Evolve Student Resources for *Pharmacology and the Nursing Process*, 7th edition, include the following features:

- **Interactive Review Questions for the NCLEX® Examination**
  Interactive NCLEX® Examination–style review questions are divided by chapter to help you review and apply important content and to help you study for the NCLEX® Examination.
- **Expanded Key Points**
  Downloadable, printable files for each chapter provide a convenient way to review essential chapter content and study for exams.
- **Interactive Unfolding Case Studies**
  Interactive Unfolding Case Studies offer an engaging way to apply important pharmacology concepts to true-to-life patient scenarios to develop your clinical reasoning skills.
- **Critical Thinking and Prioritization Questions**
  Critical Thinking and Prioritization Questions (with answer guidelines) help you focus on the most important actions and considerations necessary for safe and effective drug administration.
- **Answer Keys for Textbook Case Studies**
  Answer Keys for Textbook Case Studies allow you to gauge your mastery of textbook content and readiness for exams and clinical practice.
- **Additional Resources**
  Additional resources include Animations, IV Therapy Safety Checklists, Medication Safety Checklists, and periodic Content Updates!

REGISTER TODAY!

BRIEF CONTENTS

ABOUT THE AUTHORS

Linda Lane Lilley, RN, PhD

Linda Lilley received her diploma from Norfolk General School of Nursing, BSN from the University of Virginia, Master of Science (Nursing) from Old Dominion University, and PhD in Nursing from George Mason University. As an Associate Professor Emeritus and University Professor at Old Dominion University, her teaching experience in nursing education spans over 25 years, including almost 20 years at Old Dominion. Linda's teaching expertise includes drug therapy and the nursing process, adult nursing, physical assessment, fundamentals in nursing, oncology nursing, nursing theory, and trends in health care. The awarding of the University's most prestigious title of University Professor reflects her teaching excellence as a tenured faculty member. She has also been a two-time university nominee for the State Council of Higher Education in Virginia award for excellence in teaching, service, and scholarship. Linda received the 2012 Distinguished Nursing Alumni Award from Old Dominion University School of Nursing for her "continued work on the successful pharmacology textbook published by Elsevier" and to recognize her "extraordinary work and the impact [the book] has had on baccalaureate education." While at Old Dominion University, Linda mentored and taught undergraduate and graduate students as well as registereded nurses returning for their BSN. Linda authored the MED ERRORS column for the *American Journal of Nursing* between 1994 and 1999 as well as numerous other peer-reviewed, published articles in professional nursing journals. Since retirement in 2005, Linda has continued to be active in nursing, serving as a member on dissertation committees with the College of Health Sciences and maintaining membership and involvement in numerous professional and academic organizations. Dr. Lilley has served as a consultant with school nurses in the city of Virginia Beach, a member on the City of Virginia Beach's Health Advisory Board, and currently a member of the City of Virginia Beach's Community Health Advisory Board and the Youth Community Action Team (YCAT). Linda also served as an appointed member on the national advisory panel on medication errors prevention with the U.S. Pharmacopeia in Rockville, Maryland. She continues to educate nursing students and professional nurses about drug therapy and the nursing process and speaks on the topics of drug therapy, safe medication use, humor and healing, and grief and loss.

Shelly Rainforth Collins, PharmD

Shelly Rainforth Collins received her Doctor of Pharmacy degree from the University of Nebraska, College of Pharmacy in 1985, with High Distinction. She then completed a clinical pharmacy residency at Memorial Medical Center of Long Beach in Long Beach California. She worked as a pediatric clinical pharmacist (neonatal specialist) at Memorial Medical Center before moving to Mobile, Alabama. She was the Assistant Director of Clinical Pharmacy Services at Mobile Infirmary Medical Center. She currently serves as the Clinical Pharmacy Specialist/Coordinator of Clinical Pharmacy Services at Chesapeake Regional Medical Center in Chesapeake, Virginia. Her practice focuses on developing and implementing clinical pharmacy services as well as medication safety and Joint Commission medication management standards and national patient safety goals. She also works as staff pharmacist at Chesapeake Regional Medical Center. She is president of Drug Information Consultants, a business offering consultation and expert witness review for attorneys on medical malpractice cases. Shelly was awarded the Clinical Pharmacist of the Year Award in 2007 from the Virginia Society of Healthsystem Pharmacists. She led a multidisciplinary team that won the Clinical Achievement of the Year Award from George Mason University School of Public Health in 2007 for promoting safety with narcotics in patients with sleep apnea; this program has also received national recognition. She was awarded the Service Excellence Award from Chesapeake Regional Medical Center. Shelly's professional affiliations include the American Society of Healthsystem Pharmacists and the Virginia Society of Healthsystem Pharmacists.

Julie S. Snyder, MSN, RN-BC

Julie Snyder received her diploma from Norfolk General Hospital School of Nursing and her BSN and MSN from Old Dominion University. After working in medical-surgical nursing, she worked in nursing staff development and community education. After 8 years, she transferred to the academic setting and has since taught fundamentals of nursing, pharmacology, physical assessment, gerontologic nursing, and adult medical-surgical nursing. She has been certified by the ANCC in Nursing Continuing Education and Staff Development and currently holds ANCC certification in Medical-Surgical Nursing. She is a member of Sigma Theta Tau International and was inducted into Phi Kappi Phi as Outstanding Alumni for Old Dominion University. She has worked for Elsevier as a reviewer and ancillary writer since 1997. Julie's professional service has included serving on the Virginia Nurses' Association Continuing Education Committee, serving as Educational Development Committee chair for the Epsilon Chi chapter of Sigma Theta Tau, serving as an item writer for the ANCC, working with a regional hospital educators' group, and serving as a consultant on various projects for local hospital education departments.

PREFACE

Now in its seventh edition, *Pharmacology and the Nursing Process* provides the most current and clinically relevant nursing pharmacology content in a visually appealing, understandable, and practical format. The accessible size, clear writing style, and full-color design of *Pharmacology and the Nursing Process* are ideal for today's busy nursing student. The book not only presents drug information that the nursing student needs to know but also provides information on what the professional nurse may encounter during drug administration in a variety of health care settings, including accounts of real-life medication errors and tips for avoiding those errors. Edition after edition, the book has become increasingly inviting and engaging for the adult learner to read and study. Features that help set the book apart include:

- A focus on the role of prioritization in nursing care
- A strong focus on drug classes to help students acquire a better knowledge of how various drug classes work in the body, allowing them to apply this knowledge to individual drugs
- Ease of readability to make this difficult content more understandable
- Integrated study skills content that helps students understand and learn the particularly demanding subject of pharmacology while also equipping them with tools that they can use in other courses and as lifelong learners who are building an evidence-based practice.

The use of color has continued to complement the text by making the book more engaging for nursing students. Color is used throughout to:

- Highlight important content
- Illustrate how drugs work in the body in numerous anatomic and drug process color illustrations
- Improve the visual appearance of the content to make it more engaging and appealing to today's more visually sophisticated reader

We believe that the use of color and other visual engagement devices in these ways significantly improves students' involvement and understanding of pharmacology.

For this edition, the author team has focused even more closely on providing the most "need-to-know" information, enhancing readability, and emphasizing the nursing process and prioritization throughout. Many of the updates for this edition are in response to actual questions posed by students.

Sharing the goal of creating a nursing pharmacology textbook that is not only academically rigorous but also practical and easy to use, the authors bring together a unique combination of experience. The author team is comprised of an Associate Professor Emeritus with a PhD in nursing and more than 25 years of teaching experience, a clinical pharmacist with a PharmD and 28 years of experience in hospital pharmacy practice, and a nursing clinical instructor who holds a Master of Science in Nursing degree and has 25 years of teaching experience.

ORGANIZATION

This book includes 58 chapters presented in 10 parts, organized by body system. The 9 "concepts" chapters in Part 1 lay a solid foundation for the subsequent drug units and address the following topics:

- The nursing process and drug therapy
- Pharmacologic principles
- Lifespan considerations related to pharmacology
- Cultural, legal, and ethical considerations
- Preventing and responding to medication errors
- Patient education and drug therapy
- Over-the-counter drugs and herbal and dietary supplements
- Gene therapy and pharmacogenomics
- Drug administration techniques, including more than 100 drawings and photographs

Parts 2 through 10 present pharmacology and nursing management in a time-tested body systems/drug function framework. This approach facilitates learning by grouping functionally related drugs and drug groups. It provides an effective means of integrating the content into medical-surgical/adult health nursing courses or for teaching pharmacology in a separate course.

The 49 drug chapters in these 9 Parts constitute the main portion of the book. Drugs are presented in a consistent format with an emphasis on drug classes and key similarities and differences among the drugs in each class. Each chapter is subdivided into two discussions, beginning with (1) a brief overview of anatomy, physiology, and pathophysiology and a complete discussion of pharmacology, followed by (2) a comprehensive yet succinct application of the nursing process.

Pharmacology is presented for each drug group in a consistent format:

- Mechanism of Action and Drug Effects
- Indications
- Contraindications
- Adverse Effects (often including Toxicity and Management of Overdose)
- Interactions
- Dosages

Drug class discussions conclude with specially highlighted Drug Profiles—brief narrative "capsules" of individual drugs in the class or group, including Pharmacokinetics tables for each drug. Key drugs (prototypical drugs within a class) are identified throughout with a ♦ symbol for easy identification.

The pharmacology section is followed by a Nursing Process discussion that relates to the entire drug group. This nursing content is covered in the following, familiar nursing process format:

- Assessment
- Nursing Diagnoses
- Planning (including Goals and Outcome Criteria)
- Implementation
- Evaluation

At the end of each Nursing Process section is a Patient Teaching Tips box that summarizes key points for nursing students and/or practicing nurses to include in the education of patients about their medications. These boxes focus on teaching how the drugs work, possible interactions, adverse effects, and other information related to the safe and effective use of the drug(s). The role of the nurse as patient educator and advocate continues to grow in importance in professional practice, so there is emphasis on this key content in each chapter in this edition.

Additionally, each Part begins with a Study Skills Tips section that presents a study skills topic and relates it to the unit being discussed. Topics include time management, note taking, studying, test taking, and others. This unique feature is intended to aid students who find pharmacology difficult and to provide a tool that may prove beneficial throughout their nursing school careers. This arrangement of content can be especially helpful to faculty who teach pharmacology through an integrated approach because it helps the student identify key content and concepts.

NEW TO THIS EDITION

To further improve the hallmark readability and user-friendliness of *Pharmacology and the Nursing Process*, each line of the text has been edited for this edition with a special focus on an active, direct-address writing style. This refreshing and engaging writing style helps students navigate more easily through the textbook and thus the difficult subject of pharmacology and the nursing process.

The seventh edition of *Pharmacology and the Nursing Process* also features an enhanced focus on "need-to-know" content. The information on drug adverse effects has been streamlined to reflect only the most common and most serious adverse effects rather than listing all reported adverse effects. These adverse effects are also now listed in order of those most commonly seen. Another area that has been reduced for an optimized focus is that of drug dosages; only those dosages that are seen in most common indications are included in the text and tables. (For other dosages, the student should refer to an up-to-date drug handbook or drug reference.) This need-to-know approach to drug indications and adverse effects is crucial in helping the adult learner focus on the most essential content needed for safe drug administration.

It is important to remember that although this textbook provides all of the need-to-know *pharmacology* content that students will need for an entry level of practice, it is first and foremost a *nursing* textbook rather than a pharmacology textbook, with a strong emphasis on the nursing process and professional nursing practice. Nursing care related to the specifics of drug therapy has been further prioritized in this edition by numbering the nursing diagnoses and corresponding goals and outcome criteria in the coverage of the planning phase of the nursing process. The section on implementation also offers all of the most essential information, followed by a section on the evaluation of therapeutic and adverse effects. These changes highlight the significance of the nursing process as a foundation in drug therapy while helping the student to make strong cognitive connections among nursing diagnoses, goals, and outcome criteria.

This edition also integrates the six Quality and Safety Education for Nurses (QSEN) competencies. Funded by the Robert Wood Johnson Foundation, the QSEN project has the overall goal of addressing the challenge of preparing future nurses with knowledge, skills, and attitudes needed to continually improve the quality and safety of healthcare systems. The QSEN competencies are together aimed at reducing the 1.9 million drug-related hospitalizations seen in the United States at the outset of the initiative. Leading the integration of QSEN competencies into prelicensure nursing pharmacology textbooks, *Pharmacology and the Nursing Process* addresses the safety and quality competencies through the following special boxes:

- Evidence-Based Practice
- Patient-Centered Care: Cultural Implications
- Patient-Centered Care: Lifespan Considerations for the Elderly Patient
- Patient-Centered Care: Lifespan Considerations for the Pediatric Patient
- Safety: Herbal Therapies and Dietary Supplements
- Safety: Laboratory Values Related to Drug Therapy
- Safety and Quality Improvement: Preventing Medication Errors
- Teamwork and Collaboration: Legal and Ethical Principles
- Teamwork and Collaboration: Pharmacokinetic Bridge to Nursing Practice

The QSEN initiative is also highlighted in the new *TEACH for Nurses* Lesson Plans provided for this edition (see Supplemental Resources).

The pharmacology and nursing content in each of the 58 chapters has been thoroughly revised and critically reviewed by nursing instructors, practicing nurses, and a PharmD to reflect the latest drug information and nursing content. Key updates include:

- A more effectively organized classification of psychotherapeutic drugs in Chapter 16 into 3 subcategories: (1) anxiolytics, (2) mood stabilizers and antidepressants, and (3) antipsychotic drugs
- The most recent evidence-based guidelines on management of diabetes mellitus in Chapter 32, with an emphasis on new diabetes drugs
- The most recent evidence-based guidelines on the treatment of rheumatoid arthritis in Chapter 47
- Revision of Chapter 48 on immunosuppressant drugs to provide an emphasis on transplant therapy
- Revised NCLEX® Examination Review Questions at the end of each chapter, including alternate-item format and new dosage calculation questions

ADDITIONAL TEACHING/LEARNING FEATURES

The book also includes a variety of innovative teaching/learning features that prepare the student for important content to be covered in each chapter and encourage review and reinforcement of that content. Chapter-opener features include the following:

- Learning Objectives
- List of Evolve Resources available to students

- Summary of Drug Profiles in the chapter, with page number references
- Key terms with definitions and page number references (key terms being in **bold blue** type throughout the narrative to emphasize this essential terminology)

The following features appear at the end of each chapter:

- Patient Teaching Tips related to drug therapy
- Key Points boxes summarizing important chapter content
- NCLEX® Examination Review Questions, with answers provided upside-down at the bottom of the section for quick and easy review

In addition to the special boxes listed previously, other special features that appear throughout the text include:

- Case Studies, with answer guidelines provided on the Evolve website
- Dosages tables listing generic and trade names, pharmacologic class, usual dosage ranges, and indications for the drugs

For a more comprehensive listing of the special features, please see the inside back cover of the book.

SUPPLEMENTAL RESOURCES

A comprehensive ancillary package is available to students and instructors using classroom quantities of *Pharmacology and the Nursing Process*. The following supplemental resources have been thoroughly revised for this edition and can significantly assist teaching and learning of pharmacology:

Study Guide

The carefully prepared student workbook—written by one of the textbook authors for careful alignment with the content and focus of the book—includes the following:

- Student Study Tips that reinforce the Study Skills in the text and provide a "how to" guide to applying test-taking strategies
- Worksheets for each chapter, with NCLEX®-style questions (now with more application-based, alternate-item, and dosage calculation questions), critical thinking and application questions, and other activities
- Case Studies followed by related critical thinking questions
- An updated Overview of Dosage Calculations with helpful tips for calculating doses, sample drug labels, practice problems, and a quiz
- Answers to all questions (provided in the back of the book) to facilitate self-study

Evolve Website

Located at http://evolve.elsevier.com/Lilley/, the Evolve website for this book includes the following:

For students:

- More than 550 NCLEX® Examination Review Questions
- Critical Thinking and Prioritization Questions with answer guidelines
- 35 state-of-the-art animations
- Printable, expanded Key Points for each chapter
- Printable IV Therapy and Medication Safety Checklists
- Content Updates
- Answers to Case Studies from the book

For instructors:

- NEW *TEACH for Nurses* Lesson Plans that focus on the most important content from each chapter and provide innovative strategies for student engagement and learning. These new Lesson Plans include strategies for integrating nursing curriculum standards (QSEN, concept-based learning, and the BSN essentials), links to all relevant student and instructor resources, and an original instructor-only Case Study in each chapter.
- ExamView Test Bank that features more than 800 NCLEX® Examination–format test questions (100 new, including alternate-item questions) with text page references, rationales, and answers coded for NCLEX® Client Needs category, nursing process step, and cognitive level (new and old Bloom's taxonomy). The robust ExamView testing application, provided at no cost to faculty, allows instructors to create new tests; edit, add, and delete test questions; sort questions by NCLEX® Client Needs category, cognitive level, and nursing process step; and administer and grade tests online, with automated scoring and gradebook functionality.
- PowerPoint Lecture Slides consisting of more than 2100 customizable text slides for instructors to use in lectures. The presentations include new Unfolding Case Studies and applicable illustrations from the book's Image Collection. Audience Response System Questions (three or more discussion-oriented questions per chapter for use with i>Clicker and other systems) are folded into these presentations.
- An Image Collection with approximately 220 full-color images from the book for instructors to use in lectures
- Access to all student resources listed above

Pharmacology Online

Pharmacology Online for *Pharmacology and the Nursing Process*, seventh edition (ISBN: 978-0-323-09167-1), is a dynamic, unit-by-unit online course that includes interactive self-study modules, a collection of interactive learning activities, and a media-rich library of supplemental resources.

- *Self-Study Modules* go beyond the basic principles of pharmacology, with animations and NCLEX® Examination–style questions to help students assess their understanding of pharmacology concepts.
- *Interactive Case Studies* immerse students in true-to-life scenarios that require them to make important choices in patient care and patient teaching.
- "*Roadside Assistance*" Video Clips use humor and analogy in a uniquely fun and engaging way to teach key concepts.
- Interactive Learning Activities, Discussion Questions, Practice Quizzes for the NCLEX® Examination, and more are also included.

ACKNOWLEDGMENTS

This book truly has been a collaborative effort. We wish to thank the instructors who provided input on an ongoing basis throughout the development of the previous editions.

We thank Lee Henderson and Jackie Twomey for taking on the Lilley text as a new project. Having spent six editions with the editorial team from St. Louis, we had our anxieties about the switch to the Philadelphia team, but it has been a smooth and very productive transition. Lee and Jackie's guidance, attention to detail, and support have been much appreciated, and their suggestions for improving readability and organization of content helped to make the seventh edition better than ever. Thanks for their patience and nurturing manner! We thank Kristin Geen and Jamie Horn for their contributions and support throughout the fourth, fifth, and sixth editions. We are also grateful to Jeff Patterson and Clay Broeker for very capably guiding the project through to publication. Diane Savoca lent her study skills expertise and has updated the unique and appropriate Study Skills features for students; for her collaboration, we are most grateful. Finally, we thank Joe Albanese for his contributions to the first edition of the book, Bob Aucker for his contributions to the first three editions, and Scott Harrington for contributions through the sixth edition.

Linda thanks her daughter Karen for her unwavering and constant support. Long hours and time spent researching and writing has preempted time with family, but Karen has always understood. Linda wishes to dedicate this book to Karen Leanne Lilley Harris as she remains her inspiration and encouragement for all professional and personal endeavors and accomplishments. The memory of Linda's parents, John and Thelma Lane, who passed away during the fourth edition, and in-laws J.C. and Mary Anne Lilley, who passed away during the fifth and sixth editions, has continued to provide inspiration and a sense of pride in all her work. Students and graduates of Old Dominion University School of Nursing have been eager to provide feedback and support, beginning with the class of 1990 and continuing through the class of 2005. Without their participation, the book would not have been so user-friendly and helpful to students beginning the study of drug therapy. Linda attributes her successes and accomplishments to a strong sense of purpose, faith, and family and an appreciation for the lighthearted side of life. To Jibby Baucom, Linda offers many thanks, because without her recommendation to Mosby, Inc., the book would never have been developed. Robin Carter, Kristin Geen, Jamie Horn, Lee Henderson, and Jackie Twomey have been constant resources and more than just editors with Elsevier; they have been sources of strength and encouragement. Their excellent work ethic, positivity, and calming natures will be forever appreciated. The fifth through seventh editions have also involved Clay Broeker, who has been a tremendous resource with production issues; his contributions to this edition have been strong and forward-thinking. Elsevier has shared some of its best employees with Linda beginning with the first day of the first edition; for that, Linda is most thankful.

Shelly would like to dedicate this edition to the memory of her mother, Rogene Rainforth, who passed away in July of 2011. It was because of her inspiration and steadfast love that Shelly has succeeded both personally and professionally. To Shelly's father, Charles Rainforth of Hastings, Nebraska, your strength, compassion, optimism, pride, and love never cease to amaze. Shelly would like to thank her daughter Kristin Collins for her patience and understanding. You are her source of pride, accomplishment, and inspiration. It has been such a joy watching you grow into the beautiful young woman you are today. Your future students will be inspired by your grace. Shelly would also like to thank Linda Lilley, Julie Snyder, Lee Henderson, and Jackie Twomey for the opportunity to be part of this wonderful book; it is truly an honor to be associated with all of you. To the pharmacy staff at Chesapeake Regional Medical Center, Shelly is proud not only to call you her colleagues, but also her friends. Shelly also thanks the pharmacists at Long Beach Memorial Medical Center, for the knowledge you imparted during her residency training. Finally, to Shelly's nephew and new pharmacist, Chris Rainforth, welcome to the profession!

Julie wishes to dedicate this edition to her husband Jonathan. He has been a steadfast and loving supporter over the years. Julie also thanks her daughter Emily Martin; son-in-law Randy Martin; and her parents Willis and Jean Simmons, for their unfailing support and encouragement. They were all patient despite the long hours working on revisions. The pharmacists at Chesapeake Regional Medical Center have always been great resources, as have the staff nurses who work alongside our students in the clinical settings. Thanks also to Rick Brady and Chesapeake Regional Medical Center for their previous assistance with the photo shoot for the Photo Atlas of Drug Administration. This support and the encouragement of family, friends, and colleagues are vital to projects like this. Thanks also to Lee Henderson and Jackie Twomey at Elsevier for providing the support needed to keep this project on track. Julie is grateful to the St. Louis Elsevier team of Kristin Geen and Jamie Horn for guidance and support during the previous editions. Thanks also to Shelly Rainforth Collins for her clinical insight. Deep appreciation goes to Dr. Linda L. Lilley for her unfailing encouragement, mentoring, and friendship over the years. Dr. Lilley is a fine example of a nurse and nurse educator, and her joy in teaching is always evident. Thanks also to each student who has provided feedback and comments on the text and study aids. Most importantly, Julie gives thanks to God, our source of hope and strength. Finally, to those who teach, although your work may seem to go unnoticed or unappreciated, your impact will always be remembered in the accomplishments of your students. Your inspiration and motivation shape the future.

WE WELCOME YOUR FEEDBACK

We always welcome comments from instructors and students who use this book so that we may continue to make improvements and be responsive to your needs in future editions. Please send any comments you may have for us to the attention of the publisher at lee.henderson@elsevier.com.

PART 1

Pharmacology Basics

STUDY SKILLS TIPS

Introduction to Study Skills Concepts • PURR • Pharmacology Basics

INTRODUCTION TO STUDY SKILLS CONCEPTS

What to study? When to study? How much to study? How to study? In the best of worlds, every student would have all the skills necessary to be effective in all academic areas. Unfortunately, many students do not know how to study effectively or have developed techniques that work well in some circumstances but not in others. The purpose of the Study Skills Tips is to introduce you to the steps to follow in learning text and maintaining focus on the appropriate material. This section also offers some specific examples for selected chapters in Part 1 to help you apply the study techniques and strategies discussed here.

Extensive discussion of study skills, including how to manage time, take lecture notes, master the text, prepare for and take examinations, establish effective study groups, and develop vocabulary are presented in the Study Guide that accompanies this text. These tools are important to any student, but they become even more valuable for students in challenging technical areas such as nursing and pharmacology. The techniques described here and in the Study Guide will not necessarily make learning easy, but they will help you achieve your goals as a student.

PURR

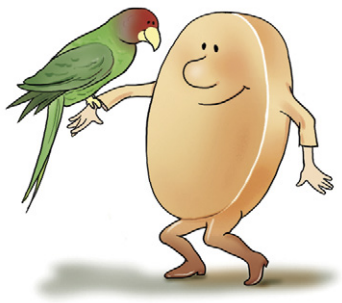
PURR is a handy mnemonic device representing a four-step process that will lead to mastery of material. These steps are as follows:

- Prepare
- Understand
- Rehearse
- Review

The PURR approach has positive and negative aspects. The negative aspect is that it requires you to go through every chapter four times. The good news is that you will not actually *read* the chapter four times. You will only *go through* it four times. Only one of those times consists of a slow, careful, intensive reading. The other trips through the chapter are much quicker. The first time you go through the chapter, it should take only 5 or 10 minutes. Each time you go through the chapter, you are processing the information in distinctly different ways. The PURR approach will enhance your learning, and if you use it from the first assignment on, you will find that it takes you less time than you were spending before you adopted the PURR approach to learn what you need.

Prepare

Reading the text, like any complex process, is not something to dive into without thought and planning. *Pharmacology and the Nursing Process* is organized to help you learn the material, but you have to take advantage of what the authors have done for you to facilitate this. Preparing to read means setting goals and objectives for your own learning, but the tools you need to help you do this are already in place. Look at the opening pages of any chapter in the text, and you will see a standard structure.



Every chapter begins with a **title.** Learn to use the title as the first step in preparing to learn. Chapter 4 is entitled "Cultural, Legal, and Ethical Considerations." This instantly identifies what the chapter is about. Do not start reading immediately; instead think about the title for a few seconds. Are there any unfamiliar terms? If your answer is "No," great. If it is "Yes," then you already have some focus for your reading, because you know you will need to learn the unfamiliar terms and their meanings.

The next feature of every chapter is the **objectives.** You need objectives for learning, and the authors have anticipated this. Read the objectives actively. Do not just look at the words; think about the objectives. Ask yourself the following questions: What do I already know about this material? How do these objectives relate to earlier assignments? How do they relate to objectives the instructor has given? The chapter objectives identify things you should be able to do after you have read the material. Do not wait until you have read the chapter to start trying to respond. *Prepare* means getting the brain engaged from the beginning. Studying the chapter objectives establishes a direction and purpose for your reading. This will enable you to maintain concentration and focus while you read.

Another feature in the opening pages of each chapter is the **key terms.** This is one of the most valuable tools the authors have provided. They know that there are many terms to learn and are giving you a head start on learning them. Spend a few minutes with the glossary. Notice the terms that are also used in the chapter objectives and are bolded in the text. Go back and look at the objectives, and think about what you have learned from the glossary. As you study the glossary, look for shared root words, prefixes, or suffixes. If words share such common word elements, these words also have a shared meaning. Learning the meaning of common word elements can simplify the whole process of learning vocabulary. Perhaps you remember in elementary school being told to "look for the little words in the big word." This is essentially the same technique—one that worked then and one that will work now.

Now make a quick pass through the chapter or the assigned pages from the chapter. Focus on the text conventions, which are described later in this chapter. Look for anything that stands out in the chapter, such as boldfaced text, boxed material, and tables. This provides a quick overview of the chapter, which will make the next steps in the PURR process much more effective and efficient.

The **chapter headings** show the major points to be covered. Study them and notice the major headings (topics) and the subordinate headings (subtopics). They essentially provide a picture of the chapter, and using this picture is a fundamental step in preparing to read. As you read through the chapter headings, turn the topics and subtopics into a series of questions that you want to be able to answer when you finish reading. Think about the objectives and how these headings relate to them. Finally, in the headings devoted to specific classes of drugs, notice that there are elements that are common to every class. The last two headings are always "Implementation" and "Evaluation." This tells you that these are two common elements that you will be expected to know at the end of every chapter. The minutes you spend *preparing* will pay off in a big way when you start to read.

Preparing makes the whole approach to learning an active one. It may not make the chapters the most exciting reading you will ever do, but it will help you accomplish your personal learning objectives as well as those set by the authors.

On-the-Run Action

Preparing is great to do during "found" time. It should not take more than 5 or 10 minutes. Time between classes, time spent waiting for the coffee water to boil, or any other small block of time that usually just slips away can be used to accomplish this step.

Understand

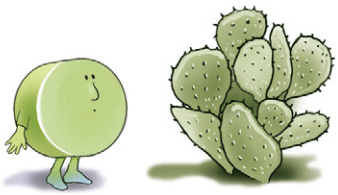
Now read the assignment. Go to your desk, the library, or wherever you have chosen for serious study. Reading the assignment is where all of your preparation pays off. If you did the *Prepare* step earlier in the day, it is not a bad idea to spend a minute or two going through the chapter features again to get your focus. As you read the assignment, remember the chapter objectives and notice the chapter headings in the body of the chapter. As you read, rephrase the chapter headings as questions to help keep you focused on the task at hand. Because this is the first time you are really focusing on the concepts and the details, this is not the time to do any text notations. Read and, as you read, think. Terms from the key terms are repeated, and their meanings are often expanded and clarified in the body of the text. Pay attention to these terms as you read. Think about what they mean and how you would define them to someone else. Read for meaning. Read to *understand.* Do not read just to get to the end of the assignment. That is a passive action. Ask yourself questions. Analyze, respond, and react as you read.

Often, reading assignments are too long to be read with complete understanding in one session. If you find that your concentration is flagging or you do not remember anything you read on the previous page, it is time to take a break. All too often students have only one objective—to finish the assignment. You

might be able to force yourself to continue reading, but you will not learn much. Mark your place and take a 5- or 10-minute break. Take a walk, read the daily comic strips, get a soda or a cup of coffee, and then go back to reading. When you come back to the assignment, spend the first 3 or 4 minutes reviewing. Look back at the previous chapter heading and think about what you were reading before the break. The chapter can be broken down into many small reading sessions, but it is critical that you not lose sight of the chapter as a whole. Spending these minutes in review may seem like time that could be better spent continuing with the reading, but this fast review will save time in the long run.

There is no quick way to read a chapter. You will not find an "on-the-run action" for this step because it cannot be done this way. However, if you do the *Prepare* step first, you will be surprised at how much more easily you get the reading done and how much more learning you have achieved in the process.

Rehearse



Rehearsing is the third step. It starts the process of consolidating your learning and establishing a basis for long-term memory. Rehearsal accomplishes two things. First, it helps you find out what you understand from the reading. Knowing what you know is really important. Second, it identifies what you do not understand, and this may be an even more important benefit. Knowing what you do not know before it comes to light during an examination is critical.

How to Rehearse

Everything you do in the *Prepare* and *Understand* steps comes into play in the *Rehearse* step. Rehearsal should begin with the features at the top of the chapter. Open the text to the beginning of the chapter. Start with the chapter title, and begin to quiz yourself on what you have read. Compose three or four questions pertaining to the chapter title, and then try to answer them to your satisfaction. The questions you ask yourself should be both literal (asking for specific information presented in the chapter) and interpretive (testing your comprehension of concepts and relationships). An example of a literal question using the Chapter 4 title might be, "What are the definitions of *cultural, legal,* and *ethical?*" This question would help you determine whether you can satisfactorily define these terms in your own words. Asking and answering questions such as this always serves to move learning from short-term to long-term memory. Literal questions are very important to help you grasp the factual information and terminology contained in the reading assignment. However, it is also necessary to ask questions that stimulate thought about the concepts and the relationships between the facts and concepts presented in the chapter. An example of an interpretive question regarding the Chapter 4 title might be, "What are the most important *cultural, legal,* and *ethical* concepts pertaining to the use of drugs?" Sometimes you will find that, even though the question is interpretive, the authors have anticipated the question and the text does contain the direct answer to your question. Other times you will need to formulate your own response by pulling together bits and pieces of information from the entire reading assignment.

Once you have exhausted the question potential for the chapter title, move on to the chapter objectives. Use the same process here. Rephrase the objectives as questions, and try to answer them. Remember that the object of rehearsal is to reinforce what you have learned and to identify areas where you need to spend additional time (review).

Go to the key terms. Cover the definitions, and try to define each term in your own words. Another method is to cover the term and, on the basis of the definition, name the term. Do not just memorize the definition, because you may find the information presented differently on an examination, and you will then be unable to respond.

Now proceed to the chapter or assigned pages. The chapter headings are the main tools for rehearsal. Apply the same question-and-answer technique used for the title and objectives to test what you may already know about the chapter content. Turn the headings into questions, and answer them. Look at the text for boldfaced and italicized items, lists, and other text conventions. These too can become the basis for questions. The tables and diagrams should also be used for this purpose. Keep in mind the importance of asking both literal and interpretive questions. Some of the questions you ask yourself should also tie different topic headings together. Ask yourself how topic A relates to topic B.

As you proceed through the chapter, do not worry if you cannot answer the questions you ask. As stated earlier, one of the goals of the rehearsal process is to identify what you need to spend more time on. If you can give no response to a particular question, put a mark in the margin of the pertinent place in the text to remind yourself to come back and spend more time on this material, but move on at this point. Rehearsal should be a relatively quick procedure. Once you become accustomed to using the PURR method, it should take no more than 15 or 20 minutes to rehearse 15 pages after completing the *Prepare* and *Understand* steps.

As you reach the end of the chapter, skim the *Implementation* and *Evaluation* sections. Make sure that the relationship between these sections and the information in the rest of the chapter is clear. If you have questions or concerns, note them in the margins and ask your instructor to clarify these points. Although the objective is to master the chapter content as an independent learner, sometimes it is essential to ask questions of the instructor to facilitate the process.

When to Rehearse

Ideally rehearsal should take place almost immediately after you finish reading the material. Take a 10- to 15-minute break, and

then start the process. The longer the gap between reading and rehearsal, the more you will forget and the longer it will take to rehearse. If you are breaking down a reading assignment into smaller segments, do the rehearsal for each segment before you begin reading the new material. This helps maintain the sense of continuity in the chapter. This seems like a lot of work to do in a study session, but with practice it will go quickly and you will be pleasantly surprised at the quality and quantity of your learning.

Review

Review is the fourth and final step in the PURR process, and it is an essential step. No matter how well you have learned material in the preceding steps, forgetting will always occur. Reviewing is the only way to store what you have learned in long-term memory. The good news is that, using the PURR approach, the review can be done for small segments of material and can be accomplished relatively quickly.

How to Review

The basic review process is essentially the same as the rehearsal process, with some limited rereading as the only difference. When you cannot immediately answer a question, read the pertinent material again. *This does not mean you should read the entire chapter again.* Often the answer to the question will pop into your mind after you have read only a few lines. When this happens, stop reading and go back to responding to your question. The idea is to reread only as much material as is necessary to make the answer clear. One or two words or one or two sentences may trigger personal recall, but it may also take two or three paragraphs for this to happen.

How Often to Review

How many times should you review material in this way? This actually depends on many factors, such as the difficulty of the material, the length of the assignment, and your personal background. Only you can determine how often you need to review, but there are some guidelines that will help you decide this for yourself.

First, consider the difficulty of the material. If it is very complex, contains many new terms and difficult concepts, and seems difficult to grasp, then you should review very frequently. On the other hand, if the material is straightforward and you are able to relate it well to what you have already learned, then less frequent reviews will serve to keep the material in your memory.

Second, consider how well the review went. If you had difficulty answering many questions to your satisfaction or had to do a lot of rereading, you should schedule another review soon (a day or two later at most).

The success of each review session should be used to help you determine when to schedule another session. The review step is a means of monitoring the success of the learning process. If reviews go well, limited rereading is necessary, and you are able to give clear answers to your questions, then you can wait several days (4 or 5) before reviewing this material again. A mediocre review, more extensive rereading, and poor answers indicate that you should let only 2 or 3 days go by before reviewing the material again. If the review goes very poorly, you should plan to review the material again the next day. It is up to you to judge the success of each review and to decide how often you need to review. The nice thing about PURR is that it enables you to monitor your success and to regulate the learning process easily.

Techniques for Rehearsal and Review

Both rehearsal and review foster active learning, which helps you maintain interest in the material and strengthens your memory. For these benefits to occur, it is essential that the review and rehearsal processes be done orally. Talking to yourself is one way to accomplish this, but working with a study group is another and sometimes more interesting way to rehearse and review. Strategies for establishing and maintaining effective study groups can be found in the Study Guide that accompanies this text. You can find a short overview in the introduction to Part 3 of this text. Study groups are not for everyone. The key is to do what works for you. If studying alone produces the results you want, then continue. If not, you may want to try a study group.

When you ask questions and give your answers out loud, this forces you to think about the material. It helps you organize it and translate it into your own words. The object is not to memorize everything you have read but to understand and be able to explain it. Eventually you will need to answer questions on an examination. Framing questions as a part of the learning process is a way to anticipate examination questions. The more questions you ask yourself during study time, the more likely some of the questions on the examination will be ones you have asked yourself. When you work with a study group, you have several brains anticipating test questions. Further, by doing the rehearsal and review orally, you will find it easier to recall the answers during the examination, because this oral model requires more than just remembering seeing the material; you will actually be able to hear the rehearsed answers in your mind. As stated earlier, another advantage of performing the rehearsal and review processes orally is that it helps to identify what needs further study. When your oral answer is fragmentary, contains many "uhs," and is really disorganized, then you know that you need to devote more time to learning the given term, fact, or concept.

The PURR system may seem like a lot of work at first. The idea of going through a chapter four times understandably seems daunting. Add to this the need for several review sessions, and the first reaction is likely to be, "This won't work" or "I don't have time to do this." Don't take that attitude. This system does work. It cultivates interest, aids concentration, fosters mastery of the material, and ensures long-term memory for the material, which is important not just for doing well on examinations but also for doing well as a nurse, when the safe care of

patients is at stake. The PURR system will work if you use it. It may take 3 or 4 weeks to get comfortable with the system, but if you keep at it, pretty soon it will become a good habit. After a while, you will not be able to imagine studying in any other way.

Like all study systems, the PURR method is a model. As you use it, you may discover ways of changing it that work better for you. That is okay. Do not hesitate to make adjustments that better suit your learning style and strategies. Just remember as you start out that *Preparation, Understanding, Rehearsal,* and *Review* are solid learning principles and cannot be ignored.

Study skills tips are included on the pages at the beginning of each part of the book. These hints are directly applied to the content found within the chapters of the following unit.

PHARMACOLOGY BASICS

Prepare

As you begin to work with individual chapters, consider how the first step in the PURR system can be used to help you set a purpose and become an active learner.

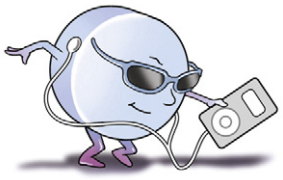
Chapter 1 Objectives

Consider Objective 1 of Chapter 1: "List the five phases of the nursing process." Now turn the objective into a question: What are the five phases of the nursing process? Now move to Objective 2 and make it a question: What are the components of the assessment process for patients receiving medications, including collection and analysis of subjective and objective data? You might recognize that this question relates to Objective 1 because assessment is one phase of the nursing process. By putting Objective 2 into question format, you will begin to expand the focus of the first objective, and you will begin to concentrate on active learning with a clear purpose.

When you begin to read Chapter 1, you will discover that the five phases of the nursing process are repeated as topic headings, and you have the Objective 2 question on which to focus your reading. Begin now to develop the habit of applying this strategy to the objectives in every chapter assigned before you begin to read. Remember to look at the chapter headings at this point as well. It is amazing how much can be learned by using the text structures provided.

Vocabulary Development

Turn to Chapter 2. Objective 1 makes an important point: "Define the common terms used in pharmacology." Success depends heavily on knowledge of the "language." The objective makes it clear that this chapter contains a number of terms that the author views as important to be mastered. This is only Chapter 2, and now is the time to begin to apply yourself to mastering the language of this content. Look at the key terms. There are seven terms that share the common element *pharmaco.* Although each of these seven words has a different meaning, the words have something in common. *Pharmaco* is an example of a group word. No matter what prefixes, group words, and/or suffixes are added to it, a part of the meaning of any word containing *pharmaco* will be "drug" or "medicine." Look up a word containing *pharmaco* in any dictionary, and you will find that its definition pertains to "drug" or "medicine" in some way. Although you probably already knew that, it is always beneficial to start working on a new technique with something that is familiar. Look at four of the words that begin with *pharmaco,* and consider the rest of the word:



dynamics *genomics* *gnosy* *kinetics*

What does each of these word parts mean? The meaning of *pharmacodynamics* is simply the combination of the meanings of *pharmaco* and *dynamics.* The definition, according to the key terms, begins "the study of the biochemical and physiologic interactions of drugs." You could simply memorize this definition, which would seem to accomplish Objective 1. However, memorization does not always equal understanding. Try another approach. What does *dynamics* mean? Think about the word, and relate it to your own experience and background. It appears to deal with movement or action. If you look it up in the dictionary, all the meanings given seem to relate in some fashion to the idea of motion and/or action. A simplistic definition of *pharmacodynamics* would be "drugs in action." Certainly this is not a technical or medical definition, but it contributes a great deal to an understanding of the definition provided in the glossary. This is the object of learning vocabulary. Do not memorize words without understanding. Apply a little thought, and relate the term and definition in a way that makes the meaning personal for you. When you do that, you will find that you understand the glossary definition better, and your ability to retain the meaning will be significantly improved. This means that the test item asking you to select the definition for *pharmacodynamics* from a list of similar definitions will be much easier to answer, because you will remember action and movement and look for the choice that best represents that concept.

Apply this same strategy to the word part *genomics.* Once you know what genomics means, you must determine how to connect that to the meaning in the text. After you have the definitions for *gnosy* and *kinetics,* you can apply the same procedure. When you have done this with all four word parts, you will discover that you will not need to spend a great amount of time trying to memorize esoteric definitions. You will have personalized the meanings. These meanings will stay with you much more readily than those learned by rote memorization. By the way, do you know what *biochemical* and *physiologic* mean? These terms are used in the definition of *pharmacodynamics.* You need to know what they mean to fully understand *pharmacodynamics.*

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 List the five phases of the nursing process.
2 Identify the components of the assessment process for patients receiving medications, including collection and analysis of subjective and objective data.
3 Discuss the process of formulating nursing diagnoses for patients receiving medications.
4 Identify goals and outcome criteria for patients receiving medications.
5 Discuss the evaluation process as it relates to the administration of medications and as reflected by goals and outcome criteria.
6 Develop a nursing care plan that is based on the nursing process as it relates to medication administration.
7 Briefly discuss the "Six Rights" associated with safe medication administration.
8 Discuss the professional responsibility and standards of practice for the professional nurse as related to the medication administration process.
9 Discuss the additional rights associated with safe medication administration.

KEY TERMS

Compliance Implementation or fulfillment of a prescriber's or caregiver's prescribed course of treatment or therapeutic plan by a patient. Use of *compliance* versus *adherence* in this textbook is supportive of the terms used in the current listing of NANDA-I nursing diagnoses. (p. 8)

Goals Statements that are time specific and describe generally what is to be accomplished to address a specific nursing diagnosis. (p. 7)

Medication error Any preventable adverse drug event involving inappropriate medication use by a patient or health care professional; it may or may not cause the patient harm. (p. 15)

Noncompliance An informed decision on the part of the patient not to adhere to or follow a therapeutic plan or suggestion. Use of *noncompliance* versus *nonadherence* in this textbook is supportive of the terms used in the current listing of NANDA-I nursing diagnoses. (p. 9)

Nursing process An organizational framework for the practice of nursing. It encompasses all steps taken by the nurse in caring for a patient: assessment, nursing diagnoses, planning (with goals and outcome criteria), implementation of the plan (with patient teaching), and evaluation. (p. 7)

Outcome criteria Descriptions of specific patient behaviors or responses that demonstrate meeting of or achievement of goals related to each nursing diagnosis. These statements, as with goals, are verifiable, framed in behavioral terms, measurable, and time specific. Outcome criteria are considered to be specific, whereas goals are broad. (p. 7)

Prescriber Any health care professional licensed by the appropriate regulatory board to prescribe medications. (p. 8)

OVERVIEW OF THE NURSING PROCESS

The **nursing process** is a well-established, research-supported framework for professional nursing practice. It is a flexible, adaptable, and adjustable five-step process consisting of assessment, nursing diagnoses, planning (including establishment of **goals** and **outcome criteria**), implementation (including patient education), and evaluation. As such, the nursing process ensures the delivery of thorough, individualized, and quality nursing care to patients, regardless of age, gender, medical diagnosis, or setting. Through use of the nursing process combined with knowledge and skills, the professional nurse will be able to develop effective solutions to meet patient's needs. The nursing process is usually discussed in nursing courses and/or textbooks that deal with the fundamentals of nursing practice, nursing theory, physical assessment, adult or pediatric nursing, and other nursing specialty areas. However, because of the importance of the nursing process in the care of patients, the process in all of its five phases is described in each chapter as it relates to specific drug groups or classifications.

Critical thinking is a major part of the nursing process and involves the use of the mind and thought processes to gather information and then develop conclusions, make decisions, draw inferences, and reflect upon all aspects of patient care. The elements of the nursing process address the physical, emotional, spiritual, sexual, financial, cultural, and cognitive aspects of a patient. Attention to these many aspects allows a more holistic approach to patient care. For example, a cardiologist may focus on cardiac functioning and pathology, a physical therapist on movement, and a chaplain on the spiritual aspects of patient care. However, it is the professional nurse who thinks critically about, processes, and incorporates all of these aspects and points of information about the patient and then uses this information to develop and coordinate patient care. Therefore, the nursing process remains a central process and framework for nursing care. Box 1-1 provides guidelines for nursing care planning related to drug therapy and the nursing process.

ASSESSMENT

During the initial assessment phase of the nursing process, data are collected, reviewed, and analyzed. Performing a comprehensive assessment allows you to formulate a nursing diagnosis related to the patient's needs—for the purposes of this textbook, specifically needs related to drug administration. Information about the patient may come from a variety of sources, including the patient; the patient's family, caregiver, or significant other; and the patient's chart. Methods of data collection include interviewing, direct and indirect questioning, observation, medical records review, head-to-toe physical examination, and a nursing assessment. Data are categorized into objective and subjective data. Objective data may be defined as any information gathered through the senses or that which is seen, heard, felt, or smelled. Objective data may also be obtained from a nursing physical assessment; nursing history; past and present medical history; results of laboratory tests, diagnostic studies, or procedures; measurement of vital signs, weight, and height; and medication profile. Medication profiles include, but are not limited to, the following information: any and all drug use; use of home or folk remedies and herbal and/or homeopathic treatments, plant or animal extracts, and dietary supplements; intake of alcohol, tobacco, and caffeine; current or past history of illegal drug use; use of over-the-counter (OTC) medications (e.g., aspirin, acetaminophen, vitamins, laxatives, cold preparations, sinus medications, antacids, acid reducers, antidiarrheals, minerals, elements); use of hormonal drugs (e.g., testosterone, estrogens, progestins, oral contraceptives); past and present health history and associated drug regimen(s); family history and racial, ethnic, and/or cultural attributes with attention to specific or different responses to medications as well as any unusual individual responses; and growth and developmental stage (e.g., Erikson's developmental tasks) and issues related to the patient's age and medication regimen. A holistic nursing assessment includes gathering of data about the whole individual, including physical/emotional realms, religious preference, health beliefs, sociocultural characteristics, race, ethnicity, lifestyle, stressors, socioeconomic status, educational level, motor skills, cognitive ability, support systems, lifestyle, and use of any alternative and complementary therapies. Subjective data include information shared through the spoken word by any reliable source, such as the patient, spouse, family member, significant other, and/or caregiver.

Assessment about the specific drug is also important and involves the collection of specific information about prescribed, OTC, and herbal/complementary/alternative therapeutic drug use, with attention to the drug's action; signs and symptoms of allergic reaction; adverse effects; dosages and routes of administration; contraindications; drug incompatibilities; drug-drug, drug-food, and drug–laboratory test interactions; and toxicities and available antidotes. Nursing pharmacology textbooks provide a more nursing-specific knowledge base regarding drug therapy as related to the nursing process. Use of current references or those dated within the last 3 years is highly recommended. Some examples of authoritative sources include the *Physicians' Desk Reference, Mosby's Drug Consult,* drug manufacturers' inserts, drug handbooks, and/or licensed pharmacists. Reliable online resources include, but are not limited to the U.S. Pharmacopeia (USP) (http://www.usp.org), U.S. Food and Drug Administration (http://www.fda.gov), and http://www.WebMD.com. Other online resources are cited throughout this textbook.

Gather additional data about the patient and a given drug by asking these simple questions: What is the patient's oral intake? Tolerance of fluids? Swallowing ability for pills, tablets, capsules, and liquids? If there is difficulty swallowing, what is the degree of difficulty and are there solutions to the problem, such as use of thickening agents with fluids or use of other dosage forms? What are the results of laboratory and other diagnostic tests related to organ functioning and drug therapy? What do renal function studies (e.g., blood urea nitrogen level, serum creatinine level) show? What are the results of hepatic function tests (e.g., total protein level, serum levels of bilirubin, alkaline phosphatase,

BOX 1-1 GUIDELINES FOR NURSING CARE PLANNING

This sample presents useful information for developing a nursing process–focused care plan for patients receiving medications. Brief listings and discussions of what must be contained in each phase of the nursing process are included. This sample may be used as a template for formatting nursing care plans in a variety of patient care situations/settings.

Assessment

Objective Data

Objective data include information available through the senses, such as what is seen, felt, heard, and smelled. Among the sources of data are the chart, laboratory test results, reports of diagnostic procedures, physical assessment, and examination findings. Examples of specific data are age, height, weight, allergies, medication profile, and health history.

Subjective Data

Subjective data include all spoken information shared by the patient, such as complaints, problems, or stated needs (e.g., patient complains of "dizziness, headache, vomiting, and feeling hot for 10 days").

Nursing Diagnoses

Once the assessment phase has been completed, the nurse analyzes objective and subjective data about the patient and the drug and formulates nursing diagnoses. The following is an example of a nursing diagnosis statement: "Deficient knowledge related to lack of experience with medication regimen and second-grade reading level as an adult as evidenced by inability to perform a return demonstration and inability to state adverse effects to report to the prescriber." This statement of the nursing diagnosis can be broken down into three parts, as follows:

- Part 1—"Deficient knowledge." This is the statement of the human response of the patient to illness, injury, medications, or significant change. This can be an actual response, an increased risk, or an opportunity to improve the patient's health status. The nursing diagnosis related to knowledge may be identified as either deficient or readiness for enhanced (knowledge).
- Part 2—"Related to lack of experience with medication regimen and second-grade reading level as an adult." This portion of the statement identifies factors related to the response; it often includes multiple factors with some degree of connection between them. The nursing diagnosis statement does not necessarily claim that there is a cause-and-effect link between these factors and the response, only that there is a connection.
- Part 3—"As evidenced by inability to perform a return demonstration and inability to state adverse effects to report to the prescriber." This statement lists clues, cues, evidence, and/or data that support the nurse's claim that the nursing diagnosis is accurate.

Nursing diagnoses are prioritized in order of criticality based on patient needs or problems. The ABCs of care (*a*irway, *b*reathing, and *c*irculation) are often used as a basis for prioritization. Prioritizing always begins with the most important, significant, or critical need of the patient. Nursing diagnoses that involve actual responses are always ranked above nursing diagnoses that involve only risks.

Planning: Goals and Outcome Criteria

The planning phase includes the identification of goals and outcome criteria, provides time frames, and is patient oriented. Goals are objective, realistic, and measurable patient-centered statements with time frames and are broad, whereas outcome criteria are more specific descriptions of patient goals.

Implementation

In the implementation phase, the nurse intervenes on behalf of the patient to address specific patient problems and needs. This is done through independent nursing actions; collaborative activities such as physical therapy, occupational therapy, and music therapy; and implementation of medical orders. Family, significant others, and caregivers assist in carrying out this phase of the nursing care plan. Specific interventions that relate to particular drugs (e.g., giving a particular cardiac drug only after monitoring the patient's pulse and blood pressure), nonpharmacologic interventions that enhance the therapeutic effects of medications, and patient education are major components of the implementation phase. See the previous text discussion of the nursing process for more information on nursing interventions.

Evaluation

Evaluation is the part of the nursing process that includes monitoring whether patient goals and outcome criteria related to the nursing diagnoses are met. Monitoring includes observing for therapeutic effects of drug treatment as well as for adverse effects and toxicity. Many indicators are used to monitor these aspects of drug therapy as well as the results of appropriately related nonpharmacologic interventions. If the goals and outcome criteria are met, the nursing care plan may or may not be revised to include new nursing diagnoses; such changes are made only if appropriate. If goals and outcome criteria are not met, revisions are made to the entire nursing care plan with further evaluation.

creatinine phosphokinase, other liver enzymes)? What are the patient's white blood cell and red blood cell counts? Hemoglobin and hematocrit levels? Current as well as past health status and presence of illness? What are the patient's experiences with use of any drug regimen? What has been the patient's relationship with health care professionals and/or experiences with previous therapeutic regimens? What are current and past values for blood pressure, pulse rate, temperature, and respiratory rate? What medications is the patient currently taking, and how is the patient taking and tolerating them? Are there issues of **compliance?** Any use of folk medicines or folk remedies? What is the patient's understanding of the medication? Are there any age-related concerns? If patients are not reliable historians, family members, significant others, and/or caregivers may provide answers to these questions.

It is worth mentioning that there is often discussion about the difference between the terms *compliance* and *adherence*. Both of these terms, though not to be used interchangeably, are used to describe the extent to which patients take medications as prescribed. Often the term *adherence* is perceived as implying more collaboration and active role between patients and their providers (see Key Terms definition of *compliance*). Once assessment of the patient and the drug has been completed, the specific prescription or medication order (from any **prescriber**) must be checked for the following six elements: (1) patient's name, (2) date the drug order was written, (3) name of drug(s), (4) drug dosage amount and frequency, (5) route of administration, and (6) prescriber's signature.

It is also important during assessment to consider the traditional, nontraditional, expanded, and collaborative roles of the nurse. Physicians and dentists are no longer the only practitioners legally able to prescribe and write medication orders. Nurse practitioners and physician assistants have gained the professional privilege of legally prescribing medications. Remain current on legal regulations as well as specific state nurse practice acts and standards of care.

Analysis of Data

Once data about the patient and drug have been collected and reviewed, critically analyze and synthesize the information. Verify all information and document appropriately, and it is at this point that the sum of the information about the patient and drug are used in the development of nursing diagnoses.

CASE STUDY

The Nursing Process and Pharmacology

Dollie, a 27-year-old social worker, is visiting the clinic today for a physical examination. She states that she and her husband want to "start a family," but she has not had a physical for several years. She was told when she was 22 years of age that she had "anemia" and was given iron tablets, but Dollie states that she has not taken them for years. She said she "felt better" and did not think she needed them. She denies any use of tobacco and illegal drugs; she states that she may have a drink with dinner once or twice a month. She uses tea tree oil on her face twice a day to reduce acne breakouts. She denies using any other drugs.

1. What other questions does the nurse need to ask during this assessment phase?
2. After laboratory work is performed, Dollie is told that she is slightly anemic. The prescriber recommends that she resume taking iron supplements as well as folic acid. She is willing to try again and says that she is "all about doing what's right to stay healthy and become a mother." What nursing diagnoses would be appropriate at this time?
3. Dollie is given a prescription that reads as follows: "Ferrous sulfate 325 mg, PO for anemia." When she goes to the pharmacy, the pharmacist tells her that the prescription is incomplete. What is missing? What should be done?
4. After 4 weeks, Dollie's latest laboratory results indicate that she still has anemia. However, Dollie states, "I feel so much better that I'm planning to stop taking the iron tablets. I hate to take medicine." How should the nurse handle this?

For answers, see http://evolve.elsevier.com/Lilley.

NURSING DIAGNOSES

Nursing diagnoses are developed by professional nurses and are used as a means of communicating and sharing information about the patient and the patient experience. Nursing diagnoses are the result of critical thinking, creativity, and accurate collection of data regarding the patient as well as the drug. Nursing diagnoses related to drug therapy will most likely grow out of data associated with the following: deficient knowledge; risk for injury; **noncompliance;** and various disturbances, deficits, excesses, impairments in bodily functions, and/or other problems or concerns as related to drug therapy. The development and classification of nursing diagnoses has been carried out by the North American Nursing Diagnosis Association International (NANDA-I) (formerly NANDA). NANDA-I is the formal organization recognized by professional nursing groups (e.g., the American Nurses Association [ANA]). NANDA-I is considered to be the major contributor to the development of nursing knowledge and the leading authority (on nursing diagnoses). The purpose of NANDA-I is to increase the visibility of nursing's contribution to the care of patients and to further develop, refine, and classify the information and phenomena related to nurses and professional nursing practice. In 2000, a classification system was adopted with a taxonomy including 13 domains divided into 106 classes and over 150 nursing diagnoses. Using this system, the nurse was able to choose a nursing diagnosis from the established list and individualize the nursing care plan. The 2009-2011 NANDA approved nursing diagnoses included many changes with revisions, as well as several new diagnoses and a listing of retired nursing diagnoses. The newest list, 2012-2014 NANDA-I approved nursing diagnoses, are still characterized with domains and classes but also with changes that include several new and revised nursing diagnoses or diagnoses with a key word changed. See Box 1-2 for more information about the 2012-2014 NANDA approved nursing diagnoses.

Formulation of nursing diagnoses is usually a three-step process with nursing diagnoses stated as follows: Part one of the statement is the human response of the patient to illness, injury, or significant change. This response can be an actual problem, an increased risk of developing a problem, or an opportunity or intent to improve the patient's health. Part two of the nursing diagnosis statement identifies the factor(s) related to the response, with more than one factor often named. The nursing diagnosis statement does not necessarily claim a cause-and-effect link between these factors and the response; it indicates only that there is a connection between them. Part three of the nursing diagnosis statement contains a listing of clues, cues, evidence, or other data that support the nurse's claim that this diagnosis is accurate. Tips for writing nursing diagnoses include

BOX 1-2 A BRIEF LOOK AT NANDA AND THE NURSING PROCESS

The North American Nursing Diagnosis Association International (NANDA-I) (formerly NANDA) fulfills the following roles: (1) increases the visibility of nursing's contribution to patient care, (2) develops, refines, and classifies information and phenomena related to professional nursing practice, (3) provides a working organization for the development of evidence-based nursing diagnoses, and (4) supports the improvement of quality nursing care through evidence-based practice and access to a global network of professional nurses. In 1987, NANDA and the American Nurses Association endorsed a framework for establishing nursing diagnoses, and in 1990 *Nursing Diagnoses* became the official journal of NANDA. In 2001 and 2003, NANDA modified and updated the listing of nursing diagnoses, but nursing diagnoses continued to be submitted for consideration by the Ad Hoc Research Committee of NANDA. This period resulted in changes such as replacement of the phrase *potential for* with *risk for.* The terms *impaired, deficient, ineffective, decreased, increased,* and *imbalanced* replaced the outdated terms *altered* and *alteration,* although the outdated terms may still be in use. In 2002, NANDA changed its name to NANDA-I ("I" for international) to reflect the organization's global reach. In 2007-2008, there were 188 nursing diagnoses (up from 172) with changes to defining characteristics and related or risk factors. There were also some 15 newly approved nursing diagnoses. More changes occurred in the 2009-2011 version of NANDA-I's *Nursing Diagnoses: Definitions and Classifications,* with 21 new, 9 revised, and 6 retired nursing diagnoses. Most current is the *2012-2014 NANDA-I Approved Nursing Diagnoses.* There are 23 new, 33 revised, and 2 retired nursing diagnoses. Other changes are discussed in the 2012-2014 NANDA-I *Nursing Diagnoses: Definitions and Classifications.*

BOX 1-3 CURRENT NANDA-I–APPROVED NURSING DIAGNOSES MOST RELEVANT TO DRUG THERAPY

Activity intolerance (and risk for)
Adverse reaction to iodinated contrast media, risk for*
Airway clearance, ineffective
Allergy response, latex (and risk for)
Aspiration, risk for
Bleeding, risk for
Body image, disturbed
Body temperature, risk for imbalanced
Breathing pattern, ineffective
Cardiac output, decreased
Caregiver role strain (and risk for)
Comfort, impaired (and readiness for enhanced)
Communication, readiness for enhanced
Confusion (acute, chronic, or risk for acute)
Constipation (perceived and risk for)
Coping (defensive, ineffective, and readiness for enhanced)
Death anxiety†
Decision-making, readiness for enhanced
Diarrhea
Electrolyte imbalance, risk for
Falls, risk for
Fatigue
Fear
Fluid volume, deficient (and excess, risk for deficient, and risk for imbalanced)
Gas exchange, impaired
Growth and development, delayed
Health maintenance, ineffective
Home maintenance, impaired
Health-seeking behaviors±
Human dignity, risk for compromised
Hyperthermia
Hypothermia
Immunization status, readiness for enhanced
Incontinence (functional urinary, overflow urinary, reflex urinary, stress urinary, urge urinary, risk for urge urinary)
Infection, risk for
Injury, risk for
Insomnia
Knowledge (deficient, readiness for enhanced)
Latex allergy response, risk for*
Lifestyle, sedentary
Liver function, risk for impaired
Loneliness, risk for
Memory, impaired
Mobility (impaired bed, impaired physical, impaired wheelchair)
Nausea
Noncompliance
Nutrition, imbalanced (less than body requirements, more than body requirements, risk for imbalanced, readiness for enhanced)
Oral mucous membrane, impaired
Pain (acute, chronic)
Peripheral neurovascular dysfunction, risk for
Poisoning, risk for
Powerlessness (and risk for)
Self-care deficit (bathing, dressing)†
Self-esteem, chronic low (and risk for)*
Self-esteem, low (situational, risk for situational)
Self-health management (ineffective and readiness for enhanced)†
Sensory perception, disturbed±
Sexual dysfunction
Sexuality pattern, ineffective
Skin integrity, impaired (and risk for)
Sleep deprivation
Sleep pattern, disturbed
Stress overload
Suicide, risk for
Surgical recovery, delayed
Swallowing, impaired
Therapeutic regimen management, ineffective family
Tissue integrity, impaired
Tissue perfusion (risk for decreased cardiac, risk for ineffective cerebral, risk for ineffective peripheral)†
Urinary elimination (impaired, readiness for enhanced)
Urinary retention
Verbal communication, impaired†
Walking, impaired

the following: begin with a statement of a human response; connect the first part of the statement or the human response with the second part, the cause, using the phrase "related to"; be sure that the first two parts are not restatements of one another; include several factors in the second part of the statement, such as associated factors, if appropriate; select a cause for the second part of the statement that can be changed by nursing interventions; avoid negative wording or language; and, finally, list clues or cues that led to the nursing diagnosis in the third part of the statement, which may also include more defining characteristics (e.g., "as evidenced by"). A listing of NANDA-approved nursing diagnoses (2012-2014) most relevant to drug therapy is provided in Box 1-3. These nursing diagnoses, as well as all other phases of the nursing process, will be presented in the chapters that follow because the nursing process provides the framework of practice for all professional nurses and is also used to organize the nursing sections of this textbook.

PLANNING

After data are collected and nursing diagnoses are formulated, the planning phase begins; this includes identification of goals and outcome criteria. The major purposes of the planning phase are to prioritize the nursing diagnoses and specify goals and

outcome criteria, including the time frame for their achievement. The planning phase provides time to obtain special equipment for interventions, review the possible procedures or techniques to be used, and gather information for oneself (the nurse) or for the patient. This step leads to the provision of safe care if professional judgment is combined with the acquisition of knowledge about the patient and the medications to be given.

Goals and Outcome Criteria

Goals are objective, measurable, and realistic, with an established time period for achievement of the outcomes, which are specifically stated in the outcome criteria. Patient goals reflect expected and measurable changes in behavior through nursing care and are developed in collaboration with the patient. Patient goals developed in the planning phase of the nursing process are behavior based and may be categorized into physiologic, psychological, spiritual, sexual, cognitive, motor, and/or other domains.

Outcome criteria are concrete descriptions of patient goals. They are patient focused, succinct, and well thought out. Outcome criteria also include expectations for behavior indicating something that can be changed and with a specific time frame or deadline. The ultimate aim of these criteria is the safe and effective administration of medications. Outcome criteria also reflect each nursing diagnosis and serve as a guide to the implementation phase of the nursing process. Formulation of outcome criteria begins with the analysis of the judgments made about patient data and subsequent nursing diagnoses and ends with the development of a nursing care plan. Outcome criteria provide a standard for measuring movement toward goals. With regard to medication administration, these outcomes may address special storage and handling techniques, administration procedures, equipment needed, drug interactions, adverse effects, and contraindications. In this textbook, specific time frames are *not* provided in each chapter's nursing process section because patient care is individualized in every situation.

IMPLEMENTATION

Implementation is guided by the preceding phases of the nursing process (i.e., assessment, nursing diagnoses, and planning). Implementation requires constant communication and collaboration with the patient and with members of the health care team involved in the patient's care, as well as with any family members, significant others, or other caregivers. Implementation consists of initiation and completion of specific nursing actions as defined by nursing diagnoses, goals, and outcome criteria. Implementation of nursing actions may be independent, collaborative, or dependent upon a prescriber's order. Statements of interventions include frequency, specific instructions, and any other pertinent information. With medication administration, you need to know and understand all of the information about the patient and about each medication prescribed (see assessment questions). In years past, nurses adhered to the "Five Rights" of medication administration: right drug, right dose, right time, right route, and right patient. However, continued support exists for referring to "Six Rights" of medication administration with the addition of "right documentation." The Six Rights are discussed in detail in the next section. These "rights" of medication administration have been identified as basic standards of care as related to drug therapy. However, even implementation of the Six Rights does not reflect the complexity of the role of the professional nurse because they focus more on the individual/patient than on the system as a whole or the entire medication administration process beginning with the prescriber's order. Viewed from an individual/patient focus, there are additional rights (or entitlements) to be considered when administering medications. These include the right to:

- Patient safety, ensured by use of the correct procedures, equipment, and techniques of medication administration and documentation
- Individualized, holistic, accurate, and complete patient education
- Double-checking and constant analysis of the system (i.e., the process of drug administration including all personnel involved, such as the prescriber, the nurse, the nursing unit, and the pharmacy department, as well as patient education)
- Proper drug storage
- Accurate calculation and preparation of the dose of medication and proper use of all types of medication delivery systems
- Careful checking of the transcription of medication orders
- Accurate use of the various routes of administration and awareness of the specific implications of their use
- Close consideration of special situations (e.g., patient difficulty in swallowing, use of a nasogastric tube, unconsciousness of the patient, advanced patient age)
- Implementation of all appropriate measures to prevent and report medication errors

Six Rights of Medication Administration

Right Drug

The "right drug" begins with the registered nurse's valid license to practice. Some states allow currently licensed practical nurses to administer medications with specific guidelines. The registered nurse is responsible for checking all medication orders and/or prescriptions. To ensure that the correct drug is given, you must check the specific medication order against the medication label or profile three times before giving the medication. Conduct the first check of the right drug/drug name while you prepare the medication for administration. At this time, consider whether the drug is appropriate for the patient and, if doubt exists or an error is deemed possible, contact the prescriber and/pharmacist immediately. It is also appropriate at this time to note the drug's indication and be aware that a drug may have multiple indications, including off-label use and non–FDA-approved indications. In this textbook, each particular drug is discussed in the chapter that deals with its main indication, but the drug may also be cross-referenced in other chapters if it has multiple uses.

All medication orders or prescriptions are required by law to be signed by the prescriber involved in the patient's care. If a verbal order is given, the prescriber must sign the order within 24 hours or as per facility protocol. Verbal and/or telephone

EVIDENCE-BASED PRACTICE

Improving Retention, Confidence, and Competence of New Graduate Nurses: A 10-Year Longitudinal Study

Review

In 1999, the Children's Hospital Los Angeles (CHLA) found that despite efforts and monies to support their internship for new graduate nurses, they continued to experience a high turnover rate: 36% of new graduates hired were leaving in less than 12 months, and 56% were leaving within 2 years. The vicious cycle of hiring, educating, and rehiring resulted in negative influences on nursing and patient care. With key nursing leaders from CHLA, the next 10 years were spent trying to find improved ways to attract new graduates into the profession and the hospital. Aggressive development, evaluation, and ideas for improvement led to a RN residency program with results of positive outcomes for hospitals, new graduates, and patient care. A model for successful "recruiting, engaging, and retaining new graduate nurses" was a beneficial outcome for CHLA and the nursing profession.

Type of Evidence

Development of the Versant RN residency program (1999) began as a 1-year pilot study with approximately 700 hours of guided clinical experience for each new graduate nurse with a one-on-one preceptor. Additionally, a mentor was assigned for each new graduate, and debriefing and self-care sessions to discuss practice issues and subsequent strategies were held. These hours of clinical included other experiences in other areas/departments of the hospital with approximately 225 hours of didactic time with corresponding hands-on skills training sessions. The pilot study's goals were to help with transition of the new graduate to the role of the professional RN; increase level of self-confidence; and provide competent, safe, and quality care while also increasing retention of new graduates within the organization. Development of the RN residency was initially treated as a basic research effort and all those who participated (organizations) had to obtain institutional review board approval prior to implementing the program. As the programs were initiated throughout the country in various hospital settings, research continued. In 2009, there were 10 years of evidence-based outcomes with support of the success of the RN residency program. At this 10-year time period, Versant moved the residency program out of traditional research status. However, data collection protocols are still intact and continue to be followed with confidentiality of responses in the measurement instruments and evaluations.

Measures used to evaluate the pilot study included self-report and observation instruments with previously established reliability and validity. Demographic and evaluation instruments were also developed for the pilot. Additional measurements included the Slater Nursing Competencies Rating Scale (Wandelt and Stewart, 1975). After completion of the pilot study, several other hospitals in California had participated. By July 2003, 118 new graduates had completed the residency program at these sites. With the increase in programs, CHLA created Versant in 2004 and then launched a web-based management system, Voyager, to provide access to the residency curriculum, measurement instruments, and other information for individual residents related to competency achievement and goal progression.

Results of the Study

Results of the residency program indicated that graduates who were hired had equal or better results on all concept outcome measures. Concepts measured included, but were not limited to, the following: competency, satisfaction, confidence, empowerment/autonomy/role dissonance, group cohesion/organizational commitment, and turnover intent. Results of the pilot study indicated that the graduates hired in the residency program had equal or better results on all measures. The pilot study then continued forward with 56 graduates. There was also modification of measurement instruments and use of a new competency rating scale (see Slater Nursing Competencies Rating Scale). Data analysis performed on the Versant National Database included various statistics including data reduction, correlation matrix analysis, descriptive statistics for demographics, and regression analysis.

Following the pilot study, more pediatric hospitals in California participated and results indicated that the program was appropriate for use in other hospitals. Furthermore, to make this happen at a national level, it was maintained that a business model with an easy method of collecting/accessing/sharing data and information needed to be developed and implemented. CHLA created Versant and then launched a web-based management system (see Type of Evidence). At the end of the 10-year mark, over 6000 new graduates had completed the Versant RN residency. Participants were from small rural hospitals to large health care systems.

Link of Evidence to Nursing Practice

After collection of data over a 10-year period and reflection back on the research, there are definite actions needed (not only on an individual level but on an organizational level) to achieve positive, successful outcomes in an RN residency program. Some of these outcomes include defining a set of standards based upon competencies that are outcome validated; teaching to those same standards; monitoring as well as managing the individual and organizational adherence to those standards; and use of quantitative as well as qualitative outcome measures to objectively evaluate the successful performance of competencies in the new graduate. Key characteristics identified in a successful RN residency program include standardization, evidence-based content/curriculum, clinical immersion, support systems (e.g., preceptors and/or experts), accountability, communication, consistent and precise evaluations, individual and organization-wide commitment, a management system for performance and outcomes, research and development, continuous outcome-driven program improvement, and a delivery system with structured framework for managing an RN residency program at an individual hospital setting or at a health care system. This fascinating study and its results support the need for a clinical immersion program for new graduate nurses. The authors recommend that an 18-week program be implemented with dedicated preceptors and extensive follow-up of the RN residents. The results also support the need for mentoring, ongoing support and guidance throughout the first year of practice for the RN resident. Further studies of significance to nursing practice included the need for additional structural supportive components throughout the first year as well as development of further evaluation and coaching strategies to help everyone focus on the residents and long-term success in nursing.

orders are often used in emergencies and time-sensitive patient care situations. To be sure that the right drug is given, information about the patient and drug (see previous discussion of the assessment phase) must be obtained to make certain that all variables and data have been considered. Approved, current authoritative references (see earlier discussion) are the reliable sources of information about prescribed drugs. Avoid relying upon the knowledge of peers as this is unsafe nursing practice.

Remain current in your knowledge of generic (nonproprietary) drug names as well as trade names (proprietary name that is registered by a specific drug manufacturer); however, use of the drug's generic name is now preferred in clinical practice to reduce the risk of medication errors. A single drug often has numerous trade names, and drugs in different classes may have similarly spelled names, increasing the possibility of medication errors. Therefore, when it comes to the "right drug" phase of

the medication administration process, use of a drug's generic name is recommended to help avoid a medication error and enhance patient safety. (See Chapter 2 for more information on the naming of drugs).

If there are questions about the medication order at any time during the medication administration process, contact the prescriber for clarification. Never make any assumptions when it comes to drug administration, and, as previously emphasized in this chapter, confirm at least three times the right drug, right dose, right time, right route, right patient, and right documentation before giving the medication.

Right Dose

Whenever a medication is ordered, a dosage is identified from the prescriber's order. Always check the dose and confirm that it is appropriate for the patient's age and size. Also, check the prescribed dose against the available drug stocks and against the normal dosage range. Recheck all mathematical calculations, and pay careful attention to decimal points, the misplacement of which could lead to a tenfold or even greater overdose. Leading zeros, or zeros placed before a decimal point, are allowed, but trailing zeros, or zeros following the decimal point, are to be avoided. For example, 0.2 mg is allowed, but 2.0 mg is not acceptable, because it could easily be mistaken for 20 mg, especially with unclear penmanship. Patient variables (e.g., vital signs, age, gender, weight, height) require careful assessment because of the need for dosage adjustments in response to specific parameters. Pediatric and elderly patients are more sensitive to medications than younger and middle-age adult patients; thus, use extra caution with drug dosage amounts for these patients.

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Right Dose?

The nurse is reviewing the orders for a newly admitted patient. One order reads: "Tylenol, 2 tablets PO, every 4 hours as needed for pain or fever."

The pharmacist calls to clarify this order, saying, "The dose is not clear." What does the pharmacist mean by this? The order says "2 tablets." Isn't that the dose?

NO! If you look up Tylenol (acetaminophen) in a drug resource book, you will see that Tylenol tablets are available in strengths of both 325 mg and 500 mg. The order is missing the "right dose" and needs to be clarified. *Never* assume the dose of a medication order!

Right Time

Each health care agency or institution has a policy regarding routine medication administration times; therefore, always check this policy. However, when giving a medication at the prescribed time, you may be confronted with a conflict between the timing suggested by the prescriber and specific pharmacokinetic or pharmacodynamic drug properties, concurrent drug therapy, dietary influences, laboratory and/or diagnostic testing, and specific patient variables. For example, the prescribed right time for administration of antihypertensive drugs may be four times a day, but for an active, professional 42-year-old male patient working 14 hours a day, taking a medication four times daily may not be feasible, and this regimen may lead to noncompliance and subsequent complications. Appropriate actions include contacting the prescriber and inquiring about the possibility of prescribing another drug with a different dosing frequency (e.g., once or twice daily).

For routine medication orders, give the medications no more than ½ hour before or after the actual time specified in the prescriber's order (i.e., if a medication is ordered to be given at 0900 every morning, you may give it at any time between 0830 and 0930); the exception is medications designated to be given stat (immediately), which you must administer within ½ hour of the time the order is written. Assess and follow the hospital or facility policy and procedure for any other specific information concerning the "½ hour before or after" rule. For medication orders with the annotation "prn" (*pro re nata,* or "as required"), you must give the medication at special times and under certain circumstances. For example, an analgesic is ordered every 4 to 6 hours *prn* for pain; after one dose of the medication, the patient complains of pain. After assessment, intervention with another dose of analgesic would occur, but only 4 to 6 hours after the previous dose. In addition, because of the increasing incidence of medication errors related to the use of abbreviations, many prescribers are using the wording "as required" or "as needed" instead of the abbreviation "prn." Military time is used when medication and other orders are written into a patient's chart (Table 1-1).

TABLE 1-1 CONVERSION OF STANDARD TIME TO MILITARY TIME

STANDARD TIME	MILITARY TIME
1 AM	0100
2 AM	0200
3 AM	0300
4 AM	0400
5 AM	0500
6 AM	0600
7 AM	0700
8 AM	0800
9 AM	0900
10 AM	1000
11 AM	1100
12 PM (noon)	1200
1 PM	1300
2 PM	1400
3 PM	1500
4 PM	1600
5 PM	1700
6 PM	1800
7 PM	1900
8 PM	2000
9 PM	2100
10 PM	2200
11 PM	2300
12 AM (midnight)	2400

Nursing judgment may lead to some variations in timing, and you must document any change and the rationale for the change. If medications are ordered to be given once every day, twice daily, three times daily, or even four times daily, the times of administration may be changed if it is not harmful to the patient or if the medication or the patient's condition does not require adherence to an exact schedule, but only if the change is approved by the prescriber. For example, suppose that an antacid is ordered to be given three times daily at 0900, 1300, and 1700, but the nurse has misread the order and gives the first dose at 1100. Depending on the hospital or facility policy, the medication, and the patient's condition, such an occurrence may not be considered an error, because the dosing may be changed once the prescriber is contacted, so that the drug is given at 1100, 1500, and 1900 without harm to the patient and without incident to the nurse. If this were an antihypertensive medication, the patient's condition and well-being could be greatly compromised by one missed or late dose. Thus, falling behind in dosing times is not to be taken lightly or ignored. Never underestimate the effect of a change in the dosing or timing of medication, because one missed dose of certain medications can be life threatening.

Other factors must be considered in determining the right time, such as multiple-drug therapy, drug-drug or drug-food compatibility, scheduling of diagnostic studies, bioavailability of the drug (e.g., the need for consistent timing of doses around the clock to maintain blood levels), drug actions, and any biorhythm effects such as occur with steroids. It is also critical to patient safety to avoid using abbreviations for *any* component of a drug order (i.e., dose, time, route). Spell out *all* terms (e.g., *three times daily* instead of *tid*) in their entirety. Be careful to write out all words and abbreviations, because the possibility of miscommunication or misinterpretation poses a risk to the patient.

Right Route

As previously stated, you must know the particulars about each medication before administering it to ensure that the right drug, dose, and route are being used. A complete medication order includes the route of administration. If a medication order does not include the route, be sure to ask the prescriber to clarify it. Never *assume* the route of administration.

Right Patient

Checking the patient's identity before giving each medication dose is critical to the patient's safety. Ask the patient to state his or her name, and then check the patient's identification band to confirm the patient's name, identification number, age, and allergies. With pediatric patients, the parents and/or legal guardians are often the ones who identify the patient for the purpose of administration of prescribed medications. With newborns and in labor and delivery situations, the mother and baby have identification bracelets with matching numbers, which must be checked before giving medications. With elderly patients or patients with altered sensorium or level of consciousness, asking the patient his or her name or having the patient state his or her name is neither realistic nor safe. Therefore, checking the identification band against the medication profile, medication order, or other treatment or service orders is crucial to avoid errors. In 2008, The Joint Commission released National Patient Safety Goals for patient care. These goals emphasize the use of two identifiers when providing care, treatment, or services to patients. To meet these goals, The Joint Commission recommends that the patient be identified "reliably" and also that the service or treatment (e.g., medication administration) be matched to that individual. The Joint Commission's statement of National Patient Safety Goals indicates that the two identifiers may be in the same location, such as on a wristband. In fact, it is patient-specific information that is the identifier. Acceptable identifiers include the patient's name, an assigned identification number, a telephone number, or other patient-specific identifier. Armbands are commonly used in the acute care setting and may serve as one identifier, with the other one being date of birth, Social Security number, or home address.

Right Documentation

Documentation of information related to medication administration is crucial to patient safety. Recording patient observations and nursing actions has always been an important ethical responsibility, but now it is becoming a major medical-legal consideration as well. Because of its significance in professional nursing practice, correct documentation is becoming known as the "sixth right" of medication administration. Always assess the patient's chart for the presence of the following information: date and time of medication administration, name of medication, dose, route, and site of administration. Documentation of drug action may also be made in the regularly scheduled assessments for changes in symptoms the patient is experiencing, adverse effects, toxicity, and any other drug-related physical and/or psychological symptoms. Documentation must also reflect any improvement in the patient's condition, symptoms, or disease process as well as no change or a lack of improvement. You must not only document these observations, but report them to the prescriber promptly in keeping with your critical thinking and judgment. Document any teaching, as well as an assessment of the degree of understanding exhibited by the patient. Other information that needs documentation includes the following: (1) if a drug is *not* administered with the reason why and any actions taken, (2) refusal of a medication with information about the reason for refusal, if possible; if a medication is refused, respect the patient's right (to refuse), determine the reason, take appropriate action including notifying the prescriber, and revise the nursing care plan; never return unwrapped medication to a container, and discard according to agency policy; if wrapper remains intact, return medication to the pharmacy and revise the nursing care plan as needed; (3) actual time of drug administration; and (4) data regarding clinical observations and treatment of the patient if a medication error has occurred. If there is a medication error, complete an incident report with the entire event, surrounding circumstances, therapeutic response, adverse effects, and notification of the prescriber described in detail. However, do not record completion of an incident report in the medical chart.

Medication Errors

When the Six Rights (and other rights) of drug administration are discussed, medication errors must be considered. Medication errors are a major problem for all of health care, regardless of the setting. The National Coordinating Council for Medication Error Reporting and Prevention defines a **medication error** as any *preventable* event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the health care professional, patient, or consumer. Such events may be related to professional practice, health care products, procedures, or systems, including prescribing; order communication; product labeling, packaging, and nomenclature; compounding; dispensing; distribution; administration; education; monitoring; and use (http://www.nccmerp.org/aboutMedErrors.html). Both patient-related and system-related factors must always be considered when the medication administration process and the prevention of medication errors are being examined. See Chapter 5 for further discussion of medication errors and their prevention.

EVALUATION

Evaluation occurs after the nursing care plan has been implemented. It is systematic, ongoing, and a dynamic phase of the nursing process as related to drug therapy. It includes monitoring the fulfillment of goals and outcome criteria, as well as monitoring the patient's therapeutic response to the drug and its adverse effects and toxic effects. Documentation is also a very important component of evaluation and consists of clear, concise, abbreviation-free charting that records information related to goals and outcome criteria as well as information related to any aspect of the medication administration process, including therapeutic effects versus adverse effects or toxic effects of medications (see the Teamwork and Collaboration: Legal and Ethical Principles box).

Evaluation also includes monitoring the implementation of standards of care. Several standards are in place to help in the evaluation of outcomes of care, such as those established by state nurse practice acts and by The Joint Commission.

TEAMWORK AND COLLABORATION: LEGAL AND ETHICAL PRINCIPLES

Charting Don'ts

- Don't record staffing problems (don't mention them in a patient's chart, but instead talk with the nurse manager and/or other appropriate personnel).
- Don't record a peer's conflicts, such as charting possible disputes between a patient and a nurse.
- Don't mention the term *incident report* in charting. These reports are confidential and filed separately. Chart only the facts of the medication error or incident and appropriate actions taken.
- Don't use the following terms: *by mistake, by accident, accidentally, unintentional,* or *miscalculated.*
- Don't chart anything but facts.
- Don't chart casual conversations with peers, prescribers, or other members of the health care team.
- Don't use abbreviations. Some agencies or facilities may still keep a list of approved abbreviations, but overall their use is discouraged.
- Don't use negative language!

Modified from Institute for Safe Medication Practices: *ISMP Medication Safety Alert,* Huntingdon Valley, PA, February 20, 2003, The Institute; and InjuryBoard.com: Medication and prescription errors, available at http://www.injuryboard.com.

Guidelines for nursing services policies and procedures are established by The Joint Commission. There are even specific standards regarding medication administration to protect both the patient and the nurse. The ANA *Code of Ethics* and Patient Rights statement are also used in establishing and evaluating standards of care.

In summary, the nursing process is an ongoing and constantly evolving process (see Box 1-1). The nursing process, as it relates to drug therapy, involves the way in which a nurse gathers, analyzes, organizes, provides, and acts upon data about the patient within the context of prudent nursing care and standards of care. The nurse's ability to make astute assessments, formulate sound nursing diagnoses, establish goals and outcome criteria, correctly administer drugs, and continually evaluate patients' responses to drugs increases with additional experience and knowledge.

KEY POINTS

- The nursing process is an ongoing, constantly changing and evolving framework for professional nursing practice. It may be applied to all facets of nursing care, including medication administration.
- The phases of the nursing process include assessment; development of nursing diagnoses; planning, with establishment of goals and outcome criteria; implementation, including patient education; and evaluation.
- Nursing diagnoses are formulated based on objective and subjective data and help to drive the nursing care plan. Nursing diagnoses have been developed through a formal process conducted by NANDA-I and are constantly updated and revised. Safe, therapeutic, and effective medication administration is a major responsibility of professional nurses as they apply the nursing process to the care of their patients.
- Nurses are responsible for safe and prudent decision-making in the nursing care of their patients, including the provision of drug therapy; in accomplishing this task, they attend to the Six Rights and adhere to legal and ethical standards related to medication administration and documentation. There are additional rights related to drug administration. These rights deserve worthy consideration before initiation of the medication administration process. Observance of all of these rights enhances patient safety and helps avoid medication errors.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 An 86-year-old patient is being discharged to home on digitalis therapy and has very little information regarding the medication. Which statement best reflects a realistic outcome of patient teaching activities?
- **a** The patient and patient's daughter will state the proper way to take the drug.
- **b** The nurse will provide teaching about the drug's adverse effects.
- **c** The patient will state all the symptoms of digitalis toxicity.
- **d** The patient will call the prescriber if adverse effects occur.

2 A patient has a new prescription for a blood pressure medication that may cause him to feel dizzy during the first few days of therapy. Which is the best nursing diagnosis for this situation?
- **a** Activity intolerance
- **b** Risk for injury
- **c** Disturbed body image
- **d** Self-care deficit

3 A patient's chart includes an order that reads as follows: "Lanoxin 250 mcg once daily at 0900." Which action by the nurse is correct?
- **a** The nurse gives the drug via the transdermal route.
- **b** The nurse gives the drug orally.
- **c** The nurse gives the drug intravenously.
- **d** The nurse contacts the prescriber to clarify the dosage route.

4 The nurse is compiling a drug history for a patient. Which question from the nurse will obtain the most information from the patient?
- **a** "Do you depend on sleeping pills to get to sleep?"
- **b** "Do you have a family history of heart disease?"
- **c** "When you have pain, what do you do to relieve it?
- **d** "What childhood diseases did you have?"

