolones, rifabutin, clofazimine, and combinations of medications (ATS, CDC, & IDSA, 2003).

Recommended treatment guidelines for newly diagnosed cases of presumably drug-susceptible active pulmonary TB have two parts: an initial treatment phase and a continuation phase. The initial phase consists of multiple medications (INH, rifampin, pyrazinamide, and ethambutol) and multiple dosing regimen choices of these four medications. This initial intensive treatment regimen is administered for 8 weeks and has 4 dosing options that range from daily to 2 or 5 times per week. Once susceptibilities of the TB to INH, rifampin, and pyrazinamide are confirmed, ethambutol can be discontinued (Horsburgh, Barry, & Lange, 2015). The continuation phase of treatment, which includes INH and rifampin or INH and rifapentine, lasts for an additional 18 or 31 weeks. The 18-week period is used for the large majority of patients. The 31-week period is recommended for patients with cavitary pulmonary TB whose sputum culture after the initial 2 months of treatment is positive; those whose initial phase of treatment did not include pyrazinamide (PZA); and those being treated once weekly with INH and rifapentine whose sputum culture is positive at the end of the initial phase of treatment. In general, people are considered noninfectious after 2 to 3 weeks of continuous medication therapy. Usually

vitamin B (pyridoxine) is administered with INH to prevent INH-associated peripheral neuropathy. The total number of doses taken, not simply the duration of treatment, more accurately determines whether a course of therapy has been completed (Ellner, 2016).

Several types of drug-resistant TB have emerged over the last two decades. Multidrug resistant and extensively drug resistant TB are identified by sputum culture and sensitivity, but it may take weeks for results to be available. Nucleic acid testing (GeneXpert MTB/RIF and MTBDRplus) can provide results in a few days (Theron et al., 2014; Steingart et al., 2014). Treatment for resistant TB requires additional antimicrobial agents (up to six) and for a longer duration (Horsburgh et al., 2015; Wilson & Tsukayama, 2016).

INH also may be used as a prophylactic (preventive) measure for people who are at risk for significant disease, including:

- Household family members of patients with active disease
- Patients with HIV infection who have a PPD test reaction with 5 mm of induration or greater
- Patients with fibrotic lesions suggestive of old TB detected on a chest x-ray and a PPD reaction with 5 mm of induration or greater
- Patients whose current PPD test results show a change from former test results, suggesting recent exposure to TB and possible infection (skin test converters)
- Users of IV/injection drugs who have PPD test results with 10 mm of induration or greater
- Patients with high-risk comorbid conditions and a PPD result with 10 mm of induration or greater

Other candidates for preventive INH therapy are those 35 years or younger who have PPD test results with 10 mm of induration or more and one of the following criteria:

- Foreign-born individuals from countries with a high prevalence of TB
- High-risk, medically underserved populations
- Institutionalized patients

Prophylactic INH treatment involves taking daily doses for 6 to 12 months. Liver enzymes, blood urea nitrogen (BUN), and creatinine levels are monitored monthly to detect changes in liver and kidney function. Sputum culture results are monitored for AFB to evaluate the effectiveness of treatment and the patient's adherence to the treatment regimen.

Side Effects of Medication Therapy

It is important to assess medication side effects, because often they are a reason why patients fail to adhere to the prescribed medication regimen. Efforts are made to reduce the side effects and to motivate the patient to take the medications as prescribed.

The nurse instructs the patient to take the medication either on an empty stomach or at least 1 hour before meals because food interferes with medication absorption (although taking medications on an empty stomach frequently results in gastrointestinal upset). Patients taking INH should avoid foods that contain tyramine and histamine (tuna, aged cheese, red wine, soy sauce, yeast extracts) because eating them while taking INH may

result in headache, flushing, hypotension, lightheadedness, palpitations, and diaphoresis.

In addition, rifampin can increase the metabolism of certain other medications, making them less effective. These medications include beta-blockers, oral anticoagulants such as warfarin, digoxin, quinidine, corticosteroids, oral hypoglycemic agents, oral contraceptives, theophylline, and verapamil. This issue should be discussed with the prescriber and pharmacist so that medication dosages can be adjusted accordingly. The nurse informs the patient that rifampin may discolor contact lenses and that the patient may want to wear eyeglasses during treatment. The nurse monitors for other side effects of anti-TB medications, including hepatitis, neurologic changes (hearing loss, neuritis, visual changes, neuropathy), and rash. Renal and hepatic function tests as well as sputum AFB results are monitored closely. The nurse carefully monitors vital signs and observes for spikes in temperature or changes in the patient's clinical status. Changes in the patient's respiratory status are reported to the primary health care provider. The nurse instructs the patient about the risk of drug resistance if the medication regimen is not followed strictly and continuously.

The strict adherence to complex medication regimens is an important area of education of the TB patient. Drugs must be taken exactly as prescribed, and noncompliance can lead to continued infection and drug resistance. Directly observed therapy (DOT) can be implemented to ensure that patients are compliant with medications regimens. In DOT, a trained health care provider administers each dose of anti-TB medication. DOT can be prescribed by a health care provider such as a physician, nurse practitioner, or a local board of health.

Patient Teaching

The care of TB patients involves education related to halting the spread of the infection and its complex drug regimens. Patients should be instructed to cover their mouth and nose when they cough or sneeze, dispose of facial tissues in plastic bags, and wear a mask when in public until sputum samples are documented as free of AFB.

Patients in hospital settings will be placed on airborne precautions, including staying in a negative-pressure room that vents air to the outside, and staff must wear fitted filtration masks (N95 or high-efficiency particulate air respirators) when in the room. Health care providers who have the potential to be in contact with TB patients must be fit tested at least yearly and when their weight changes or if they have respiratory disorders such as asthma. Also patients must wear surgical masks when outside of the negative-pressure rooms.

Malnutrition may be a consequence of the patient's lifestyle, lack of knowledge about adequate nutrition and its role in health maintenance, lack of resources, fatigue, or lack of appetite because of coughing and mucus production and medication side effects. To counter the effects of these factors, the nurse collaborates with the dietitian, provider, social worker, family, and patient to identify strategies to ensure an adequate nutritional intake and the availability of nutritious food. Identifying facilities (e.g., shelters, soup kitchens, Meals on Wheels) that provide meals in the patient's neighborhood may increase the likelihood that the patient with limited resources and energy will have access to a more nutritious intake. High-calorie nutritional supplements may be suggested as a strategy for increasing dietary intake using food products normally found in the home. Purchasing food

supplements may be beyond the patient's budget, but dietitians can help develop recipes to increase caloric intake despite minimal resources.

PULMONARY EDEMA

Pulmonary edema is defined as abnormal accumulation of fluid within the lung tissue, the alveolar space, or both. Acute pulmonary edema, often called "flash" pulmonary edema, is a severe, life-threatening condition. Classification of pulmonary edema is based on its causative origin: cardiogenic or noncardiogenic. Noncardiogenic pulmonary edema includes ARDS, neurogenic, re-expansion, and negative-pressure pulmonary edema. ARDS will be discussed later in this chapter, and cardiogenic pulmonary edema is discussed in Chapter 15.

Pathophysiology

In each type of pulmonary edema, capillary fluid leaks or is forced by high capillary hydrostatic pressure into alveolar spaces. The edematous alveoli are unable to participate in gas exchange, causing intrapulmonary shunting of blood and hypoxemia. The pathophysiology of cardiogenic pulmonary edema is discussed in Chapter 15. The most common form of noncardiogenic pulmonary is ARDS, a form of acute lung injury (ALI) in which a precipitating injury (direct or indirect) to the lung triggers a systemic inflammatory response that causes pulmonary capillaries to leak fluid into the alveoli. Neurogenic pulmonary edema can occur after epileptic seizures or injuries to the head, brain, or spine. It is theorized to occur as the result of the massive surge of central sympathetic output, which increases blood flow to pulmonary vasculature. The vasoconstriction causes elevations in hydrostatic pressure, which results in extravasation of fluid into the pulmonary interstitium. Re-expansion pulmonary edema may result from a rapid reinflation of the lung after removal of air from a pneumothorax or evacuation of fluid from a large pleural effusion or hemothorax. This rapid negative-pressure change within the lungs causes capillary fluid to be pulled into the alveolar spaces. This is similar to negative-pressure pulmonary edema, in which an obstruction in the trachea or large bronchi causes a person to attempt to forcefully inhale against a closed glottis or airway. This pulls fluid into the alveolar spaces. Common causes of this type of edema are choking, angioedema, and manual strangulation.

Clinical Manifestations and Assessment

Increasing respiratory distress, characterized by dyspnea, air hunger, and hypoxemia is present. Usually patients are very anxious and often agitated. As the fluid leaks into the alveoli and mixes with air, a foam or froth is formed (more common in cardiogenic edema). The patient coughs up (or the nurse suctions out) these foamy, frothy, and often blood-tinged or pink secretions. The patient experiences acute respiratory distress and may become confused or stuporous.

Auscultation reveals crackles in the lung bases (especially in the dependent lung areas) that rapidly progress toward the apices of the lungs. These crackles are caused by the movement of air through the alveolar fluid. Also patients may present with wheezing. The chest x-ray reveals increased bilateral interstitial markings, often in a patchy appearance, with or without cardiomegaly. The patient may have tachycardia. Pulse oximetry values begin to fall, and ABG analysis demonstrates worsening hypoxemia.

Medical Management

Management focuses on correcting the underlying disorder. If the pulmonary edema is cardiac in origin, then improvement in left ventricular function is the goal (see Chapter 15). Oxygen is administered to correct the hypoxemia; in some circumstances, intubation and mechanical ventilation are necessary. Noncardiogenic pulmonary edema treatment is aimed at treating the underlying cause of the ALI (i.e., infection), removing obstructions causing negative-pressure edema, and providing supportive care such as oxygen, mechanical ventilation, and judicious IV fluids.

Nursing Management

Nursing management includes assisting with administration of oxygen and intubation and mechanical ventilation if respiratory failure occurs. The nurse also administers medications (e.g., morphine, vasodilators, inotropic medications, diuretics, and pre- and afterload agents) as prescribed, and monitors the patient's responses.

PLEURAL CONDITIONS

Pleural conditions are disorders that involve the membranes covering the lungs (visceral pleura) and the surface of the chest wall (parietal pleura) or disorders affecting the pleural space. The most common pleural conditions are pleurisy, pleural effusions, and empyemas.

PLEURISY

Pathophysiology

Pleurisy (pleuritis) refers to inflammation of both layers of the pleurae (parietal and visceral). Pleurisy may develop in conjunction with pneumonia or an upper respiratory tract infection, TB, or collagen diseases; after trauma to the chest, pulmonary infarction, or PE; in patients with primary or metastatic cancer; and after thoracotomy. The parietal pleura has nerve endings; the visceral pleura does not. When the inflamed pleural membranes rub together during respiration (intensified on inspiration), the result is severe, sharp, knifelike pain.

Clinical Manifestations and Assessment

The key characteristic of pleuritic pain is its relationship to respiratory movement: Taking a deep breath, coughing, or sneezing worsens the pain. Pleuritic pain is limited in distribution rather than diffuse; it usually occurs only on one side. The pain may become minimal or absent when the breath is held, leading to rapid shallow breathing. It may be localized or may radiate to the shoulder or abdomen. Later, as pleural fluid accumulates, the pain decreases. A pleural friction rub may be heard on auscultation.

Medical and Nursing Management

The objectives of treatment are to discover the underlying condition causing the pleurisy and to relieve the pain. As the underlying disease (e.g., pneumonia, infection) is treated, the pleuritic inflammation usually resolves. At the same time, it is necessary to monitor for signs and symptoms of pleural effusion, such as shortness of breath, pain (typically sharp and worsens with inspiration), assumption of a position that decreases pain, decreased chest wall excursion, dullness to percussion in the area of the effusion, along with diminished breath sounds and absent tactile fremitus.

Prescribed analgesics and topical applications of heat or cold provide symptomatic relief. Nonsteroidal anti-inflammatory agents (NSAIDs) may provide pain relief while allowing the patient to take deep breaths and cough more effectively. If the pain is severe, a narcotic or an intercostal nerve block may be required.

PLEURAL EFFUSION AND EMPYEMA

Pleural effusion, a collection of fluid in the pleural space, is rarely a primary disease process but usually occurs secondary to other diseases (Fig. 10-6). Normally, the pleural space contains a small amount of fluid (20 to 25 cc), which acts as a lubricant that allows the pleural surfaces to move without friction. Pleural effusion may be a complication of heart failure, TB, pneumonia, pulmonary infections (particularly viral infections), nephrotic syndrome, connective tissue disease, pulmonary embolus, and neoplastic tumors. In addition, abdominal processes such as pancreatitis or cirrhosis with ascites can cause pleural effusions. The most common malignancies associated with a pleural effusion are bronchogenic carcinoma and breast cancer. An empyema is an accumulation of thick, purulent fluid (pus) within the pleural space and is a type of pleural effusion.

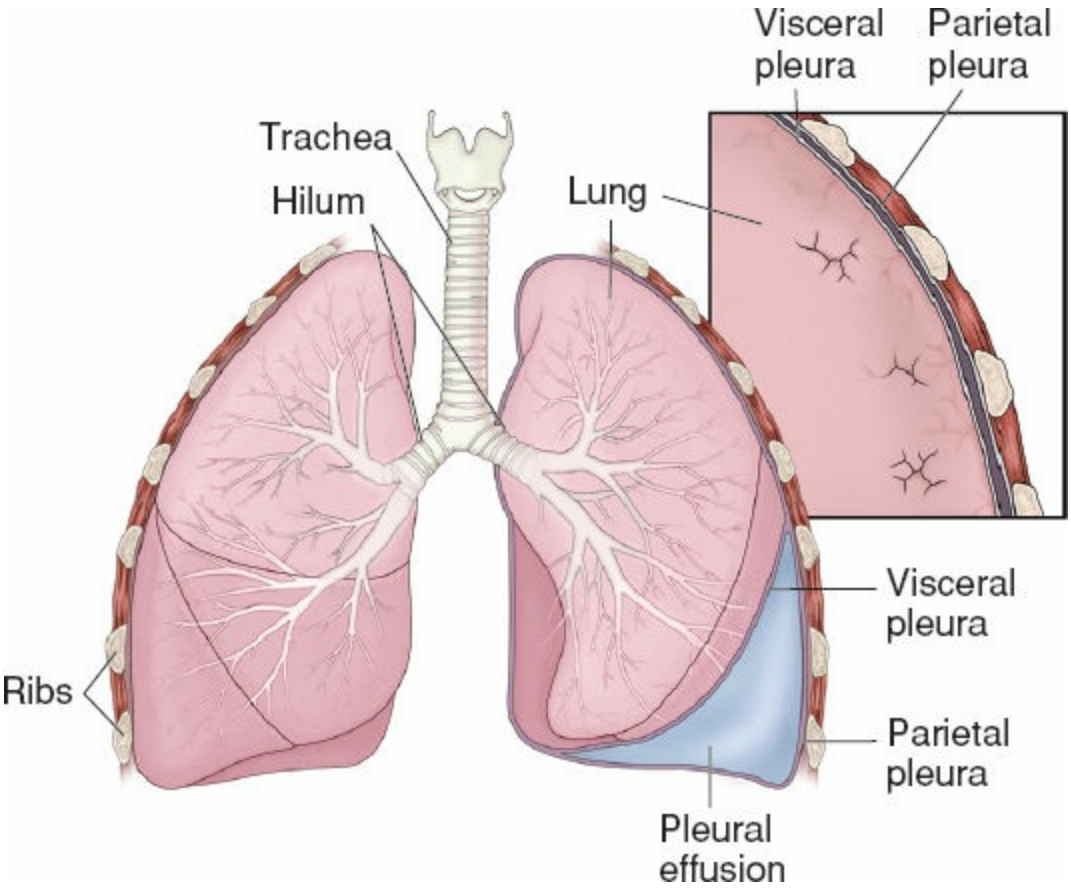

FIGURE 10-6 In pleural effusion, an abnormal volume of fluid collects in the pleural space, causing pain and shortness of breath. Pleural effusion is usually secondary to other disease processes.

Pathophysiology

In certain disorders, fluid may accumulate in the pleural space to a point at which it becomes clinically evident. This almost always has pathologic significance. A pleural effusion can be composed of a relatively clear fluid or it can be bloody or purulent. An effusion of clear fluid may be a transudate or an exudate. A transudate (filtrate of plasma that moves across intact capillary walls) occurs when factors influencing the formation and reabsorption of pleural fluid are altered, usually by imbalances in hydrostatic or oncotic pressures. The finding of a transudative effusion generally implies that the pleural membranes are not diseased. A transudative effusion most commonly results from heart failure or volume resuscitation causing volume overload. An exudate (extravasation of fluid into tissues or a cavity) usually results from inflammation by bacterial products or tumors involving the pleural surfaces. Empyemas are exudative pleural effusions by definition.

Most empyemas occur as complications of bacterial pneumonia or lung abscess, with streptococcus pneumonia being the most common causative microbe. They also result from penetrating chest trauma, hematogenous infection of the pleural space, nonbacterial infections, and iatrogenic causes (after thoracic surgery or thoracentesis). At first, the pleural fluid is thin, with a low leukocyte count, but it frequently progresses to a fibropurulent stage and, finally, to a stage at which it encloses the lung within a thick exudative membrane ("peel"). A chest x-ray, CT scan, or ultrasound determines whether fluid is free flowing or loculated (fixed pocket).

Clinical Manifestations and Assessment

Usually, the clinical manifestations are caused by the underlying disease. Pneumonia causes fever, chills, and pleuritic chest pain, whereas a malignant effusion may result in dyspnea, difficulty lying flat, and coughing. The severity of symptoms is determined by the size of the effusion, the speed of its formation, whether it is a transudate or exudate, and the underlying lung disease. A large pleural effusion causes dyspnea. A small to moderate pleural effusion usually causes minimal or no dyspnea. Patients with empyemas tend to be acutely ill, with more severe inflammatory symptoms (fever, chills, pain, cough, dyspnea, and tachycardia).

Assessment of the area of the pleural effusion reveals decreased or absent breath sounds, decreased fremitus, and a dull, flat sound on percussion. In the case of an extremely large or rapidly accumulating pleural effusion, the assessment reveals a patient in acute respiratory distress. The patient may have tracheal deviation away from the affected side, hypoxemia (SpO_2 less than 90%), hypotension, and tachycardia.

Physical examination, chest x-ray, chest CT, ultrasound, and thoracentesis confirm the presence of fluid. In some instances, a lateral decubitus x-ray is obtained. For this x-ray, the patient lies on the unaffected side in a side-lying position. A pleural effusion can be diagnosed because this position allows for the "layering out" of the fluid, and an air-fluid line is visible.

Pleural fluid is analyzed by bacterial culture, Gram stain, AFB stain (for TB), red blood cell and WBC counts and differential, chemistry studies (glucose, amylase, lactic dehydrogenase, protein), cytologic analysis for malignant cells, and pH. A pleural biopsy also may be performed as a diagnostic tool.

Medical Management

The objectives of treatment are to discover the underlying cause of the pleural effusion; to prevent reaccumulation of fluid; and to relieve discomfort, dyspnea, and respiratory compromise. Specific treatment is directed at the underlying cause (e.g., heart failure, pneumonia, cirrhosis). If the pleural fluid is an exudate, more extensive diagnostic procedures are performed to determine the cause. Treatment for the primary cause is then instituted.

Thoracentesis is performed to remove fluid, to obtain a specimen for analysis, and to relieve dyspnea and respiratory compromise. Thoracentesis may be performed under ultrasound guidance or blindly. Depending on the size of the pleural effusion, the patient may be treated by removing the fluid during the thoracentesis procedure or by inserting a chest tube connected to a water-seal drainage system or suction to evacuate the pleural space and re-expand the lung. If the empyema is loculated, fibrinolytic agents, such as tissue plasminogen activator (TPA) and DNase, can be instilled via a chest tube to dissolve fibrinous septations and improve drainage (Rahman et al., 2011; Hedley et al., 2013; Mccool, 2016). Often surgical management via thoracotomy or video-assisted thoracoscopic surgery (VATS) with lung decortication is required for patients with acute respiratory compromise, sepsis, or hemodynamic instability. Decortication is the surgical removal of fibrous tissue in the pleural space; this procedure is called a *pleural peel.*

However, if the underlying cause is a malignancy, the effusion tends to recur within a few days or weeks. Repeated thoracenteses result in pain, depletion of protein and electrolytes, and sometimes pneumothorax. Once the pleural space is drained adequately, a chemical pleurodesis may be performed to obliterate the pleural space and prevent reaccumulation of fluid. Pleurodesis may be performed using either a VATS or a chest tube. A chemically irritating agent (e.g., talc, bleomycin, doxycycline) is instilled into the pleural space. With the chest tube approach, after the agent is instilled, the chest tube is clamped for 60 to 90 minutes, and the patient is assisted to assume various positions to promote uniform distribution of the agent and to maximize its contact with the pleural surfaces. The tube is unclamped as prescribed, and chest drainage may be continued several days longer to prevent reaccumulation of fluid and to promote the formation of adhesions between the visceral and parietal pleurae.

Other treatments for malignant pleural effusions include repeated needle thoracentesis, tube thoracostomy, chemical pleurodesis, surgical pleurectomy and decortication, pleuroperitoneal shunt, and tunneled pleural catheters (TPCs). Pleuracotomy involves the insertion of a small catheter attached to a drainage bottle for outpatient management (PleurX catheter [Denver Biomedical]), or implantation of a pleuroperitoneal shunt. A pleuroperitoneal shunt consists of two catheters connected by a pump chamber containing two one-way valves. Fluid moves from the pleural space to the pump chamber and then to the peritoneal cavity. The patient manually pumps on the reservoir daily to move fluid from the pleural space to the peritoneal space. Because pleuroperitoneal shunts have a median length of patency of 2.5 months due to clotting of the shunt (25% of the time), risk of shunt infection, and need for manual operation, pleuroperitoneal shunts have largely been replaced with TPCs (Thomas & Musani, 2013). The TPC catheter is a soft silicone tube inserted percutaneously as an outpatient, allowing the patient to return home with

minimum sedation and less time spent in the hospital. Patients manage their catheter drainage in their home.

Nursing Management

The nurse's role in the care of patients with a pleural effusion or empyema includes implementing the medical regimen. The nurse prepares and positions the patient for thoracentesis and offers support throughout the procedure. The nurse is responsible for making sure the thoracentesis fluid amount is recorded and sent for appropriate laboratory testing. If a chest tube drainage and water-seal system is used, the nurse is responsible for monitoring the system's function and recording the amount of drainage at prescribed intervals. Nursing care related to the underlying cause of the pleural effusion is specific to the underlying condition. Pain management is a priority, and premedication for the procedure with a narcotic analgesic and antianxiety drug should be considered. If the patient is undergoing TPA/DNase or pleurodesis, the patient requires frequent turning and movement to facilitate adequate spreading of the agents over the pleural surface. Treatment of pleurisy pain is similar to the care of patients with chest tubes because the patient has considerable pain on inspiration. The nurse offers suggestions to enhance comfort, such as turning frequently onto the affected side to splint the chest wall and reduce the stretching of the pleurae. The nurse also teaches the patient to use the hands or a pillow to splint the rib cage while coughing. Administration and assessment of the effects of narcotics or NSAIDs is necessary.

ACUTE RESPIRATORY FAILURE

Acute respiratory failure (ARF) is a sudden and life-threatening deterioration of the gas exchange function of the lung. It exists when the exchange of oxygen for carbon dioxide in the lungs cannot keep up with the rate of oxygen consumption and carbon dioxide production by the cells of the body. ARF is classified as hypoxemic (decrease in arterial oxygen tension [PaO_2] to less than 50 mm Hg on room air) and or hypercapnic (increase in arterial carbon dioxide tension [$PaCO_2$] to greater than 50 mm Hg with an arterial pH of less than 7.35).

It is important to distinguish between ARF and chronic respiratory failure. Chronic respiratory failure is defined as deterioration in the gas exchange function of the lung that has developed insidiously or has persisted for a long period. The absence of acute symptoms and the presence of a chronic respiratory acidosis (elevated $PaCO_2$ and bicarbonate, and hypoxemia) suggest the chronicity of the respiratory failure. Two causes of chronic respiratory failure are COPD (discussed in Chapter 11) and neuromuscular diseases (discussed in Chapter 46). Patients with these disorders develop a tolerance to the gradually worsening hypoxemia and hypercapnia. However, patients with chronic respiratory failure can develop ARF. For example, a patient with COPD may develop an exacerbation or infection that causes additional deterioration of gas exchange. The principles of management of acute versus chronic respiratory failure are different; the following discussion is limited to ARF.

Pathophysiology

In ARF, the ventilation or perfusion mechanisms in the lung are impaired. Impaired respiratory system mechanisms leading to ARF include:

- *Alveolar hypoventilation,* which is the inability to deliver oxygen to the alveoli and remove CO_2 from the alveoli, may be due to a variety of causes including obesity, chest wall deformities, neuromuscular disorders, CNS depression, or COPD.
- *Diffusion abnormalities* are related to problems with gas transfer across the alveolar–capillary membrane, which may be due to increased resistance, increased thickness of the alveolar–capillary membrane, or any pathology that impacts the alveolar epithelium, the capillary endothelium, or the interstitial space between them.
- *Ventilation–perfusion mismatching.* Alveolar ventilation brings oxygen to the lung and removes the alveolar CO_2 (ventilation), while blood brings CO_2 to the alveoli and takes up the O_2 from the alveoli (perfusion). Thus, the O_2 and CO_2 levels are determined by the matching of ventilation with perfusion.
- *Shunting* occurs when perfusion is adequate to the lung but ventilation is impaired, thus deoxygenated blood continues to the left side of the heart. (Conditions associated with this include right-to-left shunts with cardiac abnormalities such as septal defects, or pulmonary diseases such as pneumonia, ARDS, or pulmonary edema, in which the alveoli are affected and unable to be ventilated.)
- *Increased physiologic dead space,* which describes situations in which ventilation of the lung is adequate but perfusion is impaired, as with pulmonary emboli. This mismatch also results in impaired gas exchange.

Common causes of ARF can be classified into four categories: decreased respiratory drive, dysfunction of the chest wall, dysfunction of the lung parenchyma, and other causes.

Decreased Respiratory Drive

Decreased respiratory drive may occur with severe brain injury with increased intracranial pressure, lesions or trauma of the brainstem (multiple sclerosis, tumor, or herniation), use of sedative medications, and metabolic disorders such as severe hypothyroidism. These disorders impair the response of chemoreceptors in the brain to normal respiratory stimulation.

Dysfunction of the Chest Wall

The impulses arise in the respiratory center and travel through nerves that extend from the brainstem down the spinal cord to receptors in the muscles of respiration. Any disease or disorder of the nerves, spinal cord, muscles, or neuromuscular junction involved in respiration seriously affects ventilation and may ultimately lead to ARF. These include musculoskeletal disorders (muscular dystrophy, polymyositis, chest wall trauma), neuromuscular junction disorders (myasthenia gravis, poliomyelitis), some peripheral nerve

disorders, and spinal cord disorders (amyotrophic lateral sclerosis, Guillain–Barré syndrome, and cervical spinal cord injuries). Chest wall trauma, such a flail chest, can cause instability of the thorax and impair ventilation.

Nursing Alert
With cervical spinal injuries, the rigid cervical collar is left in place until the provider confirms stability of the C spine. The nurse is aware that motor innervations to the diaphragm are from the phrenic nerve at the C3–C5 level, thus any fracture in the area risks respiratory paralysis.

Dysfunction of Lung Parenchyma

Pleural effusion, hemothorax, pneumothorax, and airway obstruction are conditions that interfere with ventilation by preventing expansion of the lung. These conditions, which may cause respiratory failure, usually are produced by an underlying lung disease, pleural disease, or trauma and injury. Other diseases and conditions of lung parenchyma that lead to ARF include pneumonia, pulmonary contusions, status asthmaticus, atelectasis, PE, exacerbation of COPD, ARDS, and pulmonary edema.

Other Causes

In the postoperative period, especially after major thoracic or abdominal surgery, inadequate ventilation and respiratory failure may occur because of several factors. During this period, for example, ARF may be caused by the effects of anesthetic agents, analgesics, and sedatives, which may depress respiration (as described earlier) or enhance the effects of opioids and lead to hypoventilation. Pain may interfere with deep breathing and coughing.

Clinical Manifestations and Assessment

Early signs are those associated with impaired oxygenation and may include restlessness, fatigue, headache, dyspnea, air hunger, mild tachycardia and tachypnea, and increased BP. As the hypoxia progresses, more obvious signs may be present, including confusion, lethargy, tachycardia, tachypnea, central cyanosis, diaphoresis, and finally respiratory arrest. Physical findings are those of acute respiratory distress, including use of accessory muscles, decreased breath sounds if the patient cannot adequately ventilate, and other findings related specifically to the underlying disease process and cause of ARF.

Medical Management

The objectives of treatment are to correct the underlying cause and to restore adequate gas exchange in the lungs. Supplemental oxygen administration is used to improve hypoxemia. If narcotics are thought to be the cause of hypoventilation, reversal agents, such as naloxone (for opiates) or flumazenil (for benzodiazepines) can be administered. Mechanical ventilation may be required to maintain adequate ventilation and oxygenation while the underlying cause is corrected.

Nursing Management

Nursing management of patients with ARF includes assisting with intubation and maintaining mechanical ventilation. Usually patients are managed in the ICU. The nurse assesses the patient's respiratory status by monitoring the level of responsiveness, ABG levels, POX, and vital signs. In addition, the nurse assesses the entire respiratory system and implements strategies (e.g., turning schedule, mouth care, skin care, range-of-motion exercises for the extremities) to prevent complications. The nurse also assesses the patient's understanding of the management strategies that are used and initiates some form of communication to enable the patient to express concerns and needs to the health care team.

Finally, the nurse addresses the problems that led to the ARF. As the patient's status improves, the nurse assesses the patient's knowledge of the underlying disorder and provides teaching as appropriate to address the disorder.

ACUTE RESPIRATORY DISTRESS SYNDROME

Acute respiratory distress syndrome (ARDS) (previously called adult respiratory distress syndrome) is a severe form of acute lung injury that affects over 200,000 persons each year. This clinical syndrome is characterized by a sudden and progressive pulmonary edema, increasing bilateral infiltrates on chest x-ray, hypoxemia refractory to supplemental oxygen, and reduced lung compliance. These signs occur in the absence of left-sided heart failure. Patients with ARDS usually require mechanical ventilation with a higher-than-normal airway pressure. ARDS has been associated with a mortality rate as high as 50% to 60%. The major cause of death in ARDS is multisystem organ failure.

Pathophysiology

ARDS occurs as a result of an inflammatory trigger that initiates the release of cellular and chemical mediators, causing diffuse epithelial cell injury to the alveolar capillary membrane. This leads to leakage of protein-rich fluid and blood cells into the alveolar interstitial spaces and alterations in the capillary bed.

Severe ventilation–perfusion mismatching occurs in ARDS. Alveoli collapse because of the inflammatory infiltrate, blood, fluid, and surfactant dysfunction. Small airways are narrowed because of interstitial fluid and bronchial obstruction. Lung compliance becomes markedly decreased (stiff lungs), and the result is a characteristic decrease in functional residual capacity (FRC) and severe hypoxemia. The blood returning to the lung for gas exchange is pumped through the nonventilated, nonfunctioning areas of the lung, causing shunting. This means that blood is interfacing with nonfunctioning alveoli, and gas exchange is markedly impaired, resulting in severe, refractory hypoxemia. Figure 10-7 shows the sequence of pathophysiologic events leading to ARDS.

Risk Factors

A wide range of factors are associated with the development of ARDS, including direct injury to the lungs (e.g., smoke inhalation, near drowning) or indirect insult to the lungs (e.g., septic shock, massive fluid resuscitation) (see Box 10-8 for risk factors). Transfusion-related acute lung injury (TRALI) and transfusion-associated circulatory overload (TACO) are two forms of ALI that result from transfusion of blood products. TRALI is an immune reaction that causes an increase in pulmonary vascular permeability, and TACO causes an increase in hydrostatic pressure, both causing pulmonary edema.

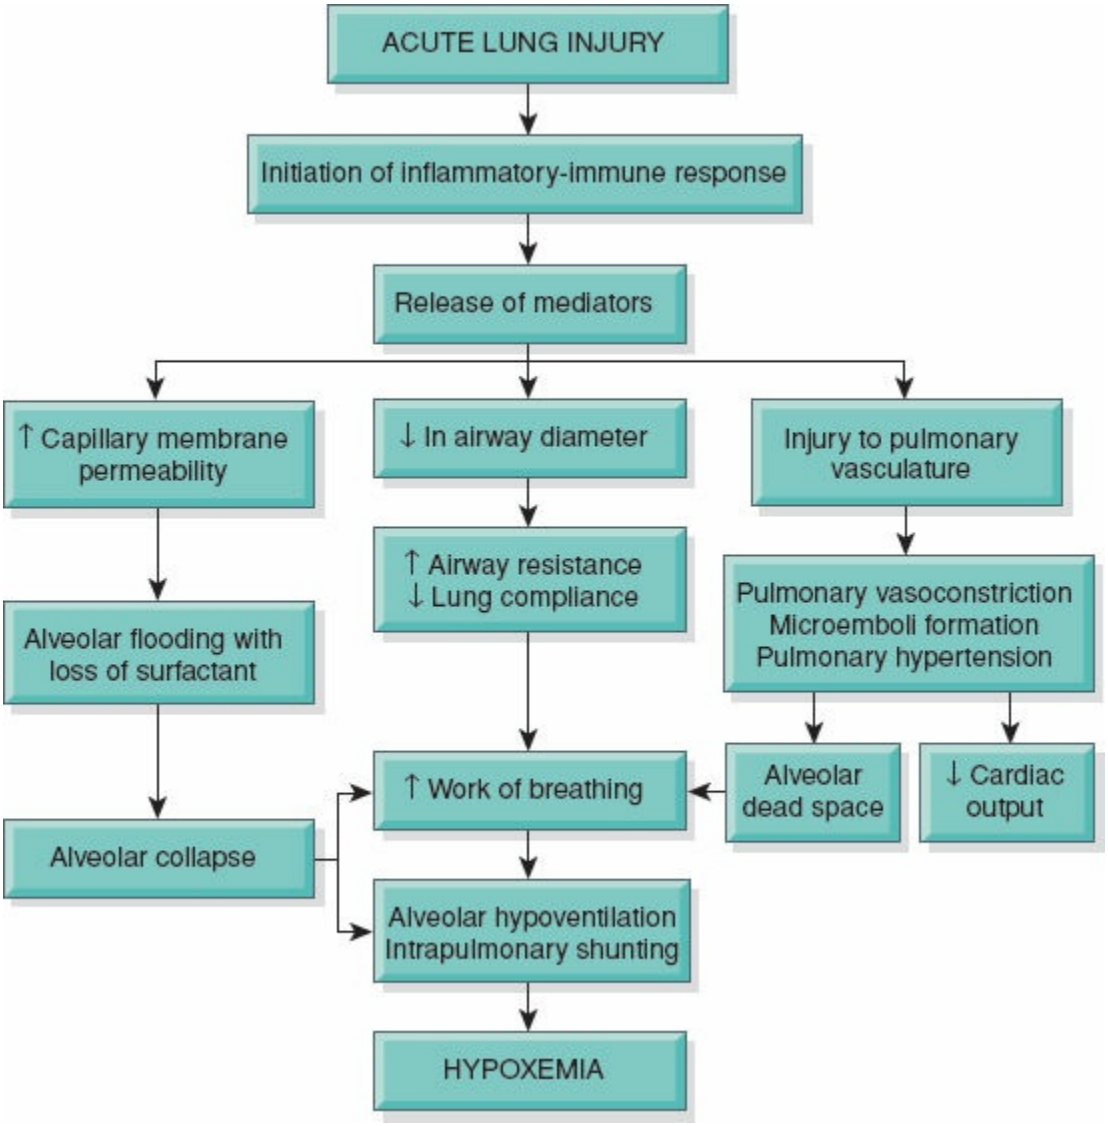

FIGURE 10-7 Pathogenesis of acute respiratory distress syndrome (ARDS).

Clinical Manifestations and Assessment

Clinically, the acute phase of ARDS is marked by a rapid onset of severe dyspnea that usually occurs 12 to 48 hours after the initiating event. A characteristic feature is arterial hypoxemia that does not respond to supplemental oxygen. On chest x-ray, the findings are similar to those seen with cardiogenic pulmonary edema and appear as bilateral, patchy infiltrates that quickly worsen. On chest CT, bilateral, patchy infiltrates with consolidation are usually more pronounced in the dependent (posterior) lung areas. The ALI then progresses to fibrosing alveolitis with persistent, severe hypoxemia. The patient also has increased alveolar dead space (ventilation to nonperfused alveoli) and decreased pulmonary compliance ("stiff lungs," which are difficult to ventilate). Clinically, the patient is thought to be in the recovery phase if the hypoxemia begins to resolve, the chest x-ray improves, and the lungs become more compliant.

BOX 10-8 Risk Factors for Acute Respiratory Distress Syndrome (ARDS)

- Systemic sepsis (40%)
- Aspiration: near-drowning, aspiration of gastric contents (more than 30% of cases)
- Trauma (more than 20% of cases)
- Multiple transfusions, blood products
- Drugs (overdose of morphine, methadone, heroin; reaction to nitrofurantoin)
- Hematologic disorders (e.g., disseminated intravascular coagulopathy, massive transfusions, cardiopulmonary bypass)
- Noxious inhalation (high concentrations of oxygen; chlorine gas)
- Postresuscitation
- Localized infection
- Metabolic disorders (pancreatitis, uremia)
- Shock
- Major surgery
- Fat or air embolism

Adapted from Ferri (2016).

Intercostal retractions and crackles, as the fluid begins to leak into the alveolar interstitial space, are evident on physical examination. ABGs are analyzed to assess the severity of hypoxemia. A diagnosis of ARDS may be made based on the following criteria: a history of systemic or pulmonary risk factors, acute onset of respiratory distress, bilateral pulmonary infiltrates, clinical absence of left-sided heart failure, and a ratio of PaO_2 to fraction of inspired oxygen (FiO_2) of less than 300 mm Hg (severe refractory hypoxemia). The normal ratio of PaO_2 to FiO_2 is over 300 mm Hg. Severity of ARDS is measured by calculation of PaO_2/FiO_2 ratio. A ratio of 200 to 300 is mild, 100 to 199 is moderate, and less than 100 is severe (Matthay & Slutsky, 2016).

Nursing Alert

A quick calculation the nurse can perform to assess the patient's pulmonary status is the ratio of the patient's arterial oxygen level (PaO_2), obtained from ABGs and the amount of oxygen inspired (FiO_2). This is also known as the P/F ratio. If the patient's PaO_2 is 75 mm Hg on 45% FiO_2, then the nurse converts the FiO_2 to a percentage. Thus an FiO_2 of 45% become 0.45. The simple calculation is 75/0.45, which equals a P/F ratio of 167, suggesting a moderate ARDS. To illustrate a patient with normal pulmonary function, an ABG may reveal a PaO_2 of 100 mm Hg on room air (FiO_2 of 21%); therefore the patient's PF ratio would be 100/0.21 = 476.

Medical Management

The primary focus in the management of ARDS includes identification and treatment of the underlying causative condition. Aggressive, supportive care must be provided to compensate for the severe respiratory dysfunction. This supportive therapy almost always includes intubation and mechanical ventilation. In addition, circulatory support, adequate fluid volume, and nutritional support are important. Supplemental oxygen is used as the patient begins the initial spiral of hypoxemia. As the hypoxemia progresses, intubation and mechanical ventilation are instituted. The concentration of oxygen and ventilator settings and modes are determined by the patient's status. This is monitored by ABG analysis, POX, and bedside pulmonary compliance testing.

Positive End-Expiratory Pressure

PEEP is a critical part of the treatment of ARDS. Use of PEEP helps increase FRC and reverse alveolar collapse by keeping the alveoli open, resulting in improved arterial oxygenation and a reduction in the severity of the ventilation–perfusion imbalance. Also the use of PEEP can allow for the use of lower, safer FiO_2 levels (60% or less FiO_2). The goal is a PaO_2 of greater than 60 mm Hg or an oxygen saturation level of greater than 90% at the lowest possible FiO_2. Evidence suggests that ARDS should be managed with a low tidal volume (6 cc/kg of ideal body weight), pressure-limited approach (plateau pressure of 30 mm Hg or less) with low or moderately high PEEP. Although the optimal level of PEEP has not been established, higher levels of PEEP may be beneficial for moderate to severe ARDS (Matthay & Slutsky, 2016).

The use of positive-pressure ventilation (as opposed to normal negative-pressure breathing) increases intrathoracic pressure and causes a decrease in preload to the heart. This drop in preload can result in decreased cardiac output and hypotension. Systemic hypotension also may occur in ARDS as a result of hypovolemia secondary to leakage of fluid into the interstitial spaces. Hypovolemia must be treated carefully without causing further fluid overload. IV crystalloid or colloid solutions are administered with careful monitoring of pulmonary status. Inotropic (e.g., dobutamine) or vasopressor agents (e.g., norepinephrine, dopamine, and epinephrine) may be required. Central venous catheters and, occasionally, pulmonary artery pressure catheters may be used to monitor the patient's fluid status and the severe and progressive pulmonary hypertension sometimes observed in ARDS. Arterial catheterization is required as patients with ARDS need frequent blood gas analysis.

Pharmacologic Therapy

Numerous pharmacologic treatments are under investigation to stop the cascade of events leading to ARDS; however, the mainstay of treatment is related to improving oxygenation and preventing complications. Thus prophylaxis for prevention of DVT and stress ulcer is common.

ARDS patients often require IV sedation and pain medication to combat anxiety and agitation from hypoxemia and intubation. In extreme cases, patients may require chemical

paralysis with neuromuscular blockers in order to adequately ventilate and oxygenate them.

Nutritional Therapy

Adequate nutritional support is vital in the treatment of ARDS. Patients with ARDS require 20 to 25 kcal/kg/day to meet caloric requirements. Enteral feeding is the first consideration; however, parenteral nutrition also may be required (McClave et al., 2016).

Nursing Management

General Measures

A patient with ARDS is critically ill and requires close monitoring in the intensive care unit. Many different respiratory modalities can be used in this situation (oxygen administration, nebulizer therapy, CPT, endotracheal intubation or tracheostomy, mechanical ventilation, suctioning, bronchoscopy). Frequent assessment of the patient's status is necessary to evaluate the effectiveness of treatment.

In addition to implementing the medical plan of care, the nurse considers other patient needs. Positioning is important. The nurse turns the patient frequently to improve ventilation and perfusion in the lungs and enhance secretion drainage. However, the nurse must monitor the patient closely for deterioration in oxygenation with changes in position. Oxygenation in patients with ARDS is sometimes improved in the prone position, and data indicate this position reduces mortality in patients with moderate to severe ARDS (initial P/F less than 150 mm Hg) (Matthay & Slutsky, 2016). This position may be evaluated for improvement in oxygenation and used in special circumstances. Devices and specialty beds are available to assist the nurse in placing the patient in a prone position.

The patient can be extremely anxious and agitated because of the increasing hypoxemia, dyspnea, and intubation. The nurse explains all procedures and provides care in a calm, reassuring manner. It is important to reduce the patient's anxiety, because anxiety increases oxygen expenditure by preventing rest. Rest is essential to limit oxygen consumption and reduce oxygen needs.

Ventilator Considerations

If the patient is intubated and receiving mechanical ventilation with PEEP, several considerations must be addressed. PEEP is an unnatural pattern of breathing that feels strange to patients. The patients may be anxious and "fight" the ventilator. It is important for the nurse to assess for problems with ventilation that may be causing the anxiety reaction: tube blockage by kinking or retained secretions, other acute respiratory problems (e.g., pneumothorax, pain), a sudden decrease in the oxygen level, the level of dyspnea, or ventilator malfunction. In most cases, sedation may be required to decrease the patient's oxygen consumption, allow the ventilator to provide full support of ventilation, and decrease the patient's anxiety. Sedatives that may be used are lorazepam, midazolam, dexmedetomidine, and propofol. Judicious use of sedatives is necessary to prevent or reduce ICU delirium.

If satisfactory oxygen levels cannot be maintained despite the use of sedatives, neuromuscular blocking agents, such as pancuronium, vecuronium, atracurium, or rocuronium, may be administered to paralyze the patient. These agents paralyze skeletal muscles, including respiratory muscles, leading to respiratory arrest if the patient is not intubated and on adequate ventilator settings. With paralysis, the patient appears to be unconscious, loses motor function, and cannot breathe, talk, or blink independently. However, the patient retains sensation and is awake and able to hear. Paralytic agents should be used only by personnel who are trained in airway and ventilator management. The nurse must reassure the patient that the paralysis is a result of the medication and is

temporary. Paralysis should be used for the shortest possible time and never without adequate sedation and pain management.

Use of paralytic agents has many dangers and side effects. The nurse must be sure the patient does not become disconnected from the ventilator because respiratory muscles are paralyzed and the patient will be apneic. Consequently, the nurse ensures that the patient is closely monitored, and all ventilator and patient alarms must be on at all times. Eye care is important as well, because the patient cannot blink, thus increasing the risk of corneal abrasions. Neuromuscular blockers predispose the patient to deep venous thrombosis (DVT), muscle atrophy, and skin breakdown; therefore, passive range-of-motion exercises and skin assessment are important nursing actions.

Nursing Alert

If a patient is on concurrent administration of aminoglycosides and/or steroids, this increases the chance of the chemically paralyzed patient developing critical illness polyneuropathy. This is a severe form of muscle atrophy and deconditioning that can occur within 24 hours; it requires intensive physical therapy to correct, increases the patient's risks of developing complications, and prolongs hospital lengths of stay.

The patient may have discomfort or pain but cannot communicate these sensations. Signs of pain, such as tachycardia, diaphoresis, and hypertension, must be assessed for and treated. Analgesia must be administered concurrently with neuromuscular blocking agents. The nurse must anticipate the patient's needs regarding pain and comfort. The nurse checks the patient's position to ensure it is comfortable and in normal body alignment.

The nurse talks to, and not about, the patient while in the patient's presence; remember the patient is awake and able to hear. In addition, it is important for the nurse to describe the purpose and effects of the paralytic agents to the patient's family. If family members are unaware that these agents have been administered, they may become distressed by the change in the patient's status.

PULMONARY ARTERIAL HYPERTENSION

Pulmonary circulation is a low-pressure system intended to accommodate high blood flow from the right ventricle. The pulmonary vasculature is compliant and thin walled in order to facilitate gas exchange. The normal mean pulmonary pressure is 12 to 15 mm Hg with the capacity to dilate and constrict as needed. Pulmonary arterial hypertension (PAH) exists when the mean pulmonary artery pressure exceeds 25 mm Hg at rest or 30 mm Hg with activities. Unlike systemic BP, these pressures cannot be measured indirectly; instead, they must be measured via right-sided heart catheterization with a pulmonary artery catheter or estimated with an echocardiogram. In the absence of these measurements, clinical recognition becomes the only indicator for the presence of pulmonary hypertension; however, PAH is a condition that is not clinically evident until late in its progression.

There are two types of PAH: idiopathic PAH (formerly known as primary) and secondary PAH due to a known cause. Idiopathic PAH is a very uncommon disease. It occurs most often in women 20 to 40 years of age, either sporadically or in patients with a family history, and is usually fatal within 5 years of diagnosis. There are several possible causes, but the exact cause is unknown (Papadakis, McPhee, & Rabow, 2016).

In contrast, secondary PAH due to a known cause is more common and results from existing cardiac (left ventricular failure, mitral stenosis) or pulmonary disease (emphysema, pulmonary fibrosis, or thromboembolism). The prognosis depends on the severity of the underlying disorder and the changes in the pulmonary vascular bed. A common cause of PAH is pulmonary artery constriction due to chronic hypoxemia and hypercapnia from COPD (Box 10-9) (Papadakis et al., 2016). Conditions such as collagen vascular disease, congenital heart disease, portal hypertension, and HIV infection increase the risk for PAH in susceptible patients.

Pathophysiology

In patients with PAH, the pulmonary vasculature is injured, which leads to endothelial and smooth muscle thickening and hypertrophy, leading to noncompliant and narrowed vessels. Normally, the pulmonary vascular bed can handle the blood volume delivered by the right ventricle. It has a low resistance to blood flow and compensates for increased blood volume by dilation of the vessels in the pulmonary circulation. However, if the pulmonary vascular bed is destroyed or obstructed, the ability to handle whatever flow or volume of blood it receives is impaired, and the increased blood flow then increases the pulmonary artery pressure. As the pulmonary arterial pressure increases, the pulmonary vascular resistance also increases. This increased workload affects right ventricular function. The myocardium ultimately cannot meet the increasing demands imposed on it, leading to right ventricular hypertrophy (enlargement and dilation) and failure (cor pulmonale).

BOX 10-9 Causes of Pulmonary Arterial Hypertension (PAH)

- Collagen vascular diseases
- Congenital systemic-to-pulmonary shunts
- Portal hypertension
- Altered immune mechanisms (HIV infection)
- Diseases associated with significant venous or capillary involvement
- Chronic thrombotic or embolic disease
- Pulmonary venous hypertension
- Pulmonary vasoconstriction due to hypoxemia
- Chronic obstructive pulmonary disease (COPD), interstitial lung disease, sleep-disordered breathing
- Miscellaneous causes: Sarcoidosis, histiocytosis, compression of pulmonary vessels

Clinical Manifestations and Assessment

Dyspnea, the main symptom of both types of PAH, occurs at first with exertion and eventually at rest. Other signs and symptoms include chest pain, weakness, fatigue, syncope, occasional hemoptysis, and signs of right-sided heart failure (peripheral edema, ascites, distended neck veins, hepatomegaly, crackles, heart murmur, splitting of second heart sound).

Diagnosis of idiopathic PAH is made by exclusion of secondary causes such as COPD, pulmonary emboli (PE), HIV, and cardiac disease. Several tests are used to determine whether there is a known cause for the pulmonary hypertension. Complete diagnostic evaluation includes a history, physical examination, chest x-ray, pulmonary function studies, electrocardiogram (ECG), echocardiogram, ventilation–perfusion scan ($\dot{V}/\dot{Q}$ scan), CT or magnetic resonance (MR) angiography, sleep studies, autoantibody tests (to identify diseases of collagen vascular origin), HIV tests, liver function testing, hypercoagulation studies, and cardiac catheterization. Pulmonary function studies may be normal or show a slight decrease in vital capacity and lung compliance with a mild decrease in the diffusing capacity. The PaO_2 also is decreased (hypoxemia). Complete blood count is usually normal but may show polycythemia (hematocrit of more than 54% in males or 51% in females). The ECG reveals right atrial enlargement (and tall peaked P waves in inferior leads), right axis deviation, right ventricular hypertrophy (tall R waves in V_2 and tall R waves in V_5); and ST-segment depression, T-wave inversion, or both in $V_{1–4}$. An echocardiogram can assess the progression of the disease and rule out other conditions with similar signs and symptoms. A $\dot{V}/\dot{Q}$ scan or pulmonary CT or MR angiography detects defects in pulmonary vasculature, such as pulmonary emboli. Cardiac catheterization of the right side of the heart reveals elevated pulmonary arterial pressure and determines whether there is a vasoactive component to the pulmonary hypertension. Acute vasodilator testing can be performed with the right heart catheterization to determine if there is a reduction in mean pulmonary artery pressure when a short-acting vasodilator (adenosine, epoprostenol, or inhaled nitric oxide) is administered. A positive response is a decrease in mean PAP of more than 10 mm Hg to a value of less than 40 mm Hg, with increased or unchanged cardiac output (Ferri, 2016). Fewer than 10% of patients are responsive in idiopathic PAH, but these patients benefit from calcium-channel blockers.

Medical Management

The goal of treatment is to manage the underlying condition related to PAH of known cause. Hypoxemia, at rest or during exertion, should be treated with supplemental oxygen. Appropriate oxygen therapy can reverse the vasoconstrictive effect and reduce the pulmonary hypertension. Pharmacologic agents such as diuretics, digoxin, anticoagulant therapy (increased incidence of clots in pulmonary system), and calcium-channel blockers (nifedipine, diltiazem) (if they responded to the vasodilator testing described above) may be prescribed. Because calcium-channel blockers are effective in only a small percentage of patients, other treatment options, including prostacyclin, which acts as a potent vasodilator of pulmonary arteries and inhibitor of platelet aggregation, are often necessary (Ferri, 2016).

Vasodilating agents can be used to improve exercise tolerance and hemodynamic function as well as extend survival. Epoprostenol is given by continuous infusion, treprostinil by subcutaneous injection, bosentan and sildenafil by mouth, and iloprost by inhalation. Current therapies are not curative, have considerable side effects, and are often quite expensive. Lung or heart–lung transplantation is reserved for patients who have advanced disease despite maximal medical therapy (Hill, Cawley, & Heggen-Peay, 2016; Papadakis et al., 2016).

Nursing Management

The major nursing goal is to identify patients at high risk for PAH, such as those with COPD, pulmonary emboli, congenital heart disease, and mitral valve disease. The nurse also must be alert for signs and symptoms of deterioration such as worsening dyspnea, hypoxemia, and right ventricular failure. Oxygen therapy is administered as ordered, and the patient and family are instructed about the use of home oxygen supplementation. In patients treated with prostacyclin (i.e., epoprostenol or treprostinil), education about the need for central venous access (epoprostenol), or subcutaneous infusion (treprostinil) is discussed. In addition, the nurse reviews proper administration and dosing of the medication, usual side effects such as pain at the injection site, and potential severe side effects of hypotension, flushing of skin, bradycardia, and headache associated with IV administration. Emotional and psychosocial aspects of this disease must be addressed.

PULMONARY EMBOLISM

Pulmonary embolism (PE) refers to the obstruction of the pulmonary artery or one of its branches by a thrombus (or thrombi) that originates somewhere in the venous system or right side of the heart. Hospitalized patients are at a high risk for PE; it is estimated that more than 900,000 people suffer from DVT/PE, and almost 100,000 deaths are attributed to PE annually (CDC, 2015c). It is the third leading cause of death in hospitalized patients, often not diagnosed until autopsy. PE is a common disorder and often is associated with trauma, arrhythmia (atrial fibrillation), surgery (orthopedic, major abdominal, pelvic, gynecologic), pregnancy, heart failure, malignancies, age greater than 50 years, hypercoagulable states, and prolonged immobility. It also may occur in apparently healthy people. Risk factors for thromboembolism are identified in Box 10-10.

BOX 10-10 Risk Factors for Thromboembolism

- Acute medical illness (CVA, acute MI, heart failure, neuromuscular diseases)
- Major surgery (abdominal, orthopedic, gynecologic, urologic, neurosurgical, oncologic)
- Trauma (multisystem trauma, spinal cord injury or fracture, hip or pelvic fractures)
- Cancer (localized or metastatic) receiving chemotherapy or radiation therapy
- History of thromboembolism
- Obesity
- Immobility for more than 2 days
- Age older than 40 years
- Hypercoagulable conditions
- Prolonged mechanical ventilation
- Neuromuscular paralytic use
- Central venous catheters
- Severe sepsis
- Heparin-induced thrombocytopenia (HIT)

Pathophysiology

Most commonly, PE is due to a blood clot or thrombus. However, there are other types of emboli: air, fat, amniotic fluid, tumor cells, intravenously injected particulates, and septic (from bacterial invasion of the thrombus). Although most thrombi originate in the deep veins of the legs, other sites include the pelvic veins and the right atrium of the heart. Venous thrombosis can result from slowing of blood flow (stasis) secondary to damage to the blood vessel wall (particularly the endothelial lining) or changes in the blood coagulation mechanism. In atrial fibrillation, blood stagnates in the fibrillating atria, and stagnant blood forms clots. These clots can travel into the pulmonary circulation.

When a thrombus completely or partially obstructs a pulmonary artery or its branches, the alveolar dead space is increased. Alveolar dead space is an area that is ventilated but receives little or no blood flow. Therefore, gas exchange is impaired or absent in this area. In addition, various vasoactive substances are released from the clot and surrounding area, and these cause regional blood vessels and bronchioles to constrict. The reflex bronchoconstriction and vasoconstriction causes impaired gas exchange and the loss of alveolar surfactant, which results in atelectasis and hypoxemia. The hemodynamic consequences are increased pulmonary vascular resistance and pulmonary artery pressures, which put a strain on the right ventricle. When the work requirements of the right ventricle exceed its capacity, right ventricular failure occurs, leading to a decrease in cardiac output followed by a decrease in systemic blood pressure and the development of shock.

Clinical Manifestations and Assessment

Symptoms depend on the size of the thrombus and the area of the pulmonary artery occluded by the thrombus. Acute onset of dyspnea is the most frequent symptom, followed by pleuritic chest pain, cough, hemoptysis, and palpitations. The most common signs found on physical assessment are tachypnea, crackles, tachycardia, and presence of an S_4 heart sound and split S_2. Deep venous thrombosis (DVT) is closely associated with development of PE. Typically, these patients report sudden onset of pain and/or swelling and warmth of the proximal or distal extremity, skin discoloration (red or dusky blue in color), and superficial vein distention.

Shock can develop with massive PEs ("saddle" embolisms) or in patients with pre-existing heart failure. Pronounced dyspnea, sudden substernal pain, rapid and weak pulse, hypotension, syncope, and sudden death can occur. Multiple small emboli can lodge in the terminal pulmonary arterioles, producing multiple small infarctions of the lungs. A pulmonary infarction causes necrosis of an area of the lung. The clinical picture may mimic that of bronchopneumonia or heart failure. In atypical instances, PE causes few signs and symptoms, whereas in other instances it mimics various other cardiopulmonary disorders.

Death from PE commonly occurs within hours of the onset of symptoms; therefore, early recognition and diagnosis are priorities. Because the symptoms of PE can vary from mild to severe, a diagnostic workup is performed to rule out other diseases. The initial diagnostic workup includes chest x-ray, ECG, peripheral vascular studies (duplex ultrasound, venogram), ABG analysis, and D-dimer.

The chest x-ray is most helpful in excluding other possible causes such as pneumonia, COPD, and pulmonary edema due to heart failure. ABG analysis may show hypoxemia and hypocapnia (from tachypnea); however, ABG measurements may be normal even in the presence of PE. The classic ECG pattern associated with PE, although rare, is S_1, Q_3, T_3, meaning a deep S wave in lead I, a Q wave in lead III and an inverted T wave in lead III. More common ECG findings are sinus tachycardia, PR-interval depression, and nonspecific T-wave changes. Peripheral vascular studies used to diagnose a DVT may include impedance plethysmography, Doppler ultrasonography, or venography. If a DVT is present with the associated signs and symptoms of PE, the patient is treated for both. The D-dimer assay is used to evaluate patients with possible PE. Emergency departments in particular have used this as a rapid, cost-effective test. D-dimer is a product of fibrin degradation and occurs as a result of fibrin lysis. D-dimer is used only to rule out a PE; as a negative result, it has a 95% predictive ability, meaning 95% of patients with PE have an elevated D-dimer. If the D-dimer is negative, the diagnosis of PE is excluded, whereas a positive test generally prompts a computed tomographic pulmonary angiography (CTPA) (Weitz, 2016), or spiral CT. For most patients with suspected PE, CTPA is the first-choice diagnostic imaging modality because it is sensitive and specific for the diagnosis of PE (Thompson, 2016).

Nursing Alert

The nurse understands that there is a higher rate of false-positive D-dimers in patients with acute illness, those over 50 years, pregnant women, and those with

kidney disease (Thompson, 2016).

If a facility does not have access to a spiral CT scanner or CTPA, a V̇/Q̇ scan is ordered. The V̇/Q̇ scan was once the second choice for diagnosis of a PE (with pulmonary angiogram [discussed below] considered the best diagnostic procedure). It is minimally invasive, involving the administration of a radioactive agent (both IV and inhaled). This scan evaluates different regions of the lung (upper, middle, lower) and allows comparisons of the percentage of ventilation and perfusion in each area. This test has a high sensitivity but can be more cumbersome than a CT scan and is not as accurate as a pulmonary angiogram. Patients who have an underlying lung disease, such as COPD or pneumonia, often have inconclusive V̇/Q̇ scan results; also patients who are mechanically ventilated cannot undergo this test.

Contrast angiogram CT scan has gained popularity for use in the diagnosis of PE. Limitations to the use of CT scanning are that patients must be cooperative and able to have IV contrast (no contrast allergies, normal renal function), and it is less sensitive than a pulmonary angiogram. Pulmonary angiography allows for the visualization of the pulmonary vasculature under fluoroscopy with IV contrast. It requires interventional radiologists to perform the test with specific equipment and personnel that may not be available in many hospitals, and the test is costly.

Prevention

For patients at risk for PE, the most effective approach for prevention is to prevent DVT. General preventive measures include active leg exercises to avoid venous stasis, early ambulation, and use of elastic compression or intermittent pneumatic compression stockings.

Prophylactic anticoagulation therapy is prescribed based on assessment of a patient's risk level. Table 10-3 illustrates the risk stratification and recommended prophylaxis. Anticoagulant therapy may be prescribed for patients who are older than 40 years of age, whose hemostasis is adequate, and who are undergoing major abdominal or thoracic surgery. Low doses of heparin may be administered before surgery to reduce the risk of postoperative DVT and PE. Heparin should be administered subcutaneously 2 hours before surgery and continued every 8 to 12 hours until the patient is discharged. Low-dose heparin is thought to enhance the activity of antithrombin III, a major plasma inhibitor of clotting factor X. This regimen is not recommended for patients with an active thrombotic process or for those undergoing major orthopedic surgery, open prostatectomy, or surgery on the eye or brain. Low–molecular-weight heparins (e.g., enoxaparin [Lovenox], dalteparin [Fragmin], fondaparinux [Arixtra]) are additional therapies. They have a longer half-life, enhanced subcutaneous absorption, a reduced incidence of thrombocytopenia, and reduced interaction with platelets, compared with unfractionated heparin (Kearon et al., 2016).

Often sequential compression devices (SCDs) are used to prevent venous stasis through compression and relaxation of the calf muscles, similar to the effect of muscle contraction. SCDs have been proved to effectively reduce the risk of DVT and have been shown to be an effective primary therapy for patients who are unable to receive anticoagulation therapy, but a combination of pharmacologic agents with SCDs is more effective (Kakkos et al., 2011). Several types of SCDs, using foot, calf, and thigh-high compression as well as graduated, asymmetric, and circumferential compression, are available. There is little evidence favoring any particular type of compression. Graduated compression involves the sequential movement of air in the sleeve up the leg, followed by relaxation of the sleeve. The advantage of this therapy is the extended duration of compression compared with standard inflation. Asymmetric compression involves inflating only the area on the back of the leg or foot, whereas, circumferential compression involves even compression of the entire leg. Assessment of the patient's skin is an important nursing function when SCDs are in use.

Medical Management

Because PE is often a medical emergency, emergency management is of primary concern. After emergency measures have been initiated and the patient is stabilized, the treatment goal is to dissolve (lyse) the existing emboli and prevent new ones from forming. Treatment may include a variety of modalities:

- General measures to improve respiratory and vascular status
- Anticoagulation therapy
- Thrombolytic therapy
- Surgical intervention

TABLE 10-3 Recommended Deep Vein Thrombosis Prophylaxis

Risk Level	Recommended Prophylaxis
Low risk:	Early mobilization mechanical aid (intermittent pneumatic compression devices) until ambulatory (>300 feet/day)
Minor surgery + age under 40 years and no additional DVT risk factors	Mechanical aid (intermittent pneumatic compression devices) until ambulatory
Moderate risk: Major surgery + age over 40 years and no additional DVT risk factors	Mechanical aid (intermittent pneumatic) until ambulatory >300 feet per day OR Heparin: 5,000 units SC q12h (start 2 hours prior to surgery) or Enoxaparin) 40 mg. SC daily or Dalteparin 2,500 units SC daily
High risk: Major surgery + Age over 40 years and/or other DVT risk factors	Mechanical aid (intermittent pneumatic compression or graded compression stockings) AND Heparin 5,000 units SC q8h (start 2 hours prior to surgery) or Enoxaparin 40 mg SC daily or Dalteparin 5,000 units SC daily
Hip arthroplasty	Enoxaparin 30 mg SC q 12 hours × 10–14 days Fondaparinux 2.5 mg SC daily × 10–14 days Dabigatran 220 mg PO daily × 28–35 days Warfarin (INR 2.0–3.0) for 14–21 days
Knee arthroplasty	Enoxaparin 30 mg SC q 12 hours × 10–14 days Apixaban 2.5 mg PO BID × 12 days Edoxaban 30 mg PO daily × 11–14 days Rivaroxaban 10 mg PO daily × 12 days Warfarin (target INR 2.0–3.0) for 14–21 days

Emergency Management

Massive PE is a life-threatening emergency. The immediate objective is to stabilize the cardiopulmonary system. A sudden increase in pulmonary resistance increases the work of the right ventricle, which can cause acute right-sided heart failure with cardiogenic shock. Emergency management consists of the following actions:

- Oxygen is administered immediately to relieve hypoxemia, respiratory distress, and central cyanosis.
- Intravenous infusion lines are inserted to establish routes for medications or fluids that will be needed.
- A perfusion scan, hemodynamic measurements, and ABG determinations are performed. CT angiogram or pulmonary angiography may be performed.
- An echocardiogram can be done at the bedside to assess right ventricular function.

- Hypotension is treated with IV fluid resuscitation, vasopressors (dopamine, norepinephrine, epinephrine) or inotropic support (dobutamine).
- The ECG is monitored continuously for arrhythmias and right ventricular failure, which may occur suddenly.
- Digitalis glycosides, IV diuretics, and antiarrhythmic agents are administered when appropriate.
- Blood is drawn for serum electrolytes, complete blood count, and coagulation studies (PT, international normalized ratio [INR], partial thromboplastin time [PTT], D-dimer).
- If clinical assessment and ABG analysis indicate the need, the patient is intubated and placed on a mechanical ventilator.
- If the patient has suffered massive embolism and is hypotensive, an indwelling urinary catheter is inserted to monitor urinary output.
- Small doses of IV morphine or sedatives are administered to relieve patient anxiety, to alleviate chest discomfort, to improve tolerance of the endotracheal tube, and to ease adaptation to the mechanical ventilator.
- IV thrombolytic agents (tissue plasminogen activator [Alteplase, Reteplase]) may be used in patients who are hemodynamically unstable (hypotension, ECG strain patterns or echocardiographic evidence of right ventricular strain or failure) to lyse the clot(s).
- Initiation of low–molecular-weight heparins (SC route) or IV heparin should be considered.

Pharmacologic Therapy

Anticoagulation Therapy

Anticoagulant therapy (unfractionated or low–molecular-weight heparins) is traditionally the primary method for managing acute DVT and PE. Heparin is used to prevent recurrence of emboli but has no effect on emboli that are already present. Heparin is generally recommended for all patients who have been diagnosed with PE and should be administered by continuous intravenous infusion and dosed using weight-based nomograms. In general, a therapeutic heparin dose is administered as a one-time 80 units/kg bolus, and then a continuous IV infusion (18 units/kg/hr) is started to maintain the PTT at 1.5 to 2.5 times the normal level (Weitz, 2016). Rapid achievement and maintenance of a therapeutic PTT are important to reduce the risk for recurrent PE. In addition to examining the PTT, a complete blood count is monitored, generally a minimum of two to three times per week due to the risk for bleeding and heparin-induced thrombocytopenia (HIT), discussed in Chapter 14 (Weitz, 2016). Enoxaparin, a low–molecular-weight heparin, is administered subcutaneously at 1 mg/kg every 12 hours. This should be reserved for hemodynamically stable patients in order to ensure that the drug is being absorbed into the vasculature. Enoxaparin has an advantage over heparin as its levels do not need to be monitored and IV access is not an issue (Marino, 2014).

Therapy may be changed to an oral regimen, such as warfarin, as soon as the patient is able to take oral medications. Heparin must be continued until the INR is within a therapeutic range, typically 2.0 to 3 (Weitz, 2016). Once the patient starts an oral regimen,

it is important that he or she continues to take the same brand of warfarin because the bioavailability may vary greatly among brands.

High doses of subcutaneous low–molecular-weight heparin or heparinoids may also be used to maintain a therapeutic PTT while oral anticoagulation therapy is being adjusted. Lepirudin (Refludan) and argatroban are alternatives for patients in whom heparin or heparinoids are contraindicated (e.g., patients with HIT). These agents are direct thrombin inhibitors; therefore, they require less frequent monitoring and dose adjustment. Both medications have contraindications and side effects that the nurse must be aware of before administration. Heparins, lepirudin, and argatroban are all contraindicated in patients with overt major bleeding and in patients who are hypersensitive to these agents or at high risk for bleeding (e.g., recent CVA), anomaly of vessels or organs, recent major surgery, recent puncture of large vessels, or organ biopsy. Major side effects are bleeding anywhere in the body and anaphylactic reaction resulting in shock or death. Other side effects include fever, abnormal liver function, and allergic skin reaction. Patients must continue to take some form of anticoagulation for at least 3 to 6 months after the embolic event.

Novel oral anticoagulants such as apixaban and rivaroxaban (factor Xa inhibitors) are now approved for the initial treatment of DVT and PE. Dabigatran (direct thrombin inhibitor) and edoxaban (factor Xa inhibitor) are approved for treatment or DVT and PE after initial therapy with parenteral anticoagulation is used (Meyer, Vieillard-Baron, & Planquette, 2016). These agents have the advantage of not requiring monitoring of INR or PTT levels, but renal function must be assessed during therapy (refer to Chapter 18 for more details on DVT).

Thrombolytic Therapy

Thrombolytic therapy (urokinase, streptokinase, alteplase, anistreplase, reteplase) also may be used in treating PE, particularly for patients who are severely compromised (e.g., those who are hypotensive, RV dysfunction, patent foramen ovale, large or saddle embolism, or have significant hypoxemia despite oxygen supplementation). Thrombolytic therapy dissolves the thrombi or emboli more quickly and restores more normal hemodynamic functioning of the pulmonary circulation, thereby reducing pulmonary hypertension and improving perfusion, oxygenation, and cardiac output. However, bleeding is a significant side effect. Absolute contraindications to thrombolytic therapy include history of hemorrhagic CVA, active intracranial neoplasm, recent brain or spinal surgery (less than 2 months), and internal bleeding within the last 6 months. Relative contraindications for thrombolytic therapy are bleeding tendency, uncontrolled hypertension (SBP greater than 200 or DBP greater than 100), nonhemorrhagic CVA within 2 months, surgery in the last 10 days, or thrombocytopenia of less than 100,000 platelets per mm^3.

Before thrombolytic therapy is started, INR, PTT, hematocrit, and platelet counts are obtained. Heparin is stopped prior to administration of a thrombolytic agent. During therapy, all but essential invasive procedures are avoided because of potential bleeding. If necessary, packed red cells, cryoprecipitate, or frozen plasma is administered to replace blood loss and reverse the bleeding tendency. After the thrombolytic infusion is completed (which varies in duration according to the agent used and the condition being treated), anticoagulant therapy is initiated.

Surgical Management

A surgical embolectomy is rarely performed but may be indicated if the patient has a massive PE or hemodynamic instability and must have the clot removed to help reduce right-sided heart failure, or if there are contraindications to thrombolytic therapy. This invasive procedure involves removal of the actual clot and must be performed by a cardiovascular surgical team with the patient on cardiopulmonary bypass. The procedure has a high intraoperative mortality rate and has typical postoperative complications.

Venous catheter embolectomy via rheolytic (injection of pressured saline or TPA) or rotating blades can be used to break up clots in the pulmonary vasculature. These catheters are placed via the femoral vein, threaded through the right heart, and up to the clot. An inferior vena cava (IVC) filter is usually inserted at the time of surgery to protect against a recurrence.

IVC filters are mesh-like devices used to trap thrombi from the pelvic and lower extremities to prevent them from traveling to the lungs. The IVC filters can be either permanent or retrievable. Recent research reveals that the filters do not have prolonged survival, in part because permanent filters can be associated with complications such as IVC occlusion because of clots, and recurrent DVT. Alternatively retrievable filters have recently been noted for problems of device migration or thrombosis in up to 10% of patients. Thus the insertion of IVC filters generally is restricted to patients who have high risk for recurrent PE and an absolute contraindication for anticoagulation, experience significant bleeding while on anticoagulation, or have recurrent PE despite adequate treatment. The IVC filters (e.g., Greenfield filter) are inserted via the femoral or internal jugular vein (Fig. 10-8). This filter is advanced into the IVC, where it is opened.

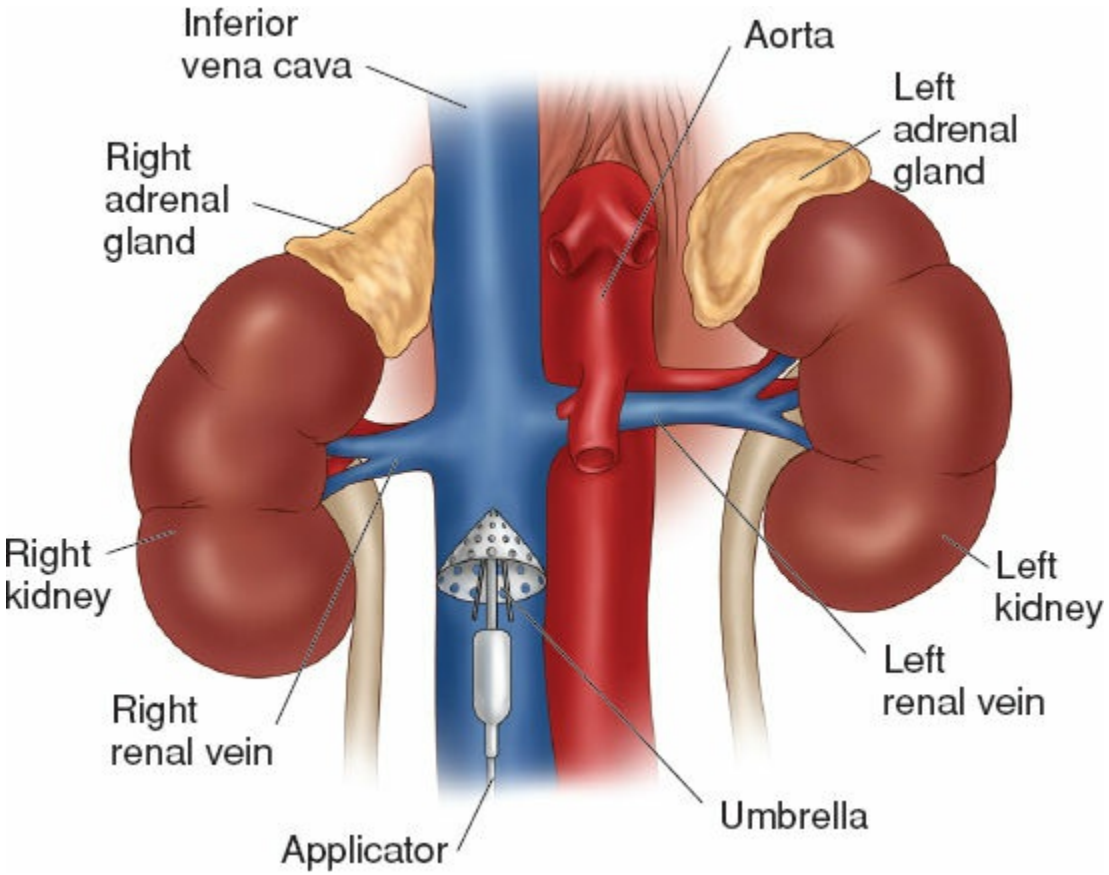

FIGURE 10-8 An umbrella filter is in place in the inferior vena cava to prevent pulmonary embolism.

The filter (compressed within an applicator catheter) is inserted through an incision in the right internal jugular vein. The applicator is withdrawn when the filter fixes itself to the wall of the inferior vena cava after ejection from the applicator.

Nursing Management

Minimizing the Risk of Pulmonary Embolism

A key role of the nurse is to identify the patient at high risk for PE and to minimize the risk of PE in all patients. The nurse must have a high degree of suspicion for PE in all patients but particularly in those with conditions predisposed to a slowing of venous return.

Preventing Thrombus Formation

Preventing thrombus formation is a major nursing responsibility. The nurse encourages ambulation and active and passive leg exercises to prevent venous stasis in patients who are prescribed bed rest. The nurse instructs the patient to move the legs in a "pumping" exercise so that the leg muscles can help increase venous flow. The nurse also advises the patient not to sit or lie in bed for prolonged periods, not to cross the legs, and not to wear constrictive clothing. Legs should not be dangled or feet placed in a dependent position while the patient sits on the edge of the bed; instead, feet should rest on the floor or on a chair. In addition, IV catheters (for parenteral therapy or measurements of central venous pressure) should not be left in place for prolonged periods.

Assessing Potential for Pulmonary Embolism

All patients are evaluated for risk factors for thrombus formation and PE. The nurse does a careful assessment of the patient's health history, family history, and medication record. On a daily basis, the patient is asked about pain or discomfort in the extremities. In addition, the extremities are evaluated for unilateral leg warmth, redness, and inflammation.

Monitoring Thrombolytic Therapy

The nurse is responsible for monitoring thrombolytic and anticoagulant therapy. Thrombolytic therapy (streptokinase, urokinase, tissue plasminogen activator) causes lysis of deep vein thrombi and pulmonary emboli, which helps dissolve the clots. During thrombolytic infusion, while the patient remains on bed rest, vital signs are assessed every 15 minutes for 2 hours, then every 2 hours for 4 hours, and invasive procedures are avoided. PTT testing should be performed every 6 hours after thrombolytics are started.

Nursing Alert

The activated PTT (APTT) is a more sensitive test than the PTT for the monitoring of heparin therapy. A normal APTT is 21 to 35 seconds. The goal of heparin therapy is to extend the APTT to 2 or 2.5 the normal level. The nurse is aware that when the APTT is over 70 seconds, the risk for spontaneously bleeding increases. Many institutions have protocols for increasing or decreasing the heparin dosage depending on the APTT. The nurse follows hospital protocol but anticipates that if the APTT is over 90 seconds to stop the anticoagulant for 1 hour and restart as mandated by protocol, typically at a lower rate per hour. In general, heparin infusion should be restarted (without a bolus) when PTT is less than 60 seconds. If no protocols are available, the nurse contacts the provider immediately with APTTs of

greater than 90 seconds.

The INR was developed as a consistent way of monitoring prothrombin times, which are used for monitoring Coumadin therapy. A normal INR is about 1. The goal of Coumadin therapy is to extend the INR to 2 to 3, depending on the reason the patient is anticoagulated. The higher the number, the longer the blood takes to clot. A patient with atrial fibrillation may have a goal INR of 2.5, whereas a patient with a mechanical heart valve may have a maximum goal of an INR of 3.5. Any INR over 3.6 is a critical value that necessitates notification of the patient's provider. With an elevated APTT and/or INR, the nurse observes the patient for hematuria, hematemesis, melena, petechiae, unusual bruising, and any evidence of bleeding (hypotension, tachycardia, dyspnea, etc.) (Fischbach & Dunning, 2014; Smithburger, Campbell, & Kane-Gill, 2013).

Managing Pain

Chest pain, if present, is usually pleuritic rather than cardiac in origin. A semi-Fowler position provides a more comfortable position for breathing. It is important to continue to turn patients frequently and reposition them to improve the ventilation–perfusion ratio in the lung. The nurse administers opioid analgesics as prescribed for severe pain.

Managing Oxygen Therapy

It is important to ensure that the patient understands the need for continuous oxygen therapy. The nurse assesses the patient frequently for signs of hypoxemia and monitors the POX values to evaluate the effectiveness of the oxygen therapy. Deep breathing and IS are indicated for all patients to minimize or prevent atelectasis and improve ventilation. Nebulizer therapy or percussion and postural drainage may be used for management of secretions.

Relieving Anxiety

The nurse encourages the stabilized patient to talk about any fears or concerns related to this frightening episode, answers the patient's and family's questions concisely and accurately, explains the therapy, and describes how to recognize untoward effects early.

Monitoring for Complications

When caring for a patient who has had PE, the nurse must be alert for the potential complication of cardiogenic shock or right ventricular failure subsequent to the effect of PE on the cardiovascular system.

Providing Postoperative Care

The nurse measures the patient's pulmonary arterial pressure or central venous pressure (CVP), and urinary output. The nurse also assesses the insertion site of the arterial catheter for hematoma formation and infection. It is important to maintain the BP at a level that supports perfusion of vital organs. To prevent peripheral venous stasis and edema of the lower extremities, the nurse encourages isometric exercises, use of elastic compression

stockings or SCDs, and walking when the patient is permitted out of bed. Sitting is discouraged, because hip flexion compresses the large veins in the legs.

Nursing Alert
The nurse is aware that a mean arterial pressure (MAP) of 65 mm Hg is recommended to maintain adequate tissue perfusion.

OCCUPATIONAL LUNG DISEASES

Diseases of the lungs occur in numerous occupations as a result of exposure to several different types of agents. Examples include mineral dusts (asbestos, silica, coal), metal dusts, biologic dusts (spores, mycelia, bird droppings), manufactured fibers (glass or ceramic fibers), and toxic fumes (nitrogen dioxide, sulfur dioxide, chlorine, ammonia). One category of occupational lung disease that causes chronic fibrotic lung disease is pneumoconiosis, which is caused by the inhalation of inert, inorganic, or silicate dusts. The effects of inhaling these materials depend on the composition of the substance, its concentration, its ability to initiate an immune response, its irritating properties, the duration of exposure, and the individual's response or susceptibility to the irritant. The most common types of pneumoconiosis are coal worker's pneumoconiosis, silicosis, and asbestosis. Smoking may compound the problem and may increase the risk of lung cancers in people exposed to the mineral asbestos and other potential carcinogens. Many people with early pneumoconiosis are asymptomatic, but advanced disease often is accompanied by disability and premature death. Between 1996 and 2005, pneumoconiosis was cited as the cause of death of 9,646 people in the United States (CDC, 2014a).

Silicosis is a chronic fibrotic pulmonary disease caused by inhalation of silica dust (silicon dioxide). Exposure to silica and silicates occurs in almost all mining, quarrying, and tunneling operations. Glass manufacturing, stone-cutting, manufacturing of abrasives and pottery, and foundry work are other occupations with exposure hazards. Finely ground silica, such as that found in soaps, polishes, and filters, is extremely dangerous (Papadakis, McPhee, & Rabow, 2016).

Asbestosis is a disease characterized by diffuse nodular interstitial fibrosis from the inhalation of asbestos dust. Current laws restrict the use of asbestos, but many industries used it in the past. Therefore, exposure occurred, and may still occur, in people in numerous occupations, including asbestos mining and manufacturing, shipbuilding, demolition of structures containing asbestos, and roofing. Materials such as shingles, cement, vinyl asbestos tile, fireproof paint and clothing, brake linings, and filters all contained asbestos at one time, and many of these materials are still in existence. Chronic exposure may also occur by washing clothes that have been in contact with asbestos. Additional diseases related to asbestos exposure include lung cancer, mesothelioma, and asbestos-related pleural effusion (Papadakis, McPhee, & Rabow, 2016).

Coal worker's pneumoconiosis ("black lung disease") includes a variety of respiratory diseases found in coal workers who have inhaled coal dust over the years. Coal miners are exposed to dusts that are mixtures of coal, kaolin, mica, and silica (Papadakis, McPhee, & Rabow, 2016).

Pathophysiology

The pathophysiology of each type of pneumoconiosis (any chronic lung disease caused by the inhalation of particles) begins with the inhalation and deposition of industrial dusts or particles in the lungs. In silicosis, the inhaled silica particles form nodular lesions throughout the lungs. With the passage of time and further exposure, the nodules enlarge and coalesce. Dense masses form in the upper portion of the lungs, resulting in the loss of pulmonary volume. Restrictive lung disease (disease of the lungs that limits their ability to expand fully) and obstructive lung disease from secondary emphysema result. Cavities can form as a result of superimposed TB. Exposure of 15 to 20 years is usually required before the onset of the disease and shortness of breath occurs. Fibrotic destruction of pulmonary tissue can lead to emphysema, pulmonary hypertension, and cor pulmonale (right ventricular failure).

In asbestosis, inhaled asbestos fibers enter the alveoli, where they are surrounded by fibrous tissue. The fibrous tissue eventually obliterates the alveoli. Fibrous changes also affect the pleura, which thickens and develops plaque. The result of these physiologic changes is a restrictive lung disease, with a decrease in lung volume, diminished exchange of oxygen and carbon dioxide, and hypoxemia.

When coal dust is deposited in the alveoli and respiratory bronchioles, macrophages engulf the particles (by phagocytosis) and transport them to the terminal bronchioles, where they are removed by mucociliary action. In time, the clearance mechanisms cannot handle the excessive dust load, and the macrophages aggregate in the respiratory bronchioles and alveoli. Fibroblasts appear and a network of reticulin (similar in composition to collagen) is laid down surrounding the dust-laden macrophages. The bronchioles and the alveoli become clogged with coal dust, dying macrophages, and fibroblasts. This leads to the formation of the coal macule, the primary lesion of the disorder. Macules appear as blackish dots on the lungs. Fibrotic lesions develop and, as the macules enlarge, the weakening bronchioles dilate, with subsequent development of localized emphysema. The disease begins in the upper lobes of the lungs but may progress to the lower lobes.

Clinical Manifestations and Assessment

Patients with acute silicosis present with dyspnea, fever, cough, and weight loss, and progression of the disease is rapid. Symptoms are more severe in patients whose disease is complicated by progressive massive fibrosis. More commonly, this disease is a chronic problem with a long latency period. In patients with asbestosis, the onset of the disease is insidious, and patients have progressive dyspnea, persistent, dry cough, mild to moderate chest pain, anorexia, weight loss, and malaise. Early physical findings include bibasilar fine, end-inspiratory crackles, and, in more advanced cases, clubbing of the fingers. Patients with coal miner's disease usually present with a chronic cough and sputum production, similar to the signs encountered in chronic bronchitis. As the disease progresses, patients develop dyspnea and cough up large amounts of sputum with varying amounts of black fluid (melanoptysis), particularly if they are smokers.

As each of these diseases progresses, worsening dyspnea and hypoxemia occur. Eventually, patients develop respiratory failure and cor pulmonale. A high proportion of workers who have been exposed to asbestos dust, especially those who smoke or have a history of smoking, die of lung cancer. Malignant mesothelioma, a rare cancer of the pleura or peritoneum that is strongly associated with asbestos exposure, may also occur.

Medical Management

The medical treatment for these specific pneumoconioses is limited to supportive care, as the fibrotic process is irreversible. Oxygen therapy, diuretics, inhaled beta-adrenergic agonists, anticholinergics, and bronchodilator therapy can be used to maximize pulmonary and cardiac function and preserve activity tolerance. It is imperative that patients avoid any additional environmental exposures and stop smoking. There is a higher incidence of TB in patients with silicosis; therefore, they should have a tuberculin skin test and chest radiograph. Preventing this disease is key because there is no effective treatment. Instead, treatment focuses on early diagnosis and management of complications.

CHEST TUMORS

Tumors of the lung may be benign or malignant. A malignant chest tumor can be primary, arising within the lung, chest wall, or mediastinum, or it can be a metastasis from a primary tumor site elsewhere in the body. Metastatic lung tumors occur frequently because the bloodstream transports cancer cells from primary cancers elsewhere in the body to the lungs.

LUNG CANCER (BRONCHOGENIC CARCINOMA)

Lung cancer is the leading cancer killer among men and women in the United States. In 2012, 210,828 people in the United States were diagnosed with lung cancer. That same year, 157,423 people died of the disease (CDC, 2016b). There has been a statistically significant decrease in the incidence of lung cancer in both men and women (except American Indian, Alaska Native, and Asian/Pacific Islander women) in the years between 2002 and 2011 (CDC, 2016b). In approximately 70% of patients with lung cancer, the disease has spread to regional lymphatics and other sites by the time of diagnosis. As a result, the long-term survival rate is low.

Pathophysiology

Eighty percent of lung cancer in women and 90% in men are caused by cigarette smoking, with the remainder being attributed to other carcinogens, including radon gas and occupational and environmental agents (CDC, 2015b).

Classification and Staging

For purposes of staging and treatment, most lung cancers are classified into one of two major categories: small cell lung cancer (25% of lung cancers) and nonsmall cell lung cancer (75% of lung cancers) (Table 10-4). In nonsmall cell lung carcinoma (NSCLC), the cell types include squamous cell carcinoma (20% to 30%), large cell carcinoma (10%), and adenocarcinoma (30% to 40%), including bronchoalveolar carcinoma. Most small cell carcinomas arise in the major bronchi and spread by infiltration along the bronchial wall.

In addition to classification according to cell type, lung cancers are staged. The stage of the tumor refers to the size of the tumor, its location, whether lymph nodes are involved, and whether the cancer has metastasized, referred to as the TNM ("T" refers to the extent of the primary tumor, "N" refers to lymph node involvement, and "M" refers to the extent of metastasis) (Goldstraw, Chansky, Crowley, et al., 2015). NSCLC is staged as I to IV. Stage I is the earliest stage and has the highest cure rates, whereas stage IV designates metastatic spread. Small cell lung cancers are classified as limited or extensive. Diagnostic tools and further information on staging were described in Chapter 6.

Risk Factors

Various factors have been associated with the development of lung cancer (Box 10-11). Other factors that have been associated with lung cancer include genetic predisposition and underlying respiratory diseases, such as COPD and TB.

Clinical Manifestations and Assessment

Often, lung cancer develops insidiously and is asymptomatic until late in its course. The signs and symptoms depend on the location and size of the tumor, the degree of obstruction, and the existence of metastases to regional or distant sites. The most frequent symptom of lung cancer is cough or change in a chronic cough. The cough starts as a dry, persistent cough, without sputum production. When obstruction of airways occurs, the cough may become productive due to infection.

TABLE 10-4 Lung Cancer Types and Characteristics

Tumor Classification	Growth Rate	Clinical Manifestations	Treatment	Metastasis
Nonsmall Cell Lung Cancer (NSCLC)				
Squamous cell	Slow	Cough, hemoptysis, pneumonia, atelectasis, chest pain (late sign), unexplained weight loss	Surgical resection, adjunctive chemotherapy	Late: Brain, liver, bones, adrenals
Adenocarcinoma	Moderate	Dyspnea, pleuritic chest pain, pleural effusions, unexplained weight loss	Surgical resection, adjunctive chemotherapy	Early: Liver, brain, bones, kidneys, adrenals
Large cell (undifferentiated)	Rapid	Chest wall pain, cough, sputum production, hemoptysis, pleural effusion, pneumonia, unexplained weight loss	Surgical resection	Early: Brain, liver, bones, adrenals
Small Cell Lung Cancer (SCLC)				
Oat cell and intermediate cell type	Very rapid	Cough, unexplained weight loss, dyspnea, airway obstruction, hilar mass on x-ray, pneumonia, paraneoplastic syndromes (SIADH, hypercalcemia, Cushing's, myopathies)	Chemotherapy, Radiation therapy	Early: Liver, bone, bone marrow, brain, adrenals

SIADH, syndrome of inappropriate antidiuretic hormone secretion.

BOX 10-11 Risk Factors Associated with Lung Cancer

- Tobacco smoking: Assess pack/year history (number of packs smoked per day × years of smoking)
- Passive smoking
- Secondhand smoke (closed areas; home, building, automobile)
- Environmental and occupational exposure (vehicle emissions, pollutants, urban areas, radon gas, arsenic, asbestos, chromates, coal fumes, radiation)
- Family history (close relative with lung cancer)
- Low intake of fruits and vegetables

Dyspnea occurs in many patients. Hemoptysis or blood-tinged sputum may be expectorated. Chest or shoulder pain may indicate chest wall or pleural involvement by a tumor. Pain also is a late manifestation and may be related to metastasis to the bone.

In some patients, a recurring fever is an early symptom in response to a persistent infection in an area distal to the tumor. In fact, cancer of the lung should be suspected in people with repeated unresolved upper respiratory tract infections. If the tumor spreads to adjacent structures and regional lymph nodes, the patient may present with chest pain and tightness, hoarseness (involving the recurrent laryngeal nerve), dysphagia, head and neck edema, and symptoms of pleural or pericardial effusion. The most common sites of metastases are lymph nodes, bone, brain, contralateral lung, adrenal glands, and liver. Nonspecific symptoms of weakness, anorexia, and weight loss also may be present.

If pulmonary symptoms occur in smokers, cancer of the lung should always be considered. A chest x-ray is performed to search for pulmonary densities, pulmonary nodules, atelectasis, and infection. CT scans of the chest are used to identify small nodules not easily visualized on the chest x-ray and also to examine areas for lymphadenopathy.

Fiberoptic bronchoscopy provides a detailed study of the tracheobronchial tree and allows for brushings, washings, and biopsies of suspicious areas. For peripheral lesions not amenable to bronchoscopic biopsy, a transthoracic fine-needle aspiration may be performed under CT guidance to aspirate cells from a suspicious area. In some circumstances, an endoscopy with esophageal ultrasound may be used to obtain a transesophageal biopsy of enlarged subcarinal (below the carina) lymph nodes that are not easily accessible by other means.

A variety of scans may be used to assess for metastasis of the cancer. These may include bone scans, abdominal scans, positron emission tomography (PET) scans, and liver ultrasound. CT of the brain, magnetic resonance imaging (MRI), and other neurologic diagnostic procedures are used to detect CNS metastases. Mediastinoscopy or mediastinotomy may be used to obtain biopsy samples from lymph nodes in the mediastinum.

If surgery is a potential treatment, the patient is evaluated to determine whether the tumor is resectable and whether the patient can tolerate the physiologic impairment resulting from such surgery. Pulmonary function tests, ABG analysis, $\dot{V}/\dot{Q}$ scans, and exercise testing may all be used as part of the preoperative assessment.

Medical Management

The objective of management is to provide a cure, if possible. Treatment depends on the cell type, the stage of the disease, and the patient's physiologic status (particularly cardiac and pulmonary status). In general, treatment may involve surgery, radiation therapy, or chemotherapy—or a combination of these. Newer and more specific therapies to modulate the immune system (gene therapy, therapy with defined tumor antigens) are under study.

Surgical Management

Surgical resection is the preferred method of treating patients with localized nonsmall cell tumors, no evidence of metastatic spread, and adequate cardiopulmonary function. The cure rate of surgical resection depends on the type and stage of the cancer. Surgery is primarily used for NSCLCs because small cell cancer of the lung grows rapidly and metastasizes early and extensively. Lesions of many patients with bronchogenic cancer are inoperable at the time of diagnosis.

Several different types of lung resection may be performed. The most common surgical procedure for a small, apparently curable tumor of the lung is lobectomy (removal of a lobe of the lung). In some cases, an entire lung may be removed (pneumonectomy).

Radiation Therapy

Radiation therapy (XRT) may offer cure in a small percentage of patients. It is useful in controlling neoplasms that cannot be surgically resected but are responsive to radiation. Irradiation also may be used to reduce the size of a tumor, to make an inoperable tumor operable, or to relieve the pressure of the tumor on vital structures. It can reduce symptoms of spinal cord metastasis and superior vena caval compression. Also, XRT is used to treat metastases to the brain. Radiation therapy may help relieve cough, chest pain, dyspnea, hemoptysis, and bone and liver pain. Relief of symptoms may last from a few weeks to many months and is important in improving the quality of the remaining period of life. Radiofrequency ablation and cryoablation are two types of nonsurgical therapies that have been used to treat lung tumors.

Chemotherapy

Chemotherapy is used to alter tumor growth patterns, to treat distant metastases or small cell cancer of the lung, and as an adjunct to surgery or radiation therapy. Chemotherapy may provide relief, especially of pain, but it does not usually cure the disease or prolong life to any great degree. Chemotherapy is also accompanied by side effects. It is valuable in reducing pressure symptoms of lung cancer and in treating brain, spinal cord, and pericardial metastases.

The choice of agent depends on the growth of the tumor cell and the specific phase of the cell cycle that the medication affects. In combination with surgery, chemotherapy may be administered before surgery (neoadjuvant therapy) or after surgery (adjuvant therapy). Combinations of two or more medications may be more beneficial than single-dose regimens.

Palliative Therapy

Palliative therapy may include radiation therapy or chemotherapy to shrink the tumor to provide pain relief, a variety of bronchoscopic interventions to open a narrowed bronchus or airway, and pain management and other comfort measures. Evaluation and referral for hospice care are important in planning for comfortable and dignified end-of-life care for the patient and family.

Treatment-Related Complications

A variety of complications may occur as a result of treatment for lung cancer. Surgical resection may result in respiratory failure, particularly if the cardiopulmonary system is compromised before surgery. Surgical complications and prolonged mechanical ventilation are potential outcomes. Radiation therapy may result in diminished cardiopulmonary function and other complications, such as pulmonary fibrosis, pericarditis, myelitis, and cor pulmonale. Chemotherapy, particularly in combination with radiation therapy, can cause pneumonitis. Pulmonary and systemic toxicity is a potential side effect of chemotherapy.

Nursing Management

Nursing care of patients with lung cancer is similar to that for other patients with cancer and addresses the physiologic and psychological needs of the patient. The physiologic problems are primarily due to the respiratory manifestations of the disease. Nursing care includes strategies to ensure relief of pain and discomfort and to prevent complications.

Managing Symptoms

The nurse instructs the patient and family about the potential side effects of the specific treatment and strategies to manage them. Strategies for managing such symptoms as dyspnea, fatigue, nausea and vomiting, anorexia, and fatigue help the patient and family cope with therapeutic measures. See Chapter 6.