5 A 77-year-old man who has been diagnosed with an upper respiratory tract infection tells the nurse that he is allergic to penicillin. Which is the most appropriate response by the nurse?
- **a** "That's to be expected—lots of people are allergic to penicillin."
- **b** "This allergy is not of major concern because the drug is given so commonly."
- **c** "What type of reaction did you have when you took penicillin?"
- **d** "Drug allergies don't usually occur in older individuals because they have built up resistance."

6 The nurse is preparing a care plan for a patient who has been newly diagnosed with type 2 diabetes mellitus. Put into correct order the steps of the nursing process, with 1 being the first step and 5 being the last step.
- **a** Implementation
- **b** Planning
- **c** Assessment
- **d** Evaluation
- **e** Nursing diagnoses

7 The nurse is reviewing new medication orders that have been written for a newly admitted patient. The nurse will need to clarify which orders? *Select all that apply.*
- **a** Metformin (Glucophage) 1000 mg PO twice a day
- **b** Sitagliptin (Januvia) 50 mg daily
- **c** Simvastatin (Zocor) 20 mg PO every evening
- **d** Irbesartan (Avapro) 300 mg PO once a day
- **e** Docusate (Colace) as needed for constipation

1. a, 2. b, 3. d, 4. c, 5. c, 6. a = 4, b = 3, c = 1, d = 5, e = 2, 7. b, e

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Define the common terms used in pharmacology (see Key Terms).
2 Understand the general concepts such as pharmaceutics, pharmacokinetics, and pharmacodynamics and their application in drug therapy and the nursing process.
3 Demonstrate an understanding of the various drug dosage forms as related to drug therapy and the nursing process.
4 Discuss the relevance of the four aspects of pharmacokinetics (absorption, distribution, metabolism, excretion) to professional nursing practice as related to drug therapy for a variety of patients and health care settings.
5 Discuss the use of natural drug sources in the development of new drugs.
6 Develop a nursing care plan that takes into account general pharmacologic principles, specifically pharmacokinetic principles, as they relate to the nursing process.

KEY TERMS

Additive effects Drug interactions in which the effect of a combination of two or more drugs with similar actions is equivalent to the sum of the individual effects of the same drugs given alone. For example, 1 + 1 = 2 (compare with synergistic effects). (p. 33)

Adverse drug event Any undesirable occurrence related to administering or failing to administer a prescribed medication. (p. 33)

Adverse drug reaction Any unexpected, unintended, undesired, or excessive response to a medication given at therapeutic dosages (as opposed to overdose). (p. 34)

Adverse effects A general term for any undesirable effects that are a direct response to one or more drugs. (p. 31)

Agonist A drug that binds to and stimulates the activity of one or more receptors in the body. (p. 30)

Allergic reaction An immunologic hypersensitivity reaction resulting from the unusual sensitivity of a patient to a particular medication; a type of adverse drug event. (p. 34)

Antagonist A drug that binds to and inhibits the activity of one or more receptors in the body. Antagonists are also called *inhibitors*. (p. 30)

Antagonistic effects Drug interactions in which the effect of a combination of two or more drugs is less than the sum of the individual effects of the same drugs given alone (1 + 1 equals less than 2); it is usually caused by an antagonizing (blocking or reducing) effect of one drug on another. (p. 33)

Bioavailability A measure of the extent of drug absorption for a given drug and route (from 0% to 100%). (p. 22)

Biotransformation One or more biochemical reactions involving a parent drug. Biotransformation occurs mainly in the liver and produces a metabolite that is either inactive or active. Also known as *metabolism*. (p. 27)

KEY TERMS—cont'd

Blood-brain barrier The barrier system that restricts the passage of various chemicals and microscopic entities (e.g., bacteria, viruses) between the bloodstream and the central nervous system. It still allows for the passage of essential substances such as oxygen. (p. 27)

Chemical name The name that describes the chemical composition and molecular structure of a drug. (p. 19)

Contraindication Any condition, especially one related to a disease state or patient characteristic, including current or recent drug therapy, that renders a particular form of treatment improper or undesirable. (p. 31)

Cytochrome P-450 The general name for a large class of enzymes that play a significant role in drug metabolism and drug interactions. (p. 27)

Dependence A state in which there is a compulsive or chronic need, as for a drug. (p. 32)

Dissolution The process by which solid forms of drugs disintegrate in the gastrointestinal tract and become soluble before being absorbed into the circulation. (p. 21)

Drug Any chemical that affects the physiologic processes of a living organism. (p. 19)

Drug actions The processes involved in the interaction between a drug and body cells (e.g., the action of a drug on a receptor protein); also called *mechanism of action*. (p. 20)

Drug classification A method of grouping drugs; may be based on structure or therapeutic use. (p. 20)

Drug effects The physiologic reactions of the body to a drug. They can be therapeutic or toxic and describe how the body is affected as a whole by the drug. The terms *onset, peak,* and *duration* are used to describe drug effects (most often referring to therapeutic effects). (p. 29)

Drug-induced teratogenesis The development of congenital anomalies or defects in the developing fetus caused by the toxic effects of drugs. (p. 35)

Drug interaction Alteration in the pharmacologic or pharmacokinetic activity of a given drug caused by the presence of one or more additional drugs; it is usually related to effects on the enzymes required for metabolism of the involved drugs. (p. 32)

Duration of action The length of time the concentration of a drug in the blood or tissues is sufficient to elicit a response. (p. 29)

Enzymes Protein molecules that catalyze one or more of a variety of biochemical reactions, including those related to the body's physiologic processes as well as those related to drug metabolism. (p. 30)

First-pass effect The initial metabolism in the liver of a drug absorbed from the gastrointestinal tract before the drug reaches systemic circulation through the bloodstream. (p. 22)

Generic name The name given to a drug by the United States Adopted Names Council. Also called the *nonproprietary name*. The generic name is much shorter and simpler than the chemical name and is not protected by trademark. (p. 19)

Glucose-6-phosphate dehydrogenase (G6PD) deficiency A hereditary condition in which red blood cells break down when the body is exposed to certain drugs. (p. 34)

Half-life In pharmacokinetics, the time required for half of an administered dose of drug to be eliminated by the body, or the time it takes for the blood level of a drug to be reduced by 50% (also called *elimination half-life*). (p. 29)

Idiosyncratic reaction An abnormal and unexpected response to a medication, other than an allergic reaction, that is peculiar to an individual patient. (p. 34)

Incompatibility The characteristic that causes two parenteral drugs or solutions to undergo a reaction when mixed or given together that results in the chemical deterioration of at least one of the drugs. (p. 33)

Intraarterial Within an artery (e.g., intraarterial injection). (p. 23)

Intraarticular Within a joint (e.g., intraarticular injection). (p. 23)

Intrathecal Within a sheath (e.g., the theca of the spinal cord, as in an intrathecal injection into the subarachnoid space). (p. 23)

Medication error Any preventable adverse drug event (see above) involving inappropriate medication use by a patient or health care professional; it may or may not cause patient harm. (p. 33)

Medication use process The prescribing, dispensing, and administering of medications, and the monitoring of their effects. (p. 33)

Metabolite A chemical form of a drug that is the product of one or more biochemical (metabolic) reactions involving the parent drug (see later). Active metabolites are those that have pharmacologic activity of their own, even if the parent drug is inactive (see *prodrug*). Inactive metabolites lack pharmacologic activity and are simply drug waste products awaiting excretion from the body (e.g., via the urinary, gastrointestinal, or respiratory tract). (p. 34)

Onset of action The time required for a drug to elicit a therapeutic response after dosing. (p. 29)

Parent drug The chemical form of a drug that is administered before it is metabolized by the body's biochemical reactions into its active or inactive metabolites (see *metabolite)*. A parent drug that is not pharmacologically active itself is called a *prodrug.* A prodrug is then metabolized to pharmacologically active metabolites. (p. 22)

Peak effect The time required for a drug to reach its maximum therapeutic response in the body. (p. 29)

Peak level The maximum concentration of a drug in the body after administration, usually measured in a blood sample for therapeutic drug monitoring. (p. 30)

Pharmaceutics The science of preparing and dispensing drugs, including dosage form design. (p. 20)

Pharmacodynamics The study of the biochemical and physiologic interactions of drugs at their sites of activity. It examines the physicochemical properties of drugs and their pharmacologic interactions with body receptors. (p. 20)

Pharmacoeconomics The study of economic factors impacting the cost of drug therapy. (p. 20)

KEY TERMS—cont'd

Pharmacogenomics The study of the influence of genetic factors on drug response, including the nature of genetic aberrations that result in the absence, overabundance, or insufficiency of drug-metabolizing enzymes (also called *pharmacogenomics;* see Chapter 8). (p. 34)

Pharmacognosy The study of drugs that are obtained from natural plant and animal sources. (p. 20)

Pharmacokinetics The study of what happens to a drug from the time it is put into the body until the parent drug and all metabolites have left the body. Pharmacokinetics represent the drug absorption into, distribution and metabolism within, and excretion from the body. (p. 20)

Pharmacology The broadest term for the study or science of drugs. (p. 19)

Pharmacotherapeutics The treatment of pathologic conditions through the use of drugs. (p. 20)

Prodrug An inactive drug dosage form that is converted to an active metabolite by various biochemical reactions once it is inside the body. (p. 27)

Receptor A molecular structure within or on the outer surface of a cell. Receptors bind specific substances (e.g., drug molecules), and one or more corresponding cellular effects (drug actions) occurs as a result of this drug-receptor interaction. (p. 30)

Steady state The physiologic state in which the amount of drug removed via elimination is equal to the amount of drug absorbed with each dose. (p. 29)

Substrates Substances (e.g., drugs or natural biochemicals in the body) on which an enzyme acts. (p. 27)

Synergistic effects Drug interactions in which the effect of a combination of two or more drugs with similar actions is greater than the sum of the individual effects of the same drugs given alone. For example, 1 + 1 is greater than 2 (compare with *additive effects*). (p. 33)

Therapeutic drug monitoring The process of measuring drug levels to identify a patient's drug exposure and to allow adjustment of dosages with the goals of maximizing therapeutic effects and minimizing toxicity. (p. 30)

Therapeutic effect The desired or intended effect of a particular medication. (p. 30)

Therapeutic index The ratio between the toxic and therapeutic concentrations of a drug. (p. 32)

Tolerance Reduced response to a drug after prolonged use. (p. 32)

Toxic The quality of being poisonous (i.e., injurious to health or dangerous to life). (p. 20)

Toxicity The condition of producing adverse bodily effects due to poisonous qualities. (p. 30)

Toxicology The study of poisons, including toxic drug effects, and applicable treatments. (p. 20)

Trade name The commercial name given to a drug product by its manufacturer; also called the *proprietary name.* (p. 19)

Trough level The lowest concentration of drug reached in the body after it falls from its peak level, usually measured in a blood sample for therapeutic drug monitoring. (p. 30)

OVERVIEW

Any chemical that affects the physiologic processes of a living organism can broadly be defined as a **drug.** The study or science of drugs is known as **pharmacology.** Pharmacology encompasses a variety of topics, including the following:

- Absorption
- Biochemical effects
- Biotransformation (metabolism)
- Distribution
- Drug history
- Drug origin
- Excretion
- Mechanisms of action
- Physical and chemical properties
- Physical effects
- Drug receptor mechanisms
- Therapeutic (beneficial) effects
- Toxic (harmful) effects

Pharmacology includes the following several subspecialty areas: *pharmaceutics, pharmacokinetics, pharmacodynamics, pharmacogenomics (pharmacogenetics), pharmacoeconomics, pharmacotherapeutics, pharmacognosy,* and *toxicology.* Knowledge of pharmacology enables the nurse to better understand how drugs affect humans. Without understanding basic pharmacologic principles, the nurse cannot fully appreciate the therapeutic benefits and potential toxicity of drugs.

Throughout the process of its development, a drug will acquire at least three different names. The **chemical name** describes the drug's chemical composition and molecular structure. The generic name, or nonproprietary name, is often much shorter and simpler than the chemical name. The **generic name** is used in most official drug compendiums to list drugs. The **trade name,** or proprietary name, is the drug's registered trademark, and indicates that its commercial use is restricted to the owner of the patent for the drug (Figure 2-1). The patent owner is usually the manufacturer of the drug. Trade names are generally created by the manufacturer with marketability in mind. For this reason, they are usually shorter and easier to pronounce and remember than generic drug names. The *patent life* of a newly discovered drug molecule is normally 17 years. This is the length of time from patent approval until patent expiration. Because the research processes for new drug development normally require about 10 years, a drug manufacturer generally has the remaining 7 years for sales profits before patent expiration. A significant amount of these profits serves to offset the multimillion-dollar costs for research and development of the drug.

After the patent for a given drug expires, other manufacturers may legally begin to manufacture *generic* drugs with the same

Chemical name
(+/−)-2-(p-isobutylphenyl) propionic acid
Generic name
ibuprofen
Trade name
Motrin, others

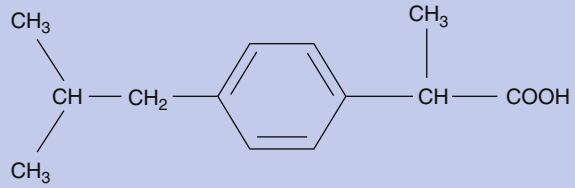

FIGURE 2-1 Chemical structure of the common analgesic ibuprofen and the chemical, generic, and trade names for the drug.

active ingredient. At this point, the drug price usually decreases substantially. Due to the high cost of drugs, many institutions have implemented programs in which one drug in a class of several drugs is chosen as the preferred agent, even though the drugs do not have the same active ingredients. This is called *therapeutic equivalence.* Before one drug can be therapeutically substituted for another, the drugs must have been proven to have the same therapeutic effect in the body.

Drugs are grouped together based on their similar properties. This is known as a **drug classification.** Drugs can be classified by their structure (e.g., beta-adrenergic blockers) or by their therapeutic use (e.g., antibiotics, antihypertensives, antidepressants). Within the broad classification, each class may have subclasses; for example, penicillins are a subclass within the group of antibiotics and beta-adrenergic blockers are a subclass within the group of antihypertensives.

Three basic areas of pharmacology—*pharmaceutics, pharmacokinetics,* and *pharmacodynamics*—describe the relationship between the dose of a drug given to a patient and the activity of that drug in treating the patient's disorder. **Pharmaceutics** is the study of how various dosage forms influence the way in which the drug affects the body. **Pharmacokinetics** is the study of what the body does to the drug. Pharmacokinetics involves the processes of absorption, distribution, metabolism, and excretion. **Pharmacodynamics,** on the other hand, is the study of what the drug does to the body. Pharmacodynamics involves drug-receptor relationships. Figure 2-2 illustrates the three phases of drug activity, starting with the pharmaceutical phase, proceeding to the pharmacokinetic phase, and finishing with the pharmacodynamic phase.

Pharmacotherapeutics (also called therapeutics) focuses on the clinical use of drugs to prevent and treat diseases. It defines the principles of **drug actions**—the cellular processes that change in response to the presence of drug molecules. Some drug mechanisms of action are more clearly understood than others. Drugs are categorized into pharmacologic classes according to their physiologic functions (e.g., beta-adrenergic blockers) and primary disease states treated (e.g., anticonvulsants, antiinfectives). The U.S. Food and Drug Administration (FDA) regulates the approval and clinical use of all drugs in the United States, including the requirement of an expiration date on all drugs. This textbook focuses almost exclusively on current FDA-approved indications for the drugs discussed in each chapter and on drugs that are currently available in the United States at the time of this writing. Only FDA-approved indications are permitted to be described in the manufacturer's

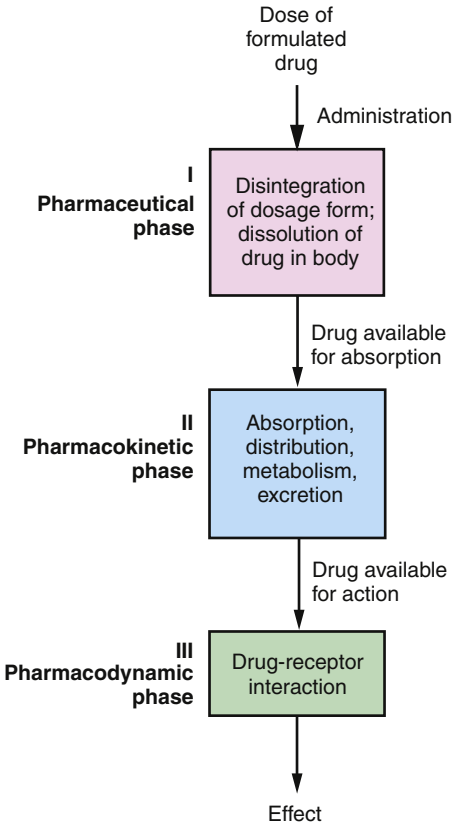

FIGURE 2-2 Phases of drug activity. (From McKenry LM, Tessier E, Hogan M: *Mosby's pharmacology in nursing,* ed 22, St Louis, 2006, Mosby.)

written information, or labeling, for a given drug product. At times, prescribers may elect to use drugs for non–FDA-approved indications. This is known as *off-label prescribing* and often requires seasoned clinical judgment on the part of the prescriber. Evolving over time in clinical practice, previously off-label indications often become FDA-approved indications for a given drug.

The study of the adverse effects of drugs and other chemicals on living systems is known as **toxicology. Toxic** effects are often an extension of a drug's therapeutic action. Therefore, toxicology frequently involves overlapping principles of both pharmacotherapy and toxicology. The study of natural (versus synthetic) drug sources (i.e., plants, animals, minerals) is called **pharmacognosy. Pharmacoeconomics** focuses on the economic aspects of drug therapy.

TABLE 2-1 DRUG ABSORPTION OF VARIOUS ORAL PREPARATIONS

Oral disintegration, buccal tablets, and oral soluble wafers	Fastest
Liquids, elixirs, and syrups	↓
Suspension solutions	↓
Powders	↓
Capsules	↓
Tablets	↓
Coated tablets	↓
Enteric-coated tablets	Slowest

TABLE 2-2 DOSAGE FORMS

ROUTE	FORMS
Enteral	Tablets, capsules, oral soluble wafers, pills, timed-release capsules, timed-release tablets, elixirs, suspensions, syrups, emulsions, solutions, lozenges or troches, rectal suppositories, sublingual or buccal tablets
Parenteral	Injectable forms, solutions, suspensions, emulsions, powders for reconstitution
Topical	Aerosols, ointments, creams, pastes, powders, solutions, foams, gels, transdermal patches, inhalers, rectal and vaginal suppositories

In summary, pharmacology is a very dynamic science that incorporates several different disciplines. Traditionally, chemistry has been seen as the primary basis of pharmacology, but pharmacology also relies heavily on physiology and biology.

PHARMACEUTICS

Different drug dosage forms have different pharmaceutical properties. Dosage form determines the rate at which drug **dissolution** (dissolving of solid dosage forms and their absorption, e.g., from gastrointestinal [GI] tract fluids) occurs. A drug to be ingested orally may be in either a solid form (tablet, capsule, or powder) or a liquid form (solution or suspension). Table 2-1 lists various oral drug preparations and the relative rate at which they are absorbed. Oral drugs that are liquids (e.g., elixirs, syrups) are already dissolved and are usually absorbed more quickly than solid dosage forms. Enteric-coated tablets, on the other hand, have a coating that prevents them from being broken down in the acidic pH environment of the stomach and therefore are not absorbed until they reach the higher (more alkaline) pH of the intestines. This pharmaceutical property results in slower dissolution and therefore slower absorption.

Particle size within a tablet or capsule can make different dosage forms of the same drug dissolve at different rates, become absorbed at different rates, and thus have different times to onset of action. An example is the difference between micronized glyburide and nonmicronized glyburide. Micronized glyburide reaches a maximum concentration peak faster than does the nonmicronized formulation. Dosage form design for injectable drugs tends to be more straightforward than that for oral dosage forms. However, some injections are carefully formulated to reduce drug toxicity (e.g., liposomal amphotericin B).

Combination dosage forms contain multiple drugs in one dose. Examples of these combination forms include the cholesterol and antihypertensive medications atorvastatin/amlodipine tablets called Caduet and bacitracin/neomycin/polymyxin B/hydrocortisone ointment (generic). There are large numbers of such combination dosage forms; key examples are cited in the various chapters of this book.

A variety of dosage forms exist to provide both accurate and convenient drug delivery systems (Table 2-2). These delivery systems are designed to achieve a desired therapeutic response with minimal adverse effects. Many dosage forms have been developed to encourage patient adherence with the medication regimen. Extended-release tablets and capsules release drug molecules in the patient's GI tract over a prolonged period of time. This ultimately prolongs drug absorption as well as duration of action. This is the opposite of immediate-release dosage forms, which release all of the active ingredient immediately upon dissolution in the GI tract. Extended-release dosage forms are normally easily identified by various capital letter abbreviations attached to their names. Examples of this nomenclature are SR (slow release or sustained release), SA (sustained action), CR (controlled release), XL (extended length), and XT (extended time). Convenience of administration correlates strongly with patient adherence, because these forms often require fewer daily doses. Extended-release oral dosage forms must not be crushed, as this could cause accelerated release of drug from the dosage form and possible toxicity. Enteric-coated tablets also are not recommended for crushing. This would cause disruption of the tablet coating designed to protect the stomach lining from the local effects of the drug and/or protect the drug from being prematurely disrupted by stomach acid. The ability to crush a tablet or open a capsule can facilitate drug administration when patients are unable or unwilling to swallow a tablet or capsule and also when medications need to be given through an enteral feeding tube. Capsules, powder, or liquid contents can often be added to soft foods such as applesauce or pudding, or dissolved in a beverage. Granules contained in capsules are usually for extended drug release and normally should not be crushed or chewed by the patient. However, they can often be swallowed when sprinkled on one of the soft foods. Consultation with a pharmacist, reading the product literature, or use of other suitable source is necessary if any question exists as to whether a drug can be crushed or mixed with specific food or beverages.

An increasingly popular dosage form is drug products that dissolve in the mouth and are absorbed through the oral mucosa. These include orally disintegrating tablets as well as thin wafers that also dissolve in the mouth. Depending on the specific drug product, the dosage form may dissolve on the tongue, under the tongue, or in the buccal (cheek) pocket.

The specific characteristics of various dosage forms have a large impact on how and to what extent the drug is absorbed. For a drug to work at a specific site in the body, either it must be applied directly at the site in an active form or it must have a way of getting to that site. Oral dosage forms rely on gastric and intestinal enzymes and pH environments to break

the medication down into particles that are small enough to be absorbed into the circulation. Once absorbed through the mucosa of the stomach or intestines, the drug is then transported to the site of action by blood or lymph.

Many topically applied dosage forms work directly on the surface of the skin. Once the drug is applied, it is already in a form that allows it to act immediately. However, with other topical dosage forms, the skin acts as a barrier through which the drug must pass to get into the circulation; once there, the drug is then carried to its site of action (e.g., fentanyl transdermal patch for pain).

Dosage forms that are administered via injection are called *parenteral* forms. They must have certain characteristics to be safe and effective. The arteries and veins that carry drugs throughout the body can easily be damaged if the drug is too concentrated or corrosive. The pH of injections must be very similar to that of the blood for these drugs to be administered safely. Parenteral dosage forms that are injected intravenously are immediately placed into solution in the bloodstream and do not have to be dissolved in the body. Therefore, 100% absorption is assumed to occur immediately upon intravenous injection.

PHARMACOKINETICS

A drug's time to onset of action, time to peak effect, and duration of action are all characteristics defined by pharmacokinetics. Pharmacokinetics is the study of what happens to a drug from the time it is put into the body until the **parent drug** and all metabolites have left the body. Thus, drug absorption into, distribution and metabolism within, and excretion from the body represent the combined focus of pharmacokinetics.

Absorption

Absorption is the movement of a drug from its site of administration into the bloodstream for distribution to the tissues. **Bioavailability** is the term used to express the extent of drug absorption. For example, a drug that is absorbed from the intestine must first pass through the liver before it reaches the systemic circulation. If a large proportion of a drug is chemically changed into inactive metabolites in the liver, then a much smaller amount of drug will pass into the circulation (i.e., will be bioavailable). Such a drug is said to have a high **first-pass effect** (e.g., oral nitrates). First-pass effect reduces the bioavailability of the drug to less than 100%. Many drugs administered by mouth have a bioavailability of less than 100%, whereas drugs administered by the intravenous route are 100% bioavailable. If two medications have the same bioavailability and same concentration of active ingredient, they are said to be bioequivalent (e.g., a brand-name drug and the same generic drug).

Various factors affect the rate of drug absorption. How a drug is administered, or its route of administration, affects the rate and extent of absorption of that drug. Although a number of dosage formulations are available for delivering medications, they can all be categorized into three basic routes of administration: enteral (GI tract), parenteral, and topical.

CASE STUDY

Pharmacokinetics

Four patients with angina are receiving a form of nitroglycerin, as follows:

Mrs. A., age 88, takes 9 mg twice a day to prevent angina.

Mr. B., age 63, takes a form that delivers 0.2 mg/hr, also to prevent angina.

Mrs. C., age 58, takes 0.4 mg only if needed for chest pain.

Mr. D., age 62, is in the hospital with severe, unstable angina and is receiving 20 mcg/hr.

You may refer to the section on nitroglycerin in Chapter 23 or to a nursing drug handbook to answer these questions.

1. State the route or form of nitroglycerin that each patient is receiving. In addition, specify the trade name(s) for each particular form.
2. For each patient, state the rationale for the route or form of drug that was chosen. Which forms have immediate action? Why would this be important?
3. Which form or forms are most affected by the first-pass effect? Explain your answer.
4. What would happen if Mrs. A. chewed her nitroglycerin dose? If Mrs. C chewed her nitroglycerin dose?

For answers, see http://evolve.elsevier.com/Lilley.

Enteral Route

In enteral drug administration, the drug is absorbed into the systemic circulation through the mucosa of the stomach and/or small or large intestine. The rate of absorption can be altered by many factors. Orally administered drugs are absorbed from the intestinal lumen into the blood system and transported to the liver. Once the drug is in the liver, hepatic enzyme systems metabolize it, and the remaining active ingredients are passed into the general circulation. Many factors can alter the absorption of drugs, including acid changes within the stomach, absorption changes in the intestines, and the presence or absence of food and fluid. Various factors that affect the acidity of the stomach include the time of day; the age of the patient; and the presence and types of medications (e.g., H_2 blockers or proton pump inhibitors [see Chapter 50]), foods, or beverages. Enteric-coating is designed to protect the stomach by having drug dissolution and absorption occur in the intestines. Taking an enteric-coated medication with a large amount food may cause it to be dissolved by acidic stomach contents and thus reduce intestinal drug absorption and negate the coating's stomach-protective properties. Anticholinergic drugs slow GI transit time (or the time it takes for substances in the stomach to be dissolved for eventual transport to and absorption from the intestines). This may reduce the amount of drug absorption and therapeutic effect for acid-susceptible drugs that become broken down by stomach acids. The presence of food may enhance the absorption of some fat-soluble drugs or of drugs that are more easily broken down in an acidic environment.

Drug absorption may also be altered in patients who have had portions of the small intestine removed because of disease. This is known as *short bowel syndrome.* Similarly, bariatric weight loss surgery reduces the size of the stomach. As a result, medication

BOX 2-1 DRUGS TO BE TAKEN ON AN EMPTY STOMACH AND DRUGS TO BE TAKEN WITH FOOD

Many medications are taken on an empty stomach with at least 6 oz of water. The nurse must give patients specific instructions regarding those medications that are not to be taken with food. Examples include alendronate sodium and risedronate sodium.

Medications that are generally taken with food include carbamazepine, iron and iron-containing products, hydralazine, lithium, propranolol, spironolactone, nonsteroidal antiinflammatory drugs, and theophylline.

Macrolides and oral opioids are often taken with food (even though they are specified to be taken with a full glass of water and on an empty stomach) to minimize the gastrointestinal irritation associated with these drugs. If doubt exists, consult a licensed pharmacist or a current authoritative drug resource. An Internet source to use is http://www.usp.org.

absorption can be altered, because stomach contents are delivered to the intestines more rapidly than usual after such surgery. This is called *gastric dumping*. Examples of drugs to be taken on an empty stomach and those to be taken with food are provided in Box 2-1. The stomach and small intestine are highly vascularized. When blood flow to this area is decreased, absorption may also be decreased. Sepsis and exercise are examples of circumstances under which blood flow to the GI tract is often reduced. In both cases, blood tends to be routed to the heart and other vital organs. In the case of exercise, it is also routed to the skeletal muscles.

Rectally administered drugs are often given for systemic effects (e.g., antinausea, analgesia, antipyretic effects), but they are also used to treat disease within the rectum or adjacent bowel (e.g., antiinflammatory ointment for hemorrhoids, corticosteroid enemas for colitis). In the latter case, rectal administration may also be thought of as a *topical* route of drug administration.

Sublingual and Buccal Routes. Drugs administered by the *sublingual* route are absorbed into the highly vascularized tissue under the tongue—the oral mucosa. Sublingual nitroglycerin is an example. Sublingually administered drugs are absorbed rapidly because the area under the tongue has a large blood supply. These drugs bypass the liver and yet are systemically bioavailable. The same applies for drugs administered by the *buccal route* (the oral mucosa between the cheek and the gum). Through these routes, drugs such as nitroglycerin are absorbed rapidly into the bloodstream and delivered to their site of action (e.g., coronary arteries).

Parenteral Route

The parenteral route is the fastest route by which a drug can be absorbed, followed by the enteral and topical routes. *Parenteral* is a general term meaning any route of administration other than the GI tract. It most commonly refers to injection. Intravenous injection delivers the drug directly into the circulation, where it is distributed with the blood throughout the body. Drugs given by intramuscular injection and subcutaneous injection are absorbed more slowly than those given intravenously. These drug formulations are usually absorbed over a period of several hours; however, some are specially formulated to be released over days, weeks, or months.

Drugs can be injected intradermally, subcutaneously, *intraarterially*, intramuscularly, *intrathecally*, intraarticularly, or intravenously. Physicians, or advanced practice nurses, usually give **intraarterial**, **intrathecal**, or **intraarticular** injections. Medications given by the parenteral route have the advantage of bypassing the first-pass effect of the liver. Parenteral administration offers an alternative route of delivery for medications that cannot be given orally and poses fewer obstacles to absorption. However, drugs that are administered by the parenteral route must still be absorbed into cells and tissues before they can exert their pharmacologic effect (Table 2-3).

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Does IV = PO?

The prescriber writes an order for "Lasix 80 mg IV STAT × 1 dose" for a patient who is short of breath with pulmonary edema. When the nurse goes to give the drug, only the PO form is immediately available. Someone must go to the pharmacy to pick up the IV dose. Another nurse says, "Go ahead and give the pill. He needs it fast. It's all the same!" But is it?

Remember, the oral forms of medications must be processed through the gastrointestinal tract, absorbed through the small intestines, and undergo the first-pass effect in the liver before the drug can reach the intended site of action. However, IV forms are injected directly into the circulation and can act almost immediately because the first-pass effect is bypassed. The time until onset of action for the PO form is 30 to 60 minutes; for the IV form, this time is *5 minutes*. This patient is in respiratory distress, and the immediate effect of the diuretic is desired. In addition, because of the first-pass effect, the available amount of orally administered drug that actually reaches the site of action would be less than the available amount of intravenously administered drug. Therefore, IV does NOT equal PO! Never change the route of administration of a medication; if questions come up, always check with the prescriber.

Subcutaneous, Intradermal, and Intramuscular Routes. Injections into the fatty subcutaneous tissues under the dermal layer of skin are referred to as *subcutaneous* injections. Injections under the more superficial skin layers immediately underneath the epidermal layer of skin and into the dermal layer are known as *intradermal* injections. Injections given into the muscle beneath the subcutaneous fatty tissue are referred to as *intramuscular* injections. Muscles have a greater blood supply than does the skin; therefore, drugs injected intramuscularly are typically absorbed faster than drugs injected subcutaneously. Absorption from either of these sites may be increased by applying heat to the injection site or by massaging the site. Both methods increase blood flow to the area, thereby enhancing drug absorption. In contrast, the presence of cold, hypotension, or poor peripheral blood flow compromises the circulation, reducing drug activity by reducing drug delivery to the tissues. Most intramuscularly injected drugs are absorbed over several hours. However, specially formulated long-acting intramuscular dosage forms called *depot drugs* have been designed for slow absorption over a period of several days to a few months or longer. The intramuscular corticosteroid known as *methylprednisolone acetate* can provide antiinflammatory effects for several weeks. The intramuscular contraceptive medroxyprogesterone acetate normally prevents pregnancy for 3 months per dose.

TABLE 2-3 ROUTES OF ADMINISTRATION AND RELATED NURSING CONSIDERATIONS

ROUTE	ADVANTAGES	DISADVANTAGES	NURSING CONSIDERATIONS
Intravenous (IV)	Provides rapid onset (drug delivered immediately to bloodstream); allows more direct control of drug level in blood; gives option of larger fluid volume, therefore diluting irritating drugs; avoids first-pass metabolism	Higher cost; inconvenience (e.g., not self-administered); irreversibility of drug action in most cases and inability to retrieve medication; risk of fluid overload; greater likelihood of infection; possibility of embolism	Continuous intravenous infusions require frequent monitoring to be sure that the correct volume and amount are administered and that the drug reaches safe, therapeutic blood levels. Intravenous drugs and solutions must be checked for compatibilities. Intravenous sites are to be monitored for redness, swelling, heat, and drainage—all indicative of complications, such as thrombophlebitis. If intermittent intravenous infusions are used, clearing or flushing of the line with normal saline before and after is generally indicated to keep the intravenous site patent and minimize incompatibilities.
Intramuscular (IM); subcutaneous	Intramuscular injections are good for poorly soluble drugs, which are often given in "depot" preparation form and are then absorbed over a prolonged period; onsets of action differ depending on route.	Discomfort of injection; inconvenience; bruising; slower onset of action compared to intravenous, although quicker than oral in most situations	Using landmarks to identify correct intramuscular and subcutaneous sites is always required and recommended as a nursing standard of care. For adults, the intramuscular site of choice is the ventral gluteal muscle with use of a 1½-inch (sometimes 1-inch in very thin or emaciated patients) and 20- to 25-gauge needle for aqueous solutions and 18- to 25-gauge needle for viscous or oil-based solutions. Subcutaneous injections are recommended to be given at a 90-degree angle with a proper size syringe and needle (½- to ⅝-inch); in emaciated or very thin patients, the subcutaneous angle is at 45 degrees. Subcutaneous injections require a 26- to 30-gauge, ½-inch needle inserted at a 90-degree angle. Selection of correct size of syringe and needle is key to safe administration by these routes and is based on thorough assessment of the patient as well as the characteristics of the drug.
Oral	Usually easier, more convenient, and less expensive; safer than injection, dosing more likely to be reversible in cases of accidental ingestion (e.g., through induction of emesis, administration of activated charcoal)	Variable absorption; inactivation of some drugs by stomach acid and/or pH; problems with first-pass effect or presystemic metabolism; greater dependence of drug action on patient variables	Enteral routes include oral administration and involve a variety of dosage forms (e.g., liquids, solutions, tablets, and enteric-coated pills or tablets). Some medications are recommended to be taken with food, while others are recommended not to be taken with food; it is also suggested that oral dosage forms of drugs be taken with at least 6 to 8 oz of fluid, such as water. Other factors to consider include other medicines being taken at the same time and concurrent use of dairy products or antacids. If oral forms are given via nasogastric tube or gastrostomy tube, tube placement in stomach must be assessed prior to giving the medication and the patient's head is to remain elevated; flushing the nasogastric tube with at least 30 to 60 mL of water before and after the drug has been given is recommended to help maintain tube patency and prevent clogging.
Sublingual, buccal (subtypes of oral, but more parenteral than enteral)	Absorbed more rapidly from oral mucosa and leads to more rapid onset of action; avoids breakdown of drug by stomach acid; avoids first-pass metabolism because gastric absorption is bypassed	Patients may swallow pill instead of keeping under tongue until dissolved; pills often smaller to handle	Drugs given via the sublingual route are to be placed under the tongue; once dissolved, the drug may be swallowed. When using the buccal route, medication is placed between the cheek and gum. Both of these dosage forms are relatively nonirritating; the drug usually is without flavor and water-soluble.
Rectal	Provides relatively rapid absorption; good alternative when oral route not feasible; useful for local or systemic drug delivery; usually leads to mixed first-pass and non–first-pass metabolism	Possible discomfort and embarrassment to patient; often higher cost than oral route	Absorption via this route is erratic and unpredictable, but it provides a safe alternative when nausea or vomiting prevents oral dosing of drugs. The patient must be placed on his or her left side so that the normal anatomy of the colon allows safe and effective insertion of the rectal dosage form. Suppositories are inserted using a gloved hand and/or gloved index finger and water-soluble lubricant. Drug must be administered exactly as ordered.
Topical	Delivers medication directly to affected area; decreases likelihood of systemic drug effects	Sometimes awkward to self-administer (e.g., eyedrops); can be messy; usually higher cost than oral route	Most dermatologic drugs are given via topical route in form of a solution, ointment, spray, or drops. Maximal absorption of topical drugs is enhanced with skin that is clean and free of debris; if measurement of ointment is necessary—such as with topical nitroglycerin—application must be done carefully and per instructions (e.g., apply 1 inch of ointment). Gloves help minimize cross-contamination and prevent absorption of drug into the nurse's own skin. If the patient's skin is not intact, sterile technique is needed.

TABLE 2-3 ROUTES OF ADMINISTRATION AND RELATED NURSING CONSIDERATIONS—cont'd

ROUTE	ADVANTAGES	DISADVANTAGES	NURSING CONSIDERATIONS
Transdermal (subtype of topical)	Provides relatively constant rate of drug absorption; one patch can last 1 to 7 days, depending on drug; avoids first-pass metabolism	Rate of absorption can be affected by excessive perspiration and body temperature; patch may peel off; cost is higher; used patches must be disposed of safely	Transdermal drugs should be placed on alternating sites and on a clean, nonhairy, nonirritated area, and only after the previously applied patch has been removed and that area cleansed and dried. Transdermal drugs generally come in a single-dose, adhesive-backed drug application system.
Inhalational	Provides rapid absorption; drug delivered directly to lung tissues where most of these drugs exert their actions	Rate of absorption can be too rapid, increasing the risk of exaggerated drug effects; requires more patient education for self-administration; some patients may have difficulty with administration technique	Inhaled medications are to be used exactly as prescribed and with clean equipment. Instructions need to be given to the patient/family/caregiver regarding medications to be used as well as the proper use, storage, and safe-keeping of inhalers, spacers, and nebulizers. Chapter 9 describes and shows how medications are inhaled.

NOTE: For more information on avoiding the use of abbreviations associated with dosage routes, dosage amounts, dosage frequency, and drug names, as well as the use of symbols, please visit www.ismp.org.

Topical Route

The topical route of drug administration involves application of medications to various body surfaces. Several topical drug delivery systems exist. Topically administered drugs can be applied to the skin, eyes, ears, nose, lungs, rectum, or vagina. Topical application delivers a uniform amount of drug over a longer period, but the effects of the drug are usually slower in their onset and more prolonged in their duration of action as compared to oral or parenteral administration. This can be a problem if the patient begins to experience adverse effects from the drug and a considerable amount of drug has already been absorbed. All topical routes of drug administration avoid first-pass effects of the liver, with the exception of rectal administration. Because the rectum is part of the GI tract, some drug will be absorbed into the capillaries that feed the portal vein to the liver. However, some drugs will also be absorbed locally into perirectal tissues. Therefore, rectally administered drugs are said to have a mixed first-pass and non–first-pass absorption and metabolism. Box 2-2 lists the various drug routes and indicates whether they are associated with first-pass effects in the liver.

Ointments, gels, and creams are common types of topically administered drugs. Examples include sunscreens, antibiotics, and nitroglycerin ointment. The drawback to their use is that their systemic absorption is often erratic and unreliable. Generally, these medications are used for local effects, but some are used for systemic effects (e.g., nitroglycerin ointment for maintenance treatment of angina). Topically applied drugs can also be used in the treatment of various illnesses of the eyes, ears, and sinuses. Eye, ear, and nose drops are administered primarily for local effects, whereas nasal sprays may be used for both systemic and local effects (e.g., oxymetazoline for nasal sinus congestion, sumatriptan for migraine headaches). Vaginal medications may also be given for systemic effects (e.g., progestational hormone therapy with progesterone vaginal suppositories) but are more commonly used for local effects (e.g., treatment of vaginal yeast infection with miconazole [Monistat] vaginal cream).

BOX 2-2 DRUG ROUTES AND FIRST-PASS EFFECTS

First-Pass Routes	Non–First-Pass Routes
Hepatic arterial	Aural (instilled into the ear)
Oral	Buccal
Portal venous	Inhaled
Rectal*	Intraarterial
	Intramuscular
	Intranasal
	Intraocular
	Intravaginal
	Intravenous
	Subcutaneous
	Sublingual
	Transdermal

*Leads to both first-pass and non–first-pass effects.

Transdermal Route. Transdermal drug delivery through adhesive patches is an elaborate topical route of drug administration that is commonly used for systemic drug effects. Some examples of drugs administered by this route are fentanyl (for pain), nitroglycerin (for angina), nicotine (for smoking cessation), estrogen (for menopausal symptoms), and clonidine (for hypertension). Transdermal patches are usually designed to deliver a constant amount of drug per unit of time for a specified time period. For example, a nitroglycerin patch may deliver 0.1 or 0.2 mg/hr over 24 hours, whereas a fentanyl patch may deliver 25 to 100 mcg/hr over a 72-hour period. This route is suitable for patients who cannot tolerate oral administration and provides a practical and convenient method for drug delivery.

Inhaled Route. Inhalation is another type of topical drug administration. Inhaled drugs are delivered to the lungs as micrometer-sized drug particles. This small drug size is necessary for the drug to be transported to the small air sacs within the lungs (alveoli). Once the small particles of drug are in the alveoli, drug absorption is fairly rapid. Many pulmonary and

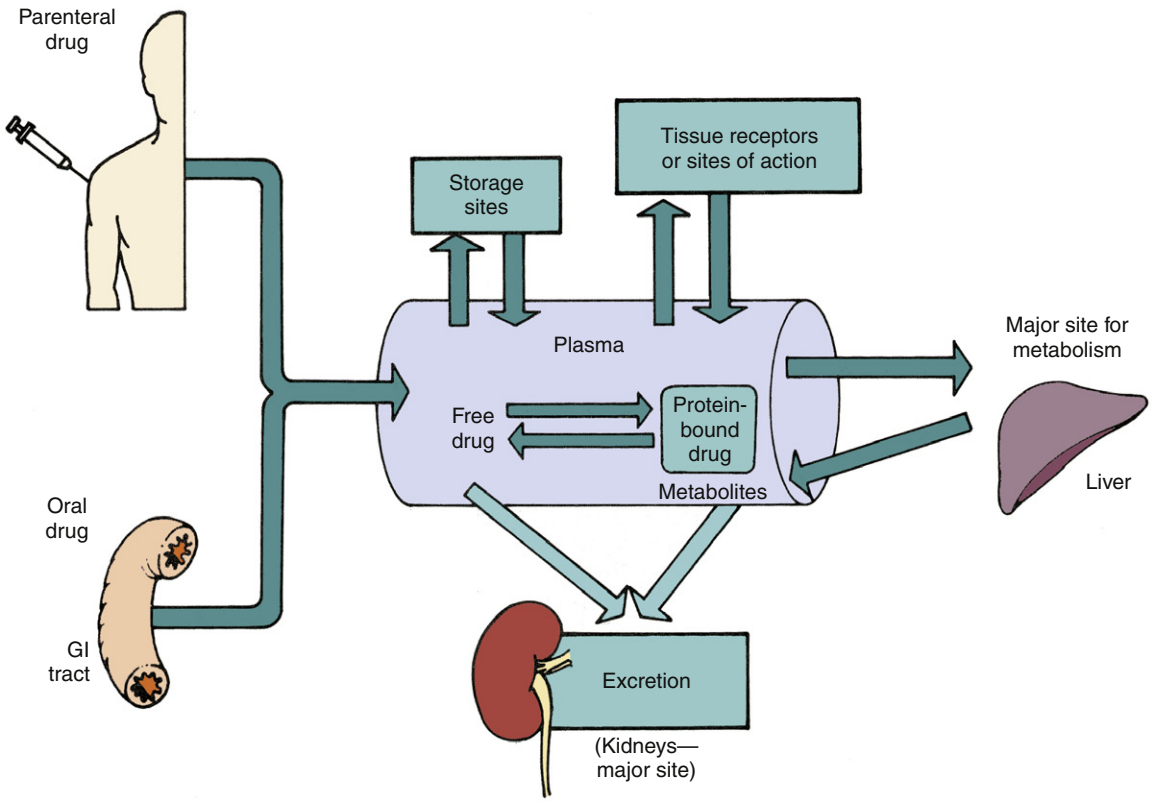

FIGURE 2-3 Drug transport in the body. *GI,* Gastrointestinal. (From McKenry LM, Salerno E: *Mosby's pharmacology in nursing,* ed 19, St Louis, 1995, Mosby.)

other types of diseases can be treated with such topically applied (inhaled) drugs. Examples of inhaled drugs are albuterol, which is used to treat bronchial constriction in individuals with asthma, and fluticasone, which is used for antiinflammatory purposes in patients with asthma and allergies.

Distribution

Distribution refers to the transport of a drug by the bloodstream to its site of action (Figure 2-3). Drugs are distributed first to those areas with extensive blood supply. Areas of rapid distribution include the heart, liver, kidneys, and brain. Areas of slower distribution include muscle, skin, and fat. Once a drug enters the bloodstream (circulation), it is distributed throughout the body. At this point, it is also starting to be eliminated by the organs that metabolize and excrete drugs—primarily the liver and the kidneys. Only drug molecules that are not bound to plasma proteins can freely distribute to *extravascular* tissue (outside the blood vessels) to reach their site of action. If a drug is bound to plasma proteins, the drug-protein complex is generally too large to pass through the walls of blood capillaries into tissues (Figure 2-4). Albumin is the most common blood protein and carries the majority of protein-bound drug molecules. If a given drug binds to albumin, then there is only a limited amount of drug that is *not* bound. This unbound portion is pharmacologically active and is considered "free" drug, whereas "bound" drug is pharmacologically inactive. Certain conditions that cause low albumin levels, such as extensive burns and malnourished states, result in a

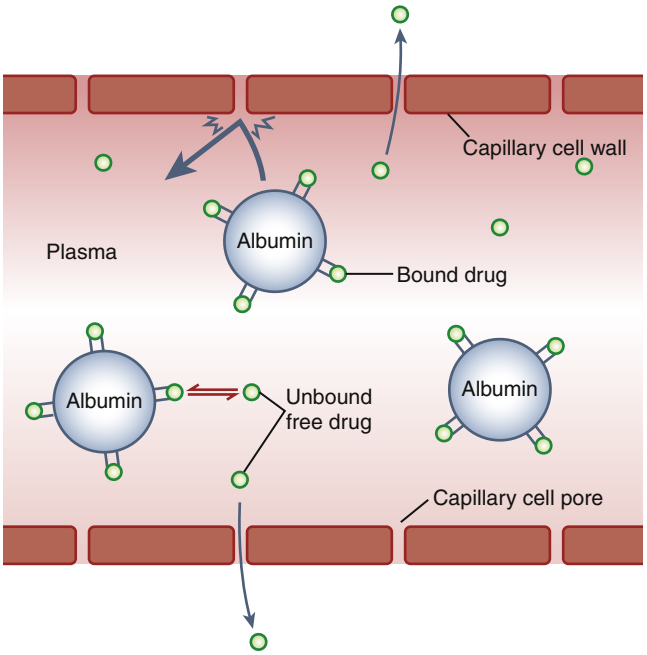

FIGURE 2-4 Protein binding of drugs. Albumin is the most prevalent protein in plasma and the most important of the proteins to which drugs bind. Only unbound (free) drug molecules can leave the vascular system. Bound molecules are too large to fit through the pores in the capillary wall.

larger fraction of free (unbound and active) drug. This can raise the risk of drug toxicity.

When an individual is taking two medications that are highly protein bound, the medications may compete for binding sites on the albumin molecule. Because of this competition, there is more free, unbound drug. This can lead to an unpredictable drug response called a *drug-drug interaction.* A drug-drug interaction occurs when the presence of one drug decreases or increases the actions of another drug that is administered concurrently (i.e., given at the same time).

A theoretical volume, called the *volume of distribution,* is sometimes used to describe the various areas in which drugs may be distributed. These areas, or *compartments,* may be the blood *(intravascular space),* total body water, body fat, or other body tissues and organs. Typically a drug that is highly water-soluble (hydrophilic) will have a smaller volume of distribution and high blood concentrations. In contrast, fat-soluble drugs (lipophilic) have a larger volume of distribution and low blood concentrations. There are some sites in the body into which it may be very difficult to distribute a drug. These sites typically either have a poor blood supply (e.g., bone) or have physiologic barriers that make it difficult for drugs to pass through (e.g., the brain due to the **blood-brain barrier**).

Metabolism

Metabolism is also referred to as **biotransformation.** It involves the biochemical alteration of a drug into an inactive metabolite, a more soluble compound, a more potent active metabolite (as in the conversion of an inactive **prodrug** to its active form), or a less active metabolite. Metabolism is the next step after absorption and distribution. The organ most responsible for the metabolism of drugs is the liver. Other metabolic tissues include skeletal muscle, kidneys, lungs, plasma, and intestinal mucosa.

Hepatic metabolism involves the activity of a very large class of enzymes known as **cytochrome P-450** enzymes (or simply P-450 enzymes), also known as *microsomal* enzymes. These enzymes control a variety of reactions that aid in the metabolism of medications. They are largely targeted at lipid-soluble (*nonpolar* [no charge]) drugs (also known as *lipophilic* ["fat loving"]), which are typically very difficult to eliminate. These include the majority of medications. Those medications with water-soluble (polar or *hydrophilic* ["water loving"]) molecules may be more easily metabolized by simpler chemical reactions such as hydrolysis. Some of the chemical reactions by which the liver can metabolize drugs are listed in Table 2-4. Drug molecules that are the metabolic targets of specific enzymes are said to be **substrates** for those enzymes. Specific P-450 enzymes are identified by standardized number and letter designations. Some of the most common P-450 enzymes and their corresponding drug substrates are listed in Table 2-5. The P-450 system is one of the most important systems that influence drug-drug interactions. The list of drugs that are metabolized by the P-450 enzyme system is constantly changing as new drugs are introduced into the market. For further information, see websites such as http://www.medicine.iupui.edu/flockhart/table.htm and http://www.nursinglink.com/training/articles/320-clinically-significant-drug-interaction-with-the-cytochrome-p450-enzyme-system.

TABLE 2-4 MECHANISMS OF BIOTRANSFORMATION

TYPE OF BIOTRANSFORMATION	MECHANISM	RESULT
Oxidation Reduction Hydrolysis	Chemical reactions	Increase polarity of chemical, making it more water-soluble and more easily excreted. This often results in a loss of pharmacologic activity.
Conjugation (e.g., glucuronidation, glycination, sulfation, methylation, alkylation)	Combination with another substance (e.g., glucuronide, glycine, sulfate, methyl groups, alkyl groups)	Forms a less toxic product with less activity.

TABLE 2-5 COMMON LIVER CYTOCHROME P-450 ENZYMES AND CORRESPONDING DRUG SUBSTRATES

ENZYME	COMMON DRUG SUBSTRATES
1A2	acetaminophen, caffeine, theophylline, warfarin
2C9	ibuprofen, phenytoin
2C19	diazepam, naproxen, omeprazole, propranolol
2D6	codeine, fluoxetine, hydrocodone, metoprolol, oxycodone, paroxetine, risperidone, tricyclic antidepressants
2E1	acetaminophen, ethanol
3A4	acetaminophen, amiodarone, cyclosporine, diltiazem, ethinyl estradiol, indinavir, lidocaine, macrolides, progesterone, spironolactone, sulfamethoxazole, testosterone, verapamil

The biotransformation capabilities of the liver can vary considerably from patient to patient. The various factors that can alter the biotransformation include genetics, diseases, and the concurrent use of other medications (Table 2-6).

Many drugs can inhibit drug-metabolizing enzymes and are called *enzyme inhibitors.* Decreases or delays in drug metabolism result in the accumulation of the drug and prolongation of the effects of the drug, which can lead to drug toxicity. In contrast, some drugs can stimulate drug metabolism and are called *enzyme inducers.* This can cause decreased pharmacologic effects. This often occurs with the repeated administration of certain drugs that stimulate the formation of new microsomal enzymes.

Excretion

Excretion is the elimination of drugs from the body. Whether they are parent compounds or active or inactive metabolites, all drugs must eventually be removed from the body. The primary organ responsible for this elimination is the kidney. Two other organs that play an important role in the excretion of drugs are the liver and the bowel. Most drugs are metabolized in the liver by various mechanisms. Therefore, by the time most drugs

TABLE 2-6 EXAMPLES OF CONDITIONS AND DRUGS THAT AFFECT DRUG METABOLISM

		DRUG METABOLISM	
CATEGORY	EXAMPLE	INCREASED	DECREASED
Diseases	Cardiovascular dysfunction		X
	Renal insufficiency		X
Conditions	Starvation		X
	Obstructive jaundice		X
	Genetic constitution		
	Fast acetylator	X	
	Slow acetylator		X
Drugs	Barbiturates	X	
	rifampin (P-450 inducer)	X	
	phenytoin (P-450 inducer)	X	
	ketoconazole (P-450 inhibitor)		X

reach the kidneys, they have undergone extensive biotransformation, and only a relatively small fraction of the original drug is excreted as the original compound. Other drugs may bypass hepatic metabolism and reach the kidneys in their original form. Drugs that have been metabolized by the liver become more polar and water-soluble. This makes their elimination by the kidneys much easier, because the urinary tract is water-based. The kidneys themselves are also capable of metabolizing various drugs, although usually to a lesser extent than the liver.

The actual act of renal excretion is accomplished through *glomerular filtration, active tubular reabsorption,* and *active tubular secretion.* Free (unbound) water-soluble drugs and metabolites go through passive glomerular filtration. Many substances present in the nephrons go through active reabsorption and are taken back up into the systemic circulation and transported away from the kidney. This process is an attempt by the body to retain needed substances. Some substances may also be secreted into the nephron from the vasculature surrounding it. The processes of filtration, reabsorption, and secretion for urinary elimination are shown in Figure 2-5.

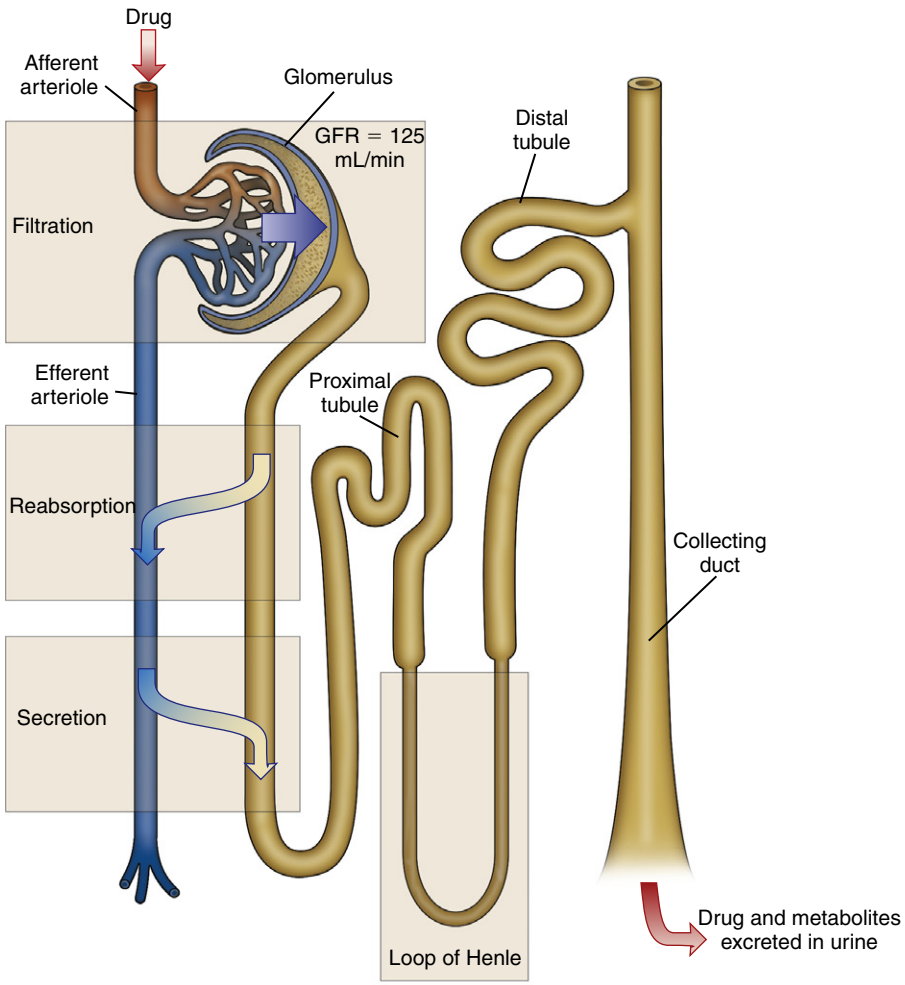

FIGURE 2-5 Renal drug excretion. The primary processes involved in drug excretion and the approximate location where these processes take place in the kidney are illustrated. *GFR,* Glomerular filtration rate.

The excretion of drugs by the intestines is another route of elimination. This process is referred to as *biliary excretion.* Drugs that are eliminated by this route are taken up by the liver, released into the bile, and eliminated in the feces. Once certain drugs, such as fat-soluble drugs, are in the bile, they may be reabsorbed into the bloodstream, returned to the liver, and again secreted into the bile. This process is called *enterohepatic recirculation.* Enterohepatically recirculated drugs persist in the body for much longer periods. Less common routes of elimination are the lungs and the sweat, salivary, and mammary glands.

Half-Life

Another pharmacokinetic variable is the **half-life** of the drug. By definition, the half-life is the time required for one-half (50%) of a given drug to be removed from the body. It is a measure of the rate at which the drug is eliminated from the body. For instance, if the peak level of a particular drug is 100 mg/L and the measured drug level is 50 mg/L in 8 hours, then the estimated half-life of that drug is 8 hours. The concept of drug half-life viewed from several different perspectives is shown in Table 2-7.

TABLE 2-7 EXAMPLE OF DRUG HALF-LIFE VIEWED FROM DIFFERENT PERSPECTIVES

METRIC	CHANGING VALUES					
Hours after peak concentration	0	8	16	24	32	40
Drug concentration (mg/L)	100 (peak)	50	25	12.5	6.25	3.125 (trough)
Number of half-lives	0	1	2	3	4	5
Percentage of drug removed	0	50	75	88	94	97

After about five half-lives, most drugs are considered to be effectively removed from the body. At that time approximately 97% of the drug has been eliminated, and what little amount remains is usually too small to have either therapeutic or toxic effects.

The concept of half-life is clinically useful for determining when steady state will be reached in a patient taking a particular drug. **Steady state** refers to the physiologic state in which the amount of drug removed via elimination (e.g., renal clearance) is equal to the amount of drug absorbed with each dose. This physiologic plateau phenomenon typically occurs after four to five half-lives of administered drug. Therefore, if a drug has an extremely long half-life, it will take much longer for the drug to reach steady-state blood levels. Once steady-state blood levels have been reached, there are consistent levels of drug in the body that correlate with maximum therapeutic benefits.

Onset, Peak, and Duration

The pharmacokinetic terms *absorption, distribution, metabolism,* and *excretion* are all used to describe the movement of drugs through the body. Drug actions are the processes involved in the interaction between a drug and a cell (e.g., a drug's action on a receptor). In contrast, **drug effects** are the physiologic reactions of the body to the drug. The terms *onset, peak, duration,* and *trough* are used to describe drug effects. *Peak* and *trough* are also used to describe drug concentrations, which are usually measured from blood samples.

A drug's **onset of action** is the time required for the drug to elicit a therapeutic response. A drug's **peak effect** is the time required for a drug to reach its maximum therapeutic response. Physiologically, this corresponds to increasing drug concentrations at the site of action. The **duration of action** of a drug is the length of time that the drug concentration is sufficient (without more doses) to elicit a therapeutic response. These concepts are illustrated in Figure 2-6.

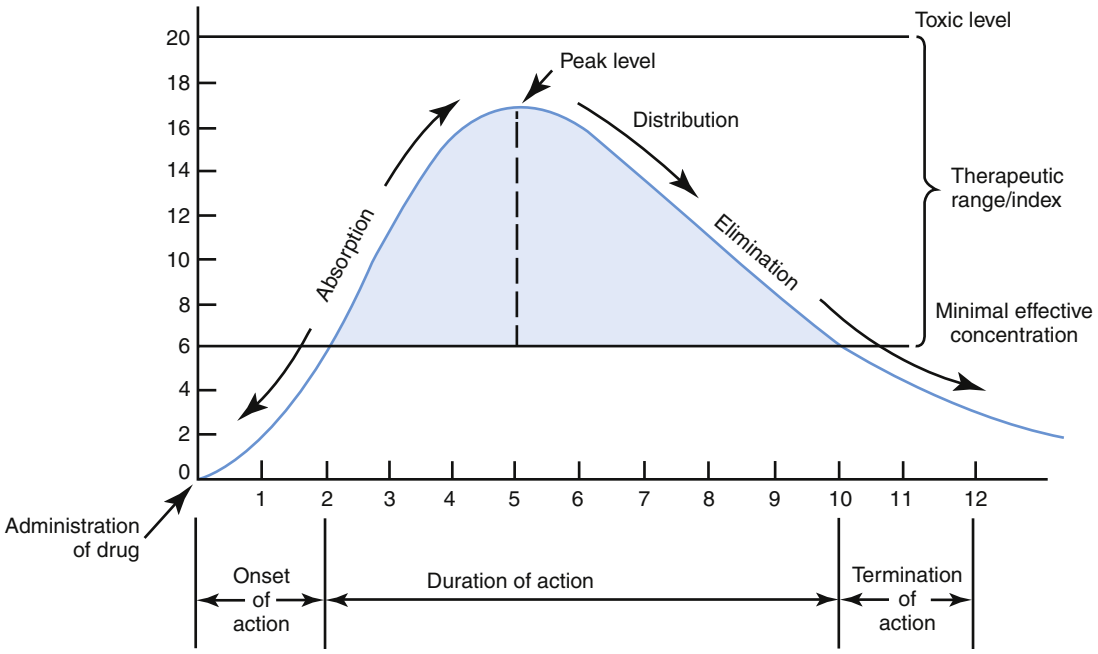

FIGURE 2-6 Characteristics of drug effect and relationship to the therapeutic window. (From McKenry LM, Tessier E, Hogan M: *Mosby's pharmacology in nursing,* ed 22, St Louis, 2006, Mosby.)

The length of time until the onset and peak of action and the duration of action play an important part in determining the **peak level** (highest blood level) and **trough level** (lowest blood level) of a drug. If the peak blood level is too high, then drug **toxicity** may occur. The toxicity may be mild, such as intensification of the effects of the given drug (e.g., excessive sedation resulting from overdose of a drug with sedative properties). However, it can also be severe (e.g., damage to vital organs due to excessive drug exposure). If the trough blood level is too low, then the drug may not be at therapeutic levels to produce a response. (A common example is antibiotic drug therapy with aminoglycoside antibiotics [see Chapter 39]). In **therapeutic drug monitoring,** peak (highest) and trough (lowest) values are measured to verify adequate drug exposure, maximize therapeutic effects, and minimize drug toxicity. This monitoring is often carried out by a clinical pharmacist working with other members of the health care team.

PHARMACODYNAMICS

Pharmacodynamics is concerned with the mechanisms of drug action in living tissues. Drug-induced changes in normal physiologic functions are explained by the principles of pharmacodynamics. A positive change in a faulty physiologic system is called a **therapeutic effect** of a drug. Such an effect is the goal of drug therapy. Understanding the pharmacodynamic characteristics of a drug can aid in assessing the drug's therapeutic effect.

Mechanism of Action

Drugs can produce actions (therapeutic effects) in several ways. The effects of a particular drug depend on the characteristics of the cells or tissue targeted by the drug. Once the drug is at the site of action, it can modify (increase or decrease) the rate at which that cell or tissue functions, or it can modify the strength of function of that cell or tissue. A drug cannot, however, cause a cell or tissue to perform a function that is not part of its natural physiology.

Drugs can exert their actions in three basic ways: through receptors, enzymes, and *nonselective interactions.* It should also be noted that not all mechanisms of action have been identified for all drugs. Thus, a drug may be said to have an unknown or unclear mechanism of action, even though it has observable therapeutic effects in the body.

Receptor Interactions

A **receptor** can be defined as a reactive site on the surface or inside of a cell. If the mechanism of action of a drug involves a receptor interaction, then the molecular structure of the drug is critical. Drug-receptor interaction is the joining of the drug molecule with a reactive site on the surface of a cell or tissue. Most commonly, this site is a protein structure within the cell membrane. Once a drug binds to and interacts with the receptor, a pharmacologic response is produced (Figure 2-7). The degree to which a drug attaches to and binds with a receptor is called its *affinity.* The drug with the best "fit" and strongest affinity for the receptor will elicit the greatest response from the cell or tissue. A drug becomes bound to the receptor through the formation of chemical bonds between the receptor on the cell and the active site on the drug molecule. Drugs interact with receptors in different ways either to elicit or to block a physiologic response. Table 2-8 describes the different types of drug-receptor interaction.

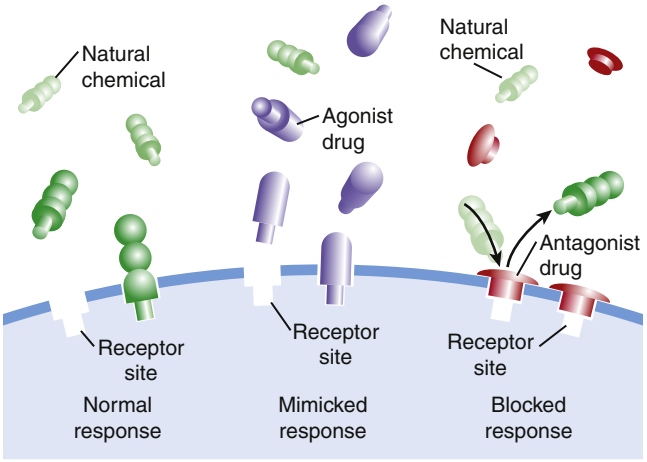

FIGURE 2-7 Drugs act by forming a chemical bond with specific receptor sites, similar to a key and lock. The better the "fit," the better the response. Drugs with complete attachment and response are called *agonists.* Drugs that attach but do not elicit a response are called *antagonists.*

TABLE 2-8 DRUG-RECEPTOR INTERACTIONS

DRUG TYPE	ACTION
Agonist	Drug binds to the receptor; there is a response.
Partial agonist (agonist-antagonist)	Drug binds to the receptor; the response is diminished compared with that elicited by an agonist.
Antagonist	Drug binds to the receptor; there is no response. Drug prevents binding of agonists.
Competitive antagonist	Drug competes with the agonist for binding to the receptor. If it binds, there is no response.
Noncompetitive antagonist	Drug combines with different parts of the receptor and inactivates it; agonist then has no effect.

Enzyme Interactions

Enzymes are the substances that catalyze nearly every biochemical reaction in a cell. Drugs can produce effects by interacting with these enzyme systems. For a drug to alter a physiologic response in this way, it may either inhibit (more common) or enhance (less common) the action of a specific enzyme. This process is called *selective interaction.* Drug-enzyme interaction occurs when the drug chemically binds to an enzyme molecule in such a way that it alters (inhibits or enhances) the enzyme's interaction with its normal target molecules in the body.

Nonselective Interactions

Drugs with nonspecific mechanisms of action do not interact with receptors or enzymes. Instead, their main targets are cell membranes and various cellular processes such as metabolic activities. These drugs can either physically interfere with or chemically alter cellular structures or processes. Some cancer

drugs and antibiotics have this mechanism of action. By incorporating themselves into the normal metabolic process, they cause a defect in the final product or state. This defect may be an improperly formed cell wall that results in cell death through cell lysis, or it may be the lack of a necessary energy substrate, which leads to cell starvation and death.

PHARMACOTHERAPEUTICS

Before drug therapy is initiated, an end point or expected outcome of therapy needs to be established. This desired therapeutic outcome is patient-specific, established in collaboration with the patient, and, if appropriate, determined with other members of the health care team. Outcomes need to be clearly defined and must be either measurable or observable by monitoring. Outcome goals must be realistic and prioritized so that drug therapy begins with interventions that are essential to the patient's well-being. Examples include curing a disease, eliminating or reducing a preexisting symptom, arresting or slowing a disease process, preventing a disease or other unwanted condition, or otherwise improving quality of life. These goals and outcomes are not the same as nursing goals and outcomes. See Chapter 1 for a more specific discussion of the nursing process.

Patient therapy assessment is the process by which a practitioner integrates his or her knowledge of medical and drug-related facts with information about a specific patient's medical and social history. Items to be considered in the assessment are drugs currently used (prescription, over-the-counter, herbal, and illicit or street drugs), pregnancy and breastfeeding status, and concurrent illnesses that could contraindicate initiation of a given medication. A **contraindication** for a medication is any patient condition, especially a disease state, that makes the use of the given medication dangerous for the patient. Careful attention to this assessment process helps to ensure an optimal therapeutic plan. The implementation of a treatment plan can involve several types and combinations of therapies. The type of therapy can be categorized as *acute, maintenance, supplemental* (or *replacement*), *palliative, supportive, prophylactic,* or *empiric.*

Acute Therapy

Acute therapy often involves more intensive drug treatment and is implemented in the acutely ill (those with rapid onset of illness) or the critically ill. It is often needed to sustain life or treat disease. Examples are the administration of vasopressors to maintain blood pressure and cardiac output after open heart surgery, the use of volume expanders for a patient who is in shock, and intensive chemotherapy for a patient with newly diagnosed cancer.

Maintenance Therapy

Maintenance therapy does not eradicate problems the patient may already have but will prevent progression of a disease or condition. It is used for the treatment of chronic illnesses such as hypertension. In the latter case, maintenance therapy maintains the patient's blood pressure within given limits, which prevents certain end-organ damage. Another example of maintenance therapy is the use of oral contraceptives for birth control.

Supplemental Therapy

Supplemental (or replacement) therapy supplies the body with a substance needed to maintain normal function. This substance may be needed either because it cannot be made by the body or because it is produced in insufficient quantity. Examples are the administration of insulin to diabetic patients and of iron to patients with iron-deficiency anemia.

Palliative Therapy

The goal of palliative therapy is to make the patient as comfortable as possible. Palliative therapy focuses on providing patients with relief from the symptoms, pain, and stress of a serious illness. The goal is to improve quality of life for both the patient and the family. It is typically used in the end stages of an illness when attempts at curative therapy have failed; however, it can be provided along with curative treatment. Examples are the use of high-dose opioid analgesics to relieve pain in the final stages of cancer.

Supportive Therapy

Supportive therapy maintains the integrity of body functions while the patient is recovering from illness or trauma. Examples are provision of fluids and electrolytes to prevent dehydration in a patient with influenza who is vomiting and has diarrhea, and administration of fluids, volume expanders, or blood products to a patient who has lost blood during surgery.

Prophylactic Therapy and Empiric Therapy

Prophylactic therapy is drug therapy provided to *prevent* illness or other undesirable outcome during *planned* events. A common example is the use of preoperative antibiotic therapy for surgical procedures. The antibiotic is given before the incision is made, so that the antibiotic can kill any potential pathogens. Another example is the administration of disease-specific vaccines to individuals traveling to geographic areas where a given disease is known to be endemic.

Empiric therapy is based on clinical probabilities. It involves drug administration when a certain pathologic condition has an uncertain but high likelihood of occurrence based on the patient's initial presenting symptoms. A common example is use of antibiotics active against the organism most commonly associated with a specific infection before the results of the culture and sensitivity reports are available.

Monitoring

Once the appropriate therapy has been implemented, the effectiveness of the therapy—that is, the clinical response of the patient to the treatment—must be evaluated. Evaluating the clinical response requires familiarity with both the drug's intended therapeutic action (beneficial effects) and its unintended possible **adverse effects** (predictable adverse drug reactions). Examples of monitoring include observing for the therapeutic effect of reduced blood pressure following administration of antihypertensive drugs and observing for the toxic effect of leukopenia after administering antineoplastic (cancer chemotherapy) drugs. Another example is performing a pain assessment after giving pain medication. It should be noted that

this text generally highlights only the most common adverse effects of a given drug; however, the drug may have many other less commonly reported adverse effects. Always keep in mind that patients may sometimes experience less common and less readily identifiable adverse drug effects. Consult comprehensive references, pharmacists, or poison and drug information center staff when there is uncertainty regarding adverse effects that a patient may be experiencing.

All drugs are potentially toxic and can have cumulative effects. Recognizing these toxic effects and knowing their manifestations are integral components of the monitoring process. A drug can accumulate when it is absorbed more quickly than it is eliminated or when it is administered before the previous dose has been metabolized or cleared from the body. Knowledge of the organs responsible for metabolizing and eliminating a drug combined with knowledge of how a particular drug is metabolized and excreted enables the nurse to anticipate problems and treat them appropriately if they occur.

Therapeutic Index

The ratio of a drug's toxic level to the level that provides therapeutic benefits is referred to as the drug's **therapeutic index.** The safety of a particular drug therapy is determined by this index. A low therapeutic index means that the difference between a therapeutically active dose and a toxic dose is small. A drug with a low therapeutic index has a greater likelihood than other drugs of causing an adverse reaction, and therefore its use requires closer monitoring. Examples of such drugs are warfarin and digoxin. In contrast, a drug with a high therapeutic index, such as amoxicillin, is rarely associated with overdose events.

Drug Concentration

All drugs reach a certain concentration in the blood. Drug concentrations can be an important tool for evaluating the clinical response to drug therapy. Certain drug levels are associated with therapeutic responses, whereas other drug levels are associated with toxic effects. Toxic drug levels are typically seen when the body's normal mechanisms for metabolizing and excreting drugs are compromised. This commonly occurs when liver and kidney functions are impaired or when the liver or kidneys are immature (as in neonates). Dosage adjustments should be made in these patients to appropriately accommodate their impaired metabolism and excretion.

Patient's Condition

Another patient-specific factor to be considered is the patient's concurrent diseases or other medical conditions. A patient's response to a drug may vary greatly depending on physiologic and psychological demands. Disease of any kind, infection, cardiovascular function, and GI function are just a few of the physiologic elements that can alter a patient's therapeutic response. Stress, depression, and anxiety can also be important psychological factors affecting response.

Tolerance and Dependence

To provide optimal drug therapy, it is important to understand and differentiate between tolerance and dependence. **Tolerance** is a decreasing response to repeated drug doses. **Dependence** is a physiologic or psychological need for a drug. *Physical dependence* is the physiologic need for a drug to avoid physical withdrawal symptoms (e.g., tachycardia in an opioid-addicted patient). *Psychological dependence* is also known as *addiction* and is the obsessive desire for the euphoric effects of a drug. Addiction typically involves the recreational use of various drugs such as benzodiazepines, opioids, and amphetamines. See Chapter 17 for further discussion of dependence and addiction.

TABLE 2-9 COMMON FOOD AND DRUG INTERACTIONS

FOOD	DRUG (CATEGORY)	RESULT
Leafy green vegetables	warfarin (anticoagulant)	Decreased anticoagulant effect from warfarin
Dairy products	tetracycline, levofloxacin, ciprofloxacin, moxifloxacin (antibiotics)	Chemical binding of the drug leading to decreased effect and treatment failures
Grapefruit juice	amiodarone (antidysrhythmic), buspirone (antianxiety), carbamazepine (antiseizure), cyclosporine, tacrolimus (immunosuppressants), felodipine, nifedipine, nimodipine, nisoldipine (calcium channel blockers), simvastatin, atorvastatin (anticholesterol drugs)	Decreased metabolism of drugs and increased effects
Aged cheese, wine	Monoamine oxidase inhibitors	Hypertensive crisis

Interactions

Drugs may interact with other drugs, with foods, or with agents administered as part of laboratory tests. Knowledge of drug interactions is vital for the appropriate monitoring of drug therapy. The more drugs a patient receives, the more likely that a drug interaction will occur. This is especially true in older adults, who typically have an increased sensitivity to drug effects and are receiving several medications. In addition, over-the-counter medications and herbal therapies can interact significantly with prescribed medications. Food also can interact significantly with certain drugs. See Table 2-9 for the most common food and drug interactions.

Alteration of the action of one drug by another is referred to as **drug interaction.** A drug interaction can either increase or decrease the actions of one or both of the involved drugs. Drug interactions can be either beneficial or harmful. Numerous drug interactions can occur and have been reported. Please note that only those drug interactions that are considered to be significant with at least a good probability of occurring and/or those that require dosage/therapy adjustment are discussed in this textbook. An authoritative resource may be used as a means of exploring all possible drug interactions.

Concurrently administered drugs may interact with each other and alter the pharmacokinetics of one another during any

TABLE 2-10 EXAMPLES OF DRUG INTERACTIONS AND THEIR EFFECTS ON PHARMACOKINETICS

PHARMACOKINETIC PHASE	DRUG COMBINATION	MECHANISM	RESULT
Absorption	Antacid with levofloxacin	Antacids bind to the levofloxacin preventing adequate absorption	Decreased effectiveness of levofloxacin, resulting from decreased blood levels (harmful)
Distribution	warfarin with amiodarone	Both drugs compete for protein-binding sites	Higher levels of free (unbound) warfarin and amiodarone, which increases actions of both drugs (harmful)
Metabolism	erythromycin with cyclosporine	Both drugs compete for the same hepatic enzymes	Decreased metabolism of cyclosporine, possibly resulting in toxic levels of cyclosporine (harmful)
Excretion	amoxicillin with probenecid	Inhibits the secretion of amoxicillin into the kidneys	Elevation and prolongation of plasma levels of amoxicillin (can be beneficial)

of the four phases of pharmacokinetics: absorption, distribution, metabolism, or excretion. Table 2-10 provides examples of drug interactions during each of these phases. Most commonly, drug interactions occur when there is competition between two drugs for metabolizing enzymes, such as the cytochrome P-450 enzymes listed in Table 2-5. As a result, the speed of metabolism of one or both drugs may be enhanced or reduced. This change in metabolism of one or both drugs can lead to subtherapeutic or toxic drug actions.

Many terms are used to categorize drug interactions. When two drugs with similar actions are given together, they can have **additive effects** (1 + 1 = 2). Examples are the many combinations of analgesic products, such as antihistamine and opioid combinations (e.g., promethazine and codeine) for treatment of cold symptoms, and acetaminophen and opioid combinations (e.g., acetaminophen and oxycodone) for treatment of pain. Often drugs are used together for their additive effects so that smaller doses of each drug can be given.

Synergistic effects occur when two drugs administered together interact in such a way that their combined effects are greater than the sum of the effects for each drug given alone (1 + 1 = greater than 2). The combination of hydrochlorothiazide with lisinopril for the treatment of hypertension is an example.

Antagonistic effects are said to occur when the combination of two drugs results in drug effects that are less than the sum of the effects for each drug given separately (1 + 1 = less than 2). An example of this type of interaction occurs when the antibiotic ciprofloxacin is given simultaneously with antacids, vitamins, iron, or dairy products. These drugs reduce the absorption of ciprofloxacin and lead to decreased effectiveness of the antibiotic.

Incompatibility is a term most commonly used to describe parenteral drugs. Drug incompatibility occurs when two parenteral drugs or solutions are mixed together and the result is a chemical deterioration of one or both of the drugs or the formation of a physical precipitate. The combination of two such drugs usually produces a precipitate, haziness, or color change in the solution. Before administering any intravenous medication, the nurse must always inspect the bag for precipitate. If the solution appears cloudy or if visible flecks are seen, the bag must be discarded and not given to the patient. An example of incompatible drugs is the combination of parenteral furosemide and heparin.

Adverse Drug Events

The recognition of the potential hazards and detrimental effects of medication use is a topic that continues to receive much attention in the literature. This focus has contributed to an increasing body of knowledge regarding this topic as well as the development of new terminology. Health care institutions are under increasing pressure to develop effective strategies for preventing adverse effects of drugs.

Adverse drug event (ADE) is a broad term for any undesirable occurrence involving medications. A similarly broad term also seen in the literature is *drug misadventure.* Patient outcomes associated with adverse drug events vary from no effects to mild discomfort to life-threatening complications, permanent disability, disfigurement, or death. Adverse drug events can be preventable (see discussion of medication errors later in Chapter 5) or nonpreventable. Fortunately, many adverse drug events result in no measurable patient harm. Adverse drug events can be both external and internal. The most common causes of adverse drug events *external* to the patient are errors by caregivers (both professional and nonprofessional) and malfunctioning of equipment (e.g., intravenous infusion pumps). An adverse drug event can be internal, or *patient induced,* such as when a patient fails to take medication as prescribed or drinks alcoholic beverages that he or she was advised not to consume while taking a given medication. An impending adverse drug event that is noticed before it actually occurs is considered a *potential* adverse drug event (and appropriate steps must be taken to avoid such a "near miss" in the future). A less common situation, but one still worth mentioning, is an *adverse drug withdrawal event.* This is an adverse outcome associated with discontinuation of drug therapy, such as hypertension caused by abruptly discontinuing blood pressure medication or return of infection caused by stopping antibiotic therapy too soon.

The two most common broad categories of adverse drug event are medication errors and adverse drug reactions. A **medication error** is a preventable situation in which there is a compromise in the "Six Rights" of medication use: *right drug, right dose, right time, right route, right patient,* and *right documentation.* Medication errors are more common than adverse drug reactions. Medication errors occur during the *prescribing, dispensing, administering,* or *monitoring* of drug therapy. These four phases are collectively known as the **medication use process.** See Chapter 5 for further discussion of medication errors.

An **adverse drug reaction** (ADR) (see Chapter 5) is any reaction to a drug that is unexpected and undesirable and occurs at therapeutic drug dosages. Adverse drug reactions may or may not be caused by medication errors. Adverse drug reactions may result in hospital admission, prolongation of hospital stay, change in drug therapy, initiation of supportive treatment, or complication of a patient's disease state. Adverse drug reactions are caused by processes inside the patient's body. They may or may not be preventable, depending on the situation. Mild adverse drug reactions (e.g., *drug adverse effects*—see later in the chapter) usually do not require a change in the patient's drug therapy or other interventions. More severe adverse drug reactions, however, are likely to require changes to a patient's drug regimen. Severe adverse drug reactions can be permanently or significantly disabling, life threatening, or fatal. They may require or prolong hospitalization, lead to organ damage (e.g., to the liver, kidneys, bone marrow, skin), cause congenital anomalies, or require specific interventions to prevent permanent impairment or tissue damage.

Adverse drug reactions that are specific to particular drug groups are discussed in the corresponding drug chapters in this book. Four general categories are discussed here: pharmacologic reaction, hypersensitivity (allergic) reaction, idiosyncratic reaction, and drug interaction.

A pharmacologic reaction is an extension of the drug's normal effects in the body. For example, a drug that is used to lower blood pressure in a patient causes a pharmacologic adverse drug reaction when it lowers the blood pressure to the point at which the patient becomes unconscious.

Pharmacologic reactions that result in adverse effects are predictable, well-known adverse drug reactions resulting in minor or no changes in patient management. They have predictable frequency and intensity, and their occurrence is related to the dose. They also usually resolve upon discontinuation of drug therapy.

An **allergic reaction** (also known as a *hypersensitivity reaction*) involves the patient's immune system. Immune system proteins known as *immunoglobulins* (see Chapters 48 and 49) recognize the drug molecule, its **metabolite(s),** or another ingredient in a drug formulation as a dangerous foreign substance. At this point, an *immune response* may occur in which immunoglobulin proteins bind to the drug substance in an attempt to neutralize the drug. Various chemical mediators, such as *histamine,* as well as *cytokines* and other inflammatory substances (e.g., *prostaglandins* [see Chapter 44]) usually are released during this process. This response can result in reactions ranging from mild reactions such as skin erythema or mild rash to severe, even life-threatening reactions such as constriction of bronchial airways and tachycardia.

It can be assumed throughout this textbook that use of any drug is contraindicated if the patient has a known allergy to that specific drug product. Allergy information may be reported by the patient as part of his or her history or may be observed by health care personnel during a patient encounter. In either case, every effort must be made to document as fully as possible the name of the drug product and the degree and details of the adverse reaction that occurred. For example: "Penicillin; skin rash, pruritus" or "Penicillin; urticaria and anaphylactic shock requiring emergency intervention."

In more extreme cases of disease or injury (e.g., cancer, snakebite), it may be deemed reasonable to administer a given drug *in spite of* a reported allergic or other adverse reaction. In such cases, the patient will likely be premedicated with additional medications (e.g., acetaminophen [Tylenol], diphenhydramine [Benadryl], prednisone) as an attempt to control any adverse reactions that may occur.

An **idiosyncratic reaction** is not the result of a known pharmacologic property of a drug or of a patient allergy, but instead occurs unexpectedly in a particular patient. Such a reaction is a genetically determined abnormal response to normal dosages of a drug. The study of such traits, which are solely revealed by drug administration, is called **pharmacogenomics** (see Chapter 8). Idiosyncratic drug reactions are usually caused by a deficiency or excess of drug-metabolizing enzymes. Many pharmacogenomic disorders exist. An example is **glucose-6-phosphate dehydrogenase (G6PD) deficiency.** This disease affects approximately 100 million people. People who lack proper levels of G6PD have idiosyncratic reactions to a wide range of drugs. There are more than 80 variations of the disease, and all produce some degree of drug-induced hemolysis. Drugs that are capable of inducing hemolysis in such patients are listed in Box 2-3.

The final type of adverse drug reaction is due to drug interaction. As described earlier, drug interaction occurs when the presence of two (or more) drugs in the body produces an unwanted effect. This unwanted effect can result when one drug either enhances or reduces the effects of another drug. Some drug interactions are intentional and beneficial (see Table 2-10). However, most clinically significant drug interactions

PATIENT-CENTERED CARE: CULTURAL IMPLICATIONS

Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) is an enzyme found in abundant amounts in the tissues of most individuals. It reduces the risk of hemolysis of red blood cells when they are exposed to oxidizing drugs such as aspirin. Approximately 13% of African-American men and 20% of African-American women carry the gene that results in G6PD deficiency. Approximately 14% of Sardinians and more than 50% of the Kurdish Jewish population also show G6PD deficiencies. When exposed to drugs such as sulfonamides, antimalarials, and aspirin, patients with this deficiency may suffer life-threatening hemolysis of the red blood cells, whereas individuals with adequate quantities of the enzyme have no problems in taking these drugs.