Relieving Breathing Problems

Airway clearance techniques are key to maintaining airway patency through the removal of excess secretions. This may be accomplished through deep-breathing exercises, CPT, directed cough, suctioning, and, in some instances, bronchoscopy. Bronchodilator medications may be prescribed to promote bronchial dilation. As the tumor enlarges or spreads, it may compress a bronchus or involve a large area of lung tissue, resulting in an impaired breathing pattern and poor gas exchange. At some stage of the disease, supplemental oxygen will probably be necessary.

Nursing measures focus on decreasing dyspnea by encouraging the patient to assume positions that promote lung expansion and to perform breathing exercises for lung expansion and relaxation. Patient education about energy conservation and airway clearance techniques is also necessary. Many of the techniques used in pulmonary rehabilitation can be applied to patients with lung cancer. Depending on the severity of disease and the patient's wishes, a referral to a pulmonary rehabilitation program may be helpful in managing respiratory symptoms.

Providing Psychological Support

Another important part of the nursing care of patients with lung cancer is provision of psychological support and identification of potential resources for the patient and family. Refer to Chapter 6.

Gerontologic Considerations

At the time of diagnosis of lung cancer, most patients are older than 65 years of age and have stage III or IV disease (CDC, 2016b). Although age is not a significant prognostic factor for overall survival and response to treatment for either NSCLC or small cell lung cancer, older patients have specific needs. Depending on the comorbidities and functional status of elderly patients, chemotherapy agents, doses, and cycles may need to be adjusted to maintain quality of life. Issues that must be considered in the care of elderly patients with lung cancer include functional status, comorbid conditions, nutritional status, cognition, concomitant medications, and psychological and social support.

TUMORS OF THE MEDIASTINUM

Tumors of the mediastinum include neurogenic tumors, tumors of the thymus, lymphomas, germ cell tumors, cysts, and mesenchymal tumors. These tumors may be malignant or benign. They are usually described in relation to location: anterior, middle, or posterior masses or tumors.

Clinical Manifestations and Assessment

Nearly all symptoms of mediastinal tumors result from the pressure of the mass against important intrathoracic organs. Symptoms may include cough, wheezing, dyspnea, anterior chest or neck pain, bulging of the chest wall, heart palpitations, angina, other circulatory disturbances, central cyanosis, superior vena cava syndrome (i.e., swelling of the face, neck, and upper extremities; Fig. 10-9), marked distention of the veins of the neck and the chest wall (evidence of the obstruction of large veins of the mediastinum by extravascular compression or intravascular invasion), and dysphagia and weight loss from pressure or invasion into the esophagus.

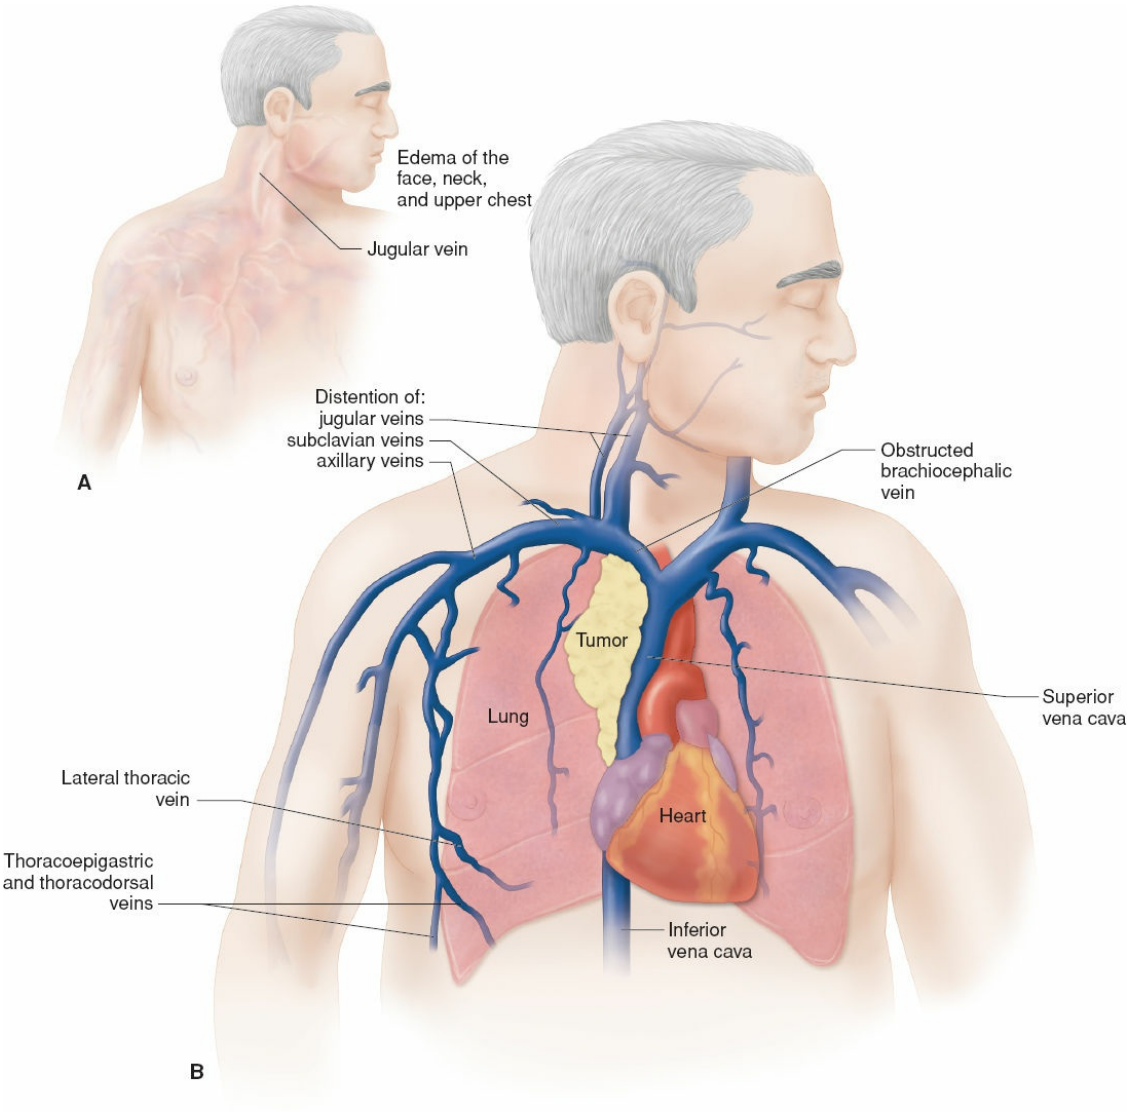

FIGURE 10-9 Clinical signs of the superior vena cava syndrome. (A) shows facial edema, plethora, jugular venous distention, and prominent superficial vessels in the neck and upper chest. (B) depicts the vascular anatomy and collateral vessel formation in a patient with superior vena cava syndrome. (DeVita, V. T., Jr., Lawrence, T. S., & Rosenberg, S. A. *DeVita, Hellman, and Rosenberg's cancer, principles and practice of oncology: Review* (10th ed.). Philadelphia, PA: Wolters Kluwer. (2016). Used with permission.)

Most often, chest x-rays are used to diagnose mediastinal tumors and cysts. CT is the standard diagnostic test for assessment of the mediastinum and surrounding structures. MRI, as well as PET, may be used in some circumstances.

Medical and Nursing Management

If the tumor is malignant and has infiltrated the surrounding tissue and complete surgical removal is not feasible, radiation therapy, chemotherapy, or both are used.

Many mediastinal tumors are benign and operable. The location of the tumor (anterior, middle, or posterior compartment) in the mediastinum dictates the type of incision. The common incision used is a median sternotomy; however, a thoracotomy may be used, depending on the location of the tumor. Additional approaches include a bilateral anterior thoracotomy (clamshell incision) and video-assisted thoracoscopic surgery (VATS). The care is the same as for any patient undergoing thoracic surgery. Major complications include hemorrhage, injury to the phrenic or laryngeal nerve, and infection.

CHEST TRAUMA

Major chest trauma may occur alone or in combination with multiple other injuries. Chest trauma is classified as either blunt or penetrating. Blunt chest trauma results from rapid deceleration injury (e.g., motor vehicle accident [MVA], falls) or direct injury (abuse, crushing, and explosions). Penetrating trauma occurs when a foreign object penetrates the chest wall (stabbing, gunshot wounds, and shrapnel).

BLUNT TRAUMA AND PENETRATING TRAUMA

Blunt thoracic injures are responsible for 53% of trauma deaths (Davis et al., 2014). It is often difficult to identify the extent of the damage because the symptoms may be occult and vague.

Pathophysiology

The most common causes of blunt chest trauma are MVAs (trauma from steering wheel, seat belt), falls, and bicycle crashes (trauma from handlebars) (Fair et al., 2015). Mechanisms of blunt chest trauma include acceleration (moving object hitting the chest or patient being thrown into an object), deceleration (sudden decrease in rate of speed or velocity, such as an MVA), shearing (stretching forces to areas of the chest causing tears, ruptures, or dissections), and compression (direct blow to the chest, such as a crush injury or explosion). Injuries to the chest are often life-threatening and result in one or more of the following pathologic states:

- Hypoxemia from disruption of the airway; injury to the lung parenchyma, rib cage, and respiratory musculature; massive hemorrhage; collapsed lung; pulmonary contusion and pneumothorax
- Hypovolemia from massive fluid loss from the great vessels, cardiac rupture, or hemothorax
- Cardiac failure from cardiac tamponade, cardiac contusion, or increased intrathoracic pressure

These pathologic states frequently result in impaired ventilation and perfusion leading to ARF, hypovolemic shock, and death.

Gunshot and stab wounds are the most common causes of penetrating chest trauma. These wounds are classified according to their velocity. In general, stab wounds are considered low-velocity trauma because the weapon destroys a small area around the wound. The appearance of the external wound may be very deceptive because pneumothorax, hemothorax, lung contusion, and cardiac tamponade, along with severe and continuing hemorrhage, can occur from any small wound, even one caused by a small-diameter instrument such as an ice pick.

Gunshot wounds may be classified as low-, medium-, or high-velocity. The factors that determine the velocity and resulting extent of damage include the distance from which the gun was fired, the caliber of the gun, and the construction and size of the bullet. A bullet can cause damage at the site of penetration and along its pathway, and a gunshot wound to the chest can produce a variety of pathophysiologic changes. The bullet may ricochet off bony structures and damage the chest organs and great vessels or can travel into the abdomen. If the diaphragm is involved in a gunshot wound or a stab wound, injury to the chest cavity must be considered.

Clinical Manifestations and Assessment

Time is critical in treating chest trauma. Therefore, it is essential to assess the patient immediately to determine the following:

- Time elapsed since injury occurred
- Mechanism of injury
- Level of responsiveness
- Specific injuries
- Estimated blood loss
- Recent drug or alcohol use
- Prehospital treatment

Initial assessment of thoracic injuries includes assessment for airway obstruction, tension pneumothorax, open pneumothorax, massive hemothorax, flail chest, and cardiac tamponade and rupture. These injuries are life-threatening and require immediate treatment. Secondary assessment includes assessment for simple pneumothorax, hemothorax, pulmonary contusion, traumatic aortic rupture, tracheobronchial disruption, sternal fracture, esophageal perforation, traumatic diaphragmatic injury, and penetrating wounds to the mediastinum. Although listed as secondary, these injuries may be life-threatening as well (Davis et al., 2014; Fair et al., 2015; Sarkar, Brunsvold, Cherry-Bukoweic, et al., 2011).

The rapid assessment of thoracic injuries involves the use of the Advanced Trauma Life Support (ATLS) algorithm of "Circulation, Airway, Breathing, Disability (neurologic), and Exposure/Environmental control":

- *Circulation:* The vital signs and skin color are assessed for signs of shock.
- *Airway:* Assessment includes noting the rate and depth of breathing and observing for abnormalities such as stridor, cyanosis, nasal flaring, use of accessory muscles, drooling, and overt trauma to the face, mouth, or neck.
- *Breathing:* The chest is assessed for symmetric movement, symmetry of breath sounds, open chest wounds, entrance or exit wounds, impaled objects, distended neck veins, and paradoxical chest wall motion. The thorax is palpated for tenderness and crepitus (subcutaneous emphysema), and the position of the trachea is also assessed. In addition, the chest wall is assessed for bruising, petechiae, lacerations, and burns.
- *Disability:* Assess the patient's level of consciousness and note if concurrent head or spinal cord injuries are present.
- *Exposure/Environmental:* Assess for exposure injuries such as hypothermia or hyperthermia.

The initial diagnostic workup includes a chest x-ray, CT scan, complete blood count, clotting studies, type and cross-match, electrolytes, oxygen saturation, ABG analysis, and ECG. The patient is completely undressed to avoid missing additional injuries that may complicate care. Many patients with injuries involving the chest have associated head and

abdominal injuries that require attention. Ongoing assessment is essential to monitor the patient's response to treatment and to detect early signs of clinical deterioration.

Medical Management

The medical management of penetrating and blunt chest trauma are similar. The objective of immediate management is to restore and maintain cardiopulmonary function. After an adequate airway is ensured and ventilation is established, examination for shock and intrathoracic and intra-abdominal injuries is necessary. There is a high risk for associated intra-abdominal injuries with stab wounds below the level of the fifth anterior intercostal space.

The diagnostic workup includes a chest x-ray, chemistry profile, ABG analysis, POX, and ECG. The patient's blood is typed and cross-matched in case blood transfusion is required. After the status of the peripheral pulses is assessed, a large-bore IV line is inserted. An indwelling catheter is inserted to monitor urinary output. A nasogastric tube is inserted and connected to low suction to prevent aspiration, minimize leakage of abdominal contents, and decompress the gastrointestinal tract.

Shock is treated simultaneously with colloid solutions, crystalloids, or blood, as indicated by the patient's condition. Diagnostic procedures are carried out as dictated by the needs of the patient (e.g., CT scans of chest or abdomen, flat plate x-ray of the abdomen, abdominal ultrasound to check for bleeding).

A chest tube is inserted into the pleural space in most patients with penetrating wounds of the chest to achieve rapid and continuing re-expansion of the lungs, especially in wounds above the fifth intercostal space (nipple line). The insertion of the chest tube frequently results in a complete evacuation of the blood and air. The chest tube also allows early recognition of continuing intrathoracic bleeding, which would make surgical exploration necessary. If the patient has a penetrating wound of the heart or great vessels, the esophagus, or the tracheobronchial tree, surgical intervention is required.

Patients with penetrating chest wound usually require exploratory surgery. In extreme cases, an emergency thoracotomy may be performed in the trauma room to access bleeding from large vessels such as the aorta, pulmonary artery, or heart.

Chest Tubes

Chest tubes may be inserted to drain fluid or air from any of the three compartments of the thorax (the right and left pleural spaces and the mediastinum). The pleural space, located between the visceral and parietal pleura, normally contains 25 mL or less of fluid, which helps lubricate the visceral and parietal pleura. Surgical incision of the chest wall almost always causes some degree of pneumothorax (air accumulating in the pleural space) or hemothorax (buildup of serous fluid or blood in the pleural space). Air and fluid collect in the pleural space, restricting lung expansion and reducing gas exchange. Placement of a chest tube in the pleural space restores the normal negative intrathoracic pressure needed for lung re-expansion after surgery or trauma.

The mediastinal space is an extrapleural space that lies between the right and left thoracic cavities and contains the large blood vessels, heart, mainstem bronchus, and thymus gland. If fluid accumulates here, the heart can become compressed and stop beating, causing death. Mediastinal chest tubes can be inserted either anteriorly or posteriorly to the heart to drain blood after surgery.

Catheters

There are two types of chest tubes: small-bore and large-bore catheters. Small-bore catheters (7 to 12 Fr) have a one-way valve apparatus to prevent air from moving back into the patient. They can be inserted through a small skin incision. Large-bore catheters, which range in size up to 40 Fr, are usually connected to a chest drainage system (Fig. 10-10) to collect any pleural fluid and monitor for air leaks. After the chest tube is positioned, it is sutured to the skin and connected to a drainage apparatus to remove the residual air and fluid from the pleural or mediastinal space. This results in the re-expansion of remaining lung tissue.

Chest Drainage Systems

Chest drainage systems have a suction source, a collection chamber for pleural drainage, and a mechanism to prevent air from re-entering the chest with inhalation. Various types of chest drainage systems are available for use in removal of air and fluid from the pleural space and re-expansion of the lungs. Chest drainage systems come with either wet (water seal) or dry suction control. In wet suction systems, the amount of suction is determined by the amount of water instilled in the suction chamber. Wet systems use a water seal to prevent air from moving back into the chest on inspiration. Dry systems use a one-way valve and may have a suction control dial in place of the water. Both systems can operate by gravity drainage, without a suction source (Fig. 10-10; Box 10-12).

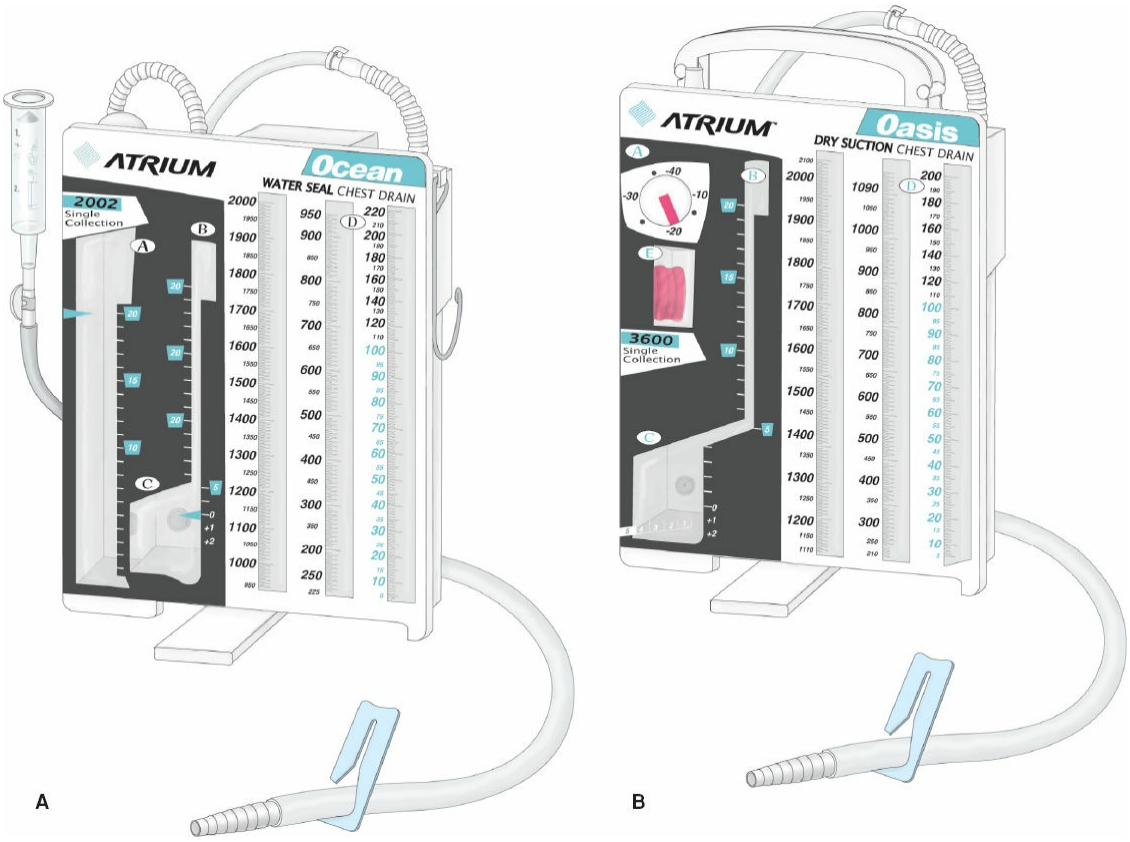

FIGURE 10-10 Chest drainage systems. A. The Atrium Ocean is an example of a water-seal chest drain system composed of a drainage chamber and water-seal chamber. The suction control is determined by the height of the water column in that chamber (usually 20 cm). *A*, suction control chamber; *B*, water-seal chamber; *C*, air leak zone; *D*, collection chamber. B. The Atrium Oasis is an

example of a dry suction water-seal system that uses a mechanical regulator for vacuum control, a water-seal chamber, and a drainage chamber. *A*, dry suction regulator; *B*, water-seal chamber; *C*, air leak monitor; *D*, collection chamber; *E*, suction monitor bellows. (Art redrawn with permission from Atrium Medical Corporation, Hudson, New Hampshire.)

Water-Seal Systems

The traditional water-seal system (or wet suction) for chest drainage has three chambers: a collection chamber, a water-seal chamber, and a wet suction control chamber. The collection chamber acts as a reservoir for fluid draining from the chest tube. It is graduated to permit easy measurement of drainage. Suction may be added to create negative pressure and promote drainage of fluid and removal of air. The suction control chamber regulates the amount of negative pressure applied to the chest. The amount of suction is determined by the water level. It is usually set at 20 cm H_2O; adding more fluid results in more suction. After the suction is turned on, bubbling appears in the suction chamber. A positive-pressure valve is located at the top of the suction chamber that automatically opens with increases in positive pressure within the system. Air is automatically released through a positive-pressure relief valve if the suction tubing is inadvertently clamped or kinked.

The water-seal chamber has a one-way valve or water seal that prevents air from moving back into the chest when the patient inhales. There is an increase in the water level with inspiration and a return to the baseline level during exhalation; this is referred to as *tidaling*. If bubbling is present, either intermittent or continuous, an air leak is present within the system or the patient. The nurse must investigate the system for loose connections. Bubbling and tidaling do not occur when the tube is placed in the mediastinal space; however, fluid may pulsate with the patient's heartbeat. If the chest tube is connected to gravity drainage only, suction is not used. Two-chamber chest drainage systems (water-seal chamber and collection chamber) are available for use with patients who need only gravity drainage.

BOX 10-12 GUIDELINES FOR NURSING CARE

Managing Chest Drainage Systems

Equipment

- Chest drainage system
- Dressings
- Sterile water
- Tape
- Marker

ACTION	RATIONALE
1. If using a chest drainage system with a water seal, fill the water-seal chamber with sterile water to the level specified by the manufacturer.	1. Water-seal drainage allows air and fluid to escape into a drainage chamber. The water acts as a seal and keeps the air from being drawn back into the pleural space.
2. When using suction in chest drainage systems with a water seal, fill the suction control chamber with sterile water to the 20 cm level or as prescribed. In systems without a water seal, set the regulator dial at the appropriate suction level.	2. The water level regulator dial setting determines the degree of suction applied.
 Pleur-evac system.	
3. Attach the drainage catheter exiting the thoracic cavity to the tubing coming from the collection chamber. Tape securely with adhesive tape.	3. In chest drainage units, the system is closed.
4. If suction is used, connect the suction control chamber tubing to the suction unit. If using a wet suction system, turn on the suction unit and increase pressure until slow but steady bubbling appears in the suction control chamber. If using a chest drainage system with a dry suction control chamber, turn the regulator dial to 20 cm H_2O.	4. With a wet suction system, the degree of suction is determined by the amount of water in the suction control chamber and is not dependent on the rate of bubbling or the pressure gauge setting on the suction unit. With a dry suction control chamber, the regulator dial replaces the water.
5. Mark the drainage from the collection chamber with tape on the outside of the drainage unit. Mark hourly/daily increments (date and time) at the drainage level.	5. This marking shows the amount of fluid loss and how fast fluid is collecting in the drainage chamber. It serves as a basis for determining the need for blood replacement, if the fluid is blood. Visibly bloody drainage will appear in the chamber in the immediate postoperative period but should gradually become serous. If the patient is bleeding as heavily as 100 mL every 15 minutes, check the drainage every few minutes. A reoperation or autotransfusion may be needed. Drainage of 200 mL/hr is usually associated with bleeding complications. The transfusion of blood collected in the drainage chamber must be reinfused within 4–6 hours. Usually, however, drainage decreases progressively in the first 24 hours.

6. Ensure that the drainage tubing does not kink, loop, or interfere with the patient's movements.	6. Kinking, looping, or pressure on the drainage tubing can produce back pressure, which may force fluid back into the pleural space or impede its drainage.
7. Encourage the patient to assume a comfortable position with good body alignment. With the lateral position, make sure that the patient's body does not compress the tubing. The patient should be turned and repositioned every 1.5 to 2 hours. Provide adequate analgesia.	7. Frequent position changes promote drainage, and good body alignment helps prevent postural deformities and contractures. Proper positioning also helps breathing and promotes better air exchange. Analgesics may be needed to promote comfort.
8. Assist the patient with range-of-motion exercises for the affected arm and shoulder several times daily. Provide adequate analgesia.	8. Exercise helps to prevent ankyloses (abnormal stiffening and immobility of a joint) of the shoulder and to reduce postoperative pain and discomfort. Analgesics may be needed to relieve pain.
9. If the drainage is bloody, gently drain the tubing in the direction of the drainage chamber. Gentle "milking" may be warranted if allowed according to institutional policy in cases of active bleeding to prevent obstruction in the tubing. If "gentle milking" is allowed, ***do not compress the tubing completely***. In general, the prevention of dependent loops, laying of the tubing horizontally across the bed that then drops vertically into the chest drainage system is sufficient for fluid drainage.	9. Gentle "milking" may prevent the tubing from becoming obstructed by clots and fibrin. Constant attention to maintaining the patency of the tube facilitates prompt expansion of the lung and minimizes complications. However, compressing the tubing may cause high negative pressure in the pleural space and lung entrapment, thus routine "milking" is discouraged.
10. Make sure there is fluctuation ("tidaling") of the fluid level in the water-seal chamber (in wet systems), or check the air leak indicator for leaks (in dry systems with a one-way valve). *Note:* Fluid fluctuations in the water-seal chamber or air leak indicator area will stop when: • The lung has re-expanded • The tubing is obstructed by blood clots, fibrin, or kinks • A loop of tubing hangs below the rest of the tubing • Suction motor or wall suction is not working properly	10. Fluctuation of the water level in the water seal shows effective connection between the pleural cavity and the drainage chamber and indicates that the drainage system remains patent. Fluctuation is also a gauge of intrapleural pressure in systems with a water seal (wet and dry, but not with the one-way valve).
11. With a dry system, assess for the presence of the indicator (bellows or float device) when setting the regulator dial to the desired level of suction.	11. An air leak indicator shows changes in intrathoracic pressure in dry systems with a one-way valve. Bubbles will appear if a leak is present. The air leak indicator takes the place of fluid fluctuations in the water-seal chamber. The indicator shows that the vacuum is adequate to maintain the desired level of suction.
12. Observe for air leaks in the drainage system; they are indicated by constant bubbling in the water-seal chamber, or by the air leak indicator in dry systems with a one-way valve. Also assess the chest tube system for correctable external leaks. Notify the provider immediately of excessive bubbling in the water-seal chamber not due to external leaks.	12. Leaking and trapping of air in the pleural space can result in tension pneumothorax.
13. When turning down the dry suction, depress the manual high-negativity vent, and assess for a rise in the water level of the water-seal chamber.	13. A rise in the water level of the water-seal chamber indicates high negative pressure in the system that could lead to increased intrathoracic pressure.
14. Observe and immediately report rapid and shallow breathing, cyanosis, pressure in the chest, subcutaneous emphysema, symptoms of hemorrhage, or significant changes in vital signs.	14. Many clinical conditions can cause these signs and symptoms, including tension pneumothorax, mediastinal shift, hemorrhage, severe incisional pain, pulmonary embolus, and cardiac tamponade. Surgical intervention may be necessary.
15. Encourage the patient to breathe deeply and cough at frequent intervals. Provide adequate analgesia. If needed, request an order for patient-controlled analgesia. Also teach the patient how to perform incentive spirometry.	15. Deep breathing and coughing help to raise the intrapleural pressure, which promotes drainage of accumulated fluid in the pleural space. Deep breathing and coughing also promote removal of secretions from the tracheobronchial tree, which, in turn, promotes lung expansion and prevents atelectasis (alveolar collapse).

16. If the patient is lying on a stretcher and must be transported to another area, place the drainage system below the chest level. If the tubing disconnects, cut off the contaminated tips of the chest tube and tubing, insert a sterile connector in the cut ends, and reattach to the drainage system. Do *not* clamp the chest tube during transport.	**16.** The drainage apparatus must be kept at a level lower than the patient's chest to prevent fluid from flowing backward into the pleural space. Clamping can result in a tension pneumothorax.
17. When assisting in the chest tube's removal, instruct the patient to perform a gentle Valsalva maneuver or to breathe quietly. Then the chest tube is clamped and removed quickly. Simultaneously, a small bandage is applied and made airtight with petrolatum gauze covered by a 4 × 4-inch gauze pad and thoroughly covered and sealed with nonporous tape.	**17.** The chest tube is removed as directed when the lung is re-expanded (usually within 24 hours to several days), depending on the cause of the pneumothorax. During tube removal, the chief priorities are preventing air from entering the pleural cavity as the tube is withdrawn and preventing infection.

The water level in the water-seal chamber reflects the negative pressure present in the intrathoracic cavity. A rise in the water level of the water-seal chamber indicates negative pressure in the pleural or mediastinal space. Excessive negative pressure can cause trauma to tissue. Most chest drainage systems have an automatic means to prevent excessive negative pressure. By pressing and holding a manual high-negativity vent (usually located on the top of the chest drainage system) until the water level in the water-seal chamber returns to the 2-cm mark, excessive negative pressure is avoided, thus preventing damage to tissue.

Dry Suction Water-Seal Systems

Dry suction water-seal systems, also referred to as dry suction, have a collection chamber for drainage, a water-seal chamber, and a dry suction control chamber. The water-seal chamber is filled with water to the 2 cm level. Bubbling in this area can indicate an air leak. The dry suction control chamber contains a regulator dial that regulates vacuum to the chest drain. Water is not needed for suction in these systems. Without the bubbling in the suction chamber, the system is quieter. However, if the container is knocked over, the water seal may be lost.

Once the tube is connected to the suction source, the regulator dial allows the desired level of suction to be dialed in; the suction is increased until an indicator appears. The indicator has the same function as the bubbling in the traditional water-seal system; that is, it indicates that the vacuum is adequate to maintain the desired level of suction. Some drainage systems use a bellows (a chamber that can be expanded or contracted) or an orange-colored float device as an indicator of when the suction control regulator is set.

When the water in the water seal rises above the 2 cm level, intrathoracic pressure increases. Dry suction water-seal systems have a manual high-negativity vent located on top of the drain. The manual high-negativity vent is pressed until the indicator appears (either a float device or bellows) and the water level in the water seal returns to the desired level, indicating that the intrathoracic pressure is decreased.

Dry Suction Systems with a One-Way Valve

A third type of chest drainage system is dry suction with a one-way mechanical valve. This system has a collection chamber, a one-way mechanical valve, and a dry suction control chamber. The valve permits air and fluid to leave the chest but prevents their movement back into the pleural space. This model lacks a water-seal chamber and therefore can be set up quickly in emergency situations, and the dry control drain still works even if it is knocked over. This makes the dry suction systems useful for the patient who is ambulating

or being transported. However, without the water-seal chamber, there is no way to tell by inspection whether the pressure in the chest has changed, even though an air leak indicator is present so that the system can be checked. If an air leak is suspected, 30 mL of water is injected into the air leak indicator or the container is tipped so that fluid enters the air leak detection chamber. Bubbles will appear if a leak is present.

If the chest tube has been inserted to re-expand a lung after pneumothorax, or if very little fluid drainage is expected, a one-way valve (Heimlich valve) may be connected to the chest tube (Fig. 10-11). This valve may be attached to a collection bag or covered with a sterile dressing if no drainage is expected.

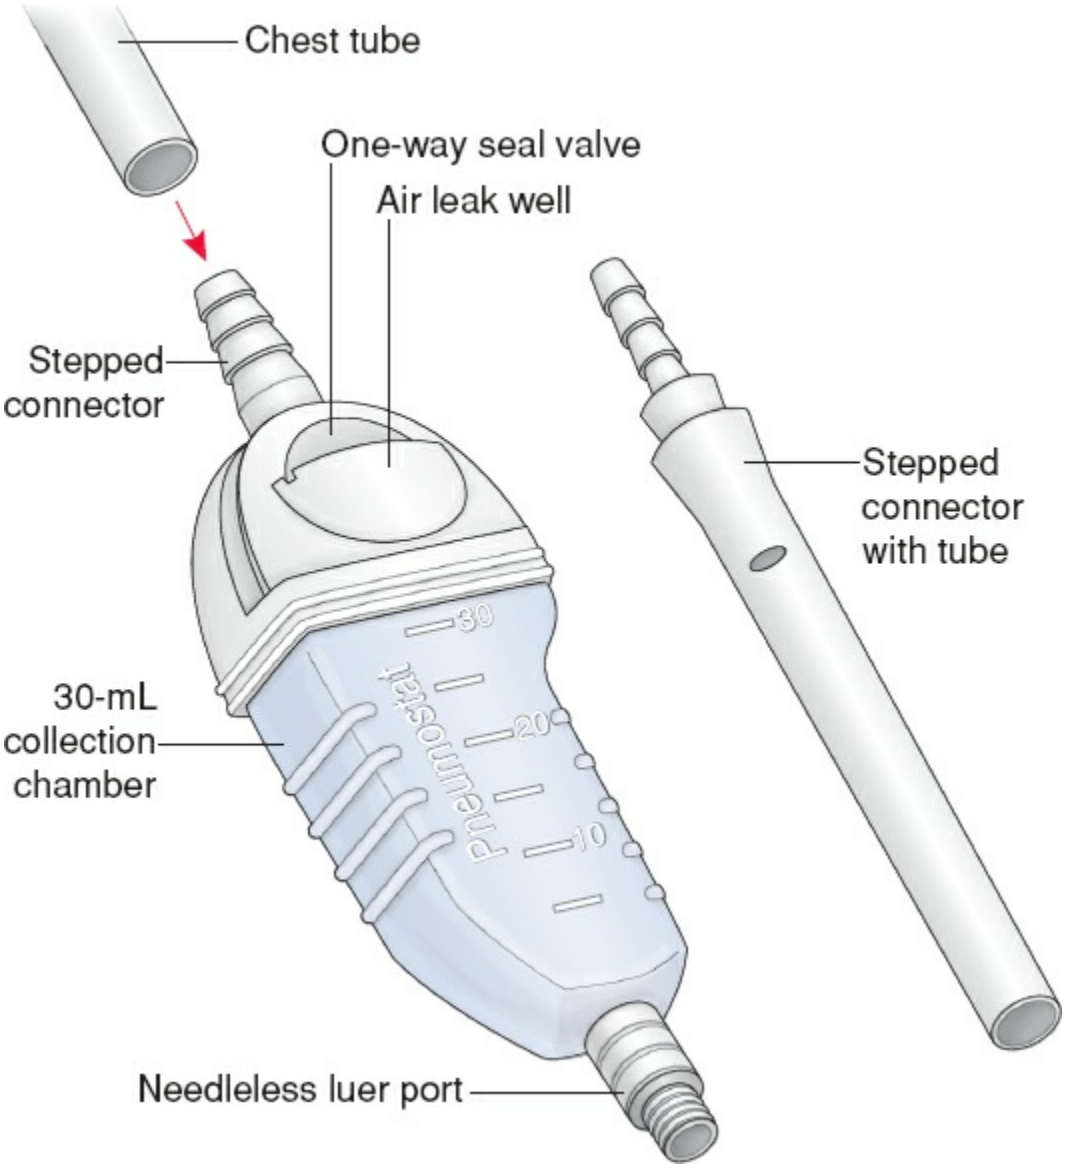

FIGURE 10-11 One-way (Heimlich) valve, a disposable, single-use chest drainage system with 30-mL collection volume. Used when minimal volume of chest drainage is expected.

STERNAL AND RIB FRACTURES

Sternal fractures are most common in MVAs, caused by a direct blow to the sternum via

the steering wheel. Rib fractures are the most common type of chest trauma, occurring in more than 62% of patients admitted with blunt chest injury (Sharma et al., 2008). Most rib fractures are benign and are treated conservatively. Fractures of the first three ribs are rare but can result in a high mortality rate because they are associated with laceration of the subclavian artery or vein. The fifth through ninth ribs are the most common sites of fractures. Fractures of the lower ribs are associated with injury to the spleen and liver, which may be lacerated by fragmented sections of the rib.

Clinical Manifestations and Assessment

Patients with sternal fractures have anterior chest pain, overlying tenderness, ecchymosis, crepitus, swelling, and possible chest wall deformity. For patients with rib fractures, clinical manifestations are similar: severe pain, point tenderness, and muscle spasm over the area of the fracture that is aggravated by coughing, deep breathing, and movement. The area around the fracture may be bruised. To reduce the pain, the patient splints the chest by breathing in a shallow manner and avoids sighs, deep breaths, coughing, and movement. This reluctance to move or breathe deeply results in diminished ventilation, atelectasis (collapse of unaerated alveoli), pneumonitis, and hypoxemia. Respiratory insufficiency and failure can be the outcomes of such a cycle.

The patient must be evaluated closely for underlying cardiac or abdominal injuries. A crackling, grating sound in the thorax (subcutaneous crepitus) may be detected with auscultation or palpation. The diagnostic workup may include a chest x-ray, rib films of a specific area, ECG, continuous POX, and ABG analysis.

Medical and Nursing Management

Medical management is directed toward relieving pain, avoiding excessive activity, and treating any associated injuries. Surgical fixation is rarely necessary unless fragments are grossly displaced and pose a potential for further injury.

The goals of treatment for rib fractures are to control pain and to detect and treat the injury. Narcotics are most often used to relieve pain and to allow deep breathing and coughing. Care must be taken to avoid oversedation and suppression of respiratory drive. Alternative strategies to relieve pain include an intercostal nerve block and ice over the fracture site. A chest binder may be used as supportive treatment to provide stability to the chest wall and may decrease pain. The patient is instructed to apply the binder snugly enough to provide support but not so tight as to impair respiratory excursion. Usually the pain abates in 5 to 7 days, and discomfort can be relieved with epidural analgesia, patient-controlled analgesia, or nonopioid analgesia (NSAIDs). Most rib fractures heal in 3 to 6 weeks.

FLAIL CHEST

Flail chest is frequently a complication of blunt chest trauma from a steering wheel injury. It usually occurs when three or more adjacent ribs (multiple contiguous ribs) are fractured at two or more sites, resulting in free-floating rib segments. It may also result as a combination fracture of ribs and costal cartilages or sternum (Fig. 10-12). As a result, the chest wall loses stability, causing respiratory impairment and usually severe respiratory distress. In addition, due to the force needed to break ribs or the sternum, often an underlying pulmonary or cardiac contusion is present.

Pathophysiology

During inspiration, as the chest expands, the detached part of the rib segment (flail segment) moves in a paradoxical manner (pendelluft movement) in that it is pulled inward during inspiration, reducing the amount of air that can be drawn into the lungs. On expiration, because the intrathoracic pressure exceeds atmospheric pressure, the flail segment bulges outward, impairing the patient's ability to exhale. The mediastinum then shifts back to the affected side. This paradoxical action results in increased dead space, a reduction in alveolar ventilation, and decreased compliance. Retained airway secretions and atelectasis frequently accompany flail chest. The patient has hypoxemia, and if gas exchange is greatly compromised, respiratory acidosis develops as a result of carbon dioxide retention. Hypotension, inadequate tissue perfusion, and metabolic acidosis often follow as the paradoxical motion of the mediastinum decreases cardiac output.

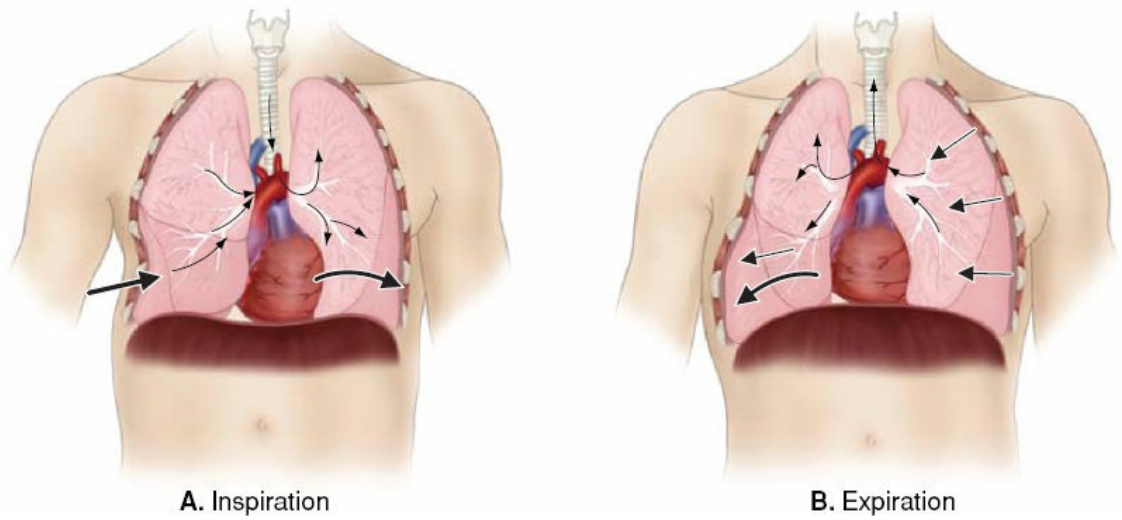

FIGURE 10-12 Flail chest is caused by a free-floating segment of rib cage resulting from multiple rib fractures. A. Paradoxical movement on inspiration occurs when the flail rib segment is sucked inward and the mediastinal structures shift to the unaffected side. The amount of air drawn into the affected lung is reduced. B. On expiration, the flail segment bulges outward, and the mediastinal structures shift back to the affected side.

Medical and Nursing Management

As with rib fracture, treatment of flail chest is usually supportive. Management includes providing ventilatory support, clearing secretions from the lungs, and controlling pain. Specific management depends on the degree of respiratory dysfunction. If only a small segment of the chest is involved, the objectives are to clear the airway through positioning, coughing, deep breathing, and suctioning to aid in the expansion of the lung, and to relieve pain by intercostal nerve blocks, high thoracic epidural blocks, or cautious use of IV opioids.

For mild to moderate flail chest injuries, the underlying pulmonary contusion is treated by monitoring fluid intake and appropriate fluid replacement while relieving chest pain. Pulmonary physiotherapy focusing on lung volume expansion includes deep breathing exercises, IS, and nebulized bronchodilators and mucolytics.

For severe flail chest injuries, endotracheal intubation and mechanical ventilation are required to provide internal pneumatic stabilization of the flail chest and to correct abnormalities in gas exchange. This helps treat the underlying pulmonary contusion, serves to stabilize the thoracic cage to allow the fractures to heal, and improves alveolar ventilation and intrathoracic volume by decreasing the work of breathing. In rare circumstances, surgery may be required to more quickly stabilize the flail segment.

Regardless of the type of treatment, the patient is carefully monitored by serial chest x-rays, ABG analysis, POX, and bedside pulmonary function monitoring. Pain management is key to successful treatment. Patient-controlled analgesia, intercostal nerve blocks, epidural analgesia, and intrapleural administration of opioids may be used to relieve or manage thoracic pain.

PULMONARY CONTUSION

Pulmonary contusion is a common thoracic injury and is frequently associated with blunt trauma. It is defined as damage to the lung tissues resulting in hemorrhage and localized edema (i.e., bruised lung). Pulmonary contusion represents a spectrum of lung injury characterized by the development of infiltrates and various degrees of respiratory dysfunction and sometimes respiratory failure. A contusion is sustained in up 64% of patients who experience blunt force trauma (Hammer et al., 2016). Pulmonary contusion may not be evident initially on examination but develops in the posttraumatic period; it may involve a small portion of one lung, a massive section of a lung, one entire lung, or both lungs.

Pathophysiology

The primary pathologic defect is an abnormal accumulation of fluid in the interstitial and intra-alveolar spaces. It is thought that injury to the lung parenchyma and its capillary network results in a leakage of serum protein and plasma. The leaking serum protein exerts an osmotic pressure that enhances loss of fluid from the capillaries. Blood, edema, and cellular debris (from cellular response to injury) enter the lung and accumulate in the bronchioles and alveoli, where they interfere with gas exchange. The patient has hypoxemia and carbon dioxide retention. Occasionally, a contused lung occurs on the other side of the point of body impact; this is called a *contrecoup contusion.*

Clinical Manifestations and Assessment

The clinical manifestations of pulmonary contusions can vary based on the severity of bruising and parenchymal involvement. The most common signs and symptoms are crackles, decreased breath sounds, or bronchial breath sounds in peripheral lung areas, dyspnea, tachypnea, tachycardia, chest pain, blood-tinged secretions, hypoxemia, and respiratory acidosis. Patients with moderate pulmonary contusions often have a constant, but ineffective cough and cannot clear their secretions. Patients with severe pulmonary contusion have the signs and symptoms of ARDS; these may include hypoxemia, dyspnea, agitation, combativeness, and productive cough with frothy, bloody secretions.

The efficiency of gas exchange is determined by POX and ABG measurements. Pulse oximetry is also used to measure oxygen saturation continuously. The initial chest x-ray may show no changes; changes may not appear for 1 or 2 days after the injury and appear as pulmonary infiltrates on chest x-ray.

Medical and Nursing Management

Treatment priorities include maintaining the airway, providing adequate oxygenation, and controlling pain. In mild pulmonary contusion, judicious hydration via IV fluids and oral intake is important to mobilize secretions. However, fluid intake must be monitored closely to avoid hypervolemia, which can worsen the contusion. Volume expansion techniques, postural drainage, physiotherapy including coughing, and endotracheal suctioning are used to remove the secretions. Pain is managed by intercostal nerve blocks or by opioids via patient-controlled analgesia or other methods. Usually supplemental oxygen is given by mask or cannula for hypoxemia (saturation less than 90%).

In patients with moderate pulmonary contusions, bronchoscopy may be required to remove secretions. Intubation and mechanical ventilation with PEEP may also be necessary to maintain the pressure and keep the lungs inflated. In patients with severe contusion, who may develop respiratory failure, aggressive treatment with endotracheal intubation and ventilatory support, diuretics, and fluid restriction may be necessary.

Antimicrobial medications may be prescribed for the treatment of pulmonary infection. This is a common complication of pulmonary contusion because the fluid and blood that extravasates into the alveolar and interstitial spaces serve as an excellent culture medium.

CARDIAC TAMPONADE

Cardiac tamponade is compression of the heart resulting from fluid or blood within the pericardial sac. It usually is caused by blunt or penetrating trauma to the chest. A penetrating wound of the heart is associated with a high mortality rate. Cardiac tamponade also may follow diagnostic cardiac catheterization, angiographic procedures, and pacemaker insertion, which can produce perforations of the heart and great vessels. Pericardial effusion with fluid compressing the heart also may develop from metastases to the pericardium from malignant tumors of the breast, lung, or mediastinum and may occur with lymphomas and leukemias, renal failure, TB, and high-dose radiation to the chest. Cardiac tamponade is discussed in detail in Chapter 15.

PNEUMOTHORAX

Pneumothorax occurs when the parietal or visceral pleura are punctured and the pleural space is exposed to positive atmospheric pressure. Normally, the pressure in the pleural space is negative or subatmospheric; this negative pressure is required to maintain lung inflation. When either pleura is breached, air enters the pleural space, and the lung or a portion of it collapses.

Types of Pneumothorax

Types of pneumothorax include simple, traumatic, and tension pneumothorax (Fig. 10-13).

Simple Pneumothorax

A simple, or spontaneous, pneumothorax most commonly occurs as air enters the pleural space through the rupture of a bleb or a bronchopleural fistula. A spontaneous pneumothorax may occur in an apparently healthy person (most commonly in young men) in the absence of trauma due to rupture of an air-filled bleb, or blister, on the surface of the lung, allowing air from the airways to enter the pleural cavity. It may also be associated with bullous lung diseases such as emphysema or pulmonary fibrosis.

Traumatic Pneumothorax

A traumatic pneumothorax occurs when air escapes from a laceration in the lung itself and enters the pleural space or enters the pleural space through a wound in the chest wall. It may result from blunt trauma, penetrating chest or abdominal trauma, or diaphragmatic tears. Traumatic pneumothorax may occur during invasive thoracic procedures (i.e., thoracentesis, transbronchial lung biopsy, insertion of a subclavian line) in which the pleura is punctured inadvertently or with barotrauma from mechanical ventilation. A traumatic pneumothorax resulting from major trauma to the chest is often accompanied by a hemothorax (collection of blood in the pleural space resulting from torn intercostal vessels, lacerations of the great vessels, or lacerations of the lungs). Often both blood and air are found in the chest cavity (hemopneumothorax) after major trauma.