BOX 2-3 DRUGS TO AVOID IN PATIENTS WITH GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

Aspirin
Nitrofurantoin
Primaquine
Probenecid
Sulfonamides

are harmful. Drug interactions specific to particular drugs are discussed in detail in the chapters dealing with those drugs.

Other Drug Effects

Other drug-related effects that must be considered during drug therapy are teratogenic, mutagenic, and carcinogenic effects. These can result in devastating patient outcomes and may be prevented in many instances by appropriate monitoring.

Teratogenic effects of drugs or other chemicals result in structural defects in the fetus. Compounds that produce such effects are called *teratogens.* Prenatal development involves a delicate program of interrelated embryologic events. Any significant disruption in this process of *embryogenesis* can have a teratogenic effect. Drugs that are capable of crossing the placenta can cause **drug-induced teratogenesis.** Drugs administered during pregnancy can produce different types of congenital anomalies. The period during which the fetus is most vulnerable to teratogenic effects begins with the third week of development and usually ends after the third month. Chapter 3 describes the FDA safety classification for drugs used by pregnant women.

Mutagenic effects are permanent changes in the genetic composition of living organisms and consist of alterations in chromosome structure, the number of chromosomes, or the genetic code of the deoxyribonucleic acid (DNA) molecule. Drugs that are capable of inducing mutations are called *mutagens.* Radiation, viruses, chemicals (e.g., industrial chemicals such as benzene), and drugs can all act as mutagenic agents in humans. Drugs that affect genetic processes are active primarily during cell reproduction (mitosis).

Carcinogenic effects are the cancer-causing effects of drugs, other chemicals, radiation, and viruses. Agents that produce such effects are called *carcinogens.* Some exogenous causes of cancer are listed in Box 2-4.

PHARMACOGNOSY

The source of all early drugs was nature, and the study of these natural drug sources (plants and animals) is called *pharmacognosy*. Although many drugs in current use are synthetically derived, most were first isolated in nature. The four main sources for drugs are plants, animals, minerals, and laboratory synthesis. Plants provide many weak acids and weak bases (alkaloids) that are very useful and potent drugs. Alkaloids are more common, including atropine (belladonna plant), caffeine (coffee bean), and nicotine (tobacco leaf). Animals are the source of many hormone drugs. Conjugated estrogens are derived from the urine of pregnant mares, hence the drug trade name Premarin. *Equine* is the term used for any horse-derived drug. Insulin comes from two sources: pigs (porcine) and humans. Human insulin is now far more commonly used than animal insulins thanks to the use of recombinant DNA techniques. Heparin is another commonly used drug that is derived from pigs (porcine heparin). Some common mineral sources of currently used drugs are salicylic acid, aluminum hydroxide, and sodium chloride.

BOX 2-4 EXOGENOUS CAUSES OF CANCER

Dietary customs	Environmental pollution
Drug abuse	Food-processing procedures
Carcinogenic drugs	Food production procedures
Workplace chemicals	Oncogenic viruses
Radiation	Smoking

PHARMACOECONOMICS

Pharmacoeconomics is the study of the economic factors influencing the cost of drug therapy. One example is performing a *cost-benefit analysis* of one antibiotic versus another when competing drugs are considered for inclusion in a hospital formulary. Such studies typically examine treatment outcomes data (e.g., how many patients recovered and how soon) in relation to the comparative total costs of treatment with the drugs in question.

TOXICOLOGY

The study of poisons and unwanted responses to both drugs and other chemicals is known as *toxicology.* Toxicology is the science of the adverse effects of chemicals on living organisms. Clinical toxicology deals specifically with the care of the poisoned patient. Poisoning can result from a variety of causes, ranging from drug overdose to ingestion of household cleaning agents to snakebite. Poison control centers are health care institutions equipped with sufficient personnel and information resources to recommend appropriate treatment for the poisoned patient.

Effective treatment of the poisoned patient is based on a system of priorities, the first of which is to preserve the patient's vital functions by maintaining the airway, ventilation, and circulation. The second priority is to prevent absorption of the toxic substance and/or speed its elimination from the body using one or more of the variety of clinical methods available. Several common poisons and their specific antidotes are listed in Table 2-11.

TABLE 2-11 COMMON POISONS AND THEIR ANTIDOTES*

SUBSTANCE	ANTIDOTE
Acetaminophen	Acetylcysteine
Organophosphates (e.g., insecticides)	Atropine
Tricyclic antidepressants, quinidine	Sodium bicarbonate
Calcium channel blockers	Intravenous calcium
Iron salts	Deferoxamine
Digoxin and other cardiac glycosides	Digoxin antibodies
Ethylene glycol (e.g., automotive antifreeze solution), methanol	Ethanol (same as alcohol used for drinking), given intravenously
Benzodiazepines	Flumazenil
Beta blockers	Glucagon
Opiates, opioid drugs	Naloxone
Carbon monoxide (by inhalation)	Oxygen (at high concentration), known as bariatric therapy

*These and other antidotes are discussed throughout this textbook where applicable.

SUMMARY

A thorough understanding of the pharmacologic principles of pharmacokinetics, pharmacodynamics, pharmacotherapeutics, and toxicology is essential in drug therapy and to safe, quality nursing practice. Medications may be very helpful in treating disease, but unless the nurse has an adequate, up-to-date knowledge base and clinical skills and engages in critical thinking and good decision-making, any treatment may become harmful. Application of pharmacologic principles enables the nurse to provide safe and effective drug therapy while always acting on behalf of the patient and respecting the patient's rights. Nursing considerations associated with various routes of drug administration are summarized in Table 2-3.

KEY POINTS

- The following definitions related to drug therapy are important to remember: *pharmacology*—the study or science of drugs; *pharmacokinetics*—the study of drug distribution among various body compartments after a drug has entered the body, including the phases of absorption, distribution, metabolism, and excretion; *pharmaceutics*—the science of dosage form design.
- The nurse's role in drug therapy and the nursing process is more than just the memorization of the names of drugs, their uses, and associated interventions. It involves a thorough comprehension of all aspects of pharmaceutics, pharmacokinetics, and pharmacodynamics and the sound application of this drug knowledge to a variety of clinical situations. See Chapter 1 for further discussion of drug therapy as it relates to the nursing process.
- Drug actions are related to the pharmacologic, pharmaceutical, pharmacokinetic, and pharmacodynamic properties of a given medication, and each of these has a specific influence on the overall effects produced by the drug in a patient.
- Selection of the route of administration is based on patient variables and the specific characteristics of a drug.
- Nursing considerations vary depending on the drug as well as the route of administration.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 An elderly woman took a prescription medicine to help her to sleep; however, she felt restless all night and did not sleep at all. The nurse recognizes that this woman has experienced which type of reaction or effect?
   a Allergic reaction
   b Idiosyncratic reaction
   c Mutagenic effect
   d Synergistic effect

2 While caring for a patient with cirrhosis or hepatitis, the nurse knows that abnormalities in which phase of pharmacokinetics may occur?
   a Absorption
   b Distribution
   c Metabolism
   d Excretion

3 A patient who has advanced cancer is receiving opioid medications around the clock to "keep him comfortable" as he nears the end of his life. Which term best describes this type of therapy?
   a Palliative therapy
   b Maintenance therapy
   c Supportive therapy
   d Supplemental therapy

4 The nurse is giving medications to a patient in heart failure. The intravenous route is chosen instead of the intramuscular route. The nurse knows that the factor that most influences the decision about which route to use is the patient's
   a altered biliary function.
   b increased glomerular filtration.
   c reduced liver metabolism.
   d diminished circulation.

5 A patient has just received a prescription for an enteric-coated stool softener. When teaching the patient, the nurse should include which statement?
   a "Take the tablet with 2 to 3 ounces of orange juice."
   b "Avoid taking all other medications with any enteric-coated tablet."
   c "Crush the tablet before swallowing if you have problems with swallowing."
   d "Be sure to swallow the tablet whole without chewing it."

6 Each statement describes a phase of pharmacokinetics. Put the statements in order, with 1 indicating the phase that occurs first and 4 indicating the phase that occurs last.
   a Enzymes in the liver transform the drug into an inactive metabolite.
   b Drug metabolites are secreted through passive glomerular filtration into the renal tubules.
   c A drug binds to the plasma protein albumin and circulates through the body.
   d A drug moves from the intestinal lumen into the mesenteric blood system.

7 A drug that delivers 500 mg has a half-life of 4 hours. How many milligrams of drug will remain in the body after 1 half-life?

1. b, 2. c, 3. a, 4. d, 5. d, 6. a = 3, b = 4, c = 2, d = 1, 7. 250 mg

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the influences of the patient's age on the effects of drugs and drug responses.
2 Identify drug-related concerns during pregnancy and lactation and provide an explanation of the physiologic basis for these concerns.
3 Summarize the impact of age-related physiologic changes on the pharmacokinetic aspects of drug therapy.
4 Explain how these age-related changes in pharmacokinetics influence various drug effects and drug responses across the lifespan.
5 Provide several examples of how age affects the absorption, distribution, metabolism, and excretion of drugs.
6 Calculate a drug dose for a pediatric patient using the various formulas available.
7 Identify the importance of a body surface area nomogram for drug calculations in pediatric patients.
8 Develop a nursing care plan for drug therapy and the nursing process that takes into account lifespan considerations.

KEY TERMS

Active transport The active (energy-requiring) movement of a substance between different tissues via pumping mechanisms contained within cell membranes. (p. 38)

Diffusion The passive movement of a substance (e.g., a drug) between different tissues from areas of higher concentration to areas of lower concentration. (Compare with *active transport.*) (p. 38)

Elderly Pertaining to a person who is 65 years of age or older. (Note: Some sources consider "elderly" to be 55 years of age or older.) (p. 42)

Neonate Pertaining to a person younger than 1 month of age; newborn infant. (p. 38)

Nomogram A graphic tool for estimating drug dosages using various body measurements. (p. 40)

Pediatric Pertaining to a person who is 12 years of age or younger. (p. 39)

Polypharmacy The use of many different drugs concurrently in treating a patient, who often has several health problems. (p. 42)

From the beginning to the end of life, the human body changes in many ways. These changes have a dramatic effect on the four phases of pharmacokinetics—drug absorption, distribution, metabolism, and excretion. Newborn, pediatric, and elderly patients each have special needs. Drug therapy at the two ends of the spectrum of life is more likely to result in adverse effects and toxicity. This is especially true if certain basic principles are not understood and followed. Fortunately, response to drug therapy changes in a predictable manner in younger and older patients. Knowing the effect that age has on the pharmacokinetic characteristics of drugs helps predict these changes.

Most experience with drugs and pharmacology has been gained from the adult population. The majority of drug studies have focused on the population between 13 and 65 years of age. It has been estimated that 75% of currently approved drugs lack U.S. Food and Drug Administration (FDA) approval for pediatric use and therefore lack specific dosage guidelines for **neonates** and children. Fortunately, many excellent pediatric drug dosage books are available. Most drugs are effective in younger and older patients, but drugs often behave very differently in patients at the opposite ends of the age spectrum. It is vitally important from the standpoint of safe and effective drug administration to understand what these differences are and how to adjust for them.

DRUG THERAPY DURING PREGNANCY

A fetus is exposed to many of the same substances as the mother, including any drugs that she takes—prescription, nonprescription, or street drugs. The first trimester of pregnancy is generally the period of greatest danger of drug-induced developmental defects.

Transfer of both drugs and nutrients to the fetus occurs primarily by **diffusion** across the placenta, although not all drugs cross the placenta. Recall from chemistry that diffusion is a passive process based on differences in concentration between different tissues. **Active transport** requires the expenditure of energy and often involves some sort of cell-surface protein pump. The factors that contribute to the safety or potential harm of drug therapy during pregnancy can be broadly broken down into three areas: drug properties, fetal gestational age, and maternal factors.

Drug properties that impact drug transfer to the fetus include the drug's chemistry, dosage, and concurrently administered drugs. Examples of relevant chemical properties include molecular weight, protein binding, lipid solubility, and chemical structure. Important drug dosage variables include dose and duration of therapy.

Fetal gestational age is an important factor in determining the potential for harmful drug effects to the fetus. The fetus is at greatest risk for drug-induced developmental defects during the first trimester of pregnancy. During this period, the fetus undergoes rapid cell proliferation. Skeleton, muscles, limbs, and visceral organs are developing at their most rapid rate. Self-treatment of minor illness is strongly discouraged anytime during pregnancy, but especially during the first trimester. Gestational age is also important in determining when a drug can most easily cross the placenta to the fetus. During the last trimester, the greatest percentage of maternally absorbed drug gets to the fetus.

Maternal factors also play a role in determining drug effects on the fetus. Any change in the mother's physiology can affect the amount of drug to which the fetus may be exposed. Maternal kidney and liver function affect drug metabolism and excretion. Impairment in either kidney or liver function may result in higher drug levels and/or prolonged drug exposure, and thus increased fetal transfer. Maternal genotype may also affect how certain drugs are metabolized (pharmacogenetics). The lack of certain enzyme systems may result in adverse drug effects to the fetus when the mother is exposed to a drug that is normally metabolized by the given enzyme.

Although exposure of the fetus to drugs is most detrimental during the first trimester, drug transfer to the fetus is more likely during the last trimester. This is the result of enhanced blood flow to the fetus, increased fetal surface area, and increased amount of free drug in the mother's circulation.

It is important to use drugs judiciously during pregnancy; however, there are certain situations that require their use. Without drug therapy, maternal conditions such as hypertension, epilepsy, diabetes, and infection could seriously endanger both the mother and the fetus, and the potential for harm far outweighs the risks of appropriate drug therapy.

The FDA classifies drugs according to their safety for use during pregnancy. This system of drug classification is based primarily on animal studies and limited human studies. This is due in part to ethical dilemmas surrounding the study of potential adverse effects on fetuses. We have learned from several unfortunate mistakes, such as the maternal use of thalidomide, which causes birth defects, and diethylstilbestrol (DES), which causes a high incidence of gynecologic malignancy in female offspring. The most widely used index of potential fetal risk of drugs is the FDA's pregnancy safety category system. The five safety categories are described in Table 3-1. The FDA is in the process of changing the pregnancy categories; however, the information is not yet published at the time of this writing. The information will be posted on http://evolve.elsevier.com/Lilley once it becomes available.

DRUG THERAPY DURING BREASTFEEDING

Breastfed infants are at risk for exposure to drugs consumed by the mother. A wide variety of drugs easily cross from the mother's circulation into the breast milk and subsequently to the breastfeeding infant. Drug properties similar to those discussed in the previous section influence the exposure of infants to drugs via breastfeeding. The primary drug characteristics that increase the likelihood of drug transfer via breastfeeding include fat solubility, low molecular weight, nonionization, and high concentration.

Fortunately, breast milk is not the primary route for maternal drug excretion. Drug levels in breast milk are usually lower than those in the maternal circulation. The actual amount of exposure depends largely on the volume of milk consumed. The ultimate decision as to whether a breastfeeding mother takes a particular drug depends on the risk/benefit ratio. The risks of drug transfer to the infant in relation to the benefits of continuing breastfeeding and the therapeutic benefits to the mother must be considered on a case-by-case basis.

TABLE 3-1 PREGNANCY SAFETY CATEGORIES

CATEGORY	DESCRIPTION
Category A	Studies indicate no risk to the human fetus.
Category B	Studies indicate no risk to the animal fetus; information for humans is not available.
Category C	Adverse effects reported in the animal fetus; information for humans is not available.
Category D	Possible fetal risk in humans has been reported; however, in selected cases consideration of the potential benefit versus risk may warrant use of these drugs in pregnant women.
Category X	Fetal abnormalities have been reported, and positive evidence of fetal risk in humans is available from animal and/or human studies. These drugs are not be used in pregnant women.

TABLE 3-2 CLASSIFICATION OF YOUNG PATIENTS

AGE RANGE	CLASSIFICATION
Younger than 38 weeks' gestation	Premature or preterm infant
Younger than 1 month	Neonate or newborn infant
1 month up to 1 year	Infant
1 year up to 12 years	Child

NOTE: The meaning of the term *pediatric* may vary with the individual drug and clinical situation. Often the maximum age for a pediatric patient may be identified as 16 years of age. Consult manufacturer's guidelines for specific dosing information.

CONSIDERATIONS FOR NEONATAL AND PEDIATRIC PATIENTS

Pediatric patients are defined based on age. A *neonate* is defined as between birth and 1 month of age. An *infant* is between 1 and 12 months of age, and a *child* is between 1 and 12 years of age. The age ranges that correspond to the various terms applied to pediatric patients are shown in Table 3-2.

Physiology and Pharmacokinetics

Pediatric patients handle drugs much differently than adult patients, based primarily on the immaturity of vital organs. In both neonates and older pediatric patients, anatomic structures and physiologic systems and functions are still in the process of developing. The Patient-Centered Care: Lifespan Considerations for the Pediatric Patient box on this page lists those physiologic factors that alter the pharmacokinetic properties of drugs in young patients.

Pharmacodynamics

Drug actions (or pharmacodynamics) are altered in young patients, and the maturity of various organs determines how drugs act in the body. Certain drugs may be more toxic, whereas others may be less toxic. The sensitivity of receptor sites may also vary with age; thus, higher or lower dosages may be required depending on the drug. In addition, rapidly developing tissues may be more sensitive to certain drugs, and therefore smaller dosages may be required. Certain drugs are contraindicated during the growth years. For instance, tetracycline may permanently discolor a young person's teeth; corticosteroids may suppress growth when given systemically (but not when delivered via asthma inhalers, for example); and quinolone antibiotics may damage cartilage.

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

Pharmacokinetic Changes in the Neonate and Pediatric Patient

Absorption
- Gastric pH is less acidic because acid-producing cells in the stomach are immature until approximately 1 to 2 years of age.
- Gastric emptying is slowed because of slow or irregular peristalsis.
- First-pass elimination by the liver is reduced because of the immaturity of the liver and reduced levels of microsomal enzymes.
- Intramuscular absorption is faster and irregular.

Distribution
- Total body water is 70% to 80% in full-term infants, 85% in premature newborns, and 64% in children 1 to 12 years of age.
- Fat content is lower in young patients because of greater total body water.
- Protein binding is decreased because of decreased production of protein by the immature liver.
- More drugs enter the brain because of an immature blood-brain barrier.

Metabolism
- Levels of microsomal enzymes are decreased because the immature liver has not yet started producing enough.
- Older children may have increased metabolism and require higher dosages once hepatic enzymes are produced.
- Many variables affect metabolism in premature infants, infants, and children, including the status of liver enzyme production, genetic differences, and substances to which the mother was exposed during pregnancy.

Excretion
- Glomerular filtration rate and tubular secretion and resorption are all decreased in young patients because of kidney immaturity.
- Perfusion to the kidneys may be decreased, which results in reduced renal function, concentrating ability, and excretion of drugs.

Dosage Calculations for Pediatric Patients

Most drugs have not been sufficiently investigated to ensure their safety and effectiveness in children. In spite of this, there are numerous excellent pediatric dosage references. Because pediatric patients (especially premature infants and neonates) have small bodies and immature organs, they are very susceptible to drug interactions, toxicity, and unusual drug responses. Pediatric patients require different dosage calculations than do adults. Characteristics of pediatric patients that have a significant effect on dosage include the following:

- Skin is thinner and more permeable.
- Stomach lacks acid to kill bacteria.
- Lungs have weaker mucous barriers.

- Body temperature is less well regulated, and dehydration occurs easily.
- Liver and kidneys are immature, and, therefore, drug metabolism and excretion are impaired.

Many formulas for pediatric dosage calculation have been used throughout the years. Formulas involving age, weight, and body surface area (BSA) are most commonly employed as the basis for calculations. BSA-based formulas are the most accurate of these dosage formulas.

To use the BSA method, the nurse needs the following information:

- Drug order with drug name, dose, route, time, and frequency
- Information regarding available dosage forms
- Pediatric patient's height in centimeters (cm) and weight in kilograms (kg)
- BSA **nomogram** for children (e.g., West nomogram, shown in Figure 3-1)
- Recommended adult drug dosage

The West nomogram (see Figure 3-1) uses a child's height and weight to determine the child's BSA. This information is then inserted into the BSA formula to obtain a drug dosage for a specific pediatric patient. Consider the following examples:

$$\frac{\text{BSA of adult}}{\text{BSA of child}} \times \text{adult dose} = \text{estimated child's dose}$$

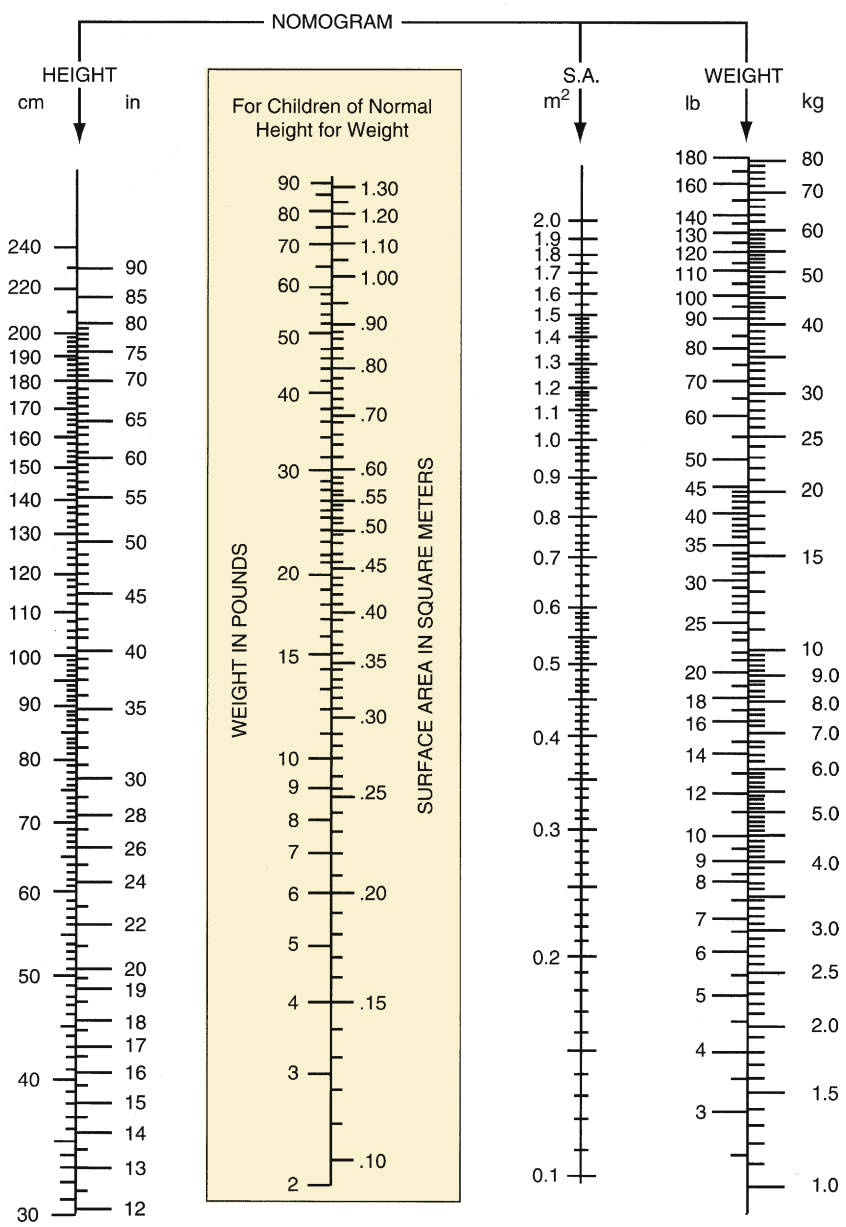

FIGURE 3-1 West nomogram for infants and children. S.A., Surface area. (Modified from data by Boyd E, West CD. In Kliegman RM, Stanton BF, St. Geme III JW, et al, editors: *Nelson textbook of pediatrics,* ed 19, Philadelphia, 2011, Saunders.)

$$\text{BSA of child } (m^2) \times \frac{\text{manufacturer's recommended dose}}{m^2} = \text{estimated child's dose}$$

Calculating the dosage according to the body weight is the most commonly used method today. Most drug references recommend dosages based on milligrams per kilogram of body weight. The following information is needed to calculate the pediatric dosage:

- Drug order (as discussed previously)
- Pediatric patient's weight in kilograms (1 kilogram = 2.2 pounds) (For example, a 10-lb baby weighs 4.5 kg; divide the number of pounds by 2.2 to determine kilograms.)
- Pediatric dosage as per manufacturer or drug formulary guidelines
- Information regarding available dosage forms

When using either of the previous methods, you must do the following to ensure the correct pediatric dose:

- Determine the pediatric patient's weight in kilograms.
- Use a current drug reference to determine the usual dosage range per 24 hours in milligrams (mg) per kilogram (kg). It must be noted that some drugs are stated as mg/kg/dose.
- Determine the dose parameters by multiplying the weight by the minimum and maximum daily doses of the drug (the safe range).
- Determine the total amount of the drug to administer per dose and per day.
- Compare the drug dosage prescribed with the calculated safe range.
- If the drug dosage raises any concerns or varies from the safe range, contact the health care provider or prescriber immediately and do not give the drug!

A common source of medication error and potential toxicity is confusing pounds with kilograms. Unless otherwise noted, the child's weight is to be given in kilograms, not pounds. Take great care to ensure that the correct weight is reported to the prescriber. In calculating pediatric dosages, the factor of organ maturity must always be considered along with BSA, age, and weight. When all of these physical developmental factors are

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

Age-Related Considerations for Medication Administration from Infancy to Adolescence

General Interventions

- Always come prepared for the procedure (e.g., prepare for injections with needleless syringe, and gather all needed equipment).
- Ask the parent and/or child (if age-appropriate) if the parent will remain for the procedure (for in-hospital administration).
- Assess for comfort methods that are appropriate before and after drug administration.

Infants

- While maintaining safe and secure positioning of the infant (e.g., with parent holding, rocking, cuddling, soothing), perform the procedure (e.g., injection) swiftly and safely.
- Allow self-comforting measures as age-appropriate (e.g., use of pacifier, fingers in mouth, self-movement).

Toddlers

- Offer a brief, concrete explanation of the procedure but with realistic expectations of the child's actual understanding of the information. Parents, caregivers, or other legal guardians must be part of the process. Hold the child securely while administering the medication.
- Accept aggressive behavior as a healthy response, but only within reasonable limits.
- Provide comfort measures immediately after the procedure (e.g., touching, holding).
- Help the child understand the treatment and his or her feelings through puppet play or play with stuffed animals or hospital equipment such as empty, needleless syringes.
- Provide for healthy ways to release aggression such as age-appropriate supervised playtime.

Preschoolers

- Offer a brief, concrete explanation of the procedure at the patient's level and with the parent or caregiver present.
- Provide comfort measures after the procedure (e.g., touching, holding).
- Identify and accept aggressive responses and provide age-appropriate outlets.
- Make use of magical thinking (e.g., using ointments or "special medicines" to make discomfort go away).
- Note that the role of the parent in providing comfort and understanding is very important.

School-Age Children

- Explain the procedure, allowing for some control over body and situation.
- Provide comfort measures.
- Explore feelings and concepts through the use of therapeutic play. Art may be used to help the patient express fears. Use of age-appropriate books and realistic hospital equipment may also be helpful.
- Set appropriate behavior limits (e.g., okay to cry or scream, but not to bite).
- Provide activities for releasing aggression and anger.
- Use the opportunity to teach about the relationship between receiving medication and body function and structure (e.g., what a seizure is and how medication helps prevent the seizure).
- Offer the complete picture (e.g., need to take medication, relax with deep breaths; medication will help prevent pain).

Adolescents

- Prepare the patient in advance for the procedure but without scare tactics.
- Allow for expression in a way that does not cause losing face, such as giving the adolescent time alone after the procedure (e.g., once a seizure is controlled) and giving the adolescent time to discuss his or her feelings.
- Explore with the adolescent any current concepts of self, hospitalization, and illness, and correct any misconceptions.
- Encourage self-expression, individuality, and self-care.
- Encourage participation in procedures as appropriate.

Modified from McKenry LM, Salerno E: *Mosby's pharmacology in nursing*, ed 22, St Louis, 2006, Mosby; Blaber M: Related to nursing intervention in pain. Newington's Children's Hospital manual for global pediatric nursing assessment (unpublished manuscript).

considered and doses are calculated correctly, the likelihood of safe and effective drug administration is increased. Emotional developmental considerations must also be a part of the decision-making process in drug therapy for pediatric patients (see the Patient-Centered Care: Lifespan Considerations for the Pediatric Patient box on p. 41).

CONSIDERATIONS FOR ELDERLY PATIENTS

Due to the decline in organ function that occurs with advancing age, elderly patients handle drugs physiologically differently than adult patients. Drug therapy in the elderly is more likely to result in adverse effects and toxicity.

In this textbook, the word *elderly* is used instead of the word *geriatric*; however, these terms are synonymous. An **elderly** patient is defined as a person who is 65 years of age or older. This segment of the population is growing at a dramatic pace (see the Patient-Centered Care: Lifespan Considerations for the Elderly Patient box on this page). At the beginning of the twentieth century, the elderly constituted a mere 4% of the total population. At that time, more people died of infections than of chronic illnesses such as heart disease, cancer, and diabetes. As medical and health care technology has advanced, so has the ability to prolong life. This has resulted in a growing population of older adults. Today patients older than 65 years of age constitute 13% of the population. Life expectancy is currently approximately 78.1 years, and it is estimated that 20% of the population will be 65 years of age or older by 2030. These trends are expected to continue as new disease prevention and treatment methods are developed.

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

Percentage of Population Older than Age 65

YEAR	PERCENTAGE OLDER THAN AGE 65
1900	4%
2000	12%
2020	20%

Issues in Clinical Drug Use in the Elderly

The elderly population consumes a larger proportion of all medications than other population groups, taking 30% of all prescription drugs and over 40% of over-the-counter drugs. At any given time, the average elderly patient takes four or five prescription drugs as well as two over-the-counter medications, which can increase the risk of drug interactions. Commonly prescribed drugs for the elderly include antihypertensives, beta blockers, diuretics, insulin, and potassium supplements. The most commonly used over-the-counter drugs are analgesics, laxatives, and nonsteroidal anti-inflammatory drugs (NSAIDs). Elderly patients, especially those of certain ethnicities, may use various folk remedies of unknown composition that are unfamiliar to their health care providers.

Not only do elderly patients consume a greater proportion of prescription and over-the-counter medications, they commonly take multiple medications on a daily basis. About 1 in 3 elderly patients take more than 8 different drugs each day, with many taking 15 or more. One reason for the use of multiple medications is the more frequent occurrence of chronic diseases and the multiple drug options available for treatment. More than 80% of patients taking eight or more drugs have one or more chronic illnesses. More complicated medication regimens predispose elderly patients to self-medication errors, especially those with reduced visual acuity and manual dexterity. Such sensory and motor deficits can be particularly problematic when elderly patients split their own tablets. The practice of pill splitting occurs commonly for financial reasons, because lower- and higher-strength tablets often have similar costs. Furthermore, some insurance companies require tablet splitting for this reason. Other factors that may contribute to medication errors in the elderly include lack of adequate patient education and understanding of their drug regimens, and use of multiple prescribers and multiple pharmacies. In this age of medical specialization, patients may see several prescribers for their many illnesses. Because of this, it is very important for the patient to use only one pharmacy so that monitoring for drug interactions and duplicate therapy can occur.

Elderly patients are hospitalized frequently due to adverse drug reactions. Many people, including the elderly, use complementary and alternative medicines such as herbal remedies and dietary supplements, which can interact with prescription drugs. The simultaneous use of multiple medications is called **polypharmacy.** As the number of medications a person takes increases, so does the risk of drug interaction. For example, the chance of a drug interaction is approximately 6% for a patient receiving two medications. This risk rises dramatically as the number of drugs the patient is taking increases. For a patient taking five medications, the chance of a drug interaction is 50%, and for those taking 10 or more medications, the chance is 100%.

Some drugs may be given specifically to counteract the adverse effects of other drugs (e.g., a potassium supplement to counteract the potassium loss caused by certain diuretic medications), which is one example of what is known as the *prescribing cascade*. Sometimes it is difficult to distinguish adverse drug effects from disease symptoms. Although such prescribing is sometimes appropriate, it also increases the potential for more adverse drug events (including drug interactions, hospitalization or prolonged hospital stays, hip fractures secondary to drug-induced falls, addiction risk, anorexia, confusion, urinary retention, and fatigue). Recognizing polypharmacy and taking steps to reduce it whenever possible by decreasing the number and/or dosages of drugs taken can significantly reduce the incidence of adverse outcomes. Appropriate drug doses for elderly patients may sometimes be one-half to two-thirds of the standard adult dose. As a general rule, dosing for the elderly should follow the admonition, "Start low and go slow," which means to start with the lowest possible dose (often less than an average adult dose) and increase the dose slowly, based on patient response.

Another important issue is noncompliance, or nonadherence, with prescribed medication regimens. Drug nonadherence is reported to occur in roughly 40% of elderly patients and is associated with increased rates of hospitalization. Some patients want to adhere to their medication regimen but truly cannot

TABLE 3-3 PHYSIOLOGIC CHANGES IN THE ELDERLY PATIENT

SYSTEM	PHYSIOLOGIC CHANGE
Cardiovascular	↓ Cardiac output = ↓ absorption and distribution
	↓ Blood flow = ↓ absorption and distribution
Gastrointestinal	↑ pH (alkaline gastric secretions) = altered absorption
	↓ Peristalsis = delayed gastric emptying
Hepatic	↓ Enzyme production = ↓ metabolism
	↓ Blood flow = ↓ metabolism
Renal	↓ Blood flow = ↓ excretion
	↓ Function = ↓ excretion
	↓ Glomerular filtration rate = ↓ excretion

afford the medicine. Patients in this situation need to be referred to a health care social worker or their prescriber. Many drug companies offer patient assistance for expensive medications.

Physiologic Changes

Physiologic changes associated with aging affect the action of many drugs. As the body ages, the functioning of several organ systems slowly declines. The collective physiologic changes associated with the aging process have a major effect on the disposition and action of drugs. Table 3-3 lists some of the body systems most affected by the aging process.

The sensitivity of the elderly patient to many drugs requires careful monitoring and dosage adjustment. The criteria for drug dosages in older adults must include consideration of body weight and organ functioning, with emphasis on liver, renal, cardiovascular, and central nervous system function (similar to the criteria for pediatric dosages). With aging, there is a general decrease in body weight.

Changes in drug molecule receptors in the body can make a patient more or less sensitive to certain medications. For example, elderly patients commonly have increased sensitivity to central nervous system depressant medications (e.g., anxiolytics, tricyclic antidepressants) because of reduced integrity of the blood-brain barrier.

It is important to monitor the results of laboratory tests that have been ordered for elderly patients. These values serve as a gauge of organ function. The most important organs from the standpoint of the breakdown and elimination of drugs are the liver and the kidneys. Kidney function is assessed by measuring serum creatinine and blood urea nitrogen levels. Creatinine is a byproduct of muscle metabolism. Because muscle mass declines with age, the serum creatinine level may provide a misleading index of renal function. For example, a frail elderly female may have a reported serum creatinine value that is lower than normal, and this may lead one to falsely think that her renal function is normal. In actuality, because this patient has limited muscle mass, she cannot produce creatinine. The seasoned clinician knows that renal function declines with age and that this value alone does not give an accurate estimate of renal function. The most accurate way to determine creatinine clearance is by collecting a patient's urine for 24 hours. This test is quite cumbersome, however, and is not used very often. Fortunately, several equations exist that allow pharmacists and prescribers to accurately assess renal function in the elderly. Frequency of testing for renal function is often dictated by the degree of renal dysfunction and the type of medications being prescribed or used.

Liver function is assessed by testing the blood for liver enzymes such as aspartate aminotransferase (AST) and alanine aminotransferase (ALT). These laboratory values can help in assessing the ability to metabolize and eliminate medications and can aid in anticipating the risk of toxicity and/or drug accumulation. Laboratory assessments need to be conducted at least annually, both for preventive health monitoring and for screening for possible toxic effects of drug therapy. Such assessments may be indicated more frequently (e.g., every 1, 3, or 6 months) in those patients requiring higher-risk drug regimens.

Pharmacokinetics

The pharmacokinetic phases of absorption, distribution, metabolism, and excretion (see Chapter 2) may be different in the older adult than in the younger adult. Awareness of these differences helps ensure appropriate administration of drugs and monitoring of elderly patients. The Patient-Centered Care: Lifespan Considerations for the Elderly Patient box on this page lists the four pharmacokinetic phases and summarizes how they are altered by the aging process.

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

Pharmacokinetic Changes

Absorption

- Gastric pH is less acidic because of a gradual reduction in the production of hydrochloric acid in the stomach.
- Gastric emptying is slowed because of a decline in smooth muscle tone and motor activity.
- Movement throughout the gastrointestinal tract is slower because of decreased muscle tone and motor activity.
- Blood flow to the gastrointestinal tract is reduced by 40% to 50% because of decreased cardiac output and decreased perfusion.
- The absorptive surface area is decreased because the aging process blunts and flattens villi.

Distribution

- In adults 40 to 60 years of age, total body water is 55% in males and 47% in females; in those older than 60 years of age, total body water is 52% in males and 46% in females.
- Fat content is increased because of decreased lean body mass.
- Protein (albumin) binding sites are reduced because of decreased production of proteins by the aging liver and reduced protein intake.

Metabolism

- The levels of microsomal enzymes are decreased because the capacity of the aging liver to produce them is reduced.
- Liver blood flow is reduced by approximately 1.5% per year after 25 years of age, which decreases hepatic metabolism.

Excretion

- Glomerular filtration rate is decreased by 40% to 50%, primarily because of decreased blood flow.
- The number of intact nephrons is decreased.

Absorption

Absorption in the older person can be altered by many mechanisms. Advancing age results in reduced absorption of both dietary nutrients and drugs. Several physiologic changes account for this reduction in absorption. Elderly patients have a gradual reduction in the ability of the stomach to produce hydrochloric acid, which results in a decrease in gastric acidity and may alter the absorption of some drugs. In addition, the combination of decreased cardiac output and advancing atherosclerosis results in a general reduction in the flow of blood to major organs, including the stomach. By 65 years of age, there is an approximately 50% reduction in blood flow to the gastrointestinal (GI) tract. Absorption, whether of nutrient or drug, is dependent on good blood supply to the stomach and intestines. The absorptive surface area of an elderly person's GI tract is often reduced, thus decreasing drug absorption.

GI motility is important for moving substances out of the stomach and also for moving them throughout the GI tract. Muscle tone and motor activity in the GI tract are reduced in older adults. This often results in constipation, for which older adults frequently take laxatives. This use of laxatives may accelerate GI motility enough to actually reduce the absorption of drugs.

Distribution

The distribution of medications throughout the body is also different in older adults. There seems to be a gradual reduction in the total body water content with aging. Therefore, the concentrations of highly water-soluble (hydrophilic) drugs may be higher in elderly patients because they have less body water in which the drugs can be diluted. The composition of the body also changes with aging, with a decrease in lean muscle mass and an increase in body fat. In both men and women, there is an approximately 20% reduction in muscle mass between 25 and 65 years of age and a corresponding 20% increase in body fat. Fat-soluble or lipophilic drugs, such as hypnotics and sedatives, are primarily distributed to fatty tissues and may result in prolonged drug actions and/or toxicity.

Elderly patients may have reduced protein concentrations, due in large part to reduced liver function. Reduced dietary intake and/or poor GI protein absorption can cause nutritional deficiencies and reduced blood protein levels. Regardless of the cause, the result is a reduced number of protein-binding sites for highly protein-bound drugs. This results in higher levels of unbound (active) drug in the blood. Remember that only drugs not bound to proteins are active. Therefore, the effects of highly protein-bound drugs may be enhanced if their dosages are not adjusted to accommodate any reduced serum albumin concentrations. Some highly protein-bound drugs include warfarin and phenytoin.

Metabolism

Metabolism declines with advancing age. The transformation of active drugs into inactive metabolites is primarily performed by the liver. The liver loses mass with age and slowly loses its ability to metabolize drugs effectively due to reduced production of microsomal (cytochrome P-450) enzymes. There is also a reduction in blood flow to the liver because of reduced cardiac output and atherosclerosis. A reduction in the hepatic blood flow of approximately 1.5% per year occurs after 25 years of age. All of these factors contribute to prolonging the half-life of many drugs (e.g., warfarin), which can potentially result in drug accumulation if serum drug levels are not closely monitored.

Excretion

Renal function declines in roughly two-thirds of elderly patients. A reduction in the glomerular filtration rate of 40% to 50%, combined with a reduction in cardiac output leading to reduced renal perfusion, can result in delayed drug excretion and therefore drug accumulation. This is especially true for drugs with a low therapeutic index such as digoxin. Renal function needs to be monitored frequently. Appropriate dose and interval adjustments may be determined based on the results of renal and liver function studies as well as the presence of therapeutic levels of the drug in the serum. If a decrease in renal and liver function is known, adjust the dosage so that drug accumulation and toxicity may be avoided or minimized.

Problematic Medications for the Elderly

Certain classes of drugs are more likely to cause problems in elderly patients because of many of the physiologic alterations and pharmacokinetic changes already discussed. Table 3-4 lists some of the more common medications that are problematic. Some drugs to be avoided in the elderly have been identified by various professional organizations such as the American Nurses Association as well as by various other authoritative sources. Since the 1990s, a very effective tool, the Beers criteria, has been used to identify drugs that may be inappropriately prescribed, ineffective, or cause adverse drug reactions in elderly patients (see the Evidence-Based Practice box on p. 45). The Beers criteria are very useful and help determine risk-associated situations for the elderly and specific drugs that may be problematic.

NURSING PROCESS

ASSESSMENT

Before any medication is administered to a pediatric patient, obtain a health history and medication history with assistance from the parent, caregiver, or legal guardian. The following are some areas to be included:

- Age
- Age-related concerns about organ functioning
- Age-related fears
- Allergies to drugs and food
- Baseline values for vital signs
- Head-to-toe physical assessment findings
- Height in feet/inches and centimeters
- Weight in kilograms and pounds
- Level of growth and development and related developmental tasks

TABLE 3-4 MEDICATIONS AND CONDITIONS REQUIRING SPECIAL CONSIDERATIONS IN THE ELDERLY PATIENT

MEDICATION	COMMON COMPLICATIONS
Analgesics	
Opioids	Confusion, constipation, urinary retention, nausea, vomiting, respiratory depression, falls
Nonsteroidal antiinflammatory drugs (NSAIDs)	Edema, nausea, gastric ulceration, bleeding, renal toxicity
Anticoagulants (heparin, warfarin)	Major and minor bleeding episodes, many drug interactions, dietary interactions
Anticholinergics	Blurred vision, dry mouth, constipation, confusion, urinary retention, tachycardia
Antidepressants	Sedation and strong anticholinergic adverse effects (see above)
Antihypertensives	Nausea, hypotension, diarrhea, bradycardia, heart failure, impotence
Cardiac glycosides (e.g., digoxin)	Visual disorders, nausea, diarrhea, dysrhythmias, hallucinations, decreased appetite, weight loss
Central nervous system (CNS) depressants (muscle relaxants, opioids)	Sedation, weakness, dry mouth, confusion, urinary retention, ataxia
Sedatives and hypnotics	Confusion, daytime sedation, ataxia, lethargy, increased risk of falls
Thiazide diuretics	Electrolyte imbalance, rashes, fatigue, leg cramps, dehydration

CONDITION	DRUGS REQUIRING SPECIAL CAUTION AND MONITORING
Bladder flow obstruction	Anticholinergics, antihistamines, decongestants, antidepressants
Clotting disorders	NSAIDs, aspirin, antiplatelet drugs
Chronic constipation	Calcium channel blockers, tricyclic antidepressants, anticholinergics
Chronic obstructive pulmonary disease	Long-acting sedatives or hypnotics, narcotics, beta blockers
Heart failure and hypertension	Sodium, decongestants, amphetamines, over-the-counter cold products
Insomnia	Decongestants, bronchodilators, monoamine oxidase inhibitors
Parkinson's disease	Antipsychotics, phenothiazines
Syncope, falls	Sedatives, hypnotics, opioids, CNS depressants, muscle relaxants, antidepressants, antihypertensives

EVIDENCE-BASED PRACTICE

Update on Application of the Beers Criteria for Prevention of Adverse Drug Events in Older Adults

Review

In 1991, a panel of experts led by Mark H. Beers, MD, identified a list of "potentially inappropriate medications" (PIM) for use in individuals 65 years of age and older. These criteria were intended for use with nursing home residents and then were expanded and revised to include all settings of geriatric care. The specific aim of the project was to predict adverse drug reactions (ADRs) in this age group. The Beers Criteria were updated in 1997 and 2002 and provided a listing of drugs and drug classes to be avoided in the elderly. The criteria also identified disease states considered to be contraindications for some drugs. In 2005, research was conducted to confirm the relationship between PIM prescribing, as defined by Beers Criteria, and the occurrence of ADRs in elderly patients treated at outpatient clinics. In 2012, a list of medications was identified and classified into three categories: (1) potentially inappropriate medications and classes to avoid in the older adult, (2) potentially inappropriate medications and classes to avoid in older adults with certain diseases and syndromes, and (3) medications to be used with caution in older adults

Type of Evidence

The 2012 Beers Criteria were considered greatly improved because of the inclusion of important updates to the previous list of medications. Additionally, there was consideration of the challenges of assisting and guiding clinicians in avoiding certain drugs in older adults and/or the need for cautious use. The quality of the criteria was also improved by: (1) application of an evidence-based approach, (2) support of the American Geriatrics Society (AGS) in conjunction with an interdisciplinary panel of experts in geriatric care and pharmacotherapy, (3) use of a time-tested method for developing care guidelines while using the Institute of Medicine's standards for evidence/transparency as an important benchmark, and, (4) an extensive review of more than 2000 high-quality research studies about prescription medications for this age group.

Results of Study

Fifty-three medications/medication classes were included in the 2012 AGS Beers Criteria. There was a list of 34 medications and types of medications labeled as "potentially inappropriate", 14 common health problems with associated medications that were also potentially inappropriate, and 14 types of potentially inappropriate drugs to be used only with caution—all with older adults. Nineteen medications/medication classes were dropped from the 2003 list. The update allows thoughtful application of the Criteria for closer monitoring of drug use, application and interventions to decrease adverse drug events in older adults, and better patient outcomes.

Link of Evidence to Nursing Practice

These Criteria are improved and provide a much needed update for drugs to avoid and use with caution in older adults. They also increase awareness of inappropriate medication use in this age group and may also be integrated into electronic health records. With the support of the AGS, the Criteria will continue to develop over time and will continue to help improve the health of older adults.

Data from American Geriatrics Society 2012 Beers Criteria Update Expert Panel: American Geriatrics Society updated Beers Criteria for potentially inappropriate medication use in older adults, *J Am Geriatr Soc* 60(4):616-631, 2012; Fick DM, Semla TP: 2012 American Geriatrics Society Beers Criteria: new year, new criteria, new perspective, *J Am Geriatr Soc* 60(4):614-615, 2012.

- Medical and medication history (including adverse drug reactions); current medications, related dosage forms, and routes; patient's tolerance of the forms and/or routes
- State of anxiety of the patient and/or family members or caregiver
- Use of prescription and over-the-counter medications in the home setting
- Usual method of medication administration, such as use of a calibrated spoon or needleless syringe
- Usual response to medications
- Motor and cognitive responses and their age-appropriateness
- Resources available to the patient and family

In addition, check and recheck the prescriber's orders because there is no room for error when administering medications to pediatric patients—or any patients for that matter. Carefully perform medication dosage calculations, and check several times for accuracy. Calculations for dosages take into account a variety of information and variables that may affect patient response, and use of body surface area (BSA) formulas and body weight formulas (milligrams per kilogram) are recommended. In addition to an assessment of the patient, an assessment of the drug and related information is needed, focusing specifically on the drug's purpose, dosage ranges, routes of administration, cautions, and contraindications. The saying that pediatric patients are just "small adults" is incorrect, because in pediatric patients every organ is anatomically and physiologically immature and not fully functioning. As pediatric patients grow older, their BSA and weight are still lower, so extreme caution is continually needed when giving them medications. Immature organ and system development will influence pharmacokinetics and thus affect the way the pediatric patient responds to a drug. Organ function may be determined through laboratory testing. The following studies may be ordered by the prescriber before beginning drug therapy as well as during and after drug therapy: hepatic and renal function studies, red blood cell and white blood cell counts, and measurement of hemoglobin and hematocrit levels and serum protein levels.

Assessment data to be gathered for the elderly patient may include the following:

- Age
- Allergies to drugs and food
- Dietary habits
- Sensory, visual, hearing, cognitive, and motor-skill deficits
- Financial status and any limitations
- List of all health-related care providers, including physicians, dentists, optometrists and ophthalmologists, podiatrists, and alternative medicine health care practitioners such as osteopathic physicians, chiropractors, and nurse practitioners
- Past and present medical history
- Listing of medications, past and present, including prescription drugs, over-the-counter medications, herbals, nutritional supplements, vitamins, and home remedies
- Existence of polypharmacy (the use of more than one medication)
- Self-medication practices
- Laboratory test results, especially those indicative of renal and liver function
- History of smoking and use of alcohol with notation of amount, frequency, and years of use
- Risk situations related to drug therapy identified by the Beers criteria (see the Evidence-Based Practice box on p. 45)

One way to collect data about the various medications or drugs being taken by the elderly is to obtain the information from the patient and/or caregiver using the brown-bag technique. This is an effective means of identifying various drugs the patient is taking, regardless of the patient's age, and may be used in conjunction with a complete review of the patient's medical history or record. The brown-bag technique requires the patient/caregiver to place all medications used in a bag and bring them to the health care provider. All medications need to be brought in their original containers. A list of medications with generic names, dosages, routes of administration, and frequencies is then compiled. This list of medications is then compared with what is prescribed to what the patient states he or she is actually taking. Medication reconciliation procedures are performed in health care facilities when assessing and tracking medications taken by the patient (see Chapter 5). In addition, the patient's insight into his or her medical problems is a very beneficial piece of information in developing a plan of care. It is also important for the nurse to realize that although elderly patients may be able to provide the required information themselves, many may be confused or poorly informed about their medications and/or health condition. In such cases, consult with a more reliable historian, such as a significant other, family member, or caregiver. Elderly patients may also have sensory deficits that require the nurse to speak slowly, loudly, and clearly while facing the patient.

With the elderly patient—as with a patient of any age—thoroughly assess support systems and the patient's ability to take medications safely. Whenever possible with the elderly, health care providers/prescribers need to opt for a nonpharmacologic approach to treatment first, if appropriate. Other data to collect include information about acute or chronic illnesses, nutritional problems, cardiac problems, respiratory illnesses, and GI tract disorders. Laboratory tests related to lifespan considerations that are often ordered include hemoglobin and hematocrit levels, red blood cell and white blood cell counts, blood urea nitrogen level, serum and urine creatinine levels, urine specific gravity, serum electrolyte levels, and protein and serum albumin levels.

NURSING DIAGNOSES

1. Imbalanced nutrition, less than body requirements, related to the impact of age and drug therapy and possible adverse effects
2. Deficient knowledge related to information about drugs and their adverse effects or about when to contact the prescriber
3. Risk for injury related to adverse effects of medications or to the method of drug administration
4. Risk for injury related to idiosyncratic reactions to drugs due to age-related drug sensitivity

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

A Brief Look at the Sixth Leading Cause of Death in the United States: Alzheimer's Disease

- In 2011, approximately 5.4 million Americans were identified as having Alzheimer's disease with nearly 4% of these individuals with early onset Alzheimer's (affecting people younger than age 65).,
- Alzheimer's is the sixth leading cause of death in the United States. It is the only cause of death among the top 10 in the United States that cannot be prevented, cured, or slowed.
- Alzheimer's mortality rate is on the rise and deaths due to Alzheimer's disease have increased approximately 66% during the years 2000 to 2008.
- Alzheimer's disease is the most common cause of dementia and accounts for approximately 50% to 80% of cases. Early clinical symptoms include difficulty remembering names and recent events as well as apathy and depression. Later clinical symptoms include impaired judgment, confusion, behavioral changes, and difficulty swallowing/speaking and walking.
- The pathology associated with Alzheimer's disease is a disruption of brain cells in specific regions involved in the formulation of new memories. Other difficulties are experienced as damage spreads. Warning signs include memory loss that is disruptive to activities of daily living; challenges in problem solving, leading to difficulty in completing the most familiar of tasks at home, work, or even at leisure; confusion to time and place; trouble with spatial relationships; and difficulty understanding visual images. For a more complete listing of the symptoms of Alzheimer's disease, refer to the 2011 Alzheimer's Disease Facts and Figures (Alzheimer's Association, 2011, available at www.alz.org).
- Alzheimer's disease is ultimately fatal.
- Advancing age is the greatest risk factor. Most of the individuals with Alzheimer's are age 65 or older, and the likelihood doubles about every 5 years after age 65. After the age of 85, the risk is almost 50%.
- Another important risk factor is family history, with an increased likelihood of developing the disease in those who have a parent, brother, sister, or child with Alzheimer's.
- New criteria and guidelines for diagnosing Alzheimer's were published in 2011 recommending that the disease be considered one with three stages beginning well before the development of symptoms. Hallmark abnormalities include deposits of protein fragment beta-amyloid (plaques) and twisted strands of the protein tau (tangles) as well as evidence of nerve cell damage and death in the brain.
- Latinos and African Americans, in the United States, have higher rates of vascular disease and so, as such, may also be at greater risk of developing Alzheimer's.

Data from Alzheimer's Association: 2011 Alzheimer's disease facts and figures, available at http://www.alz.org.

PLANNING

GOALS

1. Patient (caregiver, parent, or legal guardian) states measures to enhance nutritional status due to age- and drug-related factors, as well as any adverse drug effects on everyday nutrition.
2. Patient (caregiver, parent, or legal guardian) states the importance of adhering to the prescribed drug therapy (or takes medication as prescribed with assistance).
3. Patient contacts the prescriber when appropriate, such as when unusual effects occur during drug therapy.
4. Patient (caregiver, parent, or legal guardian) identifies ways to minimize complications, adverse effects, reactions, and injury to self associated with the therapeutic medication regimen.

OUTCOME CRITERIA

1. Patient (caregiver, parent, or legal guardian) lists recommended caloric and protein intake as well as examples of all the major food groups with the assistance of nutritional consultation.
   - Patient (caregiver, parent, or legal guardian) identifies when to contact the prescriber if nausea, vomiting, loss of appetite, diarrhea, constipation, or other problems arise during medication therapy.
2. Patient (caregiver, parent, or legal guardian) states rationale for medication as well as importance in the timing, dosage, and duration of therapy and is able to identify what the specific medication looks like.
   - Patient (caregiver, parent, or legal guardian) describes intended therapeutic effects of the medication(s), such as improvement in condition with decrease in symptoms and with limited adverse effects.
   - Patient (caregiver, parent, or legal guardian) demonstrates safe method of self- or assisted medication administration, such as use of a week-long pill mechanism with day of week and associated times, and has all medications safely labeled.
   - Patient (caregiver, parent, or legal guardian) follows instructions specific to the route of administration for the medication ordered, while also demonstrating (if appropriate) techniques, such as special application of an ointment as prescribed, measuring and taking liquid medication, and taking medication with proper food/fluids, for the duration of treatment.
3. Patient (caregiver, parent, or legal guardian) lists all unintended adverse effects and possible toxicity associated with medication regimen while also stating when to contact health care provider such as occurrence of fever, pain, vomiting, rash, diarrhea, difficulty breathing, and/or worsening of condition being treated.
4. Patient (caregiver, legal guardian, or parent) reports safe medication administration upon return appointment after beginning prescribed therapy.
   - Patient (caregiver, legal guardian, or parent) minimizes adverse effects and danger to self by taking medication(s) as prescribed, at the right time, with right dosing, and with attention to intake of proper amount of fluids (4 to 6 oz of water with oral dosages) and with or without food, as indicated while remaining cognitive of safety measures appropriate to specific drug regimen.

IMPLEMENTATION

It is always important to emphasize and practice the Six Rights of medication administration (see Chapter 1) and follow the prescriber's order and/or medication instructions. Check all drugs three times against the Six Rights and the prescriber's order before the drug is given to the patient. This usually applies for

acute care and long-term care inpatient and outpatient situations. For the *pediatric* patient, some specific nursing actions are as follows: (1) If needed, mix medications in a substance or fluid other than essential foods (e.g., milk, orange juice, or cereal) because the child may develop a dislike for the essential food item(s). Instead, find a liquid or food item that may be used to make the medication(s) taste better. Sherbet or flavored ice cream is often used. Only resort to this intervention if the patient cannot swallow the dosage form or if the taste needs to be made more palatable. (2) Do not add drug(s) to fluid in a cup or bottle because the amount of drug consumed would then be impossible to calculate if the entire amount of fluid is not consumed. (3) Always document special techniques of drug administration so that others involved in the patient's care may benefit from the suggestion. For example, if the child takes an unpleasant-tasting pill, liquid, or tablet after eating a frozen popsicle, then this information would be valuable to another caregiver. (4) Unless contraindicated, add small amounts of water or fluids to elixirs to enhance the child's tolerance of the medication. Remember that it is essential for the child to take the entire volume, so remain cautious with this practice and only use an amount of fluid mixture that you know the child will tolerate. (5) Avoid using the word *candy* in place of the word *drug* or *medication*. Medications must be called *medicines* and their dangers made known to children. Taking medications is no game, and children must understand this for their own safety! (6) Keep all medications out of the reach of children of all ages. Be sure that parents and other family members in the same household understand this and request child-protective lids or tops for their medications. Childproof locks or closures may also be used on cabinets holding medications. (7) Inquire about how the child usually takes medication (e.g., preference of liquid versus pill or tablet dosage forms) and whether there are any helpful hints from the family/caregiver that may be helpful. See the Patient-Centered Care: Lifespan Considerations for the Pediatric Patient box on p. 41 for further information on medication administration beginning with infancy through adolescence. For more information about dosage calculations for medication administration in pediatric patients, an online site providing examples and programs to help with pediatric drug dosage calculations is available at http://www.testandcalc.com and http://www.mapharm.com/dosage_calc.htm.

Encourage *elderly* patients to take medications as directed and not to discontinue them or double up on doses unless recommended or ordered to do so by their health care provider/prescriber. The patient or caregiver must understand the treatment- and/or medication-related instructions, especially those related to safety measures, such as keeping all medications out of the reach of children. Transdermal patches provide a different challenge in that if they fall off onto the floor or bedding, a child or infant in that environment may have accidental exposure to the effects of the medication. Serious adverse reactions have been reported concerning the accidental adhering of a transdermal patch to a child/infant while crawling or playing on the floor/carpet. Toxic and even fatal reactions may occur depending on the medication and dosage. Provide written and oral instructions concerning the drug name, action, purpose, dosage, time of administration, route, adverse effects, safety of administration, storage, interactions, and any cautions about or contraindications to its use. Remember that simple is always best! Always try to find ways to make the patient's therapeutic regimen easy to understand. Always be alert to polypharmacy, and be sure the patient or caregiver understands the dangers of multiple drug use. Patient education may prove to be helpful in preventing and/or minimizing problems associated with polypharmacy. If a nurse advocate or a nurse practitioner with prescription privileges has the opportunity to review the patient's chart, simplified written instructions must be provided with the purpose of the drug, how to best take the medication(s), and a list of drug interactions and adverse effects. Information must be provided in bold, large print. Among the specific interventions that have proved to be helpful in promoting medication safety in the elderly is the use of the Beers criteria (see the Evidence-Based Practice box on p. 45). These criteria provide a systematic way of identifying prescription medications that are potentially harmful to elderly patients. The prescriber and nurse must constantly remember that clinical judgment and knowledge base are important in making critical decisions about a patient's care and drug therapy. In addition, keeping abreast of evidence-based nursing, such as application of the Beers criteria, is important for the nurse to remain current in clinical nursing practice. Specific guidelines for medication administration by various routes are presented in detail in the photo atlas in Chapter 9.

In summary, drug therapy across the lifespan must be well thought out, with full consideration to the patient's age, gender, cultural background, ethnicity, medical history, and medication profile. When all phases of the nursing process and the specific lifespan considerations discussed in this chapter are included, there is a better chance of decreasing adverse effects, reducing risks to the patient, and increasing drug safety.

CASE STUDY

Polypharmacy and the Elderly

R.M., a 77-year-old retired librarian, sees several physician specialists for a variety of health problems. She uses the pharmacy at a large discount store but also has prescriptions filled at a nearby pharmacy, which she uses when she does not feel like going into the larger store. Her medication list is as follows:

Thiazide diuretic, prescribed for peripheral edema
Potassium tablets, prescribed to prevent hypokalemia
Beta blocker, prescribed for hypertension
Warfarin, taken every evening because of a history of deep vein thrombosis
Thyroid replacement hormone because of a history of hypothyroidism
Multivitamin tablet for seniors

1. What medications may cause problems for R.M.? Explain your answer.
2. What measures can be taken to reduce these problems?

R.M. visits the pharmacy to pick up some medications for a cold. She has chosen a popular over-the-counter decongestant, an antihistamine preparation, and a nonsteroidal antiinflammatory drug for her "aches and pains."

3. Should she use these medications? If not, what advice would you give to her about choosing over-the-counter medications?

For answers, see http://evolve.elsevier.com/Lilley.

EVALUATION

When dealing with lifespan issues as related to drug therapy, observation and monitoring for therapeutic effects as well as adverse effects is critical to safe and effective therapy. You must know the patient's profile and history as well as information about the drug. The drug's purpose, specific use in the patient, simply stated actions, dose, frequency of dosing, adverse effects, cautions, and contraindications need to be listed and kept available at all times. This information will allow more comprehensive monitoring of drug therapy, regardless of the age of the patient.

KEY POINTS

- There are many age-related pharmacokinetic effects that lead to dramatic differences in drug absorption, distribution, metabolism, and excretion in the young and the elderly. At one end of the lifespan is the pediatric patient, and at the other end is the elderly patient, both of whom are very sensitive to the effects of drugs.
- Most common dosage calculations use the milligrams per kilogram formula related to age; however, BSA is also used in drug calculations, and organ maturity is considered. It is important for the nurse to know that many elements besides the mathematical calculation itself contribute to safe dosage calculations. Safety must remain the first priority and concern with consideration of the Six Rights of medication administration (see Chapter 1).
- The percentage of the population older than 65 years of age continues to grow, and polypharmacy remains a concern with the increasing number of elderly patients. A current list of all medications and drug allergies must be on their person or with their family/caregiver at all times.
- Your responsibility is to act as a patient advocate as well as to be informed about growth and developmental principles and the effects of various drugs during the lifespan and in various phases of illness.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is reviewing factors that influence pharmacokinetics in the neonatal patient. Which factor puts the neonatal patient at risk with regard to drug therapy?
- **a** Immature renal system
- **b** Hyperperistalsis in the GI tract
- **c** Irregular temperature regulation
- **d** Smaller circulatory capacity

2 The physiologic differences in the pediatric patient compared with the adult patient affect the amount of drug needed to produce a therapeutic effect. The nurse is aware that one of the main differences is that infants have
- **a** increased protein in circulation.
- **b** fat composition lower than 0.001%.
- **c** more muscular body composition.
- **d** water composition of approximately 75%.

3 While teaching a 76-year-old patient about the adverse effects of his medications, the nurse encourages him to keep a journal of the adverse effects he experiences. This intervention is important for the elderly patient because of which alterations in pharmacokinetics?
- **a** Increased renal excretion of protein-bound drugs
- **b** More alkaline gastric pH, resulting in more adverse effects
- **c** Decreased blood flow to the liver, resulting in altered metabolism
- **d** Less adipose tissue to store fat-soluble drugs

4 When the nurse is reviewing a list of medications taken by an 88-year-old patient, the patient says, "I get dizzy when I stand up." She also states that she has nearly fainted "a time or two" in the afternoons. Her systolic blood pressure drops 15 points when she stands up. Which type of medication may be responsible for these effects?
- **a** NSAIDs
- **b** Cardiac glycosides
- **c** Anticoagulants
- **d** Antihypertensives

5 A pregnant patient who is at 32 weeks' gestation has a cold and calls the office to ask about taking an over-the-counter medication that is rated as pregnancy category A. Which answer by the nurse is correct?
- **a** "This drug causes problems in the human fetus, so you should not take this medication."
- **b** "This drug may cause problems in the human fetus, but nothing has been proven in clinical trials. It is best not to take this medication."
- **c** "This drug has not caused problems in animals, but no testing has been done in humans. It is probably safe to take."
- **d** "Studies indicate that there is no risk to the human fetus, so it is okay to take this medication as directed if you need it."

6 The nurse is preparing to administer an injection to a preschool-age child. Which approaches are appropriate for this age group? (Select all that apply.)
- **a** Explain to the child in advance about the injection.
- **b** Provide a brief, concrete explanation about the injection.
- **c** Encourage participation in the procedure.
- **d** Make use of magical thinking.
- **e** Provide comfort measures after the injection.

7 The nurse is preparing to give an oral dose of acetaminophen (Tylenol) to a child who weighs 12 kg. The dose is 15 mg/kg. How many milligrams will the nurse administer for this dose?

1. a, 2. d, 3. c, 4. d, 5. d, 6. b, d, e, 7. 180 mg

- Review Questions for the NCLEX® Examination
- Unfolding Case Studies

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the various cultural factors that may influence an individual's response to medications.
2 Identify various cultural phenomena affecting health care and use of medications.
3 List the drugs that are more commonly associated with variations in response due to cultural and racial/ethnic factors.
4 Briefly discuss the important components of drug legislation at the state and federal levels.
5 Provide examples of how drug legislation impacts drug therapy, professional nursing practice, and the nursing process.
6 Discuss the various categories of controlled substances, and give specific drug examples in each category.
7 Identify the process involved in the development of new drugs, including the investigational new drug application, the phases of investigational drug studies, and the process for obtaining informed consent.
8 Discuss the nurse's role in the development of new and investigational drugs and the informed consent process.
9 Discuss the ethical principles and how they apply to pharmacology and the nursing process.
10 Identify the ethical principles involved in making an ethical decision.
11 Develop a nursing care plan that addresses the cultural, legal, and ethical care of patients with a specific focus on drug therapy and the nursing process.

KEY TERMS

Bias Any systematic error in a measurement process. One common effort to avoid bias in research studies involves the use of blinded study designs (see later). (p. 57)

Black box warning A type of warning that appears in a drug's prescribing information and is required by the U.S. Food and Drug Administration (FDA) to alert prescribers of serious adverse events that have occurred with the given drug. (p. 57)

Blinded investigational drug study A research design in which the subjects are purposely unaware of whether the substance they are administered is the drug under study or a placebo. This method serves to minimize bias on the part of research subjects in reporting their body's responses to investigational drugs. (p. 57)

Controlled substances Any drugs listed on one of the "schedules" of the Controlled Substance Act (also called *scheduled drugs*). (p. 55)

Culture The customary beliefs, social forms, and material traits of a racial, religious, or social group. (p. 51)

Double-blind investigational drug study A research design in which both the investigator(s) and the subjects are purposely unaware of whether the substance administered to a given subject is the drug under study or a placebo. This method minimizes bias on the part of both the investigator and the subject. (p. 57)

Drug polymorphism Variation in response to a drug because of a patient's age, gender, size, and/or body composition. (p. 52)

KEY TERMS—cont'd

Ethics The rules of conduct recognized in respect to a particular class of human actions or a particular group. (p. 59)

Ethnicity Relating to or characteristics of a human group having racial, religious, language, and other traits in common. (p. 51)

Ethnopharmacology The study of the effect of ethnicity on drug responses, specifically drug absorption, metabolism, distribution, and excretion (i.e., pharmacokinetics; see Chapter 2) as well as the study of genetic variations to drugs (i.e., pharmacogenetics). (p. 51)

Expedited drug approval Acceleration of the usual investigational new drug approval process by the FDA and pharmaceutical companies, usually for drugs used to treat life-threatening diseases. (p. 55)

Health Insurance Portability and Accountability Act (HIPAA) An act that protects health insurance coverage for workers and their families when they change jobs. It also protects patient information. If confidentiality of a patient is breached, severe fines may be imposed. (p. 54)

Informed consent Written permission obtained from a patient consenting to a specific procedure (e.g., receiving an investigational drug), after the patient has been given information regarding the procedure deemed necessary for him or her to make a sound or "informed" decision. (p. 56)

Investigational new drug (IND) A drug not yet approved for marketing by the FDA but available for use in experiments to determine its safety and efficacy. (p. 56)

Investigational new drug application An application that must be submitted to the FDA before a drug can be studied in humans. (p. 56)

Legend drugs Another name for prescription drugs. (p. 55)

Malpractice A special type of negligence or the failure of a professional and/or individual with specialized education and training to act in a reasonable and prudent way. (p. 58)

Narcotic A legal term established under the Harrison Narcotic Act of 1914. It originally applied to drugs that produced insensibility or stupor, especially the opioids (e.g., morphine, heroin). The term is currently used in clinical settings to refer to any medically administered controlled substance and in legal settings to refer to any illicit or "street" drug. (p. 55)

Negligence The failure to act in a reasonable and prudent manner or failure of the nurse to give the care that a reasonably prudent (cautious) nurse would render or use under similar circumstances. (p. 58)

Orphan drugs A special category of drugs that have been identified to help treat patients with rare diseases. (p. 55)

Over-the-counter drugs Drugs available to consumers without a prescription. Also called nonprescription drugs. (p. 53)

Placebo An inactive (inert) substance (e.g., saline, distilled water, starch, sugar) that is not a drug but is formulated to resemble a drug for research purposes. (p. 57)

Race Descendants of a common ancestor; a tribe, family, or people believed to belong to the same lineage. (p. 51)

CULTURAL CONSIDERATIONS

The United States is a very culturally diverse nation as evidenced by its constantly and rapidly changing demographics. Minority groups, being approximately one third of the U.S. population, are expected to become the majority by 2042 and will represent 54% of the nation's population by 2050. That is, the combined population of all groups except non-Hispanic, single-race whites is projected to be approximately 235 million out of a total U.S. population of 439 million in 2050. The non-Hispanic, single-race white population is projected to be only slightly larger in 2050 (at about 203 million) than in 2010. It is predicted that nearly one in three U.S. residents will be Hispanic by 2050. The African-American population is projected to increase from 41 million (about 14%) to about 66 million (or 15%) by 2050. The Asian population is projected to increase from 15 million to about 40 million, rising from a current 5.1% to 9.2% of the total. Of the remaining racial groups, Native Americans and Alaska Natives are projected to increase in number from 4.9 million to 8.6 million (or from 1.6% to 2% of the total population). The population of Native Hawaiians and other Pacific Islanders is expected to more than double, from 1.1 million to 2.6 million. The number of people who identify themselves as being of two or more races is projected to more than triple, from about 5 million to 16 million.

The field of **ethnopharmacology** provides an expanding body of knowledge for understanding the specific impact of cultural factors on patient drug response. It is hampered, however, by the lack of clarity in terms such as **race, ethnicity,** and **culture.** For example, although some researchers have used the term *Hispanic* to encompass geographic groups as diverse as Puerto Ricans, Mexicans, and Peruvians, other researchers have used it to denote a specific racial group. It is impossible to know a patient's genotype by either physical appearance or health care history.

It is essential to be up to date in your knowledge of the nursing process and understanding of the art and science of professional nursing practice. Cultural assessment needs to be part of the assessment phase of the nursing process. Acknowledgment and acceptance of the influences of a patient's cultural beliefs, values, and customs is necessary to promote optimal health and wellness. Some relevant practices are discussed in the Patient-Centered Care: Cultural Implications box on p. 52.

Influence of Ethnicity and Genetics on Drug Response

The concept of polymorphism is critical to an understanding of how the same drug may result in very different responses in different individuals. For example, why does a Chinese patient

PATIENT-CENTERED CARE: CULTURAL IMPLICATIONS

A Brief Review of Common Practices among Selected Cultural Groups

CULTURAL GROUP	COMMON HEALTH BELIEFS AND ALTERNATIVE HEALERS	VERBAL AND NONVERBAL COMMUNICATION; TOUCH/TIME	FAMILY	BIOLOGIC VARIATIONS
African	Practice folk medicine; employ "root doctors" as healers; spiritualist Use herbs, oils, and roots	Asking personal questions of someone met for the first time seen as intrusive and not proper Direct eye contact seen as rude Present oriented	Have close extended family ties Women play important key role in making health care decisions	Keloid formation, sickle cell anemia, lactose intolerance, skin color
Asian	Believe in traditional medicine; hot and cold foods; herbs/teas/soups; use of acupuncturist, acupressurist, and herbalist	High respect of others, especially of individuals in positions of authority Not usually comfortable with custom of shaking hands with those of opposite sex Present oriented	Have close extended family ties; family needs more important than individual needs	Many drug interactions, lactose intolerance, skin color, thalassemia
Hispanic	View health as a result of good luck and living right; see illness as a result of doing a bad deed Heat, cold, and herbs used as remedies Use curandero, spiritualist	Expressing negative feelings seen as impolite Avoiding eye contact seen as respectful and attentive Touching acceptable between two persons in conversation	Have close extended family ties; all family members involved in health care decisions	Lactose intolerance, skin color
Native American	Believe in harmony with nature and ill spirits causing disease Use medicine man	Speak in low tone of voice Light touch of a person's hand is preferred versus a firm handshake as a greeting Present oriented	Have close extended family ties; emphasis on family	Lactose intolerance, skin color, cleft uvula problems

Data from Bhui K, Dinos S: Health beliefs and culture: Essential considerations for outcome measurement, *Dis Manag Health Out* 16(6):411-419, 2008; Giger JN, Davidhizar RE: *Transcultural nursing: assessment and intervention*, ed 4, St Louis, 2004, Mosby.

require lower dosages of an antianxiety drug than a white patient? Why does an African-American patient respond differently to antihypertensives than a white patient? **Drug polymorphism** refers to the effect of a patient's age, gender, size, body composition, and other characteristics on the pharmacokinetics of specific drugs. Factors contributing to drug polymorphism may be categorized into environmental factors (e.g., diet and nutritional status), cultural factors, and genetic (inherited) factors.

Medication response depends greatly on the level of the patient's compliance with the therapy regimen. Yet compliance may vary depending on the patient's cultural beliefs, experiences with medications, personal expectations, family expectations and influence, and level of education. Compliance is not the only issue, however. Prescribers must also be aware that some patients use alternative therapies, such as herbal and homeopathic remedies, that can inhibit or accelerate drug metabolism and therefore alter a drug's response.

Environmental and economic factors (e.g., diet) can contribute to drug response. For example, a diet high in fat has been documented to increase the absorption of the drug griseofulvin (an antifungal drug). Malnutrition with deficiencies in protein, vitamins, and minerals may modify the functioning of metabolic enzymes, which may alter the body's ability to absorb or eliminate a medication.

Historically, most clinical drug trials were conducted using white men, often college students, as research subjects. However, there are data that demonstrate the impact of genetic factors on drug *pharmacokinetics* and drug *pharmacodynamics* or drug response (see Chapter 8). Some individuals of European and African descent are known to be *slow acetylators.* This means that their bodies attach acetyl groups to drug molecules at a relatively slow rate, which results in elevated drug concentrations. This situation may warrant lower drug dosages. A classic example of a drug whose metabolism is affected by this characteristic is the antituberculosis drug isoniazid. In contrast, some patients of Japanese and Inuit descent are more rapid acetylators and metabolize drugs more quickly, which predisposes the patient to subtherapeutic drug concentrations and may require higher drug dosages.

Levels of the cytochrome P-450 enzymes (see Chapter 2) are also known to vary between ethnic groups. This has effects on the ability to metabolize many drugs. Most psychotropic drugs (see Chapter 16) are metabolized in the liver in a two-phase process. Cytochrome P-450 enzymes often control phase I of the hepatic metabolism of both antidepressants and antipsychotic drugs. This can affect plasma drug levels, and therefore the intensity of drug response, at different doses. Groups of Asian patients have been shown to be "poor metabolizers" of these drugs and often require lower dosages to achieve desired therapeutic effects. In contrast, white patients are more likely to be classified as "ultrarapid metabolizers" and may require higher drug dosages.

Variations are also reported between ethnic groups in the occurrence of adverse effects. For example, African American patients taking lithium may need to be monitored more closely

for symptoms of drug toxicity, because serum drug levels may be higher than in white patients given the same dosage. Likewise, Japanese and Taiwanese patients may require lower dosages of lithium. For the treatment of hypertension, thiazide diuretics appear to be more effective in African Americans than in whites. Several additional examples of racial and ethnic differences in drug response are outlined in the Patient-Centered Care: Cultural Implications box below.

PATIENT CENTERED-CARE: CULTURAL IMPLICATIONS

Examples of Varying Drug Responses in Different Racial or Ethnic Groups

RACIAL OR ETHNIC GROUP	DRUG CLASSIFICATION	RESPONSE
African Americans	Antihypertensive drugs	African Americans respond better to diuretics than to beta blockers and angiotensin-converting enzyme inhibitors. African Americans respond less effectively to beta blockers. African Americans respond best to calcium channel blockers, especially diltiazem. African Americans respond less effectively to single-drug therapy.
Asians and Hispanics	Antipsychotic and antianxiety drugs	Asians need lower dosages of certain drugs such as haloperidol. Asians and Hispanics respond better to lower dosages of antidepressants. Chinese require lower dosages of antipsychotics. Japanese require lower dosages of antimanic drugs.

NOTE: The comparison group for all responses is whites.

Individuals throughout the world share common views and beliefs regarding health practices and medication use. However, specific cultural influences, beliefs, and practices do exist. Awareness of cultural differences is critical for the care of patients because of the constantly changing U.S. demographics. As a result of these changes, attending to each patient's cultural background helps to ensure safe and quality nursing care, including medication administration.

For example, some African Americans have health beliefs and practices that include an emphasis on proper diet and rest; the use of herbal teas, laxatives, protective bracelets; and the use of folk medicine, prayer, and the "laying on of hands." Reliance on various home remedies can also be an important component of their health practices. Some Asian-American patients, especially the Chinese, believe in the concepts of *yin* and *yang*. Yin and yang are opposing forces that lead to illness or health, depending on which force is dominant in the individual and whether the forces are balanced. Balance produces healthy states. Other common health practices of Asian Americans include use of acupuncture, herbal remedies, and heat. All such beliefs and practices need to be considered—especially when the patient values their use more highly than the use of medications. Many of these beliefs are strongly grounded in religion. The Asian and Pacific Islander racial/ethnic group also includes Thais, Vietnamese, Filipinos, Koreans, and Japanese, among others.

Some Native Americans believe in preserving harmony with nature or keeping a balance between the body and mind and the environment to maintain health. Ill spirits are seen as the cause of disease. The traditional healer for this culture is the medicine man, and treatments vary from massage and application of heat to acts of purification. Some individuals of Hispanic descent view health as a result of good luck and living right and illness as a result of bad luck or committing a bad deed. To restore health, these individuals seek a balance between the body and mind through the use of cold remedies or foods for "hot" illnesses (of blood or yellow bile) and hot remedies for "cold" illnesses (of phlegm or black bile). Hispanics may use a variety of religious rituals for healing (e.g., lighting of candles), which may also be practiced by adherents of other religions and/or belief systems. It is very important to remember that these beliefs vary from patient to patient; therefore, consult with the patient rather than assume that the patient holds certain beliefs because he or she belongs to a certain ethnic group.

Barriers to adequate health care for the culturally diverse U.S. patient population include language, poverty, access, pride, and beliefs regarding medical practices. Medications may have a different meaning to different cultures, as would any form of medical treatment. Therefore, before any medication is administered, complete a thorough cultural assessment. This assessment includes questions regarding the following:

- Languages spoken, written, and understood; need for an interpreter
- Health beliefs and practices
- Past uses of medicine
- Use of herbal treatments, folk remedies, home remedies, or supplements
- Use of **over-the-counter drugs**
- Usual responses to illness
- Responsiveness to medical treatment
- Religious practices and beliefs (e.g., many Christian Scientists believe in taking no medications at all)
- Support from the patient's cultural community that may provide resources or assistance as needed, such as religious connections, leaders, family members, or friends
- Dietary habits

Cultural Nursing Considerations and Drug Therapy

It is important to be knowledgeable about drugs that may elicit varied responses in culturally diverse patients or those from different racial/ethnic groups. Varied responses may include

differences in therapeutic dosages and adverse effects, so that some patients may have therapeutic responses at lower dosages than are typically recommended. For example, in Hispanic individuals taking traditional antipsychotics, symptoms may be managed effectively at lower dosages than the usual recommended dosage range.

Another aspect of cultural care as it relates to drug therapy is the recognition that patterns of communication may differ based on a patient's race or ethnicity. Communication also includes the use of language, tone, volume, as well as spatial distancing, touch, eye contact, greetings, and naming format. It is important to assess (see Box 4-3) and apply these aspects of cultural and racial/ethnic variations to patient care and to drug therapy and the nursing process. One specific example of cultural diversity is the use of verb tense; some languages, such as the Chinese language, do not have numerous verb tenses as compared to the English language. Therefore, very precise instructions must be included in patient education about medication(s) and how to best and safely take them. Avoiding the use of contractions such as *can't, won't,* and *don't* is important with patients from other countries to prevent confusion. Instead, use of *cannot, will not,* and *do not* is recommended to improve understanding.

LEGAL CONSIDERATIONS

Prescription drug use is vital to treating and preventing illness. However, due to safety reasons, its use is regulated by several different agencies, including the Food and Drug Administration (FDA), The Drug Enforcement Agency (DEA), and individual state laws. Traditionally, only medical doctors (M.D.) and doctors of osteopathy (D.O.) had the privilege of prescribing medications. Dentists and podiatrists are also allowed to prescribe medications so long as it is within the scope of their practice. In some states, other health care professionals may also prescribe, including licensed physician's assistants (P.A.s) and advanced practice registered nurses (APRNs).

As the number and complexity of prescriptions continue to increase and technology continually changes, so do the laws regarding their use. With the ever-changing role of the professional nurse and other members of the health care team and with the increasing pace of technologic advances, each role becomes more complex. Even more autonomy has been gained by the professional nurse over his or her nursing practice. With this increasing autonomy comes greater liability and legal accountability; therefore, the professional nurse must be aware and duly consider this responsibility as he or she practices. Specific laws and regulations are discussed later and in the nursing process section of this chapter.

U.S. Drug and Related Legislation

Until the beginning of the twentieth century there were no federal rules and regulations in the United States to protect consumers from the dangers of medications. The various legislative interventions that have occurred have often been prompted by large-scale serious adverse drug reactions. One example is the sulfanilamide tragedy of 1937. Over 100 deaths occurred in the United States when people ingested a diethylene glycol solution of sulfanilamide that had been marketed as a therapeutic drug. Diethylene glycol is a component of automobile antifreeze solution, and the drug containing it was never tested for its toxicity. Another prominent example is the thalidomide tragedy that occurred in Europe between the 1940s and 1960s. Many pregnant women who took this sedative-hypnotic drug gave birth to seriously deformed infants.

A recent and significant piece of legislation is the **Health Insurance Portability and Accountability Act (HIPAA)** of 1996. HIPAA requires all health care providers, health insurance and life insurance companies, public health authorities, employers, and schools to maintain patient privacy regarding protected health information. Protected health information includes any individually identifying information such as patients' health conditions, account numbers, prescription numbers, medications, and payment information. Such information can be oral and/or recorded in any paper or electronic form. The primary purpose of federal legislation is to ensure the safety and efficacy of new drugs and, in the case of HIPAA, to protect patient confidentiality. Table 4-1 provides a timeline summary of major U.S. drug legislation.

New Drug Development

Research into and development of new drugs is an ongoing process. The pharmaceutical manufacturing industry is a multibillion-dollar industry. Pharmaceutical companies must continuously develop new and better drugs to maintain a competitive edge. The research required for the development of these new drugs may take several years. Hundreds of substances are isolated that never make it to market. Once a potentially beneficial drug has been identified, the pharmaceutical company must follow a very regulated, systematic process before the drug can be sold on the open market. This highly sophisticated process is regulated and carefully monitored by the Food and Drug Administration (FDA). The primary purpose of the FDA is to protect the patient and ensure drug effectiveness.

This U.S. system of drug research and development is one of the most stringent in the world. It was developed out of concern for patient safety and drug efficacy. Much time, funding, and documentation are required to ensure that these two very important objectives are met. Many drugs are marketed and used in foreign countries long before they receive approval for use in the United States. Drug-related calamities are more likely to be avoided by this more stringent drug approval system. The thalidomide tragedy mentioned earlier in the chapter, which resulted from the use of a drug that was marketed in Europe but not in the United States, is an illustrative example. A balance must be achieved between making new lifesaving therapies available and protecting consumers from potential drug-induced adverse effects. Historically, the FDA has had less regulatory authority over vitamin, herbal, and homeopathic preparations because they are designated as dietary supplements rather than drugs. In 1994, Congress passed the Dietary Supplement Health and Education Act, which requires manufacturers of such products at least to ensure their safety (although not necessarily their efficacy) and prohibits them from making any

TABLE 4-1 SUMMARY OF MAJOR U.S. DRUG AND RELATED LEGISLATION

NAME OF LEGISLATION (YEAR)	PROVISIONS/COMMENTS
Federal Food and Drugs Act (FFDA, 1906)	Required drug manufacturers to list on the drug product label the presence of dangerous and possibly addicting substances; recognized the *U.S. Pharmacopeia* and *National Formulary* as printed references standards for drugs
Sherley Amendment (1912) to FFDA	Prohibited fraudulent claims for drug products
Harrison Narcotic Act (1914)	Established the legal term **narcotic** and regulated the manufacture and sale of habit-forming drugs
Federal Food, Drug, and Cosmetic Act (FFDCA,1938; amendment to FFDA)	Required drug manufacturers to provide data proving drug safety with FDA review; established the investigational new drug application process (prompted by sulfanilamide elixir tragedy)
Durham-Humphrey Amendment (1951) to FFDCA	Established **legend drugs** or prescription drugs; drug labels must carry the legend, "Caution—Federal law prohibits dispensing without a prescription"
Kefauver-Harris Amendments (1962) to FFDCA	Required manufacturers to demonstrate both therapeutic efficacy *and* safety of new drugs (prompted by thalidomide tragedy)
Controlled Substance Act (1970)	Established "schedules" for **controlled substances** (Tables 4-2 and 4-3); promoted drug addiction education, research, and treatment
Orphan Drug Act (1983)	Enabled the FDA to promote research and marketing of **orphan drugs** used to treat rare diseases
Accelerated Drug Review Regulations (1991)	Enabled faster approval by the FDA of drugs to treat life-threatening illnesses (prompted by HIV/AIDS epidemic)
Health Insurance Portability and Accountability Act (1996)	More commonly known by its acronym, *HIPAA;* officially required all health-related organizations as well as schools to maintain privacy of protected health information
Medicare Prescription Drug Improvement and Modernization Act (2003)	More commonly known as *Medicare Part D;* provides seniors and disabled persons with an insurance benefit program for prescription drugs; the cost of medications is shared by the patient and the federal government

AIDS, Acquired immunodeficiency syndrome; *FDA,* Food and Drug Administration; *HIV,* human immunodeficiency virus.

unsubstantiated claims in the product labeling. For example, a product label may read "For depression" but cannot read "Known to cure depression." Reliable, objective information about these kinds of products is limited but is growing as more formal research studies are conducted. In 1998, Congress established the National Center for Complementary and Alternative Medicine as a new branch of the National Institutes of Health. The function of this center is to conduct rigorous scientific studies of alternative medical treatments and to publish the data from such studies. Consumer demand for alternative medicine products continues to drive this process. Patients must exercise caution in using such products and to communicate regularly with their health care providers regarding their use.