Open pneumothorax is one form of traumatic pneumothorax. It occurs when a wound in the chest wall is large enough to allow air to pass freely in and out of the thoracic cavity with each attempted respiration. Because the rush of air through the wound in the chest wall produces a sucking sound, such injuries are termed *sucking chest wounds.*

Tension Pneumothorax

A tension pneumothorax occurs when air is drawn into the pleural space from a lacerated lung or through a small opening or wound in the chest wall. It may be a complication of other types of pneumothorax. In contrast to open pneumothorax, the air that enters the chest cavity with each inspiration is trapped; it cannot be expelled during expiration through the air passages or the opening in the chest wall. In effect, a one-way valve or ball valve mechanism occurs, where air enters the pleural space but cannot escape. With each breath, tension (positive pressure) is increased within the affected pleural space. This causes the lung to collapse and the heart, the great vessels, and the trachea to shift toward the unaffected side of the chest (mediastinal shift). Both respiration and circulatory function are compromised because of the increased intrathoracic pressure, which decreases venous return to the heart, causing decreased cardiac output and impairment of peripheral circulation. In extreme cases, cardiac arrest can occur.

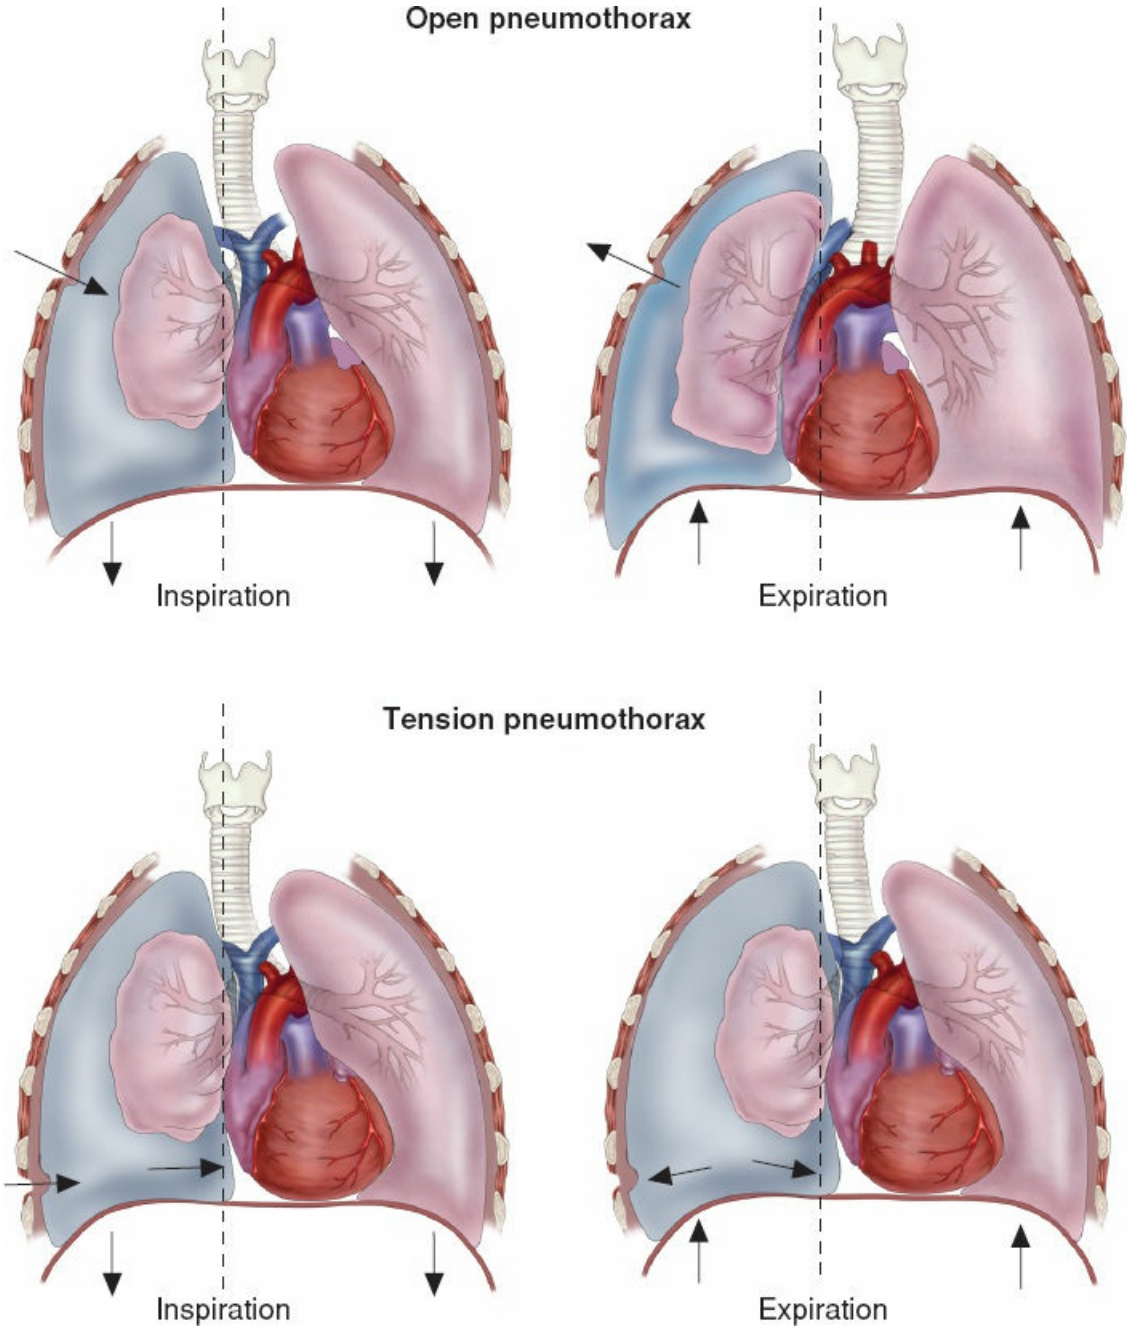

FIGURE 10-13 Open and tension pneumothorax.

Clinical Manifestations

The signs and symptoms associated with pneumothorax depend on its size and cause. Usually pain is sudden and may be pleuritic. The patient may have only minimal respiratory distress with slight chest discomfort and tachypnea with a small simple or uncomplicated pneumothorax. If the pneumothorax is large and the lung collapses totally, acute respiratory distress occurs. The patient is anxious, has dyspnea and air hunger, has increased use of the accessory muscles, and may develop severe hypoxemia. In assessing the chest for any type of pneumothorax, the nurse assesses tracheal alignment, expansion of the chest, and breath sounds, and percusses the chest. In a simple pneumothorax, the trachea is midline, expansion of the chest is decreased, breath sounds may be diminished, and percussion of the chest may reveal normal sounds or hyperresonance depending on the size of the pneumothorax. The nurse assesses the affected lung for crepitus or subcutaneous emphysema and notes the extent of it in the patient's record.

In a tension pneumothorax, the trachea may shift away from the affected side, chest expansion may be decreased or fixed in a hyperexpansion state, breath sounds are diminished or absent, and percussion to the affected side is hyperresonant. The clinical picture is one of air hunger, agitation, increasing hypoxemia, central cyanosis, hypotension, and tachycardia.

Medical and Nursing Management

Medical management of pneumothorax depends on its cause and severity. The goal of treatment is to evacuate the air or blood from the pleural space. A thoracostomy tube (chest tube) is used to evacuate any accumulated air or fluid. A small, simple pneumothorax is treated with a small chest tube (20 Fr, or 10–12 Fr pigtail catheter) inserted at the second intercostal space, at the midclavicular line. Larger pneumothoraxes, especially if there is fluid or blood present, are managed with larger-sized tubes (32–36 Fr) that are placed in the fourth or fifth intercostal space at the midaxillary line. The tube is directed posteriorly to drain the fluid and air. Once the chest tube or tubes are inserted and suction is applied (usually to –20 mm Hg suction), effective decompression of the pleural cavity (drainage of blood or air) occurs.

The severity of open pneumothorax depends on the amount and rate of thoracic bleeding and the amount of air in the pleural space. The pleural cavity can be decompressed by needle aspiration (thoracentesis) or by chest tube drainage of the blood or air. Then the lung is able to re-expand and resume the function of gas exchange. As a rule of thumb, the chest wall is opened surgically (thoracotomy) if more than 1,500 mL of blood is aspirated initially by thoracentesis (or is the initial chest tube output) or if chest tube output continues at greater than 200 mL/hr. The urgency with which the blood must be removed is determined by the degree of respiratory compromise. An emergency thoracotomy may also be performed in the emergency department if a cardiovascular injury secondary to penetrating trauma is suspected. The patient with a possible tension pneumothorax should be given a high concentration of supplemental oxygen immediately to treat the hypoxemia, and POX should be used to monitor oxygen saturation.

In an emergency situation, a tension pneumothorax can be decompressed or quickly converted to a simple pneumothorax by inserting a large-bore needle (14-gauge) at the second intercostal space, midclavicular line on the affected side. This relieves the pressure and vents the positive pressure to the external environment. A chest tube is then inserted and connected to suction to remove the remaining air and fluid, reestablish the negative pressure, and re-expand the lung. If the lung re-expands and air leakage from the lung parenchyma stops, further drainage may be unnecessary. If a prolonged air leak continues despite chest tube drainage to underwater seal, surgery may be necessary to close the leak. A plan of nursing care for the patient after thoracotomy is available online at http://thepoint.lww.com/Honan2e.

SUBCUTANEOUS EMPHYSEMA

No matter what kind of chest trauma a patient has, when the lung or the air passages are injured, air may enter the tissue planes and pass for some distance under the skin (e.g., neck, chest). The tissues give a crackling sensation when palpated, and the subcutaneous air produces an alarming appearance as the face, neck, body, and scrotum become misshapen by subcutaneous air. Fortunately, subcutaneous emphysema in and of itself usually is not a serious complication. The subcutaneous air is absorbed spontaneously if the underlying air leak is treated or stops spontaneously. In severe cases, in which there is widespread

subcutaneous emphysema, a tracheostomy is indicated if airway patency is threatened.

ASPIRATION

Aspiration of stomach contents into the lungs is a serious complication that can cause pneumonia and result in the clinical picture of tachycardia, dyspnea, hypoxemia, hypertension, hypotension, and, finally, death. It can occur when the protective airway reflexes are decreased or absent due to a variety of factors.

Pathophysiology

The primary factors responsible for death and complications after aspiration of gastric contents are the volume and character of the aspirated gastric contents. For example, a small, localized aspiration from regurgitation can cause pneumonia and acute respiratory distress; a massive aspiration is usually fatal. Factors that increase the risk of aspiration are discussed in Box 10-13.

A full stomach contains food particles. If these are aspirated, the problem then becomes one of mechanical blockage of the airways and secondary infection or chemical pneumonitis. During periods of fasting, the stomach contains acidic gastric juice, which, if aspirated, can be very destructive to the alveoli and capillaries. Fecal contamination (more likely seen in intestinal obstruction) increases the likelihood of death because the endotoxins produced by intestinal organisms may be absorbed systemically, or the thick proteinaceous material found in the intestinal contents may obstruct the airway, leading to atelectasis and secondary bacterial invasion.

Aspiration pneumonitis may develop from aspiration of gastric contents, which can also cause a chemical burn of the tracheobronchial tree and pulmonary parenchyma. An ensuing inflammatory response occurs. This results in the destruction of alveolar–capillary endothelial cells, with a consequent outpouring of protein-rich fluids into the interstitial and intra-alveolar spaces. As a result, surfactant is lost, which, in turn, causes the airways to close and the alveoli to collapse. Finally, the impaired exchange of oxygen and carbon dioxide causes respiratory failure.

BOX 10-13 Risk Factors for Aspiration

- Altered level of consciousness (cerebrovascular accident, head trauma, intracranial mass/tumor, drug overdose, alcohol intoxication, seizures, oversedation)
- Neurologic disorders (Parkinson disease, myasthenia gravis, multiple sclerosis, amyotrophic lateral sclerosis)
- Dysphagia (esophageal stricture, diverticula or neoplasm, tracheoesophageal fistula, cardiac sphincter incompetence, achalasia [lack of the lower esophageal sphincter to relax, preventing food from passing into the stomach])
- Altered airway or oropharyngeal anatomy (head and neck malignancy, surgery and/or radiation therapy to head and neck)
- Disruption via mechanical instruments (endotracheal intubation, tracheostomy, naso-/orogastric tube [any size], bronchoscopy, laryngoscopy, upper GI endoscopy)
- Recumbent position
- Protracted vomiting
- Nasogastric feeding
- Gastric outlet obstruction

Aspiration pneumonia develops after inhalation of colonized oropharyngeal material.

The pathologic process involves an acute inflammatory response to bacteria and bacterial products. Most commonly, the bacteriologic findings include gram-positive cocci, gram-negative rods, and, occasionally, anaerobic bacteria.

Prevention

Prevention is the primary goal when caring for patients at risk for aspiration. Examples of risk factors for aspiration include decreased level of consciousness, supine positioning, presence of a nasogastric tube, tracheal intubation and mechanical ventilation, and advanced age (Christiani, 2016). Evidence confirms that one of the main preventive measures for aspiration is placing at-risk patients in a semirecumbent position (elevation of the head of the bed to a 30- to 45-degree angle) (American Association of Critical Care Nurses [AACN], 2016).

Compensating for Absent Reflexes

Aspiration may occur if the patient cannot adequately coordinate protective glottic, laryngeal, and cough reflexes. This hazard is increased if the patient has a distended abdomen, is supine, has the upper extremities immobilized by IV infusions or hand restraints, receives local anesthetics to the oropharyngeal or laryngeal area for diagnostic procedures, has been sedated, or has had long-term intubation.

When vomiting, people can normally protect their airway by sitting up or turning on the side and coordinating breathing, coughing, gag, and glottic reflexes. If these reflexes are active, an oral airway should not be inserted. If an airway is in place, it should be pulled out the moment the patient gags so as not to stimulate the pharyngeal gag reflex and promote vomiting and aspiration. Suctioning of oral secretions with a catheter should be performed with minimal pharyngeal stimulation.

In addition, using the smallest effective level of sedation is prudent in patients at risk for aspiration.

Assessing Feeding Tube Placement

When a patient is intubated, aspiration may occur even with a nasogastric tube in place and may result in nosocomial pneumonia. Assessment of nasogastric tube placement is key to the prevention of aspiration. The best method for determining tube placement is via an x-ray taken immediately after an enteral feeding tube is placed and prior to beginning feeds. Nurses should mark the place where the tube exits the nares or lips and note this in the patient's chart. This marking should be assessed whenever medication is administered via the tube or at least every 4 hours. Other methods of tube confirmation have been studied, such as observation of the aspirate color, testing of its pH or glucose content, and auscultation over the stomach for an air bolus. None of these methods has been shown to accurately assess the placement of the tube (AACN, 2016). A combination of methods is recommended: assessment of the patient's tolerance to medication and feeding administration (noting abdominal distention and complaints of abdominal pain, observing for passage of flatus and stool) as well as measurement of tube length, while assessing the pH measurement of aspirate remains an area where further research is warranted. It is important for the nurse to understand that where research is ongoing, he or she should follow institutional procedures. Refer to the AACN Prevention of Aspiration Practice Alert (with AACN Levels of Evidence and complete reference list).

Patients who receive continuous or timed-interval tube feedings must be positioned

properly. Patients receiving continuous infusions are given small volumes under low pressure in an upright position, which helps prevent aspiration. Patients receiving tube feedings at timed intervals are maintained in an upright or semirecumbent position (elevation of the head of the bed to a 30- to 45-degree angle) during the feeding and for a minimum of 30 minutes afterward to allow the stomach to empty partially. Because there is controversy over the assessment of gastric residual volume (GRV) since research does not demonstrate prevention of early detection of feeding intolerance or aspiration (McClave et al., 2016), the nurse should follow institutional procedures related to GRV. Tube feedings must be given only when it is certain that the feeding tube is positioned correctly in the stomach or in the small bowel. Many patients today receive enteral feeding directly into the small intestine through a small-bore flexible feeding tube or surgically implanted tube. Feedings are given slowly and are regulated by a feeding pump (refer to Chapter 22 for more details). The nurse should be aware that the results of routine chest and abdominal x-ray will report tube location.

CHAPTER REVIEW

Critical Thinking Exercises

1. You are caring for an 82-year-old woman who was recently transferred to the hospital from a nursing home with the diagnosis of presumed health care–associated pneumonia. She has a gastrostomy feeding tube in place and is lethargic, dehydrated, and confused. What strategies would you initiate to prevent aspiration? What nursing care interventions would you use to assess for aspiration? What is the evidence base for the interventions that you consider? How will you evaluate the strength of the evidence? What suggestions might you have regarding appropriate devices for long-term enteral feeding in this patient once she is discharged back to the nursing home?

2. On a surgical unit, you are caring for a 42-year-old woman who underwent a total abdominal hysterectomy and bilateral salpingo-oophorectomy and has developed a postoperative DVT that resulted in a PE. She is a smoker and is taking multiple medications. She was stable when you started your shift, but she has become increasingly anxious with some shortness of breath in the past hour. What are potential risk factors you might observe or identify in this patient? What assessment strategies would you use to evaluate changes in her respiratory status? What decision process would you use to determine when the provider should be contacted?

3. You are caring for a patient who experienced blunt chest trauma in an MVA. A chest tube has been inserted to treat a simple pneumothorax and hemothorax. The chest drainage system has drained 400 mL of light red fluid during the first 6 hours after insertion. The patient has become increasingly short of breath during the past hour. You note that there is no longer an air leak noted in the water-seal chamber. What physical assessment skills and strategies would you use to determine potential changes in the patient's respiratory condition? What are potential causes of this increasing shortness of

breath? What would you do to prepare for an emergency situation in this patient?

4. On a surgical unit, you are caring for a 62-year-old man who has undergone right upper lobectomy for lung cancer. The patient has COPD and has continued to smoke despite the diagnoses of COPD and lung cancer. What strategies would you use to prevent or minimize pulmonary complications in this patient? What are the methods you might use to assess the patient's progress from a respiratory standpoint? What strategies would you consider to encourage the patient to stop smoking? What is the evidence base for the strategies that you consider? How will you evaluate the strength of the evidence?

NCLEX-Style Review Questions

1. The nurse is caring for a client diagnosed with ARDS. In evaluating the use of PEEP, what outcome would the nurse expect to find?
   a. Increased ventilation–perfusion mismatch
   b. Increased FRC
   c. Decreased intrathoracic pressure
   d. Decreased FRC

2. A nurse working on a general medical-surgical floor is discussing the clinical manifestations of pulmonary arterial hypertension (PAH) with a recent nursing graduate. What is the main symptom of PAH that the nurse would explain?
   a. Chest pain
   b. Fatigue
   c. Dyspnea
   d. Hemoptysis

3. A patient is receiving thrombolytic therapy for treatment of a pulmonary emboli. For what side effect should the nurse must monitor the patient?
   a. Chest pain
   b. Rash
   c. Hyperthermia
   d. Bleeding

4. A nurse is caring for a patient diagnosed with lung cancer who has a chest tube. The chest tube has continuous bubbling in the water-seal chamber. What does the nurse understand that this indicates?
   a. Tidaling
   b. The tube in the mediastinum
   c. A properly functioning system
   d. An air leak in the system

5. The nurse is assessing a patient with a blunt chest trauma due to an MVA. What finding would be indicative of a flail chest?

a. Hypertension
b. Metabolic alkalosis
c. Paradoxical chest movement
d. Respiratory alkalosis

CHAPTER 11

Nursing Management of Patients Diagnosed with Chronic Obstructive Pulmonary Disease and Asthma

Margaret Campbell Haggerty

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the pathophysiology of chronic obstructive pulmonary disease (COPD).
2. Discuss the major risk factors for developing COPD and interventions used to minimize or prevent these risk factors.
3. Use the nursing process as a framework for care of patients with COPD.
4. Develop a teaching plan for patients with COPD.
5. Describe the pathophysiology of asthma.
6. Discuss the medications used in asthma management.
7. Describe asthma self-management strategies.

Chronic obstructive pulmonary disease (COPD) and asthma are the most common chronic pulmonary disorders. Nurses working with patients with these chronic pulmonary diseases care for them across the spectrum of care, from outpatient and home care to emergency, inpatient, and critical care and, finally, in the hospice setting. Patients with COPD and asthma need care from nurses who not only have astute assessment and clinical management skills but who also understand how these disorders can affect quality of life. In addition, the nurse's knowledge of palliative and end-of-life care is important for affected patients. Patient and family teaching is an important nursing intervention to enhance self-management in patients with any chronic pulmonary disorder.

COPD

Chronic obstructive pulmonary disease (COPD) is a disease state characterized by chronic airflow limitation that is not fully reversible. The airflow limitation in COPD is usually progressive and is associated with an inflammatory response of the lungs (GOLD, 2015).

An estimated 13.7 million Americans have the diagnosis of COPD. The actual incidence of COPD is thought to be much higher as many cases are undiagnosed. COPD is the fourth leading cause of death in the United States; more women than men die from COPD. In addition, COPD is a major cause of morbidity and accounts for an annual cost estimated to be nearly $50 billion, including health care expenditures, mortality costs, lost work days, and other indirect costs (Ford et al., 2013; COPD Fast Stats, 2015).

Pathophysiology

The pathologic changes that characterize COPD are complex and include changes to the airways, lung parenchyma, and pulmonary vasculature (GOLD, 2015). Increased levels of proinflammatory cytokines that result in small airway injury, an imbalance between mediators that promote inflammation and those that protect lung tissue and increased airway hyperresponsiveness, are among the pathophysiologic changes that occur (Hoepers, Menezes, & Frode, 2015). Inflammation and narrowing of peripheral airways lead to a loss of pulmonary function, specifically FEV_1 (forced expired volume in one second). Destruction of the lung parenchyma results in emphysematous changes and contributes to airflow limitation and impaired gas exchange.

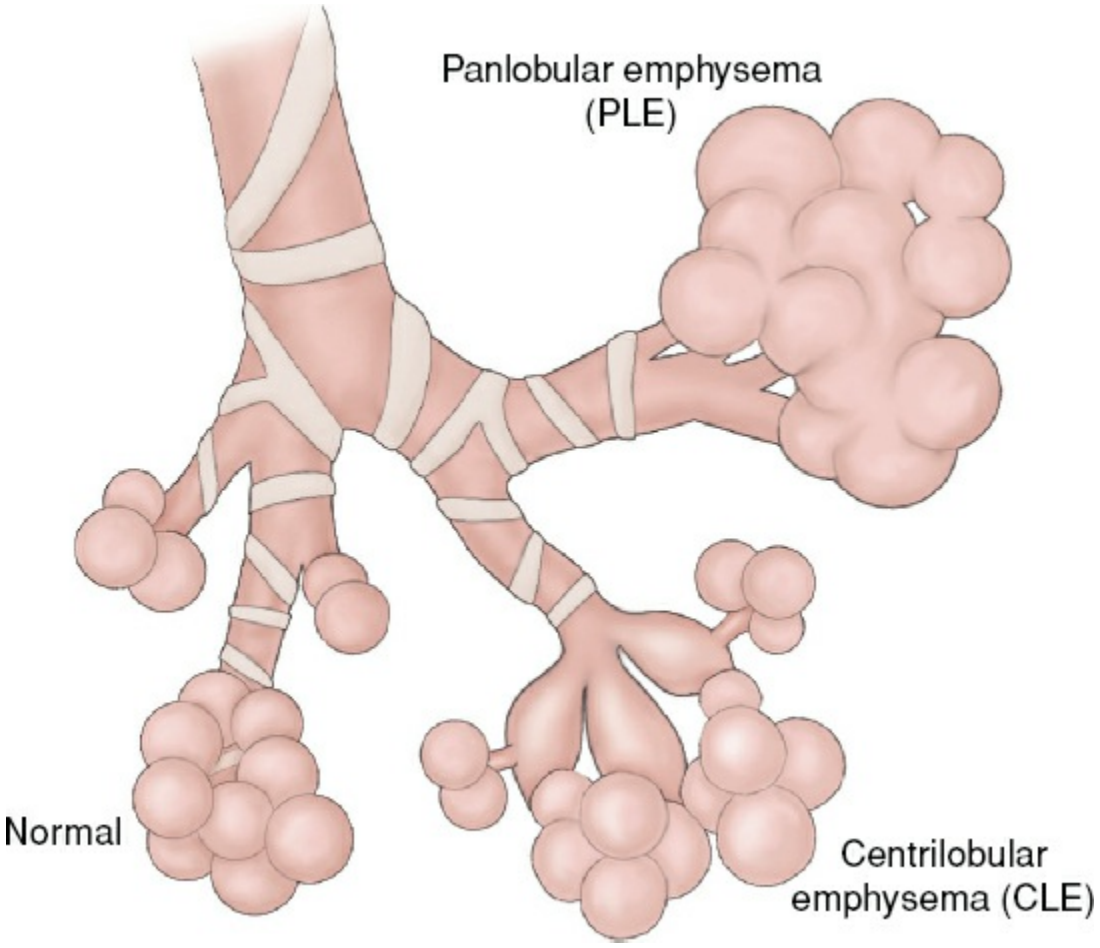

FIGURE 11-1 Changes in the alveolar structure in centrilobular and panlobular emphysema. In panlobular emphysema, the bronchioles, alveolar ducts, and alveoli are destroyed, and the airspaces within the lobule are enlarged. On centrilobular emphysema, the pathologic changes occur in the lobule, whereas the peripheral portions of the acinus are preserved.

Nursing Alert

Normally, 80% or more of the expiratory volume can be expelled in 1 second. Obstructive lung disease is defined as a postbronchodilator FEV_1/FVC (forced expired volume in one second as a ratio of forced vital capacity [volume of lungs from

full inspiration to forced maximal expiration that is expressed as a percentage of the predicted normal for a person]) ratio of less than 70%. The patient demonstrates a degree of reversibility if the pulmonary function values improve significantly (more than 12%) after administration of the bronchodilator. Usually patients who demonstrate complete reversibility to normal values are diagnosed with asthma. Patients who demonstrate some reversibility that does not reach normal values may be diagnosed with COPD with some reversible component or an overlap of COPD and asthma.

Emphysema is a pathologic term that describes an abnormal enlargement of the airspaces beyond the terminal bronchioles with destruction of the walls of the alveoli (parenchymal destruction) (Fig. 11-1). Chronic bronchitis, a disease of the airways, is defined as the presence of cough and sputum production for at least 3 months in each of 2 consecutive years. Chronic mucus hypersecretion has been implicated as a cause of lung function decline, exacerbations, and infections. Thickening of the epithelium, smooth muscle hypertrophy, and airway inflammation are implicated in remodeling of the airways (Fig. 11-2). Emphysema and chronic bronchitis may exist in patients with normal lung function and in patients with COPD (GOLD, 2015).

In the later stages of COPD, gas exchange is often impaired. As the alveolar walls continue to break down, the pulmonary capillary bed is reduced in size. Resistance to pulmonary blood flow is increased, forcing the right ventricle to maintain a higher and a higher pressure in the pulmonary artery. Chronic hypoxemia (low oxygen) increases pulmonary artery pressures and can lead to pulmonary hypertension. This higher pressure in the pulmonary artery results in right ventricular hypertrophy. Ultimately, cor pulmonale, or right ventricular failure, can occur. In addition, decreased carbon dioxide elimination results in increased carbon dioxide tension in arterial blood (hypercapnia) and leads to respiratory acidosis and chronic respiratory failure. In acute illness, worsening hypercapnia can lead to acute respiratory failure. COPD is considered a systemic disease and may affect skeletal muscle as well as the functioning of the cardiovascular, neurologic, psychiatric, and endocrine systems.

Risk Factors

The risk factors for the development for COPD are outlined in Box 11-1. The most important risk factor is tobacco smoking (cigarettes, pipe, cigar, water pipe, marijuana). Environmental tobacco smoke (ETS), also known as secondhand smoke, is also a risk factor for the development of COPD. The effects of cigarette smoke are complex and lead to the development of COPD in approximately 15% to 20% of smokers. Many experts now think the incidence may be as high as 30% to 50% in smokers (GOLD, 2015). Tobacco smoke irritates the airways and, in susceptible individuals, results in mucus hypersecretion and airway inflammation.

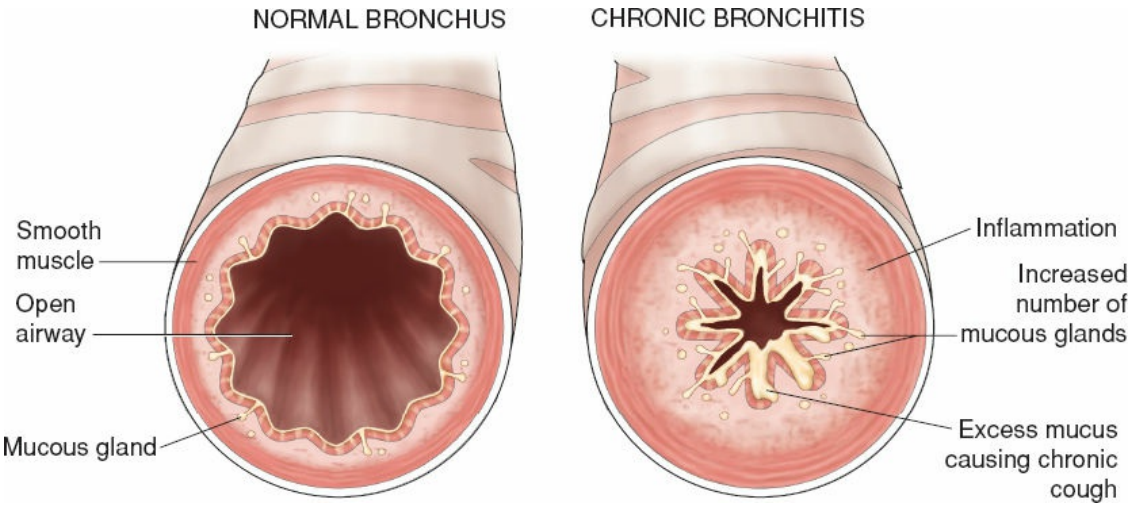

FIGURE 11-2 Pathophysiology of chronic bronchitis as compared to a normal bronchus. The bronchus in chronic bronchitis is narrowed and has impaired air flow due to multiple mechanisms: inflammation, excess mucus production, and potential smooth muscle constriction (bronchospasm).

BOX 11-1 Known Risk Factors for Chronic Obstructive Pulmonary Disease

- Tobacco smoke (cigarette, pipe, cigar, water pipe, marijuana)
- Environmental tobacco smoke
- Genetic factors, e.g., severe inherited alpha-1 antitrypsin deficiency
- Exposure to particles: organic and inorganic dusts, open fires from wood, animal dung, crop residue, and coal
- Biomass cooking in poorly ventilated areas

Possible Risk Factors

- Poverty
- Asthma/bronchial hyperreactivity
- Chronic bronchitis/mucus hypersecretion
- Severe respiratory infections in childhood

Fetuses exposed to maternal smoking in utero have impaired lung development and may go on to develop COPD later in life. Biomass (open fire) cooking and heating in poorly ventilated areas is a major risk factor for the development of COPD in third world nations. Other factors that put people at risk for COPD include prolonged and intense exposure to occupational dusts and chemicals, a history or respiratory infections as a child, and outdoor air pollution. (GOLD, 2015).

A host risk factor for COPD is a deficiency of an enzyme inhibitor that protects the lung parenchyma from injury: alpha$_1$-antitrypsin. Alpha$_1$-antitrypsin deficiency affects approximately 1 in every 3,000 Americans and accounts for approximately 80,000 to 100,000 cases of COPD (Izaguiree, 2014). Genetically susceptible people are more sensitive to environmental factors (e.g., smoking, air pollution, infectious agents, allergens) and have a higher risk of developing chronic obstructive symptoms. Not all smokers get COPD, but it does occur more frequently in families. Studies to identify other genetic factors that may be associated with COPD are as yet inconclusive (GOLD, 2015).

Clinical Manifestations and Assessment

COPD is characterized by three primary symptoms: dyspnea, chronic cough, and sputum production. Dyspnea is defined as an awareness of uncomfortable breathing that may vary in intensity. It often starts as mild and is noticed only with vigorous activities, such as stair-climbing and playing sports. As the disease progresses, dyspnea may become severe and often interferes with the person's activities of daily living. In more severe cases of COPD, dyspnea can occur at rest. Chronic cough and sputum production often precede the development of airflow limitation by many years. In early stage disease, the person may note an early morning cough productive of a small to moderate amount of white to clear sputum. During exacerbations, an increase in the amount and viscosity of sputum may occur, and the sputum may change color.

COPD is diagnosed based on history, physical examination, and pulmonary function testing. A positive history of progressive dyspnea and/or a productive cough in a cigarette smoker leads to a suspicion of COPD. Smoking history is usually expressed as "pack/years": the number of packs smoked per day times the number of years of smoking. A person who has smoked an average of 2 packs per day for 20 years has a smoking history of 40 pack/years.

Physical examination findings may be near normal in those with beginning and sometimes moderate disease. Findings consistent with more advanced COPD may include signs of hyperinflation: an increased anterior to posterior diameter of the chest, referred to as "barrel chest"; bilateral intercostal retractions at the posterior axillary line; horizontal fixation of the ribs in the inspiratory position; and hyperresonance to percussion, particularly in thin individuals. Breath sounds may be diminished; prolonged exhalation (bronchovesicular breath sounds) is usually heard throughout the chest; often adventitious sounds (coarse crackles and wheezes) are heard when the patient has increased secretions or bronchial hyperreactivity as well as during an exacerbation.

Pulmonary function studies are used to help confirm the diagnosis, determine disease severity, and monitor disease progression. Spirometry is used to evaluate airflow obstruction. Spirometry results are expressed as an absolute value and as a percentage of the predicted value using appropriate normal values for gender, race, age, weight, and height. With obstruction, the patient has difficulty exhaling or cannot forcibly exhale air from the lungs, reducing the FEV_1. Obstructive lung disease is defined as a postbronchodilator FEV_1/FVC ratio of less than 70%. The lower the FEV_1, the more severe the disease process.

Bronchodilator reversibility testing may be performed to rule out asthma and to guide initial treatment. Spirometry is first obtained; the patient is given an inhaled bronchodilator and spirometry is repeated. The patient demonstrates a degree of reversibility if the pulmonary function values improve significantly (more than 12%) after administration of the bronchodilator. Usually patients who demonstrate complete reversibility to normal values are diagnosed with asthma. Patients who demonstrate some reversibility that does not reach normal values may be diagnosed with COPD with some reversible component or an overlap of COPD and asthma. Patients who do not show a significant response to a bronchodilator test still may be given a trial of bronchodilator treatment to determine if it

helps relieve symptoms. Additional tests of pulmonary function include total lung capacity (TLC) and diffusion capacity. These tests are used to diagnose coexisting restrictive disease, in which the lung is restricted from filling to its normal capacity of air, and to help predict the contribution of emphysematous changes in the diagnosis.

Arterial blood gas (ABG) measurements may be obtained to assess baseline oxygenation and gas exchange and are especially important in advanced COPD. In addition, a chest x-ray may be obtained to establish the patient's baseline and to exclude alternative diagnoses. A chest x-ray is seldom diagnostic in COPD unless obvious bullous disease or severe hyperinflation is present. Chest x-rays are more commonly used in exacerbations to determine if the patient has an infiltrate or a concomitant lung mass. A computed tomography (CT) scan is not routinely obtained in the diagnosis of COPD, but a high-resolution CT scan may help in the differential diagnosis or to evaluate patients for surgical procedures such as bullectomy or lung-volume reduction surgery (LVRS). Screening for alpha$_1$-antitrypsin deficiency is usually recommended for symptomatic patients younger than 45 years and for those with a strong family history of COPD.

Different methods are used to classify COPD by stages depending on severity. The updated GOLD guidelines include lung function measurement and exacerbation history to stage patients. Staging is used to determine prognosis, guide therapy, and to develop research protocols. In mild disease, the patient may be asymptomatic. As lung function (FEV_1/FVC%) declines, symptoms start to appear. The more severe the decline in lung function is, the more severe the COPD. When the FEV_1 is less than 50% predicted, COPD is classified as severe. Other factors that determine prognosis include history cigarette smoking in terms of pack/years, continued cigarette smoking, passive smoking exposure, age, rate of decline of FEV_1, hypoxemia, pulmonary artery pressure, resting heart rate, weight loss, number of exacerbations, and reversibility of airflow obstruction. Staging severity serves as a guideline to treatment protocols, but variation occurs depending on the patient characteristics, comorbid conditions, and response to interventions.

The differential diagnosis of COPD includes: asthma, heart failure, bronchiectasis (abnormal widening of the bronchi or their branches, causing a risk of infection), tuberculosis, lung cancer, and bronchiolitis (inflammation of the bronchioles). These conditions may also coexist with COPD, and as many as 66% of patients have one comorbidity. Cardiac disease, peripheral atherosclerosis, stroke, diabetes mellitus, arthritis, malignancy, anxiety, and depression are common comorbid conditions. Phenotypes or overlap syndromes that are heterogeneous and usually disease manifestations are worse than when each disease is considered separately. Recent reports include COPD linked to asthma, obstructive sleep apnea, pulmonary fibrosis, bronchiectasis, and heart failure (see Box 11-2).

BOX 11-2 COPD, Common Co-existing Disorders with Overlap of Clinical Presentation

- COPD/Asthma overlap syndrome (ACOS) (Papaiwannou et al., 2014)
- Combined pulmonary fibrosis and emphysema syndrome (Portillo & Morera, 2012)
- Sleep-disordered breathing and COPD: the overlap syndrome (Owens & Malhota,

2012)

- Bronchiectasis phenotype (Martinez-Garcia et al., 2015)

Medical Management

The goals of medical therapy are to stabilize, manage, and monitor the disease; reduce symptoms; assess and reduce exacerbation risk and rate; promote maximal functional ability; prevent premature disability; assist the individual to adapt to the handicap caused by the disorder and limit adverse prognosis as the disease progresses. The management of the patient depends on the severity of the COPD. In early-stage disease, clinical strategies are aimed at maximizing pulmonary function, keeping the patient active, preventing exacerbations, and engaging the patient in self-management. In progressive stages, more intensive therapies are added. In very late-stage disease, palliative care should be considered (see Fig. 11-3).

Stabilizing Disease Progression

Smoking cessation slows the accelerated decline in lung function and the progression of COPD (GOLD, 2015). Factors associated with continued smoking vary among patients and may include the strength of the nicotine addiction, continued exposure to smoking-associated stimuli (at work or in social settings), stress, depression, and habit.

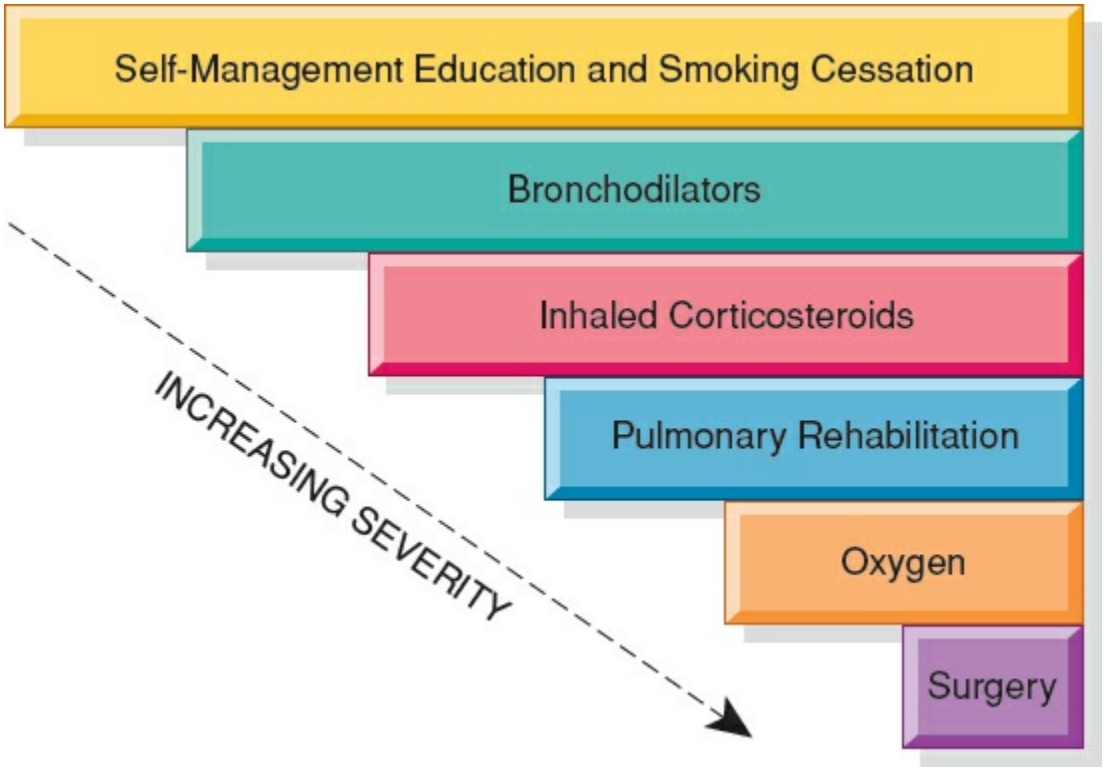

FIGURE 11-3 Treatment options for COPD. (Redrawn from *Breathing better with a COPD diagnosis,* U.S. Department of Health and Human Services, NIH publication No. 07-5841.)

Because multiple factors are associated with continued smoking, successful cessation often requires multiple strategies. Health care providers should promote cessation by explaining the risks of smoking and personalizing the "at-risk" message to the patient. Encouraging the patient to set a definite "quit date" is associated with more successful

smoking cessation. Brief counseling may work for many smokers; referral to a smoking cessation program may be helpful for those unable to quit on their own. Follow-up from the nurse within a few days after the established "quit date" is associated with an increased rate of success; the nurse can review progress and address any problems with the patient. Continued reinforcement with telephone calls or clinic visits is also beneficial. Relapses should be analyzed, and the patient and health care provider should jointly identify possible solutions to prevent future backsliding.

Pharmacotherapy increases long-term smoking abstinence rates when used in conjunction with smoking cessation counseling. Nicotine replacement (gum, inhaler, nasal spray, transferal patch, sublingual tablet, or lozenges) may be used as a single agent or in combination with other pharmacologic agents. Antidepressants such as bupropion SR (Zyban®, Wellbutrin®) and nortriptyline also have been shown to increase long-term quit rates. Bupropion is particularly useful in those concerned with weight gain during smoking abstinence as it may result in weight loss.

Drug Alert!
Bupropion is contraindicated in patients with a history of seizures as it may lower the seizure threshold.

Varenicline (Chantix®) reduces nicotine withdrawal symptoms and has been associated with increased quit rates. Electronic cigarettes, or "e-cigarettes, produced by a variety of manufactures are usually battery-operated devices that vaporize a mist of nicotine to the user. They have been used by some smokers when trying to quit. The Federal Drug Administration (FDA) has limited authority to regulate e-cigarettes as long as they are marketed as therapeutic. Concerns over unregulated additives that are potentially toxic and conflicting reports about efficacy exist. In addition, e-cigarettes may promote tobacco smoking in previous nonsmokers. A position statement issued by the multinational Forum of International Respiratory Societies (Schraufnagel et al., 2014) recommends banning or more closely regulating these products until more safety information becomes available.

Smoking cessation can begin in a variety of health care settings: outpatient clinics, pulmonary rehabilitation, community health programs, and hospitals as well as in the home. Regardless of the setting, nurses have the opportunity to teach patients about the risks of smoking and the benefits of smoking cessation. Various materials, resources, and programs developed by several organizations (e.g., Agency for Healthcare Research and Quality, U.S. Public Health Service, CDC, National Cancer Institute, American Lung Association, American Thoracic Society, American Cancer Society) are available to assist with this effort. Online programs may be useful to some smokers. One such program is "the ex" plan, which can be found at BecomeAnEX.org. Box 11-3 outlines a smoking cessation approach that incorporates the current concepts in a concise outline.

Pharmacologic Therapy

Pharmacologic agents are an important part of the treatment of COPD and fall into several categories.

Bronchodilators

Bronchodilators relieve bronchospasm, reduce airway obstruction, and aid in secretion clearance. The most frequently used classes of bronchodilators include sympathomimetics, also called beta adrenergic (both short and long acting); anticholinergics, also called muscarinic antagonists (both short and long term), or a combination of the two agents. Methylxanthines, for example, theophylline-like medications, are used less frequently than in the past but may still be useful for some patients. The methylxanthines that are currently available have a narrow therapeutic range and have serious side effects. They are often used as a third-line agent when other bronchodilators don't completely control symptoms.

Bronchodilators are usually delivered by the inhaled route (metered dose inhalers, dry powder inhalers [DPIs], or by nebulization). Oral forms of bronchodilators are rarely given because of side effects. Long-acting sympathomimetics (also known as LABAs or long-acting beta adrenergics) and anticholinergic bronchodilators (also known as LAMAs or long-acting muscarinic antagonists) are considered maintenance medications and are usually administered on a regular basis. Short-acting sympathomimetics (also known as SABAs or short-acting beta adrenergics) are most often used on an as-needed basis to help with dyspnea and secretion clearance. SABAs may be used prophylactically, before the patient participates in dyspnea-producing activity such as eating or walking. Short-acting muscarinic antagonists (SAMAs) are sometimes used for quick relief.

Corticosteroids

Inhaled and systemic corticosteroids (oral or intravenous) may also be used in COPD. Systemic steroids are usually reserved for acute exacerbations and for those with severe symptoms that do not respond adequately to bronchodilators. Long-term treatment with oral corticosteroids is associated with an increased incidence of side effects, some of which are serious (hyperglycemia, osteoporosis). Inhaled corticosteroids may be used alone by inhaler devices or in combination with LABAs and/or LAMAs. Patients should be instructed to rinse and gargle after using inhaled steroid preparations to decrease the risk of oral thrush. An association between inhaled corticosteroids and pneumonia has been shown. Most clinicians reserve their use for those with more severe disease.

BOX 11-3 Health Promotion

Quitting Smoking: Help for the Smoker

Cigarette smoking has long been known to damage the heart, lungs, and other organs of the body. Cancer, problems with circulation, and premature wrinkling are among its other effects. Cigar, pipe, and marijuana smoke are also known to be harmful. Smoking is the single most preventable cause of premature death and disability. Quitting smoking increases your chance of living a longer, healthier life. Here are some tips for helping you quit.

- *Determine your readiness to quit: how motivated are you?*
  - Have you set a date to quit? A willingness to set a quit-date within 2 weeks indicates good motivation for quitting.
  - Can you list your reasons for wanting to quit? Health, saving money, feeling

control over your habits, smelling better, and setting an example for others are some reasons for quitting. Make your reasons for quitting personal.
    - What obstacles do you anticipate?
    - Have you prepared for quitting?
        - Throw away all smoking-related materials: cigarettes, ashtrays, lighters
        - Make a plan for dealing with smoking urges
- *Develop an action plan.*
    - For immediate urges to smoke: practice the "4 Ds"
        - *Delay*: the urge to smoke will lessen in 3 minutes whether or not you have a cigarette
        - *Deep breathe*: take several deep breaths when the urge strikes to help take the edge off
        - *Drink water*: it helps to clear out the nicotine faster
        - *Do something else*: distraction helps you ignore the urges to smoke
    - Change your Thinking: remind yourself that you are choosing to become a nonsmoker and that it takes active work to do so
    - Reward Yourself for Not Smoking: set aside the money you would have spent on cigarettes and buy yourself something as a reward
- *Discuss the need for nicotine replacement or other medications.*
    - Many smokers are much more successful in quitting with the assistance of medications like Zyban™, Chantix™, and/or one of the nicotine replacement products (patch, gum, inhaler, nasal spray, or lozenge). Discuss this with your health care provider.
- *Don't give up if you have a slip or relapse.*
    - Many people need several tries at quitting before they are successful. Keep at it, and you will be successful.
- *Seek help if trying to quit on your own hasn't worked.*
    - Find a local stop smoking program in your area. Your PCP, local hospital, visiting nurse, or Lung Association may know of a local program.

Adapted from the Norwalk Hospital Patient Education Guidelines.

Medication regimens used to manage the symptoms of COPD are based on disease, symptom severity, and risk for exacerbation. For mild COPD, a short-acting bronchodilator is usually prescribed for symptom relief. For moderate to severe COPD, a short-acting bronchodilator along with regular treatment with a LABA, a LABA/steroid combination, and/or LAMA may be used. For severe or very severe COPD, medication therapy includes regular treatment with one or more bronchodilators and may include a methylxanthine and inhaled or systemic corticosteroids (GOLD, 2015).

A metered-dose inhaler (MDI) is a pressurized device that contains an aerosolized suspension of medication. A measured amount of medication is released with each activation of the canister. Patients must be instructed on the correct use of inhalers. With

correct technique, 15% to 20% of the dose of medication is inhaled into the lung. Proper technique is important to ensure adequate deposition into the airways. Common mistakes made by patients using MDIs include having difficulty coordinating actuation with inhalation, breathing in too quickly, and not breath-holding after inhalation.

A spacer (holding chamber) may also be used for patients who have difficulty coordinating activation of the MDI with inspiration. They are particularly useful for MDI steroids as less medication is deposited in the oropharynx, decreasing inhaled steroid side effects. Spacers come in several designs, but all are attached to the MDI and have a mouthpiece on the opposite end. Once the canister is activated, the aerosol particles stay suspended in the chamber for several seconds, allowing the patient to inhale after actuating the inhaler. Box 11-4 outlines the important steps for using a metered dose inhaler and spacer correctly. Patients need periodic review of correct inhaler technique to increase optimal therapeutic effect. DPIs include a variety of medications and devices. Specific package insert information is available on the use of these inhalers from the manufacturer. The most common medications administered by metered dose or DPIs used for both COPD and asthma are shown in Table 11-1. Nebulized medications (aerosolization of medication via a jet nebulizer and an air compressor) may also be effective in patients who cannot use an MDI properly or who prefer this method of administration. Several formulations of medications are available for nebulization: SABAs used alone or in combination with anticholinergics, LABAs, and some corticosteroids. Patients need to learn proper technique for administration by nebulizers. Disinfection of the medication cup needs to be performed on a regular basis to avoid bacterial growth and inhalation by the patient.

BOX 11-4 Patient Education

Using Inhalers Correctly

Many medicines taken for breathing are given by the inhaled method. Inhaled medicine goes directly to the lungs. But you need to learn to use inhalers correctly. With perfect technique, you get about 15–20% of the medication in your lungs. So, good technique is very important.

Correct Technique for Using Inhalers

- Remove the cap from mouthpiece of inhaler.
- Shake your inhaler for 5–6 seconds.
- Place the mouthpiece of the inhaler in your mouth with your tongue and teeth out of the way.
- As you depress the inhaler take a deep breath with your mouth wide open. Inhale for 5–6 seconds if you can. *Slow is the way to go.* The more slowly you breathe in, the deeper the medicine gets.
- At the end of the deep breath, hold your breath for at least 3–10 seconds.
- Exhale through pursed lips.
- If more than one puff is prescribed, repeat the above steps.

- After your last puff, rinse your mouth with mouthwash or water to help prevent dryness. If you are using inhaled steroids, rinse, gargle, and spit out the water or mouthwash.
- Rinse the mouthpiece thoroughly with warm water at least once a day. Let it air dry before assembling and storing it.

Other points: Do not use your inhaler more often than your health care provider recommends. An occasional extra puff or treatment of your quick-acting bronchodilator is ok, but, if you find yourself using your inhaler more frequently than usual, that may be a sign that you're getting ill and need to contact your provider.

Other inhaled medicines, e.g., those obtained without a prescription, should not be used unless approved by your Primary Care Provider (PCP). You can have serious side effects by mixing certain medications.

Spacer Devices

Spacer devices are used with inhalers when:

- You have a hard time using your inhaler correctly
- When the taste of the propellant in the inhaler is disturbing
- When you are using inhaled steroids and have problems with yeast infections in your mouth

The technique for using an inhaler with a spacer:

- Take the cap off the inhaler and the spacer
- Place the inhaler mouthpiece in the end of the spacer
- Shake your inhaler for 5–6 seconds
- Place the spacer mouthpiece in your mouth
- Depress the inhaler into the spacer
- Inhale slowly—over 5–6 seconds
- Hold your breath for about 10 seconds
- Repeat for the steps for each puff of medication

Other Medications

Influenza and pneumococcal vaccinations reduce the incidence of pneumonia, hospitalizations for cardiac conditions, and deaths in the general elderly population. Patients should receive a yearly influenza vaccine. The CDC currently recommends the two-step pneumococcal vaccine (PCV13/Prevnar 13® and 12 months later PPSV23/Pneumovax23®) for patients with COPD. A one-time booster of pertussis (TDAP-tetanus, diphtheria, and pertussis), is also recommended (CDC, 2016).

Roflumilast (Daliresp®) is a phosphodiesterase-4 inhibitor that suppresses inflammatory activity in the lungs and is associated with decreased COPD exacerbations and hospitalizations. Side effects, including severe nausea, weight loss, mood disturbances, and suicidal ideation, may limit its usefulness in some patients.

Other pharmacologic treatments that may be used in COPD include alpha1-antitrypsin augmentation therapy for those with a diagnosed deficiency, antibiotic agents for acute infection, and mucolytic agents for help with secretion clearance. Cough suppressants are usually reserved for nighttime use when cough interferes with sleep. In very severe COPD, narcotics and other agents may be administered to relieve uncontrolled dyspnea (Schwartzstein, 2015).

Pharmacologic treatment of COPD poses many challenges for patients. Multiple drugs and drug classes are included in treatment regimens, and many drugs go by multiple names. In addition, multiple delivery methods, poly-pharmacy particularly with other comorbid conditions, expense, and side effects can add to poor adherence. Patients often confuse the concepts of maintenance medications and "quick-relief" medications and may not use them correctly. Repeated patient education is important.

Exacerbations and Complications

Exacerbations of COPD are defined as "an acute event characterized by a worsening of the patient's symptoms that is beyond normal day-to-day variations and leads to a change in medications" (GOLD, 2015). Exacerbations of COPD are associated with worsening prognosis and an accelerated decline in pulmonary function. Signs and symptoms may include increased dyspnea, increased sputum production and purulence, respiratory failure, changes in mental status, or worsening blood gas abnormalities. The primary causes of acute exacerbations include infection (bacterial and viral), heart failure, and response to pollutants and allergens. Severe exacerbations requiring hospitalization are associated with an increase in mortality.

TABLE 11-1 Common Inhaled Medications Used in COPD and Asthma

Medication Class	Generic Name (Trade Name®)	
Short-acting beta-adrenergic (SABA) aka beta2 agonist	**albuterol solution for nebs** *(comes in three strengths)* **albuterol sulfate HFA** *ProAir®* *Proventil®* *Ventolin®* **levalbuterol HFA** *Xopenex®*	• Used "as-needed for quick relief" or may be on a timed basis • MDIs generally given as two puffs as needed or four times a day • May or may not need a spacer with MDI for good technique • MDIs now come with a dose counter • ProAir also available in RespiClick™ device
Short-acting muscarinic antagonist (SAMA) aka short-acting anticholinergic	**ipratropium HFA** *Atrovent®*	• Used as a timed medication or as alternative for "quick relief" • Generally given as two puffs four times a day (up to 12 puffs in 24 hours)
SAMA/SABA combination	**ipratropium/albuterol** *Combivent®* *Duoneb® for nebs*	• May be used as first-line therapy or quick relief • Combivent generally administered four times a day by Respimat® device
Long-acting muscarinic antagonist (LAMA) aka LA anticholinergic	**tiotropium** *Spiriva HandiHaler®* **aclidinium** *Tudorza Pressair®* **umeclidinium** *Incruse Ellipta®*	• First-line therapy for moderate to severe disease • Tiotropium given once a day; aclidinium given twice a day • Tiotropium approved for reducing COPD exacerbations • Tiotropium also available in Respimat™ device • Each medication comes with its own delivery device
Long-acting beta adrenergic (LABA) aka LA beta2 agonist	**arformoterol tartrate solution** *Brovana® for nebs* **salmeterol DPI** *Serevent®* **formoterol DPI** *Foradil®* *Perforomist® for nebs* **indacaterol** *Arcapta Neohaler®*	• Used in moderate to severe COPD often in combination with corticosteroids • Each medication comes with its own delivery device • Not for acute symptoms • Salmeterol and formoterol both one puff twice a day, indacaterol once daily • This class not used as monotherapy in asthma
Combinations of long-acting: LAMA/LABA	**umeclidinium/vilanterol** *Anoro Ellipta®* **tiotropium/olodaterol** *Stiolto*	• Used for moderate to severe COPD • Given one puff once daily • Stiolto is given two actuations once a day by Respimat®
Inhaled glucocorticosteroids (ICS)	**ciclesonide** HFA *Alvesco®* **mometasone** *Asmanex Twisthaler®* **fluticasone HFA** *Flovent®* **budesonide DPI** *Pulmicort Flexhaler®* **beclomethasone** *QVAR HFA®*	• Generally used in persistent asthma/later stages of COPD • Patients need to rinse out their mouths to prevent oral thrush • Spacers are also useful to help prevent thrush • All devices have counters except for QVAR • All come in two strengths except for Flovent, which comes in three • Are maintenance or controller medications in both asthma and COPD, not to be used as needed • Most are given twice a day, strength varies based on patient's severity of illness and history of recent exacerbation
Combinations of long acting: LABA/Corticosteroid combination	**fluticasone/salmeterol** *Advair HFA® (steroid comes in three strengths), two puffs twice a day, Advair Discus® one puff twice a day* **budesonide/formoterol** *Symbicort HFA® (steroid comes in two strengths), two puffs twice a day* **mometasone/formoterol** *Dulera® (comes in two strengths), two puffs twice a day* **fluticasone/vilanterol** *Breo Ellipta® (one strength), one puff once a day*	• Used in moderate to severe COPD and asthma • Patients need to rinse out their mouths to prevent oral thrush • Each drug has its own delivery device and technique • Breo Elipta given once daily, others every 12 hours

HFA, hydrofluoroalkane used as propellant; **DPI,** dry powder inhaler.

Prevention of exacerbations is associated with preservation of pulmonary function and a decrease in hospitalizations. Smoking cessation, influenza and pneumococcal vaccines, inhaled drugs (LABAs, LAMAs with or without corticosteroids), and phosphodiesterase inhibitors (Daliresp®) have been associated with a prolonged time between exacerbations (GOLD, 2015).

During an exacerbation, optimization of bronchodilator medications, inhaled or systemic corticosteroids, antibiotic agents, oxygen therapy, and intensive respiratory interventions may also be used. Early treatment with antibiotics in patients needing hospitalization for an acute exacerbation may result in improved outcomes.

Indications for hospitalization for an acute exacerbation of COPD include: severe COPD, marked increase in intensity of symptoms that does not respond adequately to initial therapy, inadequate home support, confusion or lethargy, respiratory muscle fatigue, paradoxical chest wall movement, peripheral edema, worsening or new onset of central cyanosis, persistent or worsening hypoxemia, and the need for noninvasive or invasive assisted mechanical ventilation (GOLD, 2015). The risk of death from an exacerbation of COPD is closely related to the development of respiratory acidosis, the presence of significant comorbidities, and the need for noninvasive or invasive positive-pressure ventilatory support (Stoller, 2015).

Respiratory insufficiency and failure are major life-threatening complications of COPD. The acuity of the onset and the severity of respiratory failure depend on baseline pulmonary function, pulse oximetry or ABG values, comorbid conditions, and the severity of other complications of COPD. Respiratory insufficiency and failure may be chronic (with severe COPD) or acute (with a severe exacerbation or pneumonia in a patient with severe COPD). Acute respiratory insufficiency and failure may necessitate ventilatory support until the underlying cause, such as infection, can be treated. Management of the patient requiring ventilatory support is discussed in Chapter 55.

Other complications of COPD include pneumonia, atelectasis, pneumothorax, and pulmonary arterial hypertension. Pulmonary hypertension is more common in patients with hypoxemia and severe disease and is associated with decreased survival. The diagnosis of pulmonary hypertension associated with COPD is suspected in patients complaining of dyspnea and fatigue that appear to be disproportionate to pulmonary function abnormalities. Enlargement of the central pulmonary arteries on chest radiograph, echocardiography suggestive of right ventricular enlargement and elevated plasma brain natriuretic peptide (BNP) may be present.

Pneumothorax is a less common complication of COPD but can be life-threatening in patients who have minimal pulmonary reserve. Patients with severe emphysematous changes can develop large bullae, which may rupture and cause a pneumothorax. Development of a pneumothorax may be spontaneous or related to an activity such as severe coughing or large intrathoracic pressure changes. Signs and symptoms of a pneumothorax include: sudden chest pain that is sharp and abrupt, a significant and sudden increase in severe shortness of breath, asymmetry of chest movement, unilateral retractions, hyperresonance on percussion, crepitus (cracking sensation when touching affected area), bilateral differences in breath sounds, and/or oxygen desaturation. Pneumothorax in a patient with underlying lung disease is a medical emergency. Rapid response teams or emergency services should be initiated.

Medical management of pulmonary hypertension associated with COPD includes stabilization of the underlying lung disease, administration of long-term supplemental oxygen and diuretics. During acute episodes, treatment may include positive-pressure ventilation.

Pathophysiology Alert

Brain Natriuretic Peptide (BNP) is secreted from the overdistended cardiac chambers. High BNP levels (greater than 100 pg/mL) indicate abnormal ventricular function or symptomatic heart failure. BNP levels are useful for diagnosing heart failure.

The clinical and economic impact of frequent readmissions has prompted an examination of factors that contribute to frequent hospitalizations. Patients with comorbidities, a history of prior exacerbations, individual patient and caregiver factors, and lack of integration of inpatient and outpatient care are suggested as possible contributing factors. Integrated care and other programs to reduce readmission rates have met with varying degrees of success (Crisafulli, Ortega, & Torres, 2015; Coughlin, Liang, & Parthasarathy, 2015).

Oxygen Therapy

Oxygen therapy may be administered during an acute exacerbation, as long-term continuous therapy for chronic hypoxemia, and during exercise and sleep for selected patients. The goal of oxygen therapy is to maintain tissue oxygenation and decrease the work of the cardiopulmonary system. Oxygen is generally administered to acutely ill COPD patients when their room air oxygen saturation is less than 90% or if they are showing signs of increased cardiopulmonary work: increased shortness of breath, tachypnea, tachycardia, or elevated blood pressure. Oxygen is administered to maintain an oxygen saturation of greater than or equal to 90%.

A small subset of COPD patients with chronic hypercapnia (elevated $PaCO_2$ levels) may be at some risk for respiratory failure should they receive too high an oxygen concentration. Concern persists that such patients would lose their "drive to breathe," also called "hypoxic drive." Over-concern may lead patients to receive too little oxygen and result in hypoxemia. While hypercapnic patients are at increased risk for respiratory failure, the risk is related to the severity of their COPD. Adequate oxygenation is as important in their management and should never be withheld. Key in the care of patients with COPD on supplemental oxygen is monitoring and assessment. Pulse oximetry is helpful in assessing response to therapy. ABGs are needed to assess $PaCO_2$ levels. Adequate oxygenation of patients (keeping the oxygen saturation *at or above* 90%) is important to prevent vital organ damage while monitoring for any possible complications of oxygen supplementation. Alternate delivery devices such as venturi-masks or ventilatory support (noninvasive by mask or by intubation) may be necessary during acute exacerbations to ensure adequate gas exchange (Stoller, 2015).

Concept Mastery Alert

For patients with advanced COPD, a venturi-mask is needed to promote adequate gas exchange.

Two seminal landmark studies showed the value of long-term supplemental oxygen in patients who are chronically hypoxemic (Nocturnal Oxygen Therapy Trial Group, 1980;

British Medical Research Working Party, 1981). Long-term oxygen therapy (worn more than 15 hours per day) was associated with increased survival, improved quality of life, a modest reduction in pulmonary arterial pressure, and decreased dyspnea. Long-term oxygen therapy is usually introduced in severe COPD. Indications generally include: a PaO_2 of 55 mm Hg or less or an oxygen saturation of 88% or less. Evidence of tissue hypoxia and organ damage such as pulmonary hypertension, secondary polycythemia, edema from right-sided heart failure, or impaired mental status indicates a need for long-term oxygen therapy. For patients with exercise-induced hypoxemia, oxygen supplementation during exercise may improve performance. Patients who are hypoxemic while awake are likely to be so during sleep. Therefore, nighttime oxygen therapy is recommended as well; the prescription for oxygen therapy is for continuous, 24-hour use. Intermittent oxygen therapy is indicated for patients who desaturate only during exercise or sleep. Oxygen may also be prescribed in patients who become hypoxemic at high-altitude situations, for example, air travel and high-altitude environments. Specialized studies done in a pulmonary function laboratory can determine which patients may need oxygen at high altitude.

Home oxygen is usually supplied by several different methods: by oxygen concentrators, compressed gas cylinders, liquid oxygen, or some combination of these. Newer concentrator/compressors allow appropriate patients to fill their own gas cylinders. Demand portable oxygen systems (liquid and gas systems) and small portable oxygen concentrators have allowed many patients to have more freedom and time away from their stationary systems. Patients need to be evaluated with the chosen system to ensure adequate oxygen saturation.

Surgical Treatments

Bullae are enlarged airspaces that do not contribute to ventilation but occupy space in the thorax. Bullae may compress areas of healthier lung and impair gas exchange. If they are limited in number, bullae may be surgically excised. A bullectomy (surgical excision of the bullae) may help reduce dyspnea and improve lung function. It can be performed thoracoscopically (with a video-assisted thoracoscope) or via a limited thoracotomy incision.

LVRS is an option for a subset of patients with severe emphysema. Patients with predominately upper lobe disease benefit the most. LVRS involves the removal of a portion of the diseased lung parenchyma. Successful LVRS results in reduced hyperinflation and improvement in the elastic recoil and diaphragmatic mechanics. LVRS is not curative but may decrease dyspnea, improve lung function, and improve the patient's overall quality of life. Careful selection of patients for LVRS is essential to decrease morbidity and mortality. The National Emphysema Treatment Trial found that the addition of LVRS to optimal medical management and rehabilitation led to overall improvement in exercise tolerance and survival in a subgroup of patients with predominantly upper lobe disease (GOLD, 2015).

Lung transplantation is an alternative surgical treatment for end-stage COPD. It has been shown to improve quality of life and functional capacity in a selected group of patients with COPD (GOLD, 2015). Single-lung transplantation may be considered for patients with end-stage emphysema who have an FEV_1 of less than 25% of the predicted and who have complications such as pulmonary hypertension, marked hypoxemia, and

hypercapnia. Specific criteria exist for referral for lung transplantation. Patients are prioritized based on the severity of their disease, age, and prognosis. Limited organ availability is a concern and may limit transplantation as an option. Patients who have had a lung transplant need special care when hospitalized. Transplanted patients are on multiple medications to prevent organ rejection and are at markedly increased risk for infection. Coordinating care with the transplant center should be made when patients require hospitalization.

Pulmonary Rehabilitation

Pulmonary rehabilitation for patients with COPD is well established and widely accepted as a means to alleviate symptoms and optimize functional status. It is now considered part of the recommended treatment for symptomatic COPD. The primary goals of rehabilitation are to reduce symptoms, improve quality of life, and increase participation in everyday activities (Nici & ZuWallack, 2012; GOLD, 2015). Pulmonary rehabilitation services are multidisciplinary and include assessment, education, physical reconditioning, skills training, and psychological support (refer to Box 11-5). Patients are taught methods to alleviate symptoms through breathing exercises and learning how to pace activities. Physical conditioning through endurance and strength training is an essential component of rehabilitation. Energy conservation skills are used to improve functional status and decrease dyspnea and fatigue. Nutritional counseling and medication education are other important components of rehabilitation.

BOX 11-5 Nursing Research

Bridging the Gap to Evidence-Based Practice

Effectiveness of a partnership-based self-management program for patients with mild and moderate chronic obstructive pulmonary disease: A pragmatic randomized controlled trial

Jonsdottir, H., Amundadottir, O., Gudmundsson, G., … Stefansdottir, I. (2015). *Journal of Advanced Nursing, 71*(11), 2634–2648.

Purpose

The purpose of this study was to evaluate the effectiveness of a 6-month, partnership-based self-management program for patients with mild and moderate chronic obstructive pulmonary disease (COPD).

Design

This was a pragmatic randomized control trial where patients aged 45–65 years, with mild and moderate COPD were invited with a family member to participate in a 6-month, partnership-based self-management program consisting of: (a) three to four conversations between nurse and patient-family member; (b) 6 months of smoking cessation; and (c) interdisciplinary team-patient-family member group meeting. The control group (n = 52) received usual care. The experimental group consisted of 48 participants (n = 48). Data were collected at months 0, 6, and 12. The trial lasted from June 2009 to March 2013.

Findings

Patients with mild and moderate COPD who participated in the partnership-based self-management program perceived less intrusiveness of the disease and its treatment than patients in the control group. Patients in the experimental group did not have better health-related quality of life, less anxiety or depression, increased physical activity, fewer exacerbations, or better smoking status than patients in the control group. Patients in both groups found participation in the research useful and important.

Nursing Implications

A concerted effort needs to be put into developing a comprehensive, long-term self-management program that takes account for that which is of concern to young people with COPD in its early stages and their families regarding life with the disease, into which an effective smoking cessation treatment is incorporated. Action needs to be taken to reach out to young people with COPD in its early stages, who might not realize that they have the disease nor comprehend the likely consequences of their own smoking. These actions should include not only development and use of health care but recruitment into research programs as well. Smoking cessation treatment for young people with COPD in its early stages warrants further developments. Family involvement was complicated for participants and is thus an area for further exploration.

The demonstrated benefits of pulmonary rehabilitation include: improvement in symptoms and exercise tolerance, improved quality of life, and a reduction in hospitalizations. Selection of a program depends on the patient's physical, functional, and psychosocial status; insurance coverage; geographic location; and preference. Patients with moderate to severe lung disease may benefit the most from pulmonary rehabilitation. Patients with very severe disease may also benefit.

Nursing Management

Nurses play a key role in the care of the patient with COPD. In an office setting, nurses may assist in the assessment of patients suspected of having COPD or help manage patients with known COPD, teach techniques for managing the common problems associated with living with COPD, and review the use of prescribed medications. In acute care settings, nursing care focuses on assessing patients for problems with dyspnea, gas exchange, and secretion clearance. In addition, nurses assess for and help manage respiratory failure, administer medications and treatments to support the cardiopulmonary system, assist the patient to recover from an acute exacerbation, and help prepare patients for discharge. Nursing care in extended-care facilities and home care focuses on helping patients maintain disease stability, improve functional capacity, and learn self-management strategies. Nursing care of patients with very severe and end-stage disease focuses on palliative measures aimed at symptom relief and helping the patient and family cope with limited prognosis.

In addition, nurses may identify potential candidates for pulmonary rehabilitation and reinforce the material learned in the rehabilitation program. Not all patients have access to a formal rehabilitation program. Nurses can teach patients and families rehabilitation concepts as well as facilitate specific services: respiratory therapy for equipment and oxygenation needs, physical therapy for exercise and breathing retraining, occupational therapy for conserving energy during activities of daily living, psychosocial therapy, and nutritional counseling. Numerous educational materials are available to assist nurses in teaching patients with COPD. Potential resources include those of organizations such as the American Lung Association, the American Association of Cardiovascular and Pulmonary Rehabilitation, the American Thoracic Society, the American College of Chest Physicians, and the American Association for Respiratory Care. Online information is also available through these organizations (see resource list at the end of the chapter).

Assessing the Patient

Assessment includes obtaining information about current symptoms as well as previous disease manifestations. In addition to the questions obtained in a basic health history, key questions should focus around the main symptoms of patients with COPD: shortness of breath (dyspnea), cough, and sputum production. Patients with moderate to severe COPD may always have some symptoms. It is helpful to ask patients how their current symptoms compare to their usual amount of shortness of breath, cough, and sputum. When quantifying dyspnea, it can be helpful to use a numerical scale based on 0 to 10, with 0 being no shortness of breath and 10 being the worst. For example, if the patient's usual rating of shortness of breath is a 4 and is now a 7, a significant change has occurred. A change in sputum color, quantity or thickness is also significant. Additional symptoms of a change in condition may include increased fatigue and a decreased ability to perform one's usual activities.

Other assessment questions may include: the presence of other medical problems (cardiovascular, diabetes, stroke, history of pneumonia, cancer), allergies, history of smoking in pack/years, current smoking, a history of past exacerbations and pulmonary

hospitalizations including a history of intubations, a description of how the patient spends a usual day, sleep quality and amount, problems with mood (anxiety and/or depression), and what self-care measures the patient is currently using.

Physical examination should focus on observing the patient's breathing pattern and body position. Accessory muscle use, shoulder elevation, and the tripod position (leaning forward with the arms braced on the knees) are associated with increased respiratory distress. A change in respiratory rate is also a significant examination finding. A normal resting respiratory rate is 8 to 16 breaths per minute (a respiratory rate of 20 is considered the upper limit of normal by some sources). Many patients with COPD will have respiratory rates of 20 to 24 at baseline. When the respiratory rate is greater than the patient's baseline, it may signal an acute problem. It is helpful to ask patients if they are aware of their increased respiratory rate. They may relate this to a recent exacerbation of symptoms. Assessment of breath sounds should include: quality (good aeration or diminished), the presence of adventitious sounds (crackles or wheezes), and whether the adventitious sounds clear with cough. Patient assessment is aided by a review of laboratory data, including pulmonary function tests, tests of oxygenation, and radiologic studies.

TABLE 11-2 Common Problems Associated with COPD

- Continued smoking
- Dyspnea
- Impaired gas exchange
- Cough and ineffective airway clearance
- Fatigue
- Decreased exercise tolerance
- Decreased functional capacity
- Deficient knowledge of self-care strategies to be performed at home
- Anxiety
- Depression
- Limited prognosis in severe disease
- Potential complications:
  - Respiratory insufficiency or failure
  - Pulmonary infection and pneumonia
  - Pulmonary hypertension
  - Cor pulmonale (right-sided heart failure)

A systematic assessment of the patient helps the nurse determine if the patient is stable, becoming acutely ill and needs medical intervention, or becoming more severely ill and needs emergency medical attention.

Common Problems

COPD is a chronic illness and by its definition is not curable. Several common problems of

COPD are amenable to treatment and nursing interventions. Table 11-2 lists the most common problems associated with a diagnosis of COPD. The nursing goals for patients are compatible with other members of the health care team and may include: smoking cessation, improved dyspnea, improved gas exchange, more effective airway clearance, increased exercise tolerance, maintaining ideal body weight, increased self-management, improved coping ability, adherence to the therapeutic program including medications and oxygen, home care, and absence of complications.

Nursing Interventions

Smoking

Although many patients believe that smoking cessation is futile, continued smoking does increase the rate of lung function decline and disabling symptoms. Even brief counseling by nurses and other health professional about the hazards of smoking can be beneficial. Hospitalized smokers may present a "teachable moment." Relating the cause of the hospitalization to smoking behavior personalizes the message to the patient. Administering and teaching patients about pharmacologic agents that increase the likelihood of a successful quit attempt is an additional nursing intervention. Refer to Box 11-3 on page 350 for helping smokers to quit.

Chronic Dyspnea

Chronic dyspnea is one of the most common problems of patients with moderate to severe COPD. Dyspnea or shortness of breath is an uncomfortable awareness of breathing that is often described by patients as an inability to get enough air into the lungs. Acute dyspnea occurs during an exacerbation, with increased activity, from anxiety and panic, and because of acute coexisting medical conditions (e.g., anemia, heart failure, pneumonia). Chronic dyspnea is different from acute dyspnea in that the patient may exhibit no visible signs of distress. Analogous to pain, dyspnea occurs "when the patient says it does" and feels like "the patient says it does."

The management of dyspnea focuses on assessing the underlying causes and administering therapies to reduce the symptoms. Nursing management includes administering bronchodilators to increase airway patency, assisting acutely ill patients with activities of daily living to decrease the work of breathing, administering oxygen therapy when hypoxemia contributes to dyspnea, and teaching strategies for relieving increased shortness of breath and for limiting future episodes.

Ineffective breathing patterns and shortness of breath are partially due to the ineffective respiratory mechanics of the chest wall, lungs, and diaphragm; airway obstruction; the metabolic cost of breathing; and stress. Breathing retraining may help improve breathing patterns. Pursed-lip breathing helps slow exhalation and is thought to prevent the collapse of the small airways, effectively allowing more air to be exhaled and decreasing hyperinflation. A simple explanation to patients is that pursed-lip breathing makes "more room to breathe." It may promote relaxation and reduce feelings of panic, allowing patients to gain control of their breathing. Box 11-6 provides a patient handout and method of helping patients deal with an acute episode of their chronic dyspnea.

An additional patient teaching strategy is to advise the use of a small handheld fan and let the air flow on the cheek. Patients frequently report that cool and moving air reduces

their sensation of dyspnea. Relaxation techniques such as progressive muscle relaxation may also be useful.

Diaphragmatic breathing has long been taught to patients with COPD. However, the technique is difficult to learn by most patients, and its benefits are limited. Patients with milder disease and those with voice or woodwind musical training may feel the technique to be beneficial, but those with more severe disease may find diaphragm breathing too difficult to do. Inspiratory muscle training (IMT) involves having the patient train against a resistive load. Several commercial devices are available for use. Training may be of benefit in some patients, but it is not currently recommended as standard care (GOLD, 2015).

Limiting future episodes of shortness of breath include exercise training to improve endurance, teaching patients how to pace their activities with their breathing, and helping patients anticipate dyspnea-producing activities and plan how they will keep their dyspnea at a manageable level. For example, if a patient is short of breath when climbing stairs, climbing more slowly and only during exhalation may help keep dyspnea at a manageable level. A simple teaching strategy is "pause-breathe in, exhale, and climb one to two steps."

In very severe COPD, simple tasks may cause severe dyspnea that is not adequately responsive to medications and breathing techniques. The administration of opioids may be needed to keep dyspnea under control. Patients and families need to be taught how to use opioids effectively. Concerns over physical dependence, addiction, and respiratory depression need to be addressed, but opioids should not be withheld in very severe patients for whom palliative care is the goal. Noninvasive positive-pressure ventilation (NPPV) also has been used for the treating dyspnea in patients with severe COPD.

BOX 11-6 Patient Education

Managing an Acute Episode of Shortness of Breath

(Use this method to control your breathing when you become more short of breath from over exertion or anxiety and to help you avoid panic)

Step One: Position *(find the most comfortable position to allow the air to move in and out of your lungs)*

- Leaning forward with your back straight
- Leaning over a table with your arms resting on the table
- Placing pillows under your arms and keeping them supported and relaxed

Step Two: Breathing *(begin to control your breathing)*

- Breathe out through pursed or slightly puckered lips
- Breathe in through your mouth if you are very short of breath
- It may help to puff your cheeks out as you breathe out
- Breathe out longer and longer each breath until it starts to feel more comfortable
- As your breathing gets more comfortable, breathe in through your nose and out through pursed lips

Step 3: Relaxation *(once your breathing starts to slow down)*

- Relax your neck and shoulders
- Allow your arms to become limp
- Close your eyes if that helps you to relax

Additional Points

- When your breathing is in control, resume your previous activity but at a slower pace.
- It may help to use your "quick-relief" medication in addition to pursed-lip breathing.
- Breathe out for the hardest part of the exertion.
  Example: While climbing stairs, breathe in while standing still; breathe out while climbing one or more steps. Pause again to breathe in; breathe out while you climb.
- Practice position, breathing, and relaxation when you are not short of breath to help you avoid panic.
- If your shortness of breath continues or gets worse, call your primary care provider.

Impaired Gas Exchange

Patients with more severe disease and those experiencing an exacerbation are at increased risk for hypoxemia, oxygen desaturation, and hypercapnia. Nursing care includes monitoring the patient for hypoxemia by oximetry and ABG measurements and administering supplemental oxygen. As mentioned under Medical Management, over-concern about hypercapnia should never result in under treating the patient. Adequate oxygenation (keeping the oxygen saturation *at or above* 90%) is important to protect vital organ function.

Patients requiring oxygen therapy need to be taught the importance of adhering to the oxygen prescription. Patients often think they can tell when they need oxygen by their symptoms. The presence or absence of dyspnea is unreliable in detecting the need for supplemental oxygen. Many hypoxemic patients do not feel dyspnea. In addition, many patients who are dyspneic do not have significant hypoxemia or oxygen desaturation.

The pulmonary arteries respond to hypoxemia by constricting, causing increased pressure to occur. Pulmonary hypertension and right ventricular hypertrophy and failure may occur as a result of chronic, untreated hypoxemia. Chronic hypoxemia affects the function of other vital organs. Cognitive impairment is greater in hypoxemic patients. Long-term oxygen is the prescribed treatment. Teaching patients who need home oxygen should include an explanation of supplemental oxygen's effect on improved cardiac and cognitive function as well as improved prognosis. The teaching plan should include the number of hours per day to wear oxygen, the dose of oxygen (usually give as number of liters per minute), and special instructions for using oxygen for sleep and exercise. Home care companies supplying oxygen to patients usually employ respiratory therapists and/or nurses. Home care professionals help patients use their oxygen more effectively, identify special equipment needs, troubleshoot equipment, and explore the use of oxygen for work and travel.

Cough and Ineffective Airway Clearance

Patients with mucus hypersecretion or a comorbidity of bronchiectasis as well as those experiencing an acute exacerbation may have increased sputum quantity and viscosity. In addition, many patients are too weak or fatigued to clear secretions effectively.

Diminishing the quantity and viscosity of sputum can help clear the airways and improve pulmonary ventilation and gas exchange. Pulmonary irritants should be eliminated or reduced, particularly cigarette smoking, secondhand smoke, aerosol cleaning and household products, cooking that produces fumes, and powders used when bathing patients. Nursing interventions include instruction in directed or controlled coughing and drinking enough fluid to prevent dehydration. Box 11-7 can be used to teach patients effective coughing and how to deal with uncontrolled coughing spasms.

BOX 11-7 Patient Education

Controlled Cough

An effective cough moves secretions (also called sputum, phlegm, or mucus) out of the smaller airways of the lungs. An effective cough should use just enough effort to remove secretions but not so much as to cause pain, coughing spasms, or exhaustion.

One Coughing Technique

- Sit up leaning slightly forward with your back straight and your head tilted down.
- Take 2 slow deep breaths and exhale through pursed lips.
- Take another deep breath in, and hold your breath for 2–3 seconds.
- Open your mouth so that your lips are slightly parted. Cough, cough, cough from your stomach without breathing in (coughing the air out of your lungs with little coughs).
- If coughing from the stomach is too hard, try: huff, huff, huffing the air out.
- Finish exhaling through pursed lips.
- Breathe in slowly through your nose, and exhale through pursed lips, 2–3 times. Then try clearing your throat or coughing the secretions out of your mouth.
- Repeat, if necessary.
- Check your sputum for color, quantity, and consistency.

If you don't cough out any sputum after 2–3 controlled coughs, wait 15–20 minutes and try again. Avoid continuous coughs to minimize your risk of injury or fatigue. Try using your inhaled bronchodilator before coughing to make it easier to get results.

Controlling Coughing Spasms

If you go into a coughing spasm:

- Take several short sniffs of air in through your nose to help cut down on the irritation.
- Avoid a inhaling quickly through your mouth as it may make you cough more; breathe out through pursed lips and relax your shoulders.

It may take a few breaths to control the coughing spasm so be patient and keep trying.

Once you get the cough under control and after resting a few minutes, try the controlled cough.

Some patients require more intense secretion-clearance techniques. Chest physiotherapy with postural drainage and/or mechanical percussion and vibration, the use of positive expiratory pressure devices (PEP therapy), and suctioning may be needed for patients who are unable to cough sputum out effectively. Patients receiving one or more of these more intense techniques need to be monitored for their response to treatment. Very frail patients may experience too much fatigue, pain, or dyspnea. Respiratory therapists are often consulted when these more intense forms of secretion clearance are needed.

Decreased Exercise Tolerance

Patients with advanced COPD experience progressive intolerance and disability during activity and exercise. Exacerbations and hospitalizations add to decreased activity, muscle weakness, and fatigue. Interventions used during acute exacerbations may weaken the patient further, for example, systemic corticosteroids are associated with myopathy (muscle weakness), particularly in the leg muscles.

Nursing interventions focus on therapies to help the patient recover from the effects of an acute exacerbation, maintain or regain independence in ambulation and performing activities of daily living, and improve stamina and strength. Early mobilization in patients experiencing an acute exacerbation, including those in intensive care, is associated with improvements in exercise tolerance and may help patients recover more quickly. Box 11-8 provides a simple handout to use with patients.

Interventions preparing the patient for discharge or when working with outpatients may include teaching alternating high-energy with low-energy activities throughout the day to better manage energy expenditure. The patient may benefit from exercise training to strengthen the muscles of the upper and lower extremities and to improve exercise tolerance and endurance. Use of walking aids may be recommended to improve activity levels, balance, and ambulation. Pulmonary rehabilitation staff, occupational therapists, and physical therapists can be consulted to assist patients with improving exercise tolerance and self-care.

Nutrition

Patients with COPD may have a number of issues related to nutrition. Some individuals become underweight and have difficulty consuming enough calories to meet their body's metabolic requirements. Others may be normal weight but have decreased muscle mass. Some may be overweight because of increased fat mass or increased fluid retention. Overweight patients may need the help of nutrition education by a dietician to help them lose weight safely. Exercise should be encouraged to help them increase muscle mass.

Hospitalized patients may have difficulty eating because the act of eating may cause increased dyspnea. Oral nutritional supplements are useful for increasing body weight and respiratory function. Weight gain in underweight patients results in improved exercise capacity and quality of life. However, some patients negate the effectiveness of the supplements by using them as meal substitutes.

Therapy is aimed at assessing the nutritional status of the patient, treating the underlying cause, and stabilizing weight and body composition. Nursing interventions include:

- timing bronchodilator therapy before meals
- assisting severely dyspneic patients during meal times to minimize energy spent eating
- teaching patients to eat small, frequent meals to help them avoid becoming too full
- encouraging choices of calorie-rich foods; and providing patients with oral supplements
- referring patients to dieticians
- encouraging progressive periods of exercise aimed at increased muscle mass

BOX 11-8 Patient Education

Exercises to Do in Bed or in a Chair When You Are in the Hospital or Recovering from Being Sick

Deep Breathing

Every hour you are awake, take 10 slow, deep breaths. Exhale through pursed lips. If you get tired after five breaths, rest a minute or two and do the second set of five.

Moving in Bed

Roll from side to side in the bed at least every hour. This helps your breathing, circulation, and skin.

Leg Work to Keep Your Muscles from Getting Too Weak

Ankle Pumps: Flex your ankles and point your toes toward your head, and then point your toes down.

Quad Sets: Tighten your knee and press it into the bed or chair for a count of 5.

Buttocks Squeeze: Squeeze your buttocks together for a count of 5.

Leg Lifts: Bend your knee and bring your leg up toward your chest. Lower your knee slowly back down on the bed. You can also try lifting your leg up and down slowly with your knee in the straight position.

Arm Work

Raise your arms above your head as you breathe in, and then lower them back down to your sides as you breathe out.

Additional Points

- *Remember to breathe as you do the exercises.* Avoid holding your breath.
- Try doing five of each arm or leg exercise every 2–3 hours.
- *As soon as you can, get out of bed to a chair.* Get up several times a day for short periods to improve your stamina and avoid too much fatigue.
- *Take short walks.* Walk with your nurse if you feel unsure of your balance.
- Wear your oxygen for activity if your provider prescribes it.

Enhancing Self-Care Strategies

Self-management strategies are aimed at involving the patient in the decision-making process and goal formation. It is important for patients to participate in setting and accepting realistic short-term and long-term goals. If COPD is mild or moderate, the goals may be to increase exercise tolerance and prevent further loss of pulmonary function. In severe disease, the goals are to preserve current pulmonary function, increase activity tolerance, and relieve symptoms as much as possible. In very severe disease, the goals may shift to relief of severe dyspnea and preparing for a peaceful death. As severity increases, goals and expectations may change.

Examples of patient goals compatible with the concept of self-care include: learning to balance diminished exercise tolerance with the desire to maintain participation in important activities; recognizing the effect that environmental factors have on breathing, and dealing with respiratory irritants; preventing and recognizing the signs and symptoms of exacerbations and complications; learning how to handle an exacerbation and/or complication; managing a complex medical regimen that includes medication, exercise, oxygen, nutrition, and other medical conditions; and deciding on the course of treatment in very severe disease.

Interventions that help patients plan participation in favorite activities with less shortness of breath can be very helpful. For example, attendance at a special event such as a wedding or graduation may be very tiring for patients with more severe disease, yet they still may wish to participate. Strategies to minimize stress and shortness of breath may include: using quick-relief medications prior to the event; planning to attend part of the event such as only the ceremony or reception to minimize fatigue; using an assistive device during the event; and maintaining prescribed medications, oxygen, and exercise program to maximize physical health. Helping patients delineate and decide on possible strategies may allow participation and enhance self-efficacy.

Many patients with COPD are sensitive to changes in air quality, fluctuations in temperature and humidity, and respiratory irritants in the environment. Nursing interventions include teaching patients to check local weather conditions and air alerts for extremes of temperature, humidity, and poor air quality. Teaching patients to create "transitions zones" when they go from one extreme temperature to another can be useful. For example, during hot, humid weather, patients can be taught to turn the air-conditioning off in the car and crack the window to allow the outside air to gradually mix with the inside air. The more gradual transition to hotter, more humid air may make breathing easier for many patients.

Prevention and early recognition of exacerbations of COPD are important self-care measures for patients to learn. Preventative measures include: handwashing to minimize the transmission of infectious agents, avoiding or minimizing contact with sick individuals, and receiving immunizations against influenza and pneumococcal pneumonia. Patients should be taught to report signs of infection, including increased dyspnea as well as fever or change in sputum color, character, consistency, or amount. Any marked worsening of symptoms (chest tightness, dyspnea, and fatigue) also suggests infection and should be reported by patients to their PCP. Viral infections may make patients more susceptible to more serious bacterial infections.

Nursing Alert
High fevers of 102°F or greater accompanied by shaking chills are signs of a more serious infection such as pneumonia. Patients should be instructed to go to the nearest emergency room as soon as possible.

Patients with more severe disease often have significant variation in daily symptoms and may have difficulty determining if they are becoming acutely ill. A change in normal routines, increased activity, family events, increased stress; and fatigue are some of the causes of "bad-breathing days." A knowledge of the patient's past response to "bad-breathing" days can help guide patient teaching. For example, a patient with moderate disease may note a slight increase in sputum volume, no change in sputum color, a slight increase in usual dyspnea (from a 4 out of 10 to a 5) and denies fever or chills. This patient had one exacerbation in the last 2 years that responded to outpatient treatment with bronchodilators and antibiotics. Instruction might include using prescribed quick-relief medication (usually a SABA), using pursed-lip breathing and cough techniques, monitoring for increased symptoms, and contacting the primary care provider should symptoms worsen or persist. Conversely, a patient with similar symptoms but a history of requiring more intensive intervention such as systemic corticosteroids, antibiotics, emergency room visits, or hospitalizations may be instructed to contact their provider more quickly.

Respiratory Failure

Patients with severe and very severe COPD and those with hypercapnia are at increased risk for acute respiratory failure. Nursing interventions of hospitalized patients include frequent monitoring for signs and symptoms of impending respiratory failure, more intensive treatments aimed at clearing the airways, and frequent communication and coordination of care with other members of the health care team, for example, internists, hospitalists, pulmonologists, and respiratory therapists.

Nursing Alert
Signs of impending respiratory failure and need for intensive care:

- *Severe dyspnea not responding to treatment*
- *Tachypnea alternating with bradypnea (slow respiratory rate below 8 breaths per minute) and apnea as fatigue ensues*
- *Hyperventilation that may deteriorate to rapid and shallow breathing*
- *Anxiety*
- *Change in mental status*
- *Worsening hypoxemia that is unresponsive to oxygen therapy*
- *Worsening hypercapnia*
- *Evidence of respiratory muscle fatigue: increased use of accessory muscles paroxysmal respiratory movement (inward movement of abdomen on inspiration) (GOLD, 2015)*

Patients who show signs and symptoms of impending acute respiratory failure must be monitored more closely until transfer to an intensive care can be accomplished. Additional interventions include providing adequate oxygenation, administration of medications to

maximize bronchodilatation, and keeping the patient awake until more intensive therapy can be initiated. NPPV may be initiated. Patients not responding to NPPV may require intubation and invasive ventilatory support. Chapter 55 covers these therapies in more detail. Patients transferred to a medical unit following an acute episode of respiratory failure require the same close monitoring to avoid another episode.

Enhancing Individual Coping Strategies

COPD and its progression promote a cycle of physical, social, and psychological consequences, all of which are interrelated. Depression may occur in as many as 30% to 50% of patients with significant disease. Nursing interventions include: assessing patients for anxiety and depression, promoting interventions to maximize physical functioning and psychological and emotional stability, and social support. After the initial assessment of the patient, the nurse may provide referrals to psychiatric and social services, pulmonary rehabilitation, pastoral care, and home care.

Nursing Alert

Anxiety may be a sign of worsening respiratory status and impending respiratory failure. Anxiety should not be attributed to psychological causes until the patient is assessed: vital signs, tests of oxygenation, mental status changes. Anxiolytics are generally contraindicated in patients with impending acute respiratory failure. Certain medications, in particular high-dose systemic corticosteroids, also can make patients feel extremely anxious and should be considered as a possible cause.

Any factor that interferes with normal breathing may induce anxiety, depression, and changes in behavior. Fatigue is a major symptom in many patients with COPD. Restricted activity, reversal of family roles due to loss of employment, the frustration of having to work to breathe, and the realization that the disease is prolonged and unrelenting may cause the patient to become angry, depressed, and demanding. Sexual function may be compromised, which also diminishes self-esteem. Nursing interventions include discussions with patients and families about the chronic nature of lung disease, support as roles change and spouses or significant others assume responsibilities once managed by the patient, and palliative and hospice care when patients near end-stage disease. Patients with severe anxiety and depression may need a referral to a mental health specialist. Many areas have support groups for patients with chronic lung disease that are usually administered by local pulmonary rehabilitation programs or local chapters of the American Lung Association. Participation in support groups may help many patients discuss common problems with professionals and patients with similar issues.

Continuing Care

Nursing interventions include assessment for and referral to community resources when hospitalized patients are nearing discharge. Nurses caring for outpatients with COPD may also identify community care needs as patients become more disabled. Referral to an inpatient pulmonary rehabilitation program or extended-care facility may be needed for patients who have had prolonged hospital stays and are severely disabled. Home care through a nursing agency may be appropriate for many patients. Home visits provide a

more accurate assessment of the patient's daily life, physical and psychological status, and adherence to the prescribed regimen. Home care visits by physical and occupational therapists may help the patient gain endurance and strength enough to attend an outpatient pulmonary rehabilitation program.

As patients become more severely ill, medical therapy may not adequately relieve symptoms. Discussions about prognosis and end of life are difficult for many patients, families, and professionals. Fears of suffering, a desire to stay alive as long as possible, and depression are some of the factors that may interfere with discussions about the end of life. Areas identified as being of major importance for patients with end-stage COPD include adequate symptom management (particularly avoiding severe, uncontrolled dyspnea); psychological, emotional, and spiritual needs; and privacy and dignity. Assurances that patients and families will not be abandoned as the disease progresses and every effort to help the patient avoid suffering are important parts of caring.

Advanced care planning includes discussing patients' wishes should the need for more invasive procedures arise such as intubation, acute and long-term mechanical ventilation, feeding tubes, and placement of a tracheostomy tube. Nursing interventions include participation in these discussions with patients and families and providing support to them as they struggle with decision-making. Chapter 3 presents a more thorough discussion of end-of-life care.

Asthma 

Asthma is a common disease of the airways that is complex and characterized by recurring and variable symptoms, airflow obstruction, and bronchial hyperresponsiveness. Inflammation is the key underlying feature and leads to recurrent episodes of asthma symptoms: cough, chest tightness, wheeze, and dyspnea. Symptoms occurrence and severity may vary over time.

An estimated 18.7 million American adults (8%) have asthma. Asthma accounts for 14.2 million outpatient visits, 1.8 million emergency room visits, approximately 439,000 hospitalizations, and 3,630 deaths per year (COPD Fast Stats, 2015).

The U.S. National Heart Lung and Blood Institute Expert Panel Guidelines (first produced in 1997 and updated in 2002 and 2007) provide evidence-based information to assist in the diagnosis and management of patients with asthma. A portion of the guidelines "Quick Reference for Asthma Care" was updated in 2011. Multinational guidelines known as the Global Strategy for Asthma Management and Prevention (GINA) were updated in 2015.

Recent research has led to the description of asthma "phenotypes." Common phenotypes include: allergic asthma, nonallergic asthma, late-onset asthma, asthma with fixed airflow limitation, and asthma with obesity (GINA, 2015).

Atopy, the genetic predisposition for the development of an IgE-mediated response to allergens, is the most common identifiable predisposing factor for asthma. Chronic exposure to airway allergens may sensitize IgE antibodies and the cells of the airway. Common allergens can be seasonal (grass, tree, and weed pollens) or perennial (e.g., mold, dust, roaches, animal dander). Atopy may also occur in the absence of asthma.

A variety of nonallergen triggers may also cause asthma symptoms and exacerbation. Most people with asthma are sensitive to a variety of triggers, both allergens and nonallergens. Asthma may vary in an individual person at different points in time. The dose and response to environmental exposures, activities engaged in, the particular asthma control measures used, the frequency of exacerbations, and other factors all influence the disease course in a given individual.