TABLE 4-2 CONTROLLED SUBSTANCES: SCHEDULE CATEGORIES

SCHEDULE	ABUSE POTENTIAL	MEDICAL USE	DEPENDENCY POTENTIAL
C-I	High	None	Severe physical and psychological
C-II	High	Accepted	Severe physical and psychological
C-III	Less than C-II	Accepted	Moderate to low physical or high psychological
C-IV	Less than C-III	Accepted	Limited physical or psychological
C-V	Less than C-IV	Accepted	Limited physical or psychological

U.S. Food and Drug Administration Drug Approval Process

The FDA is responsible for approving drugs for clinical safety and efficacy before they are brought to the market. There are stringent steps, each of which may take years, that must be completed before the drug can be approved. The FDA has made certain lifesaving investigational drug therapies available sooner than usual by offering an **expedited drug approval** process, also known as "fast track" approval. Acquired Immune Deficiency Syndrome (AIDS) was the first major public health crisis for which the FDA began granting expedited drug approval. This process allowed pharmaceutical manufacturers to shorten the approval process and allowed prescribers to give medications that showed promise during early phase I and phase II clinical trials to qualified patients with AIDS. In such cases, when a trial continues to show favorable results, the overall process of drug approval is hastened. The concept of expedited drug approval became controversial after the FDA-initiated manufacturer recall of the antiinflammatory drug rofecoxib (Vioxx) in 2004. This recall followed multiple case reports of severe cardiovascular events, including fatalities, associated with the use of this drug. Evidence then emerged suggesting that the FDA had granted approval for this drug without receiving the requisite safety data from its manufacturer. This unfortunate example has reduced the number of drugs approved via the expedited approval process. More information and specific drugs approved under this fast-track process can be found at http://www.fda.gov.

The drug approval process is quite complex and prolonged. It normally begins with *preclinical* testing phases, which include *in vitro* studies (using tissue samples and cell cultures) and animal studies. *Clinical* (human) studies follow the preclinical phase. There are four clinical phases. The drug is put on the

TABLE 4-3 CONTROLLED SUBSTANCES: CATEGORIES, DISPENSING RESTRICTIONS, AND EXAMPLES

SCHEDULE	DISPENSING RESTRICTIONS	EXAMPLES
C-I	Only with approved protocol	Heroin, lysergic acid diethylamide (LSD), marijuana, mescaline, peyote, psilocybin, and methaqualone
C-II	Written prescription only* No prescription refills Container must have warning label	Codeine, cocaine, hydromorphone, meperidine, morphine, methadone, secobarbital, pentobarbital, oxycodone, amphetamine, methylphenidate, and others
C-III	Written or oral prescription that expires in 6 months No more than five refills in a 6-month period Container must have warning label	Codeine with selected other medications (e.g., acetaminophen), hydrocodone, pentobarbital rectal suppositories, and dihydrocodeine combination products
C-IV	Written or oral prescription that expires in 6 months No more than five refills in a 6-month period Container must have warning label	Phenobarbital, chloral hydrate, meprobamate, benzodiazepines (e.g., diazepam, temazepam, lorazepam), dextropropoxyphene, pentazocine, and others
C-V	Written prescription or over the counter (varies with state law)	Medications generally for relief of coughs or diarrhea containing limited quantities of certain opioid controlled substances

*Legally permitted to be telephoned in for major emergencies only. If telephoned in, written prescription is required within 72 hours.

market after phase III is completed if an **investigational new drug application** submitted by the manufacturer is approved by the FDA. The collective goal of these phases is to provide information on the safety, toxicity, efficacy, potency, bioavailability, and purity of the new drug.

Preclinical Investigational Drug Studies

Current medical ethics still require that all new drugs undergo laboratory testing using both *in vitro* (cell or tissue) and animal studies before any testing in human subjects can be done. *In vitro* studies include testing of the response of various types of mammalian (including human) cells and tissues to different concentrations of the investigational drug. Various types of cells and tissues used for this purpose are collected from living or dead animal or human subjects (e.g., surgical or autopsy specimens). *In vitro* studies help researchers to determine early on if a substance might be too toxic for human patients. Many prospective new drugs are ruled out for human use during this preclinical phase of drug testing. However, a small percentage of the many drugs tested in this manner are referred for further clinical testing in human subjects.

Four Clinical Phases of Investigational Drug Studies

Before any testing on humans begins, the subjects must provide informed consent, and it must be documented. **Informed consent** involves the careful explanation to the human test patient or *research subject* of the purpose of the study, the procedures to be used, the possible benefits, and the risks involved. This explanation is followed by written documentation on a *consent form*. The informed consent document, or consent form, must be written in a language understood by the patient and must be dated and signed by the patient and at least one witness. Informed consent is always voluntary. By law, informed consent must be obtained more than a given number of days or hours before certain procedures are performed and must always be obtained when the patient is fully mentally competent. The informed consent process may be carried out by a nurse or other health care professional, depending on how a given study is designed.

Medical ethics dictate that participants in experimental drug studies be informed volunteers and not be coerced to participate in any way. Therefore, informed consent must be obtained from all patients (or their legal guardians) before they can be enrolled in an **investigational new drug (IND)** study. Some patients may have unrealistic expectations of the IND's usefulness. Often they have the misconception that because an investigational drug is new it must automatically be better than existing forms of therapy. Other volunteers may be reluctant to enter the study because they think they will be treated as "guinea pigs." Whatever the circumstances of the study, the research subjects must be informed of all potential hazards as well as the possible benefits of the new therapy. It must be stressed to all patients that involvement in IND studies is voluntary and that any individual can either decline to participate or quit the study at any time without affecting the delivery of any previously agreed-upon health care services.

Phase I. Phase I studies usually involve small numbers of healthy subjects rather than those who have the disease or ailment that the new drug is intended to treat. An exception might be a study involving a very toxic drug used to treat a life-threatening illness. In this case, the only study subjects might be those who already have the illness and for whom other viable treatment options may not be available. The purpose of phase I studies is to determine the optimal dosage range and the pharmacokinetics of the drug (i.e., absorption, distribution, metabolism, and excretion) and to ascertain if further testing is needed. Blood tests, urinalyses, assessments of vital signs, and specific monitoring tests are also performed.

Phase II. Phase II studies involve small numbers of volunteers who have the disease or ailment that the drug is designed to diagnose or treat. Study participants are closely monitored to determine the drug's effectiveness and identify any adverse effects. Therapeutic dosage ranges are refined during this phase. If no serious adverse effects occur, the study can progress to phase III.

Phase III. Phase III studies involve large numbers of patients who are followed by medical research centers and other types

of health care entities. The patients may be treated at the center itself or may be spread over a wider geographic area. The purpose of this larger sample size is to provide information about infrequent or rare adverse effects that may not yet have been observed during previous smaller studies. Information obtained during this clinical phase helps identify any risks associated with the new drug. To enhance objectivity, many studies are designed to incorporate a placebo. A **placebo** is an inert substance that is not a drug (e.g., normal saline). Placebos are given to a portion of the research subjects to separate out the real benefits of the investigational drug from the apparent benefits arising out of researcher or subject **bias** regarding expected or desired results of the drug therapy. A study incorporating a placebo is called a *placebo-controlled study*. If the study subject does not know whether the drug he or she is administered is a placebo or the investigational drug, but the investigator does know, the study is referred to as a **blinded investigational drug study.** In most studies, neither the research staff nor the subjects being tested know which subjects are being given the real drug and which are receiving the placebo. This further enhances the objectivity of the study results and is known as a **double-blind investigational drug study** because both the researcher and the subject are "blinded" to the actual identity of the substance administered to a given subject. Both drug and placebo dosage forms given to patients often look identical except for a secret code that appears on the medication itself and/or its container. At the completion of the study, this code is revealed or broken to determine which study patients received the drug and which were given the placebo. The code can also be broken before study completion by the principle investigator in the event of a clinical emergency that requires a determination of what substance individual patients received.

The three objectives of phase III studies are to establish the drug's clinical effectiveness, safety, and dosage range. After phase III is completed, the FDA receives a report from the manufacturer, at which time the drug company submits a new drug application (NDA). The approval of the application paves the way for the pharmaceutical company to market the new drug exclusively until the patent for the drug molecule expires. This is normally 17 years after discovery of the molecule and includes the 10- to 12-year period generally required to complete drug research. Therefore, a new drug manufacturer typically has 5 to 7 years after drug marketing to recoup research costs, which are usually in the hundreds of millions of dollars for a single drug.

Phase IV. Phase IV studies are postmarketing studies voluntarily conducted by pharmaceutical companies to obtain further proof of the therapeutic and adverse effects of the new drug. However, these studies may be mandated by the FDA. Data from such studies are usually gathered for at least 2 years after the drug's release. Often these studies compare the safety and efficacy of the new drug with that of another drug in the same therapeutic category. An example would be a comparison of a new nonsteroidal antiinflammatory drug with ibuprofen in the treatment of osteoarthritis. Some medications make it through all phases of clinical trials without causing any problems among study patients. However, when they are used in the larger general population, severe adverse effects may appear for the first time. If a pattern of severe reactions to a newly marketed drug begins to emerge, the FDA may request that the manufacturer of the drug issue a **black box warning** or a voluntary recall. A black box warning indicates that serious adverse effects have been reported with the drug. The drug can still be prescribed; however, the prescriber must be aware of the potential risk (see Table 4-1). In the rare occasion that the drug manufacturer refuses to recall the medication, and if the number and/or severity of reactions reaches a certain level, then the FDA may seek court action to condemn the product and allow it to be seized by legal authorities. Such an action, in effect, becomes an involuntary recall on behalf of the manufacturer. There are three designated classes of drug recall based on FDA response to postmarketing data for a given drug:

- **Class I:** The most serious type of recall—use of the drug product carries a reasonable probability of serious adverse health effects or death.
- **Class II:** Less severe—use of the drug product may result in temporary or medically reversible health effects, but the probability of lasting major adverse health effects is low.
- **Class III:** Least severe—use of the drug product is not likely to result in any significant health problems.

Notification by the FDA of a drug recall or drug warnings may be in the form of press releases, website announcements (http://www.fda.gov), or letters to health professionals. Such FDA items provide the latest information when a drug has newly identified hazards. The FDA has a voluntary program called MedWatch in which professionals are encouraged to report any adverse events seen with newly approved drugs. Information can be found at www.fda.gov/medwatch. Drug information of this kind is continually evolving as new events are observed and reported by clinicians and patients. Recommended actions change with time, so use the most current information available along with sound clinical judgment.

Legal Nursing Considerations and Drug Therapy

State and federal legislation dictate the boundaries for professional nursing practice. Standards of care and nurse practice acts identify the definition of the scope and role of the professional nurse (Box 4-1). Nurse practice acts further define/identify: (1) the scope of nursing practice, (2) expanded nursing roles, (3) educational requirements for nurses, (4) standards of care, (5) minimally safe nursing practice, and (6) differences between nursing and medical practice. In addition, state boards of nursing define specific nursing practices such as rules concerning the administration of intravenous therapy. Additionally, guidelines from professional nursing groups (American Nurses Association), nursing specialty groups, institutional policies and procedures, and state/federal hospital licensing laws all help to identify the legal boundaries of nursing practice. There is also case law or common law consisting of prior court rulings that affect professional nursing practice.

The American Nurses Association (ANA) has developed standards for nursing practice, policy statements, and similar resolutions. The standards describe the scope, function, and role of the nurse and establish clinical practice standards. The Joint Commission requires that accredited hospitals fulfill certain

BOX 4-1 NURSE PRACTICE ACTS

Nurse Practice Acts (NPAs) are state laws that are instrumental in defining the scope of nursing practice and protect public health, safety, and welfare. In each state, the law directs entry into nursing practice, defines the scope of practices, and identifies disciplinary actions. State boards of nursing oversee this statutory law. NPAs are the most significant part of legislation as related to professional nursing practice. Together, it is NPAs and common law that define nursing practice. The National Council of State Boards of Nursing maintain an online database of each state's NPA, and each state has a website where the NPAs are defined and outlined. For example, if the nurse is practicing in Missouri, Virginia, or West Virginia, the websites are as follows: Missouri: http://pr.mo.gov/nursing-rules-statutes.asp; Virginia: www.dhp.virginia.gov/nursing/nursing_laws_regs.htm; West Virginia: http://www.wvrnboard.com/images/pdf/6707.pdf.

standards with regard to nursing practice. One such requirement is that these institutions must have written policies and procedures. These policies are usually quite specific and are contained in policy and procedures manuals found on most nursing units. For example, a policy and procedure will outline the steps to take when changing a dressing or administering a medication. The nurse must know the policies and procedures of the employing institution, because if the nurse is involved in a lawsuit, these are one of the standards by which the nurse will be measured. Nursing specialty organizations also define standards of care for nurses who are certified in specialty areas, such as oncology, surgical care, or critical care. Standards of care help to determine whether a nurse is acting appropriately when performing professional duties. It is critical to safe nursing practice to remain up to date on the ever-changing obligations and standards of practice and care. If standards of care are not met, the nurse becomes liable for **negligence** and **malpractice** (Box 4-2). Current nursing literature remains an authoritative resource for information on new standards of care. State governments and/or state boards of nursing have websites that include links to specific nurse practice acts and standards of care.

TEAMWORK AND COLLABORATION: LEGAL AND ETHICAL PRINCIPLES

Ethical Terms Related to Nursing Practice

Autonomy: Self-determination and the ability to act on one's own; related nursing actions include promoting a patient's decision making, supporting informed consent, and assisting in decisions or making a decision when a patient is posing harm to himself or herself.

Beneficence: The ethical principle of doing or actively promoting good; related nursing actions include determining how the patient is best served.

Confidentiality: The duty to respect privileged information about a patient; related nursing actions include not talking about a patient in public or outside the context of the health care setting.

Justice: The ethical principle of being fair or equal in one's actions; related nursing actions include ensuring fairness in distributing resources for the care of patients and determining when to treat.

Nonmaleficence: The duty to do no harm to a patient; related nursing actions include avoiding doing any deliberate harm while rendering nursing care.

Veracity: The duty to tell the truth; related nursing actions include telling the truth with regard to placebos, investigational new drugs, and informed consent.

BOX 4-2 AREAS OF POTENTIAL LIABILITY FOR NURSES

AREA	EXAMPLES RELATED TO DRUG THERAPY AND THE NURSING PROCESS
Failure to assess/evaluate	Failure to see significant changes in patient's condition after taking a medication; Failure to report the changes in condition after medication; Failure to take a complete medication history and nursing assessment/history; Failure to monitor patient after medication administration
Failure to ensure safety	Lack of adequate monitoring; Failure to identify patient allergies and other risk factors related to medication therapy; Inappropriate drug adminstration technique; Failure to implement appropriate nursing actions based on a lack of proper assessment of patient's condition
Medication errors	Failure to clarify unclear medication order; Failure to identify and react to adverse drug reactions; Failure to be familiar with medication prior to its administration; Failure to maintain level of professional nursing skills for current practice; Failure to identify patient's identity prior to drug administration; Failure to document drug administration in medication profile

The legal-ethical dimensions of professional nursing care are also addressed in the legislation passed to amplify the guidelines contained in the HIPAA (1996). Under these federal regulations (see p. 54), the privacy of patient information is protected, and standards are included for the handling of electronic data about patients. HIPAA also defines the rights and privileges of patients in order to protect privacy without diminishing access to quality health care. The assurance of privacy—even prior to establishment of the HIPAA guidelines—was based on the principle of respect of an individual's right to determine when, to what extent, and under what circumstances private information can be shared or withheld from others, including family members. In addition, confidentiality must be preserved; that is, the individual identities of patients or research study participants are not to be linked to information they provide and cannot be publicly divulged. HIPAA addresses the issues of confidentiality and privacy by prohibiting prescribers, nurses, and other health care providers from sharing with others any patient health care information, including laboratory results, diagnoses, and prognoses, without the patient's consent. Conflicting obligations arise when a patient wants to keep information away from insurance companies, and matters remain complicated and challenging in the era of improving technology and computerization of medical records. Health care facilities continue to work diligently, however, to adhere to HIPAA guidelines and use special access codes to limit who can access information in computerized documents and charts.

In summary, federal and state legislation, standards of care, and nurse practice acts provide the legal framework for safe nursing practice, including drug therapy and medication

administration. Further, as discussed in Chapter 1, the standard "Six Rights" of medication administration are yet another measure for ensuring safety and adherence to laws necessary for protecting the patient. Chapter 1 also discusses other patient rights that are part of the standards of practice of every licensed registered nurse and every student studying the art and science of nursing.

ETHICAL CONSIDERATIONS

Decisions in health care are seldom made independently of other people and are made with consideration of the patient, family, nurses, and other members of the health care team. All members of the health care team must make a concentrated effort to recognize and understand their own values and be considerate, nonjudgmental, and respectful of the values of others and **ethics.** The use of drug therapy has evolved from just administering whatever was prescribed to providing responsible drug therapy for the purpose of achieving defined outcomes that improve a patient's quality of life.

Ethical principles are useful strategies for members of the health care team (e.g., physician, pharmacist, nurse) and include standards or truths on which ethical actions are made. Some of the most useful principles in nursing and health care, specifically drug therapy, include autonomy, beneficence, nonmaleficence, and veracity (see the Teamwork and Collaboration: Legal and Ethical Principles box on p. 58). However, day-to-day practice in nursing and health care pose many potential ethical conflicts. Each situation is different and requires compassionate and humane solutions. When answers to ethical dilemmas remain unclear and ethical conflict occurs, then the appropriate action must be based on ethical principles.

TEAMWORK AND COLLABORATION: LEGAL AND ETHICAL PRINCIPLES

Elements of Liability for Nursing Malpractice

ELEMENT	EXAMPLE
Duty	Being responsible for accurate assessment of a patient's intravenous (IV) and site of IV during caustic drug infusion and the timely reporting of changes in the patient's condition.
Breach of duty	Nurse does not notice that the IV site is swollen, red, painful, and warm to touch nor that the IV has quit infusing properly.
Causation	Failure of the nurse to note the signs and symptoms of extravasation at IV site (with a chemotherapy drug or other caustic drug) that results in the need for skin grafting.
Damage	Extensive skin and nerve damage with several surgical skin grafts resulting in limited use of arm.

Ethical Nursing Considerations and Drug Therapy

Ethical nursing practice is based on fundamental principles such as beneficence, autonomy, justice, veracity, and confidentiality. The American Nurses Association (ANA) *Code of Ethics for Nurses* (available at www.nursingworld.org/codeofethics) and the International Council of Nurses (ICN) *Code of Ethics for Nurses* serve as frameworks of practice for all nurses and as ethical guidelines for nursing care (see the Teamwork and Collaboration: Legal and Ethical Principles box on the ICN *Code of Ethics for Nurses* below). Adherence to these ethical principles and codes of ethics ensures that the nurse is acting on behalf of the patient and with the patient's best interests at heart. As a professional, the nurse has the responsibility to provide safe nursing care to patients regardless of the setting, person, group, community, or family involved. Although it is not within the nurse's realm of ethical and professional responsibility to impose his or her own values or standards on the patient, it *is* within the nurse's realm to provide information and to assist the patient in making decisions regarding health care.

The nurse also has the right to refuse to participate in any treatment or aspect of a patient's care that violates the nurse's personal ethical principles. However, this must be done without deserting the patient, and in some facilities the nurse may be transferred to another patient care assignment only if the transfer is approved by the nurse manager or nurse supervisor. The nurse must always remember, however, that the ANA *Code of Ethics for Nurses* and professional responsibility and accountability require the nurse to provide nonjudgmental nursing care from the start of the patient's treatment until the time of the patient's discharge. If transferring to a different assignment is not an option because of institutional policy and because of the increase in the acuteness of patients' conditions and the high patient-to-nurse workload, the nurse must always act in the

TEAMWORK AND COLLABORATION: LEGAL AND ETHICAL PRINCIPLES

***International Council of Nurses* Code of Ethics for Nurses**

The International Council of Nurses (ICN) first adopted the *ICN Code of Ethics for Nurses* in 1953; the *Code* has been revised several times since then, most recently in 2006. The 2006 revision is available in English, French, Spanish, and German. This Code is a guide for action based on social values and needs. The Preamble identifies the four fundamental responsibilities of nurses—promoting health, preventing illness, restoring health, and alleviating suffering—and points out that the need for nursing is universal. The Code makes it clear that inherent in professional nursing practice is respect for human rights including the right to life, dignity, and the right to be treated with respect. Nursing care is provided without regard to age, color, creed, culture, disability, illness, gender, nationality, politics, race, or social status. Nurses render services to the individual, family, and community. The *Code* describes four principal elements that provide a framework for the standards of ethical conduct it defines: nurses and people, nurses and practice, nurses and the profession, and nurses and co-workers. The *ICN Code of Ethics for Nurses* serves as a guide for action based on social values and needs and should be understood, internalized, and applied by nurses in all aspects of their work. Nurses can obtain assistance in translating these standards into conduct by discussing the *Code* with co-workers and collaborating with their national nurses' associations in the application of ethical standards in nursing practice, education, management, and research.

best interest of the patient while remaining an objective patient advocate. It is always the nurse's responsibility to provide the highest-quality nursing care and to practice within the professional standards of care. The ANA *Code of Ethics for Nurses*, the ICN *Code of Ethics for Nurses*, nurse practice acts, federal and state codes, ethical principles, and the previously mentioned legal principles and legislation are readily accessible and provide nurses with a sound, rational framework for professional nursing practice.

Another area of ethical consideration related to drug therapy and the nursing process is the use of placebos. A placebo is a drug dosage form (e.g., tablet or capsule) without any pharmacologic activity due to a lack of active ingredients. However, there may be reported therapeutic responses, and placebos have been found to be beneficial in certain patients, such as those being treated for anxiety. Placebos are also administered frequently in experimental studies of new drugs to evaluate and measure the pharmacologic effects of a new medicine compared with those of an inert placebo. Except in new drug studies, however, placebo use is often considered to be unethical and deceitful, possibly creating mistrust among the nurse, the prescriber, and the patient. In current clinical practice guidelines for pain management, the American Pain Society and the Agency for Health Care Policy and Research recommend the avoidance of placebos because their use is believed to be deceitful and to violate a patient's rights to the highest-quality care possible. Many health care agencies limit the use of placebos to research only to avoid the possible deceit and mistrust. If an order is received for a placebo for a patient, it is within the legal purview of a professional nurse to inquire about the order and to ask why a placebo is being prescribed; the order must never be taken lightly. If administration of the placebo is part of a research study or clinical trial, the informed consent process must be thorough and the patients must be informed of their right to (1) leave the study at any time without any pressure or coercion to stay, (2) leave the study without consequences to medical care, (3) receive full and complete information about the study, and (4) be aware of all alternative options and receive information on all treatments, including placebo therapy, being administered in the study.

NURSING PROCESS

Only information on the cultural considerations related to drug therapy and the nursing process will be presented in the following sections. Legal issues and ethical principles are integrated into professional nursing practice, whereas there are specific racial-ethnic (cultural) factors that need to be addressed in each phase of the nursing process.

ASSESSMENT

A thorough cultural assessment is needed for the provision of culturally competent nursing care. A variety of assessment tools and resources to incorporate into nursing care are provided in Box 4-3. However, various factors must be assessed and then applied to nursing care, specifically drug therapy and the nursing process. Some of the specific questions about the patient's physical, mental, and spiritual health include the following:

BOX 4-3 CULTURAL ASSESSMENT TOOLS AND RELATED WEB LINKS

- Several cultural assessment tools have been developed over the last decade. Madeline Leininger's Sunrise Model focuses on seven major areas of cultural assessment, including educational, economic, familial and social, political, technologic, religious and philosophic, and cultural values, beliefs, and practices.
- Other comprehensive cultural assessment tools include those developed by Andrews and Bowls, 1999; Friedman, Bowden, and Jones, 2003; Giger and Davidhizar, 1999; and Purnell and Pcaulanka, 1998. Rani Srivastava's (2006), found in *The Healthcare Professional's Guide to Clinical Cultural Competence* (Healthcare Professional's Guides), contains further discussion on how populations are viewed by health care workers and not through the use of ethno-cultural/religious labels.

MAINTAINING HEALTH

- *For physical health:* Where are special foods and clothing items purchased? What types of health education are of the patient's culture? Where does the patient usually obtain information about health and illness? Folklore? Where are health services obtained? Who are health care providers (e.g., physicians, nurse practitioners, community services organizations, health departments, healers)?
- *For mental health:* What are examples of culturally specific activities for the mind and for maintaining mental health, as well as beliefs about stress reduction, rest, and relaxation?
- *For spiritual health:* What are resources for meeting spiritual needs?

PROTECTING HEALTH

- *For physical health:* Where are special clothing and everyday essentials? What are examples of the patient's symbolic clothing, if any?
- *For mental health:* Who within the family and community teaches the roles in the patient's specific culture? Are there rules about avoiding certain persons or places? Are there special activities that must be performed?
- *For spiritual health:* Who teaches spiritual practices, and where can special protective symbolic objects such as crystals or amulets be purchased? Are they expensive, and how available are they for the patient when needed?

RESTORING HEALTH

- *For physical health:* Where are special remedies purchased? Can individuals produce or grow their own remedies, herbs, and so on? How often are traditional and nontraditional services obtained?
- *For mental health:* Who are the traditional and nontraditional resources for mental health? Are there culture-specific activities for coping with stress and illness?
- *For spiritual health:* How often and where are traditional and nontraditional spiritual leaders or healers accessed?*

*Modified from Spector RE: *Cultural care: guides to heritage assessment and health traditions,* ed 2, Upper Saddle River, NJ, 2000, Pearson/Prentice Hall, pp 24-25.

NURSING DIAGNOSES

1. Sleep deprivation related to a lack of adherence to cultural practices for encouraging stress release and sleep induction
2. Deficient knowledge (drug therapy) related to lack of experience and information about prescribed drug therapy
3. Risk for injury related to adverse and unpredictable reaction to drug therapy due to racial/ethnic or cultural factors

PLANNING

GOALS

1. Patient states the need for assistance with nonpharmacologic management of sleep deficit.
2. Patient requests written and verbal education about medication therapy.
3. Patient states need for information about the influence of racial/ethnic cultural factors upon specific drug therapy with emphasis on safety measures.

OUTCOME CRITERIA

1. Patient describes specific measures to enhance sleep patterns such as regular sleep habits, decrease in caffeine, meditation, relaxation therapy, journaling sleep patterns, and noting those measures that enhance or take away sleep.
2. Patient lists the various medication(s) with their therapeutic and adverse effects, dosage routes, and specific methods of adequate self administration, drug interactions, and any other special considerations.
3. Patient describes the impact of his or her racial/ethnic influences (e.g., metabolic enzyme differences) on specific medications and the resulting potential for increase in adverse effects, toxicity, and/or increased or decreased effectiveness (medication therapy).

IMPLEMENTATION

There are numerous interventions for implementation of culturally competent nursing care, but one very important requirement is that nurses maintain current knowledge about various cultures and related activities and practices of daily living, health beliefs, and emotional and spiritual health practices and beliefs. Specifically, knowledge about medications that may elicit varied responses due to racial/ethnic variations is most important with application of concepts of culturally competent care and ethnopharmacology to each patient care situation. Information of particular significance is the impact of cytochrome P-450 enzymes on certain phases of drug metabolism (see previous discussion on p. 27). Specific examples of differences in certain cytochrome P-450 enzymes can be found on p. 52. Consider additional factors, including the patient's verbal and nonverbal communication patterns; health belief systems; identification of health care provider and/or alternate healers; and interpretation of space, time, and touch. For example, with regard to adherence with the treatment regimen, Hispanics with hypertension have been found in some studies to be less likely than African Americans or whites to continue to take medication as prescribed, a finding that may reflect the patients' health belief systems. Other lifestyle decisions (e.g., use of tobacco or alcohol) may also affect responses to drugs and must be considered during drug administration. In addition, a patient's cultural background and associated socioeconomic status may create a situation that leads the patient to skip pills, split doses, and not obtain refills. This culture of poverty may be a causative factor in noncompliance and requires astute attention and individualized nursing actions.

EVALUATION

Culturally competent nursing care related to drug therapy may be evaluated through the actual compliance (or lack thereof) to the medication regimen(s). Safe, effective, and therapeutic self-administration of drugs with minimal to no adverse/toxic effects will be present only when the patient is treated as an individual and has a thorough understanding of the medication regimen.

CASE STUDY

Clinical Drug Trial

A patient on the cardiac telemetry unit has had a serious heart condition for years and has been through every known protocol for treatment. The cardiologist has admitted him to a telemetry unit for observation during a trial of a new investigational drug. The patient exclaims, "I have high hopes for this drug. I've read about it on the Internet and the reports are wonderful. I can't wait to get better!"

1. What is the best way for the nurse to answer this statement?

The physician meets with the patient and the nurse to explain the medication and how the double-blind experimental drug study will work. The purpose of the medication and potential hazards of the therapy are described, as well as the laboratory tests that will be performed to measure the drug's effectiveness. The physician then asks the nurse to have the patient sign the consent form. When the nurse goes to get the patient's signature, the patient says, "I'll sign it, but I really didn't understand what that doctor told me about the placebo."

2. Should the nurse continue with getting the consent form signed? Explain your answer.
3. The patient tells the nurse, "How can I make sure I have the real drug and not the fake drug? I really want to see if it will help my situation." What is the nurse's best response?
4. After a week, the patient tells the nurse, "I don't see that this drug is helping me. In fact, I feel worse. But I'm afraid to tell the doctor that I want to stop the medicine. What do I do?" What is the nurse's best response?

For answers, see http://evolve.elsevier.com/Lilley.

KEY POINTS

- A variety of culturally based assessment tools are available for use in patient care and drug therapy.
- Drug therapy and subsequent patient responses may be affected by racial and ethnic variations in levels of specific enzymes and metabolic pathways of drugs.
- Various pieces of federal legislation, as well as state law, state practice acts, and institutional policies, have been established to help ensure the safety and efficacy of drug therapy and the nursing process.
- HIPAA guidelines have increased awareness concerning patient confidentiality and privacy. It is important to understand this federal legislation as it relates to drug therapy and the nursing process.
- The Controlled Substance Act of 1970 provides nurses and other health care providers with information on drugs that cause little to no dependence versus those associated with a high level of abuse and dependency.
- Always obtain informed consent as needed, with complete understanding of your role and responsibilities as patient advocate in obtaining such consent.
- In the IND research process, adhere to the study protocol while also acting as a patient advocate and honoring the patient's right to safe, quality nursing care.
- Adhere to legal guidelines, ethical principles, and the ANA *Code of Ethics for Nurses* so that your actions are based on a solid foundation.
- Placebo use remains controversial and if a placebo is ordered, question the prescriber about the specific cause for its use.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A patient is undergoing major surgery and asks the nurse about a living will. He states, "I don't want anybody making decisions for me. And I don't want to prolong my life." The patient is demonstrating
   a autonomy.
   b beneficence.
   c justice.
   d veracity.

2 When caring for an elderly Chinese patient, the nurse recognizes that which of these cultural issues may influence the care of this patient?
   a Radiographs are seen as a break in the soul's integrity.
   b Hospital diets are interpreted as being healing and healthful.
   c The use of heat may be an important practice for this patient.
   d Being hospitalized is a source of peace and socialization for this culture.

3 A patient is being counseled for possible participation in a clinical trial for a new medication. After the patient meets with the physician, the nurse is asked to obtain the patient's signature on the consent forms. The nurse knows that this "informed consent" indicates which of the following?
   a Once therapy has begun, the patient cannot withdraw from the clinical trial.
   b The patient has been informed of all potential hazards and benefits of the therapy.
   c The patient has received only the information that will help to make the clinical trial a success.
   d No matter what happens, the patient will not be able to sue the researchers for damages.

4 A new drug has been approved for use, and the drug manufacturer has made it available for sale. During the first 6 months, the FDA receives reports of severe adverse effects that were not discovered during the testing and considers withdrawing the drug. This illustrates which phase of investigational drug studies?
   a Phase I
   b Phase II
   c Phase III
   d Phase IV

5 A patient of Japanese descent describes a family trait that manifests frequently: She says that members of her family often have "strong reactions" after taking certain medications, but her white friends have no problems with the same dosages of the same drugs. The nurse recognizes that, because of this trait, which statement applies?
   a She may need lower dosages of the medications prescribed.
   b She may need higher dosages of the medications prescribed.
   c She should not receive these medications because of potential problems with metabolism.
   d These situations vary greatly, and her accounts may not indicate a valid cause for concern.

6 When evaluating polymorphism and medication administration, the nurse considers which factors? (Select all that apply.)
   a Nutritional status
   b Drug route
   c Patient's ethnicity
   d Cultural beliefs
   e Patient's age

NCLEX® EXAMINATION REVIEW QUESTIONS—cont'd

7 The nurse is reviewing the four clinical phases of investigational drug studies. Place the four phases in the correct order of occurrence.

a Studies that are voluntarily conducted by pharmaceutical companies to obtain more information about the therapeutic and adverse effects of a drug.

b Studies that involve small numbers of volunteers who have the disease or ailment that the drug is designed to diagnose or treat.

c Studies that involve small numbers of healthy subjects who do not have the disease or ailment that the drug is intended to treat.

d Studies that involve large numbers of patients who have the disease that the drug is intended to treat; these studies establish the drug's clinical effectiveness, safety, and dosage range.

1. a, 2. c, 3. b, 4. d, 5. a, 6. a, c, d, e, 7. a = 4, b = 2, c = 1, d = 3

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Compare the following terms related to drug therapy in the context of professional nursing practice: *adverse drug event, adverse drug reaction, allergic reaction, idiosyncratic reaction, medical error,* and *medication error.*
2 Describe the most commonly encountered medication errors.
3 Develop a framework for professional nursing practice for prevention of medication errors.
4 Identify potential physical and emotional consequences of a medication error.
5 Discuss the impact of culture and age on the occurrence of medication errors.
6 Analyze the various ethical dilemmas related to professional nursing practice associated with medication errors.
7 Identify agencies concerned with prevention of and response to medication errors.
8 Discuss the possible consequences of medication errors for professional nurses and other members of the health care team.

KEY TERMS

Adverse drug event Any undesirable occurrence related to administration of or failure to administer a prescribed medication. (p. 65)

Adverse drug reactions Unexpected, unintended, or excessive responses to medications given at therapeutic dosages (as opposed to overdose); one type of adverse drug event. (p. 65)

Allergic reaction An immunologic reaction resulting from an unusual sensitivity of a patient to a particular medication; a type of adverse drug event and a subtype of adverse drug reactions. (p. 65)

Idiosyncratic reaction Any abnormal and unexpected response to a medication, other than an allergic reaction, that is peculiar to an individual patient. (p. 65)

Medical errors A broad term used to refer to any errors at any point in patient care that cause or have the potential to cause patient harm. (p. 65)

Medication errors Any preventable adverse drug events involving inappropriate medication use by a patient or health care professional; they may or may not cause the patient harm. (p. 65)

Medication reconciliation A procedure implemented by health care providers to maintain an accurate and up-to-date list of medications for all patients between all phases of health care delivery. (p. 70)

GENERAL IMPACT OF ERRORS ON PATIENTS

Medical errors and medication errors in particular have received much national attention. The study that brought medical errors to the public was the landmark study done in 1999 by the Institute of Medicine (IOM). According to this study, the number of patient deaths from medical errors in U.S. hospitals ranged from 44,000 to 98,000 annually based on data from two large-scale studies. The IOM conducted a similar study in 2006 and found that medical errors harm at least 1.5 million people per year, including 117,000 hospitalizations at a cost of over $4 billion. A follow-up study in 2010 showed 25.1 "harms" per 100 admissions to the hospital. This study showed no significant change in rates of preventable errors since the IOM study. Numerous health institutions have made prevention of medical errors a top priority. The most important change is to recognize that reporting of errors should not be punitive toward the reporter. In fact, all health care professionals are encouraged to report errors. It has been shown that reporting of errors can prevent errors from occurring. This study also brought forth the notion that most errors occur as a breakdown in the medication use system, as opposed to being the fault of the individual. This concept has been taken a step further and has created "just culture." Just culture recognizes that systems are generally at fault when an error occurs, but that when professionals do not follow policies or have repeated errors, that professional needs remedial education and must be held accountable.

Medical errors can occur during all phases of health care delivery and involve all categories of health professionals. Some of the more common types of error include misdiagnosis, patient misidentification, lack of patient monitoring, wrong-site surgery, and medication errors. Most studies have looked at medical errors occurring in hospitals; however, many serious medication errors occur in the home. Errors occurring in homes can be quite harmful, as potent drugs once used only in hospitals are now being prescribed for outpatients. The majority of fatal errors at home involve the mixing of prescription drugs with alcohol or other drugs. Intangible losses resulting from such adverse outcomes include patient dissatisfaction with, and loss of trust in, the health care system. This, in turn, can lead to adverse health outcomes because patients are afraid to seek health services. This chapter focuses on the issues related to medication errors and ways to prevent and respond to these errors.

MEDICATION ERRORS

An **adverse drug event** is a general term that encompasses all types of clinical problems related to medication use. These include **medication errors** and **adverse drug reactions.** The various subsets of adverse drug events and their interrelationships are illustrated in Figure 5-1. Adverse drug reactions are reactions that occur with the use of the particular drug. Two types of adverse drug reactions are **allergic reaction** (often predictable) and **idiosyncratic reaction** (usually unpredictable). Medication errors are a common cause of adverse health care outcomes and can range from having no significant effect to directly causing patient disability or death.

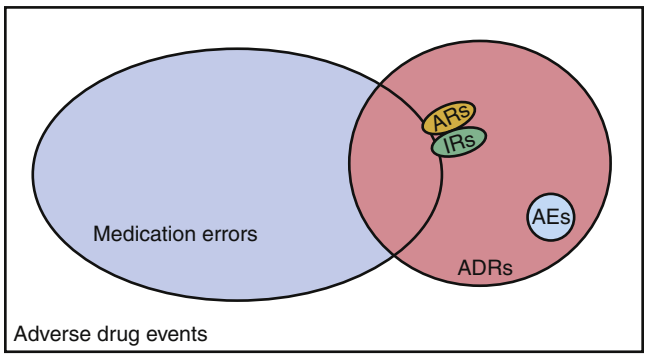

FIGURE 5-1 Diagram illustrating the various classes and subclasses of adverse drug events. *ADRs,* Adverse drug reactions; *AEs,* adverse (drug) effects; *ARs,* allergic reactions; *IRs,* idiosyncratic reactions.

It is important to consider all of the steps involved in the medication use system when discussing medication errors. Identifying, responding to, and ultimately preventing medication errors require an examination of the entire medication use process. Attention must be focused on all persons and all steps involved in the medication use process, including the prescriber, the transcriber of the order, nurses, pharmacists, and any other ancillary staff involved. A systems approach takes the "Six Rights" one step further and examines the entire health care system, the health care professionals involved, and any other factor that has an impact on the error.

Drugs commonly involved in severe medication errors include central nervous system drugs, anticoagulants, and chemotherapeutic drugs. "High-alert" medications have been identified as those that, because of their potentially toxic nature, require special care when prescribing, dispensing, and/or administering. High-alert medications are not necessarily involved in more errors than other drugs; however, the potential for patient harm is higher. Some high-alert medications are listed in Box 5-1. Medication errors also result from the fact that there are large numbers of drugs that have similarities in spelling and/or pronunciation (i.e., look-alike or sound-alike names). Several acronyms have been created to refer to these drugs, including SALAD (sound-alike, look-alike drugs) and LASA (look-alike, sound-alike). Mix-ups between such drugs are most dangerous when two drugs from very different therapeutic classes have similar names. This can result in patient effects that are grossly different from those intended as part of the drug therapy. The Safety and Quality Improvement: Preventing Medication Errors box on p. 66 lists examples of commonly confused drug names. More information on high-alert medications and sound-alike, look-alike drugs can be found at the website of the Institute for Safe Medication Practices at http://www.ismp.org.

It is widely recognized that most medication errors result from weaknesses in the systems within health care organizations rather than from individual shortcomings. System weaknesses include failure to create a "just culture" or nonpunitive work atmosphere for reporting errors, excessive workload with

BOX 5-1 EXAMPLES OF HIGH-ALERT MEDICATIONS

Drug Classes/Categories

- Adrenergic agonists, IV (e.g., epinephrine, phenylephrine, norepinephrine)
- Adrenergic antagonists, IV (e.g., propranolol, metoprolol, labetalol)
- Anesthetic agents, general, inhaled and IV (e.g., propofol, ketamine)
- Antidysrhythmics, IV (e.g., lidocaine, amiodarone)
- Antithrombotic agents (anticoagulants), including warfarin, low–molecular-weight heparin, IV unfractionated heparin, factor Xa inhibitors (e.g., fondaparinux), direct thrombin inhibitors (e.g., argatroban, lepirudin, bivalirudin), thrombolytics (e.g., alteplase, reteplase, tenecteplase), and glycoprotein IIb/IIIa inhibitors (e.g., eptifibatide)
- Cardioplegic solutions
- Chemotherapeutic agents, parenteral and oral
- Epidural or intrathecal medications
- Hypoglycemics, oral
- Inotropic drugs, IV (e.g., digoxin, milrinone)
- Moderate sedation drugs, IV (e.g., midazolam)
- Narcotics/opiates, IV, transdermal, and oral (including liquid concentrates, immediate- and sustained-release formulations)
- Neuromuscular blocking agents (e.g., succinylcholine, rocuronium, vecuronium)
- Radiocontrast agents, IV
- Total parenteral nutrition solutions

Specific Drugs

- Insulin, subcutaneous and IV
- Magnesium sulfate injection
- Methotrexate, oral, nononcologic use
- Oxytocin, IV
- Nitroprusside sodium for injection
- Potassium chloride for injection
- Potassium phosphates injection
- Promethazine, IV
- Sodium chloride for injection, hypertonic (greater than 0.9% concentration)
- Sterile water for injection, inhalation, and irrigation (excluding pour bottles) in containers of 100 mL or more

From Institute for Safe Medication Practices: ISMP's list of high-alert medications, available at http://www.ismp.org/Tools/highalertmedications.pdf.

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Institute for Safe Medication Practices: Examples of Look-Alike, Sound-Alike (LASA) Commonly Confused Drug Names

NAMES OF MEDICATIONS	COMMENTS
carboplatin vs. cisplatin	Two different antineoplastic drugs
Celebrex vs. Celexa	Antiinflammatory drug vs. antidepressant drug
Depakote vs. Depakote ER	Same drug; immediate-release vs. extended-release dosage forms
dopamine vs. dobutamine	Vasopressor drugs of markedly different strengths; dobutamine is also a strong inotropic affecting the heart
fentanyl vs. sufentanil	Both are injectable anesthetics but with a significant difference in potency and duration of action
glipizide vs. glyburide	Two different antidiabetic drugs
Humulin vs. Humalog	Short-acting vs. rapid-acting insulin
Lamictal vs. Lamisil	Anticonvulsant/mood stabilizer vs. antifungal drug
metronidazole vs. metformin	Antibiotic vs. antidiabetic drug
MiraLax vs. Mirapex	Laxative vs. antiparkinson drug
morphine vs. hydromorphone	Two different potency opioids
oxycodone vs. OxyContin	Immediate-release vs. long-acting oxycodone
Paxil vs. Plavix	Antidepressant vs. antiplatelet drug
trazodone vs. tramadol	Antidepressant vs. analgesic

Additional examples can be found at http://www.ismp.org/Tools/confuseddrugnames.pdf. Accessed February 23, 2011.

minimal time for preventive education, and lack of interdisciplinary communication and collaboration. All hospitals are required to analyze medication errors and implement ways to prevent them. Nurses must take the time to report errors, because without reporting, no changes can be made. When errors are reported, trends can be identified and processes can be changed to prevent the errors from occurring again.

ISSUES CONTRIBUTING TO ERRORS

Organizational Issues

Medication errors can occur at any step in the medication process: procuring, prescribing, transcribing, dispensing, administering, and monitoring. One study noted that half of all preventable adverse drug events begin with an error at the medication ordering (prescribing) stage. Most prescribing errors can be caught by the pharmacist before order entry and by nurses prior to administration. Administration is the next most common point in the process at which medication errors occur, followed by dispensing errors and transcription errors. It is very important for nurses to have good relationships with pharmacists, because the two professions, working together, can have a major impact in preventing medication errors. Hospital pharmacists are usually available 24/7 and serve as great resources when the nurse has any question regarding drug therapy.

The Joint Commission, the major accreditation body for hospitals, began a patient public awareness campaign in 2006 called *Speak Up*. It encourages patients to take a more active role in their health care by "speaking up" and asking questions whenever they feel the need to do so. The value of this program is twofold: patients learn more about their illnesses and the care provided, and they can advocate for their own safety at each health care encounter. Specific topics on the campaign website (http://www.jointcommission.org/speakup.aspx) include asking questions about care in general, learning about living organ donation, preventing infections in the hospital, avoiding medication errors, participating in research studies, planning for follow-up care, avoiding errors in medical tests, and knowing about patients rights in general (see Box 5-2).

Effective use of technologies such as computerized prescriber order entry and bar coding of medication packages has been shown to reduce medication errors. In February 2004, the U.S. Food and Drug Administration (FDA) announced new regulations requiring bar codes for all prescription and

over-the-counter medications. Unfortunately, only a small percentage of U.S. hospitals have implemented bar-code scanning technology, primarily due to prohibitive cost. Cost is a barrier to technologic improvements in general. The cost of implementing current technology, including automated drug dispensing cabinets with electronic charting and computerized order entry, may range from hundreds of thousands of dollars to over $20 million. Nonetheless, these various technologic advances have been shown to reduce medication errors. For example, computerized order entry (also known as computerized physician order entry [CPOE]) eliminates handwriting and standardizes many prescribing functions. Bar coding of medications allows the nurse to use electronic devices for verification of correct medication at the patient's bedside. Computer programs are used in the pharmacy to screen for potential drug interactions. Despite all the benefits technology has to offer, workload issues (i.e., nursing staff shortage), inadequate education in the use of the equipment, or difficulties in mastering the use of complex technology can prevent the technology from eliminating errors as it was designed to do. Self-medication by patients (e.g., patient-controlled analgesia) has been shown to reduce errors, provided patients have adequate cognitive ability and mental alertness.

Educational System Issues and Their Potential Impact on Medication Errors

All health professionals have an obligation to double-check any necessary information before proceeding. This includes stopping and checking medication orders and being comfortable with one's knowledge of the drug *before* administering it. Numerous drug information guides are available to be utilized by the nurse. Even the most capable health care provider cannot know everything nor have immediate recall of every fact ever read. This is especially true given the increasing complexity of health care practice.

Patient safety begins in the educational process with nursing students and faculty members. Adopting the philosophy that "no question is a stupid question" allows students to begin their careers with greater confidence and with a healthy habit of self-monitoring. In contrast, berating or otherwise penalizing a student for not immediately recalling a given fact, or for simply asking questions, instills fear and shame. It also discourages dialogue that would otherwise promote and enhance student learning. Commonly reported student nurse errors involve the following situations: unusual dosing times, medication administration record issues (unavailability of the record, failure to document doses given resulting in administration of extra doses, failure to review the record before medicating patients), administration of discontinued or "held" medications, failure to monitor vital signs or laboratory results, administration of oral liquids as injections, preparation of medications for multiple patients at the same time, and dispensing of medications in different doses than those ordered (e.g., tablets that need to be broken in half). The World Health Organization has developed information about patient safety concerns, safety initiatives, and patient safety solutions (Box 5-2).

Medication Errors and Related Sociologic Factors

Effective communication among all members of the health care team contributes to improved patient care. However, a 2008 study published in *American Nurse Today* identified disruptive physician behavior and lack of institutional response to it

BOX 5-2 WORLD HEALTH ORGANIZATION COLLABORATING CENTRE FOR PATIENT SAFETY SOLUTIONS AND SPEAK UP INITIATIVES ABOUT MEDICATIONS AND HEALTH

The World Health Organization (WHO) posts information on its website regarding initiatives to promote patient safety in medication administration and other aspects of health care. As the WHO notes, no adverse event should ever occur anywhere in the world if the knowledge exists to prevent it from happening. Knowledge is of little use, however, if it is not applied in practice. The WHO Collaborating Centre for Patient Safety Solutions has developed patient safety initiatives that can serve as a guide in redesigning the patient care process to prevent the inevitable errors from ever reaching patients. Patient safety solutions are defined by the WHO as any system design feature or intervention that has demonstrated the ability to prevent or mitigate patient harm arising from the health care process. Information about the first group of patient safety solutions (2008/2009) approved by the WHO center is available at http://www.ccforpatientsafety.org. These patient safety concerns include avoiding confusion of medications with look-alike, sound-alike names; ensuring correct patient identification; enhancing communication during patient "hand-overs" between care units or care teams; ensuring performance of the correct procedure at the correct body site; maintaining control of concentrated electrolyte solutions; ensuring medication accuracy at transition points in care; avoiding catheter and tubing misconnections; and promoting single use of injection devices and improved hand hygiene to prevent health care–associated infections.

More information about patient safety and safety initiatives is also provided in a national campaign supported by The Joint Commission and the Centers for Medicare and Medicaid. These initiatives encourage patients to take a role in preventing health care errors by becoming more active, involved, and informed regarding all aspects of their health care. The *Speak Up* campaign features various brochures, posters, and buttons addressing a variety of patient safety issues and encourages the public to do the following: **S**peak up if you have any questions. **P**ay attention to your health care, and make sure that any treatments or medications are appropriate and are ordered by the proper health care professionals. **E**ducate yourself about medical diagnoses and be informed. **A**sk a family member or friend you trust to be your advocate. **K**now the medications you take and the reason for taking them. **U**se a hospital, ambulatory, or urgent care center or other type of health care facility. **P**articipate in all decisions about your treatment because you are the very center and heart of the health care team. The success of the Speak Up initiatives is well documented in the results of a 2005 survey of more than 600 accredited health care organizations, of which approximately 81% reported that campaigns like Speak Up bring more value to the accreditation process and 82% would like to see The Joint Commission sponsor more patient education programs in the future. Some 91% of these 600 organizations viewed the initiatives and program as excellent, very good, or good. For more information on the use of Speak Up and to look at the materials available, visit http://www.jointcommission.org/speakup.aspx; or contact Joint Commission Resources at 877-223-6866 or visit http://www.jcrinc.com/. Other sources of information are listed at http://www.ccforpatientsafety.org.

TEAMWORK AND COLLABORATION: LEGAL AND ETHICAL PRINCIPLES

Use of Abbreviations

Medication errors often occur as a result of misinterpretation of abbreviations. Therefore, the National Coordinating Council for Medication Error Reporting and Prevention recommends that the following abbreviations be written out in full and the abbreviations avoided. The U.S. Pharmacopeia and Institute of Safe Medication Practices endorse the avoidance of abbreviations whenever possible. Most hospitals and nursing care units are adopting this significant change in documentation. NOTE: It is the philosophy of the authors of this textbook to avoid abbreviations whenever possible.

ABBREVIATION	INTENDED MEANING	COMMON ERROR
U	Units	Mistaken for a zero (0), a four (4), or cc.
mcg (μg)	Micrograms	Mistaken for mg (milligrams).
Q.D.	Latin abbreviation for "every day"	The period after the "Q" can be mistaken for an "I" so that a medication is given "QID" (four times daily) instead of once daily.
Q.O.D.	Latin abbreviation for "every other day"	Misinterpreted as "QD" (daily) or QID. If "O" is poorly written it may look like a period or "I."
D/C	Discharge or discontinue	Medications have been prematurely discontinued when D/C (intended to mean "discharge") was misinterpreted as "discontinue" because it was followed by a list of drugs. Use the word "Stop."
HS	Half strength	Misinterpreted as the Latin abbreviation "HS" (hour of sleep).
cc	Cubic centimeters	Mistaken for "U" (units) when written poorly.
AU, AS, AD	Both ears, left ear, right ear	Misinterpreted as the Latin abbreviation "OU" (both eyes), "OS" (left eye), "OD" (right eye). Also, some people forget which is right or left, or both, and which is eye or ear.

as significant factors affecting nurse job satisfaction and nursing staff retention. Ninety-six percent of the nurses surveyed said they had witnessed or experienced disruptive behavior by a physician. Other literature shows that nurses are the primary victims of disruptive behavior and that this behavior may not only undermine patient care but also lead to staff dissatisfaction and turnover. In response to this increasing problem, The Joint Commission requires hospitals to establish procedures for managing disruptive behavior by physicians and others who are granted clinical privileges. Disruptive behavior, as defined by the American Medical Association (AMA), is personal verbal or physical conduct that affects or potentially may affect patient care in a negative fashion. These behaviors are classified into four types by the AMA: (1) intimidation and violence, (2) inappropriate language or comments, (3) sexual harassment, and (4) inappropriate responses to patient needs or staff requests.

Fortunately, communication between prescribers and other members of the health care team has improved somewhat over the years with newer generations of prescribers. This is due in large part to more progressive approaches in medical education that emphasize a team orientation. Such approaches recognize the ever-increasing complexities of health care delivery and the reality that no one team member can know every fact and provide for all patient care needs.

PREVENTING, RESPONDING TO, REPORTING, AND DOCUMENTING MEDICATION ERRORS: A NURSING PERSPECTIVE

Preventing Medication Errors

Medication errors are considered to be any preventable event that could lead to inappropriate medication use or harm. The major categories of medication error are defined by the 2005 National Coordinating Council for Medication Error Reporting and Prevention as (1) no error, although circumstances or events occurred that could have led to an error, (2) medication error that causes no harm, (3) medication error that causes harm, and (4) medication error that results in death. Medication errors may be prevented through a variety of strategies, including: (1) Multiple systems of checks and balances should be implemented to prevent medication errors. (2) Prescribers should write legible orders that contain correct information, or orders should be written electronically if the technology is available. (3) Authoritative resources, such as pharmacists or current drug literature, should be consulted if there is any area of concern, beginning with the medication order and continuing throughout the entire medication administration process. (4) Nurses should always check the medication order three times before giving the drug and consult with authoritative resources (see earlier in the chapter) if any questions or concerns exist. Faculty members should not be the student's research source regarding medications, and the safe practice of using appropriate resources should begin early in the educational process. (5) The Six Rights of medication administration should be used consistently, which has been shown to substantially reduce the likelihood of a medication error. See the Safety and Quality Improvement: Preventing Medication Errors box on p. 69 for a more concise and detailed listing of ways to help prevent medication errors. See the Patient-Centered Care: Lifespan Considerations for the Pediatric Patient box on p. 69 for a discussion of medication errors in pediatric patients and special considerations for this age group.

Responding to, Reporting, and Documenting Medication Errors

Responding to and reporting medication errors are part of the professional responsibilities for which the nurse is accountable. If a medication error does occur, it must be reported, regardless

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

How to Prevent Medication Errors

- As the first step to defend against errors, assess information about drug allergies, vital signs, and laboratory test results.
- Use two patient identifiers before giving medications.
- Never give medications that you have not drawn up or prepared yourself.
- Minimize the use of verbal and telephone orders. If used, be sure to repeat the order to confirm with the prescriber. Speak slowly and clearly, and spell the drug name aloud.
- List the reason for use of each drug on the medication administration record and any educational materials.
- Avoid abbreviations, medical shorthand, and acronyms because they can lead to confusion, miscommunication, and risk of error (see the Teamwork and Collaboration: Legal and Ethical Principles box on p. 68.).
- Never assume anything about any drug order or prescription, including route. If a medication order is questioned for any reason (e.g., dose, drug, indication), never assume that the prescriber is correct. Always be the patient's advocate and investigate the matter until all ambiguities are resolved.
- Do not try to decipher illegibly written orders; instead, contact the prescriber for clarification. Illegible orders fall below applicable standards for quality medical care and endanger patient safety. If in doubt about any part of an order, always check with the prescriber. Compare the medication order against what is on hand by checking for the Right Drug, Right Dose, Right Time, Right Patient, and Right Route.
- Never use trailing zeros (e.g., 1.0 mg) in writing and/or transcribing medication orders. Use of trailing zeros is associated with increased occurrence of overdose. For example, "1.0 mg warfarin sodium" could be misread as "10 mg warfarin," a tenfold dose increase. Instead, use "1 mg" or even "one mg."
- Failure to use leading zeros can also lead to overdose. For example, .25 mg digoxin could be misread as 25 mg digoxin, a dose that is 100 times the dose ordered. Instead, write "0.25 mg."
- Carefully read all labels for accuracy, expiration dates, dilution requirements, and warnings (e.g., black box warnings).
- Remain current with new techniques of administration and new equipment.
- Encourage the use of generic names to avoid medication errors due to many sound-alike trade names.
- Listen to and honor any concerns expressed by patients. If the patient voices a concern about being allergic to a medication or states that a pill has already been taken or that the medication is not what he or she usually takes—then STOP, listen, and investigate.
- Strive to maintain your own health to remain alert, and never be too busy to stop, learn, and inquire. In addition, engage in ongoing continuing education.
- Become a member of professional nursing organizations to network with other nursing students or professional nurses to advocate for improved working conditions and to stand up for the rights of nurses and patients.
- Know where to find the latest information on which dosage forms can or should not be crushed or opened (e.g., capsules), and educate patients accordingly.
- Safeguard any medications that the patient had on admission or transfer so that additional doses are not given or taken by mistake. In such situations, safeguarding is accomplished by compiling a current medication history and resolving any discrepancies rather than ignoring them.
- Always verify new medication administration records if they have been rewritten or reentered for any reason, and follow policies and procedures about this action.
- Make sure the weight of the patient is always recorded before carrying out a medication order to help decrease dosage errors.
- Provide for mandatory recalculation of every drug dosage for high-risk drugs (e.g., highly toxic drugs) or high-risk patients (e.g., pediatric or elderly patients) because there is a narrow margin between therapeutic serum drug levels and toxic levels (e.g., for chemotherapeutic or digitalis drugs, or in the presence of altered liver or kidney function in a patient).
- Always suspect an error whenever an adult dosage form is dispensed for a pediatric patient.
- Seek translators when appropriate—never guess what patients are trying to say.
- Educate patients to take an active role in medication error prevention, both in the hospital setting and at home.
- Involve yourself politically in advocating for legislation that improves patient safety.

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

Medication Errors

Of all the ways a pediatric patient may be harmed during medical treatment, medication errors are the most common. As with elderly patients, when medication errors occur, there is a higher risk of death. The findings of several studies indicate that medication errors involving inpatient pediatric patients occur at a rate of 4.5 to 5.7 errors per 100 drugs used. The most common medication errors in pediatrics are dosing errors. Research has begun to identify some of the groups of pediatric patients who are at highest risk of medication errors. These include the following patients: (1) those younger than 2 years of age, (2) those in intensive care units (ICUs), specifically the neonatal ICU, (3) those in the emergency department between the hours of 4 AM and 8 AM or on the weekend and who are seriously ill, (4) those receiving intravenous and/or chemotherapeutic drugs, and (5) those whose weight has not been determined or recorded. Mathematical dosage calculations for pediatric patients are also problematic. In determination of the correct dosage once the drug has been ordered, the problems of most concern include the following: (1) inability of the nurse to understand/perform the correct calculation or dilution, (2) infrequent use of calculations, and (3) decimal point misplacement, with potential overdosing or underdosing.

The following are some of the actions that can be taken to prevent pediatric medication errors:

- Report all medication errors, because this information is part of the practice of professional nursing and helps in identifying causes of medication error.
- Know the drug thoroughly, including its on- and off-label uses, action, adverse effects, dosage ranges, routes of administration, high-alert drug status cautions (see Box 5-1), and contraindications (e.g., Is it recommended for use in pediatric patients?).
- Confirm information about the patient each and every time a dose is given, and check three times before giving the drug by comparing the drug order with the patient's medication profile and verifying for the Right Drug, Right Dose, Right Time, Right Route, and Right Patient.
- Double-check and verify information in handwritten orders that may be incomplete, unclear, or illegible.
- Avoid verbal telephone orders in general. When they are unavoidable, always repeat them back to the prescriber over the telephone. Insist that the prescriber sign off any emergency in-person verbal orders before leaving the unit.
- Avoid distractions while giving medications.
- Communicate with everyone (e.g., parent, caregiver) involved in patient care.
- Make sure all orders are clear and understood with shift changes.
- Use authoritative resources such as drug handbooks, *Physicians' Desk Reference,* or information from the Food and Drug Administration website (http://www.fda.gov). For off-label use of drugs, see http://www.fda.gov/Drugs/ResourcesForYou/Consumers/ucm143565.htm.

of whether the error was made by a nursing student or a professional nurse. Follow facility policies and procedures for reporting and documenting the error closely and cautiously. Once the patient has been assessed and urgent safety issues have been addressed, report the error immediately to the appropriate prescriber and nursing management personnel, for example, the nurse manager or supervisor. If the patient cannot be left alone due to deterioration of the patient's condition or the need for close monitoring after the medication error, a fellow nurse or other qualified health care professional should remain with the patient and provide appropriate care while the prescriber is contacted. Follow-up procedures or tests may be ordered or an antidote prescribed. These orders should be implemented as indicated by the prescriber. Remember that the nurse's highest priority at all times during the medication administration process and during a medication error is the patient's physiologic status and safety.

When a medication error has occurred, complete all appropriate forms—including an incident report—as per the facility's policies and procedures, and provide appropriate documentation. Document the medication error, however, by providing only factual information about the error. Documentation should always be accurate, thorough, and objective. Avoid using judgmental words such as *error* in the documentation. Instead, chart factual information such as the medication that was administered, the actual dose given, and other details regarding the order (e.g., wrong patient, wrong route, and/or wrong time). Also note any observed changes in the patient's physical and mental status. In addition, document the fact that the prescriber was notified and any follow-up actions or orders that were implemented. Patient monitoring should be ongoing.

Most facilities require additional documentation when a medication error occurs consisting of an incident report or unusual occurrence report. Always follow facility policies and procedures or protocols in completing an incident report. Documentation should include only factual information about the error as well as all corrective actions taken. Complete any additional sections of the form to help with the investigation of the incident. Because these forms are forwarded to the facility's risk management department, this complete and factual information may help prevent errors in the future. Do not document on the patient's chart that an incident report was filled out, and a copy of the incident report should not be kept. Incident reports are not to be placed in the patient's chart. The reporting of actual and suspected medication errors should offer the option of anonymity. This may help to foster improved error reporting and safe medication practices. Internal, facility-based systems of error tracking may generate data to help customize policy and procedure development. All institutional pharmacy departments are required to have an adverse drug event monitoring program.

Nurses as well as health care facilities may also be involved in external reporting of medication errors. There are nationwide confidential reporting programs that collect and disseminate safety information on a larger scale. One such program is the U.S. Pharmacopeia Medication Errors Reporting Program (USPMERP). The U.S. Pharmacopeia (USP) has created a nationwide database of medication errors and their causes, as well as potential errors. Any health care professional can report an error by contacting the USPMERP at 800-23-ERROR. Many important institutional changes have been made based on the data collected by this program. MedWatch is another useful error and adverse event reporting program provided by the FDA. Any member of the public can report problems with medications or medical devices via telephone or mail, or online at the FDA website. The Institute for Safe Medication Practices and the Joint Commission also provide useful information and reporting services to health care providers aimed at safety enhancement.

CASE STUDY

Preventing Medication Errors

During your busy clinical day as a student nurse, the staff nurse assigned to your patient comes to you and says, "Would you like to give this injection? We have a 'now' order for Sandostatin (octreotide) 200 mcg subcutaneously. I've already drawn it up; 200 mcg equals 2 mL. It needs to be given as soon as possible, so I drew it up to save time." She hands you a syringe that has 2 mL of a clear fluid in it and the patient's medication administration record (MAR).

1. Should you give this medication "now," as ordered? Why or why not?

You decide to check the order that is handwritten on the MAR with the order written on the chart. The physician wrote, "Octreotide, 200 mcg now, subcutaneously, then 100 mcg every 8 hours as needed." Before you have a chance to find your instructor, the nurse returns and says, "Your instructor probably won't let you give the injection unless you can show the medication ampules. Here are the ampules I used to draw up the octreotide. Be quick—your patient needs it now!"

You take the order, the MAR, the two ampules, and the syringe to your instructor. Together you read the order and then check the ampules. Each ampule is marked "Sandostatin (octreotide) 500 mcg/mL."

2. If the nurse drew up 2 mL from these two ampules, how much octreotide is in the syringe? How does this amount compare with the amount on the order?

The nurse is astonished when you point out that the ampules read "500 mcg/mL." She goes into the automated medication dispenser and sees two identical boxes of Sandostatin next to each other in the refrigerated section. One box is labeled "100 mcg/mL," and the other box is labeled "500 mcg/mL." She then realizes that she chose ampules of the wrong strength of drug and drew up an incorrect dose.

3. What would have happened if you had given the injection?
4. What needs to be done at this point? What contributed to this potential medication error, and how can it be prevented in the future?

For answers, see http://evolve.elsevier.com/Lilley.

Performing Medication Reconciliation

Medication reconciliation is a process in which medications are "reconciled" at all points of entry and exit to/from a health care entity. Medication reconciliation requires patients to provide a list of all the medications they are currently taking (including herbals and over-the-counter drugs). The prescriber is then to assess those medications and decide if they are to be continued upon hospitalization. Medication reconciliation was designed to ensure that there are no discrepancies between what the patient was taking at home and in the hospital. Medication reconciliation

is to occur at entry into the facility, upon transfer from surgery, or into or out of the intensive care unit and at discharge.

Although this seems to be an easy process, numerous problems have been encountered since its inception in 2005. The first problem is that many times patients do not know exactly what medications they are taking and may report that they take a "blue pill for blood pressure." Sometimes the patient may have a list of medications but some of the medications were discontinued prior to admission, and they oftentimes fail to provide this vital piece of information. This can lead to the prescriber continuing a medicine based on faulty information. This particular problem has grown because many hospitals now use hospitalists (physicians that only take care of the patient in the hospital), and the primary care provider who has the most accurate list of medications is not involved. Hospitals throughout the country are working feverishly to figure out ways to avoid the problems described. This is an ongoing process. The Joint Commission has made medication reconciliation a National Patient Safety Goal since 2006; however, due to the problems encountered it has now scaled back its requirements (available at http://www.jointcommission.org/standards_information/npsgs.aspx).

Medication reconciliation involves three steps (additional information can be found on either of the websites mentioned earlier in the chapter):

1. Verification—Collection of the patient's medication information with a focus on medications currently used (including prescription drugs as well as over-the-counter medications and supplements)
2. Clarification—Professional review of this information to ensure that medications and dosages are appropriate for the patient
3. Reconciliation—Further investigation of any discrepancies and documentation of relevant communications and changes in medication orders

To ensure ongoing accuracy of medication use, the steps listed need to be repeated at each stage of health care delivery:

a. Admission
b. Status change (e.g., from critical to stable). It is the role of the provider to evaluate current medications and specify in writing which medications are to be continued or discontinued with any status change, transfer, or discharge.
c. Patient transfer within or between facilities or provider teams
d. Discharge (the latest medication list should be provided to the patient to take to his or her next health care provider, or this information should be otherwise forwarded to the provider; applicable confidentiality guidelines should be followed)

Some applicable assessment and education tips regarding medication reconciliation are as follows:

1. Ask the patient open-ended questions, and gradually move to yes-no questions to help determine specific medication information. (Details are important, maybe even critical!)
2. Avoid the use of medical jargon unless it is clear that the patient understands and is comfortable with such language.
3. Prompt the patient to try to remember all applicable medications (e.g., patches, creams, eyedrops, inhalers, professional samples, injections, dietary supplements). If the patient provides a medication list, make a copy for the patient's chart.
4. Clarify unclear information to the extent possible (e.g., by talking with the home caregiver or the outpatient pharmacist who fills the patient's prescriptions, if needed).
5. Record the foregoing information in the patient's chart as the first step in the medication reconciliation process.
6. Emphasize to the patient the importance of always maintaining a current and complete medication list and bringing it to each health care encounter (e.g., as a wallet card or other list). Many patients use their own computers for this. Also encourage patients to learn the names and current dosages of their medications.

OTHER ETHICAL ISSUES

Notification of Patients Regarding Errors

A landmark article published in the *Journal of Clinical Outcomes Management* in 2001 recognized the obligation of institutions and health care providers to provide full disclosure to patients when errors have occurred in their care. The article not only emphasized the ethical basis for this practice but also addressed the legal implications and was a starting point for understanding the issue of notification of patients regarding medication errors. The point was made that patients who seek attorney services are often motivated primarily by a perceived imbalance in power between themselves and their health care providers and by fear of financial burden. Health care organizations can choose to proactively apologize and accept responsibility for obvious errors and even offer needed financial support (e.g., for travel expenses, temporary loss of wages). Research indicates that such actions help health care organizations to avoid litigation and potentially much larger financial settlements.

Possible Consequences of Medication Errors for Nurses

The possible effects of medication errors on patients range from no significant effect to permanent disability and even death in the most extreme cases. However, medication errors may also affect health care professionals, including nurses and student nurses, in a number of ways. An error that involves significant patient harm or death may take an extreme emotional toll on the nurse involved in the error. Nurses may be named as defendants in malpractice litigation, with possibly serious financial consequences. Many nurses choose to carry personal malpractice insurance for this reason, although nurses working in institutional settings are usually covered by the institution's liability insurance policy. Nurses should obtain clear written documentation of any institutional coverage provided before deciding whether to carry individual malpractice insurance.

Administrative responses to medication errors vary from institution to institution and depend on the severity of the error. One possible response is a directive to the nurse involved to obtain continuing education or refresher training. Disciplinary action, including suspension or termination of employment, may also occur depending on the specific incident. However, many hospitals have implemented a nonpunitive approach to

medication errors. Nurses who have violated regulations of their state's nurse practice act may also be counseled or disciplined by their state nursing board, which may suspend or permanently revoke their nursing license. Student nurses, given their lack of clinical experience, should be especially careful to avoid medication errors, as well as errors in general. When in doubt about the correct course of action, students should consult with clinical instructors or more experienced staff nurses. Nonetheless, if a student nurse realizes that he or she has committed an error, the student should notify the responsible clinical instructor immediately. The patient may require additional monitoring or medication, and the prescriber may also need to be notified. Although such events are preferably avoided, they can ultimately be useful, though stressful, learning experiences for the student nurse. However, student nurses who commit sufficiently serious errors or display a pattern of errors can expect more severe disciplinary action. This may range from a requirement for extra clinical time or repeating of a clinical course to suspension or expulsion from the nursing school program (see Educational System Issues and Their Potential Impact on Medication Errors earlier in the chapter).

SUMMARY

The increasing complexity of nursing practice also increases the risk for medication errors. Widely recognized and common causes of error include misunderstanding of abbreviations, illegibility of prescriber handwriting, miscommunication during verbal or telephone orders, and confusing drug nomenclature. The structure of various organizational, educational, and sociologic systems involved in health care delivery may also contribute directly or indirectly to the occurrence of medication errors. Understanding these influences can help the nurse take proactive steps to improve these systems. Such actions can range from fostering improved communication with other health care team members, including students, to advocating politically for safer conditions for both patients and staff. The first priority when an error does occur is to protect the patient from further harm whenever possible. All errors should serve as red flags that warrant further reflection, detailed analysis, and future preventive actions on the part of nurses, other health care professionals, and possibly even patients themselves.

KEY POINTS

- To prevent medication errors from misinterpretation of the prescriber's orders, avoid abbreviations. Medication errors include giving a drug to the wrong patient, confusing sound-alike and look-alike drugs, administering the wrong drug or wrong dose, giving the drug by the wrong route, and giving the drug at the wrong time.
- Measures to help prevent medication errors include being prepared and knowledgeable and taking time to always triple-check for the right patient, drug, dosage, time, and route. It is also important for nurses always to be aware of the entire medication administration process and to take a systems analysis approach to medication errors and their prevention.
- Encourage patients to ask questions about their medications and to question any concern about the drug or any component of the medication administration process.
- Encourage patients to always carry drug allergy information on their persons and to keep a current list of medications in their wallets or purses and on their refrigerators. This list should include the drug's name, reason the drug is being used, usual dosage range and dosage prescribed, expected adverse effects and possible toxicity of the drug, and the prescriber's name and contact information.
- Report medication errors. It is important to include in this documentation assessment of patient status before, during, and after the medication error, as well as specific orders carried out in response to the error.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse keeps in mind that which measure is used to reduce the risk of medication errors?
   - **a** When questioning a drug order, keep in mind that the prescriber is correct.
   - **b** Be careful about questioning the drug order a board-certified physician has written for a patient.
   - **c** Always double-check the many drugs with sound-alike and look-alike names because of the high risk of error.
   - **d** If the drug route has not been specified, use the oral route.

2 During the medication administration process, it is important that the nurse remembers which guideline?
   - **a** When in doubt about a drug, ask a colleague about it before giving the drug.
   - **b** Ask what the patient knows about the drug before giving it.
   - **c** When giving a new drug, be sure to read about it after giving it.
   - **d** If a patient expresses a concern about a drug, stop, listen, and investigate the concerns.

3 If a student nurse realizes that he or she has made a drug error, the instructor should remind the student of which concept?
   - **a** The student bears no legal responsibility when giving medications.
   - **b** The major legal responsibility lies with the health care institution at which the student is placed for clinical experience.
   - **c** The major legal responsibility for drug errors lies with the faculty members.
   - **d** Once the student has committed a medication error, his or her responsibility is to the patient and to being honest and accountable.

NCLEX® EXAMINATION REVIEW QUESTIONS—cont'd

4 The nurse is giving medications to a newly admitted patient who is to receive nothing by mouth (NPO status) and finds an order written as follows: "Digoxin, 250 mcg stat." Which action is appropriate?
- **a** Give the medication immediately (stat) by mouth because the patient has no intravenous (IV) access at this time.
- **b** Clarify the order with the prescribing physician before giving the drug.
- **c** Ask the charge nurse what route the physician meant to use.
- **d** Start an IV line, then give the medication IV so that it will work faster, because the patient's status is NPO at this time.

5 The nurse is reviewing medication orders. Which digoxin dose is written correctly?
- **a** digoxin .25 mg
- **b** digoxin .250 mg
- **c** digoxin 0.250 mg
- **d** digoxin 0.25 mg

6 The nurse is administering medications. Examples of high-alert medications include: (Select all that apply.)
- **a** Insulins
- **b** Antibiotics
- **c** Opiates
- **d** Anticoagulants
- **e** Potassium chloride for injection

7 Convert 250 micrograms to milligrams. Be sure to depict the number correctly according to the guidelines for decimals and zeroes.

1. c, 2. d, 3. d, 4. b, 5. d, 6. a, c, d, e, 7. 0.25 mg

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the importance of patient education in the safe and efficient administration of drugs (e.g., prescription drugs, over-the-counter drugs, herbal preparations, dietary supplements).
2 Summarize the various teaching and learning principles appropriate to patient education and drug therapy across the lifespan as applicable to any health care setting.
3 Identify the impact of the various developmental phases (as described by Erikson) on patient education as it relates to drug therapy and the nursing process.
4 Develop a complete patient teaching plan as part of a comprehensive nursing care plan for drug therapy and the nursing process for the adult patient.

KEY TERMS

Affective domain The most intangible domain of the learning process. It involves affective behavior, which is conduct that expresses feelings, needs, beliefs, values, and opinions; the feeling domain. (p. 75)

Cognitive domain The domain involved in the learning and storage of basic knowledge. It is the thinking portion of the learning process and incorporates a person's previous experiences and perceptions; the learning/thinking domain. (p. 75)

Health literacy The degree to which individuals have the capacity to obtain and then process and understand basic health information as well as basic health information and services needed to make appropriate health decisions (p. 75)

Learning The acquisition of knowledge or skill. (p. 75)

Psychomotor domain The domain involved in the learning of a new procedure or skill; often called the *doing domain*. (p. 75)

Teaching A system of directed and deliberate actions intended to induce learning. (p. 75)

Given the constant change in today's health care climate and increased consumer awareness, the role of the nurse as an educator continues to increase and remains a significant part of patient care, both in and out of the hospital environment. Patient education is essential in any health care setting and is a critical component of quality and safe health care. Without patient education, the highest quality and safest of care cannot be provided. Patient education is also very crucial in assisting patients, family, significant others, and caregivers to adapt to illness, prevent illness, maintain health and wellness, and provide self-care. Patient education is a process, much like the nursing process; it provides patients with a framework of knowledge that assists in the learning of healthy behaviors and assimilation of these behaviors into a lifestyle.

Patient education may be one of the more satisfying aspects of nursing care because it is essential to improved health outcomes and can be easily measured. In fact, in the current era of increasing acuteness of patient conditions and the need to decrease length of stays in hospitals, patient education and family teaching become even more essential to effectively and efficiently meet outcome criteria. Patient education has also been identified as a valued and satisfying activity for the professional nurse. Additionally, patient education is a qualifier found in professional and accreditation standards. Health teaching is not only included in the American Nurses Association document *Nursing: Scope and Standards of Practice* (2004) but is also one of the grading criteria used by The Joint Commission (2011), which was formerly known as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). Visit http://www.thejointcommission.org for more information on accreditation, certification, standards, measurement, and related topics.

Contributing to the effectiveness of patient education is an understanding of and attention to the three domains of learning: the cognitive, affective, and psychomotor domains. It is recommended that one or a combination of these domains be addressed in any patient educational session. The **cognitive domain** refers to the level at which basic knowledge is learned and stored. It is the thinking portion of the learning process and incorporates a person's previous experiences and perceptions. Previous experiences with health and wellness influence the learning of new materials, and prior knowledge and experience can serve as the foundation for adding new concepts. Thus, the learning process begins with the identification of what experiences the person has had with the subject matter or content. However, it is important to remember that thinking involves more than the delivery of new information because a patient must build relationships between prior and new experiences to formulate new meanings. At a higher level in the thinking process, the new information is used to question something that is uncertain, to recognize when to seek additional information, and to make decisions during real-life situations.

The **affective domain** is the most intangible component of the learning process. Affective behavior is conduct that expresses feelings, needs, beliefs, values, and opinions. It is well known that individuals view events from different perspectives and often choose to internalize feelings rather than express them. You must be willing to approach patients in a nonjudgmental manner, listen to their concerns, recognize the nonverbal messages being given, and assess patient needs with an open mind. If you are successful in gaining the trust and confidence of patients and family members, it may have a powerful effect on their attitudes and thus on the learning process.

The **psychomotor domain** involves the learning of a new procedure or skill and is often called the *doing domain.* Learning is generally accomplished by demonstration of the procedure or task using a step-by-step approach with return demonstrations by the learner to verify whether the procedure or skill has been mastered. Using a teaching approach that engages these domains—whether one, two, or a combination of all three—will certainly add to the quality and effectiveness of patient education sessions and subsequent learning.

The result of effective patient education is learning. **Learning** is defined as a change in behavior, and **teaching** as a sharing of knowledge. Although you may never be certain that patients will take medications as prescribed, you may carefully assess, plan, implement, and evaluate the teaching you provide to help maximize outcome criteria. Just like the nursing process, the medication administration process and the teaching-learning process provide systematic frameworks for professional nursing practice. The remainder of this chapter provides a brief look at patient education as related to the nursing process and drug therapy.

ASSESSMENT OF LEARNING NEEDS RELATED TO DRUG THERAPY

As previously mentioned, the patient education process is similar to the nursing process. A very important facet of the patient education process, like the nursing process, is a thorough assessment of learning needs. Complete this assessment before patients begin any form of drug therapy. As related to patient education and drug therapy, assessment includes gathering subjective and objective data about the following:

- Adaptation to any illnesses
- Age
- Barriers to learning (Box 6-1)
- Cognitive abilities
- Coping mechanisms
- Cultural background
- Developmental status for age group with attention to cognitive and mental processing abilities
- Education received including highest grade level completed and literacy level
- Emotional status
- Environment at home and at work
- Folk medicine, home remedies, or use of alternative/complementary therapies (e.g., physical therapy, chiropractic therapy, osteopathic medicine, meditation, yoga, aromatherapy)
- Family relationships
- Financial status
- **Health literacy** (Box 6-2)
- Psychosocial growth and development level according to Erikson's stages (Box 6-3)
- Health beliefs, including beliefs about health, wellness, and/or illness

BOX 6-1 STRATEGIES TO ENHANCE PATIENT EDUCATION AND REDUCE BARRIERS TO LEARNING

- Work with available educational resources in nursing and pharmacy to collect or order and distribute materials about drug therapy. Make sure that written materials are available to all individuals and are prepared on a reading level that is most representative of the geographical area, such as an eighth-grade reading level. Most acute care and other health care facilities have electronic resources, so that printing educational materials is easy. Some examples of electronic or computerized programs are Micromedex and Lexi-PALS; these offer patient pamphlets that are in different languages and at appropriate reading levels.
- Be sure that written and verbal instructions are available in the language most commonly spoken, such as Spanish. Identify resources within the facility and in the community that can provide assistance with translation, such as nurses or other health care providers who are proficient in Spanish and other languages. Have the information available so that education is carried out in a timely and effective manner.
- Perform a cultural assessment that includes questions about level of education, learning experiences, past and present successes of therapies and medication regimens, language spoken, core beliefs, value system, meaning of health and illness, perceived cause of illness, family roles, social organization, and health practices or lack thereof.
- Make sure that written materials are available on the most commonly used medications and that all materials are updated annually to ensure that information is current.
- Have available information for patients on how they can prevent medication errors. The Institute for Safe Medication Practices offers informative pamphlets on the patient's role in preventing medication errors as well as web-based resources such as alerts for consumers with the proper citation.
- Work collaboratively in the health care setting, inpatient and outpatient, to develop a listing of medications that may be considered error prone, such as cardiac drugs, chemotherapeutic drugs, low–molecular-weight heparin, digoxin, metered-dose inhaled drugs, and acetaminophen. Lack of time for patient education is often a concern for nurses, but efforts should be undertaken to make materials available and to review these with patients and those involved in their care. Use all available resources, such as videotapes, verbal instructions, pictures, and other health care providers.
- For the adolescent, be sure to provide clear and simple directions for each medication, including clarification of information that may well be misinterpreted. For example, teenage girls may have the false idea that oral contraceptives prevent them from contracting sexually transmitted diseases.
- Use readability tools in the development of patient education materials if you are involved in this process. Several tools are available, such as the SMOG (Simple Measure of Gobbledygook) readability measure and the Fry readability formula. It is important to know that evidenced-based measures such as these are available to help in the creation of written materials and verbal instructions for patients. Online resources include http://www.readabilityformulas.com/smog-readability-formula.php and http://www.readabilityformulas.com/fry-graph-readability-formula.php.
- Never wait until discharge to teach patients. Include family or caregivers whenever possible, so that they become contributors to patient education and not barriers!

BOX 6-2 A BRIEF LOOK AT HEALTH LITERACY

- In 2004, the Institute of Medicine estimated that over 90 million Americans have difficulty in not only understanding information about their own health concerns but also have difficulty acting on the information.
- As related to patient education, assessing and addressing health literacy is only one aspect, but a very important aspect, of health communication and the cognitive domain of learning.
- If there is health illiteracy, studies have shown that issues of noncompliance to treatment regimens and disease complications as well as difficulty accessing health care are problematic, contributing to poor health as well as higher health care costs.
- Health illiteracy has been associated with less education, lower socioeconomic status, decrease in sensorial abilities, and multiple disease processes, so assessment of these factors is important to individualized patient education.
- Other areas to assess related to health literacy include reading level, ability to follow directions/instructions, as well as ability to manage everyday living activities such as self-care, grocery shopping, and meal preparation.
- Assessment of health literacy may be done with much sensitivity and does not only relate to education but also to levels of stress/inability to cope with a new diagnosis/process new and complex information (i.e., patients with higher level of education but are stressed and unable to process due to a disturbing diagnosis).

BOX 6-3 ERIKSON'S STAGES OF DEVELOPMENT

Infancy (birth to 1 year of age): Trust versus mistrust. Infant learns to trust himself or herself, others, and the environment; learns to love and be loved.

Toddlerhood (1 to 3 years of age): Autonomy versus shame and doubt. Toddler learns independence; learns to master the physical environment and maintain self-esteem.

Preschool age (3 to 6 years of age): Initiative versus guilt. Preschooler learns basic problem solving; develops conscience and sexual identity; initiates activities as well as imitates.

School age (6 to 12 years of age): Industry versus inferiority. School-age child learns to do things well; develops a sense of self-worth.

Adolescence (12 to 18 years of age): Identity versus role confusion. Adolescent integrates many roles into self-identity through imitation of role models and peer pressure.

Young adulthood (18 to 45 years of age): Intimacy versus isolation. Young adult establishes deep and lasting relationships; learns to make commitment as a spouse, parent, and/or partner.

Middle adulthood (45 to 65 years of age): Generativity versus stagnation. Adult learns commitment to the community and world; is productive in career, family, and civic interests.

Older adulthood (over 65 years of age): Integrity versus despair. Older adult appreciates life role and status; deals with loss and prepares for death.

- Information the patient understands about past and present medical conditions, medical therapy, and medications
- Language(s) spoken
- Level of knowledge about any medication(s) being taken
- Limitations (physical, psychological, cognitive, and motor)
- Medications currently taken (including over-the-counter drugs, prescription drugs, and herbal products)
- Misinformation about drug therapy
- Mobility and motor skills
- Motivation
- Nutritional status
- Past and present health behaviors
- Past and present experience with drug regimens and other forms of therapy, including levels of compliance
- Race and/or ethnicity
- Readiness to learn
- Religion or religious beliefs
- Self-care ability
- Sensory status
- Social support

During the assessment of learning needs, be astutely aware of the patient's verbal and nonverbal communication. Often a patient will not tell you how he or she truly feels. A seeming discrepancy is an indication that the patient's emotional or physical state may need to be further assessed in relation to his or her actual readiness and motivation for learning. Use of open-ended questions is encouraged, because they stimulate more discussion and greater clarification from the patient than closed-ended questions that require only a "yes" or "no" answer. Assess level of anxiety, because mild levels of anxiety have been identified as being motivating, whereas moderate to severe levels may be obstacles. In addition, if there are physical needs that are not being met, such as relief from pain, vomiting, or other physical distress, these needs become obstacles to learning. These physical issues must be managed appropriately before any patient teaching occurs.