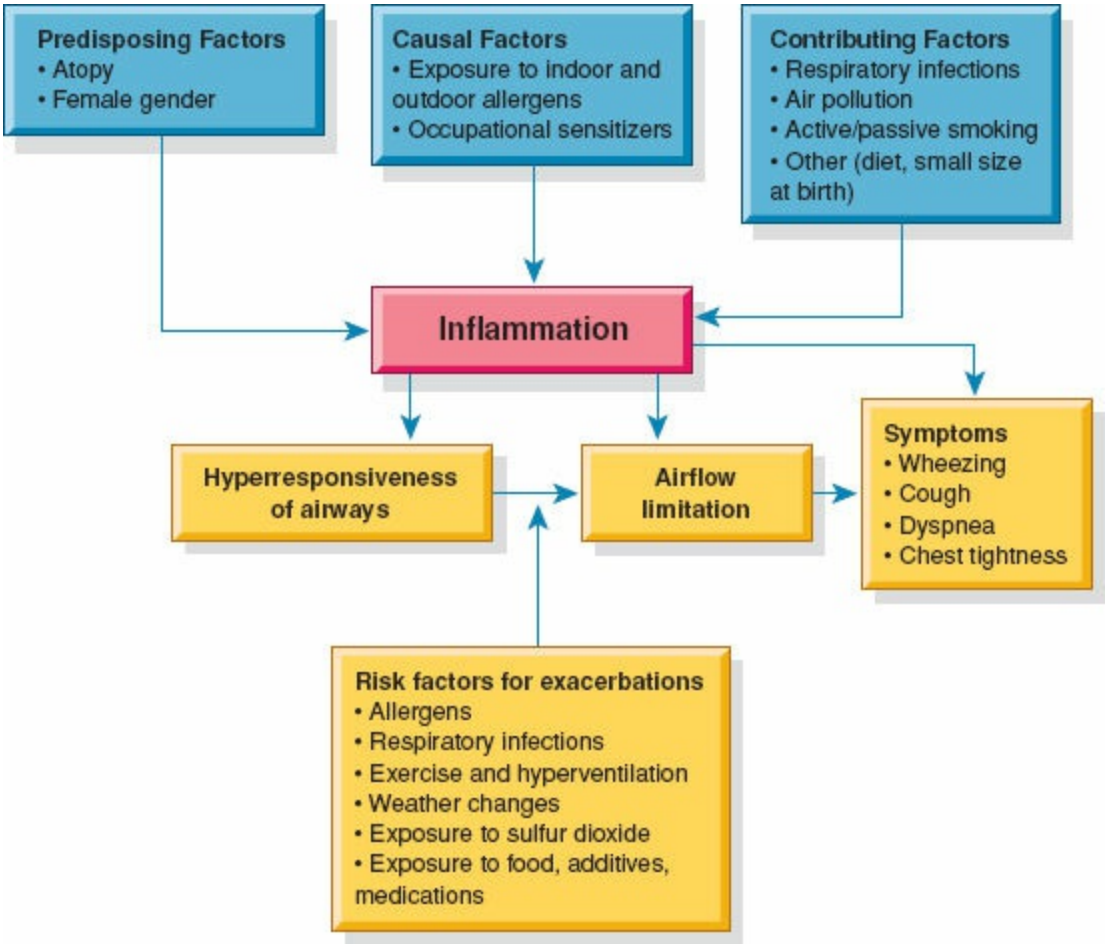

FIGURE 11-4 Pathophysiology of asthma. (Adapted from material developed for the Global Initiative for Asthma (GINA). Retrieved from http:www.ginasthma.org)

Pathophysiology

The underlying pathology in asthma is reversible and diffuse airway inflammation. Acute inflammation leads to airflow limitation and changes in the airways. Bronchoconstriction, the contraction of the smooth muscle of the airways, occurs in response to a variety of allergens and irritants. The airways become hyperresponsive (respond to stimuli in an exaggerated manner). Airway edema (swelling of the membranes that line the airways) becomes more progressive as asthma severity increases. Mucus hypersecretion and mucus plugs can occur. The airways of some asthmatics may undergo "remodeling," which includes persistent changes in airway structure, the development of sub-basement fibrosis, injury to the cells lining the airways, and hypertrophy of airway smooth muscle. Advanced changes in the airways lead to airway narrowing and potentially irreversible airflow limitation. Figure 11-4 depicts some of the pathophysiologic features of asthma.

Many cells and cellular elements play a role in the inflammation of asthma. Mast cells, neutrophils, eosinophils, and lymphocytes are implicated. Mast cells, when activated, release several chemicals called mediators which include: histamine, bradykinin, prostaglandins, and leukotrienes. These mediators perpetuate the inflammatory response and cause increased blood flow, vasoconstriction, fluid leak into the airways, attraction of white blood cells to the area, and bronchoconstriction (Porth, 2015). Regulation of these chemicals is the aim of much of the current research regarding pharmacologic therapy for asthma.

Clinical Manifestations and Assessment

Asthma is diagnosed based on history, physical examination, and spirometry. Symptoms often occur at night or early in the morning and may awaken patients. Asthma symptoms may occur suddenly or develop over several hours or days. Asthma is categorized according to symptoms and objective measures of airflow obstruction (Fig. 11-5).

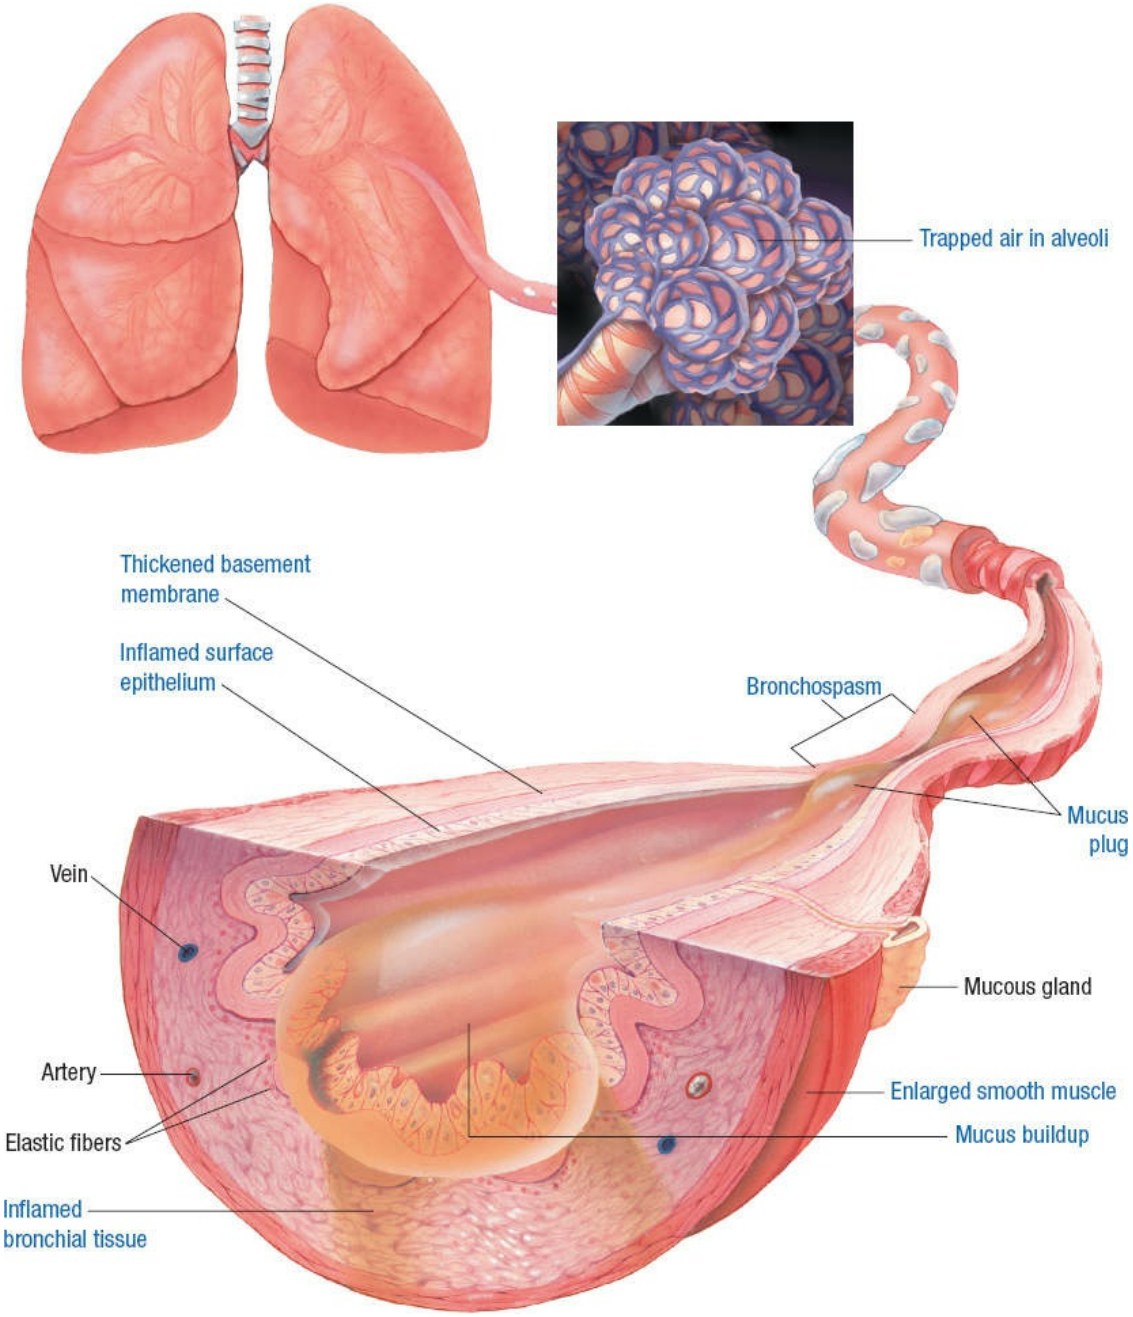

FIGURE 11-5 In asthma, inflammation and smooth muscle spasms severely constrict the airways. Released histamine stimulates the mucous membranes to secrete excessive mucus, further narrowing the bronchial lumen. On inhalation, the narrowed bronchial lumen can still expand slightly, allowing air to reach the alveoli. On exhalation, increased intrathoracic pressure may close the bronchial lumen. Mucus fills the lung bases, inhibiting alveolar ventilation. (Figure courtesy of the Anatomical Chart Company.)

A complete family, environmental, and occupational history helps establish the diagnosis. A history of cough, especially at night, recurrent wheeze, chest tightness, and/or difficulty breathing may indicate the presence of asthma. A report of symptoms that occur or worsen with exercise, exposure to allergens, irritants, occupational irritants, weather changes, stress, menstrual cycles, or strong expression of emotions such as hard laughing or crying increase the suspicion. Table 11-3 lists common allergens and irritants that may trigger an asthma episode. Cough, with or without mucus production may be the only symptom reported by some patients. Exercise-induced asthma is common and is defined as

symptoms occurring during or soon after stopping exercise. Occupational asthma is worse on work days and improved on days off. Many patients develop chronic asthma after years of exposure to an occupational trigger and may have persistent asthma even when not working.

Physical examination findings may reveal generalized wheezing initially heard during expiration. In between asthma episodes, physical examination findings may be normal.

Nursing Alert

The occurrence of a severe, continuous reaction is referred to as status asthmaticus and is considered life-threatening. In more severe episodes, diaphoresis, wheezing heard on inspiration, tachycardia, and a widened pulse pressure may occur along with hypoxemia. When airflow rates are very low, the "quiet chest" with minimal air movement may signal impending respiratory failure (Porth, 2015).

TABLE 11-3 Common Asthma Triggers

Antigens

- Pollens: tree, grass, ragweed
- Molds: indoor (basements, bathrooms, wet rugs) and/or outdoor (spring/fall)
- House dust mite
- Cockroach
- Animal dander: cats, dogs, guinea pigs, birds
- Foods: peanuts, strawberries, shellfish
- Occupational exposures: animals, baking products, toluene
- Drugs: aspirin sensitivity

Irritants

- Viral respiratory infections
- Occupational irritants: dust, fumes
- Esophageal reflux
- Sinus infection and post nasal drip
- Cigarette smoke and odor: primary and second hand
- Forceful respiratory maneuvers: hard laughing, crying, yelling
- Cold, dry air
- Foods, food additives, and preservatives
- Vapors, gases, aerosols
- Endocrine factors: menses, pregnancy, thyroid disease
- Exercise
- Air pollution
- Emotions and stress

Spirometry may reveal an obstructive pattern (FEV_1/FVC% less than 70%). Reversibility, defined as a 12% or 200 mL increase of FEV_1, FVC, or both suggests asthma. Spirometry may be normal if the patient is in between asthma episodes. Special pulmonary function tests, such as methacholine challenge, exercise challenge, or the administration of cold air to induce symptoms, may be used to diagnose asthma when simple spirometry is normal and asthma is suspected.

Other laboratory tests that are done less often may include: blood tests to detect elevated levels of eosinophils and immunoglobulin E, chest x-rays to exclude alternative diagnoses, and blood gases when patients experience symptoms of a severe exacerbation. The most common differential diagnoses in adults include: vocal cord dysfunction, foreign-body obstruction, congestive heart failure, pulmonary embolism, cough secondary to drugs, for example, angiotensin-converting enzyme (ACE) inhibitors, benign or malignant tumors

obstructing airways, eosinophilic pneumonia, and COPD. In addition to being part of the differential diagnosis, COPD and asthma can coexist (GINA, 2015).

Medical Management

The overall goals of management are to reduce impairment and reduce the risk of adverse outcomes. Reducing impairment includes: freedom from symptoms, minimal need of inhaled short-acting beta agonist (SABA) to two or fewer times a week, fewer than two nights a month of nocturnal awakenings from asthma, and satisfaction with care. The goals of reducing risk include: preventing recurrent exacerbations, providing optimal pharmacotherapy with minimal side effects, and preventing loss of function (Fanta, 2015a). The components of management include assessment and monitoring, patient education, environmental control and management of comorbid conditions, and pharmacologic therapy.

Assessment and Monitoring

Once asthma is diagnosed and disease severity is determined, ongoing assessment and monitoring which includes a determination how well asthma is controlled and how responsive it is to treatment. A determination of potential risk for exacerbations is also useful. Monitoring adverse reactions from treatment may guide changes in treatment. Measures used to periodically assess established asthma include: written or verbal reports of symptoms and symptom relief (asthma diaries), the frequency of the use of quick-relief medications, the individual's ability to participate in normal activities, the frequency of exacerbations, and monitoring of pulmonary function by periodic spirometry or home peak-flow monitoring.

Home peak-flow monitoring may be useful in some patients with asthma. A peak flow meter is a small handheld device that measures the fastest flow the patient can generate after taking a deep breath in and blowing out as hard and fast as possible. Peak-flow monitoring is used for different reasons: to establish the diagnosis in symptomatic patients with normal spirometry, to monitor disease in patients with more severe disease or a history of frequent exacerbations, or in patients who have difficulty perceiving an asthma exacerbation until it becomes severe. Proper technique is essential to make peak-flow monitoring useful (see Box 11-9). Once the baseline or personal best peak flow is determined, changes in peak flow can be used to determine the need to adjust medication protocols. Written asthma action plans based on fluctuations in peak flow and/or symptoms are useful for many patients.

BOX 11-9 Patient Teaching

How to Use a Peak Flow Meter

- Stand or sit up straight.
- Put the marker on the peak-flow meter at zero.
- Take a full, deep breath in.
- Place the meter in your mouth with your tongue and teeth out of the way and seal your lips around the meter.
- Blow out as hard and fast as possible.

- Repeat the procedure two more times.
- Write down the highest reading.

Use your peak-flow meter at the same time of day for 2 weeks to establish your "personal best." Work with your PCP, nurse, or asthma educator to help you use your peak-flow numbers to help you control your asthma better and help you decide when to call your provider or go to the emergency room.

Newer form of assessment may include analysis of expectorated sputum for eosinophilia and exhaled nitric oxide (NO). NO exhaled in breath is a method used to measure airway inflammation and provides a tool to assess airways disease, including asthma. These two techniques are not yet widely used (Fanta, 2015).

Patient Education

Asthma is a chronic illness and requires lifelong management by patients and clinicians to achieve the goals of therapy. The concept of partnership is one in which the clinician and patient work together to establish mutually agreed upon goals and treatments. Patients need to learn and manage multiple areas, for example, identification and management of triggers, monitoring for early warning signs of an acute episode, and taking prescribed medications correctly. Comorbid conditions, side effects, financial issues, living conditions, different beliefs about asthma, and other factors may influence the patient's adherence to the asthma management plan. Involving the patient in the decision-making process may increase adherence and positively affect outcomes.

Exacerbations and Complications

An asthma exacerbation is an acute or sub-acute episode of worsening shortness of breath, cough, wheeze, and/or chest tightness. Asthma exacerbations are classified by the severity of symptoms, the response to treatment, and peak-flow measurements. The standard classifications are: mild, moderate, severe, and life-threatening. Mild exacerbations are usually treated by the patient at home. Moderate exacerbations usually require an office visit or close contact with the patient's health care provider. Severe exacerbations usually result in an emergency room visit followed by possible admission to the hospital. Very severe episodes require emergency room visits and probable admission to the hospital or intensive care.

Nursing Alert

Patients at high risk for asthma death need to seek medical care early during an exacerbation. Risk factors that place the patient at high risk include: a history of a previous severe exacerbation requiring intensive care and/or intubation, two or more hospitalizations or more than three emergency room visits in the past year, using more than two canisters of a SABA per month, difficulty perceiving worsening asthma, low socioeconomic status/inner city residence, illicit drug use, severe psychiatric illness, and major comorbid conditions.

Complications of asthma may include worsening disease, status asthmaticus, and respiratory failure. Airway obstruction, particularly during acute asthmatic episodes, often results in hypoxemia, requiring the administration of oxygen and the monitoring of pulse oximetry and ABGs. Antibiotics are rarely needed but may be used for concomitant pneumonia or bacterial sinusitis.

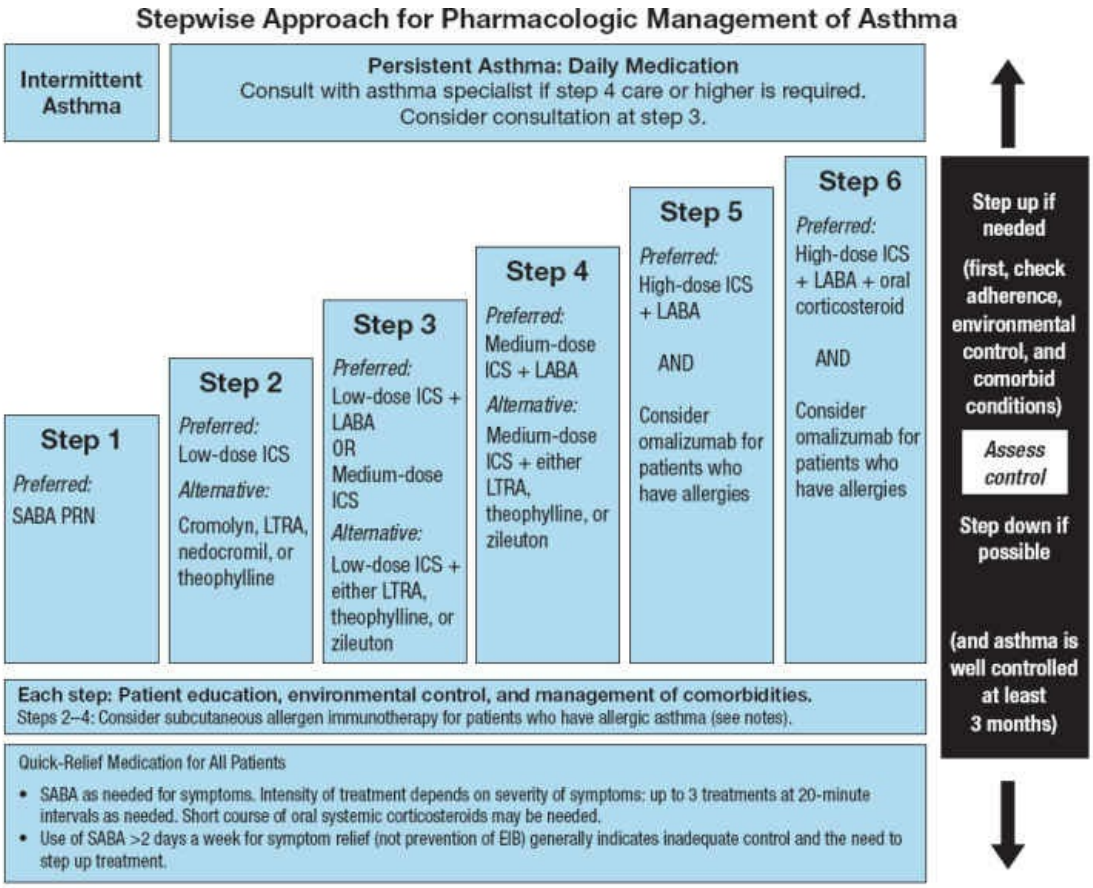
Status asthmaticus is a severe asthma episode that is refractory to initial therapy. It is a medical emergency. Patients report rapid progressive chest tightness, wheezing, dry cough, and shortness of breath. Status asthmaticus may occur following a viral respiratory infection, exposure to a trigger, or following exercise in a cold environment. Infection, anxiety, nebulizer abuse, nonadherence to controller medications, dehydration, increased adrenergic blockage, and nonspecific irritants may contribute to these episodes. It may also occur with little or no warning and can progress rapidly to severe obstruction.

Patients in *status asthmaticus* are monitored closely in the emergency room or intensive care unit. Oxygen, adequate hydration, frequent or continuous nebulization of SABAs, ipratropium, theophylline, and systemic corticosteroids are frequently used to manage *status asthmaticus.* Other treatments that have been tried include intravenous magnesium sulfate, inhaled heliox (a mixture of oxygen and helium that is seven times lighter than air), and inhaled leukotriene modifiers. These latter three treatments have not been well tested in patients with status asthmaticus and are not routinely used (Saadeh, 2017). Intubation and mechanical ventilation may be needed when patients do not respond to initial treatment (Saadeh, 2017).

Pharmacologic Therapy

The pharmacologic management of asthma involves a stepwise approach (see Fig. 11-6). Medication prescriptions are based on the severity and control of asthma symptoms. Quick-relief medications are used for the immediate treatment of asthma symptoms; long-acting medications are used to achieve and maintain control of persistent asthma. The lowest dose of medications to achieve control is recommended. When patients are stable for 3 months, a decrease in medications may be tried (Expert Panel 3 Report, Quick Reference Guide 2011). The major inhaled medications used for asthma are listed in Table 11-1 on page 352. The pharmacologic management of asthma includes many medications that are used in COPD. The stepwise approach is somewhat different from COPD and is illustrated in Figure 11-6.

For patients with mild intermittent disease, a SABA administered by MDI may be all that is needed. Control of persistent asthma is accomplished primarily with regular use of anti-inflammatory medications. Inhaled corticosteroids are the treatment of choice. The dose of inhaled corticosteroids is adjusted based on patient symptoms and asthma control. A spacer should be used with inhaled corticosteroids; patients should gargle and spit out water after administration to prevent thrush, a troublesome complication associated with the use of inhaled corticosteroids. Inhaled corticosteroids may be used alone or in combination with LABAs.



Key: **Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.** EIB, exercise-induced bronchospasm; ICS, inhaled corticosteroid; LABA, inhaled long-acting beta$_2$-agonist; LTRA, leukotriene receptor antagonist; SABA, inhaled short-acting beta$_2$-agonist

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Zileuton is a less desirable alternative due to limited studies as adjunctive therapy and the need to monitor liver function. Theophylline requires monitoring of serum concentration levels.
- In step 6, before oral systemic corticosteroids are introduced, a trial of high-dose ICS + LABA + either LTRA, theophylline, or zileuton may be considered, although this approach has not been studied in clinical trials.
- Steps 1, 2, and 3 preferred therapies are based on evidence A; step 3 alternative therapy is based on evidence A for LTRA, evidence B for theophylline, and evidence D for zileuton. Step 4 preferred therapy is based on evidence B, and alternative therapy is based on evidence B for LTRA and theophylline and evidence D for zileuton. Step 5 preferred therapy is based on evidence B. Step 6 preferred therapy is based on (EPR—2 1997) and evidence B for omalizumab.
- Immunotherapy for steps 2–4 is based on evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults.
- Clinicians who administer immunotherapy or omalizumab should be prepared and equipped to identify and treat anaphylaxis that may occur.

FIGURE 11-6 Stepwise approach for managing asthma in youths 12 years of age and older and adults. Evidence A: Quality of evidence is high (further research is very unlikely to change confidence in the estimate of effect); Evidence B: Moderate (further research is likely to have an important impact on confidence in the estimate of effect and may change the estimate); Evidence D: Very low: Estimate of effect is very uncertain. (Credit: Redrawn from Expert Panel 3 Report. (2007). Guidelines for the diagnosis and management of asthma (p. 343). NIH Publication Number 08–5846. National Asthma Education and Prevention Program. Summary Report. Bethesda, MD. U.S. Department of Health and

Human Services, National Heart, Lung and Blood Institute.)

Drug Alert!
A black box warning has been issued for a LABA for patients with asthma. One large clinical trial found an increase in asthma deaths and exacerbations in patient using a LABA. The current guidelines recommend using LABAs only in combination with inhaled corticosteroids (FDA Drug Safety Communication, 2010).

Leukotriene modifiers (inhibitors), or antileukotrienes, are a class of medications that include montelukast (Singulair®), zafirlukast (Accolate®), and zileuton (Zyflo®). Leukotriene inhibitors act either by interfering with leukotriene synthesis or by blocking the receptors where leukotrienes exert their action. They may provide an alternative to inhaled corticosteroids for mild persistent asthma, or they may be added to a regimen of inhaled corticosteroids in more severe asthma to improve control. Careful monitoring of liver function is recommended for patients taking zileuton.

Cromolyn sodium and nedocromil, also known as cromoglycates, stabilize mast cells. They are used primarily for mild persistent asthma as an alternative medication in patients not tolerating inhaled corticosteroids or as a preventive treatment for exercise asthma.

Omalizumab (anti-IgE) is used as an additional therapy for patients with severe, persistent asthma who have sensitivity to specific allergens, for example, cats, dogs, and cockroaches. Omalizumab is administered intravenously. Because of the potential for serious allergic reactions during administration, careful monitoring and possible treatment for anaphylaxis is required.

Nursing Alert
It is important for the nurse to recognize an anaphylactic reaction and initiate prompt emergency interventions. Signs and symptoms include: urticaria (hives), angioedema, bronchoconstriction, cough, stridor, cardiac arrhythmias, hypotension, and GI symptoms of nausea, vomiting, and diarrhea. Assessment of the patient's airway and cardiovascular status is essential. Supplemental oxygen therapy is administered, and endotracheal intubation may be required to provide sufficient oxygenation.

Other occasionally useful medications include methylxanthines and anticholinergics. Methylxanthines, sustained-release theophylline medications, are mild to moderate bronchodilators. They are mainly used as an adjunct when long-term controllers fail to achieve relieve of nighttime symptoms. Methylxanthines have a narrow therapeutic range that necessitates monitoring of the serum theophylline level. The anticholinergic, ipratropium, may be used as an alternative quick-relief medication when the patient cannot tolerate SABAs.

Oral corticosteroids are used to gain quick control of asthma and during acute exacerbations. Patients with severe persistent asthma that is not adequately controlled may need long-term oral corticosteroids.

Environmental Control and Management of Triggers and Comorbid Conditions

Reducing exposure to asthma triggers may reduce asthma symptoms, inflammation, and

the need for higher doses of medications. Skin testing is useful in some patients to identify specific allergens and in patients who may be candidates for immunotherapy. Effective allergen and trigger avoidance may be complicated when the patient's asthma is triggered by multiple allergens and irritants. Ongoing education and prioritizing the contribution of specific triggers in individuals may be needed. When patients have many triggers, specific trigger management may need to be designed to stress the management of the most troublesome triggers first and manage less troublesome triggers later. For example, if a patient has a severe reaction to cockroach antigen and less of a reaction to dust mites, initial efforts should be directed at cockroach control.

Drug Alert!
Patients with persistent asthma, nasal polyps, and sensitivity to aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs) need to avoid using these drugs because of the risk of severe or even fatal reactions.

Asthma management is complicated by comorbid conditions, particularly COPD, allergic bronchopulmonary aspergillosis (aspergillosis, commonly found in soil, is a fungi to which patients with asthma or cystic fibrosis may have an allergic or hypersensitive reaction), gastroesophageal reflux disease (GERD), obesity, obstructive sleep apnea, rhinitis, sinusitis, stress, and depression. Adequately treating these conditions may improve the control of asthma. Most patients with comorbid conditions should be referred to a pulmonary or asthma specialist.

Nursing Management

Nursing care of patients with asthma depends on the setting the nurse works in and on the severity of the patient's disease. Patients may be treated successfully as outpatients if asthma symptoms are relatively mild or may require hospitalization and intensive care if symptoms are acute and severe. Asthma episodes may be frightening to patients and families. Reassurance and a calm approach are important aspects of care.

Nursing assessment includes taking a history of the patient's symptoms, self-care measures used, sequence of the current asthma episode, and response to medication and treatments used. A history of allergic reactions to medications, current prescription and nonprescription medications (including complementary and alternative therapy [CAM]), recent exposure to allergens and triggers, previous hospitalizations, emergency room visits, intensive care unit admissions, intubations for asthma, and the patient's perception of asthma severity are additional elements to include in a nursing assessment. Physical examination is similar to that used with COPD. Peak-flow measurements and pulse oximetry are additional assessment measures.

Nursing interventions for patients admitted for an asthma exacerbation include administering medications and treatments as prescribed, monitoring patients' response, preparing patients for discharge, and educating patients about treatment, medication administration, identification and management of asthma triggers, prevention and treatment of future exacerbations, and medical follow-up.

The main focus of nursing management of patients in *status asthmaticus* is to actively assess the patient's airway and the response to treatment. Nursing care includes: frequent monitoring of the patient's vital signs, oxygen saturation, and cardiac rhythm until status asthmaticus is under control; assessing for signs of dehydration and managing fluid intake; administering systemic corticosteroids, bronchodilators, and other medications as ordered (often given as continuous therapy); assisting patients with daily activity to help them conserve energy; and providing a quiet environment that is free of respiratory irritants including flowers, perfumes, powders, or odors of cleaning agents. The administration of heliox and magnesium sulfate are additional interventions that may be used and require close monitoring.

Patients in *status asthmaticus* who are not responding adequately to treatment and patients with severe comorbidities may need to be transferred to intensive care. Intubation and mechanical ventilation may also be needed. Frequent communication and consultation with physicians, respiratory therapists, and rapid response teams is important in any patient hospitalized for asthma. Discharge criteria include an FEV_1 or peak flow *measurement of* 70% or higher predicted (good response) or a *measurement of* 50% to 70% predicted in some patients (moderate response), a sustained response to bronchodilator treatment, no or mild distress, and the absence of hypoxemia. Patients being discharged from an emergency room or hospital may benefit from referral to an asthma clinic, asthma or pulmonary specialist, and/or visiting nurse agency. Home visits may be particularly useful for patients with recurrent exacerbations and emergency room visits. The home visit may give a more accurate picture of the individual's allergens and triggers.

Patient Teaching

Patient teaching is a critical component of the nursing care of patients with asthma. Complex treatment regimens, including multiple and different types of inhalers, monitoring of asthma control, antiallergy therapy, therapy for comorbid conditions, identification of early warning signs, and recognition and avoidance of triggers are essential for long-term control. Patient education may include: the nature of asthma as a chronic inflammatory disease, the definition of inflammation and bronchoconstriction, the goals of asthma control, the purpose and action of each medication (quick-relief medications and controllers), triggers to avoid and how to do so, proper inhalation technique, performance and recording of peak flow, implementation of an action plan designed with their health care provider, and recognition of the signs and symptoms indicating the need for prompt medical assistance.

An assortment of excellent educational materials is available from the NHLBI and other sources. The choice of educational materials used should be based on the patient's diagnosis, causative factors, educational and reading level, and cultural background. Selected references and websites for professionals and patients can be found on the website that accompanies the book. Unfolding Patient Stories: Jennifer Hoffman • Part 1

Jennifer Hoffman is 33 years old and was diagnosed with asthma in childhood. She has come to the clinic multiple times over the last 2 months complaining of continued symptoms. Her asthma action plan was adjusted by her primary provider last month. What measures can the nurse take to determine areas needing education reinforcement? How can the nurse ensure that Jennifer is accurately following the prescribed asthma regimen and monitoring medication effectiveness? (Jennifer Hoffman's story continues in Chapter 38.)

Care for Jennifer and other patients in a realistic virtual environment: vSim for Nursing (thepoint.lww.com/vSimMedicalSurgical). Practice documenting these patients' care in (thepoint.lww.com/DocuCareEHR).

CHAPTER REVIEW

Critical Thinking Exercises

1. A 74-year-old man with severe COPD has been admitted with an acute exacerbation. He is extremely anxious and short of breath. He is unable to lie flat in bed and is on supplemental oxygen at 2 L/min. What tests or examinations might be appropriate to assess the severity of the patient's respiratory symptoms and his oxygenation status? What other nursing measures would you institute for this patient?

2. A 69-year-old woman with COPD reports that she has been using continuous oxygen for the past 5 years. She reports that she doesn't always use her oxygen as prescribed, only when she "feels she needs it." What should you teach her about oxygen?

3. As a nurse in an outpatient asthma clinic in a tertiary care medical center, you see a 35-year-old woman with asthma. When you inquire about symptom management and medication history, she reports that she uses an inhaler a few times a day when her breathing gets "really bad." She notes wheeze and cough several times a day. The inhaler she has with her is albuterol. She wakes up 3 times a week with asthma symptoms. In her medical record, you note that use of a combination LABA/corticosteroid to be taken twice a day has been repeatedly prescribed for her, but she reports that she does not use it very often. Describe the assessment method you would use to evaluate her asthma symptoms and severity. Describe teaching techniques you might use to assess the patient's knowledge of her medications, and provide education about the action of her controller and quick-relief medications, frequency of use, and correct administration. What methods would you use to monitor use of her medications and reinforce teaching?

4. As a nurse in your hospital's community outreach clinic, you are responsible for providing group education and counseling to patients with newly diagnosed asthma. What areas would you address regarding triggers for asthma? How might you have patients assess or change their home and work environments? What resources might you suggest?

NCLEX-Style Questions

1. During morning rounds on a medical floor, the nurse assesses a patient admitted the previous evening with an exacerbation of COPD. The patient is complaining of increased dyspnea. He is sitting on the side of the bed with his arms braced against his knees. His respiratory rate was 20 on admission and is now 28. His breath sounds are diminished with coarse crackles heard throughout. His oxygen saturation is 93% on 2 L/min of supplemental oxygen. The nurse would perform which of the following (Select all that apply) *except:*
   a. Administer albuterol using a spacer that has been ordered "as needed"
   b. Switch the patient's oxygen to a venturi-mask at 32%
   c. Instruct the patient to begin pursed-lip breathing
   d. Instruct the patient in controlled cough

2. The following day the patient's symptoms are improving. He is less dyspneic and able to

walk to the bathroom with minimal assistance. In preparing for discharge, a home oxygen assessment is ordered. The patient's room air oxygen saturation is 88% at rest and 86% with exertion. Oxygen administered by nasal cannula at 2 L/min raises the oxygen saturation to 94% at rest and 92% when walking. Home oxygen is ordered as 2 L/min 24 hours a day. Teaching about home oxygen would include:

a. Oxygen improves cardiac and cognitive function and improves prognosis
b. Oxygen needs to be worn only when the patient is short of breath
c. Oxygen improves cardiac and cognitive function but does not improve prognosis
d. Home oxygen is dangerous and will explode

3. A 62-year-old woman is being seen at the health care provider's office for an initial evaluation of her symptoms of shortness of breath, cough, and sputum production. Her spirometry reveals an FEV_1 of 65% predicted. Her FVC is 90%. Her FEV_1/FVC is 60%. She has been given a diagnosis of COPD. She reports a smoking history of 35 years. She now smokes 10 cigarettes a day. She has tried to quit several times and was able to stay quit for 1 week a few years ago. She is concerned about weight gain if she quits smoking. The provider gave her a prescription for bupropion and nicotine nasal spray. The nurse is asked to review an approach to smoking cessation. What should be included in the teaching plan (Select all that apply) *except:*

a. Bupropion and nicotine replacement can assist in the quitting process
b. Successful smoking cessation includes multiple approaches
c. Dealing with the habit of smoking is important to success
d. Quitting smoking once COPD is diagnosed has no effect on prognosis

4. A hospital conducts an outpatient clinic for patients with asthma. The nurse working in the clinic is responsible for teaching patients about their medications. Which is true about inhaled medications?

a. All inhalers must be given with a spacer device
b. Inhaled corticosteroids are used on an as-needed basis for quick relief
c. LABAs (long-acting beta adrenergics) can be used as monotherapy to control asthma
d. LABAs and inhaled corticosteroids are used as controllers in the management of asthma

5. A 45-year-old woman with a diagnosis of asthma comes to the emergency room with worsening symptoms of cough and wheeze. She has been using her albuterol inhaler every 3 hours for the past 2 days. She denies allergies to medications, foods, and the environment. She has no other major medical problems and has never been a smoker. She is recovering from a viral respiratory infection. Her respiratory rate is 28; she is sitting upright on the stretcher. Her breath sounds are markedly diminished. Her room air oxygen saturation is 89%. The nurse should take the following next step:

a. Administer oxygen to keep her oxygen saturation at 90–92% or above
b. Recommend discharge with follow-up to her primary care provider (PCP)

c. Administer inhaled corticosteroids
d. Review asthma triggers and early warning signs

Problems Related to Cardiovascular and Circulatory Function

A nurse is caring for an obese 60-year-old patient who smokes two packs of cigarettes a day. He is being seen in the cardiology clinic for evaluation and treatment of hypertension. His current blood pressure is 180/90. He has congestive heart failure and is currently nonadherent with his medication regimen and has not followed up with a doctor for 3 years.

- Discuss current and potential problems of the patient's nonadherence.
- What areas of teaching would be important to emphasize with this patient?
- Discuss target organs that may be affected by the patient's nonadherence with prescribed medications.

CHAPTER 12

Nursing Assessment: Cardiovascular and Circulatory Function

Janet A. Parkosewich

Learning Objectives

After reading this chapter, you will be able to:

1. Describe the relationship between the anatomic structures and physiologic function of the heart and peripheral circulation.
2. Discuss the significance of the health history and physical assessment to the diagnosis of cardiovascular disorders.
3. Discuss the clinical indications, patient preparation, and other related nursing implications for common tests and procedures used to assess cardiovascular and circulatory function.
4. Compare the various methods of hemodynamic monitoring (e.g., central venous pressure, pulmonary artery pressure, and arterial pressure monitoring) with regard to indications for use, potential complications, and nursing responsibilities.

Cardiovascular disease (CVD) refers to diseases involving the heart and blood vessels. CVD affects more than 85.6 million Americans and claims the life of 1 person every 37 seconds (American Heart Association [AHA], 2016). Given the prevalence of CVD, nurses practicing in most settings will be assessing and managing patients with one or more disorders associated with the heart or blood vessels. An understanding of the structure and function of the cardiovascular system in health and disease is essential to the development of cardiovascular assessment skills.

ANATOMIC AND PHYSIOLOGIC OVERVIEW

The unique function of the cardiovascular system is to circulate blood through a network of blood vessels (arteries, capillaries, and veins) via two interdependent circulatory systems called the *pulmonary circulatory system* (right heart) and *systemic circulatory system* (left heart) (Fig. 12-1). The *lymphatic system* complements the function of the circulatory system by draining excessive interstitial fluid from the tissues and returning it into the bloodstream via the internal jugular and subclavian veins.

Anatomy and Physiology of the Vascular System

The vascular system is composed of blood vessels that circulate blood throughout the body and back to the heart. There are several types of blood vessels, including arteries, arterioles, capillaries, venules, and veins.

Arteries and Arterioles

Arteries are thick-walled structures that transport blood containing oxygen and nutrients from the heart to the tissues of the body. The aorta, the largest artery, has a diameter of approximately 25 mm (1 in) in the average-sized adult. It has numerous branches that continue to divide into progressively smaller arteries, eventually reaching 4 mm in diameter. Once these vessels diminish to approximately 30 μm in diameter, they become *arterioles,* which are embedded within the tissues.

The walls of the arteries and arterioles are composed of the *intima,* a thin, smooth endothelial cell layer; the *media,* the middle layer of smooth muscles and elastic fibers; and the *adventitia,* a protective layer of connective tissue that anchors these vessels to surrounding structures. The media is well developed in the arteries, whereas in smaller arteries and arterioles there is much less elastic tissue.

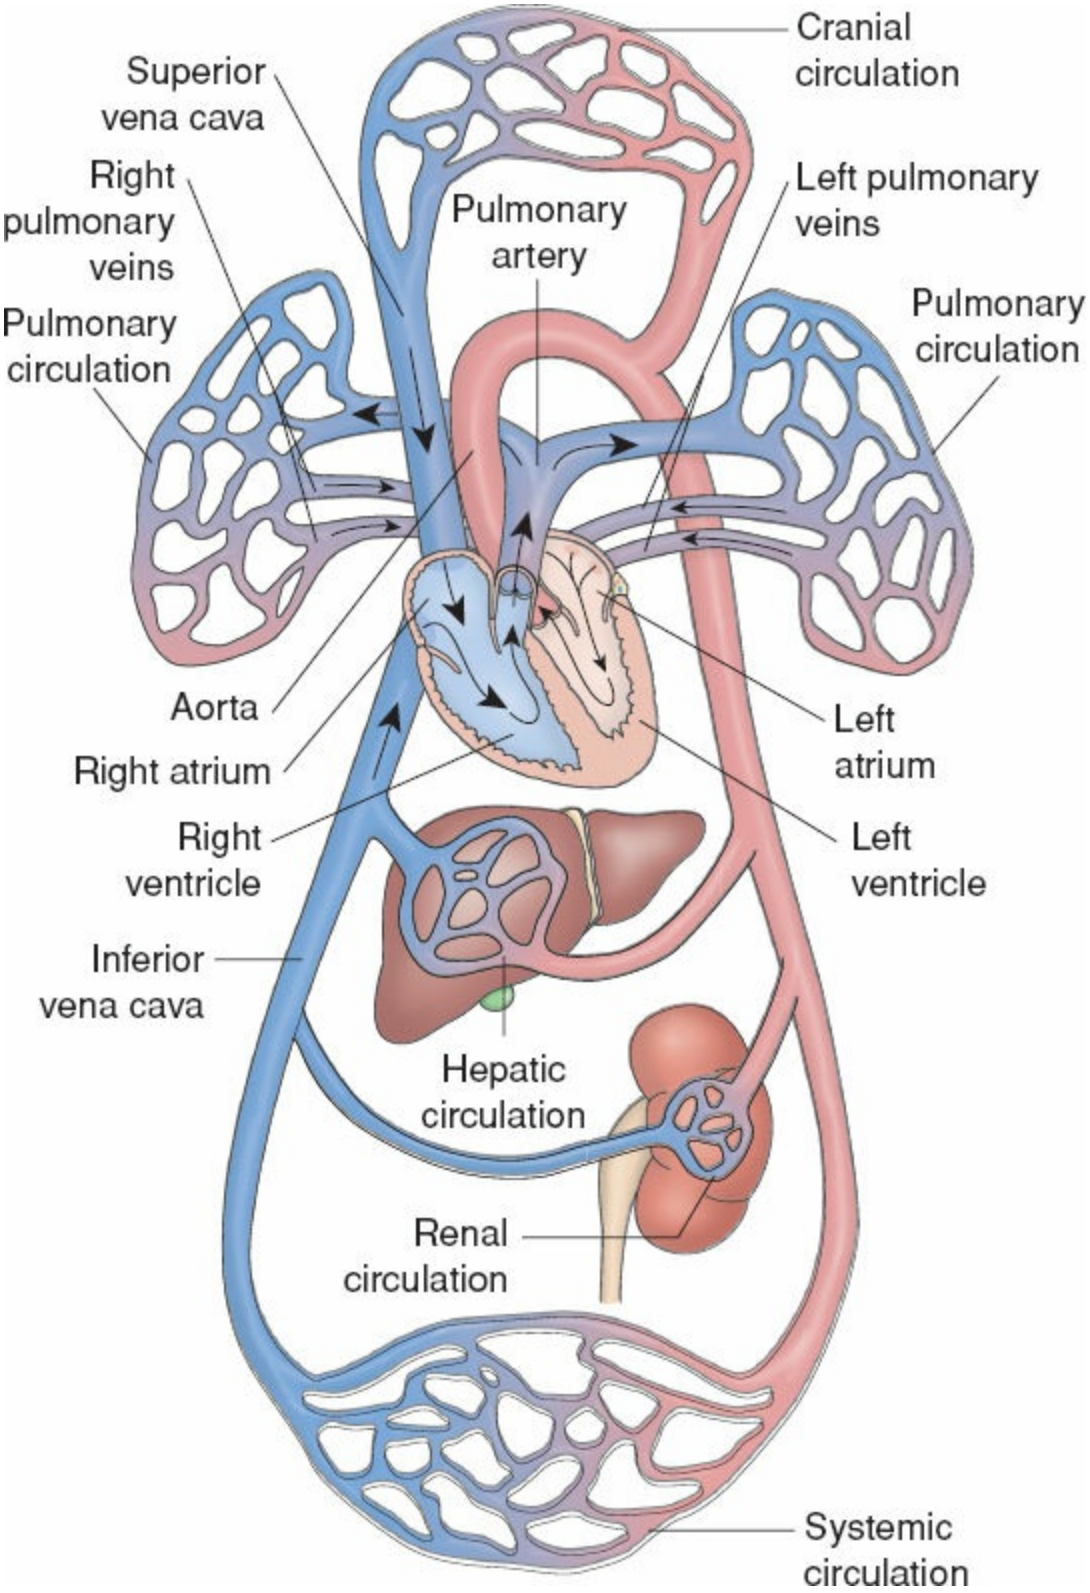

FIGURE 12-1 Pulmonary and systemic circulation. Oxygen-rich blood from the pulmonary circulation is pumped from the left side of the heart into the aorta and the systemic arteries to the capillaries, where the exchange of nutrients and waste products takes place. The deoxygenated blood returns to the right side of the heart by way of the systemic veins and is pumped into the pulmonary circulation. *Arrows* represent the direction of blood flow through the great vessels and chambers of the heart. The blue shading represents venous blood and the red shading represents arterial blood.

Capillaries

Capillaries are narrow vessels (5 to 10 μm) formed by a single layer of endothelial cells that permit continuous movement of fluid and exchange of oxygen and nutrients to the cells and removal of carbon dioxide and other metabolic wastes. The amount of oxygen extracted differs by tissue type. For example, the heart has large metabolic requirements, extracting approximately 70% to 80% of the oxygen delivered, whereas other organs extract about 25%.

Capillary membrane permeability and hydrostatic and osmotic pressures are the primary controls for the amount and direction of fluid filtering across the capillary membrane into the interstitium (space around the cells). Under normal conditions, capillary permeability remains constant. Hydrostatic pressure is generated by the blood pressure (BP), whereas osmotic pressure is created by plasma proteins (primarily albumin). The hydrostatic pressure, which is higher on the arterial side of the capillaries, tends to drive fluid out of the capillaries and into the interstitium. Interstitial fluid is reabsorbed into the capillaries on the venous side of the capillary bed, as the osmotic force predominates over hydrostatic pressure at this location. The excess interstitial fluid that is not reabsorbed into the venous end of the capillary enters the lymphatic system. These processes—filtration, reabsorption, and lymph formation—aid in maintaining tissue fluid volume and removing tissue waste and debris.

Tissue *edema*, an accumulation of excessive interstitial fluid, occurs for a variety of reasons including: abnormal conditions that obstruct lymph drainage, increased capillary membrane permeability, significantly elevated venous pressure, or decreased osmotic force generated by the plasma proteins.

Venules and Veins

The venous system has venules and veins, which are responsible for returning blood to the heart after cellular exchange of oxygen, nutrients, and metabolic waste products. The return of blood to the heart begins as capillaries merge to form thin-walled vessels called *venules* that merge to form larger vessels or veins. The veins contain approximately 75% of total blood volume. Compared with arteries, veins have three thin, less muscular layers. Thus, veins readily distend, permitting large volumes of blood to accumulate in these blood vessels under low pressure. Transport of venous blood back to the right side of the heart is facilitated by the pumping action of the skeletal muscles and the presence of one-way valves, which prevent backward blood flow and enhance the pumping action of skeletal muscles.

Circulatory Needs of Tissues

The amount of arterial blood flow needed to meet the demand for oxygen and other substances is determined by the rate of tissue metabolism, the availability of oxygen, and the function of the tissues. The central nervous system, circulating hormones, and certain chemicals are primarily responsible for regulating blood flow. When metabolic requirements increase (e.g., due to physical activity, local heat application, fever, or infection) blood vessels dilate (vasodilatation) to increase blood flow to the tissues.