NURSING DIAGNOSES RELATED TO LEARNING NEEDS AND DRUG THERAPY

Some of the most commonly used and currently approved NANDA-I (2012-2014) nursing diagnoses related to patient education and drug therapy are as follows (see Chapter 1 for a more complete listing):

- Deficient knowledge
- Falls, risk for
- Ineffective self-health management
- Readiness for enhanced self-health management
- Impaired memory
- Injury, risk for
- Noncompliance
- Sleep deprivation

As an example of how nursing diagnoses related to patient education are derived, the nursing diagnosis of *deficient knowledge* refers to a situation in which the patient, caregiver, or significant other has a limited knowledge base or skills with regard to the medication or medication regimen. A nursing diagnosis of *deficient knowledge* develops out of objective and/or subjective data showing that there is limited understanding, no understanding, or misunderstanding of the medication and its action, indications, adverse reactions, toxic effects, drug-drug and/or drug-food interactions, cautions, and contraindications. This diagnosis may also reflect decreased cognitive ability or impaired motor skill needed to perform self-medication. Deficient knowledge differs from noncompliance in that the latter occurs when the patient does not take the medication as prescribed or at all; in other words, the patient does not comply with or adhere to the instructions given about the medication. Noncompliance is usually a patient's choice. A nursing diagnosis of *noncompliance* is made when data collected from the patient show that the condition or symptoms for which the patient is taking the medication have recurred or were never resolved because the patient did not take the medication per the prescriber's orders or did not take the medication at all. Although noncompliance is usually a patient decision, other factors need to be assessed to determine the cause of the noncompliance (e.g., lack of ability of the parent, family, or caregiver to administer the medication; other physical, emotional, or socioeconomic factors). These factors are associated with the nursing diagnosis of ineffective health maintenance and provide a patient-centered approach to the plan of care.

PLANNING RELATED TO LEARNING NEEDS AND DRUG THERAPY

The planning phase of the teaching-learning process occurs as soon as a learning need has been assessed and then identified in the patient, family, or caregiver. With mutual understanding, the nurse and patient identify goals and outcome criteria that are associated with the identified nursing diagnosis and are able to relate them to the specific medication the patient is taking. The following is an example of a measurable goal with outcome criterion related to a nursing diagnosis of *deficient knowledge* for a patient who is self-administering an oral antidiabetic drug and has many questions about the medication therapy. *Sample goal:* The patient safely self-administers the prescribed oral antidiabetic drug within a given time frame. *Sample outcome criterion:* The patient remains without signs and symptoms of overmedication while taking an oral antidiabetic drug, such as hypoglycemia with tachycardia, palpitations, diaphoresis, hunger, and fatigue. When drug therapy goals and outcome criteria are developed, appropriate time frames for meeting outcome criteria must be identified (see Chapter 1 for more information on the nursing process). In addition, goals and outcome criteria need to be realistic, based on patient needs, stated in patient terms, and include behaviors that are measurable, such as *list, identify, demonstrate, self-administer, state, describe,* and *discuss.*

IMPLEMENTATION RELATED TO PATIENT EDUCATION AND DRUG THERAPY

After you have completed the assessment phase, identified nursing diagnoses, and created a plan of care, the implementation phase of the teaching-learning process begins. This phase includes conveying specific information about the medication

EVIDENCE-BASED PRACTICE

Building a Collaborative Nursing Practice to Promote Patient Education: An Inpatient and Outpatient Partnership

Review

This study took place in a large medical facility with an oncology nursing staff, located in the Midwestern region of the United States. The study looked at the communication among nurses as related to patient education to those with cancer. Specifically, the nurses were interested in looking at the lack of consistency in formal patient education between the inpatient and outpatient settings.

Type of Evidence

Initially a team was formed to help in identifying and then implementing potential solutions for improving communication about specialty-specific patient education. This team consisted of clinical nurse specialist in hematology/oncology/blood marrow transplantation (BMT), a nursing education specialist, and three nurse educators representing the facility's Cancer Education Center. The Cancer Education Center is responsible for an outpatient educational program with the mission of meeting educational needs of patients with cancer across the continuum of care. A thorough literature search was completed only to find out that there was minimal information written about nurse-to-nurse communication. The team then developed a pilot project to assist them in evaluating the effects of collaborative efforts in promoting patient education between inpatient and outpatient areas. Goals and objectives were identified and were twofold: (1) to build a collaborative nursing practice between their inpatient and outpatient practice settings, and (2) to provide an opportunity to increase the effectiveness of inpatient hematology/oncology and BMT nurses' professional development. A call for applications was sent out the staff of the hematology/oncology/BMT units with a total of 13 applicants. Five applicants were selected for formal interviews inclusive of the project team members and inpatient nurses. After orientation to the process and project, the participants began their work in the outpatient Cancer Education Center with an average patient population of about 140. A four-level evaluation model (see original journal article for more specific information) was used to help analyze the value of the pilot project.

Results of Study

Using an anonymous format, all of the information collected from interviews and surveys were analyzed for content themes. The five themes identified, after validation with nursing leadership and project participants, included increased awareness and application of knowledge, professional development, collaboration, the importance of continued collaboration, and the impact on nursing practice. The results showed a positive impact on all five themes despite the fact that each staff nurse worked only six times in the Cancer Education Center. Numerous patient responses reflected a feeling of increased comfort with the inpatient-to-outpatient transition process. For the nurse participants and other nurses in the setting, there was an increase in sharing of knowledge and experiences. Additionally, several barriers to collaboration occurred, which spurred the need for being prepared for such barriers. These potential barriers included barrier for project funding, level of participant motivation, length of time needed for acclimation to the project's setting (took longer!), and the need for more educational opportunities with specific strategies for how to best work with patients and families seeking out education in the outpatient versus inpatient setting.

Link of Evidence to Nursing Practice

There were several important findings from this study as discussed above; however, the need to foster and build strong networking and collaborative relationships among staff nurses in a continuum of settings is crucial to job satisfaction and more importantly, to the effectiveness of meeting patient education needs in cancer patients who are frequently moving from inpatient to outpatient settings. In addition, the educational needs of these patients continually change, requiring even more specific educational programs and nurses prepared for these programs. This study also found that as the nurse participant's knowledge increased, the patient benefited greatly, which is applicable to any type of patient care. It is well documented in the literature that as nurses expand their knowledge about the system and aspects of nursing care, the benefit to the patient is enhanced as noted in the depth of interactions and the level of care provided. The collaborative partnership between nurses and their patients regardless of setting is challenging, but nurses need to continue to discover opportunities to foster their education, experience, and collaborative relationships among the care continuum. In summary, this study had very positive results from the pilot evaluation and led to a shared communication and staffing model. The collaborative program in this study continues to be offered through a formal staff development program called Nursing Perspectives.

Reference: Negley DF, Ness S, Fee-Schroeder K, et al: Building a collaborative nursing practice to promote patient education: an inpatient and outpatient partnership, *Oncol Nurs Forum* 36(1):19-23, 2009.

to the patient, family, or caregiver. Teaching-learning sessions must incorporate clear, simple, concise written instructions (Box 6-4); oral instructions; and written pamphlets, pictures, videos, or any other learning aids that will help ensure patient learning. You may have to conduct several brief teaching-learning sessions with multiple strategies, depending on the needs of the patient. Several changes related to the growth and aging of patients affect teaching-learning, and Table 6-1 lists educational strategies for accommodating these changes in a plan of care. You may also need to identify aids to help the patient in the safe administration of medications at home, such as the use of medication day or time calendars, pill reminder stickers, daily medication containers with alarms, weekly pill containers with separate compartments for different dosing times for each day for the week, and/or a method of documenting doses taken to avoid overdosage or omission of doses.

Special issues arise when the patient speaks limited or no English. Communicate with the patient in the patient's native language, if at all possible. If you are not able to speak the patient's native language, a translator needs to be made available to prevent communication problems, minimize errors, and help boost the patient's level of trust and understanding. In practice, this translator may be another nurse or health care professional; a nonprofessional member of the health care team; or a layperson, family member, adult friend, or religious leader or associate. However, it is best to avoid using family members as translators if possible because of issues with bias and misinterpretation, as well as potential confidentiality issues. It is important to remember that some of these individuals may not be competent in or comfortable with communicating technical clinical information, and other resources must be used if this is the case. As the United States experiences

BOX 6-4 GENERAL TEACHING AND LEARNING PRINCIPLES

- Make learning patient-centered and individualized to each patient's needs, including his or her learning needs. This includes assessment of the patient's cultural beliefs, educational level, previous experience with medications, level of growth and development (to best select a teaching-learning strategy), age, gender, family support system, resources, preferred learning style, and level of sophistication with health care and health care treatment.
- Assess the patient's motivation and readiness to learn.
- Assess the patient's ability to use and interpret label information on medication containers.
- Some studies have shown that as much as 20% of the U.S. population is functionally illiterate. Therefore, ensure that educational strategies and materials are at a level that the patient is able to understand, while taking care to not embarrass the patient.
- If a patient is illiterate, he or she still needs to be instructed on safe medication administration. Use pictures, demonstrations, and return demonstrations to emphasize instructions.
- Consider, assess, and appreciate language and ethnicity during patient teaching. Make every effort to educate non–English-speaking patients in their native language. Ideally the patient needs to be instructed by a health professional familiar with the patient's clinical situation who also speaks the patient's native language. At the very least, provide the patient detailed written instructions in his or her native language.
- Assess the family support system for adequate patient teaching. Family living arrangements, financial status, resources, communication patterns, the roles of family members, and the power and authority of different family members must always be considered.
- Make the teaching-learning session simple, easy, fun, thorough, effective, and not monotonous. Make it applicable to daily life, and schedule it at a time when the patient is ready to learn. Avoid providing extraneous information that may be confusing or overwhelming to the patient.
- Remember that learning occurs best with repetition and periods of demonstration and with the use of audiovisuals and other educational aids.
- Patient teaching must focus on the various processes in the cognitive, affective, and/or psychomotor domains (see earlier discussion).
- Consult online resources for help in obtaining the most up-to-date and accurate patient teaching materials and information.

TABLE 6-1 EDUCATIONAL STRATEGIES TO ADDRESS COMMON CHANGES RELATED TO AGING THAT MAY INFLUENCE LEARNING

CHANGE RELATED TO AGING	EDUCATIONAL STRATEGY
Cognitive and Memory Impairment	
Slowed cognitive functioning	Slow the pace of the presentation, and attend to verbal and nonverbal patient cues to verify understanding.
Decreased short-term memory	Provide smaller amounts of information at one time. Repeat information frequently. Provide written instructions for home use.
Decreased ability to think abstractly	Use examples to illustrate information. Use a variety of methods, such as audiovisuals, props, videotapes, large-print materials, materials with vivid color, return demonstrations, and practice sessions.
Decreased ability to concentrate	Decrease external stimuli as much as possible.
Increased reaction time (slower to respond)	Always allow sufficient time, and be patient. Allow more time for feedback.
Disturbed Sensory Perception	
Hearing Impairment	
Diminished hearing	Perform a baseline hearing assessment. Use tone- and volume-controlled teaching aids; use bright, large-print material to reinforce.
Decreased ability to distinguish sounds (e.g., differentiate words beginning with *S, Z, T, D, F,* and *G*)	Speak distinctly and slowly, and articulate carefully.
Decreased conduction of sound	Sit on the side of the patient's best ear.
Loss of ability to hear high-frequency sounds	Do not shout; speak in a normal voice but a lower voice pitch.
Partial to complete loss of hearing	Face the patient so that lip reading is possible. Use visual aids to reinforce verbal instruction. Reinforce teaching with easy-to-read materials. Decrease extraneous noise. Use community resources for the hearing impaired.
Visual Impairment	
Decreased visual acuity	Ensure that the patient's glasses are clean and in place and that the prescription is current.
Decreased ability to read fine detail	Use printed materials with large print that is brightly and clearly colored.
Decreased ability to discriminate among blue, violet, and green; tendency for all colors to fade, with red fading the least	Use high-contrast materials, such as black on white. Avoid the use of blue, violet, and green in type or graphics; use red instead.
Thickening and yellowing of the lenses of the eyes, with decreased accommodation	Use nonglare lighting, and avoid contrasts of light (e.g., a darkened room with a single light).
Decreased depth perception	Adjust teaching to allow for the use of touch to gauge depth.
Decreased peripheral vision	Keep all teaching materials within the patient's visual field.
Touch and Vibration Impairment	
Decreased sense of touch	Increase the time allowed for the teaching of psychomotor skills, the number of repetitions, and the number of return demonstrations.
Decreased sense of vibration	Teach the patient to palpate more prominent pulse sites (e.g., carotid and radial arteries).

Modified from Weinrich SP, Boyd M, Nussbaum J: Continuing education: adapting strategies to teach the elderly, *J Gerontol Nurs* 15(11):17-21, 1989; McKenry LM, Salerno E: *Mosby's pharmacology in nursing,* ed 22, St Louis, 2006, Mosby.

NOTE: These strategies may also be appropriate for younger patients.

rapid growth in minority populations, our health care system will see a staggering increase in the percentage of non–English-speaking patients. According to the August 2008 projections of the U.S. Census Bureau, demographic changes will be significant, with minority groups—which currently compose one-third of the U.S. population—growing to become the majority by 2042 and projected to increase to 54% of the population by 2050. This growth in cultural diversity will continue to demand that nursing and related health care professions provide patient education materials in both English and Spanish. Publications provided for non–English-speaking patients may enable you to convey a sufficient amount of information in the patient's language to help effectively educate the patient and also allow you to share materials with family members and caregivers for their use. Companies now also publish a variety of patient education materials for the discharge process in both English and Spanish.

Non–English-speaking patients tend to notice and appreciate their health professionals' efforts to speak their own language and will often help teach them new words or phrases, if there is enthusiasm and interest. This experience may lead to significantly greater rapport, put the patient at ease, and show respect for his or her culture or race/ethnicity. Obtaining and keeping available a foreign language dictionary may be helpful. Keeping notes about newly learned words, phrases, or sentences may be helpful, too. Even if the professional does not use the correct verb tenses, he or she may often communicate sufficiently with the patient for the purpose at hand. As one begins to learn a foreign language, a major challenge may be to speak with a patient over the telephone. The important goal is to try to increase one's *listening* speed to match the *speaking* speed of the patient. With effort, this *can* be accomplished. If one can grasp even a few words of what the patient is saying, one may be able, with continued conversation with the patient, to determine and respond to the patient's needs. However, be aware that patients who are native English speakers may also have problems learning about their medications and treatment regimens because of learning deficits or difficulties, hearing and speech deficits, lack of education, or minimal previous exposure to treatment regimens and medication use.

The teaching of manual skills for specific medication administration is also part of the teaching-learning session. Sufficient time must be allowed for the patient to become familiar with any equipment and to perform several return demonstrations to you or another health care provider. Teaching-learning needs will vary from patient to patient. Make every effort to include family members, significant others, or caregivers in the teaching session(s) for reinforcement purposes. Audiovisual aids may be incorporated and based on findings from the learning needs and nursing assessment. Resources for information about medications include *USP Drug Information* volume II, *Advice for the Patient,* which is published annually (along with the *Health Care Professional* volume) by Thomson Micromedex; this information is appropriate to share with the patient. This type of resource may be helpful to the patient when he or she seeks information about a medication (e.g., purpose, adverse effects, method of administration, drug interactions) and helpful to you in developing a patient teaching plan. Create a safe, nonthreatening, nondistracting environment for learning needs, and be open and receptive to the patient's questions. The following strategies may help ensure an effective teaching-learning session:

- Begin the teaching-learning process upon the patient's admission to the health care setting (see the Teamwork and Collaboration: Legal and Ethical Principles box on p. 81).
- Individualize the teaching session to the patient.
- Provide positive rewards or reinforcement after accurate return demonstration of a procedure, technique, and/or skill during the teaching session.
- Complete a medication calendar that includes the names of the drugs to be taken along with the dosage and frequency. Allow the patient to see what the medications look like for future reference.
- Use audiovisual aids.
- Involve family members or significant others in the teaching session, as deemed appropriate.
- Keep the teaching on a level that is most meaningful to the given patient; general research on reading skills has shown that written materials must be written at an eighth-grade reading level.

PATIENT-CENTERED CARE: CULTURAL IMPLICATIONS

Patient Education

Research various cultures to enhance an individualized approach to nursing care. For example, with Mexican-American patients, aspects of nursing care must be approached in a sensitive manner with strong consideration for the family, communication needs, and religion. Approximately 90% of native Mexicans are Roman Catholic. To help meet the needs of these patients more effectively, consider speaking with them about their desire for clergy visits while in the hospital. Family members are generally involved, and Mexican Americans often have large extended families; therefore, take the time to include family members in the patient's care and when providing discharge instructions and medication instructions.

Health care professionals who work in a geographic area where a variety of non-English languages are widely spoken need to make an effort to learn one or more of these languages. Adult foreign language education is available in most U.S. cities, often at 2- and 4-year colleges or universities. Many classes are designed for working professionals and are scheduled at a variety of convenient times during the day and evening to accommodate demanding work schedules. Community colleges often offer quality courses that meet as little as 1 day or evening per week. Many employers will pay for job-related courses, and some courses may qualify for professional continuing education credits. Language courses provide a means of networking and developing quality friendships with other highly motivated, empathic individuals both within and outside of the health care profession. A variety of self-study materials are also available.

Modified from McKenry LM, Salerno E: *Mosby's pharmacology in nursing,* ed 22, St Louis, 2006, Mosby.

TEAMWORK AND COLLABORATION: LEGAL AND ETHICAL PRINCIPLES

Discharge Teaching

The safest practices for discharge teaching are as follows:

- Always follow the health care facility's policy on discharge teaching with regard to how much information to impart to the patient.
- Do not assume that any patient has received adequate teaching before interacting with you.
- Always begin discharge teaching as soon as possible when the patient is ready.
- Minimize any distractions during the teaching session.
- Evaluate any teaching of the patient and/or significant others by having the individuals repeat the instructions you have given them.
- Contact the institution's social services department or the discharge planner if there are any concerns regarding the learning capacity of the patient.
- Document what you taught, who was present with the patient during the teaching, what specific written instructions were given, what the responses of the patient and significant other or caregiver were, and what your own nursing actions were, such as specific demonstrations or referrals to community resources.
- Document teaching-learning strategies used, such as videotapes and pamphlets.

Modified from U.S. Pharmacopeia Safe Medication Use Expert Committee Meeting, Rockville, MD, May 2003, available at http://www.usp.org.

Box 6-4 lists some general teaching and learning principles to consider in providing patient education.

Upon completion of any teaching-learning process or patient education session, complete the documentation and include notes about the content provided, strategies used, and patient response to the teaching session, and an overall evaluation of learning. Because of the significance of patient education related to drug therapy and the nursing process, this textbook integrates patient education into each chapter in the implementation phase of the nursing process. In addition, a Patient Teaching Tips section is included at the end of most chapters.

EVALUATION OF PATIENT LEARNING RELATED TO DRUG THERAPY

Evaluation of patient learning is a critical component of safe and effective drug administration. To verify the success—or lack of success—of patient education, ask specific questions related to patient outcomes and request that the patient repeat information or give a return demonstration of skills, if appropriate. The patient's behavior—such as adherence to the schedule for medication administration with few or no complications—is one key to determining whether or not teaching was successful and learning occurred. If a patient's behavior is characteristic of noncompliance or an inadequate level of learning, develop, implement, and evaluate a new plan of teaching.

CASE STUDY

Patient Education and Anticoagulant Therapy

M.S., an 82-year-old retired librarian, has developed atrial fibrillation. As part of his medical therapy, he is started on the oral anticoagulant warfarin (Coumadin). His wife reports that he has some trouble hearing yet refuses to consider getting hearing aids. In addition, this is his first illness and his wife states that he has "always hated taking medications. He's read about herbs and folk healing and would rather try natural therapy." The nurse is planning education about oral anticoagulant therapy, and M.S. says that he'll "give it a try" for now, but he "knows nothing about this drug."

1. What will the nurse assess, including possible barriers to learning, before teaching?
2. Formulate an education-related nursing diagnosis for this patient based on the information given above. In addition, provide a goal and one example of an outcome criterion for the nursing diagnosis.
3. What education strategies will the nurse plan to use, considering any age-related changes the patient may have?

For answers, see http://evolve.elsevier.com/Lilley.

SUMMARY

Patient education is a critical part of patient care, and patient education about medication administration, therapies, or regimens is no exception. From the time of initial contact with the patient throughout the time you work with the patient, the patient is entitled to all information about medications prescribed as well as other aspects of his or her care. Evaluation of patient learning and compliance with the medication regimen remains a continuous process; be willing to listen to the patient about any aspect of the patient's drug therapy. Professional nurses are teachers and serve as patient advocates and thus have a responsibility to facilitate learning for patients, families, significant others, and caregivers. Accurate assessment of learning needs and readiness to learn always requires a look at the whole patient, including cultural values, health practices, and literacy issues. Every effort needs to be made to see that the patient receives effective learning to ensure successful outcomes with regard to drug therapy—and all parts of the patient's health care.

It is important to consult resources mentioned earlier, as well as the U.S. Pharmacopeia (at http://www.usp.org), which serves as an advocate for patient safety and establishes standards for medications. This organization is a tremendous resource for the health care professional in obtaining information for the patient so that quality patient education can be provided. The U.S. Pharmacopeia values patient education as a means of enhancing patient safety as well as a means of decreasing medication errors in the hospital setting or at home. In addition, the Institute for Safe Medication Practices (at http://www.ismp.org) provides nurses with a wealth of information related to patient education, safety, and prevention of medication errors. As a nonprofit organization, this institute works closely with nurses, prescribers, regulatory agencies, and professional organizations

to provide education about medication errors and their prevention, and is a premier resource in all matters pertaining to safe medication practices in health care organizations.

Another resource is the National Council on Patient Information and Education (NCPIE), which may be accessed at www.talkaboutrx.org. This site was developed with the purpose of stimulating and improving communication of information on the appropriate use of medications to consumers and health care professionals (Box 6-5). In summary, it is professional nurses who usually have the most contact with patients and see patients in a variety of settings. Because of this, nurses need to continue to be patient advocates and take the initiative to plan, design, create, and present educational materials for teaching about drug therapy.

BOX 6-5 NATIONAL COUNCIL ON PATIENT INFORMATION AND EDUCATION (NCPIE): A BRIEF REVIEW

- NCPIE is composed of over 125 diverse organizations with the mission to stimulate and improve communication and information on appropriate medication use.
- It is the leading authority for informing the general public and health care professionals on safe medication use through use of more effective communication leading to better health outcomes and quality of life.
- NCPIE has been involved in promoting and sharing of information among consumers, prescribers, pharmacists, and other members of the health care team for approximately 25 years.
- With some 3.5 billion prescriptions being dispensed annually, taking the drugs properly and with full knowledge is a challenge; NCPIE attempts to make communication better about these issues.
- NCPIE's website, available at *www.talkaboutrx.org,* helps consumers make sound decisions about the use of medicines. Other resources available on the NCPIE's website are Educate Before You Medicate: Knowledge Is the Best Medicine; Communicate Before You Medicate, Team Up and Talk, Mustforseniors.org.
- Some of the programs that were launched in 2002 include the "Be MedWise" campaign at www.bemedwise.org, which targeted the use of over-the-counter medications.

Data from National Council on Patient Information and Education: National Council on Patient Information and Education website, 2011, available at http://www.talkaboutrx.org. Accessed February 4, 2011.

PATIENT TEACHING TIPS

- Teaching needs to focus on either the cognitive, affective, or psychomotor domain or a combination of all three. The cognitive domain may involve recall for synthesis of facts, with the affective domain involving behaviors such as responding, valuing, and organizing. The psychomotor domain includes teaching someone how to perform a procedure.
- Realistic patient teaching goals and outcome criteria must be established with the involvement of the patient, caregiver, or significant other.
- Keep patient teaching on a level that is most meaningful to the individual. Most research indicates that reading materials need to be written at an eighth-grade reading level but adjusted accordingly to patient assessment.
- Follow teaching and learning principles when developing and implementing patient education.
- Be sure to control the environmental factors, such as lighting, noise, privacy, and odors. Provide dignified care while preparing the patient for teaching, and respect personal space. If there are distractions, such as television, radio, cell phone, or computer, work with the patient/family members to safely and appropriately quiet these items during teaching sessions.
- Make sure that all patient education materials are organized and at hand. If the patient wears eyeglasses or hearing aids, be sure they are made available prior to education.

KEY POINTS

- The effectiveness of patient education relies on an understanding of and attention to the cognitive, affective, and psychomotor domains of learning. After you have completed the assessment phase, identified nursing diagnoses, and created a plan of care, the implementation phase of the teaching-learning process begins; reevaluation of the teaching plan must occur frequently and as needed. The growth in cultural diversity, in particular the increase in the Hispanic population, demands that nursing and related health care professions provide patient education materials in both English and Spanish.
- In educational sessions, patients need to receive information through as many senses as possible, such as verbally and visually (e.g., through pamphlets, videotapes, and diagrams), to maximize learning. Information must be presented at the patient's reading level (in the patient's native language, if possible) and suitable for the patient's level of cognitive development (see Erikson's stages in Box 6-3).
- Teaching and learning principles also must be integrated into patient education plans. Evaluation of patient learning is a critical component of safe and effective drug administration.
- To verify the success—or lack of success—of patient education, nurses need to be very specific in their questions related to patient outcomes and request that the patient repeat information or perform a return demonstration of skills, if appropriate.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A 47-year-old patient with diabetes is being discharged to home and must take insulin injections twice a day. The nurse keeps in mind which concepts when considering patient teaching?
- a Teaching needs to begin at the time of diagnosis or admission and is individualized to the patient's reading level.
- b The nurse can assume that because the patient is in his forties he will be able to read any written or printed documents provided.
- c The majority of teaching can be done with pamphlets that the patient can share with family members.
- d A thorough and comprehensive teaching plan designed for an eleventh-grade reading level needs to be developed.

2 The nurse is developing a discharge plan regarding a patient's medication. Which of these statements about the discharge plan is true?
- a It will be developed right before the patient leaves the hospital.
- b It will be developed only after the patient is comfortable or after pain medications are administered.
- c It will include videos, demonstrations, and instructions written at least at the fifth-grade level.
- d It will be individualized and based on the patient's level of cognitive development.

3 The nurse is responsible for preoperative teaching for a patient who is mildly anxious about receiving pain medications postoperatively. The nurse recognizes that this level of anxiety may
- a impede learning because anxiety is always a barrier to learning.
- b lead to major emotional unsteadiness.
- c result in learning by increasing the patient's motivation to learn.
- d reorganize the patient's thoughts and lead to inadequate potential for learning.

4 What action by the nurse is the best way to assess a patient's learning needs?
- a Quiz the patient daily on all medications.
- b Begin with validation of the patient's present level of knowledge.
- c Assess family members' knowledge of the prescribed medication even if they are not involved in the patient's care.
- d Ask the caregivers what the patient knows about the medications.

5 Which technique would be most appropriate to use when the nurse is teaching a patient with a language barrier?
- a Obtain an interpreter who can speak in the patient's native tongue for teaching sessions.
- b Use detailed explanations, speaking slowly and clearly.
- c Assume that the patient understands the information presented if the patient has no questions.
- d Provide only written instructions.

6 A nursing student is identifying situations that involve the psychomotor domain of learning as part of a class project. Which are examples of learning activities that involve the psychomotor domain? (Select all that apply.)
- a Teaching a patient how to self-administer eyedrops
- b Having a patient list the adverse effects of an antihypertensive drug
- c Discussing what foods to avoid while taking antilipemic drugs
- d Teaching a patient how to measure the pulse before taking a beta blocker
- e Teaching a family member how to give an injection
- f Teaching a patient the rationale for checking a drug's blood level

7 The nurse is instructing an elderly patient on how to use his walker. Which education strategies are appropriate? (Select all that apply.)
- a Speak slowly and loudly.
- b Ensure a quiet environment for learning.
- c Repeat information frequently.
- d Allow for an increased number of return demonstrations.
- e Provide all the information in one teaching session.

1. a, 2. d, 3. c, 4. b, 5. a, 6. a, d, e, 7. b, c, d

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the differences between prescription drugs, over-the-counter (OTC) drugs, herbals, and dietary supplements.
2 Briefly discuss the differences between the federal legislation governing the promotion and sale of prescription drugs and the legislation governing OTC drugs, herbals, and dietary supplements.
3 Describe the advantages and disadvantages of the use of OTC drugs, herbals, and dietary supplements.
4 Discuss the role of nonprescription drugs, specifically herbals and dietary supplements, in the integrative (often called *alternative* or *complementary*) approach to nursing and health care.
5 Discuss the potential dangers associated with the use of OTC drugs, herbals, and dietary supplements.
6 Develop a nursing care plan related to OTC, herbal, and dietary supplement drug therapy and the nursing process.

KEY TERMS

Alternative medicine Herbal medicine, chiropractic, acupuncture, massage, reflexology, and any other therapies traditionally not emphasized in Western medical schools but popular with many patients. (p. 88)

Complementary medicine Alternative medicine when used simultaneously with, rather than instead of, standard Western medicine. (p. 88)

Conventional medicine The practice of medicine as taught in Western medical schools. (p. 87)

Dietary supplement A product that contains an ingredient intended to supplement the diet, including vitamins, minerals, herbs, or other botanicals. (p. 87)

Herbal medicine The practice of using herbs to heal. (p. 87)

Herbs Plant components including bark, roots, leaves, seeds, flowers, fruit of trees, and extracts of these plants that are valued for their savory, aromatic, or medicinal qualities. (p. 87)

Iatrogenic effects Unintentional adverse effects that are caused by the actions of a prescriber, other health care professional, or by a specific treatment. (p. 87)

Integrative medicine Simultaneous use of both traditional and alternative medicine. (p. 88)

Legend drugs Medications that are not legally available without a prescription from a prescriber (e.g., physician, nurse practitioner, physician assistant; also called *prescription drugs*). (p. 88)

Over-the-counter (OTC) drugs Medications that are legally available without a prescription. (p. 85)

Phytochemicals The pharmacologically active ingredients in herbal remedies. (p. 89)

OVER-THE-COUNTER DRUGS

Health care consumers are becoming increasingly involved in the diagnosis and treatment of common ailments. This has led to a great increase in the use of nonprescription or **over-the-counter (OTC) drugs.** More than 80 classes of OTC drugs are marketed to treat a variety of illnesses ranging from acne to cough and cold, pain relief, and weight control. There are currently more than 300,000 OTC products containing over 800 major active ingredients. OTC medications now account for about 60% of all medications used in the United States. Health care consumers use OTC drugs to treat or cure more than 400 different ailments. Over 40 medications that formerly required a prescription are now available OTC. Some 40% to 87% of people 65 years of age or older use one OTC product regularly, and 5.7% take five or more OTC or dietary supplements daily. Some of the most commonly used OTC products include acetaminophen (see Chapter 10), aspirin (see Chapter 44), ibuprofen (see Chapter 44), famotidine, omeprazole and antacids (see Chapter 50), loperamide (see Chapter 51), and cough and cold products (see Chapter 18).

For nurses to understand current OTC classification, it is helpful to have some knowledge of the U.S. Food and Drug Administration (FDA) approval process for these medications. In 1972, the FDA initiated an OTC Drug Review to ensure the safety and effectiveness of the OTC products available, as well as to establish appropriate labeling standards. As a result of this review, approximately one-third of the OTC products were determined to be safe and effective for their intended uses, and one-third were found to be ineffective. A small number were considered to be unsafe, and the remainder required submission of additional data before their safety and effectiveness could be established. Products determined to be unsafe were removed from the market. Some established products that were found to be ineffective but not unsafe were "grandfathered" in and allowed to remain on the market. Many of these have gradually slipped into obscurity and are no longer sold. The FDA now requires new stricter "drug facts" labeling for OTC products that includes information on the following: purpose and uses of the product; specific warnings, including when the product should not be used under any circumstances; and when it is appropriate to consult a doctor or pharmacist. This labeling also describes side effects that could occur; substances or activities to avoid; dosage instructions; and active ingredients, warnings, storage information, and inactive ingredients.

Another result of the OTC Drug Review was the reclassification from prescription to OTC status of more than 40 primary product ingredients. The FDA's Nonprescription Drugs Advisory Committee is responsible for the reclassification of prescription drug products to OTC status. A drug must meet the criteria listed in Box 7-1 to be considered for reclassification. The required information is obtained from clinical trials and postmarketing safety surveillance data, which are submitted to the FDA by the manufacturer. Although this reclassification procedure has been criticized as overly time consuming, it is structured to ensure that products reclassified to OTC status are safe and effective when used by the average consumer.

BOX 7-1 CRITERIA FOR OVER-THE-COUNTER STATUS

Indication for Use

Consumer must be able to easily:

- Diagnose condition
- Monitor effectiveness

Benefits of correct usage must outweigh risks.

Safety Profile

Drugs must have:

- Favorable adverse event profile
- Limited interaction with other drugs
- Low potential for abuse
- High therapeutic index*

Practicality for Over-the-Counter Use

Drugs must be:

- Easy to use
- Easy to monitor

*Ratio of toxic to therapeutic dosage.

OTC status has many advantages over prescription status. Patients can conveniently and effectively self-treat many minor ailments. Some professionals argue that allowing patients to self-treat minor illnesses enables prescribers to spend more time caring for patients with serious health problems. Others argue that it delays patients from seeking medical care until they are very ill. The financial effect of this status change is enormous: by 2013, OTC sales in the United States will exceed $22 billion. Manufacturers often benefit by prolonging market exclusivity without competition from generic products.

Reclassification of a prescription drug as an OTC drug may increase out-of-pocket costs for many patients because third-party health insurance payers usually do not cover OTC products. However, overall health care costs tend to decrease when products are reclassified as OTC due to a direct reduction in drug costs, elimination of prescriber office visits, and avoidance of pharmacy dispensing fees. Some examples of drugs that have recently been reclassified as OTC products appear in Box 7-2.

The importance of patient education cannot be overstated. Many patients are inexperienced in the interpretation of medication labels (Figure 7-1), which results in misuse of the products. This lack of experience and possibly a lack of information or knowledge may lead to adverse events or drug interactions with prescription medications or other OTC medications. Small print on OTC package labels often complicates the situation, especially for elderly patients. According to a report of the Institute for Safe Medication Practices, one study found that parents gave children incorrect doses of OTC fever medications over 50% of the time. Use of OTC medications can be hazardous for patients with various chronic illnesses, including diabetes, enlarged prostate, hypertension, cardiovascular disease, and glaucoma. Patients are encouraged to read labels carefully and consult a qualified health professional when in doubt.

Another problem associated with OTC drugs is that their use may postpone effective management of chronic disease states and may delay treatment of serious and/or life-threatening

BOX 7-2 RECLASSIFIED OVER-THE-COUNTER PRODUCTS

Analgesics
ibuprofen (Advil, Motrin)
naproxen sodium (Aleve, Naprosyn)

Histamine Blockers
H_1 Receptors
chlorpheniramine maleate (Chlor-Trimeton)
diphenhydramine hydrochloride (Benadryl)
fexofenadine (Allegra)
loratadine (Claritin)
cetirizine (Zyrtec)

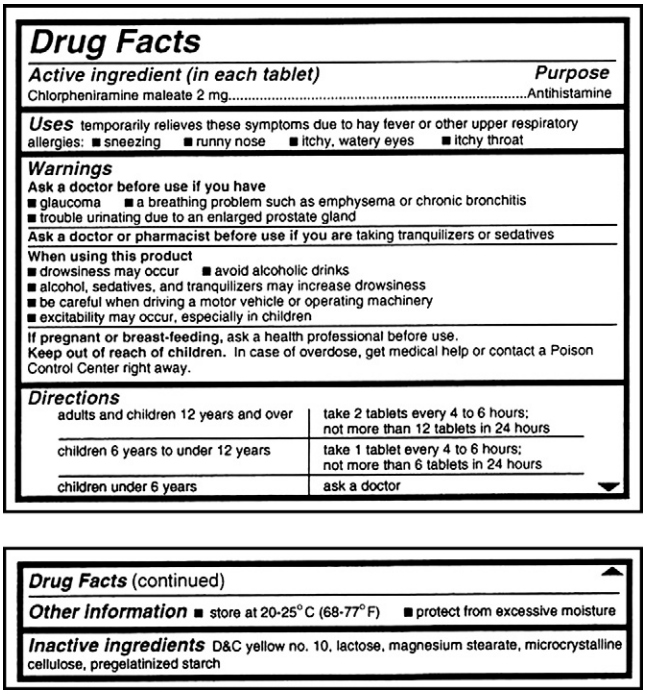
H_2 Receptors
cimetidine (Tagamet HB)
famotidine (Pepcid AC)
nizatidine (Axid AR)
ranitidine (Zantac)

Proton Pump Inhibitors
lansoprazole (Prevacid-24)
omeprazole (Prilosec-OTC)

Smoking Deterrents
nicotine polacrilex gum (Nicorette)
nicotine transdermal patches (Nicoderm) (other dosage forms available)

Topical Medications
clotrimazole (Lotrimin)
butoconazole (Femstat)
miconazole (Monistat)
minoxidil solution and hydrocortisone acetate 1% cream (Rogaine)
terbinafine (Lamisil AT)

Weight Loss Products
orlistat (Allī)



Drug Facts

Active ingredient (in each tablet) ***Purpose***
Chlorpheniramine maleate 2 mg.....Antihistamine

Uses temporarily relieves these symptoms due to hay fever or other upper respiratory allergies: ■ sneezing ■ runny nose ■ itchy, watery eyes ■ itchy throat

Warnings
Ask a doctor before use if you have
■ glaucoma ■ a breathing problem such as emphysema or chronic bronchitis
■ trouble urinating due to an enlarged prostate gland

Ask a doctor or pharmacist before use if you are taking tranquilizers or sedatives

When using this product
■ drowsiness may occur ■ avoid alcoholic drinks
■ alcohol, sedatives, and tranquilizers may increase drowsiness
■ be careful when driving a motor vehicle or operating machinery
■ excitability may occur, especially in children

If pregnant or breast-feeding, ask a health professional before use.
Keep out of reach of children. In case of overdose, get medical help or contact a Poison Control Center right away.

Directions

adults and children 12 years and over	take 2 tablets every 4 to 6 hours; not more than 12 tablets in 24 hours
children 6 years to under 12 years	take 1 tablet every 4 to 6 hours; not more than 6 tablets in 24 hours
children under 6 years	ask a doctor

Drug Facts (continued)

Other Information ■ store at 20-25°C (68-77°F) ■ protect from excessive moisture

Inactive Ingredients D&C yellow no. 10, lactose, magnesium stearate, microcrystalline cellulose, pregelatinized starch

FIGURE 7-1 Example of an over-the-counter drug label. (From U.S. Food and Drug Administration: The new over-the-counter medicine label: take a look, 2011, available at http://www.fda.gov/Drugs/EmergencyPreparedness/BioterrorismandDrugPreparedness/ucm133411.htm#.TnP-oVxzZyo.email. Accessed November 14, 2011.)

disorders. This is because the OTC medication may relieve symptoms without necessarily addressing the cause of the disorder. This situation is often complicated when patients are afraid to visit a provider, are uninsured/underinsured, have impaired health literacy (see Chapter 6), or simply want to avoid the inconvenience of visiting a provider and instead are hoping for a "quick fix" for themselves or their children.

OTC medications also have their own toxicity profiles. For example, cough and cold products usually include one or more of the following ingredients: nasal decongestants (for stuffy nose), expectorants (for loosening chest mucus), antihistamines (for sneezing and runny nose), and antitussives (for cough). In 2008, the FDA issued recommendations that OTC cough and cold products not be used in children younger than 2 years of age. This followed numerous case reports of symptoms such as oversedation, seizures, tachycardia, and even death in toddlers medicated with such products. There is also evidence that such medications are simply not efficacious in small children. A study in 2010 showed a dramatic decrease in young children emergency department visits since the FDA recommendation (Shehab et al., 2010). The FDA continues to evaluate the safety and efficacy of cough and cold products for children 2 to 11 years of age but has issued no guidelines to date. Parents are advised to be mindful of how much medication they give to their children and to be careful not to give two products that contain the same active ingredient(s).

Two other examples of OTC drug hazards include products containing acetaminophen (e.g., Tylenol) and nonsteroidal antiinflammatory drugs (NSAIDs) such as ibuprofen (e.g., Advil, Motrin) and naproxen (e.g., Aleve). Hepatic toxicity is associated with excessive doses of acetaminophen and is a leading cause of liver failure. Acetaminophen doses are not to exceed a total of 3 to 4 g/day. The use of NSAIDs is associated with gastrointestinal ulceration, myocardial infarction, and stroke. Patients may sometimes choose excessive dosages of these and other OTC medications out of ignorance or simply in hopes of easing their symptoms. In 2009, the FDA finalized regulations requiring specific labeling for acetaminophen, aspirin, and NSAIDS to enhance consumer awareness of these risks.

Abuse can also be a potential hazard with the use of OTC drug products. Pseudoephedrine is found in a variety of cough and cold products (see Chapter 17); however, this drug is also used to manufacture the widely abused street drug methamphetamine. Because of the potential for abuse, products containing pseudoephedrine must be sold from behind the pharmacy counter, and patients must sign a log book held by the pharmacist. Many patients become addicted to OTC nasal sprays because they can cause rebound congestion and dependency. Dextromethorphan (used as a cough suppressant) is also

TABLE 7-1 COMMON OVER-THE-COUNTER (OTC) DRUGS

TYPE OF OTC DRUG	EXAMPLES	WHERE DISCUSSED IN THIS BOOK
Acid-controlling drugs (H_2 blockers), antacids, and proton pump inhibitors	cimetidine (Tagamet HB), famotidine (Pepcid AC), nizatidine (Axid AR), ranitidine (Zantac); aluminum- and magnesium-containing products (Maalox, Mylanta); calcium-containing products (Tums), lansoprazole (Prevacid-24), omeprazole (Prilosec-OTC)	Chapter 50: Acid-Controlling Drugs
Antifungal drugs (topical)	clotrimazole (Lotrimin), miconazole (Monistat), terbinafine (Lamisil AT)	Chapter 56: Dermatologic Drugs
Antihistamines and decongestants	brompheniramine (Dimetapp), cetirizine (Zyrtec), chlorpheniramine (Contac, Theraflu), diphenhydramine (Benadryl), fexofenadine (Allegra), guaifenesin (Robitussin), loratadine (Claritin), pseudoephedrine (Sudafed)	Chapter 36: Antihistamines, Decongestants, Antitussives, and Expectorants
Eyedrops	artificial tears (Moisture Eyes, Murine)	Chapter 57: Ophthalmic Drugs
Hair growth drugs (topical)	minoxidil (Rogaine)	Chapter 56: Dermatologic Drugs
Pain-relieving drugs		
Analgesics	acetaminophen (Tylenol)	Chapter 10: Analgesic Drugs
Nonsteroidal antiinflammatory drugs	aspirin, ibuprofen (Advil, Motrin), naproxen sodium (Aleve)	Chapter 44: Antiinflammatory and Antigout Drugs

commonly abused. It is known by the brand name of Robitussin, and abusing it is called *Robotripping*.

Several other OTC products can cause specific problems. The use of sympathomimetics (see Chapter 18) can cause problems in patients with type 1 diabetes and patients with hypertension or angina. Aspirin is not to be used in children as it can cause a rare condition called Reye's syndrome (see Chapter 44). Long-term use of antacids can result in constipation or impaction (see Chapter 50).

Normally, OTC medications are used only for short-term treatment of common minor illnesses. An appropriate medical evaluation is recommended for all chronic health conditions, even if the final decision is to prescribe OTC medications. Patient assessment includes questions regarding OTC drug use, including what conditions are being treated. Such questions may help uncover more serious ongoing medical problems. Inform patients that OTC drugs, including herbal products, are still medications. Their use may have associated risks depending on the specific OTC drugs used, concurrent prescription medications, and the patient's overall health status and disease states.

Health care professionals have an excellent opportunity to prevent common problems associated with the use of OTC drugs. Up to 60% of patients consult a health care professional when selecting an OTC product. Provide patients with information about choice of an appropriate product, correct dosing, common adverse effects, and drug interactions with other medications.

For specific information on various OTC drugs, see the appropriate drug chapters later in this text. (Table 7-1 provides cross-references to these chapters.)

HERBALS AND DIETARY SUPPLEMENTS

History

Dietary supplement is a broad term for orally administered alternative medicines and includes the category of herbal supplements. Dietary supplements are products that contain ingredients intended to augment the diet and include vitamins, minerals, herbs or other botanicals, amino acids, and substances such as enzymes, organ tissues, glandular products, metabolites, extracts, and concentrates. Dietary supplements may be produced in many forms, such as tablets, capsules, softgels, gelcaps, liquids, and powders. These supplements may also be found in nutritional, breakfast, snack, or health food bars; drinks; and shakes.

TABLE 7-2 CONVENTIONAL MEDICINES DERIVED FROM PLANTS

MEDICINE*	PLANT
atropine	*Atropa belladonna*
capsaicin	*Capsicum frutescens*
cocaine	*Erythroxylon coca*
codeine	*Papaver somniferum*
digoxin	*Digitalis lanata*
paclitaxel	*Taxis brevifolia*
quinine	*Cinchona officinalis*
scopolamine	*Datura fastuosa*
senna	*Cassia acutifolia*
vincristine	*Catharanthus roseus*

*Includes both over-the-counter and prescription drugs.

Herbs come from nature and include the leaves, bark, berries, roots, gums, seeds, stems, and flowers of plants. They have been used for thousands of years to help maintain good health. Herbs have been an integral part of society because of their culinary and medicinal properties. About 30% of all modern drugs are derived from plants (Table 7-2). In the early nineteenth century, scientific methods became more advanced and became the preferred means of healing. At this time, the practice of botanical healing was dismissed as quackery. **Herbal medicine** lost ground to new synthetic medicines during the early part of the twentieth century. These synthetically derived medicines were touted by scientists and physicians as more effective and reliable.

In the 1960s, concerns were expressed over the **iatrogenic effects** of **conventional medicine.** These concerns, along with a desire for more self-reliance, led to a renewed interest in "natural health," and, as a result, the use of herbal products

increased. In 1974, the World Health Organization encouraged developing countries to use traditional plant medicines. In 1978, the German equivalent of the FDA published a series of herbal recommendations known as the *Commission E monographs.* These monographs focus on herbs whose effectiveness for specific indications is supported by the research literature. Recognition of the increasing use of herbal products and other nontraditional remedies, known as **alternative medicine,** led to the establishment of the Office of Alternative Medicine by the National Institutes of Health in 1992. This office was later renamed the National Center for Complementary and Alternative Medicine (NCCAM). **Complementary medicine** refers to the simultaneous use of both traditional and alternative medicine. This practice is also referred to as **integrative medicine.** NCCAM classifies complementary and alternative medicine into the following five categories: (1) alternative medical systems, (2) mind-body interventions, (3) biologically based therapies, (4) manipulative and body-based methods, and (5) energy therapies.

Many controversies remain about the safety and control of herbals and dietary supplements, although they continue to be used in the United States and abroad. Their uses and touted advantages are widely publicized. As a result, these products are sold in grocery stores, pharmacies, health food stores, and fitness gyms and can even be ordered through television, radio, and the Internet. Adverse effects are considered to be minimal by the public as well as by the companies that sell these supplements. However a false sense of security has been created because the view of the public tends to be that if a product is "natural," then it is safe. The information listed in this book regarding herbal products does not imply author or publisher endorsement of such products.

For many years, neither federal legislation nor the FDA provided any safeguards surrounding dietary supplements. Instead, manufacturers were responsible only for ensuring product safety and for not making unproven claims about their efficacy. In 1993, the FDA threatened to remove dietary supplements from the market. The American public reacted with a massive letter-writing campaign to Congress, and the 103rd Congress responded by passing the Dietary Supplement and Health Education Act (DSHEA) of 1994. The DSHEA defined dietary supplements and provided a regulatory framework. In 2002, the U.S. Pharmacopeia, an independent organization that is the government's official standard-setting authority for dietary supplements, began certifying products that it had independently tested as part of its Dietary Supplement Verification Program.

A major difference between **legend drugs** (prescription drugs) and OTC products and dietary supplements is that the DSHEA requires no proof of efficacy and sets no standards for quality control for supplements. In contrast, the FDA has specific and stringent requirements for manufacturers of legend drugs. However, in June 2007, the FDA announced that all manufacturers of dietary supplements would be required to comply with the same good manufacturing practices, as prescription manufacturers are required to do. Under these new requirements, manufacturers must provide data that demonstrate product identity, composition, quality, purity, and strength of active ingredients. They must also demonstrate that products are free from contaminants such as microbes, pesticides, and heavy metals (e.g., lead). Currently there is a bill in Congress, known as the Dietary Supplement Act of 2010, which would require more stringent control over dietary supplements. The fate of this bill is pending.

Manufacturers of supplements may currently claim an effect but cannot promise a specific cure on the product label. Dietary supplements do not need approval from the FDA before they are marketed. A manufacturer does not have to provide the FDA with the evidence to substantiate effectiveness before or after it markets the product, except in the case of a new dietary ingredient. The FDA posts warnings on herbal products on its website (http://www.fda.gov). In contrast, regulating agencies in Germany, France, the United Kingdom, and Canada require manufacturers to meet standards of herbal quality and safety.

Consumer Use of Dietary Supplements

Consumer use of dietary supplements is growing, with an estimated 50% of U.S. adults using some form of alternative medicine, despite the fact that one-fourth of the 44 million people who use them experience adverse reactions. Consumers use dietary supplements for the treatment and prevention of diseases and proactively to preserve health and wellness and boost the immune system (e.g., reduce cardiovascular risk factors, increase liver and immune system functions, increase feelings of wellness). In addition, herbs may be used as adjunct therapy to support conventional pharmaceutical therapies.

Some herbal products may be used to treat minor conditions and illnesses (e.g., coughs, colds, stomach upset) in much the same way that conventional FDA-approved OTC nonprescription drugs are used. As the number of herbal products on the market increases, nurses will need to respond to patients' educational needs about these products.

Safety

Dietary supplements, and especially herbal medicines, are often perceived as being natural and therefore harmless; however, this is not the case. Many examples exist of allergic reactions, toxic reactions, and adverse effects caused by herbs. Some herbs have been shown to have possible mutagenic effects and to interact with drugs (Table 7-3). It is estimated that 70% of patients using dietary supplements do not disclose this to their health care providers. In addition, one study identified a relatively low level of knowledge of these products and their risks, even among regular users. This demonstrates the need for health care providers to develop a clinical knowledge base regarding these products and know where to find key information as the need arises. Because of underreporting, present knowledge may represent but a small fraction of potential safety concerns. Also, the FDA has limited oversight of how dietary supplements are prepared, whether herbal or not.

There are few published scientific data regarding the safety of dietary supplements. Two recent examples indicating some of the growing concerns about herbal remedies include the FDA warnings about possible liver toxicity with the use of kava and

TABLE 7-3 SELECTED HERBS AND DIETARY SUPPLEMENTS AND THEIR POSSIBLE DRUG INTERACTIONS

HERB OR DIETARY SUPPLEMENT	POSSIBLE DRUG INTERACTION
Chamomile	Increased risk for bleeding with anticoagulants
Cranberry	Decreased elimination of many drugs that are renally excreted
Echinacea	Possible interference with or counteraction to immunosuppressant drugs and antivirals
Evening primrose	Possible interaction with antipsychotic drugs
Garlic	Possible interference with hypoglycemic therapy and the anticoagulant warfarin (Coumadin)
Gingko	May increase risk of bleeding with anticoagulants (warfarin, heparin) and antiplatelets (aspirin, clopidogrel)
Ginger root	At high dosages, possible interference with cardiac, antidiabetic, or anticoagulant drugs
Grapefruit	Decreases metabolism of drugs used for erectile dysfunction
	Decreases metabolism of estrogens and some psychotherapeutic drugs (benzodiazepines, sertraline)
	Increases risk of toxicity of immunosuppressants, HMG-CoA reductase inhibitors, and some psychotherapeutic drugs (pimozide, escitalopram)
	Increases intensity and duration of effects of caffeine
Hawthorn	May lead to toxic levels of cardiac glycosides (e.g., digitalis)
Kava	May increase the effect of barbiturates and alcohol
Saw palmetto	May change the effects of hormones in oral contraceptive drugs, patches, or hormonal replacement therapies
St. John's wort	May lead to serotonin syndrome if used with other serotonergic drugs (e.g., selective serotonin reuptake inhibitors [see Chapter 16])
Valerian	Increases central nervous system depression if used with sedatives

possible cardiovascular and stroke risks with the use of ephedra. Sale of ephedra was officially banned by the FDA in April 2004. Kava remains on the market despite a 2002 FDA consumer warning letter regarding the risk of liver toxicity. Also, a state-of-the-art paper published in the *Journal of the American College of Cardiology* in 2010 suggests that many herbal products are best avoided in patients with cardiovascular diseases (Tachjian et al., 2010). Herbal products can increase bleeding risk with warfarin (see Chapter 26), potentiate digoxin toxicity (see Chapter 24), increase the effects of antihypertensive agents (see Chapter 22), and cause heart block or dysrhythmias (see Chapter 25).

The FDA has established MedWatch, which has a toll-free number (800-332-1088) consumers can call to report adverse effects of dietary supplements or of any drugs or medical devices. Other authoritative references that can be utilized for herbal information include Pharmacist's Letter/Prescriber's Letter Natural Medicines Comprehensive Database and Natural Standard, available at www.naturalstandard.com. Health care providers need to be on the alert for announcements about the safe and effective use of dietary supplements as well as reported adverse effects. The discriminating and proper use of some dietary supplements may provide some therapeutic benefits, but the indiscriminate or excessive use of dietary supplements can be dangerous.

Level of Use

The FDA estimates that over 29,000 different dietary supplements are currently used in the United States, with approximately 1000 new products introduced annually. A great deal of public interest in the use of dietary supplements remains. Estimates of the prevalence of dietary supplement use differ greatly. The wide disparity in these estimates is most likely due to the use of varying terminology (e.g., "herbs" versus "dietary supplements") and differences in the wording of questions regarding length of use (e.g., "have you ever used" versus "have you used in the last 12 months"). One recent estimate of the amount spent on dietary supplements was in excess of $20 billion annually in the United States. The use of botanical medicines is greater in other parts of the world than in the United States.

The many different herbs in these preparations contain a wide variety of active **phytochemicals** (plant compounds). Herbal medicine is based on the premise that plants contain natural substances that can promote health and alleviate illness. Some of the more common ailments and conditions treated with herbs are anxiety, arthritis, colds, constipation, cough, depression, fever, headache, infection, insomnia, intestinal disorders, premenstrual syndrome, menopausal symptoms, stress, ulcers, and weakness.

Herbal products constitute the largest growth area in retail pharmacy. Their use is increasing at a rate of 20% to 25% per year, which far exceeds the growth in the use of conventional drugs. Insurance plans and managed care organizations are beginning to offer reimbursement for alternative treatments. Some of the most commonly used herbal remedies are aloe, black cohosh, chamomile, echinacea, feverfew, garlic, ginger, ginkgo biloba, ginseng, goldenseal, hawthorn, St. John's wort, saw palmetto, and valerian. These products are covered in more detail in the Safety: Herbal Therapies and Dietary Supplements boxes that appear in the various drug chapters (see the inside back cover for a complete listing of these boxes with page numbers throughout the textbook).

NURSING PROCESS

ASSESSMENT

OVER-THE-COUNTER DRUGS

Nursing assessments are always important to perform, but they are especially important in situations in which a patient

PATIENT-CENTERED CARE: CULTURAL IMPLICATIONS

Drug Responses and Cultural Factors

Responses to drugs—including over-the-counter (OTC) drugs, herbals, and dietary supplements—may be affected by beliefs, values, and genetics as well as by culture, race, and ethnicity (see Chapter 4 for more discussion of cultural considerations). As one example of the impact of culture on drug response and use, if patients who are Japanese experience nausea, vomiting, or bowel changes as adverse effects of OTC drugs, herbals, and/or dietary supplements, these often are not mentioned. The reason is that this culture finds it unacceptable to complain about gastrointestinal symptoms, and so they may go unreported to the point of causing risk to the patient.

Herbal and alternative therapies may also be used more extensively in some cultures than in others. Wide acceptance of herbal use without major concern for the effects on other therapies may be very problematic because of the many interactions of conventional drugs with herbals and dietary supplements. For example, the Chinese herb ginseng may inhibit or accelerate the metabolism of a specific medication and significantly affect the drug's absorption or elimination.

One genetic factor that has an influence on drug response is acetylation polymorphism; that is, prescription drugs, OTC drugs, herbals, and dietary supplements may be metabolized in different ways that are genetically determined and vary with race or ethnicity. For example, populations of European or African descent contain approximately equal numbers of individuals showing rapid and slow acetylation (which affects drug metabolism), whereas Japanese and Inuit populations may contain more rapid acetylators. See Chapter 4 for a more in-depth discussion of these specific genetic attributes.

Modified from Munoz C, Hilgenberg C: Ethnopharmacology, *Am J Nurs* 105(8):40-49, 2005.

is self-medicating. Reading level, cognitive level, motor abilities, previous use of *OTC drugs,* successes versus failures with drug therapies and self-medication, and caregiver support are just a few of the variables to be assessed, as deemed appropriate. Other assessment data include questioning about allergies to any of the ingredients of the drug. Include a list of *all* medications and substances used by the patient, including OTC drugs, prescription drugs, herbal products, vitamins, and minerals in the medication history. Also note use of alcohol, tobacco, and caffeine. Assess past and present medical history so that possible drug interactions, contraindications, and cautions are identified. Screen patients carefully before recommending an OTC drug because patients often assume that if a drug is sold OTC it is completely safe to take and without negative consequences. This is not true—OTC drugs can be just as lethal or problematic as prescription drugs if they are not taken properly or are taken in high dosages and without regard to directions (see discussion earlier in the chapter).

Assessment of the patient's knowledge about the components of self-medication, including the positive or negative consequences of the use of a given OTC drug, must be included. Assessment of the patient's (or caregiver's or family member's) level of knowledge and experience with OTC self-medication is critical to the patient's safety, as is assessment of attitudes toward and beliefs about their use, especially a too-casual attitude or a lack of respect for and concern about the use of OTC drugs. This is especially true if a casual attitude is combined with a lack of knowledge. Obviously this could result in overuse, overdosage, and potential complications. See Chapter 6 for more information on patient education.

Generally speaking, laboratory tests are not ordered before the use of OTC drugs, because they are self-administered and self-monitored. However, there are situations in which patients may be taking certain medications that react adversely with these drugs, and laboratory testing may be needed. Some patient groups are also at higher risk for adverse reactions to OTC drugs (as to most drugs in general), including pediatric and elderly patients; patients with single and/or multiple acute and chronic illnesses; those who are frail or in poor health, debilitated, or nutritionally deficient; and those with suppressed immune systems. OTC drugs must also be used with caution and may be contraindicated in patients with a history of renal, hepatic, cardiac, or vascular dysfunction. More assessment information for OTC drugs, herbals, and dietary supplements can be found in other chapters in this textbook when relevant (see Table 7-1). It is important to remember that consumer/patient safety and quality of care related to drug therapy of any kind begins with education. Thus, the best way for patients to help themselves is for them to learn how to assess each situation, weigh all the factors, and find out all they can about the OTC drug they wish to take *before* taking it!

HERBAL PRODUCTS AND DIETARY SUPPLEMENTS

Many *herbal products* and *dietary supplements* are readily available in drug, health food, and grocery stores as well as in home gardens, kitchens, and medicine cabinets. As noted earlier in the chapter, among the more commonly used herbals are aloe, black cohosh, chamomile, echinacea, feverfew, garlic, ginger, ginkgo biloba, ginseng, goldenseal, hawthorn, St. John's wort, saw palmetto, and valerian. Although patients generally self-administer these products and do not perform an assessment, in various settings you may be able to assess the patient through a head-to-toe physical examination, medical and nursing history, and medication history. Share assessment data and factors and variables to consider with the patient for the patient's safety. This sharing of assessment information allows you to be sure that the patient is taking the herbal product in as safe a manner as possible.

Many herbals and dietary supplements may lead to a variety of adverse effects. For example, some may cause dermatitis when used topically, whereas some taken systemically may be associated with kidney disorders such as nephritis. Therefore, for example, patients with existing skin problems or kidney dysfunction must seek medical advice before using certain herbals. It is also crucial to patient safety to consider any other contraindications, cautions, and potential drug-drug and drug-food interactions. See Table 7-3 for more information on drug interactions.

CASE STUDY

Over-the-Counter Drugs and Herbal Products

J.V., a 28-year-old graduate student, is at the student health clinic for a physical examination that is required before he goes on a research trip out of the country. As he completes the paperwork, he asks the nurse, "The form is asking about my medications. I don't have any prescribed medicines, but I take several herbal products and over-the-counter medicines. Do you need to know about these?"

1. How should the nurse answer J.V.?

On the form, J.V. lists the following items:

1 baby aspirin each day to prevent blood clots
Sleep-Well herbal product with valerian at night if needed
Benadryl as needed for allergies, especially at night
Stress-Away herbal product with ginseng as needed
Generic ibuprofen, 3 or 4 tablets three times a day for muscle aches from working out
Memory Boost herbal product with ginkgo every morning

2. Examine the products on J.V.'s list, and state whether there are any concerns with interactions or adverse effects. You may need to refer to descriptions of the individual herbal products (see the inside back cover for a complete listing of Safety: Herbal Therapies and Dietary Supplements boxes located throughout the textbook) or to the appropriate drug chapters for more information.
3. Upon further questioning, J.V. remembers that he has had problems with "acid stomach" for about a year and takes Prilosec-OTC for that as needed. What concerns, if any, are there about this?

For answers, see http://evolve.elsevier.com/Lilley.

NURSING DIAGNOSES

Nursing diagnoses appropriate for the patient who is taking *OTC drugs, herbals, and/or dietary supplements* include the following (without related causes, because these are too numerous to include):

1. Impaired physical mobility
2. Impaired memory
3. Impaired urinary elimination
4. Acute pain or Chronic pain
5. Fatigue
6. Activity intolerance
7. Insomnia
8. Ineffective health maintenance
9. Risk for injury

PLANNING

GOALS

1. Patient is able to increase mobility as tolerated and without distress.
2. Patient experiences increased alertness and improved short-term and long-term memory with continued use of the herbal product and/or dietary supplement.
3. Patient maintains normal elimination patterns during herbal drug use.
4. Patient experiences pain relief or relief of the symptoms of the disease process or injury.
5. Patient experiences increase in energy and/or function.
6. Patient's tolerance for activity remains within normal limits and/or improves during OTC drug or herbal therapy.
7. Patient experiences limited sleep pattern disturbance while on OTC drug or herbal therapy.
8. Patient seeks healthy maintenance behaviors with questions about the OTC drug, herbal, and/or dietary supplement, its action, therapeutic effects versus adverse effects, toxicity, cautions, contraindications, drug-drug or drug-food interactions, and appropriate dosage formulation administration.
9. Patient remains free from injury while taking OTC drug, herbal, and/or dietary supplement.

OUTCOME CRITERIA

1. Patient states that the actions of the OTC drug, herbal, and/or dietary supplement have been beneficial with relief of symptoms and increased physical mobility.
   - Patient experiences improving overall well-being and health status with minimal adverse effects or complications.
2. Patient reports any change in orientation to person, place, time, or in short-term/long-term memory immediately and seeks appropriate directions regarding discontinuing therapy.
3. Patient identifies measures to increase urinary elimination and enhance urinary elimination patterns such as increasing fluid intake to 6 to 8 glasses of water per day, unless contraindicated, and taking time to void at regular intervals.
4. Patient describes nonpharmacologic approaches to the treatment of acute and chronic pain such as the use of hot or cold packs, physical therapy, massage, relaxation therapy, biofeedback, imagery, and hypnosis.
5. Patient takes measures to minimize fatigue through the use of herbal and dietary supplements, sleeping 6 to 8 hours per night, increasing fluid intake, and intake of recommended daily amounts of food/caloric/protein.
6. Patient states that the actions of the OTC drug, herbal, and/or dietary supplement have been beneficial with relief of symptoms and subsequent increased ability to participate in activities of daily living (ADLs) as well as increase in other physical activities.
7. Patient states increased hours of sleep (i.e., 6 to 8 hours of sleep) and less difficulty with onset of sleep while using OTC, herbal, and/or dietary supplement.
8. Patient experiences healthier behaviors as related to health maintenance by being more knowledgeable about self-medication administration with OTC drugs, herbals, and/or dietary supplements.
   - Patient inquires of pharmacist or health care provider about the safe daily healthy maintenance behavior of taking herbals and/or dietary supplements and deciphers information appropriately.
9. Patient states the importance of taking drugs as directed and of immediately reporting any severe adverse effects

or complications associated with the use of an OTC drug, herbal, and/or dietary supplement to the health care provider and pharmacist and to contact the poison control center, if needed.

- Patient is able to self-administer OTC drugs, herbals, and/or dietary supplements as directed and with proper administration technique (e.g., transdermal patch, suppository, liquid, quick-dissolve tablet) with experiencing of minimal adverse effects and decrease in risk for self-injury.

IMPLEMENTATION

With *OTC drugs, herbals,* and *dietary supplements,* patient education is an important strategy to enhance patient safety. Patients need to receive as much information as possible about the safe use of these products and to be informed that, even though these are not prescription drugs, they are *not* completely safe and are not without toxicity. Include information about safe use, frequency of dosing and dose, specifics of how to take the medication (e.g., with food or at bedtime), as well as strategies to prevent adverse effects, drug interactions, and toxicity in the patient instructions. Another consideration is the dosage form, because a variety are available such as liquids, tablets, enteric-coated tablets, transdermal patches, gum, and quick-dissolve tablets or strips. For transdermal patches (e.g., for smoking cessation), it is important to emphasize proper use and application. Make sure the patient is aware that the FDA does not regulate these products unless there is sufficient data to support a recall of the product. The companies that manufacture OTC drugs, herbals, and/or dietary supplements are not required to provide evidence of safety and effectiveness. As previously mentioned, many consumers believe that no risks exist if a medication is available OTC or is an herbal or a "natural" substance. See Box 7-1 for more information about the criteria for moving a drug from prescription to OTC status. The fact that a drug is an herbal or a dietary supplement does not mean that it can be safely administered to children, infants, pregnant or lactating women, or patients with certain health conditions that put them at risk.

EVALUATION

Patients taking *OTC drugs, herbals,* and/or *dietary supplements* need to carefully monitor themselves for unusual or adverse reactions and therapeutic responses to the medication to prevent overuse and overdosing. The range of therapeutic responses will vary, depending on the specific drug and the indication for which it is used. Therapeutic responses also vary depending on the drug's action; a few examples are decreased pain; decreased stiffness and swelling in joints; decreased fever; increased activity or mobility, as in increased ease of carrying out ADLs; increased hair growth; increased ease in breathing; decrease in constipation, diarrhea, bowel irritability, or gastrointestinal reflux or hyperacidity; resolution of allergic symptoms; decreased vaginal itching and discharge; increased healing; increased sleep; and decreased fatigue or improved energy. For more specific information about nursing diagnoses, planning with goals and outcome criteria, implementation, and evaluation related to various OTC drugs, herbals, and/or dietary supplements, see the appropriate chapters later in the book. Table 7-1 provides cross-references to these chapters.

PATIENT TEACHING TIPS

- Provide verbal and written information about how to choose an appropriate OTC drug or herbal or dietary supplement as well as information about correct dosing, common adverse effects, and possible interactions with other medications.
- Many patients believe that no risks exist if a medication is herbal and "natural" or if it is sold OTC, so provide adequate education about the drug or product as well as all the advantages and disadvantages of its use, because this is crucial to patient safety.
- Provide instructions on how to read OTC drug, herbal, and dietary supplement labels and directions. Encourage the reading of ingredients if using more than one product, as the ingredient/chemical may occur in both products. For example, a multivitamin supplement may contain ginseng, and taking additional ginseng supplements may lead to toxicity. Another example is with products containing acetaminophen (Tylenol). If the patient is taking acetaminophen and then also takes a cold/flu product, there may also be acetaminophen in that product, and consequently the risk of adverse effects and toxicity increases.
- Emphasize the importance of taking all OTC drugs, herbals, and dietary supplements with extreme caution, and being aware of all the possible interactions and/or concerns associated with the use of these products.
- Instruct the patient that all health care providers (e.g., nurses, dentists, osteopathic and chiropractic physicians) need to be aware about the use of any OTC drugs, herbals, and dietary supplements (and, of course, any prescription drug use).
- Encourage journaling of any improvement of symptoms noted with the use of a specific OTC drug, herbal, and/or dietary supplement.
- Encourage the use of appropriate and authoritative resources for patient information, such as a registered pharmacist, literature provided from the drug company and pharmacist, and web-based information from reliable sites at an appropriate reading level for the patient (e.g., www.Webmd.com).
- Instruct the patient that all medications, whether an OTC drug, herbal, and/or dietary supplement, must be kept out of the reach of children and pets.
- Provide thorough instructions regarding the various dosage forms of OTC drugs, herbals, and dietary supplements. Provide specific instructions such as how to mix powders and how to properly use transdermal patches, inhalers, ointments, lotions, nose drops, ophthalmic drops, elixirs, suppositories, vaginal suppositories or creams, and all other dosage forms (see Chapter 9); also provide information about proper storage and cleansing of any equipment.

KEY POINTS

- Consumers use herbal products therapeutically for the treatment of diseases and pathologic conditions, prophylactically for long-term prevention of disease, and proactively for the maintenance of health and wellness.
- The FDA has established the MedWatch program to track adverse events and/or problems related to drug therapy. The toll-free number for reporting adverse effects of prescription drugs, OTC drugs, herbals, and dietary supplements is 800-332-1088. Nurses may report adverse events anonymously and without consequence via telephone. Adverse event reporting is also available inside of medical reference applications such as Epocrates or Medscape.
- Herbal products are not FDA-approved drugs, and therefore their labeling cannot be relied on to provide consumers and patients with adequate instructions for use or even information about warnings.
- The fact that a drug is an herbal product, dietary supplement, or OTC medication is no guarantee that it can be safely administered to children, infants, pregnant or lactating women, or patients with certain health conditions that may put them at risk.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is reviewing dietary supplements and recalls that under the DSHEA, manufacturers of dietary supplements are required to
   - **a** follow FDA standards for quality control.
   - **b** prove efficacy and safety of dietary supplements.
   - **c** identify the active ingredients on the label.
   - **d** obtain FDA approval before the products are marketed.

2 When educating patients about the safe use of herbal products, the nurse remembers to include which concept?
   - **a** Herbal and over-the-counter products are approved by the FDA and under strict regulation.
   - **b** Herbal products are tested for safety by the FDA and the U.S. Pharmacopeia.
   - **c** No adverse effects are associated with these products because they are natural and may be purchased without a prescription.
   - **d** Take the product with caution because labels may not contain reliable information.

3 When taking a patient's drug history, the nurse asks about use of over-the-counter drugs. The patient responds by saying, "Oh, I frequently take aspirin for my headaches, but I didn't mention it because aspirin is nonprescription." What is the best response from the nurse?
   - **a** "That's true, over-the-counter drugs are generally not harmful."
   - **b** "Aspirin is one of the safest drugs out there."
   - **c** "Although aspirin is over the counter, it's still important to know why you take it, how much you take, and how often."
   - **d** "We need you to be honest about the drugs you are taking. Are there any others that you haven't told us about?"

4 When making a home visit to a patient who was recently discharged from the hospital, the nurse notes that she has a small pack over her chest and that the pack has a strong odor. She also is drinking herbal tea. When asked about the pack and the tea, the patient says, "Oh, my grandmother never used medicines from the doctor. She told me that this plaster and tea were all I would need to fix things." Which response by the nurse is most appropriate?
   - **a** "You really should listen to what the doctor told you if you want to get better."
   - **b** "What's in the plaster and the tea? When do you usually use them?"
   - **c** "These herbal remedies rarely work, but if you want to use them, then it is your choice."
   - **d** "It's fine if you want to use this home remedy, as long as you use it with your prescription medicines."

5 A patient tells the nurse that he has been using an herbal supplement that contains kava for several years to help him to relax in the evening. However, the nurse notes that he has a yellow tinge to his skin and sclera, and is concerned about liver toxicity. The nurse advises the patient to stop taking the kava and to see his health care provider for an examination. What else, if anything, should the nurse do at this time?
   - **a** Report this incident to MedWatch.
   - **b** Notify the state's pharmaceutical board.
   - **c** Contact the supplement manufacturer.
   - **d** No other action is needed.

6 The nurse is reviewing the drug history of a patient, and during the interview the patient asks, "Why are some drugs over-the-counter and others are not?" The nurse keeps in mind that criteria for over-the-counter status include: (Select all that apply.)
   - **a** The condition must be diagnosed by a health care provider.
   - **b** The benefits of correct usage of the drug outweigh the risks.
   - **c** The drug has limited interaction with other drugs.
   - **d** The drug is easy to use.
   - **e** The drug company sells OTC drugs at lower prices.

7 A patient comes to the clinic complaining of elbow pain after an injury. He states that he has been taking two pain pills, eight times a day, for the past few days. The medication bottle contains acetaminophen, 325-mg tablets. Calculate how much medication he has been taking per day. Is this a safe dose of this medication?

1. c, 2. d, 3. c, 4. b, 5. a, 6. b, c, d, 7. 5200 mg/day, No

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Understand the basic terms related to genetics and drug therapy.
2 Briefly discuss the major concepts of genetics as an evolving segment of health care, such as principles of genetic inheritance; deoxyribonucleic acid (DNA), ribonucleic acid (RNA), and their functioning; the relationship of DNA to protein synthesis; and the importance of amino acids.
3 Describe the basis of the Human Genome Project and its impact on the role of genetics in health care.
4 Discuss the different gene therapies currently available.
5 Differentiate between direct and indirect forms of gene therapy.
6 Identify the regulatory and ethical issues related to gene therapy as related to nursing and health care professionals.
7 Briefly discuss pharmacogenomics and pharmacogenetics.
8 Discuss the evolving role of professional nurses as related to gene therapy.

KEY TERMS

Acquired disease Any disease triggered by external factors and not *directly* caused by a person's genes (e.g., an infectious disease, noncongenital cardiovascular diseases). (p. 96)

Alleles The two or more alternative forms of a gene that can occupy a specific locus (location) on a chromosome (see *chromosomes*). (p. 95)

Chromatin A collective term for all of the chromosomal material within a given cell. (p. 96)

Chromosomes Structures in the nuclei of cells that contain threads of deoxyribonucleic acid (DNA), which transmit genetic information, and are associated with ribonucleic acid (RNA) molecules and synthesis of protein molecules. (p. 95)

Gene The biologic unit of heredity; a segment of a DNA molecule that contains all of the molecular information required for the synthesis of a biologic product such as an RNA molecule or an amino acid chain (protein molecule). (p. 95)

Gene therapy New therapeutic technologies that directly target human genes in the treatment or prevention of illness. (p. 97)

Genetic disease Any disorder caused directly by a genetic mechanism. (p. 96)

Genetic material DNA or RNA molecules or portions thereof. (p. 95)

Genetic polymorphisms (PMs) Variants that occur in the chromosomes of 1% or more of the general population (i.e., they occur too frequently to be caused by a random recurrent mutation). (p. 98)

Genetic predisposition The presence of certain factors in a person's genetic makeup, or *genome* (see next page), that increase the individual's likelihood of eventually developing one or more diseases. (p. 96)

KEY TERMS—cont'd

Genetics The study of the structure, function, and inheritance of genes. (p. 96)

Genome The complete set of genetic material of any organism. It may be contained in multiple chromosomes (groups of DNA or RNA molecules) in higher organisms; in a single chromosome, as in bacteria; or in a single DNA or RNA molecule, as in viruses. (p. 96)

Genomics The study of the structure and function of the genome, including DNA *sequencing, mapping,* and *expression,* and the way genes and their products work in both health and disease. (p. 96)

Genotype The particular alleles present at a given site (locus) on the chromosomes of an organism that determine a specific genetic trait for that organism (compare *phenotype*). (p. 96)

Heredity The characteristics and qualities that are genetically passed from one generation to the next through reproduction. (p. 96)

Human Genome Project (HGP) A scientific project of the U.S. Department of Energy and National Institutes of Health to describe in detail the entire genome of a human being. (p. 97)

Inherited disease Genetic disease that results from defective alleles passed from parents to offspring. (p. 96)

Nucleic acids Molecules of DNA and RNA in the nucleus of every cell. DNA makes up the chromosomes and encodes the genes. (p. 95)

Personalized medicine The use of molecular and genetic characterizations of both the disease process and the patient for the customization of drug therapy. (p. 99)

Pharmacogenetics A general term for the study of the genetic basis for variations in the body's response to drugs, with a focus on variations related to a single gene. (p. 98)

Pharmacogenomics A branch of *pharmacogenetics* (see earlier) that involves the survey of the entire genome to detect multigenic (multiple-gene) determinants of drug response. (p. 98)

Phenotype The expression in the body of a genetic trait that results from a person's particular *genotype* (see earlier) for that trait. (p. 96)

Proteome The entire set of proteins produced from the information encoded in an organism's genome. (p. 97)

Proteomics The detailed study of the proteome, including all biologic actions of proteins. (p. 97)

Recombinant DNA (rDNA) DNA molecules that have been artificially synthesized or modified in a laboratory setting. (p. 97)

Genetic processes are a highly complex part of physiology and are far from completely understood. Genetic research is one of the most active branches of science today, involving many types of health care professionals, including nurses. Expected outcomes of this research include a deeper knowledge of the genetic influences on disease, along with the development of gene-based therapies. The practice of nursing requires an understanding of genetic concepts as well as genetically related health issues and therapeutic techniques. The goal of this chapter is to introduce some of the major concepts in this very complex and emerging branch of health science. In 1996, the National Coalition for Health Professional Education in Genetics (NCHPEG) was founded as a joint project of the American Medical Association, the American Nurses Association, and the National Human Genome Research Institute (http://www.nchpeg.org). The purpose of NCHPEG is to promote the education of health professionals and the public regarding advances in applied genetics.

Since the 1960s, published literature has described the role of nursing in genetics and genetic research. The Genetics Nursing Network was formed in 1984 and later became the International Society of Nurses in Genetics (ISONG). In 1997, the American Nurses Association designated genetics nursing as an official nursing specialty. In 2001, ISONG approved formation of the Genetic Nursing Credentialing Commission (GNCC). The growing understanding of genetics is quickly creating demand for clinicians in all fields who can educate patients and provide clinical care that tailors health care services to each patient's inherent genetic makeup. This reality also calls for increasing the level of genetics education in nursing school curricula as well as continuing nursing education. Interestingly, the study of genetics has become commonplace in secondary and even primary education.

BASIC PRINCIPLES OF GENETIC INHERITANCE

Nucleic acids are biochemical compounds consisting of two types of molecules: deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). DNA molecules make up the **genetic material** that is passed between all types of organisms during reproduction. In some viruses (e.g., human immunodeficiency virus), it is actually RNA molecules that pass the virus's genetic material between generations; however, this is an exception to the norm. A chromosome is a long strand of DNA that is contained in the nuclei of cells. DNA molecules, in turn, act as the template for the formation of RNA molecules, from which proteins are made. Humans normally have 23 pairs of **chromosomes** in each of their somatic cells. Somatic cells are the cells in the body other than the sex cells (sperm cells or egg cells), which have 23 single (unpaired) chromosomes. One pair of chromosomes in each cell is termed the sex chromosomes, which can be designated as either X or Y. The sex chromosomes are normally XX for females and XY for males. One member of each pair of chromosomes in somatic cells comes from the father's sperm and one from the mother's egg. **Alleles** are the alternative forms of a **gene** that can vary with regard to a specific genetic trait.

Genetic traits can be desirable (e.g., lack of allergies) or undesirable (e.g., predisposition toward a specific disease). Each person has two alleles for every gene-coded trait: one allele from the mother, the other from the father. An allele may be dominant or recessive for a given genetic trait. The particular combination of alleles, or **genotype,** for a given trait determines whether or not a person manifests that trait, or the person's **phenotype.** Genetic traits that are passed on differently to male and female offspring are said to be sex-linked traits because they are carried on either the X or Y chromosome. For example, hemophilia genes are carried by females but manifest as a bleeding disorder only in males. Hemophilia is an example of an **inherited disease;** that is, a disease caused by passage of a genetic defect from parents to offspring. A more general term is **genetic disease,** which is any disease caused by a genetic mechanism. Note, however, that not all genetic diseases are inherited. Chromosomal abnormalities (aberrations) can also occur spontaneously during embryonic development. In contrast, an **acquired disease** is any disease that develops in response to external factors and is not directly related to a person's genetic makeup. Genetics can play an indirect role in acquired disease, however. For example, atherosclerotic heart disease is often acquired in middle or later life. Many people have certain genes in their cells that increase the likelihood of this condition. This is known as a **genetic predisposition.** In some cases, a person may be able to offset his or her genetic predisposition by lifestyle choices, such as consuming a healthy diet and exercising to avoid developing heart disease.

Current literature differentiates "old genetics," which focused on single-gene inherited diseases such as hemophilia, from the "new genetics." The new genetic perspective recognizes that common diseases, including Alzheimer's disease, cancer, and heart disease, are the product of complex relationships between genetic and environmental factors. These environmental factors, such as diet or toxic exposures, can initiate or worsen disease processes. Research into disease treatment is beginning to look at genetically tailored therapy.

DISCOVERY, STRUCTURE, AND FUNCTION OF DNA

Genetics is the study of the structure, function, and inheritance of genes. **Heredity** refers to the qualities that are genetically transferred from one generation to the next during reproduction. A major turning point in the understanding of genetics came in 1953, when Drs. James Watson and Francis Crick first reported the chemical structures of human genetic material and named the primary biochemical compound deoxyribonucleic acid (DNA). They later received a Nobel Prize for their discovery.

It is now recognized that DNA is the primary molecule in the body that serves to transfer genes from parents to offspring. It exists in the nucleus of all body cells as strands in chromosomes, collectively called **chromatin.** As described in Chapter 40, DNA molecules contain four different organic bases, each of which has its own alphabetical designation: adenine (A), guanine (G), thymine (T), and cytosine (C). These bases are linked to a type of sugar molecule known as deoxyribose. In turn, these sugar molecules are linked to a "backbone" chain of phosphate molecules, which results in the classic double-helix structure of two side-by-side spiral macromolecular chains. An important related biomolecule is ribonucleic acid (RNA). RNA has a chemical structure similar to that of DNA, except that its sugar molecule is the compound ribose instead of deoxyribose and it contains the base uracil (U) in place of thymine. RNA more commonly occurs as a single-stranded molecule, although in some genetic processes it can also be double-stranded. In double-stranded structures, the base of each strand binds (via hydrogen bonds) to that of the other strand in the space between the two strands. This binding is based on complementary base pairings determined by the chemistry of the base molecules themselves. Specifically, adenine can only bind with thymine or uracil, whereas cytosine can only bind with guanine.

A nucleotide is the structural unit of DNA and consists of a single base and its attached sugar and phosphate molecules. A nucleoside is the base and attached sugar without the phosphate molecule. A relatively small sequence of nucleotides is called an oligonucleotide (the prefix *oligo-* means "a small number"). Certain new drug therapies involve synthetic analogues of both nucleosides and nucleotides (see Chapters 40, 45, 46, and 47). A related field is targeted drug therapy. Targeted drug therapy focuses on modifying the function of immune system cells (T cells and B cells) and biochemical mediators of immune response (cytokines). However, it is expected to focus on modifying specific genes as well. Current examples of targeted drug therapy are presented in Chapters 45, 46, 48, and 49. One of these drugs, the ophthalmic antiviral drug fomivirsen, is an oligonucleotide with a chemical structure that is opposite (complementary) to that of a critical part of the messenger RNA (mRNA) of the cytomegalovirus. For this reason, it is called an *antisense* oligonucleotide, and it is the first of this new class of drugs.

An organism's entire DNA structure is its **genome.** This word is a combination of the terms *gene* and *chromosome,* and it refers to all the genes in an organism taken together. **Genomics** is the relatively new science of determining the location (mapping), structure (DNA base sequencing), identification (genotyping), and expression (phenotyping) of individual genes along the entire genome, and determining their function in both health and disease processes.

Protein Synthesis

Protein molecules drive the functioning of all biochemical reactions. Protein synthesis is the primary function of DNA in human cells. There is a direct relationship between DNA nucleotide sequence and corresponding amino acid sequences. This allows for precision in protein synthesis. Interestingly, it is estimated that only 2% to 3% of the human genome is involved in protein synthesis. Amino acid sequences control the shape of protein molecules, which ultimately affects their ability to function in the body. Mutations, undesired changes in DNA sequence, can affect the shape of protein molecules and impair or destroy their functioning.

In the cell nuclei, the double strands of DNA uncoil and separate, and a strand of mRNA forms on each separate DNA

strand through complementary base pairing as described earlier in the chapter. This process is called *transcription* of the DNA. These mRNA molecules then detach from their corresponding DNA strands, leave the cell nucleus, and enter the cytoplasm, where they are then "read," or translated, by the ribosomes. Ribosomes are composed of a second type of RNA known as *ribosomal* RNA (rRNA), as well as several accessory proteins. Individual sequences of three bases along the mRNA molecule serve to code for specific amino acid molecules. This translation process involves molecules of a third type of RNA, *transfer* RNA (tRNA). The tRNA molecules transport the corresponding amino acid molecules to the site of ribosomal translation along the mRNA strand in sequence according to the three-base codes along the mRNA strand. This in turn results in the creation of chains of multiple amino acids (polypeptide chains), which are known as protein molecules. The specificity of this genetic code is very important for proper protein synthesis, and the process is similar for all living organisms—plant and animal.

There are countless specific amino acid sequences (polypeptides) that result in the synthesis of many thousands of types of protein molecules. Proteins include hormones, enzymes, immunoglobulins, and numerous other biochemical molecules that regulate processes throughout the body. They are involved in both healthy physiologic processes and the pathophysiologic processes of many diseases. The biomedical literature continues to identify and describe many proteins that are part of disease processes. Manipulation of genetic material, as in gene therapy (see later in the chapter), can theoretically modify the synthesis of these proteins and therefore aid in the treatment of disease. This emerging science continues to give rise to novel terminology. The entire set of proteins produced by a genome is now known as the **proteome. Proteomics** is the study of the proteome, including protein expression, modification, localization, and function, as well as the protein-protein interactions that are part of biologic processes. This science is expected to provide new drug therapies in the future. Furthermore, most clinically approved drugs interact with body proteins such as cell membrane receptors, hormones, and enzymes.