Vasodilatation and resultant lowering of BP is caused by relaxation of the blood vessel smooth muscles. This develops when potent substances, such as nitric oxide, prostacyclin, histamine, bradykinin, and prostaglandin, enter the circulation.

Blood vessels constrict (vasoconstriction) to reduce blood flow when metabolic demands are low (e.g., due to rest, local cold application, and cooling of the body). Vasoconstriction is due to contraction of the smooth muscles of the arteries, arterioles, and veins. This action causes narrowing of the lumen of the blood vessels and an elevation in BP. It is stimulated by the release of norepinephrine from the sympathetic nervous system, epinephrine from the adrenal medulla, and angiotensin II. Angiotensin II is the end result of a series of interactions beginning with renin (synthesized by the kidney) and angiotensinogen, a circulating serum protein produced by the liver, which forms angiotensin I. An enzyme (angiotensin-converting enzyme) secreted by the pulmonary vasculature converts angiotensin I into angiotensin II.

Anatomy and Physiology of the Heart

The heart is a hollow, muscular organ located in the center of the thorax, where it occupies the space between the lungs (mediastinum) and rests on the diaphragm. It weighs approximately 300 g (10.6 oz) and is about the size of a clenched fist, although size varies based on age, gender, body stature, physical condition, and presence of CVD.

The walls of the heart are made up of three layers (Fig. 12-2). The inner layer, or *endocardium*, consists of endothelial tissue and lines the inside of the heart and valves. The middle layer, or myocardium, forms an interconnected network of muscle fibers, which encircles the heart in a figure-of-eight pattern. During myocardial contraction, this configuration facilitates a twisting and compressive movement beginning from the top to the bottom of the heart. The exterior layer of the heart is called the *epicardium.*

The heart is encased in a thin fibrous sac called the *pericardium*, which is composed of two layers. Adhering to the epicardium is the *visceral pericardium*. Enveloping the visceral pericardium is the *parietal pericardium*, a tough fibrous tissue that attaches to the great vessels (superior and inferior vena cava, pulmonary artery [PA], pulmonary veins, and aorta), diaphragm, sternum, and vertebral column and supports the heart in the mediastinum. The space between these two layers (pericardial space) is filled with about 30 mL of fluid, which lubricates the surface of the heart and reduces friction during systole.

The *base* and *apex* are common terms used to describe the top and bottom of the heart. The base of the heart is the upper portion, where the great vessels enter and exit the heart. The lowest aspect of the heart is called the apex or the point of maximal impulse (PMI), where the pulsation caused by contraction of the heart can be palpated. The apex of the heart is located in the midclavicular line of the chest wall at the fifth intercostal space or 7 to 9 cm from the left sternal border.

Coronary Arteries

The coronary arteries, originating from the aorta just above the aortic valve, supply arterial blood to the heart (Fig. 12-3). The coronary arteries, which feed the heart muscle, receive most of the blood during diastole, when the aortic valve closes. The left coronary, often referred to as the *left main coronary artery,* bifurcates into the left anterior descending artery that supplies the anterior wall of the heart and the *circumflex artery* that circles to the left side feeding the lateral wall of the heart.

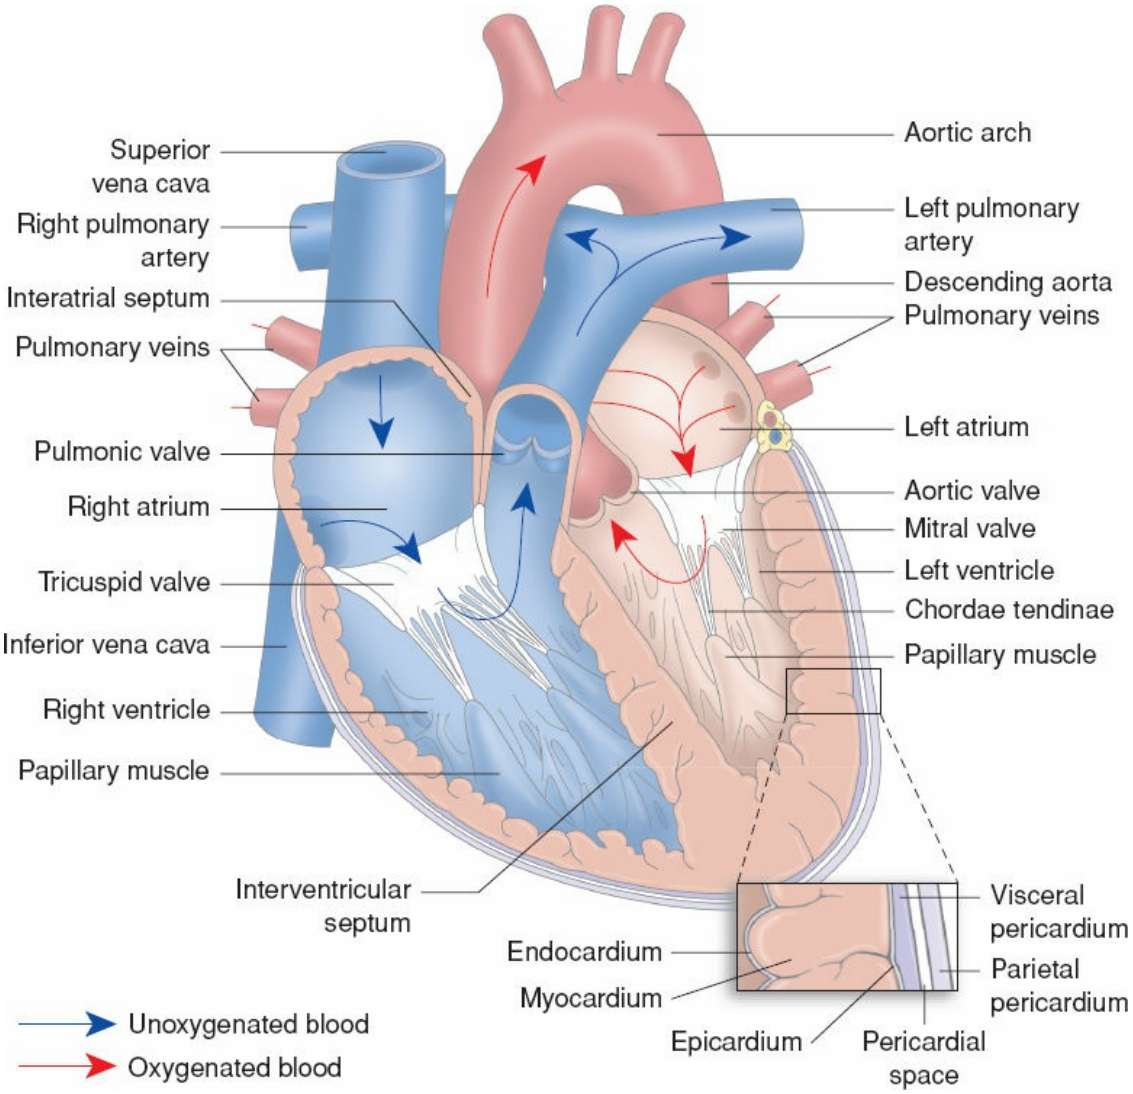

FIGURE 12-2 Anatomy of the heart. *Arrows* represent blood flow through the chambers of the heart.

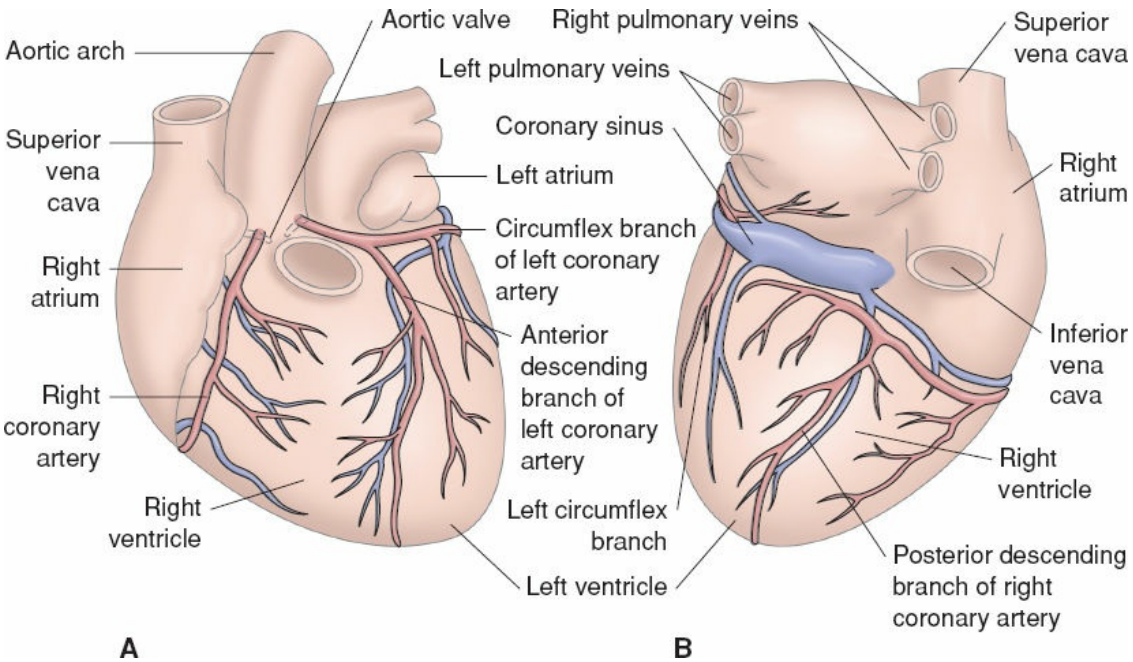

FIGURE 12-3 The coronary arteries supply the heart muscle with oxygenated blood, adjusting the flow according to metabolic needs. (A) Anterior view and (B) posterior view of the heart.

The right side of the heart is supplied by the right coronary artery, which progresses around to the bottom or inferior wall of the left ventricle. The right coronary artery branches into the posterior descending artery, which supplies the posterior wall of the left ventricle. Superficial to the coronary arteries are the coronary veins. Venous blood from these veins returns to the heart primarily through the coronary sinus, which is located in the posterior wall of the right atrium.

Heart Chambers, Valves, and Great Vessels

The right and left sides of the heart each have an upper chamber, or atrium, that collects blood and a larger lower pumping chamber, called a *ventricle* (see Fig. 12-2). Blood flows into the right atrium from the superior and inferior vena cava, passes through the tricuspid valve to the right ventricle. The right ventricle pumps the blood in need of oxygenation across the pulmonary valve into the PA. The PA is the only artery carrying deoxygenated blood (other than the umbilical arteries in the fetus). Oxygenated blood returns to the left atrium via the pulmonary veins. The left atrium contracts, and blood flows through the mitral valve to the left ventricle. The left ventricle pumps the blood through the aortic valve into systemic circulation. Thus, two sets of valves are located within the right and left heart that provide one-way blood flow through these chambers. Valves separating the atria from the ventricles are termed *atrioventricular (AV) valves*, whereas valves located between the right and left ventricles and their respective great vessels (PA and aorta) are called *semilunar valves.*

Cardiac Conduction System

The cardiac conduction system is composed of specialized cells that are capable of spontaneously initiating an electrical impulse (automaticity), responding to an electrical impulse (excitability), and propagating these impulses from one cell to another (conductivity) (Fig. 12-4). The sinoatrial (SA) node, the primary pacemaker of the heart, initiates electrical impulses at an inherent rate of 60 to 100 beats per minute (bpm). These impulses move across the atria via internodal pathways causing the atria to contract and then move onto the AV node. At the AV node, a slight delay occurs, which synchronizes atrial and ventricular activity and permits adequate time for the ventricles to fill. If the SA node fails in its pacemaker role, the AV node is capable of assuming this function by discharging electrical impulses at an inherent rate of 40 to 60 bpm. Impulses are then conducted to the ventricles via the bundle of His, to the right bundle branch (located in the right ventricle) and left bundle branches (located in the left ventricle), and finally to the Purkinje fibers, the point at which the ventricles are stimulated to contract (ventricular systole). The conduction tissue in the ventricles has an inherent rate of 30 to 40 bpm, which will assume the pacemaker role should the SA and AV nodes fail to provide electrical impulses.

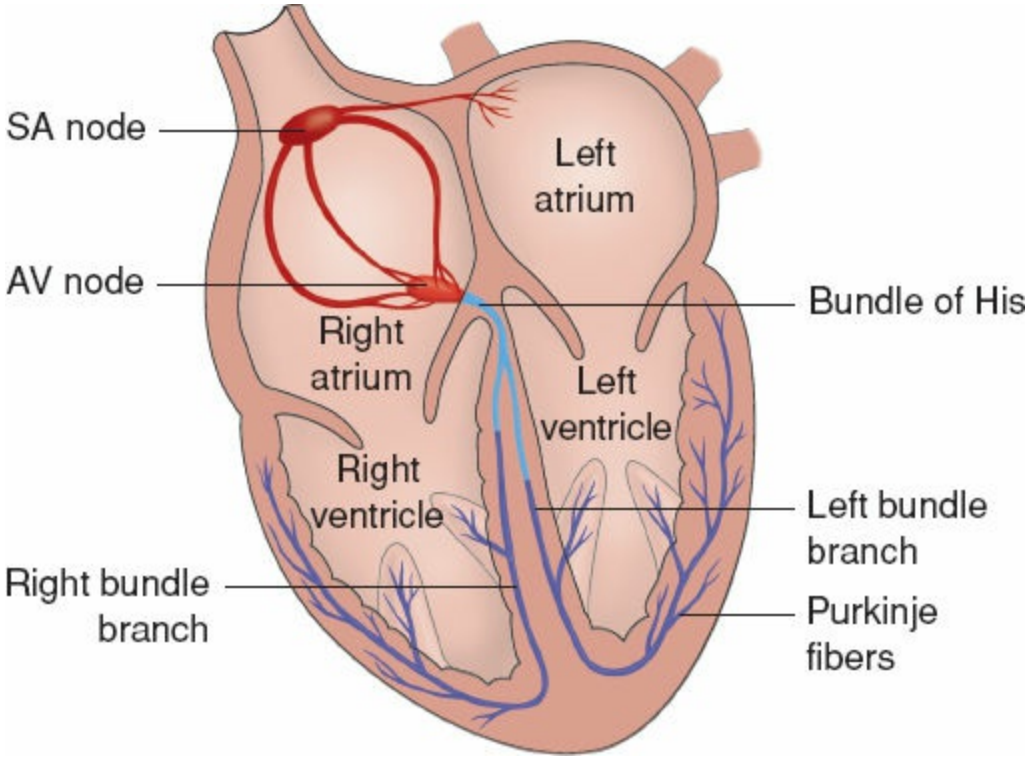

FIGURE 12-4 Cardiac conduction system. AV, atrioventricular; SA, sinoatrial.

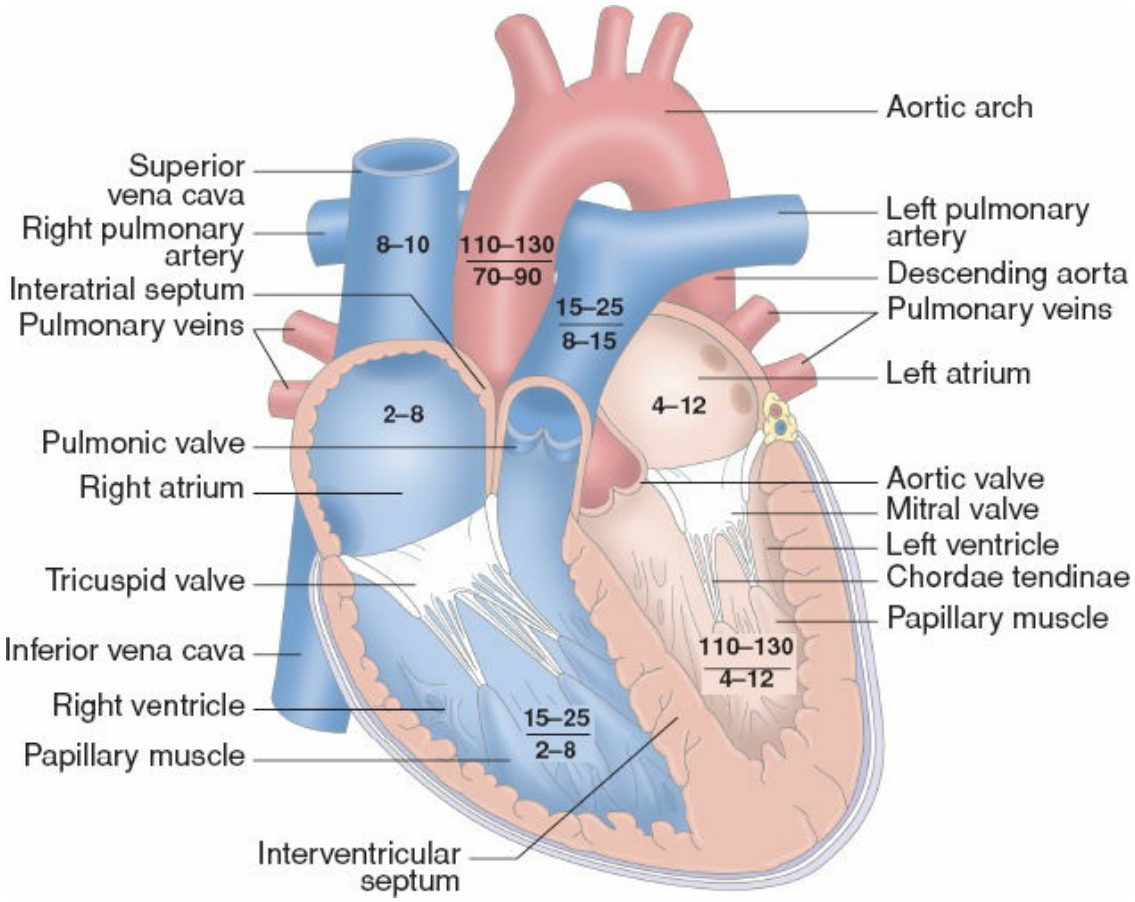

FIGURE 12-5 Great vessel and chamber pressures. Pressures are identified in mm Hg as mean pressure or systolic over diastolic pressure.

At the cellular level, the electrical activity of the heart is due to the exchange of electrically charged particles, called *ions*, across channels located in the cellular membranes. These channels regulate the movement and speed of ions, specifically sodium and potassium. When the cell is in its resting or polarized state, sodium is the primary extracellular ion, whereas potassium is the primary intracellular ion. This difference in ion concentration causes the inside of the cell to have a negative charge, compared with the positive charge on the outside. A reversal of these charges occurs during electrical stimulation of the myocardial cells, as sodium ions move into the cell and potassium ions exit. This exchange of ions characterizes the period known as depolarization, which is followed rapidly by the contraction of the stimulated myocardium. Once depolarization is complete, the exchange of ions reverts back to its polarized state. This period is known as repolarization. It is analogous to a rest period that allows the myocardial cells to prepare for the next depolarization and subsequent contraction.

Cardiac Hemodynamics

Cardiac hemodynamics describes the pumping forces or pressure required by the heart to maintain blood flow throughout the cardiovascular system. An important determinant of blood flow is the principle that fluid flows from a region of higher pressure to one of lower pressure. The pressures responsible for blood flow are generated during systole and diastole. Figure 12-5 identifies the pressures in the great vessels and heart chambers during systole and diastole.

Cardiac Cycle 

The cardiac cycle is the term used to describe the events that occur in the heart from the beginning of one heartbeat to the beginning of the subsequent one. Therefore, the number of cardiac cycles completed in a minute is dependent on the heart rate. Each cardiac cycle has three major sequential events, which include diastole, atrial systole, and ventricular systole. Diastole is the period in which the atria and ventricles are in a relaxed state, allowing the ventricles to fill with blood. Systole refers to the period of myocardial contraction.

Deoxygenated blood (venous blood) from the tissues enters the pulmonary circulation by flowing into the right atrium via the superior vena cava (head, neck, and upper extremities), inferior vena cava (trunk and lower extremities), and coronary sinus (heart). On the left side of the heart, oxygenated blood from the pulmonary circulation returns to the left atrium via the pulmonary veins. During diastole, the pressure in the ventricles is reduced, allowing the AV valves (tricuspid valve in the right heart and mitral valve in the left heart) to open. Blood flows freely from both atria into the ventricles. At the end of diastole, the atria contract (atrial systole), forcing the remaining blood into the ventricles. Atrial systole, better known as the "atrial kick," is an important event because it augments ventricular blood volume by 15% to 25%.

Nursing Alert
Loss of the atrial kick decreases cardiac output, leading to the development of symptoms in the

patient such as dizziness, lightheadedness, syncope, decreased activity tolerance, and hypotension. Atrial fibrillation is an arrhythmia that is known to be associated with the loss of the atrial kick. Loss of coordinated atrial contraction into the ventricle will decrease the left ventricular preload and significantly lower cardiac output.

During ventricular systole, rising pressure in the ventricles closes the AV valves and forces the semilunar valves (pulmonic valve in the right side of the heart and aortic valve in the left side of the heart) to open. Additional structures attached to the AV valves (chordae tendineae and papillary muscles) keep the valve leaflets closed, thereby preventing regurgitation of blood into the atria. This function permits the one-way flow of blood from the right ventricle into the PA and into the lungs for oxygenation (pulmonary circulation) and from the left ventricle into the aorta and out into the remainder of the body via the systemic circulation.

Cardiac Output

Cardiac output refers to the amount of blood pumped by each ventricle in liters per minute (L/min). In an adult at rest, the cardiac output is about 4 to 6 L/min but varies greatly depending on the metabolic needs of the body.

Cardiac output is a function of the stroke volume and the heart rate. Stroke volume is the amount of blood ejected with each heartbeat. The average resting stroke volume is about 70 mL. Each time the heart beats, only a fraction of the blood present in the ventricles is ejected, which is referred to as the ejection fraction (EF). The EF of the left ventricle (normally 50% to 70%) is commonly assessed because it is an important noninvasive measure of myocardial contractility: the EF is lower in conditions that depress myocardial contractility (e.g., myocardial infarction [MI] and heart failure [HF]).

Effect of Heart Rate on Cardiac Output. Cardiac output meets the metabolic demands of the tissues, in part, by changes in heart rate. For example, the heart rate increases during periods of high oxygen demand, such as physical activity, and returns to baseline heart rate at rest. Changes in heart rate are accomplished by inhibition or stimulation of the SA node, through the parasympathetic and sympathetic divisions of the autonomic nervous system. The parasympathetic impulses, which travel to the SA node via the vagus nerve, slow the heart rate, whereas sympathetic innervations via $beta_1$ receptor sites increase heart rate.

Heart rate is also stimulated by an increased level of circulating catecholamines (secreted by the adrenal gland) and by excess thyroid hormone, which produces a catecholamine-like effect.

In addition, heart rate is affected by central nervous system and baroreceptor activity. Baroreceptors, located in the aortic arch and the right and left internal carotid arteries (at the point of bifurcation from the common carotid arteries), are sensitive to changes in BP. During elevations in BP (hypertension), these cells increase their rate of discharge, transmitting impulses to the medulla. This initiates parasympathetic activity and inhibits sympathetic response, lowering the heart rate and the BP. In contrast, low BP (hypotension) exerts less baroreceptor stimulation, decreasing the parasympathetic action on the SA node and allowing for enhanced sympathetic activity. The resultant vasoconstriction and increased heart rate elevate the BP.

Effect of Stroke Volume on Cardiac Output. Stroke volume is a major determinant of cardiac output and is influenced by three interdependent factors: preload, afterload, and contractility.

Preload refers to the pressure generated in the ventricles at the end of diastole and the resultant stretching of the muscle fibers. A direct relationship exists between end-diastolic blood volume and the degree of stretch. As the volume of blood increases, the degree of stretch increases, resulting in stronger contraction and a greater stroke volume. This relationship, called the Frank-Starling (or Starling) law of the heart, is maintained until the physiologic limit of the muscle is reached.

Preload is decreased by a reduction in the volume of blood returning to the ventricles. Vasodilatation and loss of fluid volume from bleeding, diuresis, vomiting, or excessive diaphoresis reduce preload. Preload is increased by increasing the return of circulating blood volume to the ventricles. Controlling the loss of blood or body fluids and replacing fluids (i.e., blood transfusions and intravenous [IV] fluid administration) are examples of ways to increase preload.

Afterload, the amount of resistance to ejection of blood from the ventricle, is the second determinant of stroke volume. The right side of the heart collects venous blood, which has a very low pressure and is met with little resistance as blood is ejected into the pulmonary vascular system, better known as pulmonary vascular resistance (PVR). On the other hand, the left side of the heart requires significantly higher pressures to overcome resistance created by the arteries in the systemic circulation. This resistance is called systemic vascular resistance (SVR).

An inverse relationship exists between afterload and stroke volume. For example, afterload is increased by arterial vasoconstriction, which leads to decreased stroke volume. The opposite is true with arterial vasodilation, a situation that reduces afterload and improves stroke volume.

Nursing Alert

Preload reflects the volume of blood returning to the right and left ventricles at the end of diastole. Central venous pressure (CVP) monitoring measures right heart preload, whereas, PA monitoring measures left ventricular preload.

Afterload is directly affected by arterial vascular tone. Afterload is increased as SVR increases due to vasoconstriction of the aorta and arteries. The opposite affect occurs with arterial vasodilatation. SVR greater than 1,200 dynes implies vasoconstriction, whereas SVR less than 900 dynes implies vasodilation.

Contractility refers to the force generated by the contracting myocardium under any given condition. Contractility is enhanced by circulating catecholamines, sympathetic neuronal activity, and certain medications (e.g., digoxin [Lanoxin], IV dopamine [Intropin], or dobutamine [Dobutrex]). Increased contractility results in increased stroke volume. Contractility is depressed by hypoxemia, acidosis, and certain medications (e.g., beta-adrenergic blocking medications).

Anatomy and Physiology of the Lymphatic System

The lymphatic system and the cardiovascular system are closely linked. The lymphatic system is formed by lymph, lymph vessels, and lymph nodes. This system collects interstitial fluid, called lymph, and returns it to the cardiovascular system, thus helping to maintain preload. The lymphatic system plays an important role in the immune system as well by producing lymphocytes (a white blood cell [WBC]), which defend the body against disease.

Lymph is a fluid similar to plasma that contains plasma proteins, lymphocytes, and other factors. It is formed by the filtration of interstitial fluid into the lymph vessels. Lymph vessels are a complex network of thin-walled vessels that resemble veins with a few exceptions: lymph vessels have thinner walls, have more valves, and contain lymph nodes. Lymph readily filters into these vessels because they are very permeable and are not pressurized.

As lymph circulates through these vessels, it passes through one or more lymph nodes before it is returned to the venous blood via openings in the right or left subclavian vein. Lymph nodes, small bean-shaped structures, filter lymph and provide an environment for lymphocytes to perform their immune function after exposure to foreign antigens, such as bacteria or viruses. Lymph nodes are located in clusters primarily in the neck, axilla, and groin.

The lymphatic vessels converge into two main structures: the thoracic duct and the right lymphatic duct. The lymphatic vessels rely on one-way valves, arterial pulsations, and contraction of the lymphatic walls and adjacent skeletal muscle to propel lymph toward the venous drainage points in the subclavian veins.

Gerontologic Considerations

As people age, myocardial muscle mass shrinks (atrophy) and its walls thicken (hypertrophy). The aging process also results in decreased elasticity and widening of the aorta, calcification and stiffening of the blood vessels, thickening and increased rigidity of the cardiac valves, and increased connective tissue in the cardiac conduction system. These changes lead to decreased cardiac output and impaired blood flow to the tissues. As a result, the aging heart has limited ability to respond to increased demands for oxygen and nutrients caused by physical or emotional stress and disease states. These age-associated changes place the elderly at risk for the development of serious symptoms, including fatigue, shortness of breath, angina, palpitations, leg pain, dizziness, or syncope. Age-related changes of the cardiovascular system are summarized in Table 12-1.

Gender Considerations

The heart of a woman is smaller and weighs less, compared with the heart of a man. Coronary arteries of the female heart are smaller and thus occlude from atherosclerosis more easily and make procedures such as cardiac catheterization and percutaneous coronary interventions technically more difficult, with a higher incidence of postprocedural complications. In addition, the resting heart rate, stroke volume, and EF of a woman's heart are higher than those of a man's heart. The first onset of coronary artery disease (CAD) in women is almost a decade later than in their male counterparts. These gender differences in disease presentation are attributed to the premenopausal protection of circulating estrogen.

ASSESSMENT OF THE CARDIOVASCULAR SYSTEM

The frequency and extent of the nursing assessment of the cardiovascular system are based on several factors, including the severity of the patient's symptoms, the presence of risk factors, the practice setting, and the purpose of the assessment. Although the key components of the cardiovascular assessment remain the same, the assessment priorities vary according to the needs of the patient. For example, an emergency department nurse caring for a patient who is admitted with symptoms associated with acute coronary syndrome (ACS—a term used for any condition brought on by a sudden blockage of blood flow to the heart) performs a rapid and focused assessment because treatment of ACS is time-dependent.

Health History

Nurses practicing in settings where patients with CVD are seen must be expert at recognizing cardiac symptoms as well as expediting timely and, oftentimes, lifesaving care. Likewise, patients must be able to recognize when they are experiencing these symptoms and know how to manage them. All too often, patients fail to appreciate the significance of new or worsening cardiac symptoms. This problem results in prolonged delays in seeking treatment. Major barriers to seeking prompt lifesaving care include lack of knowledge about personal risk and symptoms of heart disease, attributing symptoms to a benign source, denying symptom significance, and feeling embarrassed about having symptoms (Gillis, Arslanian-Engoren, & Struble, 2014). Box 12-1 discusses results of a study testing the effect of an educational intervention on Latinas' knowledge of CVD risk factors and prevention strategies.

TABLE 12-1 GERONTOLOGIC CONSIDERATIONS / Age-Related Changes in the Cardiovascular System

Cardiovascular System Component	Structural Changes	Functional Changes	History and Physical Examination Findings
Ventricular myocardium	Loss of muscle mass Hypertrophy	Stiff, noncompliant ventricles Decrease in cardiac output	Fatigue, ↓ exercise tolerance HF or arrhythmia signs/ symptoms PMI palpated lateral to midclavicular line Auscultation reveals S_4
Valves	Calcification of AV valves	Turbulent blood flow across valves	Murmurs and thrills
Conduction system	Deposits of connective tissue	↓ SA node rate and ↓ speed of conduction	Bradycardia Heart block
Sympathetic nervous system	↓ response to beta-adrenergic stimulation	↓ HR and contractility "in" response "to" exercise ↑ time for HR to return to baseline	Fatigue and ↓ exercise tolerance
Aorta and arteries	Calcification and stiffening of the blood vessels ↓ Elasticity and widening of aorta	Left ventricular hypertrophy	Progressive ↑ systolic BP; ↑ diastolic BP Widening pulse pressure
Baroreceptor response	↓ Baroceptor sensitivity to episodes of hypertension and hypotension	Baroreceptors fail to regulate HR and vascular tone, causing a slow response to postural changes	Postural hypotension, dizziness, or syncope when sitting or standing up

AV, atrioventricular; BP, blood pressure; HF, heart failure; HR, heart rate; PMI, point of maximal impulse; SA, sinoatrial; ↓, decreased; ↑, increased.

Common Complaints

Common CVD signs and symptoms, with related medical diagnoses in parentheses, are covered in the section below.

- Chest pain or discomfort (ACS that includes unstable angina and acute MI, arrhythmias, valvular heart disease)

- Pain or discomfort in other areas of upper body, including one or both arms, back, neck, jaw, or stomach (ACS)
- Dizziness, syncope, or changes in level of consciousness (ACS, cardiogenic shock, cerebrovascular disorders, arrhythmias, hypotension, postural hypotension, vasovagal episode)
- Intermittent claudication or rest pain in lower extremities, especially at night (peripheral arterial disease [PAD])
- Palpitations or tachycardia (ACS, caffeine or other stimulants, electrolyte imbalances, HF, stress, valvular heart disease, ventricular aneurysm)
- Peripheral edema (HF, PAD), weight gain (HF), or ascites and abdominal distension due to enlarged liver and spleen (HF)
- Shortness of breath or dyspnea, with or without chest pain (ACS, cardiogenic shock, HF, pulmonary edema, valvular heart disease)
- Unusual fatigue characterized by feeling more tired or fatigued than usual (early warning symptom of ACS, HF, valvular heart disease)

Chest Pain

Chest pain and chest discomfort are common symptoms caused by a number of cardiac and noncardiac problems. Table 12-2 identifies the characteristics of common causes of chest pain. To differentiate among these causes of pain, the nurse asks the patient to identify the quantity (0 = no pain to 10 = worst pain), location, and quality of pain. It is important to identify the events that precipitated symptom onset, the duration of the symptom, measures that aggravate or relieve the symptom, and associated signs and symptoms, such as diaphoresis or nausea. The nurse should keep the following points in mind when assessing patients with chest pain or discomfort:

- The severity and duration of chest pain or discomfort does not predict the seriousness of its cause. For example, a patient experiencing esophageal spasm may rate chest pain as a "10/10," whereas, a patient experiencing an acute MI may report only mild to moderate chest pressure.
- More than one cardiac condition may occur simultaneously. During an acute MI, patients may report chest pain from myocardial ischemia (inadequate oxygen supply to the tissues), shortness of breath from HF, and palpitations from arrhythmias. Both HF and arrhythmias are complications of acute MI.

BOX 12-1 Nursing Research

Bridging the Gap to Evidence-Based Practice

What does the current evidence reveal about the effect of an educational intervention on immigrant Latinas' knowledge of cardiovascular risk factors and prevention strategies?

Koniak-Griffin, D., & Brecht, M. L. (2015). Awareness of cardiovascular disease and preventive behaviors among overweight immigrant Latinas. *Journal of Cardiovascular Nursing, 30*(5), 447–455.

Purpose

Almost one third of Latino women die from all forms of cardiovascular disease (CVD), including heart disease and stroke, making it the leading cause of death in this population. It is alarming to note that disparities in Latino women's awareness and knowledge about CVD risk factors and prevention strategies exist despite efforts made by the American Heart Association, the National Alliance for Hispanic Health, the Office of Women's Health, and other community outreach programs. The purpose of this study was to evaluate the effect of a lifestyle behavior intervention (LSBI) on awareness and knowledge of CVD risk factors and prevention strategies in overweight, Spanish-speaking, immigrant Latinas.

Design

This randomized controlled trial was conducted in two communities of Los Angeles, California. Eligible participants were Spanish and/or English-speaking Latina, between the ages of 35 and 64 years, and had a body mass index (BMI) of 25 or greater. Exclusion criteria included impaired physical mobility, type 1 diabetes, uncontrolled hypertension, or history of a heart attack or stroke. A health clearance was required for those with type 2 diabetes or hypertension controlled by diet and/or oral medications prior to enrollment. The women were randomly assigned to an experimental group and received a 6-month LSBI (2 months of group education on CVD prevention followed by 4 months of individual teaching and coaching) or a control group in which women received 6 months of safety and disaster preparedness education. The LSBI curriculum was based upon Su Corazón, Su Vida/Your Heart, Your Life, a National Heart Lung and Blood program designed specifically for use with Latinos. The intervention group was facilitated by promotora, specially trained lay health advisors. CVD knowledge was examined using an 11-item true-or-false test. Dietary habits were determined using a 27-item survey with a Likert scale response that had been used extensively in previous projects. The study was approved by the institutional review board of the University of California, Los Angeles.

Findings

The results of a preliminary analysis of data from 90 women in the intervention group were reported in this publication. These women had a mean age of 42.6 years, were obese (BMI, mean, 32.5 ± 5.2) and the majority was of Mexican descent (83%). This group of low income women had low acculturation and educational attainment with 51.7% having completed eighth grade or less.

There was a statistically significant improvement in total CVD knowledge scores and in nine of the 11 items postintervention, controlling for age and education. Almost all of the women postintervention knew that overweight women face increased risk for heart disease and diabetes (97.8%), eating smaller portions of a variety of foods lower in fat and calories is the healthiest way to lose weight (96.67%), physical activity can lower a woman's risk for heart disease (95.6%), and high blood pressure is a heart disease risk factor that you can do something about (94.4%). Although the item regarding heart disease as the leading cause of death in women improved significantly, eight women answered incorrectly despite the intensive education. Another concern was related to the fact that 87.8% of the women failed to recognize that women may have heart attack

symptoms that are different from those in men. There were no significant correlations between CVD knowledge scores and overall dietary habits score, demographic characteristics (age, education, acculturation, and years living in the United States), BMI, or physical activity.

Nursing Implications

More than a decade of public education campaigns aimed at enhancing women's CVD awareness have not reached all women. Latino women with lower acculturation and socioeconomic status may benefit most from local community-based LSBI lead by promotora. Knowledge alone is not associated with lifestyle behaviors including heart-healthy nutrition and physical activity. Latino women at high risk for CVD may benefit from ongoing support to translate new knowledge into lifestyle changes. The results of this study illustrate the need for continued testing of interventions designed to effect CVD risk reduction over the lifespan.

Symptoms of Acute Coronary Syndrome

Nurses must take complaints of patients with cardiac symptoms seriously until the cause is determined. Because CAD is so prevalent, all patients reporting new or worsening cardiac symptoms, particularly those at risk for CAD or who have a history of CAD, should be evaluated initially for ACS. There are several distinct characteristics of ACS symptoms that need to be kept in mind during assessment:

- The majority of patients with ACS experience prodromal symptoms sometimes a month or more prior to developing this acute event. Prodromal symptoms include unusual fatigue, shortness of breath, sleep disturbances, anxiety, or fleeting chest discomfort (aching, pressure) that comes and goes. Because these symptoms are less severe than what is experienced during ACS, patients often attribute them to a benign problem, such as stress, and fail to seek medical care. Nurses should include a question regarding presence of prodromal symptoms when assessing patients with cardiac symptoms.
- Approximately 50% of men and women with ACS experience chest symptoms, whereas the remainder may develop a variety of symptoms such as upper back, shoulder, arm, or neck pain; epigastric burning; or shortness of breath. There are many misconceptions that men and women have about their cardiac risk factors and signs and symptoms of heart disease.
- During the onset of ACS, people experience a group of at least four or more symptoms that can include chest discomfort or pain; upper back, shoulder, arm, or neck pain; epigastric burning or indigestion; shortness of breath; unusual fatigue; and diaphoresis. The combination of symptoms can vary from person to person (Gillis, Arslanian-Engoren, & Struble, 2014).
- Neuropathies in elderly patients and those with diabetes may prevent these patients from experiencing pain or discomfort associated with myocardial ischemia. Instead, they may report unusual fatigue or shortness of breath. In some patients, ACS may be asymptomatic, which is referred to as *silent ischemia.*

- A 12-lead electrocardiogram (ECG) and serum laboratory analysis of cardiac biomarkers are necessary to determine if the patient with ACS symptoms is experiencing unstable angina or acute MI.

TABLE 12-2 Characteristics of Cardiac and Noncardiac Causes of Chest Pain

Location	Character	Duration	Precipitating Events and Aggravating Factors	Alleviating Factors
Angina pectoris Acute coronary syndrome (ACS) (unstable angina, myocardial infarction [MI])  Less common sites of pain with myocardial ischemia	Angina: Uncomfortable pressure, squeezing, or fullness in substernal chest area Can radiate across chest to the medial aspect of one or both arms and hands, jaw, shoulders, upper back, or epigastrium Radiation to arms and hands, described as numbness, tingling, or aching ACS: Same as angina pectoris Pain or discomfort ranges from mild to severe Associated with shortness of breath, diaphoresis, palpitations, unusual fatigue, and nausea or vomiting	Angina: 5–15 minutes ACS: 15 min or more	Angina: Physical exertion, emotional upset, eating large meal, or exposure to extremes in temperature ACS: Emotional upset or unusual physical exertion occurring within 24 hours of symptom onset Can occur at rest or while asleep	Angina: Rest, nitroglycerin, oxygen ACS: Morphine, reperfusion of coronary artery with thrombolytic agent or percutaneous coronary intervention
Pericarditis 	Sharp, severe substernal or epigastric pain Can radiate to neck, arms, and back Associated symptoms include fever, malaise, dyspnea, cough, nausea, dizziness, and palpitations	Intermittent	Sudden onset Pain increases with inspiration, swallowing, coughing, and rotation of trunk	Sitting upright, analgesia, anti-inflammatory medications
Pulmonary disorders (pneumonia, pulmonary embolism) 	Sharp, severe substernal or epigastric pain arising from inferior portion of pleura (referred to as pleuritic pain). Patient may be able to localize the pain	30 minutes or more	Follows an infectious or noninfectious process (MI, cardiac surgery, cancer, immune disorders, uremia) Pleuritic pain increases with inspiration, coughing, movement, and supine positioning Occurs in conjunction with community-acquired or nosocomial lung infections (pneumonia) or deep vein thrombosis (pulmonary embolism)	Treatment of underlying cause

Esophageal disorders (hiatal hernia, reflux esophagitis or spasm) 	Substernal pain described as sharp, burning, or heavy Often mimics angina Can radiate to neck, arm, or shoulders	5–60 minutes	Recumbency, cold liquids, exercise	Food or antacid
Anxiety and panic disorders 	Pain described as stabbing to dull ache Associated with diaphoresis, palpitations, shortness of breath, tingling of hands or mouth, feeling of unreality, or fear of losing control	Peaks in 10 minutes	Can occur at any time, including during sleep Can be associated with a specific trigger	Removal of stimulus, relaxation, medications to treat anxiety or underlying disorder
Musculoskeletal disorders (costochondritis) 	Sharp or stabbing pain localized in anterior chest Most often unilateral Can radiate across chest to epigastrium or back	Hours to days	Most often follows respiratory tract infection with significant coughing, vigorous exercise, or posttrauma Some cases are idiopathic Exacerbated by deep inspiration, coughing, sneezing, and movement of upper torso or arms	Rest, ice, or heat Analgesic or anti-inflammatory medications
Dissecting aorta	Severe, persistent tearing pain in anterior chest/back Radiates to shoulders, epigastrium or abdomen Associated with diaphoresis and tachycardia	Sudden onset	Hypertension, blunt chest trauma, or cocaine use	Medical or surgical interventions

History

Epidemiologic studies show that certain conditions or behaviors (i.e., risk factors) are associated with a greater incidence of CAD, cerebrovascular disease, and PAD (AHA, 2016). The nurse might ask some of the following questions:

- How is your health? Have you noticed any changes from last year? From 5 years ago?
- Do you have a cardiologist or primary health care provider? How often do you go for checkups?
- What are your risk factors for heart disease? What do you do to reduce these risk factors? Box 12-2 lists risk factors for CVD and treatment goals.

Patients who lack understanding of their risk factors and diagnosis may be less motivated to make lifestyle changes or manage their cardiac disease effectively. On the other hand, patients who have this awareness and believe that they have the power to modify their risk factors may be more likely to engage in prevention measures. Once patients' risk factors are identified, the nurse determines if patients have a plan for making necessary lifestyle changes and if assistance is needed to support these changes.

BOX 12-2 Risk Factors for Cardiovascular Diseases (CVD)

Nonmodifiable Risk Factors

- Older age
- Male gender
- Heredity, including race

Modifiable Risk Factors and Treatment Goals[a]

- Hyperlipidemia (LDL less than 100 mg/dL and preferably less than 70 mg/dL if CAD present; LDL less than 160 mg/dL if one or more risk factors or 130 mg/dL if two or more risk factors; HDL greater than 40 mg/dL and triglycerides less than 150 mg/dL)
- Hypertension (less than 140/90 mm Hg; less than 130/80 if diabetes or chronic renal disease present)
- Cigarette smoking (complete cessation, no secondhand tobacco exposure)
- Diabetes mellitus (fasting serum glucose less than 110 mg/dL and hemoglobin A_{1c} less than 7%)
- Obesity and overweight (BMI 18.5–24.9 kg/m^2; waist circumference: male 40 in or less, female 35 in or less)
- Physical inactivity (30–60 minutes moderate intensity aerobic activity 5 days or more)

[a]American Heart Association; recommended goals are given in parentheses.

Family History

The nurse inquires about a history of cardiac disease in the patient's family, including:

- A history of sudden death in family members of all ages with or without symptoms or known CAD
- A family member with a biochemical or neuromuscular condition (e.g., hemochromatosis [excessive iron retention in the body] or muscular dystrophy)
- DNA mutation or other genetic testing that was performed on any family member

Cardiovascular disorders associated with genetic abnormalities include familial hypercholesterolemia, hypertrophic cardiomyopathy, long QT syndrome, hereditary hemochromatosis, and elevated homocysteine levels (discussed later in this chapter).

Social History

Medications

Nurses collaborate with other health care providers to obtain a complete list of the patient's medications, including dose and frequency. Vitamins, herbals, and over-the-counter medications are included on this list. During this aspect of the health assessment, the nurse solicits answers to the following questions to ensure that patients are taking their mediations safely and effectively:

- Is the patient independent in taking medications?
- Are the medications taken as prescribed?
- Does the patient know what side effects to report to the prescriber?
- Does the patient understand why the medication regimen is important?
- Are doses ever forgotten or skipped, or does the patient ever decide to stop taking a medication?
- An aspirin a day is a common nonprescription medication that improves patient outcomes after an acute MI. However, if patients are not aware of this benefit, they may be inclined to stop taking aspirin if they think it is a trivial medication. A careful medication history often uncovers common medication errors and causes for nonadherence to the medication regimen.

Nutrition and Metabolism

Dietary modifications, exercise, weight loss, and careful monitoring are important strategies for managing three major cardiovascular risk factors: hyperlipidemia, hypertension, and diabetes mellitus. Diets that are restricted in sodium, fat, cholesterol, and/or calories are commonly prescribed. The nurse obtains the following information:

- How often the patient self-monitors BP, blood glucose, and weight as appropriate to the medical diagnoses
- The patient's knowledge regarding target goals for each of the risk factors, and any problems achieving or maintaining these goals
- What the patient normally eats and drinks in a typical day, and any food preferences (including cultural or ethnic preferences)
- Eating habits (canned or commercially prepared foods versus fresh foods, restaurant cooking versus home cooking, assessing for high-sodium foods, dietary intake of fats)
- Who shops for groceries and prepares meals

Elimination

Typical bowel and bladder habits need to be identified. Nocturia (awakening at night to urinate) is common in patients with HF. Fluid collected in the dependent tissues (extremities) during the day redistributes into the circulatory system once the patient is recumbent at night. The increased circulatory volume is excreted by the kidneys (increased urine production).

When straining during defecation, the patient bears down (the Valsalva maneuver),

which momentarily increases pressure on the baroreceptors. This triggers a vagal response, causing the heart rate to slow, which may lead to syncope in some patients. Straining during urination can produce the same response.

Because many cardiac medications can cause GI side effects or bleeding, the nurse asks about bloating, diarrhea, constipation, stomach upset, heartburn, loss of appetite, nausea, and vomiting. Patients taking platelet-inhibiting medications such as aspirin and clopidogrel (Plavix); platelet aggregation inhibitors such as abciximab (ReoPro), eptifibatide (Integrilin), and tirofiban (Aggrastat); and IV anticoagulants such as low–molecular-weight heparin (i.e., dalteparin [Fragmin], enoxaparin [Lovenox]), heparin, or oral anticoagulants (i.e., warfarin [Coumadin] rivaroxaban [Xarelto] or apixaban [Eliquis]) are screened for bloody urine (hematuria) or stools (red, black, or tarry), epistaxis (nosebleed), or unusual bruising.

Activity and Exercise

Changes in patients' activity tolerance may be gradual and go unnoticed. The nurse determines if there are recent changes by comparing the patient's current activity level with that performed in the past 6 to 12 months. New symptoms or a change in the usual symptoms during activity is a significant finding. Activity-induced angina or shortness of breath (SOB) may indicate CAD, which requires medical attention. Arterial insufficiency is suspected if the patient experiences intermittent claudication, described as a lower extremity muscular, cramping pain that occurs with activity and is relieved by rest. Angina and intermittent claudication occur when there is tissue ischemia or inadequate arterial blood supply, in the setting of increased demand (e.g., exercise, stress, or anemia). As the tissues are forced to function without adequate nutrients and oxygen, muscle metabolites and lactic acid are produced. Pain is experienced as the metabolites aggravate the nerve endings of the surrounding tissue. Rest pain is a persistent pain in the anterior portion of the foot at rest that can worsen at night and indicates significant arterial insufficiency and a critical state of ischemia.

Fatigue, associated with a low left ventricular EF (less than 40%) and certain medications (e.g., beta-adrenergic blocking agents), can result in activity intolerance. Patients with fatigue may benefit from having their medications adjusted and learning energy-conservation techniques.

Additional areas to explore include the presence of architectural barriers in the home (stairs, multilevel home), the patient's involvement in cardiac rehabilitation, and the patient's typical exercise pattern, including intensity, frequency, and duration.