Human Genome Project

In 1990, an unprecedented genetic research project began in the United States, the **Human Genome Project (HGP).** It was coordinated by the U.S. Department of Energy and the National Institutes of Health (NIH). The project was completed in 2003, two years ahead of schedule. The goals of this project were to identify the estimated 30,000 genes and 3 billion base pairs in the DNA of an entire human genome. Additional goals included developing new tools for genetic data analysis and storage, transferring newly developed technologies to the private sector, and addressing the inherent ethical, legal, and social issues involved in genetic research and clinical practice. However, the ultimate goal was to develop improved prevention, treatment, and cures for disease. When the HGP began, there were 100 known human disease-related genes. By its completion, there were 1400.

GENE THERAPY

Background

Gene therapy is an experimental technique that uses genes to treat or prevent disease. It allows doctors to treat a disorder by inserting a gene into a patient's cells instead of using drugs or surgery. Researchers are testing several approaches to gene therapy, including:

- Replacing a mutated gene with a healthy copy of the gene
- Introducing a new gene into the body to help fight a disease
- Inactivating a mutated gene that is functioning improperly

Gene therapy research is based on the ongoing discovery of new details regarding cellular processes, including biochemical processes that occur at the molecular level. In addition, the increased understanding of allelic variation and its role in disease susceptibility can be used to guide attempts at preventive therapy based on a person's genotypic risk factors.

Although hundreds of gene therapy clinical trials have been approved by the U.S. Food and Drug Administration (FDA), no gene therapy to date has been approved for routine treatment of disease. The goal of gene therapy is to transfer exogenous genes that will either provide a temporary substitute for, or initiate permanent changes in, the patient's own genetic functioning to treat a given disease. Originally projected to provide treatment primarily for inherited genetic diseases, gene therapy techniques are now being researched for treatment of acquired illnesses such as cancer, cardiovascular diseases, diabetes, infectious diseases, and substance abuse. In the future, *in utero* gene therapy may be used to prevent the development of serious diseases as part of prenatal care for the unborn infant.

Description

During gene therapy, segments of DNA are injected into the patient's body in a process called *gene transfer.* These artificially produced DNA splices are also known as **recombinant DNA (rDNA)** and must be inserted into some kind of carrier or vector for the gene transfer process. Vectors currently being evaluated include spherical lipid compounds known as *liposomes,* free DNA splices known as *plasmids,* DNA conjugates in which DNA splices are linked (conjugated) to either protein or gold particles, and various types of viruses. Viruses are the most widely studied rDNA vectors thus far. One commonly used group of viruses is the adenoviruses, which include the human influenza (flu) viruses.

Limitations

Viruses used for gene transfer can also induce viral disease and can be immunogenic in the human host. The proteins produced by artificial methods can be immunogenic. Even in the absence of significant virus-induced disease, the positive effects (e.g., supplemented protein synthesis) may only be temporary, and further treatments may be required. As a result, viruses must be carefully chosen and modified in an effort to optimize therapeutic effects while minimizing undesirable adverse effects. The determination of an ideal gene transfer method remains a major challenge for gene therapy researchers. Figure 8-1 provides a clinical example of the potential use of gene therapy.

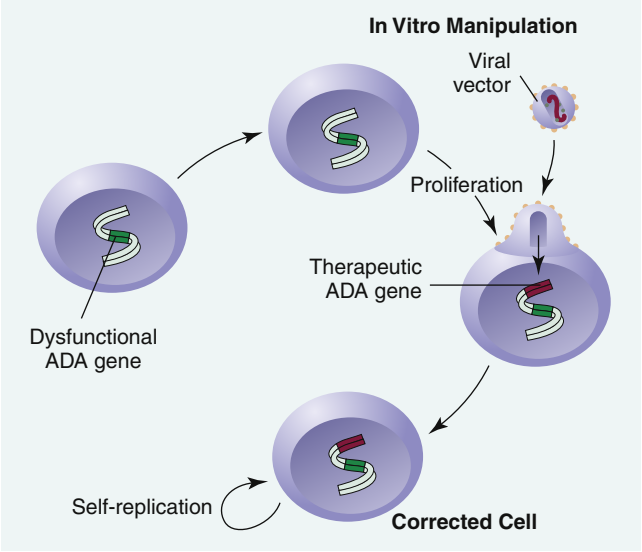

FIGURE 8-1 Gene therapy for adenosine deaminase (ADA) deficiency attempts to correct this immunodeficiency state. The viral vector containing the therapeutic gene is inserted into the patient's lymphocytes. These cells can then make the ADA enzyme. (From Lewis SM et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 7, St Louis, 2007, Mosby.)

Current Application

One indirect form of gene therapy is well established and is called *rDNA technology*. It involves the use of rDNA vectors in the laboratory to make recombinant forms of drugs, especially biologic drugs such as hormones, vaccines, antitoxins, and monoclonal antibodies. The most common example is the use of the *Escherichia coli* bacterial genome to manufacture a recombinant form of human insulin. When the human insulin gene is inserted into the genome of the bacterial cells, the resulting culture artificially generates human insulin on a large scale. Although this insulin must be isolated and purified from its bacterial culture source, the majority of the world's medical insulin supply has been produced by this method for well over a decade.

Regulatory and Ethical Issues Regarding Gene Therapy

Gene therapy research is inherently complex and can also carry great risks for its recipients. Thus, the issue of patient safety becomes significant. Research subjects who receive gene therapy often have a life-threatening illness, such as cancer, which may justify the risks involved. However, case reports of patient deaths in gene therapy trials have underscored these risks and raised the awareness of patient safety. In the 1980s, the NIH Recombinant DNA Advisory Committee was assigned responsibility for oversight of gene therapy research in the United States. It reviews clinical trials involving human gene transfer. The FDA must also review and approve all human clinical gene therapy trials, as it does for any type of drug therapy.

Any institution that conducts any type of research involving human subjects must have an institutional review board, whose purpose is to protect research subjects from unnecessary risks. Also required for institutions engaging in gene therapy research is an institutional biosafety committee. The role of this committee is to ensure compliance with the NIH *Guidelines for Research Involving Recombinant DNA Molecules.*

A major ethical issue related to gene therapy is that of eugenics. Eugenics is the intentional selection before birth of genotypes that are considered more desirable than others. For similar reasons, the prospect of being able to manipulate genes in human germ cells (sperm and eggs) is also a potential ethical hazard of gene therapy. Theoretically, even cosmetic modifications could be attempted by using such techniques as a part of routine family planning. Because of ethical concerns such as these, U.S. gene therapy research is limited to somatic cells only. Gene therapy in germ-line (reproductive) cells is currently not approved for funding by the National Institutes of Health. This limitation remains despite arguments from those who believe that human germ-cell research could potentially yield cures for many serious chronic illnesses and disabilities, such as Parkinson's disease and spinal paralysis.

PHARMACOGENETICS AND PHARMACOGENOMICS

Pharmacogenetics is a general term for the study of genetic variations in drug response and focuses on single-gene variations. A related science that pertains more directly to the HGP is **pharmacogenomics.** Pharmacogenomics is the combination of two scientific disciplines: pharmacology and genomics. Pharmacogenomics involves how genetics (genome) affect the body's response to drugs. Pharmacogenomics offer physicians the opportunity to individualize drug therapy based on a patient's genetic makeup, rather than giving the "standard" dose to all patients. The ultimate goal is to predict patient drug response and proactively tailor drug selection and dosages for optimal treatment outcomes. Warfarin is an anticoagulant drug that is used to prevent blood clots (see Chapter 26). Research has shown that people with certain genetic variations (*CYP2C9*2* or *CYP2C9*3* alleles) are at increased risk of bleeding and require lower doses than those without the variation. In addition, variations in the gene that encodes *VKORC1* may make a patient more or less sensitive to warfarin. This genetic variation occurs most frequently in the Asian population.

Individual differences in alleles that occur in at least 1% of a population are known as **genetic polymorphisms (PMs).** The word *polymorphism* literally means "many forms." Polymorphisms are considered to be too frequent to result from random genetic mutations. Polymorphisms that alter the amount or actions of drug-metabolizing enzymes can alter the reactions to medications. Known examples include those PMs that affect the metabolism of certain antimalarial drugs, the antituberculosis drug isoniazid, and the variety of drugs that are metabolized by the subtypes of cytochrome (CYP) enzymes. They can also alter the functioning of drug receptor proteins, cell membrane ion channels and drug transport proteins, and intracellular second messenger proteins (which carry out drug actions after a drug molecule binds to a cell membrane receptor).

TABLE 8-1 CLINICAL APPLICATIONS OF PHARMACOGENOMICS

GENETIC TECHNIQUE	APPLICATION
Genotyping for the presence of the CYP2D6 isoenzyme and for *CYP2D6* alleles determining whether patients are poor, intermediate, extensive, or ultra- rapid metabolizers related to these enzymes (under study)	*Psychiatry* and *general medicine:* Helps guide the prescribing of selected medications such as anticoagulants, immunosuppressants, antidepressants, antipsychotics, mood stabilizers, anticonvulsants, beta blockers, and antidysrhythmics
Genotyping for the presence of the *p-glycoprotein* drug transport protein (under study)	*Cardiology, infectious diseases, oncology, and other practice areas:* Assists in drug selection and dosing for drugs such as digoxin, antiretrovirals, and antineoplastics
Genotyping for the presence of thiopurine methyltransferase enzyme	*Oncology:* Used to temper toxicity through more careful dosing of the cancer drug 6-mercaptopurine in pediatric leukemia patients
Genotyping for variations in beta-adrenergic receptors (under study)	*Pulmonology:* Determines which asthma patients are more or less responsive to beta-agonist therapy (e.g., albuterol) and which patients might benefit from other types of drug therapy
Genotyping for the presence of the Philadelphia chromosome	*Oncology:* Identifies those patients with chronic myelogenous leukemia who may be stronger candidates for therapy with the cancer drug imatinib (Gleevec)
Genotyping for the presence of the *HER2/neu* protooncogene	*Oncology:* Identifies a subset of breast cancer patients whose tumors express this gene, which indicates their suitability for treatment with the cancer drug trastuzumab (Herceptin)
Viral genotyping of hepatitis C viruses (under study)	*Infectious diseases:* Can determine whether a particular infection warrants 26 versus 48 weeks of drug therapy (thereby reducing both costs and adverse drug effects)
Genotyping for the presence of factor V gene mutation	*Women's health:* Identifies women with a 7 to 100 times greater risk of thrombosis with oral contraceptive use compared to women without the mutation
Muscle biopsy test for patients with a family history of malignant hyperthermia	*Surgery:* Assesses the patient's risk of this adverse effect known to occur with administration of various inhalation anesthetics and intraoperative paralyzing drugs
Genotyping for the presence of sodium channels associated with renin-angiotensin receptors and adrenal gland receptors	*Cardiology:* Allows refined antihypertensive drug selection
Race-based drug selection	*Cardiology:* Indicates use of the drug isosorbide dinitrate/hydralazine (BiDil) for treatment of hypertension in African-American patients due ultimately to genotypic variations in this patient population

CYP2D6, Cytochrome P-450 enzyme subtype 2D6; *HER2/neu,* human epidermal growth factor receptor 2.

Differences in CYP enzymes (see Chapter 2) are the best studied PM effects thus far. Depending on their existing genes for these enzymes, patients can be genetically classified as "poor" or "rapid" metabolizers of CYP-metabolized drugs such as warfarin, phenytoin, codeine, and quinidine. With warfarin and phenytoin, a rapid metabolizer may need a higher dose of medication for the same effect, whereas a lower dose may be best for a poor metabolizer. With codeine, a poor metabolizer may actually need a higher dose to get the same analgesic effect that occurs when codeine is metabolized to morphine. In contrast, a rapid metabolizer may convert codeine to morphine too quickly, resulting in oversedation, and a lower dose may be sufficient. A similar situation is also likely to occur with quinidine. Because CYP enzymes are known to vary among racial and ethnic groups, the principle of "cultural safety" becomes one of the imperatives for routine gene-based drug dosing.

Studying both the genome of the patient and the genetic features of the pathology (e.g., tumor cells, infectious organisms) before treatment could allow for customized drug selection and dosing. Such analysis could permit the avoidance of drugs not likely to be effective as well as optimization of drug dosages to minimize the risk of adverse drug effects. These applications of pharmacogenomics are examples of **personalized medicine.**

DNA Microarray Technology

Most drug dosage changes are still usually made on a trial-and-error basis by monitoring patient response. Researchers have developed an analytical tool known as a high-density microarray. This technology uses tiny microchip plates that contain thousands of microscopic DNA samples. A patient's blood can then be screened for thousands of corresponding DNA sequences that bind from the patient's blood sample to the sequences on the chip. This allows determination of the presence or absence of various genes, such as those related to drug metabolism. For example, the enzymes in the CYP system help metabolize from 25% to 30% of currently available drugs. Over 40 specific *CYP* genes have been identified thus far. In December 2004, the FDA approved the first DNA microchip for clinical use—the AmpliChip Microarray. It is used to screen blood samples for the individual's CYP enzyme profile. Although this type of genotypic profiling is not yet practical for widespread use, it will eventually become a standard in clinical practice.

Table 8-1 lists several other examples of current clinical applications of pharmacogenomics.

APPLICATION OF GENETIC PRINCIPLES RELATED TO DRUG THERAPY AND THE NURSING PROCESS

As noted previously, the recognition that genetic factors contribute, at some level, to most diseases continues to grow. Thus, genetic influences on health, including the interaction of genetic and environmental (nongenetic) factors, will routinely affect nursing care delivery. In general, it is expected that in the next few years genetic research will move from the laboratory to more clinical practice settings.

Nurses in general practice settings will not be expected to perform in-depth genetic testing or counseling. Nurses—or other health care providers—with specialty certification in the field of genetics will conduct genetic testing and counseling. However, all nurses will need to have a working knowledge of relevant genetic principles. In this era of the "new genetics" paradigm, nurses are fully aware of the fact that nearly all diseases have a genetic component. Conditions such as myocardial infarction, cancer, mental illness, diabetes, and Alzheimer's disease are now viewed in a different light because of the known complex interactions between a number of factors, including the influence of one or more genes and a variety of environmental exposures for patients.

There are several other applicable skills regarding genetics for nurses in general practice settings. Assessment is the first step of the nursing process, and during the assessment the nurse may uncover factors that may point to a risk for genetic disorders. During the initial assessment, the nurse obtains a patient's personal and family history. The family history is most effective if it covers at least three generations and includes the current and past health status of each family member. Assessment of factors possibly indicating an increased risk for genetic disorders is also important. A few examples of such factors are a higher incidence of a particular disease or disorder in the patient's family than in the general population; diagnosis of a disease in family members at an unusually young age; or diagnosis of a family member with an unusual form of cancer or with more than one type of cancer.

It is also important to inquire about any unusual reactions to a drug—on the part of both the patient, family members, significant others, and/or caregivers. An unusual or other than expected reaction to a drug in family members may point to a difference in the patient's ability to metabolize certain drugs. As indicated earlier in the chapter (as well as in Chapter 2), genetic factors may alter a patient's metabolism of a particular drug, resulting in either increased or decreased drug action. Each and every time a medication is administered, the patient's response to that drug must be assessed. Any unusual medication responses in a patient may point to a need for further investigation. Once a genetic variation is known, drug therapy may be adjusted accordingly.

As DNA chip technology becomes more affordable and accessible, it will be possible for patients to know in advance their relative risks for different diseases in later life. Genotype testing to identify a patient's drug-metabolizing enzymes will help prescribers better predict a patient's response to drug therapy.

Teaching about genetic testing and counseling may be another responsibility of the nurse. Patients will have questions and concerns about genetic testing and other issues. Nurses in general practice are not experts in genetic issues. However, the nurse may help with suggestions about genetic counseling if appropriate. If genetic testing is ordered, the nurse may be a part of the testing process and will need to ensure that the informed decision-making and consent procedure has been carried out correctly.

Maintaining privacy and confidentiality is of utmost importance during genetic testing and counseling. The patient is the one who decides whether to include or exclude any family members from the discussion and from knowledge of the results of genetic testing. The patient needs to be reminded that he or she is not required to undergo the genetic test and that the patient has the right to disclose or withhold test results from anyone. Nurses must protect against improper disclosure of information to other family members, friends of the family, other health care providers, and insurance providers. Nurses share the responsibility with other health care providers to protect patients and their families against the misuse of the patients' genetic information.

Other responsibilities of the professional nurse may include development of clinical and social policy such as genetic nondiscrimination and prenatal testing policies, testing of genetic products for reliability, and tasks in genetic informatics to meet the challenge of sifting through a continually expanding body of knowledge.

CASE STUDY

Genetic Counseling

During the nurse's assessment of a newly admitted 38-year-old patient, the patient tells the nurse, "I'm allergic to codeine. Whenever I take it, it just knocks me out!" The patient tells the nurse that codeine does the same thing to all of her sisters.

1. Does the patient have an actual allergy to codeine? What else could be happening?

The next day, the patient's oncologist comes in and explains the results of a genetic test that was performed on an outpatient basis. The patient agrees to allow the nurse to sit in on the conversation. The physician tells the patient that she has a type of gene which indicates that she has a strong chance of developing breast cancer within the next 5 years. The oncologist recommends that she undergo a bilateral mastectomy soon to avoid the possibility of developing breast cancer and suggests that she share this information with her sisters and her daughter, who is 18 years old. After the physician leaves, the patient tells the nurse, "I don't know what to do. I haven't talked to one of my sisters for years and I just know she won't believe me. I also don't want to worry my daughter. She is so young, and I'm sure she's too young to get cancer."

2. Should the nurse tell the patient's sister and daughter? Explain your answer.
3. What is the best way for the nurse to handle this situation?

For answers, see http://evolve.elsevier.com/Lilley.

SUMMARY

Increasing scientific understanding of genetic processes is expected to revolutionize modern health care in many ways. The artificial manipulation and transfer of genetic material, although not yet a standard treatment for disease, is the focus of over 300 current human clinical gene therapy trials. The spectrum of diseases that may eventually be treatable by gene therapy includes inherited diseases that are present from birth, disabilities such as paralysis from spinal cord injuries, life-threatening illnesses such as cancer, and even chronic

illnesses acquired later in life for which a person may have a genetic predisposition. The science of pharmacogenomics has already identified some of the genetic nuances in how different individuals' bodies metabolize drugs to their benefit or harm. Continued study in this area is expected to result in proactive customization of drug therapy to promote therapeutic benefits while minimizing or eliminating toxic effects. Genetic procedures and therapeutic techniques will likely become an increasing part of nursing practice as well as of health care delivery in general. As the role and impact of genetics and genetically based drug therapy increase, so will their role in the nursing process.

KEY POINTS

- Genetic processes are a highly complex facet of human physiology, and genetics is becoming an integral part of health care that holds much promise in the form of new treatments for alterations in health.
- The Human Genome Project (HGP), spearheaded by the U.S. Department of Energy and the NIH, described in detail the entire genome of a human individual.
- Basic genetic inheritance is carried by 23 pairs of chromosomes in each of the somatic cells; one pair of chromosomes in each cell is the *sex chromosomes,* identified as XX for females and XY for males.
- Applicable skills for general nurses include taking thorough patient, family, and drug histories, recognizing situations that may warrant further investigation through genetic testing, identifying resources for patients, maintaining confidentiality and privacy, and ensuring that informed consent is obtained for genetic testing and counseling.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 Which is the most appropriate example of a product formed by an indirect form of gene therapy?
- **a** Stem cells
- **b** Insulin
- **c** Antigen substitution
- **d** Platelet inhibitors

2 The nurse is explaining the general goal of gene therapy to a patient. With gene therapy, the general goal is to transfer exogenous genes to a patient for which result?
- **a** To change the patient's own genetic functioning to treat a given disease
- **b** To improve drug metabolism
- **c** To prevent genetic disorders in the patient's future children
- **d** To stimulate the growth of stem cells

3 The NIH Recombinant DNA Advisory Committee has what responsibility?
- **a** Approving all forms of human clinical gene therapy
- **b** Identifying all major risks to the human subjects in a specific research protocol
- **c** Reviewing clinical trials involving human gene transfer
- **d** Analyzing genomes and determining whether they appear mutagenic

4 The presence of certain factors in a person's genetic makeup that increase the likelihood of eventually developing one or more diseases is known as a
- **a** genetic mutation.
- **b** genetic polymorphism.
- **c** genetic predisposition.
- **d** genotype.

5 The nurse is reviewing gene therapy. Which is a commonly studied adenovirus?
- **a** Hepatitis A and C virus
- **b** Genovirum
- **c** Human influenza virus
- **d** Pallodium

6 General responsibilities of the nurse regarding genetics may include which of these activities? (Select all that apply.)
- **a** Assessing the patient's personal and family history
- **b** Referring the patient to a genetic counselor or other genetics specialist
- **c** Communicating the results of genetic tests to the patient and patient's family
- **d** Maintaining privacy and confidentiality during the testing process
- **e** Answering questions about genetic test results

7 The nurse is assessing a patient for a possible increased risk for genetic disorders. Which of these, if present, may indicate an increased risk for a genetic disorder? (Select all that apply.)
- **a** Having a brother who died of a myocardial infarction at age 29
- **b** Having a family member who has been diagnosed with more than one type of cancer
- **c** Having an uncle who was diagnosed with prostate cancer at age 73
- **d** A history of allergy to shellfish and iodine
- **e** Having a maternal grandmother, two maternal aunts, and a sister who were diagnosed with colon cancer

1. b, 2. a, 3. b, 4. c, 5. c, 6. a, b, d, 7. a, b, e

CHAPTER

9

Photo Atlas of Drug Administration

PREPARING FOR DRUG ADMINISTRATION

NOTE: This photo atlas is designed to illustrate general aspects of drug administration. For detailed instructions, please refer to a nursing fundamentals or nursing skills book.

When giving medications, remember safety measures and correct administration techniques to avoid errors and to ensure optimal drug actions. Keep in mind the basic "Six Rights":

1. Right drug
2. Right dose
3. Right time
4. Right route
5. Right patient (using two identifiers)
6. Right documentation

Refer to Chapter 1 for additional rights regarding drug administration. Other things to keep in mind when preparing to give medications are as follows:

- Remember to perform hand hygiene before preparing or giving medications (Box 9-1)
- If you are unsure about a drug or dosage calculation, do not hesitate to double-check with a drug reference or with a pharmacist. **DO NOT** administer a medication if you are unsure about it!
- Be punctual when giving drugs. Some medications must be given at regular intervals to maintain therapeutic blood levels.
- Figure 9-1 shows an example of a computer-controlled drug-dispensing system. To prevent errors, obtain the drugs for one patient at a time.
- Remember to check the drug at least three times before giving it. The nurse is responsible for checking original medication labels against the transcribed medication order. In Figure 9-2, the nurse is checking the drug against the medication administration record after taking it out of the dispenser drawer. The drug must then be checked before opening it and again after opening it but before giving it to the patient. Some drugs (i.e., heparin and insulin) must be checked by two licensed nurses.
- Health care facilities have various means of checking the medication record when a new one is printed, so be sure that you are working from one that has been checked or verified before giving the medication. If the patient's medication record has a new drug order on it, the best rule of practice is to double-check that order against the original medication order on the patient's medical record.
- Check the expiration date of all medications. Medications used past the expiration date may be less potent or even harmful.
- Make sure that drugs that are given together are compatible. For example, bile acid sequestrants and antacids (see Chapters 27 and 50) must not be given with other drugs, because they will interfere with drug absorption and action. Check with a pharmacist if unsure. Before administering any medication, check the patient's identification bracelet (Figure 9-3). The Joint Commission's standards require two patient identifiers (name and birthday, or name and account number, according to the facility policy). In some facilities, patient information is in a barcode system that is scanned. In

FIGURE 9-1 Using a computer-controlled drug-dispensing system to remove medication.

addition, assess the patient's drug allergies before giving any medication.
- Be sure to take time to explain the purpose of each medication, its action, possible adverse effects, and any other pertinent information, especially drug-drug or drug-food interactions, to the patient and/or caregiver.
- Open the medication at the bedside into the patient's hand or into a medicine cup. Try not to touch the drugs with your hands. Leaving the drugs in their packaging until you get to the patient's room helps to avoid contamination and waste in case the patient refuses the drug.
- If the patient refuses a drug, the drug may be returned to the automated medication dispenser or to the pharmacy if the package is unopened. Check facility policy. Discard opened drugs per facility protocol. Scheduled drugs that are not given will need a witness if discarded. Note on the patient's record which drug was refused and the patient's reason for refusal.
- Discard any medications that fall to the floor or become contaminated by other means.
- Stay with the patient while the patient takes the drugs. Do not leave the drugs on the bedside table or the meal tray for the patient to take later.
- Document the medication given on the medication record (see Figure 9-9) as soon as it is given and before going to the next patient. Be sure also to document therapeutic responses, adverse effects (if any), and other concerns in the nurse's notes. Some facilities use manual documentation, and others use electronic documentation.
- Return to evaluate the patient's response to the drug. Remember that the expected response time will vary according to the drug route. For example, responses to sublingual nitroglycerin or intravenous (IV) push medications need to be evaluated within minutes, but it may take an hour or more for a response to be noted after an oral medication is given.
- See the Patient-Centered Care: Lifespan Considerations for the Pediatric Patient box on p. 41 (in Chapter 3) for age-related considerations for medication administration to infants and children.

BOX 9-1 STANDARD PRECAUTIONS

Always adhere to Standard Precautions, including the following:
- Wear clean gloves when exposed to or when there is potential exposure to blood, body fluids, secretions, excretions, and any items that may contain these substances. Always wash hands immediately when there is direct contact with these substances or any item contaminated with blood, body fluids, secretions, or excretions. Gloves must always be worn when giving injections and may be necessary during medication preparation. Be sure to assess the patient for latex allergies and use nonlatex gloves if indicated.
- Perform hand hygiene after removing gloves and between patient contacts. According to the Centers for Disease Control and Prevention, the preferred method of hand decontamination is with an alcohol-based hand rub, but washing with an antimicrobial soap and water is an alternative to the alcohol rub. Use soap and water to wash hands when hands are visibly dirty.
- Perform hand hygiene:
  - Before direct contact with patients
  - After contact with blood, body fluids, excretions, mucous membranes, wound dressings, or nonintact skin
  - After contact with a patient's skin (i.e., when taking a pulse or positioning a patient)
  - After removing gloves
- Wear a mask, eye protective gear, and face shield during any procedure or patient care activity with the potential for splashing or spraying of blood, body fluids, secretions, or excretions. Use of a gown may also be indicated for these situations.
- When administering medications, once the exposure or procedure is completed and exposure is no longer a danger, remove soiled protective garments or gear and perform hand hygiene.
- Never remove, recap, cap, bend, or break any used needle or needle system. Be sure to discard any disposable syringes and needles in the appropriate puncture-resistant container.

For detailed information on Standard Precautions, see the guidelines posted on the Centers for Disease Control and Prevention website at http://www.cdc.gov/hicpac/pdf/isolation/Isolation2007.pdf. Accessed June 11, 2012.

FIGURE 9-2 Checking the medication against the order on the medication administration record.

FIGURE 9-3 Always check the patient's identification, using two patient identifiers, and allergies before giving medications.

ENTERAL DRUGS

Administering Oral Drugs

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). When administering oral drugs, keep in mind the following points:

Oral Medications

- Administration of some oral medications (and medications by other routes) requires special assessments. For example, it is recommended that the apical pulse be auscultated for 1 full minute before any digitalis preparation is given (Figure 9-4). Administration of other oral medications may require blood pressure monitoring. Be sure to document all parameters. In addition, do not forget to check the patient's identification and allergies before giving any oral medication (or medication by any other route).
- If the patient is experiencing difficulty swallowing (dysphagia), some types of tablets can be crushed with a pill-crushing device (Figure 9-5) for easier administration. Crush one type of pill at a time, because if you mix together all of the medications before crushing (instead of crushing them one at a time) and then spill some, there is no way to know which drug has been wasted. Also, if all are mixed together, you cannot check the Six Rights three times before giving the drug. Mix the crushed medication in a small amount of soft food, such as applesauce or pudding. Be sure that the pill-crushing device is clean before and after you use it. See Chapter 2 for more information on medications that are not to be crushed.
- **CAUTION:** Be sure to verify whether a medication can be crushed by consulting a drug reference book or a pharmacist. Some oral medications, such as capsules, enteric-coated tablets, and sustained-release or long-acting drugs, must *not* be crushed, broken, or chewed (Figure 9-6). These medications are formulated to protect the gastric lining from irritation or protect the drug from destruction by gastric acids, or are designed to break down gradually and slowly release the medication. If these drugs, designated with labels such as *sustained release* or *extended release,* are crushed or opened, then the intended action of the dosage form is destroyed. As a result, gastric irritation may occur, the drug may be inactivated by gastric acids, or the immediate availability of a drug that was supposed to be released slowly may cause *toxic* effects. Check with the prescriber to see if an alternate form of the drug is needed.
- Be sure to position the patient to a sitting or side-lying position to make it easier for the patient to swallow oral medications and to avoid the risk of aspiration (Figure 9-7). Always provide aspiration prevention measures as needed.
- Offer the patient a full glass of water; 4 to 6 oz of water or other fluid is recommended for the best dissolution and absorption of oral medications. *Age-related considerations:* Young patients and the elderly may not be able to drink a full glass of water but need to take enough fluid to ensure that the medication reaches the stomach. If the patient prefers another fluid, be sure to check for interactions between the medication and the fluid of choice. If fluid restriction is ordered, be sure to follow the guidelines.
- If the patient requests, you may place the pill or capsule in the patient's mouth with your gloved hand.
- Lozenges are not be chewed unless specifically instructed/ordered.
- Effervescent powders and tablets need to be mixed with water and then given immediately after they are dissolved.
- Remain with the patient until all medication has been swallowed. If you are unsure whether a pill has been swallowed, ask the patient to open his or her mouth so that you can inspect to see if it is gone. Assist the patient to a comfortable position after the medication has been taken.
- Document the medication given on the medication record (see Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.

Sublingual and Buccal Medications

The sublingual and buccal routes prevent destruction of the drugs in the gastrointestinal tract and allow for rapid absorption into the bloodstream through the oral mucous membranes. These routes are not often used. Be sure to provide instruction to the patient before giving these medications.

- Sublingual tablets are placed under the tongue (Figure 9-8). Buccal tablets are placed between the upper or lower molar teeth and the cheek.
- Be sure to wear gloves if you are placing the tablet into the patient's mouth. Adhere to Standard Precautions (see Box 9-1).
- Instruct the patient to allow the drug to dissolve completely before swallowing.
- These drug forms are not taken with fluids. Instruct the patient not to drink anything until the tablet has dissolved completely.
- Be sure to instruct the patient not to swallow the tablet; saliva should not be swallowed until the drug is dissolved.
- When using the buccal route, alternate sides with each dose to reduce risk of oral mucosa irritation.
- Document the medication given on the medication record (Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.

Orally Disintegrating Medications

Orally disintegrating medications, either in tablet or medicated strip form, dissolve in the mouth without water within 60 seconds. These medications are placed *on* the tongue, not under the tongue, as in the sublingual route. The absorption through the oral mucosa is rapid with a faster onset of action than for drugs that are swallowed. The patient must be instructed to allow the medication to dissolve on the tongue and not to chew or swallow the medication.

- Be sure to wear gloves if you are placing the medication on the patient's tongue. Adhere to Standard Precautions (see Box 9-1).
- Make sure the patient has not eaten or had anything to drink for 5 minutes before and after taking these medications.
- Orally disintegrating medications are often packed in foil blister packs. Do not open the package until just before giving the medication. Carefully open *one* dose at a time. These medications are fragile and may break if they are pushed through the blister pack. Once a blister or foil pack is

opened, the tablet must either be taken or discarded; it cannot be stored for another time.
- Orally disintegrating medications cannot be split, broken, or torn.
- Instruct the patient to hold the medication on the tongue to allow it to dissolve, instead of chewing or swallowing it. This usually takes about a minute. Warn the patient that there may be a sweet or even slightly bitter taste. Remind the patient not to drink water or to eat for 5 minutes after taking the medication.
- Document the medication given on the medication record (see Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.

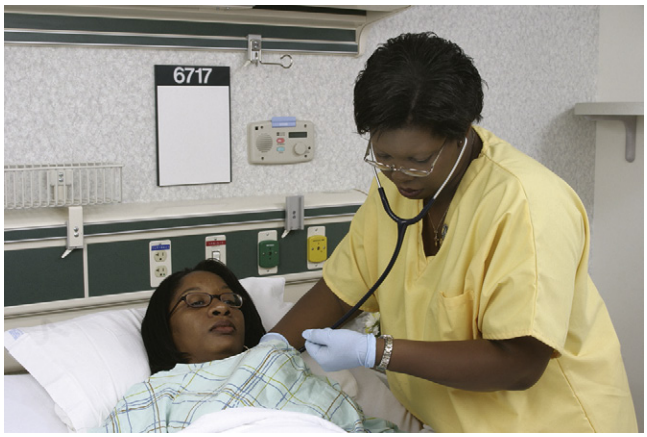

FIGURE 9-4 Some medications require special assessment before administration, such as taking an apical pulse.

MAYFIELD GENERAL HOSPITAL

Virginia Shores, VA

PAGE 1 of 1

FIGURE 9-9 Example of a medication administration record.

Liquid Medications

- Liquid medications may come in a single-dose (unit-dose) package, may be poured into a medicine cup from a multidose bottle, or may be drawn up in an oral-dosing syringe (Figure 9-10).
- When pouring a liquid medication from a container, first shake the bottle gently to mix the contents if indicated. Remove the cap and place it upside down on a paper towel on the counter. Hold the bottle with the label against the palm of your hand to keep any spilled medication from altering the label. Place the medicine cup at eye level, and fill to the proper level on the scale (Figure 9-11). Pour the liquid so that the base of the meniscus is even with the appropriate line measure on the medicine cup.
- If you overfill the medicine cup, discard the excess in the sink. Do not pour it back into the multidose bottle. Before replacing the cap, wipe the rim of the bottle with a paper towel.
- Doses of medications that are less than 5 mL cannot be measured accurately in a calibrated medicine cup. For small volumes, use a calibrated oral syringe. Do not use a hypodermic syringe or a syringe with a needle or syringe cap. If hypodermic syringes are used, the drug may be inadvertently given parenterally, or the syringe cap or needle, if not removed from the syringe, may become dislodged and accidentally aspirated by the patient when the syringe plunger is pressed.
- Document the medication given on the medication record (see Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.

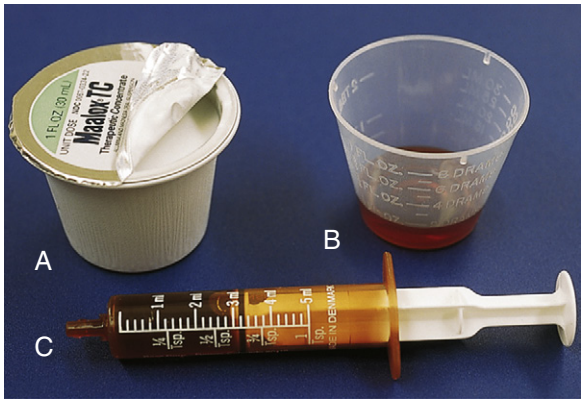

FIGURE 9-10 **A,** Liquid medication in a unit-dose package. **B,** Liquid measured into a medicine cup from a multidose container. **C,** Liquid medicine in an oral-dosing syringe.

FIGURE 9-11 Measuring liquid medication.

Oral Medications for Infants and Children

- Liquids are usually ordered for infants and young children because they cannot swallow pills or capsules.
- A plastic disposable oral-dosing syringe is recommended for measuring small doses of liquid medications. Use of an oral-dosing syringe prevents the inadvertent parenteral administration of a drug once it is drawn up into the syringe.
- Position the infant so that the head is slightly elevated to prevent aspiration. Not all infants will be cooperative, and many need to be partially restrained (Figure 9-12).
- Place the plastic dropper or syringe inside the infant's mouth, beside the tongue, and administer the liquid in small amounts while allowing the infant to swallow each time.
- A clean empty nipple may be used to administer the medication. Place the liquid inside the empty nipple and allow the infant to suck the nipple. Add a few milliliters of water to rinse any remaining medication into the infant's mouth, unless contraindicated.
- Take great care to prevent aspiration. A crying infant can easily aspirate medication. If the infant is crying, wait until the infant is calmer before trying again to give the medication.
- Do not add medication to a bottle of formula; the infant may refuse the feeding or may not drink all of it. Make sure that all of the oral medication has been taken, and then return the infant to a safe, comfortable position.
- A child will reject oral medications that taste bitter. The drug may be mixed with a teaspoon of a sweet-tasting food such as jelly, applesauce, ice cream, or sherbet. Using honey in infants is *not* recommended because of the risk of botulism. Do not mix the medication in an essential food item, such as formula, milk, or orange juice, because the child may reject that food later. After the medication is taken, offer the child juice, a flavored frozen ice pop, or water.

FIGURE 9-12 Administering oral liquid medication to an infant.

Administering Drugs through a Nasogastric or Gastrostomy Tube

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Gloves must be worn. When administering drugs via these routes, keep in mind the following points:

- Before giving drugs via these routes, position the patient in a semi-Fowler's or Fowler's position and leave the head of the bed elevated for at least 30 minutes afterward to reduce the risk of aspiration (Figure 9-13).
- Assess whether fluid restriction or fluid overload is a concern. It will be necessary to give water along with the medications to flush the tubing.
- Check to see if it is recommended for the drug to be given on an empty or full stomach. In addition, some drugs are incompatible with enteral feedings. If the drug is to be given on an empty stomach, or if incompatibility exists, the feeding may need to be stopped before and/or after giving the medication. Follow the guidelines for the specific drug if this is necessary. Examples of drugs that are not compatible with enteral feedings are phenytoin and carbidopa-levodopa. Whenever possible, give liquid forms of drugs to prevent clogging the tube.
- If tablets must be given, crush the tablets individually into a fine powder. Administer the drugs separately (Figure 9-14). Keeping the drugs separate allows for accurate identification if a dose is spilled. Be sure to check whether the medication can be crushed; enteric-coated and sustained-release tablets or capsules are not to be crushed (see Chapter 2). Check with a pharmacist if you are unsure.

FIGURE 9-13 Elevate the head of the bed before administering medications through a nasogastric or other enteric tube.

- Before administering the drugs, follow the institution's policy for verifying tube placement and checking gastric residual. Reinstill gastric residual per institutional policy, and then clamp the tube.
- Dilute a crushed tablet or liquid medication in 15 to 30 mL of warm water. Some capsules may be opened and dissolved in 30 mL of warm water; check with a pharmacist.
- Remove the piston from an adaptable-tip syringe and attach it to the end of the tube. Unclamp the tube and pinch the tubing to close it again. Add 30 mL of warm water and release the pinched tubing. Allow the water to flow in by gravity to flush the tube, and then pinch the tubing closed again before all the water is gone to prevent excessive air from entering the stomach. If a stopcock valve device is present on the enteral tube, then open and close the stopcock instead of pinching the tubing to clamp it.
- Pour the diluted medication into the syringe and release the tubing to allow it to flow in by gravity (Figure 9-15). Flush between each drug with 10 mL of warm water. Be careful not to spill the medication mixture. Adjust fluid amounts if fluid restrictions are ordered, but sufficient fluid must be used to dilute the medications and to flush the tubing.
- If water or medication does not flow freely, you may apply gentle pressure with the plunger or bulb of the syringe. Do not try to force the medicine through the tubing.
- After the last drug dose, flush the tubing with 30 mL of warm water, and then clamp the tube. Resume the tube feeding when appropriate.
- Have the patient remain in a high Fowler's or slightly elevated right-side-lying position to reduce the risk of aspiration.
- Document the medications given on the medication record (see Figure 9-9), the amount of fluid given on the patient's intake and output record, and the patient's response in the patient's record.

FIGURE 9-14 Medications given through gastric tubes need to be administered separately. Dilute crushed pills in 15 to 30 mL of water before administration.

FIGURE 9-15 Pour liquid medication into the syringe, then unclamp the tubing and allow it to flow in by gravity.

Administering Rectal Drugs

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Gloves must be worn. When administering rectal drugs, keep in mind the following points:

- Assess the patient for the presence of active rectal bleeding or diarrhea, which generally are contraindications for the use of rectal suppositories.
- Suppositories should not be divided to provide a smaller dose. The active drug may not be evenly distributed within the suppository base.
- Position the patient on his or her left side, unless contraindicated. The uppermost leg needs to be flexed toward the waist (Sims' position). Provide privacy and drape.
- Do not insert the suppository into stool. Gently palpate the rectal wall for the presence of feces. If possible, have the patient defecate. DO NOT palpate the patient's rectum if the patient has had rectal surgery.
- Remove the wrapping from the suppository and lubricate the rounded tip with water-soluble gel (Figure 9-16).
- Insert the tip of the suppository into the rectum while having the patient take a deep breath and exhale through the mouth. With your gloved finger, quickly and gently insert the suppository into the rectum, alongside the rectal wall, at least 1 inch beyond the internal sphincter (Figure 9-17).
- Have the patient remain lying on his or her left side for 15 to 20 minutes to allow absorption of the medication.
- *Age-related considerations:* With children it may be necessary to gently but firmly hold the buttocks in place for 5 to 10 minutes until the urge to expel the suppository has passed. Older adults with loss of sphincter control may not be able to retain the suppository.
- If the patient prefers to self-administer the suppository, give specific instructions on the purpose and correct procedure. Be sure to tell the patient to remove the wrapper.
- Use the same procedure for medications administered by a retention enema, such as sodium polystyrene sulfonate (see Chapter 29). Drugs given by enemas are diluted in the smallest amount of solution possible. Retention enemas need to be held for 30 minutes to 1 hour before expulsion, if possible, for maximum absorption.
- Document the medication given on the medication record (see Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.

FIGURE 9-16 Lubricate the suppository with a water-soluble lubricant.

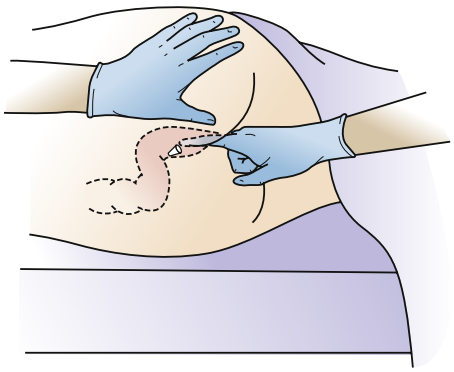

FIGURE 9-17 Inserting a rectal suppository.

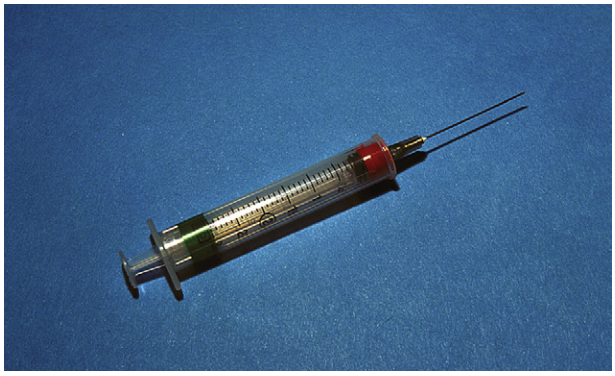
PARENTERAL DRUGS

Preparing for Parenteral Drug Administration

FIGURE 9-18 NEVER RECAP A USED NEEDLE! Always dispose of uncapped needles in the appropriate sharps container. See Box 9-1 for Standard Precautions.

FIGURE 9-19 An UNUSED needle may need to be recapped before the medication is given to the patient. The "scoop method" is one way to recap an unused needle safely. Be sure not to touch the needle to the countertop or to the outside of the needle cap.



FIGURES 9-20 and 9-21 There are several types of needlestick prevention syringes. This example (Figure 9-20) has a guard over the unused syringe. After the injection, the nurse pulls the guard up over the needle until it locks into place (Figure 9-21).

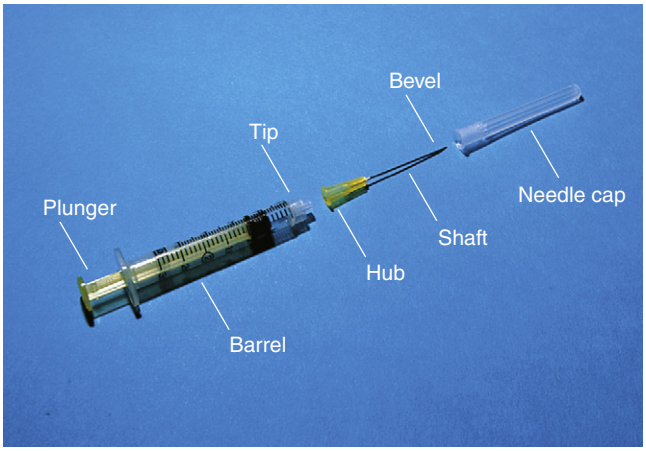


FIGURE 9-22 The parts of a syringe and hypodermic needle.

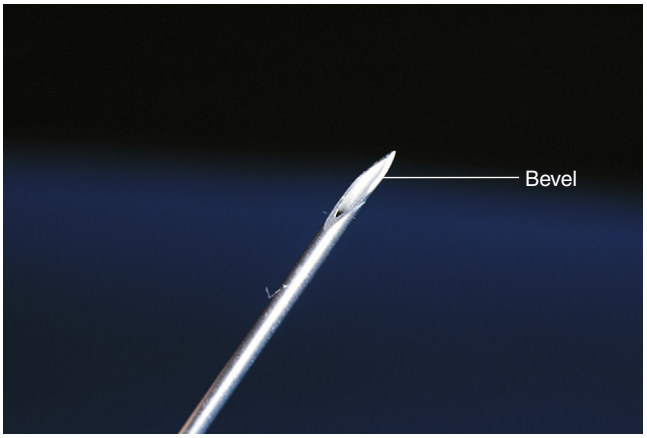

FIGURE 9-23 Close-up view of the bevel of a needle.

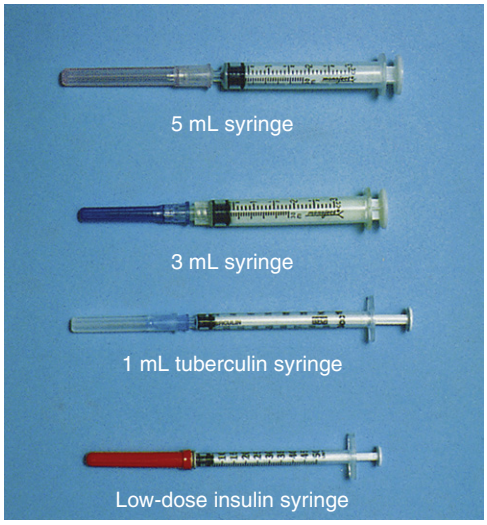

FIGURE 9-24 Be sure to choose the correct size and type of syringe for the drug ordered.

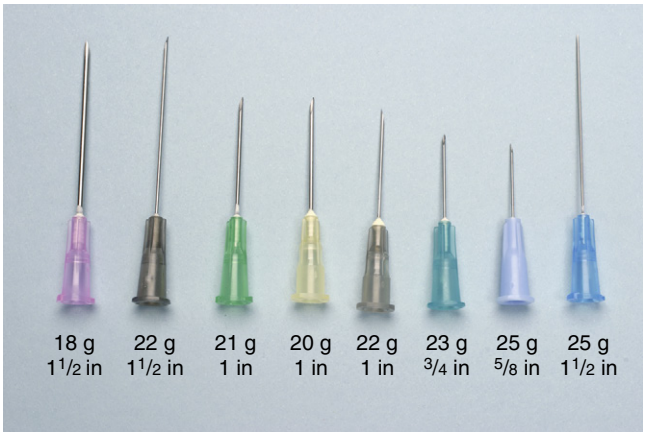

FIGURE 9-25 Needles come in various gauges and lengths. The larger the gauge number, the smaller the needle. Be sure to choose the correct needle—gauge and length—for the type of injection ordered.

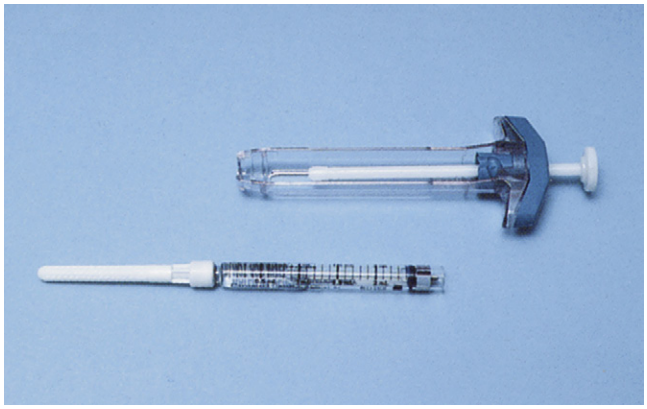
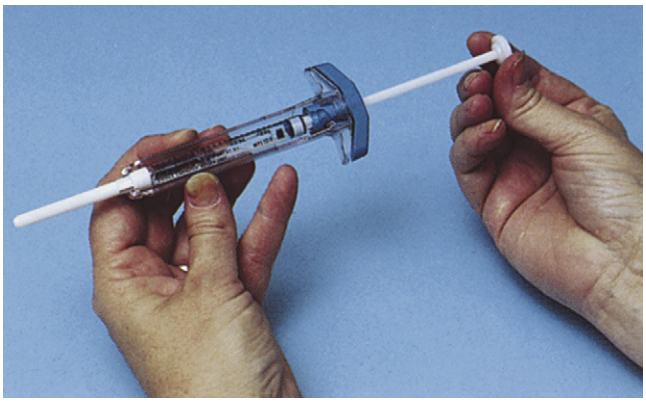




FIGURES 9-26 and 9-27 Some medications come in prefilled sterile medication cartridges. Figures 9-26 and 9-27 show the Carpuject prefilled cartridge and syringe system. Follow the manufacturer's instructions for assembling prefilled syringes. After use, dispose of the syringe in a sharps container; the cartridge is reusable. Some prefilled syringes come with an air bubble in the syringe; do not expel the bubble before administration.

FIGURE 9-28 Ampules containing medications come in various sizes. The neck of the ampule must be broken carefully before the medication is withdrawn.

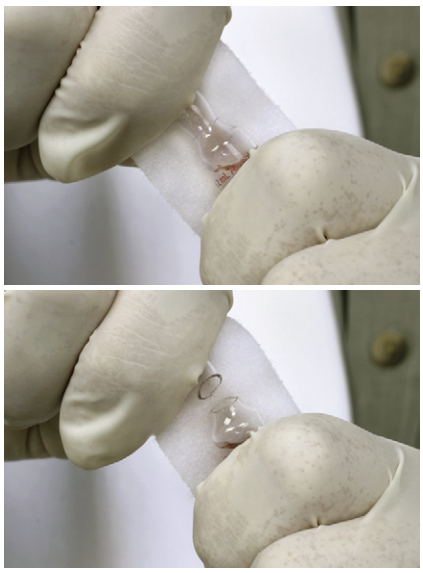
FIGURE 9-29 Use a filter needle when withdrawing medication from an ampule. Filter needles help to remove tiny glass particles that may result from the ampule breakage. DO NOT USE A FILTER NEEDLE FOR INJECTION INTO A PATIENT! Some facilities may also require the use of a filter needle to withdraw medications from a vial.

Removing Medications from Ampules

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Gloves may be worn. When performing these procedures, keep in mind the following points:

- When removing medication from an ampule, use a sterile filter needle (Figure 9-29). These needles are designed to filter out glass particles that may be present inside the ampule after it is broken. The filter needle IS NOT intended for administration of the drug to the patient.
- Medication often rests in the top part of the ampule. Tap the top of the ampule lightly and quickly with your finger until all fluid moves to the bottom portion of the ampule (Figure 9-30).
- Place a small gauze pad or dry alcohol swab around the neck of the ampule to protect your hand. Snap the neck quickly and firmly, and break the ampule *away* from your body (Figures 9-31 and 9-32).
- To draw up the medication, either set the open ampule on a flat surface or hold the ampule upside down. Insert the filter needle (attached to a syringe) into the center of the ampule opening. Do not allow the needle tip or shaft to touch the rim of the ampule (Figure 9-33).

FIGURE 9-30 Tapping an ampule to move the fluid below the neck.



FIGURES 9-31 AND 9-32 Breaking an ampule. Carefully break the neck of the ampule in a direction *away* from you and away from others near you.

- Gently pull back on the plunger to draw up the medication. Keep the needle tip below the fluid within the vial; tip the ampule to bring all of the fluid within reach of the needle.
- If air bubbles are aspirated, do not expel them into the ampule. Remove the needle from the ampule, hold the syringe with the needle pointing up, and tap the side of the syringe with your finger to cause the bubbles to rise toward the needle. Draw back slightly on the plunger, and slowly push the plunger upward to eject the air. Do not eject fluid.
- Excess medication is disposed of into a sink. Hold the syringe vertically with the needle tip up and slanted toward the sink. Slowly eject the excess fluid into the sink, and then recheck the fluid level by holding the syringe vertically.
- Remove the filter needle and replace with the appropriate needle for administration. NEVER use a filter needle to administer medications to a patient!
- Be sure to ensure the sterility of the injection needle throughout the process. Do not touch the open end of the needle hub, or the tip of the syringe, when attaching a needle to a syringe.
- Dispose of the glass ampule pieces and the used filter needle in the appropriate sharps container.

Removing Medications from Vials

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Gloves may be worn. When performing these procedures, keep in mind the following points:

- Vials can contain either a single dose or multiple doses of medication. Follow the institution's policy for using opened multidose vials, such as vials of insulin. Mark multidose vials with the date and time of opening and the discard date (per facility policy). If you are unsure about the age of an opened vial of medication, discard it and obtain a new one.
- Check institutional policies regarding which type of needle to use to withdraw fluid from a vial. With the exception of insulin, which must be withdrawn using an insulin syringe, fluid may be withdrawn from a vial using a blunt fill needle or a filter needle. Using a blunt fill needle reduces the chance of injury with a sharp needle (Figure 9-34).
- If the vial is unused, remove the cap from the top of the vial.

FIGURE 9-33 Using a filter needle to withdraw medication from an ampule.

- If the vial has been previously opened and used, wipe the top of the vial vigorously with an alcohol swab.
- Air must first be injected into a vial before fluid can be withdrawn. The amount of air injected into a vial needs to equal the amount of fluid that needs to be withdrawn.
- Determine the volume of fluid to be withdrawn from the vial. Pull back on the syringe's plunger to draw an amount of air into the syringe that is equivalent to the volume of medication to be removed from the vial. Insert the syringe into the vial, preferably using a needleless system. Figure 9-35 shows a needleless system for vial access. Inject the air into the vial.
- While holding onto the plunger, invert the vial and remove the desired amount of medication (Figure 9-36).
- Gently but firmly tap the syringe to remove air bubbles. Excess fluid, if present, must then be discarded into a sink.
- Some vials are not compatible with needleless systems and therefore require a needle for fluid withdrawals (Figure 9-37). Use a blunt fill needle if available (see Figure 9-34).
- When an injection requires two medications from two different vials, begin by injecting air into the first vial (without touching the fluid in the first vial), and then inject air into the second vial. Immediately remove the desired dose from the second vial. Change needles (if possible), and then remove the exact prescribed dose of drug from the first vial. Take great care not to contaminate the drug in one vial with the drug from the other vial. Check with a pharmacist to make sure the two drugs are compatible for mixing in the same syringe.
- For injections, if a needle has been used to remove medication from a vial, always change the needle before administering the dose. Changing needles ensures that a clean and sharp needle is used for the injection. Medication that remains on the outside of the needle may cause irritation to the patient's tissues. In addition, the needle may become dull if used to puncture a rubber stopper. However, some syringes, such as insulin syringes, have needles that are fixed onto the syringe and cannot be removed.
- Ensure the sterility of the injection needle throughout the process. Do not touch the open end of the needle hub, or the tip of the syringe, when attaching a needle to a syringe.

FIGURE 9-36 Withdrawing medication from a vial (needleless system shown).

FIGURE 9-37 Using a needle and syringe to remove medication from a vial.

Injections Overview

Needle Insertion Angles for Intramuscular, Subcutaneous, and Intradermal Injections

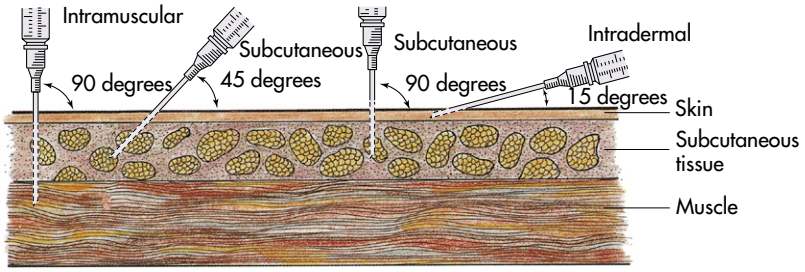

FIGURE 9-38 Comparison of angles of needle insertion for injections.

- For any injection, if syringes are prepared at a medication cart or in a medication room, then each parenteral medication should be prepared separately and a label identifying the patient, the medication, the dose, and the route placed on the barrel of the syringe before the nurse leaves the preparation area.
- For intramuscular (IM) injections, insert the needle at a 90-degree angle (Figure 9-38). Intramuscular injections deposit the drug deep into muscle tissue, where the drug is absorbed through blood vessels within the muscle. The rate of absorption of medication given by the intramuscular route is slower than that of medications given by the intravenous route but faster than that of medications given by the subcutaneous route. Intramuscular injections generally require a longer needle to reach the muscle tissue, but shorter needles may be needed for older patients, children, and adults who are malnourished. The site chosen will also determine the length of the needle needed. In general, aqueous medications can be given with a 22- to 27-gauge needle, but oil-based or more viscous (thick) medications are given with an 18- to 25-gauge needle. Average needle lengths for children range from ⅝ to 1 inch, and needles for adults range from 1 to 1½ inches. The nurse must choose the needle length based on the size of the muscle at the injection site, the age of the patient, and the type of medication used. For a normal, well-developed adult, 3 mL is the maximum amount used in a single injection. Follow agency policy. If more than 3 mL is needed for the ordered dose, then the medication will need to be given in 2 separate injections. However, if the patient is an older adult, or thin, a smaller maximum volume, such as 2 mL, is recommended.
- For subcutaneous (subcut) injections, insert the needle at either a 45- or 90-degree angle. Subcutaneous injections deposit the drug into the loose connective tissue under the dermis. This tissue is not as well supplied with blood vessels as is the muscle tissue; as a result, drugs are absorbed more slowly than drugs given intramuscularly. Doses are usually 0.5 to 1 mL. In general, use a 25-gauge, ½- to ⅝-inch needle. A *90-degree angle* is used for an *average-sized* patient; a *45-degree angle* may be used for *thin, emaciated, and/or malnourished* adults and for children. To ensure correct needle length, grasp the skinfold with thumb and forefinger, and choose a needle that is approximately half the length of the skinfold from top to bottom.
- Intradermal (ID) injections are given into the outer layers of the dermis in very small amounts, usually 0.01 to 0.1 mL. These injections are used mostly for diagnostic purposes, such as testing for allergies or tuberculosis, and for local anesthesia. Very little of the drug is absorbed systemically. In general, choose a tuberculin or 1-mL syringe with a 25- or 27-gauge needle that is ⅜ to ⅝ inch long. The angle of injection is 5 to 15 degrees.
- For specific information about giving injections to children, see Box 9-2.

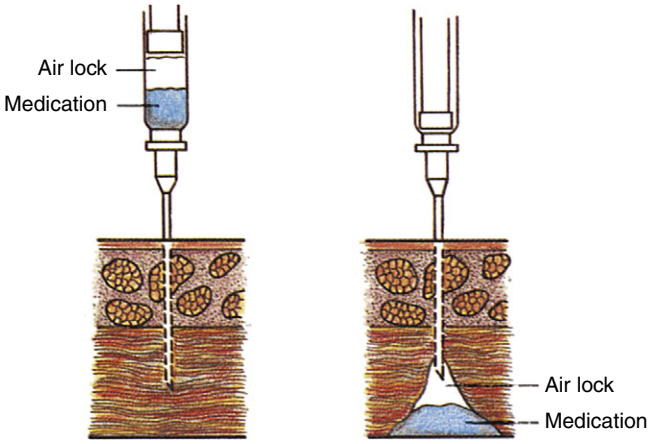

FIGURE 9-39 Air-lock technique for intramuscular injections.

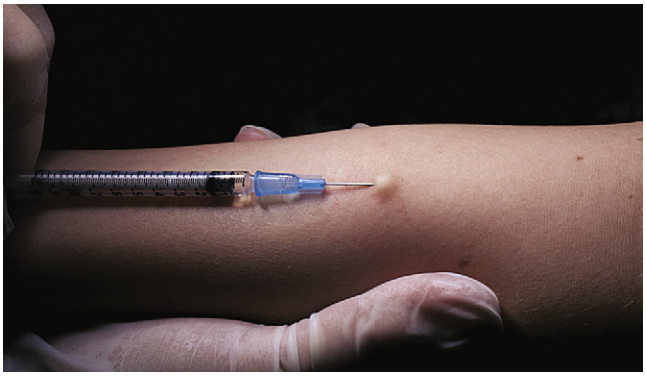
Air-Lock Technique

- Some facilities recommend administering intramuscular injections using the air-lock technique (Figure 9-39). Check institutional policies.
- After withdrawing the desired amount of medication into the syringe, withdraw an additional 0.2 mL of air. Be sure to inject using a 90-degree angle. The small air bubble that follows the medication during the injection may help prevent the medication from leaking through the needle track into the subcutaneous tissues.

Intradermal Injections



FIGURES 9-40 and 9-41 Intradermal injection.

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Gloves must be worn. When giving an intradermal injection, keep in mind the following points:

- Be sure to choose an appropriate site for the injection. Avoid areas of bruising, rashes, inflammation, edema, or skin discoloration.
- Help the patient to a comfortable position. Extend and support the elbow and forearm on a flat surface.
- In general, three to four finger widths below the antecubital space and one hand width above the wrist are the preferred locations on the forearm. Areas on the back that are also suitable for subcutaneous injection may be used if the forearm is not appropriate for the intradermal injection.
- Cleanse the site with an alcohol or antiseptic swab. Apply the swab at the center of the site, and cleanse outward in a circular direction for about 2 inches (5 cm) (see Figure 9-43); then let the skin dry.
- After cleansing the site, stretch the skin over the site with your nondominant hand.
- With the needle almost against the patient's skin, insert the needle, bevel UP, at a 5- to 15-degree angle until resistance is felt, and then advance the needle through the epidermis, approximately 3 mm (Figures 9-40 and 9-41). The needle tip should still be visible under the skin.
- Do not aspirate. This area under the skin contains very few blood vessels.
- Slowly inject the medication. It is normal to feel resistance, and a bleb that resembles a mosquito bite (about 6 mm in diameter) will form at the site if accurate technique is used.
- Withdraw the needle slowly while gently applying a gauze pad at the site, but do not massage the site.
- Dispose of the syringe and needle in the appropriate container. DO NOT RECAP the needle. Perform hand hygiene after removing gloves.
- Provide instructions to the patient as needed for a follow-up visit for reading the skin testing, if applicable.
- Document on the medication record the date of the skin testing and the date that results need to be read, if applicable.

Subcutaneous Injections

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Gloves must be worn. When giving a subcutaneous injection, keep in mind the following points:

- Be sure to choose an appropriate site for the injection. Avoid areas of bruising, rashes, inflammation, edema, or skin discoloration (Figure 9-42).
- Ensure that the needle size is correct. Grasp the skinfold between your thumb and forefinger, and measure from top to bottom. The needle must be approximately one-half this length.
- Cleanse the site with an alcohol or antiseptic swab. Apply the swab at the center of the site, and cleanse outward in a circular direction for about 2 inches (5 cm) (Figure 9-43); then let the skin dry.
- Tell the patient that he or she will feel a "stick" as you insert the needle.
- For an average-sized patient, pinch the skin with your nondominant hand and inject the needle quickly at a 45- or 90-degree angle (Figure 9-44).
- For an obese patient, pinch the skin and inject the needle at a 90-degree angle. Be sure the needle is long enough to reach the base of the skinfold.
- *Age-related considerations:* For a child or a thin patient, pinch the skin gently and be sure to use a 45-degree angle when injecting the needle.
- Injections given in the abdomen must be given at least 2 inches away from the umbilicus because of the surrounding vascular structure (Figure 9-45). The injection site must also be 2 inches away from any incisions, stomas, or open wounds, if present.
- After the needle enters the skin, grasp the lower end of the syringe with your nondominant hand. Move your dominant hand to the end of the plunger—be careful not to move the syringe.
- Aspiration of medication to check for blood return is not necessary for subcutaneous injections, but some institutions may require it. Check institutional policy. Heparin injections and insulin injections are NOT aspirated before injection.
- With your dominant hand, slowly inject the medication.
- Withdraw the needle quickly, and place a swab or sterile gauze pad over the site.
- Apply gentle pressure but do not massage the site. If necessary, apply a bandage to the site.
- Dispose of the syringe and needle in the appropriate container. DO NOT RECAP the needle. Perform hand hygiene after removing gloves.
- Document the medication given on the medication record (see Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.
- For injections of heparin or other subcutaneous anticoagulants, follow the manufacturer's instructions for injection technique as needed. Many manufacturers recommend the area of the abdomen known as the "love handles" for injection of anticoagulants. DO NOT ASPIRATE before injecting, and DO NOT massage the site after injection. These actions may cause a hematoma at the injection site.
- Heparin doses are ordered in units, but it is important to note that units of heparin are not the same as units of insulin. Heparin is *never* measured with insulin syringes.

Insulin Syringes

- *Always use an insulin syringe to measure and administer insulin.* When giving small doses of insulin, use an insulin syringe that is calibrated for smaller doses. Figure 9-46 shows insulin syringes with two different calibrations. Notice that in the 100-unit syringe, each line represents 2 units; in the 50-unit syringe, each line represents 1 unit. NOTE: A unit of insulin is NOT equivalent to a milliliter of insulin!
- Figure 9-47 shows several examples of devices that can be used to help the patient self-administer insulin. These devices feature a multidose container of insulin and easy-to-read dials for choosing the correct dose. The needle is changed with each use. These devices are for single-patient use only and cannot be used by more than one patient due to the risk of blood contamination of the medication reservoir.
- When two different types of insulin are drawn up into the same syringe, always draw up the clear insulin into the syringe first (Figure 9-48). See p. 113 for information about mixing two types of insulin in one syringe.

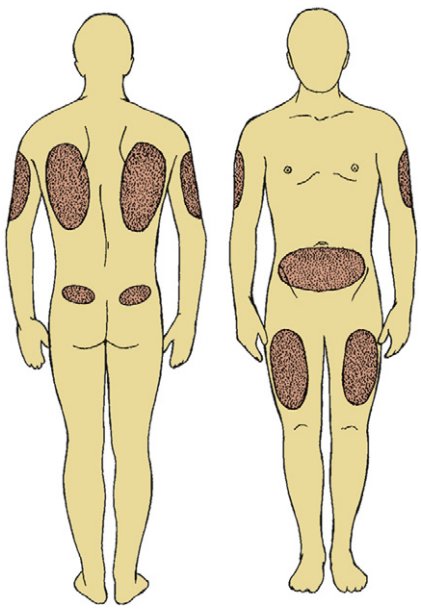


FIGURE 9-42 Potential sites for subcutaneous injections.

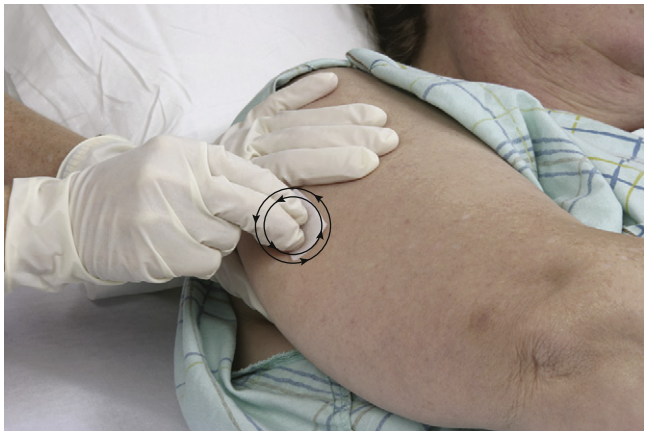

FIGURE 9-43 Before giving an injection, cleanse the skin with an alcohol or antiseptic swab using a circular motion.

FIGURE 9-44 Giving a subcutaneous injection at a 90-degree angle.

FIGURE 9-45 When giving a subcutaneous injection in the abdomen, be sure to choose a site at least 2 inches away from the umbilicus.

FIGURE 9-46 Insulin syringes are available in 100-unit and 50-unit calibrations.

FIGURE 9-47 A variety of devices are available for insulin injections.

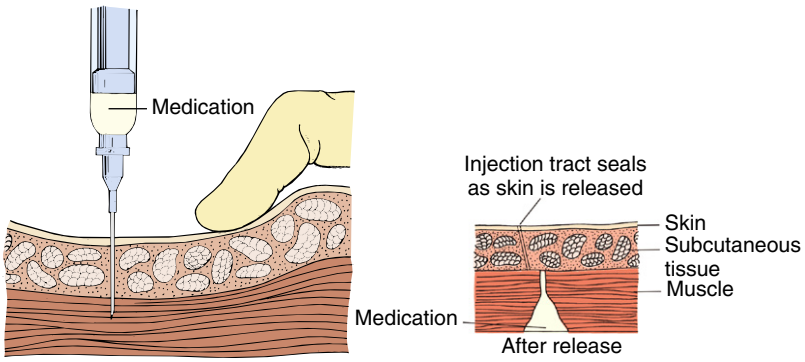
FIGURE 9-48 Mixing two types of insulin in the same syringe. NOTE: The clear insulin is always drawn up into the syringe first.

Intramuscular Injections

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Gloves must be worn. When giving an intramuscular (IM) injection, keep in mind the following points:

- Choose the appropriate site for the injection by assessing not only the size and integrity of the muscle but the amount and type of injection. Palpate potential sites for areas of hardness or tenderness, and note the presence of bruising or infection.
- The dorsogluteal injection site is no longer recommended for injections because of the close proximity to the sciatic nerve and major blood vessels. Injury to the sciatic nerve from an injection may cause partial paralysis of the leg. The dorsogluteal site is not to be used for intramuscular injections; instead, the ventrogluteal site is the preferred intramuscular injection site for adults and children.
- Assist the patient to the proper position, and ensure his or her comfort.
- Locate the proper site for the injection. Cleanse the site with an alcohol or antiseptic swab. Apply the swab at the center of the site, and cleanse outward in a circular direction for about 2 inches (5 cm) (see Figure 9-43); then let the skin dry. Keep a sterile gauze pad nearby for use after the injection.
- With your nondominant hand, pull the skin taut. Follow the instructions for the Z-track method (see later) if appropriate.
- Grasp the syringe with your dominant hand as if holding a dart and position the needle at a 90-degree angle to the skin. Tell the patient that he or she will feel a "stick" as you insert the needle.
- Insert the needle quickly and firmly into the muscle. Grasp the lower end of the syringe with the nondominant hand while still holding the skin back, to stabilize the syringe. With the dominant hand, pull back on the plunger for 5 to 10 seconds to check for blood return.
- If no blood appears in the syringe, inject the medication slowly, at the rate of 1 mL every 10 seconds. After injecting the drug, wait 10 seconds, and then withdraw the needle smoothly while releasing the skin.
- Apply gentle pressure at the site, and watch for bleeding. Apply a bandage if necessary.
- If blood does appear in the syringe, remove the needle, dispose of the medication and syringe, and prepare a new syringe with the medication.
- Dispose of the syringe and needle in the appropriate container. DO NOT RECAP the needle. Perform hand hygiene after removing gloves.
- Document the medication given on the medication record (see Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.

Z-Track Method



FIGURES 9-49 and 9-50 Z-track method for intramuscular injections.

- The Z-track method is used for injections of irritating substances such as iron dextran and hydroxyzine. The technique reduces pain, irritation, and staining at the injection site. Some facilities recommend this method for *all* intramuscular injections (Figures 9-49 and 9-50).
- After choosing and preparing the site for injection, use your nondominant hand to pull the skin laterally and hold it in this position while giving the injection. Insert the needle at a 90-degree angle, aspirate for 5 to 10 seconds to check for blood return, and then inject the medication slowly. After injecting the medication, wait 10 seconds before withdrawing the needle. Withdraw the needle slowly and smoothly, and maintain the 90-degree angle.
- Release the skin immediately after withdrawing the needle to seal off the injection site. This technique forms a Z-shaped track in the tissue that prevents the medication from leaking through the more sensitive subcutaneous tissue from the muscle site of injection. Apply gentle pressure to the site with a dry gauze pad.

Ventrogluteal Site

- The ventrogluteal site is the *preferred* site for adults and children. It is considered the safest of all sites because the muscle is deep and away from major blood vessels and nerves (Figure 9-51).
- Position the patient on his or her side, with knees bent and upper leg slightly ahead of the bottom leg. If necessary, the patient may remain in a supine position.
- Palpate the greater trochanter at the head of the femur and the anterosuperior iliac spine. As illustrated in Figure 9-52, use the left hand to find landmarks when injecting into the patient's right ventrogluteal site, and use the right hand to find landmarks when injecting into the patient's left ventrogluteal site. Place the palm of your hand over the greater trochanter and your index finger on the anterosuperior iliac spine. Point your thumb toward the patient's groin and fingers toward the patient's head. Spread the middle finger back along the iliac crest, toward the buttocks, as much as possible.
- The injection site is the center of the triangle formed by your middle and index fingers (see arrow in Figure 9-52).
- Before giving the injection, you may need to switch hands so that you can use your dominant hand to give the injection (Figure 9-53).
- Follow the general instructions for giving an intramuscular injection.

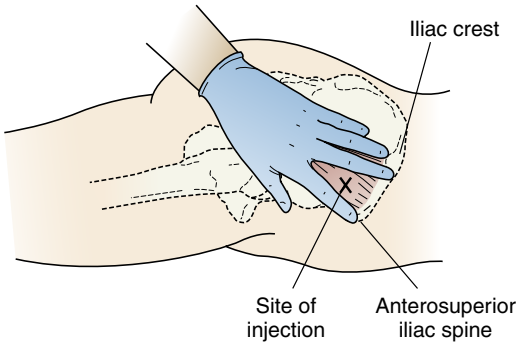


FIGURE 9-51 Finding landmarks for a ventrogluteal injection.

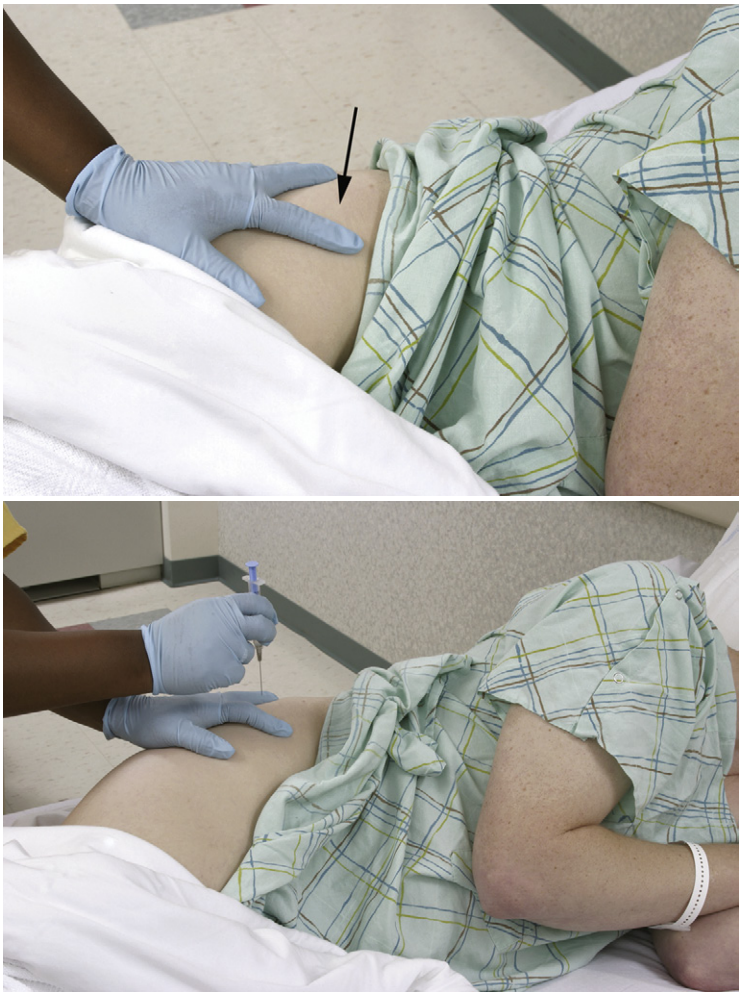
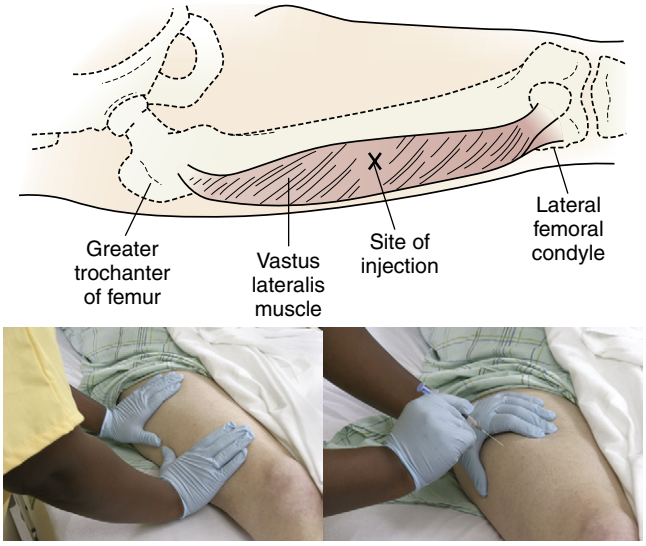


FIGURES 9-52 and 9-53 Ventrogluteal intramuscular injection.

Vastus Lateralis Site

FIGURE 9-54 Vastus lateralis intramuscular injection in a small child. The nurse stabilizes the leg before giving the injection.



FIGURES 9-55, 9-56, and 9-57 Vastus lateralis intramuscular injection.

- Generally the vastus lateralis muscle is well developed and not located near major nerves or blood vessels. It is the preferred site of injection of drugs such as immunizations for infants (Figure 9-54). For specific information about giving injections to children, see Box 9-2.
- The patient may be sitting or lying supine; if supine, have the patient bend the knee of the leg in which the injection will be given.
- To find the correct site of injection, place one hand above the knee and one hand below the greater trochanter of the femur. Locate the midline of the anterior thigh and the midline of the lateral side of the thigh. The injection site is located within the rectangular area (Figures 9-55, 9-56, and 9-57).

BOX 9-2 PEDIATRIC INJECTIONS

Site selection is crucial for pediatric injections. Factors to consider are the age of the child, the size of the muscle at the injection site, the type of injection, the thickness of the solution, and the ease with which the child can be positioned properly. There is no universal agreement in the literature on the "best" intramuscular injection site for children. For infants, the preferred site is the vastus lateralis muscle. The ventrogluteal site may also be used in children of all ages. For immunizations in toddlers and older children, the deltoid muscle may be used *if* the muscle mass is well developed. Intramuscular injections for older infants and small children should not exceed 1 mL in a single injection. Refer to facility policy.

Children are often extremely fearful of needles and injections. Even a child who appears calm may become upset and lose control during an injection procedure. For safety reasons, it is important to have another person available for positioning and holding the child.

Distraction techniques are helpful. Say to the child, "If you feel this you can ask me to take it out, please." Be quick and efficient when giving the injection.

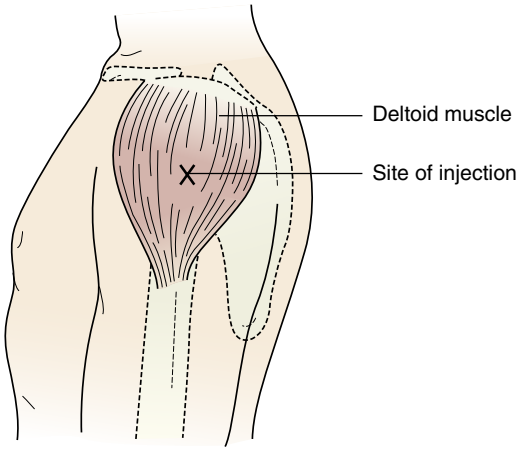
Have a small, colorful bandage on hand to apply after the injection. If the child is old enough, have the child hold the bandage and apply it after the injection. If possible, offer a reward sticker after the injection.

After the injection, allow the child to express his or her feelings. For young children, encourage parents to offer comfort with holding and cuddling. Older children respond better if they receive praise.

EMLA (lidocaine/prilocaine) cream or a vapocoolant spray, if available, may be used before the injection to reduce the pain from the needle insertion. However, because these agents do not absorb down into the muscle, the child may still experience pain when the medication enters the muscle. Apply EMLA cream to the site at least 1 hour and up to 3 hours before the injection. Vapocoolant spray is applied to the site immediately before the injection. Another option is to apply a wrapped ice cube to the injection site for a minute before the injection.

From Hockenberry MJ, Wilson D: *Wong's nursing care of infants and children,* ed 9, St Louis, 2011, Mosby.

Deltoid Site



FIGURES 9-58, 9-59, and 9-60 Deltoid intramuscular injection. The deltoid site is not considered a primary site for intramuscular injections but is used for immunizations for toddlers, older children, and adults. This site is not used for infants.

- Even though the deltoid site (Figure 9-58) is easily accessible, it is *not* the first choice for intramuscular injections because the muscle may not be well developed in some adults, and the site carries a risk for injury because the axillary nerve lies beneath the deltoid muscle. In addition, the brachial artery and radial, brachial, and ulnar nerves are also located in the upper arm. Always check medication administration policies, because some facilities do not permit the use of the deltoid site for intramuscular injections. The deltoid site must only be used for administration of immunizations to toddlers, older children, and adults (not infants) and only for small volumes of medication (0.5 to 1 mL).
- The patient may be sitting or lying down. Remove clothing to expose the upper arm and shoulder; do not roll up tight-fitting sleeves. Have the patient relax his or her arm and slightly bend the elbow.
- Palpate the lower edge of the acromion process. This edge becomes the base of an imaginary triangle (Figure 9-59).
- Place three fingers below this edge of the acromion process. Find the point on the lateral arm in line with the axilla. The injection site will be in the center of this triangle, three finger widths (1 to 2 inches) below the acromion process.
- *Age-related considerations:* In children and smaller adults, it may be necessary to bunch the underlying tissue together before giving the injection and/or use a shorter (⅝-inch) needle (Figure 9-60).
- To reduce patient anxiety, have the patient look away before giving the injection.

Preparing Intravenous Medications

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Gloves must be worn for most of these procedures. When administering intravenous (IV) drugs, keep in mind the following points:

- The intravenous route for medication administration provides for rapid onset and faster therapeutic drug levels in the blood than other routes. However, the intravenous route is also potentially more dangerous. Once an intravenous drug is given, it begins to act immediately and cannot be removed. The nurse must be aware of the drug's intended effects and possible adverse effects. In addition, hypersensitivity (allergic) reactions may occur quickly.
- Since the passage of the Needle Safety and Prevention Act of 2001, many institutions now use a needleless system for all infusion lines.
- Before giving an intravenous medication, assess the patient's drug allergies, assess the intravenous line for patency, and assess the site for signs of phlebitis or infiltration.
- When more than one intravenous medication is to be given, check with the pharmacy for compatibility if the medications are to be infused at the same time.
- Check the expiration date of both the medication and infusion bags.
- *Age-related considerations:* For children, infusion pumps *must* be used to prevent the risk of infusing the fluid and medication too fast.
- The Joint Commission requires that the pharmacy prepare intravenous solutions and intravenous piggyback (IVPB) admixtures under a special laminar airflow hood. Most IVPB medications come in vials that are added to the intravenous bag just before administration. On the rare occasion when you must dilute a drug for intravenous use, contact the pharmacist for instructions. Be sure to verify which type of fluid to use and the correct amount of solution for the dosage.
- It is important to choose the correct solution for diluting intravenous medications. For example, phenytoin must be infused with normal saline, not dextrose solutions (see Chapter 14). Check with the pharmacist if necessary.
- Most IVPB medications are provided as part of an "add-a-vial" system that allows the intravenous medication vial to be attached to a small-volume minibag for administration. Figure 9-61 shows two examples of IVPB medications attached to small-volume infusion bags.

FIGURE 9-61 Two types of intravenous piggyback medication delivery systems. These intravenous systems must be activated before the drug is administered to the patient.

- These IVPB medication setups allow for mixing of the drug and diluent immediately before the medication is given. Remember that if the seals are not broken and the medication is not mixed with the fluid in the infusion bag, then the medication stays in the vial! As a result, the patient does not receive the ordered drug dose; instead, the patient receives a small amount of plain intravenous fluid.
- One type of IVPB system that needs to be activated before administration is illustrated in Figure 9-62. To activate this type of IVPB system, snap the connection area between the intravenous infusion bag and the vial (Figure 9-63). Gently squeeze the fluid from the infusion bag into the vial and allow the medication to dissolve (Figure 9-64). After a few minutes, rotate the vial gently to ensure that all of the powder is dissolved. When the drug is fully dissolved, hold the IVPB apparatus by the vial and squeeze the bag; fluid will enter the bag from the vial. Make sure that all of the medication is returned to the IVPB bag.
- When hanging these IVPB medications, take care NOT to squeeze the bag. This may cause some of the fluid to leak back into the vial and alter the dose given.
- Always label the IVPB bag with the patient's name and room number, the name of the medication, the dose, the date and time mixed, your initials, and the date and time the medication was given.
- Some intravenous medications must be mixed using a needle and syringe. Again, in many facilities, this procedure will be performed in the pharmacy. Follow the facility policy. After checking the order and the compatibility of the drug and the intravenous fluid, wipe the port of the intravenous bag with an alcohol swab (Figure 9-65).
- Carefully insert the needle into the center of the port and inject the medication (Figures 9-66 and 9-67). Note how the medication remains in the lower part of the intravenous infusion bag. Turn the bag gently, end to end, to mix the fluid and added medication (Figure 9-68).
- Always add medication to a *new* bag of intravenous fluid, not to a bag that has partially infused. The concentration of the medication may be too strong if it is added to a partially full bag.
- Always label the intravenous infusion bag when a drug has been added (Figure 9-69). Label as per institution policy and include the patient's name and room number, the name of the medication, the date and time mixed, your initials, and the date and time the infusion was started. In addition, label all intravenous infusion tubing per institution policy.

FIGURE 9-68 Mix the medication thoroughly before infusing by gently turning end to end. Do not shake the bag.

FIGURE 9-69 Label the intravenous infusion bag when medication has been added.

Infusions of Intravenous Piggyback Medications

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Gloves must be worn.

- Refrigerated medications may need to be left on the counter to warm to room temperature before administering. If you are infusing the IVPB medication for the first time, you will need to attach the medication bag to the appropriate tubing and "prime" the tubing by allowing just enough fluid through the tubing to flush out the air. Take care not to waste too much of the medication when flushing the tubing.
- If you are adding IVPB medication to an infusion that already has tubing, then use the technique of "backpriming" to flush the tubing (Figure 9-70). Backpriming allows for the administration of multiple intravenous medications without multiple disconnections, and thus reduces the risk of contamination of the intravenous tubing system.
- Backpriming allows the removal of the old medication fluid that has remained in the IVPB tubing from the previous dose of intravenous medication. After ensuring that the medication in the primary infusion (if any) is compatible with the medication in the IVPB bag, close the roller clamp on the primary infusion if the intravenous fluid is infusing by gravity flow (not necessary if an infusion pump is used). Remove the empty IVPB container from the intravenous pole, lower it to below the level of the primary infusion bag, and open the clamp on the IVPB tubing. This will allow fluid to flow from the primary intravenous bag into the empty IVPB bag. Then, close the clamp on the IVPB tubing and squeeze the fluid that is in the drip chamber into the old IVPB bag to remove the old medication fluid. At this point you may add the new dose of intravenous medication to the IVPB tubing.
- Backpriming will not be possible if the primary intravenous infusion contains heparin, aminophylline, a vasopressor, or multivitamins. Check with a pharmacist if unsure about compatibility.
- Stopping intravenous infusions of medications such as vasopressors for an IVPB medication may affect a patient's blood pressure; stopping intravenous heparin may affect the patient's coagulation levels. Be sure to assess carefully before adding an IVPB medication to an existing infusion. A separate intravenous line may be necessary.
- Figure 9-71 shows an IVPB medication infusion (also known as the *secondary infusion*) with a primary gravity infusion. When the IVPB bag is hung higher than the primary intravenous infusion bag, the IVPB medication will infuse until empty, then the primary infusion will take over again.
- When beginning the infusion, attach the IVPB tubing to the upper port on the primary intravenous tubing. A back-check valve above this port prevents the medication from infusing up into the primary intravenous infusion bag.
- Fully open the clamp of the IVPB tubing and regulate the infusion rate with the roller clamp of the primary infusion tubing. Be sure to note the drip factor of the tubing, and calculate the drops per minute to set the correct infusion rate for the IVPB medication.
- Monitor the patient during the infusion. Observe for hypersensitivity and for adverse reactions. In addition, observe the intravenous infusion site for infiltration. Have the patient report if pain or burning occurs.
- Monitor the rate of infusion during the IVPB medication administration. Changes in arm position may alter the infusion rate.
- When the infusion is complete, clamp the IVPB tubing and check the primary intravenous infusion rate. If necessary, adjust the clamp to the correct infusion rate.
- Figure 9-72 shows an IVPB medication infusion with a primary infusion that is going through an electronic infusion pump.
- When giving IVPB drugs through an intravenous infusion controlled by a pump, attach the IVPB tubing to the port on the primary intravenous tubing above the pump. Open the roller clamp of the IVPB medication tubing. Make sure that the IVPB bag is higher than the primary intravenous infusion bag.
- Following the manufacturer's instructions, set the infusion pump to deliver the IVPB medication. Entering the volume of the IVPB bag and the desired time frame of the infusion (e.g., over a 60-minute period) will cause the pump to automatically calculate the flow rate for the IVPB medication. Start the IVPB infusion as instructed by the pump.
- Monitor the patient during the infusion, as described earlier.
- When the infusion is complete, the primary intravenous infusion will automatically resume.
- Document the medication given on the medication record (see Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.
- When giving intravenous medications through a saline (heparin) lock, follow the facility's guidelines for the flushing protocol before and after the medication is administered.
- Figure 9-73 illustrates a volume-controlled administration set that can be used to administer intravenous medications. The chamber is attached to the infusion between the intravenous infusion bag and the intravenous tubing. Fill the chamber with the desired amount of fluid, and then add the medication via the port above the chamber, as shown in the photo. Be sure to cleanse the port with an alcohol swab before inserting the needle in the port. Label the chamber with the medication's name, dose, and time added and your initials. Infuse the drug at the prescribed rate.
- In patient-controlled analgesia (PCA), a specialized pump is used to allow patients to self-administer pain medications, usually opiates (Figure 9-74). These pumps allow the patient to self-administer only as much medication as needed to control the pain by pushing a button for intravenous bolus doses. Safety features of the pump prevent accidental overdoses. A patient receiving PCA pump infusions must be monitored closely for his or her response to the drug, excessive sedation, hypotension, and changes in mental and respiratory status. Follow the facility's guidelines for setup and use.

FIGURE 9-70 Flush the intravenous piggyback (secondary) tubing by using the backpriming method. Fluid is drained through the tubing into the old intravenous piggyback bag, which is then discarded. The new dose of medication is then attached to the primed secondary tubing.

FIGURE 9-71 Infusing an intravenous piggyback medication with a primary gravity infusion. Note how the primary bag is lower than the IVPB.

FIGURE 9-72 Infusing an intravenous piggyback medication with the primary infusion on an electronic infusion pump.

FIGURE 9-73 Adding a medication to a volume-controlled administration set.

FIGURE 9-74 Instructing the patient on the use of a patient-controlled analgesia pump.

- Figure 9-75 displays a smart pump, a new type of IV infusion safety system that has been designed to reduce IV medication errors. A smart pump contains built-in software that is programmed with facility-specific dosing profiles. The pump is able to "check" the dose-limits and other clinical guidelines, and when the pump is set up for patient use, it can warn the nurse if a potentially unsafe drug dose or therapy is entered.

Intravenous Push Medications

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1).

When administering intravenous push (or bolus) medications, keep in mind the following points:

- Registered nurses are usually the only nursing staff members, besides a nurse anesthetist, allowed to give intravenous push medications. This may vary at different facilities.
- Intravenous push injections allow for rapid intravenous administration of a drug. The term *bolus* refers to a dose given all at once. Intravenous push injections may be given through an existing intravenous line, through an intravenous (saline or heparin) lock, or directly into a vein.
- Because the medication may have an immediate effect, monitor the patient closely for adverse reactions as well as for therapeutic effects.
- Follow the manufacturer's instructions carefully when preparing an intravenous push medication. Some drugs require careful dilution. Consult a pharmacist if you are unsure about the dilution procedure. Improper dilution may increase the risk of phlebitis and other complications.
- Some drugs are *never* given by intravenous push. Examples include dopamine, potassium chloride, and antibiotics such as vancomycin.
- Small amounts of medication, less than 1 mL, need to be diluted in 5 to 10 mL of normal saline or another compatible fluid to ensure that the medication does not collect in a "dead space" of the tubing (such as the Y-site port). Check the facility's policy.
- Most drugs given by intravenous push injection are to be given over a period of 1 to 5 minutes to reduce local or systemic adverse effects. Always time the administration with your watch, because it is difficult to estimate the time accurately. Adenosine, however, must be given very rapidly, within 2 to 3 seconds, for optimal action. ALWAYS check packaging information for guidelines, because many errors and adverse effects have been associated with too-rapid intravenous drug administration.

Intravenous Push Medications through an Intravenous Lock

- Obtain two syringes of 0.9% normal saline (NS). Most facilities provide prefilled 10-mL syringes. Prepare medication for injection. (Facilities may differ in the protocol for intravenous lock flushes—follow institutional policies.) If ordered, prepare a syringe with heparin flush solution.
- Follow the guidelines for a needleless system, if used.
- Cleanse the injection port of the intravenous lock vigorously with an antiseptic swab for 15 seconds (Figure 9-76).
- Insert the syringe of NS into the injection port (Figure 9-77; a needleless system is shown). Open the clamp of the intravenous lock tubing, if present.
- Gently aspirate and observe for blood return. Absence of blood return does not mean that the intravenous line is occluded; further assessment may be required.
- Flush gently with saline while assessing for resistance. If resistance is felt, do not apply force. Stop and reassess the intravenous lock.
- Observe for signs of infiltration while injecting NS.
- Reclamp the tubing (if a clamp is present) and remove the NS syringe. Repeat cleansing of the port, and attach the medication syringe. Open the clamp again.
- Inject the medication over the prescribed length of time. Measure time with a watch or clock (Figure 9-78).
- When the medication is infused, clamp the intravenous lock tubing (if a clamp is present) and remove the syringe.
- Repeat cleansing of the port; attach an NS syringe and inject the contents into the intravenous lock slowly. If a heparin flush is ordered, attach the syringe containing heparin flush solution and inject slowly (per the institution's protocol).

Intravenous Push Medications through an Existing Infusion

- Prepare the medication for injection. Follow the guidelines for a needleless system, if used.
- Check compatibility of the intravenous medication with the existing intravenous solution.
- Choose the injection port that is closest to the patient.
- Remove the cap, if present, and cleanse the injection port with an antiseptic swab.
- Occlude the intravenous line by pinching the tubing just above the injection port (Figure 9-79). Attach the syringe to the injection port.
- Gently aspirate for blood return.
- While keeping the intravenous tubing clamped, slowly inject the medication according to administration guidelines. Be sure to time the injection with a watch or clock.
- After the injection, release the intravenous tubing, remove the syringe, and check the infusion rate of the intravenous fluid.

After Injection of Intravenous Push Medications

- Monitor the patient closely for adverse effects. Monitor the intravenous infusion site for signs of phlebitis and infiltration.
- Document medication given on the medication record (see Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.

FIGURE 9-75 A smart pump.

FIGURE 9-76 Cleanse the port vigorously for 15 seconds before attaching the syringe.

FIGURE 9-77 Attaching the syringe to the intravenous lock, using a needleless system.

FIGURE 9-78 Slowly inject the intravenous push medication through the intravenous lock; use a watch to time the injection.

FIGURE 9-79 When giving an intravenous push medication through an intravenous line, pinch the tubing just above the injection port.

TOPICAL DRUGS

Administering Eye Medications

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Gloves must be worn. When administering eye preparations, keep in mind the following points:

- Assist the patient to a supine or sitting position. Tilt the patient's head back slightly. Make sure the patient is not wearing contact lenses.
- Remove any secretions with a sterile gauze pad; be sure to wipe from the inner to outer canthus (Figure 9-80).
- Have the patient tilt his or her head slightly back and look up. With your nondominant hand, gently pull the lower lid open to expose the conjunctival sac.

Eyedrops

- With your dominant hand resting on the patient's forehead, hold the eye medication dropper 1 to 2 cm above the conjunctival sac. Do not touch the tip of the dropper to the eye or with your fingers (Figure 9-81).
- Drop the prescribed number of drops into the conjunctival sac. Never apply eyedrops to the cornea.
- If the drops land on the outer lid margins (if the patient moved or blinked), repeat the procedure.
- *Age-related considerations:* Infants often squeeze the eyes tightly shut to avoid eyedrops. To give drops to an uncooperative infant, restrain the head gently and place the drops at the corner near the nose where the eyelids meet. When the eye opens, the medication will flow into the eye.

Eye Ointment

- Gently squeeze the tube of medication to apply an even strip of medication (about 1 to 2 cm) along the border of the conjunctival sac. Start at the inner canthus and move toward the outer canthus (Figure 9-82).

After Instillation of Eye Medications

- Ask the patient to close the eye gently. Squeezing the eye shut may force the medication out of the conjunctival sac. A tissue may be used to blot liquid that runs out of the eye, but instruct the patient not to wipe the eye.
- You may apply gentle pressure to the patient's nasolacrimal duct for 30 to 60 seconds with a gloved finger wrapped in a tissue. This will help to reduce systemic absorption of the drug through the nasolacrimal duct and may also help to reduce the taste of the medication in the nasopharynx (Figure 9-83).
- If multiple eyedrops are due at the same time, then wait several minutes before administering the second medication. Check the instructions for the specific drug.
- Assist the patient to a comfortable position. Warn the patient that vision may be blurry for a few minutes.
- Document the medication given on the medication record (see Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.

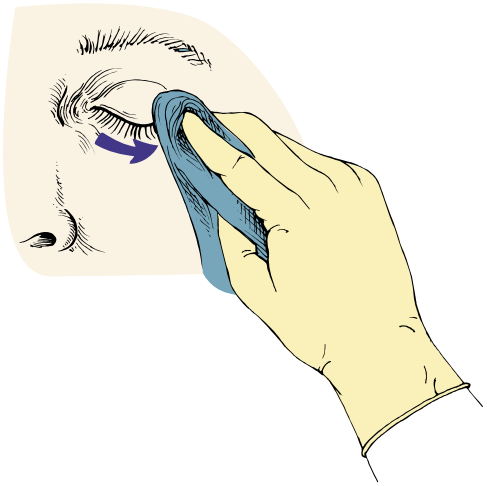

FIGURE 9-80 Cleanse the eye, washing from the inner to outer canthus, before giving eye medications.

FIGURE 9-81 Insert the eyedrop into the lower conjunctival sac.

FIGURE 9-82 Applying eye ointment. Move from the inner to outer canthus, along the border of the conjunctival sac.

FIGURE 9-83 Applying gentle pressure against the nasolacrimal duct after giving eye medication.

Administering Eardrops

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Gloves may be worn. When administering ear preparations, keep in mind the following points:

- After explaining the procedure to the patient, assist the patient to a side-lying position with the affected ear facing up. If cerumen or drainage is noted in the outer ear canal, remove it carefully without pushing it back into the ear canal.
- Remove excessive amounts of cerumen before instillation of medication.
- If refrigerated, warm the ear medication by taking it out of refrigeration for at least 30 minutes before administration. Instillation of cold eardrops can cause nausea, dizziness, and pain.
- *Age-related considerations:* For an adult or a child older than 3 years of age, pull the pinna up and back (Figure 9-84). For an infant or a child younger than 3 years of age, pull the pinna down and back (Figure 9-85).
- Administer the prescribed number of drops. Direct the drops along the sides of the ear canal rather than directly onto the eardrum.
- Instruct the patient to lie on his or her side for 5 to 10 minutes. Gently massaging the tragus of the ear with a finger will help to distribute the medication down the ear canal.
- If ordered, a loose cotton pledget can be gently inserted into the ear canal to prevent the medication from flowing out. The cotton must remain somewhat loose to allow any discharge to drain out of the ear canal. To prevent the dry cotton from absorbing the eardrops that were instilled, moisten the cotton with a small amount of medication before inserting the pledget. Insertion of cotton too deeply may result in increased pressure within the ear canal and on the eardrum. Remove the cotton after about 15 minutes.
- If medication is needed in the other ear, wait 5 to 10 minutes after instillation of the first eardrops before administering.
- Document the medication given on the medication record (see Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.

FIGURE 9-84 For adults, pull the pinna up and back.

FIGURE 9-85 For infants and children younger than 3 years of age, pull the pinna down and back.

Administering Inhaled Drugs

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Gloves may be worn. Patients with asthma need to monitor their peak expiratory flow rates by using a peak flowmeter. A variety of inhalers are available (Figure 9-86). Be sure to check for specific instructions from the manufacturer as needed. Improper use will result in inadequate dosing. When administering inhaled preparations, keep in mind the following points.

Metered-Dose Inhalers

- Shake the metered-dose inhaler (MDI) gently before using.
- Remove the cap; hold the inhaler upright and grasp with the thumb and first two fingers.
- Tilt the patient's head back slightly.
- If the inhaler is used without a spacer, do the following:
  1. Have the patient open his or her mouth; position the inhaler 1 to 2 inches away from the patient's mouth (Figure 9-87). For self-administration, some patients may measure this distance as 1 to 2 finger widths.
  2. Have the patient exhale, then press down once on the inhaler to release the medication; have the patient breathe in slowly and deeply for 5 seconds.
  3. Have the patient hold his or her breath for approximately 10 seconds, then exhale slowly through pursed lips.
- *Age-related considerations:* Spacers can be used with children and adults who have difficulty coordinating inhalations with activation of metered-dose inhalers (see Chapter 37). If the inhaler is used with a spacer, do the following:
  1. Attach the spacer to the mouthpiece of the inhaler after removing the inhaler cap.
  2. Place the mouthpiece of the spacer in the patient's mouth.
  3. Have the patient exhale.
  4. Press down on the inhaler to release the medication, and have the patient inhale deeply and slowly through the spacer. The patient then needs to breathe in and out slowly for 2 to 3 seconds, and then hold his or her breath for 10 seconds (Figure 9-88).
- If a second puff of the same medication is ordered, wait 1 to 2 minutes between puffs.
- If a second type of inhaled medication is ordered, wait 2 to 5 minutes between medication inhalations or as prescribed.
- If both a bronchodilator and a corticosteroid inhaled medication are ordered, the bronchodilator needs to be administered first so that the passages will be more open for the second medication.
- Instruct the patient to rinse his or her mouth after inhaling a corticosteroid medication to prevent the development of an oral fungal infection.
- Document the medication given on the medication record (see Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.
- It is important to teach the patient how to calculate the number of doses in the inhaler and to keep track of uses. Simply shaking the inhaler to "estimate" whether it is empty is not accurate and may result in its being used when it is empty. Many MDIs now come with devices that help to count the remaining doses. If the inhaler does not have a dose-counting device, then the patient needs to be taught to count the number of puffs needed per day (doses) and divide this amount into the actual number of actuations (puffs) in the inhaler to estimate the number of days the inhaler will last. Then, a calendar can be marked a few days before this date with a note that it is time to obtain a refill. In addition, the date can be marked on the inhaler with a permanent marker. For example, an inhaler with 200 puffs, ordered to be used 4 times a day (2 puffs per dose, 8 puffs per day), would last for 25 days (200 divided by 8).
- Dry powder inhalers have varied instructions, so follow the manufacturer's instructions closely. Instruct patients to cover the mouthpiece completely with their mouths. Capsules that are intended for use with these inhalers must NEVER be taken orally. Some dry powder inhalers also have convenient built-in dose counters.

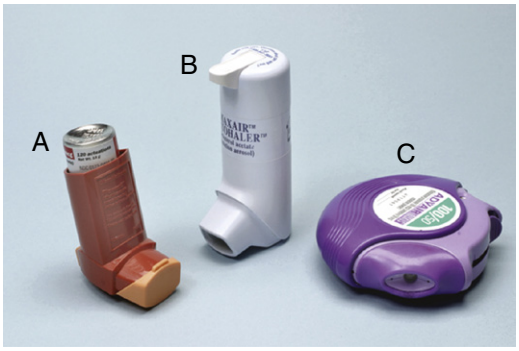

FIGURE 9-86 **A,** Metered-dose inhaler (MDI). **B,** Automated, or breath-activated, MDI. **C,** Dry powder inhaler that delivers powdered medication.

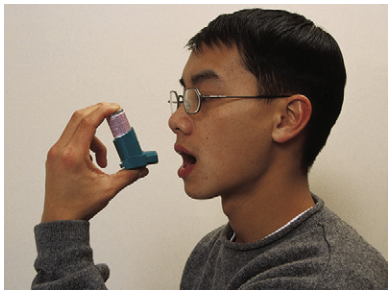

FIGURE 9-87 Using a metered-dose inhaler without a spacer.

FIGURE 9-88 Using a spacer device with a metered-dose inhaler.

Small-Volume Nebulizers

- In some facilities, the air compressor is located in the wall unit of the room. In other facilities and at home, a small portable air compressor is used. Be sure to follow the manufacturer's instructions for use.
- In some facilities, nebulizer treatments may be performed by a respiratory therapist. However, closely monitor the patient before, during, and after the drug administration.
- Be sure to take the patient's baseline heart rate, especially if a beta-adrenergic drug is used. Some drugs may increase the heart rate.
- After gathering the equipment, add the prescribed medication to the nebulizer cup (Figure 9-89). Some medications will require a diluent; others are premixed with a diluent. Be sure to verify before adding a diluent.
- Have the patient hold the mouthpiece between his or her lips (Figure 9-90).
- *Age-related considerations:* Use a face mask for a child or an adult who is too fatigued to hold the mouthpiece. Special adaptors are available if the patient has a tracheostomy.
- Before starting the nebulizer treatment, have the patient take a slow, deep breath, hold it briefly, then exhale slowly. Patients who are short of breath should be instructed to hold their breath every fourth or fifth breath.
- Turn on the small-volume nebulizer machine (or turn on the wall unit) and make sure that a sufficient mist is forming.
- Instruct the patient to repeat the breathing pattern mentioned previously during the treatment.
- Occasionally tap the nebulizer cup during the treatment and toward the end to move the fluid droplets back to the bottom of the cup.
- Monitor the patient throughout treatment to ensure that the nebulizer medication is properly administered.
- Monitor the patient's heart rate during and after the treatment.
- If inhaled steroids are given, instruct the patient to rinse his or her mouth afterward.
- After the procedure, clean and store the tubing per institutional policy.
- Document the medication given on the medication record (see Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.
- If the patient will be using a nebulizer at home, instruct the patient to rinse the nebulizer parts after each use with warm, clear water and to air-dry. Wash the parts daily with warm, soapy water and allowed to air-dry. Once a week, soak the nebulizer parts in a solution of vinegar and water (four parts water and one part white vinegar) for 30 minutes; rinse thoroughly with clear, warm water; and air-dry. Storing nebulizer parts that are still wet will encourage bacterial and mold growth.

FIGURE 9-89 Adding medication to the nebulizer cup.

FIGURE 9-90 Administering a small-volume nebulizer treatment.

Administering Medications to the Skin

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Gloves must be worn. Avoid touching the preparations to your own skin. When administering skin preparations, keep in mind the following points.

Lotions, Creams, Ointments, and Powders

- Apply powder to clean, dry skin. Have the patient turn his or her head to the other side during application to avoid inhalation of powder particles.
- Apply lotion to clean, dry skin. Remove residual from previous applications with soap and water.
- Before administering any dose of a topical skin medication, ensure that the site is dry and free of irritation. Thoroughly remove previous applications using soap and water, if appropriate for the patient's condition, and dry the area thoroughly. Be sure to remove any debris, drainage, or pus if present.
- *Age-related considerations:* The skin of an older patient may be more fragile and easily bruised. Be sure to handle the skin gently when cleansing to prepare the site for medication and when applying medications.
- With lotion, cream, or gel, obtain the correct amount with your gloved hand (Figure 9-91). If the medication is in a jar, remove the dose with a sterile tongue depressor and apply to your gloved hand. Do not contaminate the medication in the jar.
- Apply the preparation with long, smooth, gentle strokes that follow the direction of hair growth (Figure 9-92). Avoid excessive pressure. Be especially careful with the skin of elderly persons, because age-related changes may result in increased capillary fragility and tendency to bruise.
- Some ointments and creams may soil the patient's clothes and linens. If ordered, cover the affected area with gauze or a transparent dressing.
- Nitroglycerin ointment in a tube is measured carefully on clean ruled application paper before it is applied to the skin (Figure 9-93). Unit-dose packages are not to be measured. Do not massage nitroglycerin ointment into the skin. Apply the measured amount onto a clean, dry site, and then secure the application paper with a transparent dressing or a strip of tape. Always remove the old medication before applying a new dose. Rotate application sites.

Transdermal Patches

- Be sure that the old patch is removed as ordered. Some patches may be removed before the next patch is due—check the order. Clear patches may be difficult to find, and patches may be overlooked in obese patients with skinfolds. Cleanse the site of the old patch thoroughly. Observe for signs of skin irritation at the old patch site. Rotate sites of application with each dose.
- Transdermal patches need to be applied at the same time each day if ordered daily.
- The old patch can be pressed together and then wrapped in a glove as you remove the glove from your hand. Dispose in the proper container according to the facility's policy.
- Select a new site for application and ensure that it is clean and without powder or lotion. For best absorption and fewest adverse effects, the site needs to be hairless and free from scratches or irritation. If it is necessary to remove hair, clip the hair instead of shaving to reduce irritation to the skin. Application sites may vary. Follow the drug manufacturer's specific instructions as to where to apply the patch.
- Remove the backing from the new patch (Figure 9-94). Take care not to touch the medication side of the patch with your fingers.
- Place the patch on the skin site and press firmly (Figure 9-95). Press around the edges of the patch with one or two fingers to ensure that the patch is adequately secured to the skin. If an overlay is provided by the drug manufacturer, apply it over the patch.
- Instruct the patient not to cut transdermal patches. Cutting transdermal patches releases all of the medication at once and may result in a dangerous overdose.

After Administration of Topical Skin Preparations

- Document the medication given on the medication record (see Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.
- Provide instruction on administration to the patient and/or caregiver.

FIGURE 9-91 Use gloves to apply topical skin preparations.

FIGURE 9-92 Spread the lotion on the skin with long, smooth, gentle strokes.

FIGURE 9-93 Measure nitroglycerin ointment carefully before application.

FIGURE 9-94 Opening a transdermal patch medication.

FIGURE 9-95 Ensure that the edges of the transdermal patch are secure after applying.

Administering Nasal Medications

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Patients may self-administer some of these drugs after proper instruction. Gloves must be worn. When administering nasal medications, keep in mind the following points:

- Before giving nasal medications, explain the procedure to the patient and tell him or her that temporary burning or stinging may occur. Instruct the patient that it is important to clear the nasal passages by blowing his or her nose, unless contraindicated (e.g., with increased intracranial pressure or nasal surgery), before administering the medication. Assess for deviated septum or a history of nasal fractures, because these may impede the patient's ability to inhale through the affected nostril.
- Figure 9-96 illustrates various delivery forms for nasal medications: sprays, drops, and metered-dose sprays.
- Assist the patient to a supine position. Support the patient's head as needed.
- If specific areas are targeted for the medication, position as follows:
  - For the posterior pharynx, position the head backward.
  - For the ethmoid or sphenoid sinuses, place the head gently over the top edge of the bed or place a pillow under the shoulders and tilt the head back.
  - For the frontal or maxillary sinuses, place the head back and turned toward the side that is to receive the medication.

Nasal Drops

- Hold the nose dropper approximately ½ inch above the nostril. Administer the prescribed number of drops toward the midline of the ethmoid bone (Figure 9-97).
- Repeat the procedure as ordered, instilling the indicated number of drops per nostril.
- Keep the patient in a supine position for 5 minutes.
- *Age-related considerations:* Infants are nose breathers, and the potential congestion caused by nasal medications may make it difficult for them to suck. If nose drops are ordered, administer them 20 to 30 minutes before a feeding.

Nasal Spray

- Have the patient sitting upright, and occlude one nostril by pressing a finger against the outer nare. After gently shaking the nasal spray container, insert the tip into the nostril. Squeeze the spray bottle into the nostril while the patient inhales through the open nostril (Figure 9-98).
- Repeat the procedure as ordered, instilling the indicated number of sprays per nostril.
- Keep the patient in a supine position for 5 minutes.

After Administration of Nasal Medicines

- Offer the patient tissues for blotting any drainage, but instruct the patient to avoid blowing his or her nose for several minutes after instillation of the drops.
- Assist the patient to a comfortable position.
- Document the medication given on the medication record (see Figure 9-9), and document drainage, if any. Monitor the patient for a therapeutic response as well as for adverse reactions.

FIGURE 9-96 Nasal medications may come in various delivery forms.

FIGURE 9-97 Administering nose drops.

FIGURE 9-98 Before self-administering the nasal spray, the patient needs to occlude the other nostril.

Administering Vaginal Medications

Always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Gloves must be worn. When administering vaginal preparations, keep in mind the following points:

- Vaginal suppositories are larger and more oval than rectal suppositories (Figure 9-99).
- Figure 9-100 shows examples of a vaginal suppository in an applicator and vaginal cream in an applicator.
- Before giving these medications, explain the procedure to the patient and have her void the bladder.
- If possible, administer vaginal preparations at bedtime to allow the medications to remain in place as long as possible.
- Some patients may prefer to self-administer vaginal medications. Provide specific instructions if necessary.
- Position the patient in the lithotomy position and elevate the hips with a pillow, if tolerated. Be sure to drape the patient to provide privacy.

Creams, Foams, or Gels Applied with an Applicator

- Fit the applicator to the tube of the medication, and then gently squeeze the tube to fill the applicator with the correct amount of medication.
- Lubricate the tip of the applicator with water-soluble lubricant.
- Use your nondominant hand to spread the labia and expose the vagina. Gently insert the applicator as far as possible into the vagina (Figure 9-101).
- Push the plunger to deposit the medication. Remove the applicator and wrap it in a paper towel for cleaning.

Suppositories or Vaginal Tablets

- For suppositories or vaginal tablets, remove the wrapping and lubricate the suppository with a water-soluble lubricant. Be sure that the suppository is at room temperature.

FIGURE 9-99 Vaginal suppositories *(right)* are larger and more oval than rectal suppositories *(left)*.

FIGURE 9-100 Vaginal cream and suppository, with applicators.

- Using the applicator provided, insert the suppository or tablet into the vagina, and then push the plunger to deposit the suppository. Remove the applicator.
- If no applicator is available, use your dominant index finger to insert the suppository about 2 inches into the vagina (Figure 9-102).
- Have the patient remain in a supine position with hips elevated for 5 to 10 minutes to allow the suppository to melt and the medication to be absorbed.
- If the patient desires, apply a perineal pad.
- If the applicator is to be reused, wash with soap and water and store in a clean container for the next use.
- Document the medication given on the medication record (see Figure 9-9), and monitor the patient for a therapeutic response as well as for adverse reactions.

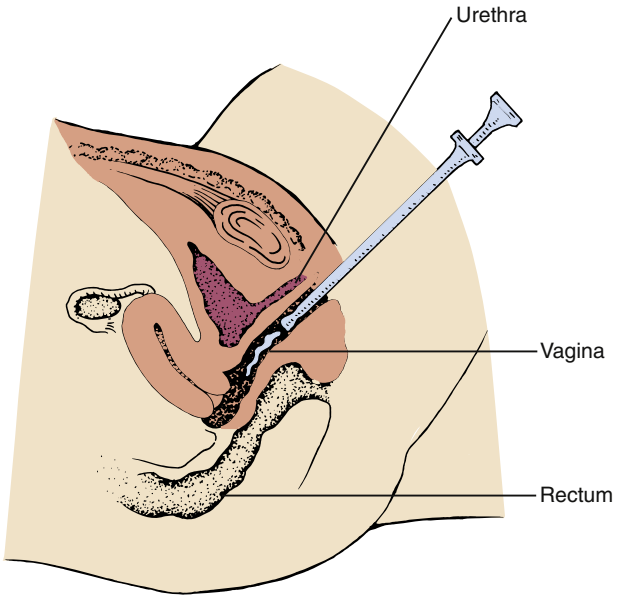

FIGURE 9-101 Administering vaginal cream with an applicator.

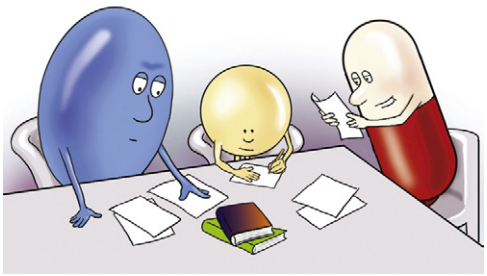
PART 2

Drugs Affecting the Central Nervous System

STUDY SKILLS TIPS

Vocabulary • Text Notation • Language Conventions

VOCABULARY



In any subject matter, mastering the vocabulary is essential to mastering the content. However, in a complex, technical subject such as nursing pharmacology, if the vocabulary is not mastered, understanding the content will be almost impossible. Each chapter in this text contains a list of key terms at the beginning, and as an independent learner, you should spend some time and energy on the vocabulary contained in the key terms. Do not expect to completely understand and master the words from the key terms alone. The terms are further defined and explained in the body of the chapter, and it is when you read the chapter that you should expect to fully master the vocabulary. However, the time you spend working on the key terms will pay off when you read the chapter.

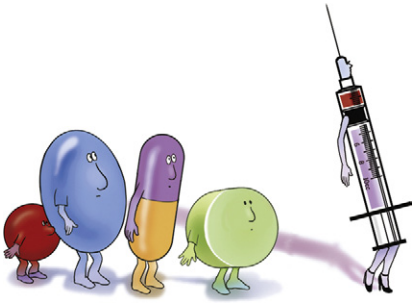
Consider the terms *agonist* and *antagonist* in the Chapter 10 key terms. These terms share a common word part, which means the words are related in meaning. This is an important first step in mastering them. What does *agonist* mean? What is the similarity between *agonist* and *antagonist?* What is the essential difference between the two? Asking these questions as you start to work on Chapter 10 is a valuable technique for beginning to master the content. Do not simply memorize the terms. Learn what they mean and link relationships between words with common elements. As you practice this technique it will become easier to retain the meaning. The Chapter 10 key terms also contain other words that should be viewed as a group that shares an important relationship. The first of these words is *pain.* The definition provided is clear and relatively easy to understand, but your focus should be not just on that single word, because there are 13 other words that relate to pain: *acute, breakthrough, cancer, central, chronic, deep, neuropathic, phantom, referred, somatic, superficial, vascular,* and *visceral.* Each of these words defines and categorizes pain in a very specific way. As you go about setting up vocabulary cards, look at the opening pages in this chapter. You will find considerable discussion of these terms, which is useful in helping you obtain the fullest understanding of these terms. Do not simply focus on a meaning of each term, but also ask what the similarities and/or differences are and how these words relate to one another.

TEXT NOTATION

The Study Skills Tips for Part 1 discussed a method for text underlining. If it is done carefully, this strategy is particularly useful for later review of text material. The object of text underlining is to pick out important

terms, ideas, and key information so you can come back to it later for quick review. The three key elements in successful text notation are as follows:

1. Read the material once before attempting any underlining.
2. Be acutely aware of the author's language.
3. Be selective in underlining. The most common fault in underlining is to mark too much material.



The following are three paragraphs from Chapter 10 that have been underlined. The underlining should be viewed as an example of what can be done. Each reader will mark the text somewhat differently based on his or her background and experience. As you study this example, think not only about what has been underlined but also about why that material was chosen.

Pain *is most commonly defined as an unpleasant sensory and emotional experience associated with either actual or potential tissue damage. It is a very personal and individual experience. Pain can be defined as whatever the patient says it is, and it exists whenever the patient says it does. Although the mechanisms of pain are becoming better understood, a patient's perception of pain is a complex process. Pain involves physical, psychological, and even cultural factors. Because pain intensity cannot be precisely quantified, health care providers must cultivate relationships of mutual trust with their patients to provide optimal care.*

There is no single approach to effective pain management. Instead, pain management is tailored to each patient's needs. The cause of the pain, the existence of concurrent medical conditions; the characteristics of the pain; and the psychological and cultural characteristics of the patient need to be considered. It also requires ongoing reassessment of the pain and the effectiveness of treatment. The patient's emotional response to pain depends on his or her psychological experiences of pain. Pain results from the stimulation of sensory nerve fibers known as **nociceptors.** *These receptors transmit pain signals from various body regions to the spinal cord and brain, which leads to the sensation of pain, or* **nociception.**

The physical impulses that signal pain activate various nerve pathways from the periphery to the spinal cord and to the brain. The level of stimulus needed to produce a painful sensation is referred to as the **pain threshold.** *Because this is a measure of the physiologic response of the nervous system, it is similar for most persons. However, variations in pain sensitivity may result from genetic factors.*

LANGUAGE CONVENTIONS

Certain words and phrases are like signal lights at an intersection. They serve to tell the reader that something special, important, or noteworthy is happening. To the attentive, active reader, these conventions contribute significantly to understanding what the author is trying to convey. Whether you are highlighting, underlining, writing margin notes, or studying the material using the PURR model, it is important that you become sensitive to these conventions.

The text following the topic heading *Anatomy, Physiology, and Pathophysiology Overview* in Chapter 10 contains several examples. The first sentence of the third paragraph contains the phrase *classified as.* Whenever an author says that something is being classified it means that there are at least two (and perhaps several more) elements of the term or idea that are being classified. This means that you should immediately ask a question about the reading, "What is being classified? How many classifications are there for this?" These questions will help you focus on what to learn and keep your attention firmly fixed on the process of learning.

As you read this chapter, or any other chapter, become aware of words and phrases like these that are intended to draw your attention to something the author wanted to emphasize. The more aware of language conventions you become, the easier it will be to become a selective reader. Selective readers do not try to remember everything they read, but they are able to select from the mass of information those concepts and/or terms that the writers tried to stress.

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Define *acute pain* and *chronic pain.*
2 Contrast the signs, symptoms, and management of acute and chronic pain.
3 Discuss the pathophysiology and characteristics associated with cancer pain and other special pain situations.
4 Describe pharmacologic and nonpharmacologic approaches for the management of acute and chronic pain.
5 Discuss the use of nonopioids, nonsteroidal antiinflammatory drugs, opioids (opioid agonists, opioids with mixed actions, opioid agonists-antagonists and antagonists), and miscellaneous drugs in the management of pain, including acute and chronic pain, cancer pain, and special pain situations.
6 Identify examples of drugs classified as nonopioids, nonsteroidal antiinflammatory drugs, opioids (opioid agonists, opioids with mixed actions, opioid agonists-antagonists and antagonists), and miscellaneous drugs.
7 Briefly describe the mechanism of action, indications, dosages, routes of administration, adverse effects, toxicity, cautions, contraindications, and drug interactions of nonopioids, nonsteroidal antiinflammatory drugs (see Chapter 44), opioids (opioid agonists, opioids with mixed actions, opioid agonists-antagonists and antagonists), and miscellaneous drugs.
8 Contrast the pharmacologic and nonpharmacologic management of acute and chronic pain with the management of pain associated with cancer and pain experienced in terminal conditions.
9 Briefly describe the specific standards of pain management as defined by the World Health Organization and The Joint Commission.
10 Develop a nursing care plan based on the nursing process related to the use of nonopioid and opioid drug therapy for patients in pain.
11 Identify various resources, agencies, and professional groups that are involved in establishing standards for the management of all types of pain and for promotion of a holistic approach to the care of patients with acute or chronic pain and those in special pain situations.

DRUG PROFILES

- **acetaminophen, p. 157**
  codeine sulfate, p. 153
  fentanyl, p. 153
  lidocaine, transdermal, p. 157
  meperidine hydrochloride, p. 154
  methadone hydrochloride, p. 154
- **morphine sulfate, p. 151**
- **naloxone hydrochloride, p. 155**
  naltrexone hydrochloride, p. 155
  oxycodone hydrochloride, p. 154
  tramadol hydrochloride, p. 157

♦ *Key drug*

KEY TERMS

Acute pain Pain that is sudden in onset, usually subsides when treated, and typically occurs over less than a 6-week period. (p. 142)

Addiction A chronic, neurobiologic disease whose development is influenced by genetic, psychosocial, and environmental factors (same as *psychological dependence*). (p. 144)

Adjuvant analgesic drugs Drugs that are added for combined therapy with a primary drug and may have additive or independent analgesic properties, or both. (p. 141)

Agonist A substance that binds to a receptor and causes a response. (p. 147)

Agonists-antagonists Substances that bind to a receptor and cause a partial response that is not as strong as that caused by an agonist (also known as a *partial agonist*). (p. 147)

Analgesic ceiling effect What occurs when a given pain drug no longer effectively controls a patient's pain despite the administration of the highest safe dosages. (p. 147)

Analgesics Medications that relieve pain without causing loss of consciousness (sometimes referred to as *painkillers*). (p. 141)

Antagonist A drug that binds to a receptor and prevents (blocks) a response. (p. 147)

Breakthrough pain Pain that occurs between doses of pain medication. (p. 146)

Cancer pain Pain resulting from any of a variety of causes related to cancer and/or the metastasis of cancer. (p. 143)

Central pain Pain resulting from any disorder that causes central nervous system damage. (p. 143)

Chronic pain Persistent or recurring pain that is often difficult to treat. Includes any pain lasting longer than 3 to 6 months, pain lasting longer than 1 month after healing of an acute injury, or pain that accompanies a nonhealing tissue injury. (p. 142)

Deep pain Pain that occurs in tissues below skin level; opposite of *superficial pain.* (p. 143)

Gate theory The most well-described theory of pain transmission and pain relief. It uses a gate model to explain how impulses from damaged tissues are sensed in the brain. (p. 143)

Narcotics A legal term established under the Harrison Narcotic Act of 1914. It originally applied to drugs that produce insensibility or stupor, especially the opioids (e.g., morphine, heroin). Currently used to refer to any medically used controlled substances and in legal settings to refer to any illicit or "street" drug. (NOTE: This term is falling out of use in favor of *opioid* and will not be used further in this text.)

Neuropathic pain Pain that results from a disturbance of function or pathologic change in a nerve. (p. 143)

Nociception Processing of pain signals in the brain that gives rise to the feeling of pain. (p. 142)

Nociceptors A subclass of sensory nerves (A and C fibers) that transmit pain signals to the central nervous system from other body parts. (p. 142)

Nonopioid analgesics Analgesics that are not classified as opioids. (p. 143)

Nonsteroidal antiinflammatory drugs (NSAIDs) A large, chemically diverse group of drugs that are analgesics and also possess antiinflammatory and antipyretic activity but are not corticosteroids. (p. 143)

Opioid analgesics Synthetic drugs that bind to opiate receptors to relieve pain. (p. 141)

Opioid naïve Describes patients who are receiving opioid analgesics for the first time and who therefore are not accustomed to their effects. (p. 150)

Opioid tolerance A normal physiologic condition that results from long-term opioid use, in which larger doses of opioids are required to maintain the same level of analgesia and in which abrupt discontinuation of the drug results in withdrawal symptoms (same as *physical dependence*). (p. 144)

Opioid tolerant The opposite of opioid naïve; describes patients who have been receiving opioid analgesics (legally or otherwise) for a period of time (1 week or longer) and who are at greater risk of opioid withdrawal syndrome upon sudden discontinuation. (p. 145)

Opioid withdrawal The signs and symptoms associated with abstinence from or withdrawal of an opioid analgesic when the body has become physically dependent on the substance. (p. 150)

Pain An unpleasant sensory and emotional experience associated with actual or potential tissue damage. (p. 141)

Pain threshold The level of a stimulus that results in the sensation of pain. (p. 142)

Pain tolerance The amount of pain a patient can endure without its interfering with normal function. (p. 142)

Partial agonist A drug that binds to a receptor and causes a response that is less than that caused by a full agonist (same as *agonist-antagonist*). (p. 147)

Phantom pain Pain experienced in the area of a body part that has been surgically or traumatically removed. (p. 143)

Physical dependence A condition in which a patient takes a drug over a period of time and unpleasant physical symptoms (withdrawal symptoms) occur if the drug is stopped abruptly or smaller doses are given. The physical adaptation of the body to the presence of an opioid or other addictive substance. (p. 142)

Psychologic dependence A pattern of compulsive use of opioids or any other addictive substance characterized by a continuous craving for the substance and the need to use it for effects other than pain relief (also called *addiction*). (p. 144)

Referred pain Pain occurring in an area away from the organ of origin. (p. 143)

Somatic pain Pain that originates from skeletal muscles, ligaments, or joints. (p. 143)

Special pain situations The general term for pain control situations that are complex and whose treatment typically involves multiple medications, various health care personnel, and nonpharmacologic therapeutic modalities (e.g., massage, chiropractic care, surgery). (p. 164)

Superficial pain Pain that originates from the skin or mucous membranes; opposite of *deep pain.* (p. 143)

KEY TERMS—cont'd

Synergistic effects Drug interactions in which the effect of a combination of two or more drugs with similar actions is greater than the sum of the individual effects of the same drugs given alone. For example, 1 + 1 is greater than 2. (p. 146)

Tolerance The general term for a state in which repetitive exposure to a given drug, over time, induces changes in drug receptors that reduce the drug's effects (same as *physical dependence*). (p. 142)

Vascular pain Pain that results from pathology of the vascular or perivascular tissues. (p. 143)

Visceral pain Pain that originates from organs or smooth muscles. (p. 143)

World Health Organization (WHO) An international body of health care professionals, including clinicians and epidemiologists among many others, that studies and responds to health needs and trends worldwide. (p. 146)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

The management of pain is a very important aspect of nursing care in a variety of settings and across the lifespan. Pain is the most common reason that patients seek health care, resulting in some 70 million office visits annually in the United States. Surgical and diagnostic procedures often require pain management, as do several diseases including arthritis, diabetes, multiple sclerosis, cancer, and acquired immunodeficiency syndrome (AIDS). Pain leads to much suffering and is a tremendous economic burden in terms of lost workplace productivity, workers' compensation payments, and other related health care costs.

To provide quality patient care, you must be well informed about both pharmacologic and nonpharmacologic methods of pain management. This chapter focuses on pharmacologic methods of pain management. Nonpharmacologic methods of pain management are listed in Box 10-1.

Medications that relieve pain without causing loss of consciousness are classified as **analgesics.** They are also commonly referred to as *painkillers.* There are various classes of analgesics, determined by their chemical structures and mechanisms of action. This chapter focuses primarily on the **opioid analgesics,** which are used to manage moderate to severe pain. Often drugs from other chemical categories are added to the opioid regimen as **adjuvant analgesic drugs** (or adjuvants) and are described later.

BOX 10-1 NONPHARMACOLOGIC TREATMENT OPTIONS FOR PAIN

- Acupressure
- Acupuncture
- Art therapy
- Behavioral therapy
- Biofeedback
- Comfort measures
- Counseling
- Distraction
- Hot or cold packs
- Hypnosis
- Imagery
- Massage
- Meditation
- Music therapy
- Pet therapy
- Physical therapy
- Reduction of fear
- Relaxation
- Surgery
- Therapeutic baths
- Therapeutic communication
- Therapeutic touch
- Transcutaneous electric nerve stimulation
- Yoga

Pain is most commonly defined as an unpleasant sensory and emotional experience associated with either actual or potential tissue damage. It is a very personal and individual experience. Pain can be defined as whatever the patient says it is, and it exists whenever the patient says it does. Although the mechanisms of pain are becoming better understood, a patient's perception of pain is a complex process. Pain involves physical, psychological, and even cultural factors (see Patient-Centered Care: Cultural Implications box). Because pain intensity cannot be precisely quantified, health care providers must cultivate relationships of mutual trust with their patients to provide optimal care.

PATIENT-CENTERED CARE: CULTURAL IMPLICATIONS

The Patient Experiencing Pain

- Each culture has its own beliefs, thoughts, and ways of approaching, defining, and managing pain. Attitudes, meanings, and perceptions of pain vary with culture, race, and ethnicity.
- African Americans believe in the power of healers who rely strongly on the religious faith of people and often use prayer and the laying on of hands for relief of pain.
- Hispanic Americans believe in prayer, the wearing of amulets, and the use of herbs and spices to maintain health and wellness. Specific herbs are used in teas and therapies, often including religious practices, massage, and cleansings.
- Some traditional methods of healing for the Chinese include acupuncture, herbal remedies, yin and yang balancing, and cold treatment. *Moxibustion,* in which cones or cylinders of pulverized wormwood are burned on or near the skin over specific meridian points, is another form of healing.
- Asian and Pacific Islander patients are often reluctant to express their pain because they believe that the pain is God's will or is punishment for past sins.
- For many Native Americans, treatments for pain include massage, the application of heat, sweat baths, herbal remedies, and being in harmony with nature.
- In Arab culture, patients are expected to express their pain openly and anticipate immediate relief, preferably through injections or intravenous drugs.
- Remain aware of all cultural influences on health-related behaviors and on patients' attitudes toward medication therapy and thus, ultimately, on its effectiveness. A thorough assessment that includes questions about the patient's cultural background and practices is important to the effective and individualized delivery of nursing care.

There is no single approach to effective pain management. Instead, pain management is tailored to each patient's needs. The cause of the pain, the existence of concurrent medical conditions; the characteristics of the pain; and the psychological and cultural characteristics of the patient need to be considered. It also requires ongoing reassessment of the pain and the effectiveness of treatment. The patient's emotional response to pain depends on his or her psychological experiences of pain. Pain results from the stimulation of sensory nerve fibers known as **nociceptors.** These receptors transmit pain signals from various body regions to the spinal cord and brain, which leads to the sensation of pain, or **nociception** (Figure 10-1).

The physical impulses that signal pain activate various nerve pathways from the periphery to the spinal cord and to the brain. The level of stimulus needed to produce a painful sensation is referred to as the **pain threshold.** Because this is a measure of the physiologic response of the nervous system, it is similar for most persons. However, variations in pain sensitivity may result from genetic factors.

There are three main receptors believed to be involved in pain. The mu receptors in the dorsal horn of the spinal cord appear to play the most crucial role. Less important but still involved in pain sensations are the kappa and delta receptors. Pain receptors are located in both the central nervous system (CNS) and various body tissues. Pain perception—and, conversely, emotional well-being—is closely linked to the number of mu receptors. This number is controlled by a single gene, the mu opioid receptor gene. When the number of receptors is high, pain sensitivity is diminished. Conversely, when the receptors are reduced or missing altogether, relatively minor noxious stimuli may be perceived as painful.

The patient's emotional response to the pain is also molded by the patient's age, sex, culture, previous pain experience, and anxiety level. Whereas pain threshold is the physiologic element of pain, the psychological element of pain is called **pain tolerance.** This is the amount of pain a patient can endure without its interfering with normal function. Because it is a subjective response, pain tolerance can vary from patient to patient. Pain tolerance can be modulated by the patient's personality, attitude, environment, culture, and ethnic background. Pain tolerance can even vary within the same person depending on the circumstances involved. Table 10-1 lists the various conditions that can alter one's pain tolerance.

Pain can also be further classified in terms of its onset and duration as either acute or chronic. **Acute pain** is sudden and usually subsides when treated. One example of acute pain is postoperative pain. **Chronic pain** is persistent or recurring, lasting 3 to 6 months. It is often more difficult to treat, because changes occur in the nervous system that often require increasing drug dosages. This situation is known by the general term **tolerance** or **physical dependence** (see Chapter 17). Acute and chronic pain differ in their onset and duration, their associated diseases or conditions, and the way they are treated. Table 10-2 lists the different characteristics of acute and chronic pain and various diseases and conditions associated with each.

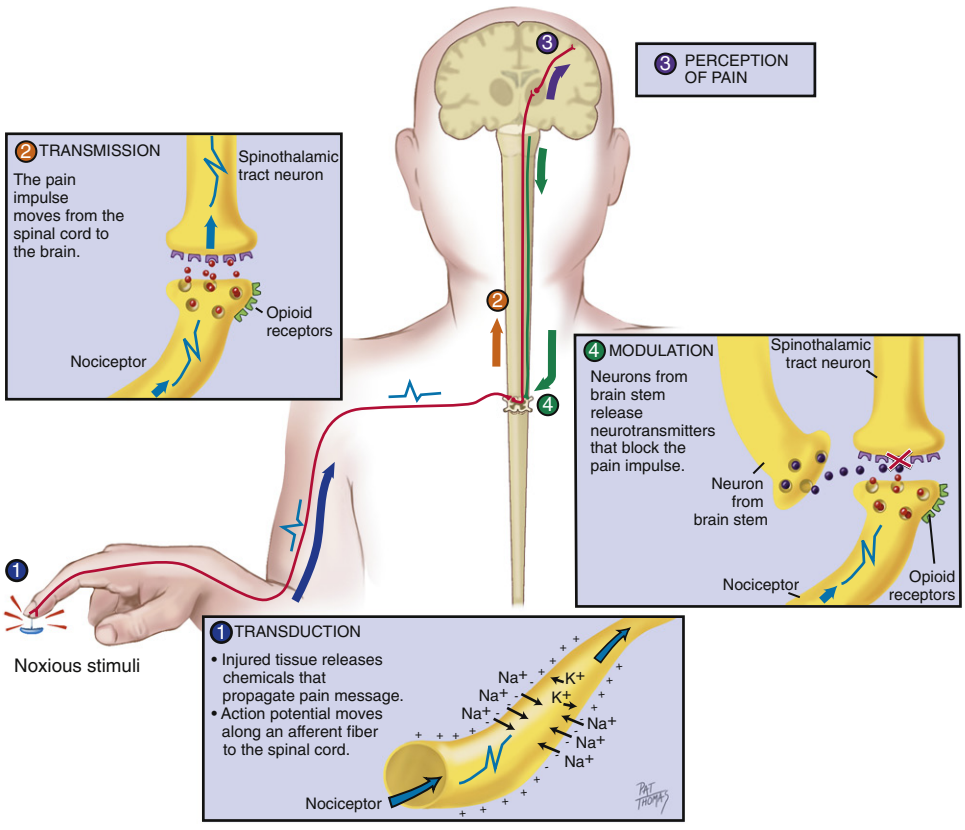

FIGURE 10-1 Illustration of the four processes of nociception. (From Jarvis C: *Physical examination and health assessment,* ed 6, St Louis, 2012, Saunders.)

Pain can be further classified according to its source. The two most common sources of pain are somatic and visceral. **Somatic pain** originates from skeletal muscles, ligaments, and joints. **Visceral pain** originates from organs and smooth muscles. Sometimes pain is described as superficial. **Superficial pain** originates from the skin and mucous membranes. **Deep pain** occurs in tissues below skin level. Pain may be appropriately treated when the source of the pain is known. For example, visceral and superficial pain usually require opioids for relief, whereas somatic pain (including bone pain) usually responds better to **nonopioid analgesics** such as **nonsteroidal antiinflammatory drugs (NSAIDs)** (see Chapter 44).

Pain may be further subclassified according to the diseases or other conditions that cause it. **Vascular pain** is believed to originate from the vascular or perivascular tissues and is thought to account for a large percentage of migraine headaches. **Referred pain** occurs when visceral nerve fibers synapse at a level in the spinal cord close to fibers that supply specific subcutaneous tissues in the body. An example is the pain associated with cholecystitis, which is often referred to the back and scapular areas. **Neuropathic pain** usually results from damage to peripheral or CNS nerve fibers by disease or injury but may also be idiopathic (unexplained). **Phantom pain** occurs in the area of a body part that has been removed—surgically or traumatically—and is often described as burning, itching, tingling, or stabbing. It can also occur in paralyzed limbs following spinal cord injury. **Cancer pain** can be acute or chronic or both. It most often results from pressure of the tumor mass against nerves, organs, or tissues. Other causes of cancer pain include hypoxia from blockage of blood supply to an organ, metastases, pathologic fractures, muscle spasms, and adverse effects of radiation, surgery, and chemotherapy. **Central pain** occurs with tumors, trauma, inflammation, or disease (e.g., cancer, diabetes, stroke, multiple sclerosis) affecting CNS tissues.

TABLE 10-1 CONDITIONS THAT ALTER PAIN TOLERANCE

PAIN THRESHOLD	CONDITIONS
Lowered	Anger, anxiety, depression, discomfort, fear, isolation, chronic pain, sleeplessness, tiredness
Raised	Diversion, empathy, rest, sympathy, medications (analgesics, antianxiety drugs, antidepressants)

TABLE 10-2 ACUTE VERSUS CHRONIC PAIN

TYPE OF PAIN	ONSET	DURATION	EXAMPLES
Acute	Sudden (minutes to hours); usually sharp, localized; physiologic response (SNS: tachycardia, sweating, pallor, increased blood pressure)	Limited (has an end)	Myocardial infarction, appendicitis, dental procedures, kidney stones, surgical procedures
Chronic	Slow (days to months); long duration; dull, persistent aching	Persistent or recurring (endless)	Arthritis, cancer, lower back pain, peripheral neuropathy

SNS, Sympathetic nervous system.

Several theories attempt to explain pain transmission and pain relief. The most common and well described is the **gate theory.** This theory, proposed by Melzack and Wall in 1965, uses the analogy of a gate to describe how impulses from damaged tissues are sensed in the brain. First, the tissue injury causes the release of several substances from injured cells, such as bradykinin, histamine, potassium, prostaglandins, and serotonin. Some current pain medications work by altering the actions and levels of these substances (e.g., NSAIDs → prostaglandins; antidepressants → serotonin). The release of these pain-mediating chemicals initiates action potentials (electrical nerve impulses) at the distal end of sensory nerve fibers through pain receptors known as *nociceptors.* These nerve impulses are conducted along sensory nerve fibers and activate pain receptors in the *dorsal horn* of the spinal cord. It is here that the so-called gates are located. These gates regulate the flow of sensory nerve impulses. If impulses are stopped by a gate at this junction, no impulses are transmitted to the higher centers of the brain. Conversely, if the gates permit a sufficient number and intensity of action potentials to be conducted from the spinal cord to the cerebral cortex, the sensation of pain is then felt. This is known as *nociception.* Figure 10-2 depicts the gate theory of pain transmission.

Both the opening and the closing of this gate are influenced by the relative activation of large-diameter A fibers and small-diameter C fibers (Table 10-3). Closing of the gate seems to be affected by the activation of A fibers. This causes the inhibition of impulse transmission to the brain and avoidance of pain sensation. Opening of the gate is affected by the stimulation of C fibers. This allows impulses to be transmitted to the brain and pain to be sensed. The gate is innervated by nerve fibers that originate in the brain and modulate the pain sensation by sending impulses to the gate in the spinal cord. These nerve fibers enable the brain to evaluate, identify, and localize the pain. Thus, the brain can control the gate, either keeping the gate closed or allowing it to open so that the brain is stimulated and pain is sensed. The cells that control the gate have a threshold. Impulses that reach these cells must rise above this threshold before an impulse is permitted to travel up to the brain.

The body is also equipped with certain endogenous neurotransmitters known as *enkephalins* and *endorphins.* These substances are produced within the body to fight pain and are considered the body's painkillers. Both are capable of bonding with opioid receptors and inhibiting the transmission of pain impulses by closing the spinal cord gates, in a manner similar to that of opioid analgesic drugs. The term *endorphin* is a condensed version of the term "endogenous morphine." These endogenous analgesic substances are released whenever the

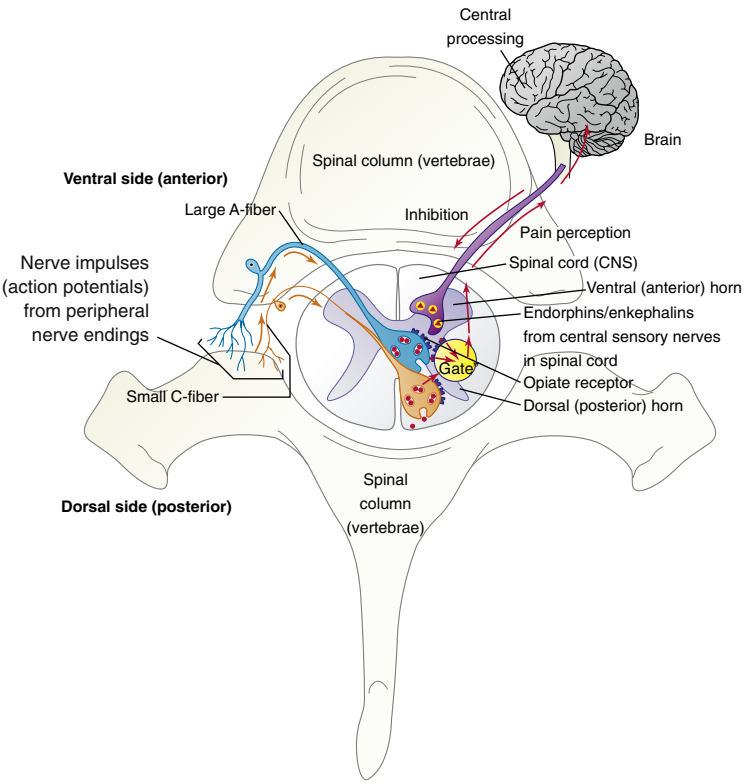

FIGURE 10-2 Gate theory of pain transmission. *CNS,* Central nervous system.

TABLE 10-3 A AND C NERVE FIBERS

TYPE OF FIBER	MYELIN SHEATH	FIBER SIZE	CONDUCTION SPEED	TYPE OF PAIN
A	Yes	Large	Fast	Sharp and well localized
C	No	Small	Slow	Dull and nonlocalized

body experiences pain or prolonged exertion. For example, they are responsible for the phenomenon of "runner's high." Figure 10-1 depicts this entire process.

Another phenomenon of pain relief that may be explained by the gate theory is the fact that massaging a painful area often reduces the pain. When an area is rubbed or liniment is applied, large sensory A nerve fibers from peripheral receptors carry pain-modulating impulses to the spinal cord. Remember, the A fibers tend to close the gate, which reduces pain sensation in the brain.

TREATMENT OF PAIN IN SPECIAL SITUATIONS

It is estimated that one of every three Americans experiences ongoing pain. Pain is poorly understood and often undertreated. In addition to enduring their baseline chronic pain, patients with illnesses such as cancer, AIDS, and sickle cell anemia may also experience crisis periods of acute pain. Effective management of acute pain is often different from management of chronic pain in terms of medications and dosages used. Routes of drug administration may include oral, intravenous (IV), intramuscular (IM), subcutaneous (subcut), transdermal, and rectal. One intravenous route commonly used in the hospital setting is patient-controlled analgesia (PCA). In this situation, patients are able to self-medicate by pressing a button on a PCA infusion pump. This has been shown to be very effective and reduces the total opioid dose used. Morphine and hydromorphone are commonly given by PCA. Potential hazards of PCA include well-meaning family members' pressing the dosing button rather than letting able patients do so on their own. For patients truly not able to self-medicate using the PCA pump, a different method of pain control needs to be used. Numerous deaths have occurred when well-meaning family members have administered too much of the opioid drug. This is called *PCA by proxy.* The Institute for Safe Medication Practices (www.ismp.org) advises against PCA by proxy.

Patients with complex pain syndromes often benefit from a holistic or multimodal clinical approach that involves pharmacologic and/or nonpharmacologic treatment. Effective drug therapy may include use of opioid and/or nonopioid drugs. The goals of pain management include reducing and controlling pain, and improving body function and quality of life.

In situations such as pain associated with cancer, the main consideration in pain management is patient comfort and not trying to prevent drug **addiction** (or **psychologic dependence;** see Chapter 17). **Opioid tolerance** is a state of adaptation in which exposure to a drug causes changes in drug receptors that result in reduced drug effects over time. This can occur in as little as 1 week. Because of increasing pathology (e.g., tumor burden), cancer patients usually require increasingly higher opioid doses and thus

do become physically dependent on the drugs. Cancer patients are likely to experience withdrawal symptoms (see Chapter 17) if opioid doses are abruptly reduced or discontinued; however, actual psychological dependence or addiction in such patients is unusual. For long-term pain control, oral, intravenous, subcutaneous, transdermal, and sometimes even rectal dosing routes are favored over multiple intramuscular injections due to associated puncture trauma (bruising) and erratic drug absorption.

One controversial issue in pain management is the use of placebos, inert dosage forms that actually lack medication. Some prescribers feel that this practice may be helpful by taking advantage of the well-documented placebo effect. The placebo effect is a psychological therapeutic effect that occurs even in the absence of actual medication. It is believed to arise from activation of the patient's own endorphins. It is also attributed to the patient's belief that any "treatment" is effective, as well as the patient's high level of trust in the health care provider. Critics argue that the use of placebos is unethical, because it requires that the patient be deceived in the process. The use of placebos for pain management has fallen out of favor, and they are rarely used today (see Chapter 4 for further discussion).

The treatment of acute pain in patients who are addicted to opioids is of great concern to clinicians, who may be reluctant to prescribe opioid therapy. However, habitual street opioid users are **opioid tolerant** and generally require high dosages. Longer-acting opioids such as methadone or extended-release oxycodone are usually better choices than shorter-acting immediate-release drug products for these patients. This is because the shorter-acting drugs are more likely to produce a psychological "high" or euphoria, which only reinforces addictive tendencies. Genetic differences in cytochrome P-450 enzymes (see Chapters 2 and 8) can cause different patients, whether addicted or not, to respond more or less effectively to a given drug. For this reason, patients must not automatically be viewed with suspicion if they complain that a given drug does not work for them.

The label of "addict" can be used unfairly to justify refusal to prescribe pain medications, resulting in undertreatment of pain, even in patients who do not use street drugs. This is now regarded as an inappropriate and inhumane clinical practice. In these situations, control of the patient's pain takes ethical and clinical priority over concerns regarding drug addiction. Nonetheless, prescribers must contend with the reality of abuse of street and/or prescription drugs by patients without genuine pain conditions (see Chapter 17). Such patients often request excessive numbers of prescriptions and may use multiple prescribers and/or pharmacies. At times, they may also forge prescriptions and/or use a telephone to call in prescriptions for non–Schedule II opioids such as hydrocodone/acetaminophen (Vicodin). Community pharmacists work collaboratively to detect such abuses and notify law enforcement authorities. Creating a phony prescription for a controlled substance is a felony under federal and state laws.

EVIDENCE-BASED PRACTICE

Student Nurses' Misconceptions of Adults with Chronic Nonmalignant Pain

Review

The purpose of this study was to identify some of the misconceptions that student nurses have, across 3 years of undergraduate education, about adults who are experiencing chronic nonmalignant pain. Previously identified misconceptions about patients with chronic nonmalignant pain reported in an extensive literature search served as the basis of the study. The rationale for this study was to identify potential gaps in attitudes and knowledge of student nurses. The results were then used to discuss educational approaches focused on improving care of the patient experiencing chronic nonmalignant pain. The two major questions that this study sought to explore included the following: (1) Do student nurses hold misconceptions about adults with chronic nonmalignant pain, and (2) If so, to what extent do they develop during their undergraduate education?

Type of Evidence

The researchers developed, tested, and validated a survey tool specifically for this cross-sectional study to evoke responses from students at three points during their undergraduate nursing education in New Zealand. The survey began with a vignette of a 22-year-old client who was experiencing back pain for 6 months. The injury that caused the pain resulted when the woman suffered a fall while lifting a patient. It was thought that the vignette represented demographics that would be most familiar to the participants. Part of the vignette also purposely alluded to some of the basic details of misconceptions of pain (McCaffery and Pasero, 1999) but without giving many specific details. The patient in the vignette was also someone who was a healthy, fit young adult prior to the injury. There were two slight variations in the vignettes with the hopes of eliciting possible differences in responses toward patients, depending on whether a specific pathology had been identified. A series of eight items, the misconception items, were directly linked to each of the misconceptions identified by McCaffery and Pasero (1990), and the responses were gathered using a seven-point Likert scale seeking differing levels of agreement in relation to the items. A tool was designed and used with another group of students from a different discipline but within the same facility. This was done to get feedback from a group of students similar to the participants but prior to the final study. Some minor changes were made in the tool before moving forward with the study.

Results of Study

Some 435 students were approached to participate in the research study, and 430 completed and returned the surveys for a total response rate of 99%. A convenience sampling was used because the students were easily accessible; they represented about 75% of students enrolled in the facility in semesters one, four, and six of the undergraduate nursing degree program in the city of Auckland and around 13% of those enrolled in New Zealand. These participants were distributed over a 3-year period of undergraduate studies during six semesters of full-time studies. The majority were female students, although there was no further specific demographic data collected about the participants. A cross-sectional design meant that data gathered came from each participant only once during the study. A research assistant, and one who had not taught the students, met with the students and invited them to participate in the study. Sessions were held in the middle of the semester to increase the response rate as well as diminish anxiety during final exam time. More than 38% of the participants demonstrated a misconception about people with chronic pain and that they were tolerant to some degree of pain. More than 60% did not hold this misconception about tolerance to pain. More than one-half of the students' (59%) responses indicated that they held the misconception that psychological impairment is related to chronic pain.

Continued

EVIDENCE-BASED PRACTICE—cont'd

Student Nurses' Misconceptions of Adults with Chronic Nonmalignant Pain

Approximately 79% of the students suggested that they believed stress was a contributory cause of chronic pain, whereas less than one-fourth indicated that they accurately understood that this was not the case. The misconception of compensation and exaggeration in chronic pain was held by 47.9% of the participants, and 51.7% did not hold this same misconception. About one-third of the students indicated that they held the misconception that patients with chronic pain were manipulative, and the majority indicated that they did not.

Approximately 64% of the participants held the misconception that depression plays a role in the chronic pain experience. Opioid addiction was a misconception held by about one-half of the participants, such that 54.8% believed that patients taking opioids were likely to be addicted. Some 58% of the students indicated that they did hold the misconception that patients with chronic pain were noncompliant and dependent, whereas 41.4% indicated that they did not hold this misconception. Another question that was posed to the students was the extent to which they had developed their misconceptions of patients with chronic pain during their undergraduate education. There were significantly positive trends across the semesters, suggesting that students held their misconceptions to a lesser degree as they progressed through their course of study. In summary, analysis of the results indicate that a substantial proportion of students who participated in the study hold misconceptions about patients with chronic pain to some extent.

The analysis of the misconception scores across the semesters indicates that the knowledge and attitudes of students toward adults experiencing chronic nonmalignant pain developed to some degree because their misconceptions were held to a lesser degree by the end of the program of study.

Link of Evidence to Nursing Practice

It is a known phenomenon that a gap exists between theory and practice across many areas of professional nursing practice. Therefore, it would be ideal for nursing educators and the nursing educational experience to equip students with the knowledge, skills, and attitudes to participate in the discussion, planning, and implementing of care for patients suffering from chronic nonmalignant pain. Nursing faculty and schools of nursing need to make available experiential learning situations that will enhance the blending of knowledge, skills, and attitudes into professional nursing practice so that these gaps in care are closed. The findings of this study show that students, like many practicing nurses, hold misconceptions about adults with chronic nonmalignant pain, representing a lack of knowledge and inappropriate attitudes. An integrated approach to teaching chronicity and disability needs to be included in the nursing curriculum; however, critical thinking, linking theory to practice, and developing compassion also need to be part of the educational process.

References: Shaw S, Lee A: Student nurses' misconceptions of adults with chronic nonmalignant pain, *Pain Manag Nurs* 11(1):2-14, 2010; McCaffery M, Pasero C: *Pain: clinical manual,* St Louis, 1990, Mosby; McCaffery M, Pasero C: *Pain: clinical manual,* ed 2, St Louis, 1999, Mosby.

For patients receiving long-acting opioids, **breakthrough pain** often occurs between doses of pain medications. This is because the analgesic effects wear off as the drug is metabolized and eliminated from the body. Treatment with prn (as needed) doses of immediate-release dosage forms (e.g., oxycodone IR) given between scheduled doses of extended-release dosage forms (e.g., oxycodone ER) is often helpful in these cases. Chewing or crushing of any extended-release opioid drug can cause oversedation, respiratory depression, and even death due to rapid drug absorption. If the patient is requiring larger doses for breakthrough pain, the dose of the scheduled extended-release opioid may need to be shortened or a more potent drug started.

Drugs from other chemical categories are often added to the opioid regimen as adjuvant drugs. These assist the primary drugs in relieving pain. Such adjuvant drug therapy may include NSAIDs (see Chapter 44), antidepressants (see Chapter 16), antiepileptic drugs (see Chapter 14), and corticosteroids (see Chapter 33), all of which are discussed further in their corresponding chapters. This approach allows the use of smaller dosages of opioids and reduces some of the adverse effects that are seen with higher dosages of opioids, such as respiratory depression, constipation, and urinary retention. It permits drugs with different mechanisms of action to produce **synergistic effects.** Antiemetics (see Chapter 52) and laxatives (see Chapter 51) may also be needed to prevent or relieve associated constipation, nausea, and vomiting (Box 10-2).

One common use of adjuvant drugs is in the treatment of neuropathic pain. Opioids are not completely effective in such cases. Neuropathic pain usually results from some kind of nerve damage secondary to disease (e.g., diabetic neuropathy, postherpetic neuralgia secondary to shingles, trigeminal neuralgia, AIDS or injury, including nerve damage secondary to surgical procedures [e.g., post-thoracotomy pain syndrome occurring after cardiothoracic surgery]). Common symptoms include hypersensitivity or hyperalgesia to mild stimuli such as light touch or a pinprick, or the bed sheets on a person's feet. This is also known as *allodynia.* It can also manifest as hyperalgesia to uncomfortable stimuli, such as pressure from an inflated blood pressure cuff on a patient's limb. It may be described as heat, cold, numbness and tingling, burning, or electrical sensations. Examples of adjuvants commonly used in these cases are the antidepressant amitriptyline and the anticonvulsants gabapentin and pregabalin.

The three-step analgesic ladder defined by the **World Health Organization (WHO)** is often applied as the pain management standard for cancer pain. Examples of nonopioid analgesic drugs include NSAIDs (see Chapter 44) as well as acetaminophen and tramadol (see Drug Profiles). Step 1 is the use of nonopioids (with or without adjuvant medications) once the pain has been identified and assessed. If pain persists and/or increases, treatment moves to step 2, which is defined as the use of opioids with or without nonopioids and with or without adjuvants. If pain persists or increases, management then rises to step 3, which is the use of opioids indicated for moderate to severe pain, administered with or without nonopioids or adjuvant medications. Many experts now question the effectiveness of Step 2, and the WHO is considering adjusting the ladder. Not all patients will be treated effectively using the ladder method and may need to seek an experienced pain management physician.

BOX 10-2 POTENTIAL OPIOID ADVERSE EFFECTS AND THEIR MANAGEMENT

Constipation

Opioids decrease gastrointestinal (GI) tract peristalsis because of their central nervous system (CNS) depression, with subsequent constipation as an adverse effect. Stool becomes excessively dehydrated because it remains in the GI tract longer. **Preventative measures:** Constipation may be managed with increased intake of fluids, stool softeners such as docusate sodium, or the use of stimulants such as bisacodyl or senna. Agents such as lactulose, sorbitol, and polyethylene glycol (Miralax) have been proven effective. Less commonly used are bulk-forming laxatives such as psyllium, for which increased fluid intake is especially important to avoid fecal impactions or bowel obstructions.

Nausea and Vomiting

Opioids decrease GI tract peristalsis, and some also stimulate the vomiting center in the CNS, so nausea and vomiting are often experienced. **Preventative measures:** Nausea and vomiting may be managed with the use of antiemetics such as phenothiazines.

Sedation and Mental Clouding

Any change in mental status should always be evaluated to ensure that causes other than drug-related CNS depression are ruled out. **Preventative measures:** Persistent drug-related sedation may be managed with a decrease in the dosage of opioid or change in drug used. The prescriber may also order various CNS stimulants (see Chapter 13).

Respiratory Depression

Long-term opioid use is generally associated with tolerance to respiratory depression. **Preventative measures:** For severe respiratory depression, opioid antagonists (naloxone) may be used to improve respiratory status and, if they are titrated in small amounts, the respiratory depression may be reversed without analgesia reversal.

Subacute Overdose

Subacute overdose may be more common than acute respiratory depression and may progress slowly (over hours to days), with somnolence and respiratory depression. Before analgesic dosages are changed or reduced, advancing disease must be considered, especially in the dying patient. **Preventative measures:** Often, holding one or two doses of an opioid analgesic is enough to judge if the mental and respiratory depression is associated with the opioid. If there is improvement with this measure, the opioid dosage is often decreased by 25%.

Other Opioid Adverse Effects

Dry mouth, urinary retention, pruritus, myoclonus, dysphoria, euphoria, sleep disturbances, sexual dysfunction, and inappropriate secretion of antidiuretic hormone may occur but are less common than the aforementioned adverse effects. **Preventative measures:** Ongoing assessment is needed for each of the adverse effects so that appropriate measures may be implemented (e.g., sucking of sugar-free hard candy or use of artificial saliva drops or gum for dry mouth; use of diphenhydramine for pruritus).

PHARMACOLOGY OVERVIEW

Opioids are classified as both mild **agonists** (codeine, hydrocodone) and strong agonists (morphine, hydromorphone, levorphanol, oxycodone, oxymorphone, meperidine, fentanyl, and methadone). Meperidine is not recommended for long-term use because of the accumulation of a neurotoxic metabolite, *normeperidine.* In fact, many hospitals have tried to prohibit the use of meperidine due to its adverse CNS effects, including seizures. In 2010, the mild agonist, propoxyphene (Darvocet) was withdrawn from the market due to adverse effects. The opiate **agonists-antagonists** such as pentazocine and nalbuphine are associated with an **analgesic ceiling effect.** This means that the drug reaches a maximum analgesic effect, so that analgesia does not improve even with higher dosages (see Drug Profiles). Such drugs are useful only in patients who have not been previously exposed to opioids and can be used for nonescalating moderate to severe pain. Finally, because of associated bruising and bleeding risks, as well as injection discomfort, there is now a strong trend away from intramuscular injections in favor of intravenous, oral, and transdermal routes of drug administration.

OPIOID DRUGS

The pain-relieving drugs currently known as *opioid analgesics* originated from the opium poppy plant. The word *opium* is a Greek word that means "juice." More than 20 different alkaloids are obtained from the unripe seed of the poppy. The properties of opium and its many alkaloids have been known for centuries. Opium-smoking immigrants brought opium to the United States, where unrestricted availability of opium prevailed until the early twentieth century.

Chemical Structure

Opioid analgesics are very strong pain relievers. They can be classified according to their chemical structure or their action at specific receptors. Of the 20 different natural alkaloids available from the opium poppy plant, only three are clinically useful: morphine, codeine, and papaverine. Of these, only morphine and codeine are pain relievers; papaverine is a smooth muscle relaxant. Relatively simple synthetic chemical modifications of these opium alkaloids have produced the three different chemical classes of opioids: morphine-like drugs, meperidine-like drugs, and methadone-like drugs (Table 10-4).

Mechanism of Action and Drug Effects

Opioid analgesics can also be characterized according to their mechanism of action. They are agonists, agonists-antagonists, or antagonists (nonanalgesic). An *agonist* binds to an opioid pain receptor in the brain and causes an analgesic response—the reduction of pain sensation. An *agonist-antagonist,* also called a **partial agonist** or a *mixed agonist,* binds to a pain receptor and causes a weaker pain response than does a full agonist. Different drugs in this class exert their agonist and/or antagonist effects by binding in different degrees to kappa and mu opioid receptors. Although not normally used as first-line analgesics, they are sometimes useful in pain management in opioid-addicted patients as well as obstetrical patients (because they avoid oversedation of the mother and/or fetus). An **antagonist** binds to a pain receptor but does not reduce pain signals. It functions as a *competitive antagonist* because it competes with

TABLE 10-4 CHEMICAL CLASSIFICATION OF OPIOIDS

CHEMICAL CATEGORY	OPIOID DRUGS
Meperidine-like drugs	Meperidine, fentanyl, remifentanil, sufentanil, alfentanil
Methadone-like drugs	Methadone
Morphine-like drugs	Morphine, heroin, hydromorphone, oxymorphone, levorphanol, codeine, hydrocodone, oxycodone
Other	Tramadol, tapentadol

TABLE 10-5 OPIOID RECEPTORS AND THEIR CHARACTERISTICS

RECEPTOR TYPE	PROTOTYPICAL AGONIST	EFFECTS OF OPIOID STIMULATION
mu	morphine	Supraspinal analgesia, respiratory depression, euphoria, sedation*
kappa	ketocyclazocine	Spinal analgesia, sedation,† miosis
delta	Enkephalins	Analgesia

*Moderate level of sedation.
†Twice as much sedation compared to mu receptors.

and reverses the effects of agonist and agonist-antagonist drugs at the receptor sites.

The receptors to which opioids bind to relieve pain are listed in Table 10-5. The mu, kappa, and delta receptors are most responsive to drug activity, with the mu being the most important. Many of the characteristics of a particular opioid, such as its ability to sedate, its potency, and its ability to cause hallucinations, can be attributed to relative affinity for these various receptors.

Understanding the relative potencies of various drugs becomes important in clinical settings. *Equianalgesia* refers to the ability to provide equivalent pain relief by calculating dosages of different drugs and/or routes of administration that provide comparable analgesia. Box 10-3 lists equianalgesic doses for several common opioids and shows how to calculate dosage conversions for patients. Because fentanyl is most commonly used transdermally, it is discussed separately in its drug profile.

Indications

The main use of opioids is to alleviate moderate to severe pain. The amount of pain control or unwanted adverse effects depends on the specific drug, the receptors to which it binds, and its chemical structure.

Strong opioid analgesics such as fentanyl, sufentanil, and alfentanil are commonly used in combination with anesthetics during surgery. These drugs are used not only to relieve pain but also to maintain a balanced state of anesthesia. The practice of using combinations of drugs to produce anesthesia is referred to as *balanced anesthesia* (see Chapter 11). Use of fentanyl injection for management of postoperative and procedural pain has become popular due to its rapid onset and short duration. Transdermal fentanyl comes in a patch formulation for use in long-term pain management and is not to be used for postoperative or any other short-term pain control (see the Safety and Quality Improvement: Preventing Medication Errors box).

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Fentanyl Transdermal Patches

When giving fentanyl transdermal patches, keep in mind several important points to avoid improper administration:

- These patches are recommended to be used only by patients who are considered opioid tolerant. To be considered opioid tolerant, a patient needs to have been taking, for a week or longer, morphine 60 mg daily, oral oxycodone 30 mg daily, or oral hydromorphone 8 mg daily (or an equianalgesic dose of another opioid). Giving fentanyl transdermal patches to non–opioid-tolerant patients may result in severe respiratory depression. Thorough assessment is important.
- Inform patients that heat, such as in the form of a heating pad/pack, must never be applied over a fentanyl transdermal patch. The increased circulation that results from the application of heat may result in increased absorption of medication, causing an overdose.
- Teach about the proper disposal of transdermal patches. Children have pulled used patches from the trash, which has resulted in death due to exposure to the drug. For disposal at home, the product insert recommends that the patch be disposed of by flushing down the toilet. However, disposal practices may vary by area because of concerns for the water systems. Disposal policies in facilities also vary, but some require that used patches be placed in a sharps container rather than be flushed.
- Keep patches, as well as all medications, away from children and pets. Do not store medications in warm, moist places such as medicine cabinets in the bathroom.

The Institute for Safe Medication Practices has described examples of fatal patient incidents resulting from failure to follow the above points. It is essential for the patient's safety to read the product labeling and follow instructions precisely. For more information, go to www.ismp.org.

Strong opioids such as morphine, meperidine, hydromorphone, and oxycodone are often used to control postoperative and other types of pain. Because morphine and hydromorphone are available in injectable forms, they are often first-line analgesics in the immediate postoperative setting. There is a trend away from using meperidine due to its greater risk for toxicity (see Drug Profile). All available oxycodone dosage forms are orally administered. The product OxyContin is a sustained-release form of oxycodone that is designed to last up to 12 hours. The "Contin" in the product name is a trademark of the original drug manufacturer, and refers to the "continuous-release" nature of the drug formulation. Recall that a continuous- or extended-release dosage form of a drug means that it has a prolonged duration of action, most often 8 to 24 hours (see Chapter 2). Similarly, the drug product MS Contin is a long-acting or sustained-release form of morphine that is also designed to provide 8 to 12 hours of pain relief. The "MS" stands for morphine sulfate. Both drugs are also available generically.

There are also immediate-release dosage forms of oxycodone and morphine in tablet, capsule, and liquid form. Meperidine is available only in immediate-release dosage forms, both oral

BOX 10-3 CALCULATING DOSAGE CONVERSIONS BETWEEN COMMONLY USED OPIOIDS

	EQUIANALGESIC DOSES			
	ORAL DOSE (mg)	PARENTERAL DOSE (mg)	ORAL-TO-PARENTERAL DOSE RATIO	DOSING INTERVAL (hr)
morphine	30	10	3:1	12 (continuous release) 4 (immediate release)
hydromorphone	7.5	1.5	5:1	4 (immediate release)
oxycodone	15	N/A	N/A	4 (immediate release)
hydrocodone	30	N/A	N/A	N/A
fentanyl	See fentanyl Drug Profile			

Basic Conversion Equation

$$\frac{\text{24-hour amount of current drug}}{x} = \frac{\text{EA dose of current drug}}{\text{EA dose of desired drug}}$$

Where x = amount of desired opioid in 24 hours and EA = equianalgesic dose obtained from the table above

For example: A patient with colon cancer is currently taking oral oxycodone 80 mg every 12 hours and needs to be converted to intravenous morphine due to a bowel obstruction. What is the equivalent IV morphine dose?

Step 1: **Determine the 24-hour amount of oxycodone taken by this patient:**

80 mg × 2 doses per 24 hours = 160 mg per 24 hours

Step 2: **Using the conversion table above, find the equianalgesic (EA) doses of oxycodone and parenteral morphine:**

15 mg oxycodone = 10 mg parenteral morphine

Step 3: **Use the above equation and solve for *x* by cross-multiplying:**

$$\frac{\text{24-hour amount of oxycodone (160 mg)}}{x} = \frac{\text{EA of current oxycodone (15 mg)}}{\text{EA dose of parenteral morphine (10 mg)}}$$

Where x = amount of parenteral morphine in 24 hours (solve by cross-multiplying)

$$160 \text{ mg} \times 10 \text{ mg} = 15 \text{ mg } x \quad x = \frac{1600 \text{ mg}}{15 \text{ mg}}$$

x = 107 mg (approximately 100 mg of injectable morphine per 24 hours)

N/A, Not applicable.

and injectable. The analgesic effects of immediate-release oral dosage forms of all three drugs typically last for about 4 hours.

Opioids also suppress the medullary cough center, which results in cough suppression. The most commonly used opioid for this purpose is codeine (see Chapter 36). Hydrocodone is also used in many cough suppressants, either alone or in combination with other drugs. Sometimes they have a depressant effect on the CNS and cause sedation. To avoid this problem, dextromethorphan, a nonopioid cough suppressant, is often given instead (see Chapters 17 and 36).

Constipation is often an unwanted side effect of opioids due to decreased gastrointestinal (GI) tract motility. It occurs because opioid drugs bind to intestinal opioid receptors. However, this effect is sometimes helpful in treating diarrhea. Some of the opioid-containing antidiarrheal preparations are camphorated opium tincture (paregoric) and diphenoxylate/atropine (Lomotil) tablets.

Contraindications

Contraindications to the use of opioid analgesics include known drug allergy and severe asthma. It is not uncommon for patients to state they are allergic to codeine, when in the overwhelming majority of these patients nausea was the "allergic" reaction. Many patients will claim to be allergic to morphine because it causes itching. Itching is a pharmacologic effect due to histamine release and not an allergic reaction. Thus, it is important to determine the exact nature of a patient's stated allergy. Although not absolute contraindications, extreme caution is to be used in cases of respiratory insufficiency, especially when resuscitative equipment is not available; conditions involving elevated intracranial pressure (e.g., severe head injury); morbid obesity and/or sleep apnea; myasthenia gravis; paralytic ileus (bowel paralysis); and pregnancy, especially with long-term use or high dosages.

Adverse Effects

Many of the unwanted effects of opioid analgesics are related to their pharmacologic effects in areas other than the CNS. Some of these unwanted effects can be explained by the drug's selectivity for the receptors listed in Table 10-5. The various body systems that the opioids affect and their specific adverse effects are summarized in Table 10-6.

Opioids that have an affinity for mu receptors and have rapid onset of action produce marked euphoria. These are the opioids that are most likely to be abused. All opioid drugs have a strong abuse potential. They are common recreational drugs of abuse among the lay public and also among health care professionals,

TABLE 10-6 OPIOID-INDUCED ADVERSE EFFECTS BY BODY SYSTEM

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Hypotension, flushing, bradycardia
Central nervous	Sedation, disorientation, euphoria, lightheadedness, dysphoria
Gastrointestinal	Nausea, vomiting, constipation, biliary tract spasm
Genitourinary	Urinary retention
Integumentary	Itching, rash, wheal formation
Respiratory	Respiratory depression and possible aggravation of asthma

For further information on transdermal fentanyl, visit http://www.ismp.org/Newsletters/acutecare/articles/20050811.asp.