Sleep and Rest

Clues to worsening cardiac disease, especially HF, can be revealed by sleep-related events. Determining where the patient sleeps or rests and any recent changes in sleep habits is important. Worsening HF is characterized by pulmonary congestion resulting in dyspnea at rest or when lying down. *Orthopnea* is the term used to indicate the need to sit upright or stand to avoid dyspnea. Thus, patients with worsening HF will report that they sleep upright in a chair instead of in bed; increase the number of pillows used; awaken from sleep with sudden onset of dyspnea, often associated with coughing and wheezing, called *paroxysmal nocturnal dyspnea* (PND); or awaken with angina (nocturnal angina). PND

occurs at night and is caused by the reabsorption of fluid from dependent areas of the body (arms and legs) back into the circulatory system within hours of lying in bed. This sudden fluid shift increases preload and places too great a demand on the heart of patients with HF, causing sudden pulmonary congestion.

There is mounting evidence pointing to the cardiac consequences associated with sleep-disordered breathing (SDB). SDB is an abnormal respiratory pattern due to intermittent episodes of upper airway obstruction causing apnea and hypopnea (shallow respirations) during sleep. These abnormal sleep events cause intermittent hypoxemia, sympathetic nervous system activation, and increased intrathoracic pressure that puts mechanical stress on the heart and large artery walls. Untreated SDB has been linked to CAD, hypertension, HF, and arrhythmias. SDB is treated by the use of continuous positive airway pressure (CPAP) and mandibular advancement devices (MAD). These devices maintain an open airway during sleep, preventing hypoxemia and resulting abnormal elevations in BP. The cardinal signs of SBD are loud, disruptive snoring and apnea lasting 10 seconds or more. Obesity and large neck circumference are two important risk factors for SDB (Ayas, Owens, & Kheirandish-Gozal, 2015).

During the health history, the nurse assesses for SDB by asking high-risk patients if they snore loudly, have frequent bouts of awakening from sleep, waking with a headache, or experience severe daytime sleepiness (hypersomnolence). For patients with a diagnosis of SDB, the nurse determines if the patient has been prescribed a CPAP or MAD and the frequency of its use. Patients who are being admitted to the hospital or going for an ambulatory surgical procedure should be instructed to bring their sleep aid devices with them.

Cognition and Perception

Evaluating cognitive ability helps determine whether the patient has the capacity to manage safe and effective self-care independently. Is the patient's short-term memory intact? Is there any history of dementia? Is there evidence of depression or anxiety? Can the patient read? Can the patient read English? What is the patient's reading level? What is the patient's preferred learning style? What information does the patient perceive as important? Providing the patient with written information can be a valuable part of patient education but only if the patient can read and comprehend the information.

Related assessments include possible hearing or visual impairments. If vision is impaired, patients with HF may not be able to weigh themselves independently or keep records of weight, BP, pulse, or other data requested by the health care team.

Self-Perception and Self-Concept

Self-perception and self-concept are related to the cognitive and emotional processes that people use to formulate their beliefs and feelings about themselves. It is important for the nurse to understand patients' beliefs and feelings about their health as these concepts are key determinants of patients' adherence to new medical regimens and lifestyle changes (e.g., smoking cessation, weight reduction, exercise), which are necessary for effective self-management after an acute cardiac event. Patients who have misperceptions about the health consequences of their cardiac illness are at risk for nonadherence to their treatment plan. Responses of patients to the following questions will guide the nurse in planning

interventions to assure that patients are prepared to manage their illness and that adequate services are in place to support the patient's recovery and self-management needs.

- What is your cardiac problem, and what do you think has contributed to this problem?
- What consequences do you think this illness will have on your current lifestyle (leisure and physical activities, work, role in the family and social relationships)?
- How much of an influence do you think you have on controlling this illness?

Sexuality and Reproduction

A common problem for patients with cardiac diseases is a decrease in frequency of and satisfaction with sexual activity. These changes are associated with inadequate information, depression, and fear of having a cardiac event (e.g., AMI, sudden death) or development of bothersome symptoms (e.g., chest discomfort, shortness of breath, palpitations). In men, impotence may develop as a side effect of cardiac medications (e.g., beta-blockers); some men will stop taking their medication as a result. Other medications may be substituted so patients should be encouraged to discuss this problem with their health care providers.

Patients and their partners may not have adequate information about the physical demands related to sexual activity and ways in which these demands can be modified. The physiologic demands are greatest during orgasm, reaching 5 or 6 metabolic equivalents (METs), which is equivalent to walking 3 to 4 miles per hour on a treadmill. The METs expended before and after orgasm are considerably less, at 3.7 METs. Sharing this information may make the patient and his or her partner more comfortable about resuming sexual activity (Steinke et al., 2013).

A reproductive history is necessary for women of childbearing age, particularly those with seriously compromised cardiac function. These women may be advised by their health care providers not to become pregnant. The reproductive history includes information about previous pregnancies, plans for future pregnancies, oral contraceptive use (especially in women older than 35 years of age who smoke), menopausal status, and use of hormone therapy.

Coping and Stress Tolerance

Anxiety, depression, and stress are known to influence both the development of and recovery from CAD and HF. High levels of anxiety are associated with an increased incidence of CAD and in-hospital complications after MI. Patients with a diagnosis of an acute MI and depression have an increased risk of rehospitalization and death, more frequent angina, more physical limitations, and poorer quality of life, compared with people without depression. Although the association between depression and CAD is not completely understood, it is postulated that both biologic factors (e.g., platelet abnormalities, inflammatory responses) and lifestyle factors contribute to the development of CAD. People who are depressed are known to be less motivated to adhere to the recommended lifestyle changes and medical regimens necessary to prevent future cardiac events. Patients with CVD should be assessed for depression by asking them if they are feeling sad or blue, if they have lost interest in things they usually enjoy, or have thoughts about death or suicide. Other indications of depression include feelings of worthlessness or guilt, problems falling asleep or staying asleep, having difficulty concentrating, restlessness,

and recent changes in appetite or weight (Havranek et al., 2015; Lichtman et al., 2014).

Stress initiates a variety of physiologic responses, including increased levels of catecholamines and cortisol, and has been strongly linked to cardiovascular events. Therefore, patients need to be assessed for sources of stress, previous coping styles and effectiveness, and perception of their current mood and coping ability. Consultation with a psychiatric advanced practice nurse, psychologist, psychiatrist, or social worker is indicated for anxious or depressed patients or those patients having difficulty coping with their cardiac illness.

Roles and Relationships

Patients with CVD are being managed with complex medical regimens and sophisticated technology, such as implantable cardioverter defibrillators and left ventricular assist devices. Hospital stays for cardiac disorders have shortened, and many invasive diagnostic cardiac procedures, such as cardiac catheterization, are being performed in the ambulatory setting. Therefore, social support is often necessary to facilitate patient's self-management of cardiac illnesses. Patients with lower levels of social support have been shown to have an increased risk for cardiac-related mortality and stroke, compared with others having higher levels of support (Havranek et al., 2015).

To assess patients' role in the family and their relationships, both components of social support, the nurse asks the patient: With whom do you live? Who is your primary caregiver at home? Who helps you manage your health? The nurse also assesses for any significant effects that the cardiac illness has had on the patient's role in the family. Are there adequate finances and health insurance? The answers to these questions help the nurse determine if consultation with social services or others is necessary to tailor the plan of care to meet the patient's self-care needs.

Physical Assessment

During the physical assessment, the nurse is evaluating the cardiovascular system for any deviations from normal with regard to the following (examples of abnormalities are in parentheses):

- The heart as a pump (reduced pulse pressure, gallop sounds, murmurs, displaced PMI)
- Atrial and ventricular filling volumes and pressures (elevated jugular venous distension [JVD], peripheral edema, ascites, crackles, postural changes in BP)
- Cardiac output (reduced pulse pressure, hypotension, tachycardia, reduced urine output, or level of consciousness)
- Compensatory mechanisms (peripheral vasoconstriction, tachycardia)

Assessment of General Appearance and Cognition

The nurse notes signs of distress, which may include pain or discomfort, SOB, or anxiety.

The patient's height and weight are measured to calculate body mass index (BMI) (weight in kilograms/square of the height in meters), as well as the waist circumference. These measures are used to determine if obesity (BMI greater than 30 kg/m^2) and abdominal fat (males, waist circumference greater than 40 in; and females, waist circumference greater than 35 in) are placing the patient at risk for CAD.

To assess cognition, the nurse evaluates the patient's level of consciousness (alert, lethargic, stuporous, comatose) and mental status (oriented to person, place, time; coherence). Changes in level of consciousness and mental status may be attributed to inadequate perfusion of the brain from a compromised cardiac output or thromboembolic event (stroke).

Inspection and Palpation of the Skin

The signs and symptoms of an acute obstruction of arterial blood flow in the extremities are referred to as the six *P*s, which are *p*ain, *p*allor, *p*ulselessness, *p*aresthesia, *p*oikilothermia (coldness), and *p*aralysis. Additional changes resulting from a chronically reduced supply of oxygen and nutrients to the skin include hair loss, brittle nails, dry or scaling skin, atrophy, skin color changes, and ulcerations. Table 12-3 summarizes common skin findings in patients with CVD.

The nurse assesses capillary refill time, which indicates the adequacy of arterial perfusion to the extremities. To perform this test, the nurse compresses the nail bed briefly to occlude perfusion (nail bed blanches). Then, the nurse releases pressure and determines the time it takes to restore perfusion. Normally, reperfusion occurs within 2 seconds, as evidenced by the return of color to the nail bed. Prolonged capillary refill time indicates compromised arterial perfusion, a problem associated with cardiogenic shock and HF.

TABLE 12-3 Common Skin Findings Associated with Cardiovascular Diseases

Findings	Associated Causes and Conditions
Clubbing of the fingers or toes (thickening of the skin under the fingers or toes)	Chronic hemoglobin desaturation most often due to congenital heart disease, advanced pulmonary diseases and lung cancer; also associated with malignancies and inflammatory bowel disease
Cool/cold skin and diaphoresis	Low cardiac output (e.g., cardiogenic shock, AMI) causing sympathetic nervous system stimulation with resultant vasoconstriction
Cold, pain, pallor of the fingertips or toes	Intermittent arteriolar vasoconstriction (Raynaud disease). Skin may change in color from white, to blue and red accompanied by numbness, tingling, and burning pain.
Cyanosis, central (a bluish tinge observed in the lips, tongue, and buccal mucosa)	Serious cardiac disorders (pulmonary edema, cardiogenic shock, congenital heart disease) as venous blood passes through the pulmonary circulation without being oxygenated.
Cyanosis, peripheral (a bluish tinge, most often of the nails and extremities)	Peripheral vasoconstriction, allowing more time for the hemoglobin molecules to become desaturated. It can be caused by exposure to cold environment, anxiety, or ↓ cardiac output.
Ecchymosis or bruising (a purplish-blue color fading to green, yellow, or brown)	Blood leaking outside of the blood vessels. Excessive bruising is a risk for patients on anticoagulants or platelet-inhibiting medications; coagulopathies, trauma.
Edema, lower extremities (collection of fluid in the interstitial spaces of the tissues)	HF and vascular problems (PAD, chronic venous insufficiency, DVT, thrombophlebitis)
Hematoma (localized collection of clotted blood in the tissue)	Bleeding after catheter removal/tissue injury in patients on anticoagulant/antithrombotic agents.
Pallor (↓ skin color in fingernails, lips, oral mucosa and lower extremities)	Anemia or ↓ arterial perfusion. Suspect PAD if feet develop pallor after elevating legs 60° from a supine position.
Rubor (A reddish-blue discoloration of the legs, seen within 20 seconds to 2 minutes after placing the patient in a dependent position)	Filling of dilated capillaries with deoxygenated blood, indicative of PAD.
Ulcers, feet and ankles (Superficial, irregular ulcers at medial malleolus. Red to yellow granulation tissue). (Painful, deep, round ulcers on feet or from exposure to pressure. Pale to black wound base)	Rupture of small skin capillaries from chronic venous insufficiency Prolonged ischemia to tissues due to PAD. Can lead to gangrene.
Thinning of skin around a pacemaker or an implantable cardioverter defibrillator	Erosion of the device through the skin.
Xanthelasma (yellowish, raised plaques observed along nasal portion of eyelids)	Elevated cholesterol levels (hypercholesterolemia)

AMI, acute myocardial infarction; DVT, deep vein thrombosis; HF, heart failure; PAD, peripheral arterial disease.
Adapted from Bickley, 2013.

Peripheral edema, fluid accumulation in dependent areas of the body (feet, legs, and sacrum in the bedridden patient) is a common finding in patients with CVD. The nurse assesses the patient for pitting edema (a depression over an area of pressure) by using the thumb to place firm pressure over the dorsum of each foot, behind each medial malleolus, and over the shins or sacral area for 5 seconds. The depression created by this pressure is graded as absent or as present on a scale from slight (1+) to very marked (4+). Scales exist to measure the degree of pitting edema that rely on a clinician's judgment of depth of edema or time the indentation remains after release of pressure. It is important that clinicians use a consistent scale in order to ensure reliable clinical measurements and management.

Peripheral edema is observed in patients with HF and peripheral vascular diseases, such as deep vein thrombosis or chronic venous insufficiency.

Assessment of Blood Pressure

Systemic arterial BP is the pressure exerted on the walls of the arteries during ventricular

systole and diastole. It is affected by factors such as cardiac output; distention of the arteries; and the volume, velocity, and viscosity of the blood. The ideal BP is 120/80 mm Hg. A BP of 140/90 mm Hg or greater is defined as *hypertension,* whereas a BP of less than 90/60 mm Hg is called *hypotension.*

During the first encounter with a new patient, BP measurements should be obtained in both arms. There may be a 5 to 10 mm Hg difference in pressure between extremities. A BP difference greater than 10 mm Hg may be indicative of arterial obstruction (on the limb with lower pressure) or aortic dissection and requires further evaluation. See Chapter 13 for more information on BP.

Pulse Pressure

Pulse pressure is the difference between the systolic and the diastolic pressures, which normally is 30 to 40 mm Hg. It indicates how well the body is maintaining cardiac output.

Nursing Alert
A pulse pressure of less than 30 mm Hg signifies a serious reduction in cardiac output and requires further evaluation.

Postural Blood Pressure Changes

Postural (orthostatic) hypotension is a significant decrease in BP with a change in body position from supine to sitting/standing or from sitting to standing. It may be accompanied by dizziness, lightheadedness, or syncope.

The most common cause of postural hypotension in patients with CVD is due to a reduction in preload from over-diuresis, dehydration, or use of medications that cause vasodilatation (nitrates and antihypertensive agents). The following recommendations are important when assessing the patient for postural changes in BP:

- The patient is positioned supine for 10 minutes before obtaining the initial BP and heart rate.
- After obtaining supine measurements, the patient is positioned on the side of the bed with feet dangling, then, if appropriate, with the patient standing at the side of the bed.
- Wait 1 to 3 minutes after each position change before obtaining the BP and heart rate.
- Return the patient to a supine position if dizziness or lightheadedness is reported after the patient sits or stands.
- Record heart rate and BP in each position and any symptoms that accompany the postural change.

Normal postural responses that occur when a person moves from a lying to a sitting or standing position include (1) a heart rate increase of 5 to 20 bpm above the resting rate (to offset reduced stroke volume and maintain cardiac output); (2) a decrease of 10 mm Hg or less in systolic pressure; and (3) a slight increase of 5 mm Hg in diastolic pressure. An increase in heart rate of 15 bpm with either a 20 mm Hg decrease in systolic pressure or a 10 mm Hg decrease in diastolic pressure within 3 minutes are abnormal findings and require further evaluation to determine etiology (Bickley, 2013; LeBlond, Brown, Suneja, & Szot, 2015).

Palpation of Arterial Pulses

The examination of arterial pulses involves assessment of the pulse rate, rhythm, and quality.

Pulse Rate

The normal pulse rate varies from a low of 50 bpm in healthy, athletic young adults to rates well in excess of 100 bpm after exercise or during times of excitement. Anxiety frequently raises the pulse rate during the physical examination. If the rate is higher than expected, the nurse should reassess the pulse at the end of the physical examination when the patient may be more relaxed. A heart rate less than 60 is termed bradycardia, whereas a heart rate greater than 100 is termed tachycardia.

Pulse Rhythm

The rhythm of the pulse is normally regular; although slight irregularities in rhythm can occur due to changes in vagal tone during the respiratory cycle (pulse rate accelerates with inspiration and slows with expiration). This phenomenon, called *sinus arrhythmia,* normally occurs in children and young adults.

During the initial cardiac examination, or if the pulse rhythm is irregular, the nurse assesses pulse rate for a *pulse deficit*, defined as the difference between the apical (apex of the heart, apical impulse is visible in 20% of normal people) and the peripheral pulse rates (Leblond et al., 2015). The pulse deficit is ascertained by simultaneously auscultating the apical pulse and palpating the radial pulse for 1 minute. The nurse should anticipate finding a pulse deficit in patients with arrhythmias, especially atrial fibrillation, atrial flutter, and ventricular arrhythmias. Some of the ventricular systoles generated by these arrhythmias may be much weaker than others; therefore, they are heard during auscultation but do not produce a palpable pulse.

Pulse Quality

The pulse quality or amplitude is indicative of the BP in the artery and is used to assess peripheral arterial circulation. The right and left temporal, common carotid, brachial, radial, and lower extremity arteries are palpated, one side at a time, and compared for symmetry in quality. Light palpation is essential as firm finger pressure can obliterate the temporal, dorsalis pedis, and posterior tibial arteries.

The quality of each of the pulses is reported by using descriptors (absent, diminished, normal, or bounding) or the following 0-to-4 scale:

0: Pulse not palpable or absent
+1: Weak, thready pulse; difficult to palpate; obliterated with pressure
+2: Diminished pulse; cannot be obliterated
+3: Easy to palpate, full pulse; cannot be obliterated
+4: Strong, bounding pulse; may be abnormal

When documenting the pulse quality, specify the artery location and scale range (e.g., “left radial +3/+4”). Other pulse scales exist; the nurse uses the institution’s scale to ensure consistent clinical measurements and management.

Inspection of Jugular Venous Pulsations

Right-sided heart function can be estimated by observing the pulsations of the jugular veins of the neck, which reflects the CVP (right ventricular end-diastolic pressure or right ventricular preload). If internal jugular vein pulsations are difficult to visualize, the external jugular veins are used because they are more superficial and visible right above the clavicles, adjacent to the sternocleidomastoid muscles. In the supine position, the patient's external jugular veins are quite visible but disappear as the head is elevated greater than 30 degrees. The nurse assesses the right internal jugular vein rather than the left because it is anatomically straighter.

Obvious distention of the veins with the patient's head elevated 45 to 90 degrees indicates an abnormal increase in the CVP. This occurs with right-sided HF, cardiac tamponade (see Chapter 15), less commonly with obstruction of blood flow in the superior vena cava, and rarely with acute massive pulmonary embolism.

Inspection and Palpation of the Heart

The heart is examined by inspection, palpation, and auscultation of the precordium or anterior chest wall that covers the heart and lower thorax. A systematic approach is used to examine the precordium in the following areas (see Fig. 12-6).

1. *Aortic area:* Second intercostal space to the right of the sternum. To determine the correct intercostal space, the nurse first finds the angle of Louis by locating the bony ridge at the junction of the body of the sternum and the manubrium. From this angle, the second intercostal space is located by sliding one finger to the right of the sternum. Subsequent intercostal spaces are located from this reference point by palpating down the rib cage.

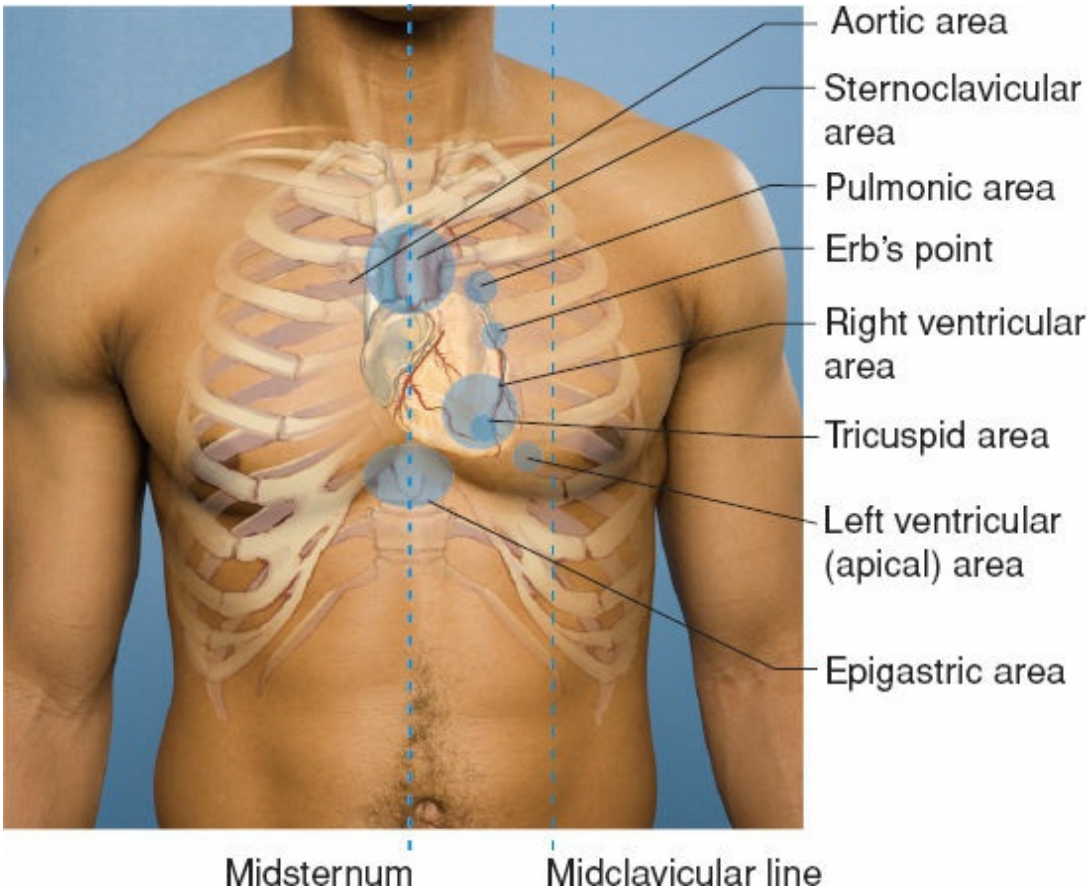

FIGURE 12-6 Areas of the precordium to be assessed when evaluating heart function.

FIGURE 12-7 Locating and palpating the apical impulse, also called the point of maximal impulse (PMI), in the left lateral position. The apical pulse is normally located at the fifth intercostal space to the left of the sternum at the midclavicular line. The nurse locates the impulse with the palm of the hand and palpates with the fingerpads. (© B. Proud.)

2. *Pulmonic area:* Second intercostal space, left sternal border (LSB)
3. *Erb's point:* Third intercostal space, LSB
4. *Tricuspid area:* Fourth and fifth intercostal spaces, LSB
5. *Mitral (apical area):* Left fifth intercostal space at the midclavicular line (MCL)

For most of the examination, the patient lies supine with the head of the bed slightly elevated. A right-handed examiner stands at the right side of the patient; a left-handed examiner at the left side.

Each area of the precordium is inspected for abnormal pulsations. A subtle pulsation located over the apical area, called the apical impulse or PMI, is a normal finding observed in young patients and adults who have thin chest walls. The nurse uses the palm of the hand to locate the apical impulse initially and the fingerpads to assess its size and quality. Palpation of the apical impulse may be facilitated by placing the patient in the left lateral position as this position brings the heart into closer contact with the chest wall (see Fig. 12-7).

Normally, the apical impulse is palpable in only one intercostal space and is no larger than 2 cm in diameter. Feeling the impulse in two or more adjacent intercostal spaces indicates left ventricular enlargement. A vibration or purring sensation felt over any of the precordial areas indicates abnormal, turbulent blood flow. It is best detected by using the palm of the hand. This vibration is called a *thrill*, which is associated with a loud murmur. Depending on the location of the thrill, it may be indicative of serious valvular heart disease or a defect (abnormal opening) in the septum of the atria or ventricles. Thrills that are palpated over blood vessels are associated with significant obstruction of a large artery, such as the carotid artery.

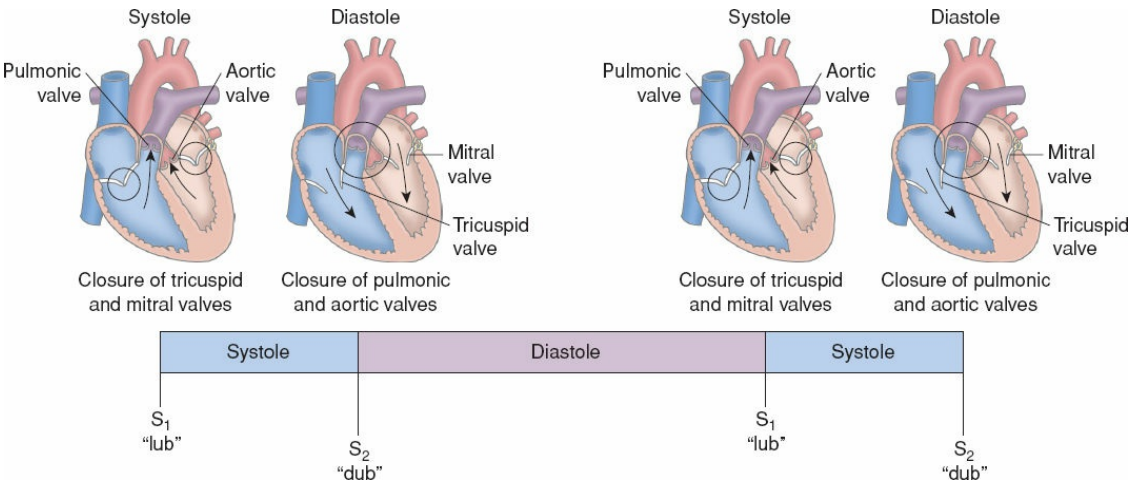

FIGURE 12-8 Normal heart sounds. The first heart sound (S_1) is produced by closure of the mitral and tricuspid valves ("lub"). The second heart sound (S_2) is produced by closure of the aortic and pulmonic valves ("dub"). *Arrows* represent the direction of blood flow during systole and diastole.

Auscultation of the Heart

A stethoscope is used to auscultate each of the locations identified in Figure 12-6, to assess heart rate and rhythm, and to evaluate heart sounds. The apical area is auscultated for 1

minute to determine the apical pulse rate and the regularity of the heartbeat.

Heart Sounds

Normal Heart Sounds. Normal heart sounds, referred to as S_1 and S_2, are produced by closure of the AV valves and the semilunar valves, respectively. The period between S_1 and S_2 corresponds with ventricular systole (Fig. 12-8). When the heart rate is within the normal range, diastole (period between S_2 and S_1) is twice as long as systole. However, as the heart rate increases, diastole shortens.

S_1—First Heart Sound. Tricuspid and mitral valve closure creates the first heart sound (S_1). The word "lub" is used to replicate its sound. S_1 is usually heard the loudest at the apical area (5th ICS left MCL). S_1 is easily identifiable and serves as the point of reference for the remainder of the cardiac cycle. If you are having difficulty determining S_1 from S_2, palpate the pulse, which will cue you into the S_1.

S_2—Second Heart Sound. Closure of the pulmonic and aortic valves produces the second heart sound (S_2), commonly referred to as the "dub" sound. S_2 is heard the loudest over the aortic (2nd ICS, RSB) and pulmonic areas (2nd ICS LSB).

Abnormal Heart Sounds. Abnormal sounds develop during systole or diastole when structural or functional heart problems are present. High-pitched heart sounds are heard best with the diaphragm of the stethoscope (e.g., aortic, pulmonic, tricuspid and mitral valve closure, and regurgitant murmurs), whereas low-pitched sounds (e.g., gallop rhythms or mitral stenosis) are better heard with the bell.

S_3—Third Heart Sound. An S_3 is an abnormal sound heard early in diastole as blood flows from the atrium into a noncompliant ventricle. It is heard immediately after S_2. "Lub-dub-DUB" is used to imitate the abnormal sound of a beating heart when an S_3 (DUB) is present. It represents a normal finding in children and young adults, up to 35 or 40 years of age. In these cases it is called a *physiologic S_3* (Fig. 12-9). In adults, S_3 is a significant finding, suggesting HF. It is heard best by using the bell of the stethoscope with the patient in the left lateral position.

S_4—Fourth Heart Sound. S_4 occurs late in diastole (see Fig. 12-9). S_4, heard just before S_1, is generated during atrial contraction as blood forcefully enters a noncompliant ventricle. This resistance to blood flow is due to ventricular hypertrophy caused by hypertension, CAD, cardiomyopathies, aortic stenosis, and numerous other conditions. The mnemonic used to imitate this gallop sound is "LUB-lub-dub." S_4 (LUB) is auscultated using the bell of the stethoscope over the apical area with the patient in the left lateral position. There are times when both S_3 and S_4 are present, creating a quadruple rhythm, which sounds like "LUB lub-dub DUB." During a tachycardia, all four sounds combine into a loud sound, referred to as a *summation gallop.*

Snaps and Clicks. Opening and closing of diseased valve leaflets create abnormal sounds, called snaps and clicks. Opening snaps are high-pitched diastolic sounds heard as stenotic AV valves are forced open. Systolic clicks, a brief high-pitched sound, are heard early in systole as ridged, calcified semilunar valves are forced open during ventricular contraction. These sounds are the loudest in the areas directly over the diseased valve.

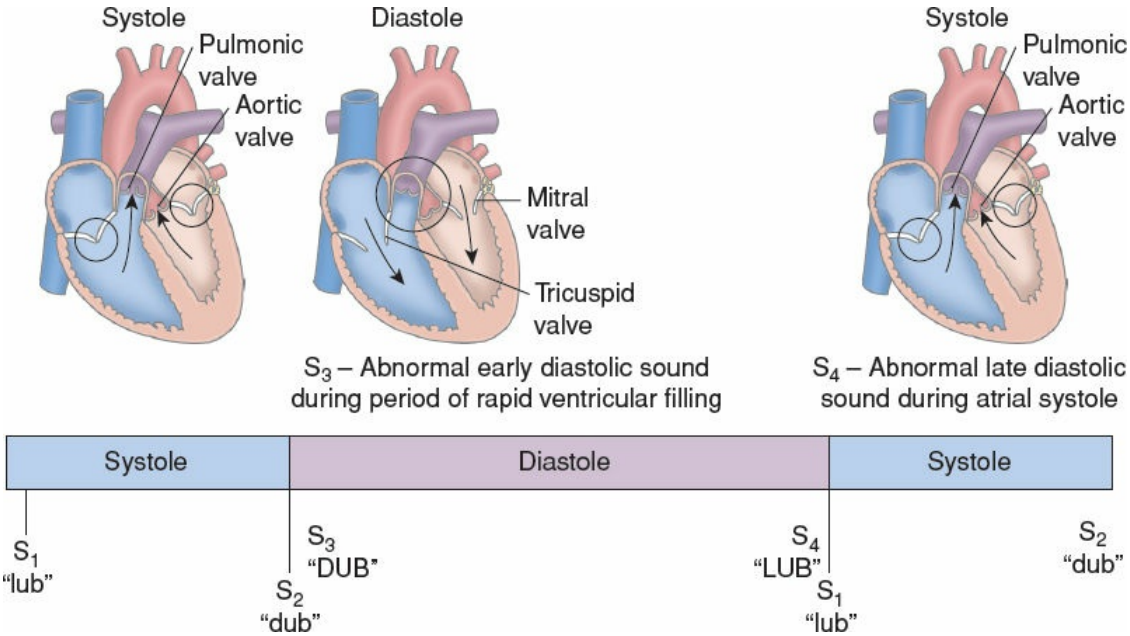

FIGURE 12-9 Gallop sounds. An S_3 ("DUB") is an abnormal sound heard early in diastole, immediately following S_2 (closure of the semilunar valves). This sound is generated very early in diastole as blood flowing into the right or left ventricle is met with resistance. S_4 ("LUB") is an abnormal sound created during atrial systole as blood flowing into the right or left ventricle is met with resistance. *Arrows* show the direction of blood flow.

Murmurs. These are a result of turbulent blood flow across rigid, calcified valves; leaky valves that allow backward blood flow (regurgitation); defects (abnormal openings) in the septum, aorta, or PA; or abnormally high velocity of blood flow through a normal structure (e.g., with fever, pregnancy, hyperthyroidism). Murmurs are described by several characteristics (see Box 12-3) that are used to determine the cause and clinical significance.

BOX 12-3 Characteristics of Heart Murmurs

The following characteristics provide information needed to determine the cause and clinical significance of heart murmurs.

Location: Pinpoints where the murmur is heard the loudest to identify the involved underlying structures (see Fig. 12-6)

Timing: Describes when the murmur is heard (systole, diastole, or both)

Intensity: A grading system is used to describe the intensity or loudness of a murmur:

Grade 1: Very faint and difficult for the inexperienced clinician to hear

Grade 2: Quiet, but readily perceived by the experienced clinician

Grade 3: Easily heard, no palpable thrill

Grade 4: Loud and may be associated with a thrill (a thrill feels like a purring cat under the area)

Grade 5: Very loud; heard when stethoscope is partially off the chest; associated with a thrill

Grade 6: Extremely loud; detected with the stethoscope off the chest; associated with a thrill

Pitch: Describes the sound frequency, ranging from high to medium to low

Quality: Describes the sound that the murmur resembles (rumbling, blowing, whistling)

Radiation: Identifies if the sound of the murmur is transmitted to other precordial areas

Friction Rub. A harsh, grating sound that can be heard in both systole and diastole is called a friction rub. It is caused by abrasion of the inflamed pericardial surfaces from pericarditis. A pericardial friction rub can be heard best using the diaphragm of the stethoscope, with the patient sitting up and leaning forward.

Auscultative Procedure

During auscultation, the patient remains supine. Using the diaphragm of the stethoscope, the nurse auscultates the precordium to identify S_1 and S_2 and then listens for abnormal systolic or diastolic sounds. Repositioning the patient into the left lateral position may facilitate detection of S_3, S_4, and murmurs. Positioning the patient sitting and leaning forward will facilitate detection of the high-pitched diastolic murmur of aortic regurgitation. Ask the patient to exhale and hold their breath as you listen. The characteristics of abnormal findings are documented by identifying the location, timing, intensity, pitch, quality, and presence of radiation (see Box 12-3).

Evaluation of Other Systems

Lungs

The details of the respiratory assessment are described in Chapter 8. Abnormal findings exhibited by patients with CVD include the following:

- *Hemoptysis:* Pink, frothy sputum indicative of acute pulmonary edema.
- *Cough:* A dry, hacking cough from irritation of small airways from pulmonary congestion associated with HF.
- *Crackles:* Typically, first noted at the bases (due to the effect of gravity on fluid accumulation and decreased ventilation of basilar tissue). Crackles may progress to all portions of the lung fields as a result of worsening HF or atelectasis associated with bed rest; splinting from ischemic pain; or the effects of analgesics, sedatives, or anesthetic agents.
- *Wheezes:* Compression of the small airways by interstitial pulmonary edema may cause

wheezing. Beta-adrenergic blocking agents (beta-blockers), such as propranolol (Inderal), may cause airway narrowing, especially in patients with underlying pulmonary disease.

Abdomen

The abdomen is assessed for distention and ascites, hepatojugular reflux, and pulsatile mass.

- *Abdominal distension:* A protuberant abdomen with bulging flanks indicates ascites. Ascites develops in the late stages of HF as abnormally high pressures in the right side of the heart impede the return of venous blood. As a result, the liver and spleen become engorged with excessive venous blood (hepatosplenomegaly). As pressure in the portal system rises, fluid shifts from the vascular bed into the abdominal cavity. Ascitic fluid, found in the dependent or lowest points in the abdomen, will shift with position changes.
- *Hepatojugular reflux:* This test is performed when right ventricular or biventricular HF is suspected. The patient is positioned so that the jugular venous pulse is visible in the lower part of the neck. While observing the jugular venous pulse, firm pressure is applied over the right upper quadrant of the abdomen for at least 5 seconds (see Chapter 15 for further details). An increase of 1 cm or more in jugular venous pressure is indicative of a positive hepatojugular reflux. This positive test aids in confirming the diagnosis of HF.
- *Pulsatile mass:* The most important diagnostic indication of an abdominal aortic aneurysm (a localized dilation formed at a weak point in the arterial wall) is a pulsatile mass in the middle and upper abdomen. About 80% of aneurysms that are 5 cm or larger can be palpated. A systolic bruit (abnormal sound associated with turbulent blood flow in an artery) may be heard over the mass.

Gerontologic Considerations

Peripheral pulses of elderly patients are readily palpable because of decreased elasticity of the arteries and a loss of adjacent connective tissue. In older patients, symptoms of PAD may be more pronounced than in younger patients. Intermittent claudication may occur after walking only a few blocks or after walking up a slight incline. Prolonged pressure exerted on areas of the toes or feet further compromises arterial perfusion, which can lead to ulceration, infection, and gangrene.

Isolated systolic hypertension, associated with significant cardiovascular morbidity and mortality, is a common finding in the elderly. There is a higher risk for postural hypotension in the elderly, reflecting a decrease in the sensitivity of the postural reflexes and must be considered prior to prescribing new cardiovascular medications.

It may be difficult to palpate the PMI or detect audible heart sounds due to changes in the shape of the chest (e.g., chronic obstructive lung disease) and spinal deformities (e.g., kyphoscoliosis), which worsen with the aging process. When heart sounds are audible, an S_4 is detectable in most elderly patients, caused by a decrease in compliance of the left ventricle. The S_2 is usually split, meaning that the semilunar valves are not closing

simultaneously. Murmurs are also audible in more than one half of elderly patients due to sclerotic changes in the aortic valve. These murmurs are heard over the aortic valve during systole (systolic ejection murmur).

Diagnostic Evaluation

Diagnostic tests and procedures are used to confirm the data obtained by the history and physical assessment. Some tests are easy to interpret, but others must be interpreted by expert clinicians. All tests should be explained to the patient. Some necessitate special preparation before they are performed and special monitoring by the nurse after the procedure.

Laboratory Tests

Laboratory tests may be performed for the following reasons:

- To assist in identifying the cause of cardiovascular signs and symptoms
- To identify abnormalities in the blood that affect the prognosis of a patient with CVD
- To assess the degree of inflammation
- To screen for risk factors associated with CAD
- To determine baseline values before initiating therapeutic interventions
- To ensure that therapeutic levels of medications (e.g., antiarrhythmic agents and warfarin) are maintained
- To assess the effects of medications (e.g., the effects of diuretics on serum potassium levels)

Because different laboratories use various types of equipment and methods of measurements, normal test values may vary depending on the laboratory and the health care institution.

Cardiac Biomarker Analysis

Plasma levels of cardiac biomarkers are used to diagnose acute MI in conjunction with the history, physical examination, and ECG. These substances leak into the bloodstream after injured myocardial cells rupture their cell membranes. Biomarkers have a specific timeline for when they first rise, peak, and then return to normal. This timeline helps the clinician decide which test to order, based on the timing of patient's symptom onset.

- *Creatine kinase (CK)/CK-MB:* CK is released from three types of damaged tissue (myocardium, skeletal muscle, brain). CK-MB is the cardiac-specific isoenzyme that rises within 4 to 8 hours after myocardial injury, peaks in 12 to 24 hours, and returns to normal within 3 to 4 days.
- *Myoglobin:* This heme protein transports oxygen. Its small molecular structure allows it to be released rapidly from damaged myocardial tissue and accounts for its early rise. Myoglobin is not used alone to diagnose MI because elevations can also occur in patients with renal or musculoskeletal disease. However, negative results are helpful in ruling out acute MI. Myoglobin rises within 1 to 3 hours of tissue injury, peaks in 4 to 12 hours, and returns to normal in 24 hours.
- *Troponin T and I:* These heme proteins regulate the contractile function of the

myocardium. After myocardial injury, these biomarkers rise early (within 3 to 4 hours), peak in 4 to 24 hours, and remain elevated for 1 to 3 weeks. These early and prolonged elevations make very early diagnosis of acute MI possible and allow for late diagnosis in patients who have delayed seeking care for several days after the onset of acute MI symptoms.

Blood Chemistry, Hematology, and Coagulation Studies

Table 12-4 provides information about common serum laboratory tests and the implications for patients with CVD.

Lipid Profile. The lipid profile helps evaluate a person's risk for developing atherosclerosis or to diagnose a specific lipoprotein abnormality. Cholesterol and triglycerides are transported in the blood by combining with protein molecules to form lipoproteins. The lipoproteins are referred to as low-density lipoproteins (LDL) and high-density lipoproteins (HDL). The risk of CAD increases as the ratio of LDL to HDL or the ratio of total cholesterol (LDL + HDL) to HDL increases. The blood specimen for the lipid profile should be obtained after a 12-hour fast.

Cholesterol Levels. Cholesterol is a lipid required for hormone synthesis and cell membrane formation. Cholesterol comes from the diet (animal products) and the liver, where cholesterol is synthesized. Elevated cholesterol levels increase the risk of atherosclerosis. Factors that contribute to variations in cholesterol levels include age, gender, diet, exercise patterns, genetics, menopause, tobacco use, and stress levels. Normal level is less than 200 mg/dL.

LDL is the primary transporter of cholesterol and triglycerides into the cell. One harmful effect of LDL is the deposition of these substances into the walls of arteries. Normal level is less than 160 mg/dL. Elevated LDL levels are associated with a greater incidence of CAD. In people with known CAD or diabetes, the LDL goal is less than 70 mg/dL.

TABLE 12-4 Common Serum Laboratory Tests and Implications for Patients with Cardiovascular Disease (CVD)

Laboratory Test/Reference Range	Implications
Blood Chemistries	
Sodium (Na^+) 135–145 mEq/L	*Hyponatremia:* ↓ Na levels can be due to thiazide diuretics or from fluid excess, as seen in HF. *Hypernatremia:* ↑ Na levels indicate fluid deficits and can result from ↓ water intake or hypovolemia.
Potassium (K^+) 3.5–5 mEq/L	*Hypokalemia:* ↓ K levels often due to use of K-excreting diuretics, which can cause ventricular tachycardia and fibrillation and predispose digitalis toxicity in patients taking digoxin. *Hyperkalemia:* ↑ K levels due to ↑ intake of foods high in K or overuse of K supplements; ↓ renal excretion of K; use of K-sparing diuretics (e.g., spironolactone); or use of angiotensin-converting enzyme inhibitors (ACE inhibitors). Can cause heart block, asystole, and ventricular arrhythmias.
Calcium (Ca^{++}) 8.5–10.2 mg/dL	Necessary for blood coagulability, neuromuscular activity, and automaticity of the sinoatrial and atrioventricular nodes. *Hypocalcemia:* ↓ calcium levels slow nodal function and impair myocardial contractility. Latter effect ↑ risk of HF. *Hypercalcemia:* ↑ Ca levels are associated with use of thiazide diuretics that ↓ renal excretion of Ca. Hypercalcemia potentiates digitalis toxicity, causes ↑ myocardial contractility, and ↑ risk of heart block and ventricular fibrillation.
Magnesium (Mg^{++}) 1.3–2.3 mEq/L	Needed to absorb Ca, maintain K stores, metabolize adenosine triphosphate, synthesize protein and carbohydrate, and maintain muscular contraction. *Hypomagnesemia:* ↓ Mg levels are due to enhanced renal excretion of Mg from diuretic or digitalis therapy. ↓ Mg levels predispose patients to atrial or ventricular tachycardias. *Hypermagnesemia:* ↑ magnesium levels are caused by use of cathartics or antacids containing Mg. ↑ Mg levels depress myocardial contractility and excitability heart block or asystole.
Blood urea nitrogen (BUN) 10–20 mg/dL Creatinine Males: 0.9–1.4 mg/dL Females: 0.8–1.3 mg/dL	End products of protein metabolism excreted by the kidneys. Renal impairment is detected by an ↑ in BUN and creatinine. A normal creatinine level and an ↑ BUN detect an intravascular fluid volume deficit, bleeding, or increased protein intake.

Glucose (fasting): 65–110 mg/dL	↑ Glucose levels result from stress as endogenous epinephrine is mobilized to convert of liver glycogen to glucose.
Glycosylated hemoglobin (HbA_{1c}) 2.2–4.8%	Monitored in people with diabetes, as it reflects blood glucose levels over 2–3 months. Goal: hemoglobin A_{1c} less than 7%.
Coagulation Studies	
Activated partial thromboplastin time (aPTT) 23–32 seconds	It is used to monitor patient's response to unfractionated heparin. Heparin dose is adjusted to maintain a therapeutic range of 1.5–2.5 times baseline values. aPTT is a more sensitive version of partial thromboplastin time (PTT) used to monitor heparin therapy.
Prothrombin time (PT) 12–15 seconds	Measures the activity of five factors in the blood clotting pathway (prothrombin, fibrinogen, factors V, VII, X). Used to monitor patients on warfarin therapy. Therapeutic range is 1.5–2 times normal.
International Normalized Ratio (INR)	Standardized method for monitoring prothrombin levels in patients receiving warfarin therapy. Therapeutic range 2–3.5, depending upon diagnosis.
Hematologic Studies	
Complete blood count (CBC)	Identifies the total number of white and red blood cells and platelets, and measures hemoglobin and hematocrit.
White blood cell count (WBC) 4,500–11,000/mm^3	WBC counts are monitored in immunocompromised patients (e.g., post-heart transplant) or those at risk for infection (e.g., after invasive procedures or surgery).
Red Blood Cells (RBC) Normal range men: 4.32–5.72 million cells/mm^3; non-pregnant women 3.90–5.03 million cells/mm^3	RBCs, also called erythrocytes, are primarily composed of hemoglobin needed for oxygen transport from the lungs to the tissues.
Hematocrit Male: 40–50% Female: 38–47% Hemoglobin Male: 13.5–18 g/100 mL Female: 12–16 g/100 mL	Represents the percentage of red blood cells found in 100 mL of whole blood. The red blood cells contain hemoglobin, which transports oxygen to the cells. Low hemoglobin and hematocrit levels can cause more frequent angina episodes or acute MI in patients with cardiovascular diseases.
Platelets 150,000–400,000/mm^3	Initiate thrombus formation by clumping together at sites of vessel wall injury. Monitor for thrombocytopenia if aspirin, clopidogrel (Plavix), eptifibatide (Integrilin), or tirofiban (Aggrastat) is prescribed.

Refer to Table 14-5 for cardiac biomarkers.

HDL has a protective action by transporting cholesterol away from the arterial wall to the liver for excretion. Normal level for men is 35 to 70 mg/dL, for women, 35 to 85 mg/dL. Higher HDL levels are known to lower CAD risk; therefore, an HDL level over 40 mg/dL is desirable in patients with known CAD. Factors associated with lowering HDL levels are smoking, diabetes, obesity, and physical inactivity.

Triglycerides. Triglycerides, composed of free fatty acids and glycerol, are stored in the adipose tissue and are a source of energy. Normal level is less than 150 mg/dL. Triglyceride levels increase after meals and are affected by stress. Diabetes, alcohol use, and obesity can elevate triglyceride levels. Triglyceride levels have a direct correlation with LDL and an inverse one with HDL.

Brain (B-Type) Natriuretic Peptide. Brain (B-type) natriuretic peptide (BNP), secreted from the ventricles, is a neurohormone that responds to volume overload in the heart by acting as a diuretic and vasodilator. BNP levels are useful for the prompt diagnosis of HF. A BNP level of 100 to 300 pg/mL indicates HF is present, and increasingly higher values are correlated with greater severity of HF.

C-Reactive Protein. C-Reactive protein (CRP) is protein produced by the liver in response to systemic inflammation. Inflammation is thought to play a role in the development and

progression of atherosclerosis. High levels of CRP (3.0 mg/dL) are used as an adjunct to other tests to predict CAD risk.

Homocysteine. Homocysteine, an amino acid, can damage the endothelial lining of arteries and promote thrombus formation. Elevated levels are linked to the development of atherosclerosis and an increased risk for CAD, stroke, and peripheral vascular disease. Elevated homocysteine levels are associated with genetic factors and a diet low in folic acid, vitamin B_6, and vitamin B_{12}. A 12-hour fast is necessary prior to obtaining the blood sample. Test results are interpreted as normal (5 to 15 μmol/L), moderate (16 to 30 μmol/L), intermediate (31 to 100 μmol/L), and severe (more than 100 μmol/L).

Electrocardiogram

The ECG is a graphic recording of the electrical activity of the heart. The ECG is obtained by placing disposable electrodes in standard positions on the skin of the chest wall and extremities. The standard 12-lead ECG records electrical impulses of the heart on special graph paper from 12 different reference points referred to as *leads.* It is used to diagnose arrhythmias, conduction abnormalities, enlarged heart chambers, and myocardial ischemia or infarction.