TABLE 10-7 OPIOID ANTAGONISTS (REVERSAL DRUGS)

GENERIC NAME	TRADE NAME	ADVERSE EFFECTS
naloxone (IV)	Narcan	Raised or lowered blood pressure, dysrhythmias, pulmonary edema, withdrawal
naltrexone (PO)	ReVia	Nervousness, headache, nausea, vomiting, pulmonary edema, withdrawal

IV, Intravenous; *PO,* oral.

who often have relatively easy access. The person taking them to alter his or her mental status will soon become psychologically dependent (addicted; see Chapter 17).

In addition, opioids cause histamine release. It is thought that this histamine release is responsible for many of the drugs' unwanted adverse effects, such as itching or pruritus, rash, and hemodynamic changes. Histamine release causes peripheral arteries and veins to dilate, which leads to flushing and orthostatic hypotension. The amount of histamine release that an opioid analgesic causes is related to its chemical class. The naturally occurring opiates (e.g., morphine) elicit the most histamine release; the synthetic opioids (e.g., meperidine) elicit the least histamine release. (See Table 10-4 on p. 148 for a list of the various opioids and their respective chemical classes.)

The most serious adverse effect of opioid use is CNS depression, which may lead to respiratory depression. When death occurs from opioid overdose, it is almost always due to respiratory depression. When opioids are given, care must be taken to titrate the dose so that the patient's pain is controlled without affecting respiratory function. Individual responses to opioids vary, and patients may occasionally experience respiratory compromise despite careful dose titration. Respiratory depression can be prevented in part by using drugs with very short duration of action and no active metabolites. Respiratory depression seems to be more common in patients with a preexisting condition causing respiratory compromise, such as asthma, chronic obstructive pulmonary disease, or sleep apnea. Respiratory depression is strongly related to the degree of sedation (see Toxicity and Management of Overdose later).

GI tract adverse effects are common in patients receiving opioids due to stimulation of GI opioid receptors. Nausea, vomiting, and constipation are the most common adverse effects. Opioids can irritate the GI tract, stimulating the chemoreceptor trigger zone in the CNS, which in turn may cause nausea and vomiting. Opioids slow peristalsis and increase absorption of water from intestinal contents. These two actions combine to produce constipation. This is more pronounced in hospitalized patients who are nonambulatory. Patients may require laxatives (see Chapter 51) to help maintain normal bowel movements.

Urinary retention, or the inability to void, is another unwanted adverse effect of opioid analgesics, caused by increasing bladder tone. This is sometimes prevented by giving low dosages of an opioid agonist-antagonist or an opioid antagonist or a cholinergic agonist (see Chapter 20), such as bethanechol.

Severe hypersensitivity or anaphylactic reaction to opioid analgesics is rare. Many patients will experience GI discomforts or histamine-mediated reactions to opioids and call these "allergic reactions." However, true anaphylaxis is rare, even with intravenously administered opioids. Some patients may complain of flushing, itching, or wheal formation at the injection site, but this is usually local and histamine mediated, and not a true allergy. Box 10-2 (p. 147) provides additional information on opioid adverse effects and their management.

Toxicity and Management of Overdose

Naloxone and naltrexone are opioid antagonists, and they bind to and occupy all of the receptor sites (mu, kappa, delta). They are competitive antagonists with a strong affinity for these binding sites. Through such binding they can reverse the adverse effects induced by the opioid drug, such as respiratory depression. These drugs are used in the management of both opioid overdose and opioid addiction. The commonly used opioid antagonists (reversal drugs) are listed in Table 10-7.

When treating an opioid overdose or toxicity, the symptoms of withdrawal need to be considered. However, regardless of potential withdrawal symptoms, when a patient experiences severe respiratory depression, naloxone must be given. Some degree of physical dependence is expected in opioid-tolerant patients. The extent of opioid tolerance is most visible when an opioid drug is discontinued abruptly or when an opioid antagonist is administered. This usually leads to symptoms of **opioid withdrawal,** also known as *abstinence syndrome* (see Chapter 17). This can occur after as little as 2 weeks of opioid therapy in **opioid-naïve** patients. Gradual dosage reduction after chronic opioid use, when possible, helps to minimize the risk and severity of withdrawal symptoms.

Respiratory depression is the most serious adverse effect associated with opioids. Stimulating the patient may be adequate to reverse mild hypoventilation. If this is unsuccessful, ventilatory assistance using a bag and mask or endotracheal intubation may be needed to support respiration. Administration of opioid antagonists (e.g., naloxone) may also be necessary to reverse severe respiratory depression. Careful titration of dose until the patient begins to breathe independently will prevent overreversal. The effects of naloxone are short lived and usually last about 1 hour. With long-acting opioids, respiratory depressant effects may reappear, and naloxone may need to be redosed.

The onset of withdrawal symptoms is directly related to the half-life of the opioid analgesic being used. Withdrawal symptoms resulting from the discontinuance or reversal of therapy with short-acting opioids (codeine, hydrocodone, morphine, and hydromorphone) will appear within 6 to 12 hours and peak at 24 to 72 hours. Withdrawal symptoms associated with the long half-life drugs (methadone, levorphanol, and transdermal fentanyl) may not appear for 24 hours or longer after drug discontinuation and may be milder.

Interactions

Potential drug interactions with opioids are significant. Coadministration of opioids with alcohol, antihistamines, barbiturates, benzodiazepines, phenothiazine, and other CNS depressants can result in additive respiratory depressant effects. The combined use of opioids (such as meperidine) with monoamine oxidase inhibitors, such as selegiline, can result in respiratory depression, seizures, and hypotension.

Laboratory Test Interactions

Opioids can cause an abnormal increase in the serum levels of amylase, alanine aminotransferase, alkaline phosphatase, bilirubin, lipase, creatinine kinase, and lactate dehydrogenase (see the Safety: Laboratory Values Related to Drug Therapy box). Other abnormal results include a decrease in urinary 17-ketosteroid levels and an increase in the urinary alkaloid and glucose concentrations.

Dosages

For the recommended initial dosages of selected analgesic drugs in opioid-naïve patients, see the Dosages table on p. 152.

DRUG PROFILES

OPIOID AGONISTS

♦ morphine sulfate

Morphine, a naturally occurring alkaloid derived from the opium poppy, is the drug prototype for all opioid drugs. It is classified as a Schedule II controlled substance. Morphine is indicated for severe pain and has a high abuse potential. It is available in oral, injectable, and rectal dosage forms. Extended-release forms include MS Contin, Kadian, and Avinza. Morphine also has a potentially toxic metabolite known as *morphine-6-glucuronide.* Accumulation of this metabolite is more likely to occur in patients with renal impairment. For this reason, other Schedule II opioids such as hydromorphone (Dilaudid), fentanyl (see fentanyl drug profile), and oxymorphone (Opana) may be safer analgesic choices for patients with renal insufficiency. Drug profile information for hydromorphone is similar to that for morphine and meperidine. However, it is essential that all health care professionals realize that hydromorphone is about eight times more potent than morphine. One milligram of IV, IM, or subcut hydromorphone is equivalent to 7 mg of IV, IM, or subcut morphine. This difference in potency often is not taken into account when prescribing, and deaths have been reported

SAFETY: LABORATORY VALUES RELATED TO DRUG THERAPY

Analgesics

LABORATORY TEST	NORMAL RANGES	RATIONALE FOR ASSESSMENT
Alkaline phosphatase (ALP)	30-120 units/L	ALP is found in many tissues but in highest concentrations in the liver, biliary tract, and bone. Detection of this enzyme is important for determining liver and bone disorders. Enzyme levels of ALP are increased in both extrahepatic and intrahepatic obstructive biliary disease and cirrhosis and/or other liver abnormalities.
Alanine aminotransferase (ALT); formerly serum glutamic-pyruvic transaminase (SGPT)	4-36 units/L Elderly may have slightly higher levels than the adult	ALT is found mainly in the liver and lesser amounts in the kidneys, heart, and skeletal muscle. If there is injury or disease to the liver parenchyma (cells), it will cause a release of this liver cellular enzyme into the bloodstream and thus elevate serum ALT levels. Most ALT elevations are from liver disease. Therefore, if medications are then metabolized by the liver, this metabolic process will be altered and possibly lead to toxic levels of drugs.
Gama-glutamyl transferase (GGT)	Male/female 45 years of age and older: 8-38 units/L	GGT is an enzyme that is present in liver tissue; when there is damage to the liver cells (hepatocytes) that manufacture bile, the enzyme will be released throughout the cell membranes and released into the blood. Individuals of African ancestry have normal values that are double the values of those who are white.
Aspartate aminotransferase (AST); formerly called serum glutamic-oxalocetic transaminase (SGOT)	0-35 units/L	AST is elevated with hepatocellular diseases. With disease or injury of liver cells, the cells lyse and the AST is released and picked up by the blood; the elevation of AST is directly related to the number of cells affected by disease or injury.
Lactic dehydrogenase (LDH)	100-190 units/L	LDH is found in cells of many body tissues including the heart, liver, red blood cells, kidneys, skeletal muscles, brain, and lungs. Because it is in so many tissues, the total LDH level is not a specific indicator of one disease. If there is disease or injury affecting cells containing LDH, the cells lyse and LDH is released from the cells into the bloodstream, thus increasing LDH levels. This enzyme is just part of the total picture of altered liver function which, if present, will then decrease the breakdown/metabolism of drugs and other chemical compounds, resulting in elevated blood levels of drugs.

DOSAGES

Selected Analgesic Drugs and Related Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
Opioids			
codeine sulfate (D)	Opiate analgesic; opium alkaloid	**Adult** 15-60 mg tid-qid	Opioid analgesia
		Pediatric 2-5 yr PO/subcut/IM: 2.5-5 mg q4-6h—do not exceed 30 mg/day	Relief of cough
		Pediatric 6-11 yr 5-10 mg q4-6h	Relief of cough
		Adult and pediatric older than 12 yr 10-20 mg q4-6h—do not exceed 120 mg/day	Relief of cough
		Adult 15-60 mg tid-qid	Opioid analgesia
fentanyl (Duragesic, Oralet, Actiq*) (D)	Opioid analgesic	All doses titrated to response, starting with lowest effective dose **Pediatric** IV/IM: 0.5-2 mcg/kg/dose	Procedural sedation or adjunct to general anesthesia
		Adult IV/IM: 50-100 mcg/dose titrated to response via continuous infusion	Relief of moderate to severe acute pain
		Duragesic (transdermal patch): 12.5-200 mcg/hr q72h; Oralet, Actiq (buccal lozenges): begin with lowest dose (200 mcg) and titrate as needed NOTE: The FDA has placed restrictions on transmucosal fentanyl (only allowed for chronic pain)	Relief of chronic pain, including cancer pain
meperidine HCl (Demerol) (D)	Opioid analgesic	**Pediatric** PO/IM/IV/subcut: 1-1.8 mg/kg q3-4h prn (max 100 mg/dose)	Meperidine use not recommended because of the unpredictable effects of neurometabolites at analgesic doses and risk for seizures
		Adult PO/IV/IM/subcut: 50-150 mg q3-4h prn	Obstetric analgesia, preoperative sedation
methadone HCl (Dolophine) (D)	Opioid analgesic	**Adult** PO/IM/IV/subcut: 2.5-10 mg q8-12h; 40 mg or more once daily	Opioid analgesia, relief of chronic pain, opioid detoxification Opioid addiction maintenance
morphine sulfate (MSIR, Roxanol, others) (D)	Opiate analgesic; opium alkaloid	**Pediatric younger than 6 mo** PO: less than 6 months: 0.1 mg/kg/dose q3-4h prn IV/IM/subcut: 0.03-0.05 mg/kg q3-8h prn **Older than 6 mo** PO: 0.2-0.5 mg/kg/dose q4h prn IV/IM/subcut: 0.05-0.2 mg/kg q2-4h prn	Opioid analgesia
		Adult PO: 10-30 mg q4h prn IV/IM /subcut: 2.5-15 mg q2-6h prn	Opioid analgesia
♦ morphine sulfate, continuous-release (MS Contin, Oramorph, Kadian, Avinza) (D)	Opiate analgesic; opium alkaloid	**Adult only** PO: 15 mg q8h to 200 mg q8-12h	Relief of moderate to severe pain
oxycodone, immediate-release (OxyIR) (D)	Opioid, synthetic	**Pediatric** PO: 0.1-0.3 mg/kg q3h prn	Relief of moderate to severe pain
		Adult PO: 5-20 mg q4-6h prn	Relief of moderate to severe pain
oxycodone, continuous-release (OxyContin) (D)	Opioid, synthetic	**Adult only** PO: 10-160 mg q8-12h	Relief of moderate to severe pain

DOSAGES—cont'd

Selected Analgesic Drugs and Related Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
Opioid Antagonists			
♦ naloxone HCl (Narcan)	Opioid antagonist	**Pediatric**	Treatment of opioid overdose
		IV: 0.01 mg/kg IV followed by 0.1 mg/kg if needed (Note: PALS doses vary)	
		IV: 0.0005-0.01 mg/kg IV—repeat at 2-3 min intervals	Postoperative anesthesia reversal
		Adult	Treatment of opioid overdose
		IV: 0.4-2 mg IV—repeat in 2-8 min if needed	
		IV: 0.1-0.2 mg IV—repeat at 2-3 min intervals	Postoperative anesthesia reversal
naltrexone HCl	Opioid antagonist	**Adult**	Maintenance of opioid-free state
		PO: 50 mg q24h or 100 mg every other day	
Nonopioids			
♦ acetaminophen (Tylenol, others) (B)	Nonopioid analgesic, antipyretic	**Pediatric**	Relief of mild to moderate pain
		PO/PR: Variable doses by age from 40 to 480 mg q4-6h	
		Adult	Relief of mild to moderate pain
		PO/PR: 325-650 mg q4-6h; not to exceed 3 g/day	
		In alcoholics, not to exceed 2 g/day	
tramadol (Ultram)	Nonopioid analgesic (with opioid-like activity)	**Adult**	Relief of moderate to moderately severe pain
		PO: 50-100 mg q4-6h; not to exceed 400 mg/day	

FDA, U.S. Food and Drug Administration; *HCl,* hydrochloride; *IM,* intramuscular; *IV,* intravenous; *IR,* immediate release; *MS,* morphine sulfate; *MSIR,* morphine sulfate immediate-release; *PCA,* patient-controlled analgesia; *PO,* oral; *PR,* rectal; *subcut,* subcutaneous.
*Actiq is not approved for use in patients younger than 16 years of age.
The maximum recommended daily dose of acetaminophen for a typical adult patient with normal liver function is 3000 mg/24 hr. For hepatically compromised patients, this dosage may be 2000 mg or even lower. If in doubt, check with a pharmacist or prescriber regarding a particular patient.

when larger doses of hydromorphone are given. Morphine is available in oral, rectal, epidural, and injectable dosage forms, including PCA cartridges. Epidural dosage forms are injected onto the dura mater of the spinal cord. DepoDur is a liposomal epidural morphine product. Liposomes are a lipid-based drug vehicle that facilitates drug absorption through the lipid layer of cell membranes. Epidural analgesics have the potential for causing increased intracranial pressure, especially with multiple injections, and increased CNS depression when given with other CNS depressant drugs. Other CNS depressant drugs are not to be given without orders from an anesthesiologist. For dosage information, see the table on p. 152.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IM	Rapid	30-60 min	1.7-4.5 hr	6-7 hr

codeine sulfate

Codeine sulfate is a natural opiate alkaloid (Schedule II) obtained from opium. It is similar to morphine in terms of its pharmacokinetic and pharmacodynamic properties. In fact, about 10% of a codeine dose is metabolized to morphine in the body. However, codeine is less effective as an analgesic and is the only agonist to possess a ceiling effect (meaning increasing the dose will not increase response). Therefore it is more commonly used as an antitussive drug in an array of cough preparations (see Chapter 36). Codeine combined with acetaminophen (tablets or elixir) is classified as a Schedule III controlled substance and is commonly used for control of mild to moderate pain as well as cough. When codeine is not combined with other drugs, it is classified as a Schedule II controlled substance, which implies a high abuse potential. Codeine causes GI tract upset, and many patients will say they are allergic to codeine, when in fact it just upsets their stomach. For dosage information, see the table on p. 152.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	15-30 min	34-45 min	2.5-4 hr	4-6 hr

fentanyl

Fentanyl is a synthetic opioid (Schedule II) used to treat moderate to severe pain. Like other opioids, it also has a high abuse potential. It is available in several dosage forms: parenteral injections, transdermal patches (Duragesic), buccal lozenges (Fentora), and buccal lozenges on a stick (Actiq). The buccal dosage forms are absorbed through the oral mucosa.

They may be especially helpful in managing breakthrough and procedural pain. The injectable form is used most commonly in perioperative settings and in intensive care unit settings for sedation during mechanical ventilation. The oral and transdermal forms are used primarily for long-term control of both malignant and nonmalignant chronic pain. Fentanyl is a very potent analgesic. Fentanyl in a dose of 0.1 mg intravenously is roughly equivalent to 10 mg of morphine intravenously.

The transdermal delivery system (patch) has been shown to be highly effective in the treatment of various chronic pain syndromes such as cancer-induced pain, especially in patients who cannot take oral medications. This route is not to be used in opioid-naïve patients or for acute pain relief. Fentanyl patches are difficult to titrate and are best used for nonescalating pain. To perform a conversion using the table in Box 10-3, first determine the daily (24-hour) opioid requirement of the patient. Second, if the opioid is not morphine, convert its dose to the equianalgesic dose of morphine using Box 10-3. Finally, calculate the equipotent transdermal fentanyl dosage. These tables are conservative in their dosages for achieving pain relief, and supplemental short-acting opioid analgesics are be added as needed.

Fentanyl patches take 6 to 12 hours to reach steady-state pain control after the first patch is applied, and supplemental short-acting therapy may be required. Most patients will experience adequate pain control for 72 hours with this method of fentanyl delivery. A new patch is to be applied every 72 hours. It is important to remove the old patch when applying a new one. It takes about 17 hours for the amount of fentanyl to reduce by 50% once the patch is removed.

The U.S. Food and Drug Administration (FDA) has issued many safety warnings about the use of fentanyl patches. Fentanyl patches are intended for management of chronic or cancer pain in opioid-tolerant patients whose pain is not adequately controlled by other types of medications. These patches are not recommended for acute pain situations such as postoperative pain. Deaths have occurred from drug-induced respiratory arrest when these conditions have not been met. According to the FDA, patients who are considered opioid tolerant are those who have been taking at least 60 mg of oral morphine daily or at least 30 mg of oral oxycodone daily or at least 8 mg of oral hydromorphone daily or an equianalgesic dose of another opioid. Other hazards associated with the use of fentanyl patches are cutting the patch and exposing the patch to heat (e.g., via a heating pad or sauna), both of which accelerate the diffusion of the drug into the patient's body.

For dosage information, see the table on p. 152.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Rapid	Minutes	1.5-6 hr	30-60 min
Transdermal	12-24 hr	48-72 hr	Delayed	13-40 hr
PO	5-15 min	20-30 min	5-15 hr	Unknown

meperidine hydrochloride

Meperidine hydrochloride (Demerol) is a synthetic opioid analgesic (Schedule II). Meperidine must be used with caution, if at all, in elderly patients and in patients who require long-term analgesia or who have kidney dysfunction. An active metabolite, normeperidine, can accumulate to toxic levels and lead to seizures. For this reason, meperidine is now used less commonly than before and is definitely not recommended for long-term pain treatment. However, it is still used for acute pain during postoperative periods, as well as in emergency department settings for acute migraine headaches. Meperidine is available in oral and injectable forms. For dosage information, see the table on p. 152.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IM	Rapid	30-60 min	3-5 hr	2-4 hr

methadone hydrochloride

Methadone hydrochloride (Dolophine) is a synthetic opioid analgesic (Schedule II). It is the opioid of choice for the detoxification treatment of opioid addicts in methadone maintenance programs. Use of agonist-antagonist opioids (e.g., pentazocine) in heroin-addicted patients or those in methadone maintenance programs can induce significant withdrawal symptoms. There has been renewed interest in the use of methadone for chronic (e.g., neuropathic) and cancer-related pain. The drug is readily absorbed through the GI tract with peak plasma concentrations at 4 hours for single dosing. Methadone is unique in that its half-life is longer than its duration of activity because it is bound into the tissues of the liver, kidneys, and brain. With repeated doses, the drug accumulates in these tissues and is slowly released, thus allowing for 24-hour dosing. Methadone is eliminated through the liver, which makes it a safer choice than some other opioids for patients with renal impairment. Recent FDA reports have cited the prolonged half-life of the drug as a cause of unintentional overdoses and deaths. There is also concern that methadone may cause cardiac dysrhythmias. Methadone is available in oral and injectable forms. For dosage information, see the table on p. 152.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-60 min	1.5-2 hr	25 hr	22-48 hr

oxycodone hydrochloride

Oxycodone hydrochloride is an analgesic drug that is structurally related to morphine and has comparable analgesic activity (Schedule II). It is also commonly combined in tablets with acetaminophen (Percocet) and with aspirin (Percodan). Oxycodone is also available in immediate-release formulations (Oxy IR) and sustained-released formulations (OxyContin).

A somewhat weaker but commonly used opioid is hydrocodone (Schedule III), which is available only in tablet form, most commonly in combination with acetaminophen (Vicodin) but also with aspirin and ibuprofen. It is available only for oral use. For dosage information, see the table on p. 152.

Pharmacokinetics (Immediate Release)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	10-15 min	1 hr	2-3 hr	3-6 hr

OPIOID AGONISTS-ANTAGONISTS

Opioids with mixed actions are often called *agonists-antagonists* (Schedule IV). They bind to the mu receptor and can therefore compete with other substances for these sites. They either exert no action (i.e., they are competitive antagonists) or have only limited action (i.e., they are partial agonists). They are similar to the opioid agonists in terms of their therapeutic indications; however, they have a lower risk of misuse and addiction. The antagonistic activity of this group can produce withdrawal symptoms in opioid-dependent patients. Their use is contraindicated in patients who have shown hypersensitivity reactions to the drugs.

These drugs have varying degrees of agonist and antagonist effects on the different opioid receptor subtypes. They are used in situations requiring short-term pain control, such as after obstetric procedures. They are sometimes chosen for patients who have a history of opioid addiction. These medications can both help prevent overmedication and reduce posttreatment addictive cravings in these patients. Combination products of buprenorphine and naloxone offer physicians an in-office treatment of addiction (see Chapter 17). These drugs are normally not strong enough for management of longer-term chronic pain (e.g., cancer pain, chronic lower back pain). They are *not* to be given concurrently with full opioid agonists, because they may both reduce analgesic effects and cause withdrawal symptoms in opioid-tolerant patients. Adverse reactions are similar to opioids but with a lower incidence of respiratory depression. Four opioid agonists-antagonists are currently available: buprenorphine (Buprenex), butorphanol (Stadol), nalbuphine (Nubain), and pentazocine (Talwin). They are available in various oral, injectable, and intranasal dosage forms as indicated in the dosage table. All except butorphanol are also available in combination with the opioid antagonist naloxone to enhance their opioid antagonistic effects, which are usually weaker than the agonistic effects of these drugs.

OPIOID ANTAGONISTS

Opioid antagonists produce their antagonistic activity by competing with opioids for CNS receptor sites.

♦ naloxone hydrochloride

Naloxone hydrochloride (Narcan) is a pure opioid antagonist. It has no agonistic morphine-like properties and works as a blocking drug for the opioid drugs. Accordingly, the drug does not produce analgesia or respiratory depression. Naloxone is the drug of choice for the complete or partial reversal of opioid-induced respiratory depression. It is also indicated in cases of suspected acute opioid overdose. Failure of the drug to significantly reverse the effects of the presumed opioid overdose indicates that the condition may not be related to opioid overdose. The primary adverse effect is opioid withdrawal syndrome, which can occur with abrupt overreversal in opioid-tolerant patients. Naloxone is available only in injectable dosage forms. Use of the drug is contraindicated in patients with a history of hypersensitivity to it. For dosage information, see the table on p. 152.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Less than 2 min	Rapid	64 min	0.5-2 hr

naltrexone hydrochloride

Naltrexone hydrochloride (ReVia) is an opioid antagonist used as an adjunct for the maintenance of an opioid-free state in former opioid addicts. The FDA has identified it as a safe and effective adjunct to psychosocial treatments of alcoholism. It is also indicated for reversal of postoperative opioid-induced respiratory depression. Nausea and tachycardia are the most common adverse effects and are related to reversal of the opioid effect. Use of naltrexone hydrochloride is contraindicated in cases of known drug allergy and in patients with hepatitis or other severe liver dysfunction. It is available only for oral use. For dosage information, see the table on p. 152.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Rapid	1 hr	4-13 hr	24-72 hr

NONOPIOID AND MISCELLANEOUS ANALGESICS

Acetaminophen (Tylenol) is the most widely used nonopioid analgesic. Acetaminophen is commonly abbreviated APAP in the U.S.; however, this abbreviation is not recognized in Canada. There is a current movement to stop using APAP as an abbreviation, because of the potential that patients will not realize they are receiving a prescription with acetaminophen and may take additional over-the-counter acetaminophen.

All of the drugs in the NSAID class (which includes aspirin, ibuprofen, naproxen, the cyclooxygenase-2 [COX-2] inhibitor celecoxib [Celebrex], and others) are nonopioid analgesics. These drugs are discussed in greater detail in Chapter 44. They are used for management of pain, especially pain associated with inflammatory conditions such as arthritis, because they have significant antiinflammatory effects in addition to their analgesic effects.

Miscellaneous analgesics include tramadol and transdermal lidocaine and are discussed in depth in their respective drug

profiles in this chapter. Capsaicin is a topical product made from several different types of peppers. It works by decreasing or interfering with substance P, a pain signal in the brain. Capsaicin is available over the counter. It can be used for muscle pain, joint pain, and nerve pain. Milnacipran (Savella) is a selective serotonin and norepinephrine dual-uptake inhibitor. It is indicated for the treatment of fibromyalgia. It is thought that patients with fibromyalgia have reduced levels of norepinephrine in their brains, and milnacipran increases norepinephrine levels, which helps reduce pain associated with the disease.

Mechanism of Action and Drug Effects

The mechanism of action of acetaminophen is similar to that of the salicylates. It blocks peripheral pain impulses by inhibition of prostaglandin synthesis. Acetaminophen also lowers febrile body temperatures by acting on the hypothalamus, the structure in the brain that regulates body temperature. Heat is dissipated through vasodilation and increased peripheral blood flow. In contrast to NSAIDs, acetaminophen lacks antiinflammatory effects. Although acetaminophen shares the analgesic and antipyretic effects of the salicylates and other NSAIDs, it does not have many of the unwanted effects of these drugs. For example, acetaminophen products are not usually associated with cardiovascular effects (e.g., edema) or platelet effects (e.g., bleeding), as are aspirin and other NSAIDs. They also do not cause the aspirin-related GI tract irritation or bleeding nor any of the aspirin-related acid-base changes.

Indications

Acetaminophen is indicated for the treatment of mild to moderate pain and fever. It is an appropriate substitute for aspirin because of its analgesic and antipyretic properties. Acetaminophen is a valuable alternative for those patients who cannot tolerate aspirin or for whom aspirin may be contraindicated.

Acetaminophen is also the antipyretic (antifever) drug of choice in children and adolescents with flu syndromes, because the use of aspirin in these populations is associated with a condition known as *Reye's syndrome.*

Contraindications

Contraindications to acetaminophen use include known drug allergy, severe liver disease, and the genetic disease known as *glucose-6-phosphate dehydrogenase (G6PD) deficiency.*

Adverse Effects

Acetaminophen is generally well tolerated and is therefore available over the counter and in many combination prescription drugs. Possible adverse effects include rash, nausea, and vomiting. Much less common but more severe are the adverse effects of blood disorders or dyscrasias (e.g., anemias) and nephrotoxicities, and, of most concern, hepatotoxicity.

Toxicity and Management of Overdose

Many people do not realize that acetaminophen, despite its over-the-counter status, is a potentially lethal drug when taken in overdose. Depressed patients (especially adolescents) may intentionally overdose on the drug as an attention-seeking gesture without realizing the grave danger involved.

The ingestion of large amounts of acetaminophen, as in acute overdose, or chronic unintentional misuse can cause hepatic necrosis. Acute ingestion of acetaminophen doses of 150 mg/kg (approximately 7 to 10 grams) or more may result in hepatic toxicity. Acute hepatotoxicity can usually be reversed with acetylcysteine, whereas long-term toxicity is more likely to be permanent.

The standard maximum daily dose of acetaminophen for healthy adults is 4000 mg. However, limitation to 2000 mg or less may be necessary for patients with risk factors such as advanced age (elderly) or liver dysfunction. Excessive dosing may occur inadvertently with the use of combination products that include a fixed ratio of an opioid drug plus acetaminophen (e.g., hydrocodone plus acetaminophen). Prescribers must be mindful of recommended daily dose limits when prescribing these medications. In 2011, the FDA announced that combination products are to be limited to 325 mg of acetaminophen, and a maximum daily dose of 3000 mg/day is being considered.

The long-term ingestion of large doses of acetaminophen is more likely to result in severe hepatotoxicity, which may be irreversible. Because the reported or estimated quantity of drug ingested is often inaccurate and not a reliable guide to the therapeutic management of the overdose, serum acetaminophen concentration is determined no sooner than 4 hours after the ingestion. If a serum acetaminophen level cannot be determined, it is assumed that the overdose is potentially toxic and treatment with acetylcysteine needs to be started. Acetylcysteine is the recommended antidote for acetaminophen toxicity and works by preventing the hepatotoxic metabolites of acetaminophen from forming. It is most effective when given within 10 hours of an overdose. Historically, the usual dosage regimen is a 140 mg/kg oral loading dose, followed by 70 mg/kg every 4 hours for 17 additional doses. This drug is notoriously bad tasting with an odor of rotten eggs, and vomiting of an oral dose is common. It is recommended that the dose be repeated if vomiting occurs within 1 hour of dosing. An intravenous dosage formulation of acetylcysteine (Acetadote) is also available.

Interactions

A few drugs can interact with acetaminophen. Alcohol is potentially the most dangerous. Chronic heavy alcohol abusers may be at increased risk of liver toxicity from excessive acetaminophen use. For this reason, a maximum daily dose of 2000 mg is generally recommended. Health care professionals need to warn patients with regular intake of alcohol not to exceed recommended dosages of acetaminophen because of the risk of liver dysfunction and possible liver failure. Ideally, alcohol consumption is not to exceed three drinks daily. Other hepatotoxic drugs need to be avoided. Other drugs that potentially can interact with acetaminophen include phenytoin, barbiturates, warfarin, isoniazid, rifampin, beta blockers, and anticholinergic drugs, all of which are discussed in greater detail in later chapters.

DRUG PROFILES

♦ acetaminophen

Acetaminophen (Tylenol) is an effective and relatively safe nonopioid analgesic used for mild to moderate pain relief. It is best avoided in patients who are alcoholic or who have hepatic disease. Acetaminophen is available in oral, rectal, and most recently, IV form. Acetaminophen is also a component of several prescription combination drug products, including hydrocodone/acetaminophen (Vicodin) and oxycodone/acetaminophen (Percocet).

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	10-30 min	0.5-2 hr	1-4 hr	3-4 hr

tramadol hydrochloride

Tramadol hydrochloride (Ultram) is categorized as a miscellaneous analgesic due to its unique properties. It is a centrally acting analgesic with a dual mechanism of action. It creates a weak bond to the mu opioid receptors and inhibits the reuptake of both norepinephrine and serotonin. Although it does have weak opioid receptor activity, tramadol is not currently classified as a controlled substance. Tramadol is indicated for the treatment of moderate to moderately severe pain. Tramadol is rapidly absorbed, and its absorption is unaffected by food. It is metabolized in the liver to an active metabolite and eliminated via renal excretion. Adverse effects are similar to those of opioids and include drowsiness, dizziness, headache, nausea, constipation, and respiratory depression. Seizures have been reported in patients taking tramadol and occur in patients taking both normal and excessive dosages. Patients who may be at risk are those receiving tricyclic antidepressants, selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors, neuroleptics, or other drugs that reduce the seizure threshold. There is also an increased risk of developing serotonin syndrome when tramadol is taken concurrently with SSRIs (see Chapter 16).

Use of tramadol is contraindicated in cases of known drug allergy, which may include allergy to opioids due to potential cross-reactivity. It is also contraindicated in cases of acute intoxication with alcohol, hypnotics, centrally acting analgesics, opioids, or psychotropic drugs. The drug is only available in oral dosage forms, including a combination with acetaminophen (Ultracet), as well as extended-release formulation (ConZip, Ryzolt, Ultram ER) and as an orally disintegrating tablet called Rybix. A new drug, tapentadol (Nucynta), is structurally related to tramadol with a duel mechanism of action. It is a mu agonist and a norepinephrine reuptake inhibitor. It is a Schedule II narcotic.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30 min	2 hr	5-8 hr	6 hr

lidocaine, transdermal

Transdermal lidocaine is a topical anesthetic (see Chapter 11) and cardiac antidysrhythmic (see Chapter 23) that is formulated into a patch (Lidoderm), which is placed onto painful areas of the skin. It is indicated for the treatment of postherpetic neuralgia, a painful skin condition that remains after a skin outbreak of shingles. Shingles is caused by the herpes zoster virus, also known as the varicella-zoster virus, which causes chickenpox in children. Lidocaine patches provide local pain relief, and up to three patches may be placed on a large painful area. However, the patches are not to be worn for longer than 12 hours a day to avoid potential systemic drug toxicity (e.g., cardiac dysrhythmias). Because they act topically, there are minimal systemic adverse effects. However, the skin at the site of treatment may develop redness or edema, and unusual skin sensations may occur. These reactions are usually mild and transient and resolve within a few minutes to hours. Patches are applied only to intact skin with no blisters. They can be used either alone or as part of adjunctive treatment with systemic therapies such as antidepressants (see Chapter 16), opioids, or anticonvulsants (see Chapter 14). Used patches must be disposed of securely because they may be dangerous to children or pets. Specific pharmacokinetic data are not listed due to the continuous nature of dosing. Studies have demonstrated that a patch can provide varying degrees of pain relief for 4 to 12 hours.

NURSING PROCESS

Pain may be acute or chronic and occurs in patients in all settings and across the lifespan, thus leading to much suffering and distress. Patients experiencing pain pose many challenges to the nurse, prescribers, and other health care providers involved in their care. The challenge is that pain is a complex and multifaceted problem that requires astute assessment skills with appropriate interventions based on the individual, the specific type of pain, related diseases, and/or health status.

Medical associations, health care organizations, governing bodies, and professional nursing organizations have been involved in defining standards and outcomes of care related to assessment and management of pain. For example, The Joint Commission (www.jointcommission.org) and the Agency for Healthcare Research and Quality (www.ahrq.gov/whatsnew.asp#qt) have developed such standards. In addition, the WHO (www.who.int/en) has developed standards related specifically to cancer pain. Professional nursing organizations, such as the Oncology Nursing Society and the American Nurses Association, have also created standards of care related to pain assessment and management. In 2009, the American Pain Society also published opioid guidelines available at http://www.ampainsoc.org/.

ASSESSMENT

Adequate analgesia requires a holistic, comprehensive, and individualized patient assessment with specific attention to the type, intensity, and characteristics of the pain and the levels of

comfort. Comfort, in this situation, is defined as the extent of physical and psychological ease that an individual experiences. Perform a thorough health history, nursing assessment, and medication history as soon as possible or upon the first encounter with the patient, including questions about the following: (1) allergies to nonopioids, opioids, partial or mixed agonists, and/or opioid antagonists (see previous pharmacologic discussion for examples of specific drugs); (2) potential drug-drug and/or drug-food interactions; (3) presence of diseases or CNS depression; (4) history of the use of alcohol, street drugs, or any illegal drug or substance and/or history of substance abuse, with information about the substance, dose, and frequency of use; (5) results of laboratory tests ordered, such as levels of serum ALT, ALP, GGT, 5′-nucleotidase, and bilirubin (indicative of liver function), and/or levels of BUN and creatinine (reflective of renal function); abnormal liver or renal function may require that lower doses of analgesic be used to prevent toxicity or overdosage (see the Safety: Laboratory Values related to Drug Therapy box on p. 151); (6) character and intensity of the pain, including onset, location, and quality (e.g., stabbing/knifelike, throbbing, dull ache, sharp, diffuse, localized, or referred); actual rating of the pain using a pain assessment scale (see later); and any precipitating, aggravating, and/or relieving factors; (7) duration of the pain (acute versus chronic); and (8) types of pharmacologic, nonpharmacologic, and/or adjunctive measures that have been implemented, with further explanation of the treatment's duration of use and overall effectiveness.

To be thorough and effective, include in your assessment the factors or variables that may impact an individual's pain experience, such as physical factors (e.g., age, gender, pain threshold, overall state of health, disease processes or pathologies) and emotional, spiritual, and cultural variables (e.g., reaction to pain, pain tolerance, fear, anxiety, stressors, sleep patterns, societal influences, family roles, phase of growth and development, and religious, racial, and/or ethnic beliefs or practices). Age-appropriate assessment tools are recommended in assessing pain across the lifespan (see later discussion). For pediatric and elderly patients, nonverbal behavior or cues and information from family members or caregivers may be helpful in identifying pain levels. In an elderly individual, physical and cognitive impairments may affect reporting of pain; however, this does not mean that the elderly patient is not experiencing pain—the patient's reporting may just be altered. Chronic pain and pain associated with cancer are both complex and multifactorial problems requiring a holistic approach with attention to other patient complaints, such as a decrease in activities of daily living, insomnia, depression, social withdrawal, anxiety, personality changes, and quality of life issues.

Perform a system-focused nursing assessment with collection of both subjective and objective data as follows: neurologic status (e.g., level of orientation and alertness, level of sedation, sensory and motor abilities, reflexes); respiratory status (e.g., respiratory rate, rhythm, and depth; breath sounds); GI status (e.g., presence of bowel sounds; bowel patterns; complaints of constipation, diarrhea, nausea, vomiting, or abdominal discomfort); genitourinary status (e.g., urinary output; any burning or discomfort on urination; urinary retention); and cardiac status (e.g., pulse rate and rhythm, blood pressure, any problems with

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

Opioid Use

- Assessment of the pediatric patient is challenging, and all types of behavior that may indicate pain, such as muscular rigidity, restlessness, screaming, fear of moving, and withdrawn behavior, must be carefully considered.
- Adequacy of pain management is more difficult to determine in children because of their inability to express themselves. Frequently the reason older pediatric patients do not verbalize their pain is their fear of treatment, such as injections. Compassionate and therapeutic communication skills, as well as the use of alternate routes of administration, as ordered, will help in these situations.
- The "ouch scale" is often used to determine the level of pain in children. This scale is used to obtain the child's rating of the intensity of pain from 0 to 5 by means of simple face diagrams, from a very happy face for level 0 (no pain) to a sad, tearful face for level 5 (severe pain). Pain assessment is very important in pediatric patients because they are often undermedicated. Always thoroughly assess the pediatric patient's verbal and nonverbal behavior, and never underestimate the patient's complaints! Remember that parents and caregivers can play a very important role in this assessment.
- The patient's baseline age, weight, and height are important to document, because drug calculations are often based on these variables. With the pediatric patient, check and double-check *all* mathematical calculations for accuracy to avoid excessive dosages; this is especially true for opioids.
- Analgesics must be given, as ordered, before pain becomes severe, with oral dosage forms used first, if appropriate.
- If suppositories are used, be careful to administer the exact dose and not to split, halve, or divide an adult dose into a child's dose. This may result in the administration of an unknown amount of medication and possible overdose.
- When subcutaneous, intramuscular, and intravenous medications are used, the principle of atraumatic care in the delivery of nursing care must be followed. One technique used to help ensure atraumatic care is the application of a mixture of local anesthetics or other prescribed substances to the injection site before the injection is given. EMLA (lidocaine/prilocaine) is a topical cream that anesthetizes the site of the injection; if ordered, apply 1 to 2½ hours before the injection. Consult institutional policies and procedures for further instructions regarding its use.
- Distraction and creative imagery may be used for older children such as toddlers or preschool-age children.
- Always monitor pediatric patients very closely for any unusual behavior while receiving opioids.
- Report the following signs and symptoms of central nervous system changes to the prescriber immediately if they occur: dizziness, lightheadedness, drowsiness, hallucinations, changes in the level of consciousness, and sluggish pupil reaction. Do not administer further medication until the nurse receives further orders from the prescriber.
- Always monitor and document vital signs before, during, and after the administration of opioid analgesics. An opioid medication is usually withheld if a patient's respirations are less than 12 breaths/min or if there are any changes in the level of consciousness. Always follow protocol, and never ignore a patient's status!
- Generally speaking, smaller doses of opioids, with very close and frequent monitoring, are indicated for the pediatric patient. Giving oral medications with meals or snacks may help to decrease GI upset.

dizziness or syncope). Assess and document vital signs, including blood pressure, pulse rate, respirations, temperature, and level of pain (now considered as the fifth vital sign). It is important to pull from one's knowledge base and remember that during the acute pain response, stimulation of the sympathetic nervous system may result in elevated values for vital signs, with an increase in blood pressure (120/80 mm Hg or higher), pulse rate (100 beats/min or higher), and respiratory rate and depth (20 breaths/min or higher and shallow breathing).

A variety of pain assessment tools are available that may be used to gather information about the fifth vital sign. One very basic assessment tool is the Numeric Pain Intensity Scale (0 to 10 pain rating scale); patients are asked to rate their pain intensity by picking the number that most closely represents their level of pain. The Verbal Rating Scale, another pain assessment tool, uses verbal descriptors for pain, including words such as *mild, moderate, severe, aching, agonizing,* or *discomfort.* The FACES Pain Rating Scale is helpful in assessing pain in patients of all ages and educational levels because it relies on a series of faces ranging from happy to sad to sad with tears. The patient is asked to identify the face that best represents the pain he or she is experiencing at that moment. When the patient is in acute pain, when pain intensity is a primary focus for assessment, and/or when the need is to determine the efficacy of pain management intervention, the simple, one-dimensional scales (e.g., the Numeric Pain Intensity Scale) work best. The elderly, especially those with cognitive impairment, may need more time to respond to the assessment tool and may also require large-print versions of written tools. There are other assessment tools that are multidimensional scales and are more beneficial in assessing patients who experience chronic rather than acute pain. One example is the Brief Pain Inventory assessment tool, which includes a body map so that the patient can identify on the figure the exact area where pain is felt. This tool also helps in obtaining information about the impact of pain on functioning. Assess pain before, during, and after the pain intervention, as well as the level of pain during activity and at rest. The following sections provide assessment information for specific drug classes.

NONOPIOIDS

For patients receiving *nonopioid analgesics,* focus the assessment not only on general data as described earlier but also on the specific drug being given. For example, in those patients taking acetaminophen, begin the assessment by determining whether the patient has allergies, is pregnant, and/or is breastfeeding. As mentioned in the pharmacology section, acetaminophen is contraindicated in those with severe liver disease and in patients with G6PD deficiency. Additionally, due to possible adverse effects of blood disorders (anemias), renal/liver toxicity, cautious use is necessary. See pharmacology discussion for more information about acute overdose and chronic unintentional misuse. Also assess for any other medications the patient is taking, because of the risk of excessive doses when taking combination products consisting of acetaminophen. Inadvertent overdosing is a possible consequence of this situation. Other drug interactions and concerns are addressed in the pharmacology discussion.

Once therapy has been initiated, closely monitor for chronic acetaminophen poisoning, looking for symptoms such as rapid, weak pulse, dyspnea, and cold and clammy extremities. Long-term daily use of acetaminophen may lead to increased risk of permanent liver damage, and therefore you must frequently monitor the results of liver function studies. Adults who ingest higher than recommended dosages may be at higher risk of liver dysfunction as well as other adverse effects such as loss of appetite, jaundice, nausea, and vomiting. Children are also at high risk of liver dysfunction if the recommended dosage ranges are exceeded. With the use of NSAIDs (e.g., ibuprofen, aspirin, and COX-2 inhibitors), assess renal and liver functioning and gather information about GI disorders such as ulcers (see Chapter 44 for more information on antiinflammatory drugs). With aspirin, age is important; this drug is not to be given to children and adolescent patients because of the risk of Reye's syndrome. Aspirin may also lead to bleeding and ulcers, so ruling out conditions that represent contraindications and cautions to its use before therapy begins is important to patient safety. With tramadol hydrochloride, assessment of age is important because this drug is not recommended for use in individuals 75 years of age or older.

A miscellaneous nonopioid analgesic, lidocaine transdermal, is another option for managing different types of pain. For lidocaine transdermal patches, understand that this transdermal drug is indicated in those with postherpetic neuralgia, and thus assess the herpetic lesion(s) and surrounding skin. When these patches are used, they must be kept away from children and are not to be prescribed for very young, small, or debilitated patients because these patients are at higher risk for toxicity. Liver function also needs to be assessed and monitored.

OPIOIDS

When *opioid analgesics,* or any other CNS depressants, are prescribed, focus assessment on vital signs; allergies; respiratory disorders; respiratory function (rate, rhythm, depth, and breath sounds); presence of head injury (which will mask signs and symptoms of increasing intracranial pressure); neurologic status, with attention to level of consciousness or alertness and the level of sedation; sensory and motor functioning; GI tract functioning (bowel sounds and bowel patterns); and genitourinary functioning (intake and output). In addition, all opioids may cause spasms of the sphincter of Oddi. If renal and liver function studies are ordered, monitor results, because the risk of toxicity increases with diminished function of these organs. An additional concern is any past or present history of neurologic disorders such as Alzheimer's disease, dementia, multiple sclerosis, muscular dystrophy, myasthenia gravis, or cerebrovascular accident or stroke, because the use of opioids may alter symptoms of the disease process, possibly masking symptoms or worsening the clinical presentation when no actual pathologic changes have occurred. In these situations, use of another analgesic or pain protocol may be indicated. Attention to age is also important, because both elderly and very young patients are more sensitive to opioids—as to many other medications. In fact, old or young age may be a contraindication to opioid use, depending on the specific drug. See the earlier pharmacology

discussion regarding cautions, contraindications, and drug interactions.

OPIOID AGONISTS-ANTAGONISTS

In patients taking *opioid agonists-antagonists,* such as buprenorphine hydrochloride, assess vital signs with attention to respiratory rate and breath sounds. The opioid agonists-antagonists still possess opioid agonist effects, and therefore the assessment information related to opioids is applicable to these drugs as well. It is also very important to remember during assessment that these drugs are still effective analgesics and still have CNS depressant effects but are subject to a ceiling effect (see earlier definition). Given the action of these drugs, the assessment may help determine whether the patient is an abuser of opioids. This is important because the simultaneous administration of agonists-antagonists with another opioid will lead to reversal of analgesia and possible opioid withdrawal. Age is another factor to assess, because these drugs are not recommended for use in patients 18 years of age or younger. See previous discussion for a listing of contraindications, cautions, and drug interactions.

OPIOID ANTAGONISTS

Remember that the *opioid antagonists* are used mainly in reversing respiratory depression secondary to opioid overdosage. Naloxone may be used in patients of all ages, including neonates and children. Assess and document vital signs before, during, and after the use of the antagonist so that the therapeutic effects can be further assessed and documented and the need for further doses determined. In addition, remember that the antagonist drug may not work with just one dosing and that repeated doses are generally needed to reverse the effects of the opioid. See the pharmacology section for information about contraindications, cautions, and drug interactions.

NURSING DIAGNOSES

1. Impaired gas exchange related to opioid-induced CNS effects and respiratory depression
2. Acute pain related to specific disease processes or conditions and other pathologies leading to various levels and types of pain
3. Chronic pain related to various disease processes, conditions, or syndromes causing pain
4. Constipation related to the CNS depressant effects on the GI system
5. Deficient knowledge related to lack of familiarity with opioids, their use, and their adverse effects

PLANNING

GOALS

1. Patient regains/maintains a respiratory rate between 10 and 20 breaths per minute without respiratory depression.
2. Patient states adequate acute pain relief associated with appropriate analgesic drug therapy regimen.
3. Patient experiences relief from chronic pain associated with appropriate pharmacologic therapy regimen.
4. Patient identifies measures to help maintain normal bowel elimination patterns and avoids/minimizes opioid-induced constipation.
5. Patient demonstrates adequate knowledge about the analgesic and/or other drug therapy and nondrug regimen.

OUTCOME CRITERIA

1. Patient states correct technique for coughing and deep breathing and adequate fluid intake while taking opioids and/or other analgesics for pain.
   - Patient's respiratory rate is within normal depth, rate, and patterns with clearing breath sounds.
2. Patient relates increased comfort levels as seen by decreased use of analgesics, increased activity and performance of activities of daily living, decreased complaints of acute pain, as well as decreased levels of pain as rated on a scale of 1 to 10.
3. Patient relates increased comfort levels as seen by decreased use of analgesics, increased activity and performance of activities of daily living, decreased complaints of chronic pain, as well as decreased levels of pain as rated on a scale of 1 to 10.
   - Patient uses nonpharmacologic measures such as relaxation therapy, distraction, and music therapy to help improve comfort and enhance any drug therapy regimens for chronic pain.
4. Patient states various measures to help minimize or avoid the occurrence of constipation with forcing of fluids, increasing fiber in the diet, and improving mobility.
5. Patient reports appropriate use of analgesics with minimal complications/adverse effects.
   - Patient states rationale for the use, action, and therapeutic effects associated with analgesic drugs for management of acute and/or chronic pain.
   - Patient states rationale for the use of nondrug approaches to pain management.
   - Patient states importance of taking medication as prescribed.

IMPLEMENTATION

Once the cause of pain has been diagnosed or other assessment and data gathering have been completed, begin pain management immediately and aggressively in conformity with the needs of each individual patient and situation. Pain management is varied and multifaceted and needs to incorporate pharmacologic as well as nonpharmacologic approaches (see Box 10-1 on p. 141 and the Safety: Herbal Therapies and Dietary Supplements box on p. 161). Pain management strategies must also include consideration of the type of pain and pain rating as well as pain quality, duration, and precipitating factors, and interventions that help the pain. Some general principles of pain management are as follows: (1) Individualize a plan of care based on the patient as a holistic and cultural being (see the Patient-Centered Care: Cultural Implications box on p. 141). (2) Manage mild pain with the use of nonopioid drugs such as acetaminophen, tramadol, and NSAIDs (see Chapter 44).

(3) Manage moderate to severe pain with a stepped approach using opioids. Other analgesics or types of analgesics may be used in addition to other categories of medication (see pharmacology discussion). (4) Administer analgesics as ordered but before the pain gets out of control. (5) Always consider the use of nonpharmacologic comfort measures (see Box 10-1) such as homeopathic and folk remedies, exercise, distraction, music or pet therapy, massage, and transcutaneous electrical stimulation. Although not always effective, these measures may prove beneficial for some patients. See Patient Teaching Tips for more information related to analgesics.

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

Feverfew (Chrysanthemum parthenium)

Overview
A member of the marigold family known for its antiinflammatory properties

Common Uses
Treatment of migraine headaches, menstrual cramps, inflammation, and fever

Adverse Effects
Nausea, vomiting, constipation, diarrhea, altered taste sensations, muscle stiffness, and joint pain

Potential Drug Interactions
Possible increase in bleeding with the use of aspirin and other nonsteroidal antiinflammatory drugs, dipyridamole, and warfarin

Contraindications
Contraindicated in those allergic to ragweed, chrysanthemums, and marigolds, as well as those about to undergo surgery

NONOPIOIDS

Give *nonopioid analgesics* as ordered or as indicated for fever or pain. Acetaminophen is to be taken as prescribed and within the recommended dosage range over a 24-hour period because of the risk of liver damage and acute toxicity. If a patient is taking other over-the-counter medications with acetaminophen, he or she needs to understand the importance of reading the labels very carefully (of other medications) to identify the total amount of acetaminophen taken and any other drug-drug interactions. In educating the patient, emphasize the signs and symptoms of acetaminophen overdose: bleeding, loss of energy, fever, sore throat, and easy bruising (due to hepatotoxicity). These must be reported immediately by the patient, family member, or caregiver to the nurse and/or prescriber. Any worsening or changing in the nature and/or characteristic of pain must also be reported. Suppository dosage forms of acetaminophen—like suppository forms of other drugs—are recommended to be placed into a medicine cup of ice. Once the suppository is unwrapped, cold water may be run over it to moisten the suppository for easier insertion. The suppository is inserted into the rectum using a gloved finger and water-soluble lubricating gel, if necessary. Acetaminophen tablets may be crushed if needed. Adult patients who take 3000 mg/day or greater of acetaminophen are at increased risk for acute hepatotoxicity. Death may occur after ingestion of more than 15 g. Liver damage from acetaminophen may be minimized by timely dosing with acetylcysteine (see previous discussion). If aceylcysteine is indicated, warn the patient about the drug's foul taste and odor. Many patients report that the drug smells and tastes like rotten eggs. Acetylcysteine is better tolerated if it is disguised by mixing with a drink such as cola or flavored water to increase its palatability. Use of a straw may help minimize contact with the mucous membranes of the mouth and is recommended. This antidote may be given through a nasogastric or orogastric tube or intravenously, if necessary.

Tramadol may cause drowsiness, dizziness, headache, nausea, constipation, and respiratory depression. If dizziness, blurred vision, or drowsiness occur, be sure to assist the patient with ambulation (as with the use of any analgesic that may lead to dizziness or lightheadedness) to minimize the risk of fall and injury. Educate the patient about injury prevention, including the need to dangle the feet over the edge of the bed before full ambulation, changing positions slowly, and asking for assistance when ambulating. In addition, while the patient is taking tramadol—as well as any other analgesics, and especially opioids—the patient needs to avoid any tasks that require mental clarity and alertness. Increasing fluids and fiber in the diet may help with constipation. Use of flat cola, ginger ale, or dry crackers may help to minimize nausea.

OPIOIDS

When *opioids* (and other analgesics) are prescribed, administer the drug as ordered after checking for the "Six Rights" of medication administration (see Chapter 1). After the prescriber's order has been double-checked, closely examine the medication profile and documentation to determine the last time the medication was given before another dose is administered. Monitor the patient's vital signs at frequent intervals with special attention to respiratory changes. A respiratory rate of 10 breaths/min (some protocols still adhere to the parameter of 12 breaths/min) may indicate respiratory depression and must be reported to the prescriber. The drug dosage, frequency, and/or route may need to be changed or an antidote (opioid antagonist) given if respiratory depression occurs. Naloxone must always be available, especially with the use of intravenous and/or other parenteral dosage forms of opioids, such as PCA (see Chapter 9 and the discussion to follow), and/or epidural infusions. Naloxone is indicated to reverse CNS depression, specifically respiratory depression, but remember that this antidote also reverses analgesia. Monitor the patient's urinary output as well; it should be at least 600 mL/24 hr. Monitor bowel sounds during therapy; decreased peristalsis may indicate the need for a dietary change, such as increased fiber, or use of a stool softener or mild laxative (see Box 10-2). Assess the patient's pupillary reaction to light. Pinpoint pupils indicate a possible overdose.

Opioids or any analgesic must be given before the pain reaches its peak to help maximize the effectiveness of the opioid or other analgesic. Once the drug is administered, return at the appropriate time (taking into consideration the times of onset and peak effect of the drug and the route) to assess the effectiveness of the drug and/or other interventions as well as

observe for the presence of adverse effects (see previous discussion of pain assessment tools). With regard to the route of administration, the recommendation is that oral dosage forms be used first, but only if ordered and if there is no nausea or vomiting. Taking the dose with food may help minimize GI upset. Should nausea or vomiting be problematic, an antiemetic may be ordered for administration before or with the dosing of medication. Crucial safety measures include keeping bed side rails up, turning bed alarms on (depending on the policies and procedures of the specific facility), and making sure the call bell/alarm is within the patient's reach. These measures will help to prevent falls or injury related to opioid use. Opioids and similar drugs lead to CNS depression with possible confusion, altered sensorium or alertness, hypotension, and altered motor functioning. Because of these drug effects, all patients are at risk for falls or injury, and the elderly are at higher risk (see Box 10-2 on p. 147 and the Patient-Centered Care: Lifespan Considerations for the Elderly Patient box below). See Box 10-4 below for more specific information concerning the handling of controlled substances and opioid counts.

When managing pain with morphine and similar drugs, withhold the dose and contact the prescriber if there is any decline in the patient's condition or if the vital signs are abnormal (see parameters mentioned earlier), especially if the respiratory rate

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

Opioid Use

- Record the patient's weight and height before opioid therapy is begun, if appropriate. Monitor the patient carefully for any changes in vital signs, level of consciousness, or respiratory rate, as well as any changes indicative of central nervous system depression, and report and document any such changes.
- Many institutionalized or hospitalized elderly patients are very stoic about pain; elderly patients may also have altered presentations of common illnesses so that the pain experience manifests in a different way or may simply be unable to state how they feel in a clear manner. Each and every patient—regardless of age—has the right to a thorough pain assessment and adequate and appropriate pain management. It is a myth that aging increases one's pain threshold. The problem is that cognitive impairment and dementia are often major barriers to pain assessment. Nevertheless, many elderly patients are still reliable in their reporting of pain, even with moderate to severe cognitive impairment.
- Over time, the elderly may lose reliability in recalling and accurately reporting chronic pain. The elderly, especially those 75 years of age or older, are at higher risk for too much or too little pain management, so you must remember that drugs have a higher peak and longer duration of action in these patients than in their younger counterparts.
- Smaller dosages of opioids are generally indicated for elderly patients because of their increased sensitivity to the central nervous system depressants and diminished renal and hepatic function. Paradoxical (opposite) reactions and/or unexpected reactions may also be more likely to occur in patients of this age group.
- In elderly male patients, benign prostatic hyperplasia or obstructive urinary diseases must be considered because of the urinary retention associated with the use of opioids. Urinary outflow can become further diminished in these patients and result in adverse reactions or complications. Dosage adjustments may need to be made by the prescriber.
- Polypharmacy is often a problem in older adults; therefore, have a complete list of all medications the patient is currently taking, and assess for drug interactions and treatment (drug) duplication.
- Frequent assessments of elderly patients are needed. Pay attention to level of consciousness, alertness, and cognitive ability while ensuring that the environment is safe by keeping a call bell or light at the bedside. Using bed alarms and/or raising side rails are indicated when appropriate.
- Decreased circulation causes variation in the absorption of intramuscular or intravenous dosage forms and often results in the slower absorption of parenteral forms of opioids.
- As stated by the American Geriatric Society on the Management of Pain, nonsteroidal antiinflammatory drugs must be used with caution because of their potential for renal and gastrointestinal toxicity. Acetaminophen is the drug of choice for relieving mild to moderate pain, but with cautious dosing because of hepatic and renal concerns. The oral route of administration is preferred for analgesia. The regimen needs to be as simple as possible to enhance compliance. Be sure to note, report, and document any unusual reactions to the opioid drugs. Hypotension and respiratory depression may occur more frequently in elderly patients taking opioids; thus very careful vital sign monitoring is needed.

BOX 10-4 CONTROLLED SUBSTANCE/OPIOID COUNTS—A MUST-DO!

Any medication that has the potential for abuse or is a controlled substance—often opioids—is handled differently from other medications. Opioids are delivered to a nursing unit by the pharmacy, and these and other controlled substances (see Chapter 4) are kept in a locked cabinet or in an automated dispensing system (see Chapter 9). At the beginning of each shift, two registered nurses must count all of the opioids and/or other controlled substances located in the locked cabinet and record the count on a controlled substance and/or opioid administration record. When opioids and other controlled substances are dispensed through an automated medication-dispensing system, the drug is counted before the nurse removes the dose from the system. Any discrepancies found in the count of opioids or other controlled substances are investigated by registered nurses. If any opioids are unaccounted for, the nurse manager or supervisor needs to be contacted immediately. The following guidelines must be adhered to when giving opioids and other controlled substances: (1) Check the opioid administration record for the number left in stock. (2) Compare this number with the actual supply available. (3) If the count is accurate, obtain the desired dose of drug. (4) If the count is incorrect, notify the nurse manager or supervisor and follow any institutional policy. (5) Record the count of the remaining supply. Once the dose is removed, the nurse may be required to record the patient's name, prescriber's name, patient's medical record number, dose of medication ordered, and the nurse's signature. (6) Administer the drug according to policy and procedures. If the controlled substance cannot be given to the patient because of patient refusal, medication contamination, changes in vital signs or status, or some other reason, the medication will need to be "wasted." However, wasting of controlled substances requires the signature of another nurse who witnesses the discarding or wasting of the medication and documentation on the appropriate form. Automated systems record this information within the computer system.

is less than 10 breaths/min. Intramuscular injections are rarely used because of the availability of other effective and convenient dosage forms, such as PCA pumps, transdermal patches, continuous subcutaneous infusions, and epidural infusions.

For transdermal patches (e.g., transdermal fentanyl), two systems are used. The oldest type of patch contains a reservoir system consisting of four layers beginning with the adhesive layer and ending with the protective backing. Between these two layers are the permeable rate-controlling membrane and the reservoir layer, which holds the drug in a gel or liquid form. The newer type of patch has a matrix system consisting of two layers: one layer containing the active drug with the releasing and adhesive mechanisms, and the protective impermeable backing layer. The advantages of the matrix system over the reservoir system are that the patch is slimmer and smaller, it is more comfortable, it is worn for up to 7 days (the older reservoir system patch is worn for up to 3 to 4 days), and it appears to result in more constant serum drug levels. In addition, the matrix system is alcohol-free; the alcohol in the reservoir system often irritates the patient's skin. It is important to know what type of delivery system is being used so that proper guidelines are followed to enhance the system's and drug's effectiveness.

Apply transdermal patches to only a clean, nonhairy area. When the patch is changed, place the new patch on a new site, but only after the old patch has been removed and the old site cleansed of any residual medication. Rotation of sites helps to decrease irritation and enhance drug effects. Transdermal patches require special discarding of old/used patches (see the Safety and Quality Improvement: Preventing Medication Errors box on p. 148). Transdermal systems are beneficial for the delivery of many types of medications, especially analgesics, and have the benefits of allowing multiday therapy with a single application, avoiding first-pass metabolism, improving patient compliance, and minimizing frequent dosing. However, the patient must be watched carefully for the development of any type of contact dermatitis caused by the patch (the prescriber is to be contacted immediately if this occurs) and maintain his or her own pain journal when at home. Journal entries are a valid source of information for the nurse, other health care professionals, the patient, and family members to assess the patient's pain control and to monitor the effectiveness not only of transdermal analgesia but also any medication regimen.

With the intravenous administration of *opioid agonists,* follow manufacturer guidelines and institutional policies regarding specific dilutional amounts and solutions as well as the time period for infusion. When PCA is used, the amounts and times of dosing must be noted in the appropriate records and tracked by appropriate personnel. The fact that a pump is being used, however, does not mean that it is 100% reliable or safe. Closely monitor and frequently check all equipment. Additionally, frequently monitor pain levels, response to medication, and vital signs with the use of other parenteral opioid administration. Always follow dosage ranges for all opioid agonists and agonists-antagonists, and pay special attention to the dosages of morphine and morphine-like drugs. For intravenous infusions, you are responsible for monitoring the intravenous needle site and infusion rates and documenting any adverse effects or complications. Another point to remember when administering opioids—as well as any other analgesics—is that each medication has a different onset of action, peak, and duration of action, with the intravenous route producing the most rapid onset (e.g., within minutes) (Table 10-8).

To reverse an opioid overdose or opioid-induced respiratory depression, an *opioid antagonist,* such as naloxone, must be

TABLE 10-8 OPIOID ADMINISTRATION GUIDELINES

OPIOID	NURSING ADMINISTRATION
buprenorphine and butorphanol	When giving IV, infuse over the recommended time (usually 3-5 min). Always assess respirations before, during, and after use. Give IM as ordered.
codeine	Give PO doses with food to minimize GI tract upset; ceiling effects occur with oral codeine resulting in no increase in analgesia with increased dosage.
fentanyl	Administer parenteral doses as ordered and as per manufacturer guidelines in regard to mg/min to prevent CNS depression and possible cardiac or respiratory arrest. Transdermal patches come in a variety of dosages. Fentanyl lozenges on a stick are also available. Be sure to remove residual amounts of the old patch before application of a new patch. Dispose of patches properly to avoid inadvertent contact with children or pets.
hydromorphone	May be given subcut, rectally, IV, PO, or IM.
levorphanol	May be given PO, subcut, or IV; give IV forms over 5 min or as indicated by manufacturer guidelines; longer acting, lasting up to 6-8 hr.
meperidine	Given by a variety of routes: IV, IM, or PO; highly protein bound, so watch for interactions and toxicity. Monitor elderly patients for increased sensitivity.
morphine	Available in a variety of forms: subcut, IM, PO, IV, extended- and immediate-release; morphine sulfate (Duramorph) for epidural infusion. Always monitor respiratory rate.
nalbuphine	IV doses of 10 mg given undiluted over 5 min.
naloxone	Antagonist given for opioid overdose; 0.4 mg usually given IV over 15 sec or less. Reverses analgesia as well.
oxycodone	Often mixed with acetaminophen or aspirin; PO and suppository dosage forms. Now available in both immediate and sustained-release tabs.
oxymorphone	Available in PO, IM, IV, subcut, and rectal suppository dosage forms. Extended-release oral form (Opana) is the only form commonly used.
pentazocine	Subcut, IV, and IM forms; mixed agonist-antagonist; IV dose of 5 mg to be given over 1 min.

CNS, Central nervous system; *GI,* gastrointestinal; *IM,* intramuscular(ly); *IV,* intravenous(ly); *PO,* oral(ly); *subcut,* subcutaneous(ly).

administered. Naloxone is given intravenously in diluted form and administered slowly (such as over 15 seconds, or as ordered; see Table 10-7). However, consider the packaging and manufacturer guidelines. Emergency resuscitative equipment must always be available in the event of respiratory or cardiac arrest.

OPIOID AGONISTS-ANTAGONISTS

Remember when giving *agonists-antagonists* that they react very differently depending on whether they are given by themselves or with other drugs. When administered alone, they are effective analgesics because they bind with opiate receptors and produce an agonist effect (see discussion in pharmacology section). If given at the same time as other opioids, however, they lead to reversal of analgesia and acute withdrawal because of the blocking of opiate receptors. Be very careful to check dosages and routes as well as to perform the interventions mentioned for opioid agonist drugs, including closely assessing vital signs, especially respiratory rate. Emphasize the importance of reporting any dizziness, unresolved constipation, urinary retention, and sedation. See Table 10-6 for additional adverse effects of opioid agonists as they are similar to the opioid agonist-antagonist drugs. Other points to emphasize with the patient include that the drug also has the ability to reverse analgesia as well as precipitate withdrawal (if taken with other opioid agonists). A list of other opioid agonists must be shared with the patient, as well.

OPIOID ANTAGONISTS

Opioid antagonists must be given as ordered and be readily available, especially when the patient is receiving PCA with an opioid, is opioid naïve, or is receiving continuous doses of opioids. Several doses of these drugs are often required to ensure adequate opioid agonist reversal (see earlier discussion). Encourage patients to report any nausea or tachycardia.

GENERAL CONSIDERATIONS

You are always responsible and accountable to maintain a current, updated knowledge base on all forms of analgesics as well as protocols for pain management with focus on the specific drug(s) as well as differences in the treatment of mild to moderate pain, severe pain, and pain in special situations (e.g., cancer pain). The WHO's three-step analgesic ladder provides a standard for pain management in cancer patients and must be reviewed and considered, as needed.

Dosing of medications for pain management is very important to the treatment regimen. As noted earlier, once a thorough assessment has been performed, it is best to treat the patient's pain before it becomes severe, which is the rationale for considering pain to be the fifth vital sign. When pain is present for more than 12 hours a day, analgesic doses are individualized and are best administered around the clock rather than on an as-needed basis, while always staying within safe practice guidelines for each drug used. Around-the-clock (or scheduled) dosing maintains steady-state levels of the medication and prevents drug troughs and pain escalation. No given dosage of an analgesic will provide the same level of pain relief for every patient; thus there is a need for a process of titration—upward or even downward—to be carried out based on the individual's needs. Aggressive titration may be necessary in difficult pain control cases and in cancer pain situations. Patients with severe pain, metastatic pain, or bone metastasis pain may need increasingly higher dosages of analgesic. These special pain situations may require an opiate such as morphine that needs to be titrated until the desired response is achieved or until adverse effects occur. A patient-rated pain level of less than 4 on a scale of 1 to 10 is considered to indicate effective pain relief.

If pain is not managed adequately by monotherapy, other drugs or adjuvants may need to be added to enhance analgesic efficacy. This includes the use of NSAIDs (for analgesic, anti-inflammatory effects), acetaminophen (for analgesic effects), corticosteroids (for mood elevation and antiinflammatory, antiemetic, and appetite stimulation effects), anticonvulsants (for treatment of neuropathic pain), tricyclic antidepressants (for treatment of neuropathic pain and for their innate analgesic properties and opioid-potentiating effects), neuroleptics (for treatment of chronic pain syndromes), local anesthetics (for treatment of neuropathic pain), hydroxyzine (for mild antianxiety properties as well as sedating effects and antihistamine and mild antiemetic actions), or psychostimulants (for reduction of opioid-induced sedation when opioid dosage adjustment is not effective). Table 10-9 provides a listing of drugs that are *not* to be used in patients experiencing cancer pain.

Dosage forms are also important, especially with chronic pain and cancer pain. Oral administration is always preferred but is not always tolerated by the patient and may not even be a viable option for pain control. If oral dosing is not appropriate, less invasive routes of administration include rectal and transdermal routes. Rectal dosage forms are safe, inexpensive, effective, and helpful if the patient is experiencing nausea or vomiting or altered mental status; however, this route is not suitable for those with diarrhea, stomatitis, and/or low blood cell counts. Transdermal patches may provide up to 7 days of pain control but are not for rapid dose titration and are used only when stable analgesia has been previously achieved. Long-acting forms of morphine and fentanyl may be delivered via transdermal patches when a longer duration of action is needed. Intermittent injections or continuous infusions via the intravenous or subcutaneous route are often used for opioid delivery and may be administered at home in **special pain situations,** such as in hospice care or management of chronic cancer pain. Subcutaneous infusions are often used when there is no intravenous access. PCA pumps may be used to help deliver opioids intravenously, subcutaneously, or even intraspinally and can be managed in home health care or hospice care for the patient at home. Use of the intrathecal or epidural route requires special skill and expertise, and delivery of pain medications using these routes is available only from certain home health care agencies for at-home care. The main reason for long-term intraspinal opioid administration is intractable pain. Transnasal dosage forms are approved only for butorphanol, an agonist-antagonist drug, and this dosage form is generally not used or recommended. Regardless of the specific drug or dosage form used, a fast-acting rescue drug needs to be ordered and available for patients with cancer pain and patients presenting other special challenges in pain management.

TABLE 10-9 DRUGS NOT RECOMMENDED FOR TREATMENT OF CANCER PAIN

CLASS	DRUG	REASON FOR NOT RECOMMENDING
Opioids with dosing around the clock	meperidine	Short (2-3 hr) duration of analgesia; administration may lead to CNS toxicity (tremor, confusion, or seizures)
Miscellaneous	Cannabinoids	Adverse effects of dysphoria, drowsiness, hypotension, and bradycardia, which preclude their routine use as analgesics; may be indicated for use in treating severe chemotherapy-induced nausea and vomiting
Opioid agonists-antagonists	pentazocine butorphanol nalbuphine	May precipitate withdrawal in opioid-dependent patients; analgesic ceiling effect; possible production of unpleasant psychological adverse effects, including dysphoria, delusions, and hallucinations
	buprenorphine	Analgesic ceiling effect; can precipitate withdrawal if given with an opioid
Opioid antagonists	naloxone naltrexone	Reverses analgesia as well as CNS depressant effects, such as respiratory depression
Combination preparations	Brompton cocktails	No evidence of analgesic benefit over use of single opioid analgesic
	DPT* (meperidine, promethazine, and chlorpromazine)	Efficacy poor compared with that of other analgesics; associated with a higher incidence of adverse effects
Anxiolytics (as monotherapy) or sedatives-hypnotics (as monotherapy)	Benzodiazepines (e.g., alprazolam)	Analgesic properties not associated with these drugs except in some situations of neuropathic pain; common risk of sedation, which may put some patients at higher risk for neurologic complications
	Barbiturates	Analgesic properties not demonstrated; sedation is problematic and limits use

CNS, Central nervous system.
*DPT is the abbreviation for the trade names Demerol, Phenergan, and Thorazine.

CASE STUDY

Opioid Administration

You are assigned to care for a patient who is in the terminal phases of breast cancer. As a home health care nurse, you have many responsibilities; however, you have not cared for many patients who are in the terminal phase of their illness. In fact, most of your patients are postoperative and have only required assessments, dressing changes, and wound care.

Mrs. D. is 48 years of age and underwent bilateral mastectomy 4 years ago. She had lymph node involvement at the time of surgery, and recently has been diagnosed with metastasis to the bone. She has been taking oxycodone (one 5-mg tab every 6 hours) at home but is not sleeping through the night and is now complaining of increasing pain to the point that her quality of life has decreased significantly. She wants to stay at home during the terminal phases of her illness but needs to have adequate and safe pain control. Her husband of 18 years is very supportive. They have no children. They are both college graduates and have medical insurance.

1. Mrs. D.'s recent increase in pain has been attributed to bone metastasis in the area of the lumbar spine. At this time, the oxycodone is not beneficial, and you as the home health care nurse need to advocate for Mrs. D. to receive adequate pain relief. When discussing her pain medications with her physician, what type of medication would you expect to be ordered to relieve the bone pain, and what is the rationale for this medication? (Provide references from within this chapter to support the selection of the specific opioid drug.)
2. Mrs. D.'s husband confides in you that he is worried that she will become addicted to the new medication. He is not sure he agrees with around-the-clock dosing. How do you address his concerns?
3. What should Mr. D. do if he feels that Mrs. D. has had an overdose?

For answers, see http://evolve.elsevier.com/Lilley.

Regardless of the drug(s) used for the pain management regimen, always remember that individualization of treatment is one of the most important considerations for effective and quality pain control. Also consider implementing the following:

- At the initiation of pain therapy, conduct a review of all relevant histories, laboratory test values, nurse-related charting entries, and diagnostic study results in the patient's medical record. If there are underlying problems, consider these variables while never forgetting to treat the patient with dignity and empathy. Never let compounding variables and any other problems overshadow the fact that there is a patient who is in pain and deserving of safe, quality care. Always look and listen!
- Develop goals for pain management in conjunction with the patient, family members, significant others, and/or caregiver. These goals include improving the level of comfort with increased levels of activities of daily living and ambulation.
- Collaborate with other members of the health care team to select a regimen that will be easy for the patient to follow while in the hospital and, if necessary, at home (e.g., for cancer patients and other patients with chronic pain).

- Be aware that most regimens for acute pain management include treatment with short-acting opioids plus the addition of other medications such as NSAIDs.
- Be familiar with equianalgesic doses of opioids, because lack of knowledge may lead to inadequate analgesia or overdose.
- Use an analgesic appropriate for the situation (e.g., short-acting opioids for severe pain secondary to a myocardial infarction, surgery, or kidney stones). For cancer pain, the regimen usually begins with short-acting opioids with eventual conversion to sustained-release formulations.
- Use preventative measures to manage adverse effects. In addition, a switch is made to another opioid as soon as possible if the patient finds that the medication is not controlling the pain adequately.
- Consider the option of analgesic adjuvants, especially in cases of chronic pain or cancer pain; these might include other prescribed drugs such as NSAIDs, acetaminophen, corticosteroids, anticonvulsants, tricyclic antidepressants, neuroleptics, local anesthetics, hydroxyzine, and/or psychostimulants. Over-the-counter drugs and herbals may be helpful.
- Be alert to patients with special needs, such as patients with breakthrough pain. Generally, the drug used to manage such pain is a short-acting form of the longer-acting opioid being given (e.g., immediate-release morphine for breakthrough pain while sustained-release morphine is also used).
- Identify community resources that can assist the patient, family members, and/or significant others. These resources may include various websites for patient education such as http://www.theacpa.org; www.painconnection.org; and www.painaction.com. Many other pain management sites may be found on the Internet by using the search terms *pain, pain clinic,* or *pain education* and looking for patient-focused materials/sites.
- Conduct frequent online searches to remain current on the topic of pain management, pain education, drug and nondrug therapeutic regimens for pain, and special pain situations. The following professional nurse and/or prescriber-focused websites are listed at www.painedu.org/resources.asp as resources for the topic of general pain management: www.aapainmanage.org, www.painmed.org; www.painfoundation.org; www.ampainsoc.org; www.aspmn.org; www.asam.org; www.paineducators.org; www.asra.com; www.iasp-pain.org; www.painpolicy.wisc.edu; www.painmedicinenews.com; www.pain-topics.org; www.pain.com; and www.painandhealth.org. On the topic of chronic pain, websites are as follows: www.theacpa.org and www.arthritis.org. On the topic of cancer pain, websites are as follows: www.cancer.org; www.apos-society.org; www.asco.org; www.cancercare.org; www.cancer.gov; and www.ons.org.
- Because fall prevention is of utmost importance in patient care (after the ABCs [airway, breathing, circulation] of care are addressed), monitor the patient frequently after an analgesic is given. Frequent measurement of vital signs, inclusion of the patient in a frequent watch program, and/or use of bed alarms is encouraged.
- Restraints may cause many injuries; therefore, if restraints are necessary, follow the appropriate procedures, including specific institutional policies and rules. Assess, monitor, evaluate, and document the reason for the restraint; also document the patient's behavior, the type of restraint used, and the assessment of the patient after the placement of restraints. Use of restraints has been largely replaced with a bed watch system and the use of bed and/or wheelchair alarms. Give instructions to the patient, family members, and/or caregivers about the risk for falls and the need for safety measures. Restraints are not used in long-term care facilities.

EVALUATION

Positive therapeutic outcomes of acetaminophen use are decreased symptoms, fever, and pain. Monitor for the adverse reactions of anemias and liver problems due to hepatotoxicity and report patient complaints of abdominal pain and/or vomiting to the prescriber. During and after the administration of other *nonopioid analgesics* such as tramadol, *opioids,* and *mixed opioid agonists,* monitor the patient for both therapeutic effects and adverse effects frequently and as needed. Therapeutic effects of analgesics include increased comfort levels as well as decreased complaints of pain and longer periods of comfort, with improvements in performance of activities of daily living, appetite, and sense of well-being. Monitoring for adverse effects will vary with each drug (see earlier discussions), but effects may consist of nausea, vomiting, constipation, dizziness, headache, blurred vision, decreased urinary output, drowsiness, lethargy, sedation, palpitations, bradycardia, bradypnea, dyspnea, and hypotension. If the patient's vital signs change, the patient's condition declines, or pain continues, contact the prescriber immediately and continue to closely monitor. Respiratory depression may be manifested by a respiratory rate of less than 10 breaths/min, dyspnea, diminished breath sounds, and/or shallow breathing. Include review of the effectiveness of multimodal and nonpharmacologic approaches to pain management in your evaluation.

PATIENT TEACHING TIPS

- Capsaicin is a topical product made from different types of peppers that may help with muscle pain and joint/nerve pain. It may cause local, topical reactions, so be sure to share information with the patient about its safe use.
- Opioids are not to be used with alcohol or with other CNS depressants, unless ordered, because of worsening of the depressant effects.
- A holistic approach to pain management may be appropriate, with the use of complementary modalities including the following: biofeedback, imagery, relaxation, deep breathing, humor, pet therapy, music therapy, massage, use of hot or cold compresses, and use of herbal products.
- Dizziness, difficulty breathing, low blood pressure, excessive sleepiness (sedation), confusion, or loss of memory must be promptly reported to the nurse, prescriber, or other health care providers.
- Opioids may result in constipation, so forcing fluids (up to 3 L/day unless contraindicated), increasing fiber consumption, and exercising as tolerated is recommended. Stool softeners may also be necessary.
- Report any nausea or vomiting. Antiemetic drugs may be prescribed.
- Any activities requiring mental clarity or alertness may need to be avoided if experiencing drowsiness or sedation. Ambulate with caution and/or assistance as needed.
- It is important for the patient to share any history of addiction with health care providers, but when such a patient experiences pain and is in need of opioid analgesia, understand that the patient has a right to comfort. Any further issues with addiction may be managed during and after the use of opioids. Keeping an open mind regarding the use of resources, counseling, and other treatment options is important in dealing with addictive behaviors.
- If pain is problematic and not managed by monotherapy, a combination of a variety of medications may be needed. Other drugs that may be used include antianxiety drugs, sedatives, hypnotics, or anticonvulsants.
- For the cancer patient or patient with special needs, the prescriber will monitor pain control and the need for other options for therapy or for dosing of drugs. For example, the use of transdermal patches, buccal tablets, and continuous infusions while the patient remains mobile or at home is often helpful in pain management. It is also important to understand that if morphine or morphine-like drugs are being used, the potential for addiction exists; however, in specific situations, the concern for quality of life and pain management is more important than the concern for addiction.
- Most hospitals have inpatient and outpatient resources such as pain clinics. Patients need to constantly be informed and aware of all treatment options and remain active participants in their care for as long as possible.
- Tolerance does occur with opioid use, so if the level of pain increases while the patient remains on the prescribed dosage, the prescriber or health care provider must be contacted. Dosages must not be changed, increased, or doubled unless prescribed.

KEY POINTS

- Pain is individual and involves sensations and emotions that are unpleasant. It is influenced by age, culture, race, spirituality, and all other aspects of the person.
- Pain is associated with actual or potential tissue damage and may be exacerbated or alleviated depending on the treatment and type of pain.
- Types of analgesics include the following:
  - Nonopioids, including acetaminophen, aspirin, and NSAIDs
  - Opioids, which are natural or synthetic drugs that either contain or are derived from morphine (opiates) or have opiate-like effects or activities (opioids), and opioid agonist-antagonist drugs
- Pediatric dosages of morphine must be calculated very cautiously with close attention to the dose and kilograms of body weight. Cautious titration of dosage upward is usually the standard.
- Elderly patients may react differently than expected to analgesics, especially opioids and opioid agonists-antagonists.
- In treating the elderly, remember that these patients experience pain the same as does the general population, but they may be reluctant to report pain and may metabolize opiates at a slower rate and thus are at increased risk for adverse effects such as sedation and respiratory depression. The best rule is to start with low dosages, reevaluate often, and go slowly during upward titration.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 For best results when treating severe pain associated with pathologic spinal fractures related to metastatic bone cancer, the nurse should remember that the best type of dosage schedule is to administer the pain medication
- **a** as needed.
- **b** around the clock.
- **c** on schedule during waking hours only.
- **d** around the clock, with additional doses as needed for breakthrough pain.

2 A patient is receiving an opioid via a PCA pump as part of his postoperative pain management program. During rounds, the nurse finds him unresponsive, with respirations of 8 breaths/min and blood pressure of 102/58 mm Hg. After stopping the opioid infusion, what should the nurse do next?
- **a** Notify the charge nurse
- **b** Draw arterial blood gases
- **c** Administer an opiate antagonist per standing orders
- **d** Perform a thorough assessment, including mental status examination

3 A patient with bone pain caused by metastatic cancer will be receiving transdermal fentanyl patches. The patient asks the nurse what benefits these patches have. The nurse's best response includes which of these features?
- **a** More constant drug levels for analgesia
- **b** Less constipation and minimal dry mouth
- **c** Less drowsiness than with oral opioids
- **d** Lower dependency potential and no major adverse effects

4 Intravenous morphine is prescribed for a patient who has had surgery. The nurse informs the patient that which common adverse effects can occur with this medication? (Select all that apply.)
- **a** Diarrhea
- **b** Constipation
- **c** Pruritus
- **d** Urinary frequency
- **e** Nausea

5 Several patients have standard orders for acetaminophen as needed for pain. When the nurse reviews their histories and assessments, the nurse discovers that one of the patients has a contraindication to acetaminophen therapy. Which patient should receive an alternate medication?
- **a** A patient with a fever of 103.4° F (39.7° C)
- **b** A patient admitted with deep vein thrombosis
- **c** A patient admitted with severe hepatitis
- **d** A patient who had abdominal surgery 1 week earlier

6 The nurse is administering an intravenous dose of morphine sulfate to a 48-year-old postoperative patient. The dose ordered is 3 mg every 3 hours as needed for pain. The medication is supplied in vials of 4 mg/mL. How much will be drawn into the syringe for this dose?

7 An opioid analgesic is prescribed for a patient. The nurse checks the patient's medical history knowing this medication is contraindicated in which disorder?
- **a** Renal insufficiency
- **b** Severe asthma
- **c** Liver disease
- **d** Diabetes mellitus

1. d, 2. c, 3. a, 4. b, c, e 5. c, 6. 0.75 mL, 7. b

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Define *anesthesia.*
2 Describe the basic differences between general and local anesthesia.
3 List the most commonly used general and local anesthetics and associated risks.
4 Discuss the differences between depolarizing neuromuscular blocking drugs and nondepolarizing blocking drugs and their impact on the patient.
5 Compare the mechanisms of action, indications, adverse effects, routes of administration, cautions, contraindications, and drug interactions for general and local anesthesia as well as drugs used for moderate or conscious sedation.
6 Develop a nursing care plan for patients before anesthesia (preanesthesia), during anesthesia, and after anesthesia (postanesthesia) related to general anesthesia.
7 Develop a nursing care plan for patients undergoing local anesthesia and/or moderate or conscious sedation.

DRUG PROFILES

dexmedetomidine, p. 173
isoflurane, p. 173
ketamine, p. 173
♦ **lidocaine, p. 176**
nitrous oxide, p. 173
pancuronium, p. 180
♦ **propofol, p. 173**
sevoflurane, p. 173
♦ **succinylcholine, p. 179**
♦ **vecuronium, p. 180**

♦ *Key drug*

KEY TERMS

Adjunct anesthetics Drugs used in combination with anesthetic drugs to control the adverse effects of anesthetics or to help maintain the anesthetic state in the patient. (See *balanced anesthesia.*) (p. 170)

Anesthesia The loss of the ability to feel pain resulting from the administration of an anesthetic drug. (p. 170)

Anesthetics Drugs that depress the central nervous system (CNS) or peripheral nerves to produce decreased or loss of consciousness, or muscle relaxation. (p. 170)

Balanced anesthesia The practice of using combinations of different drug classes rather than a single drug to produce anesthesia. (p. 171)

KEY TERMS—cont'd

General anesthesia A drug-induced state in which the CNS nerve impulses are altered to reduce pain and other sensations throughout the entire body. It normally involves complete loss of consciousness and depression of normal respiratory drive. (p. 170)

Local anesthesia A drug-induced state in which peripheral or spinal nerve impulses are altered to reduce or eliminate pain and other sensations in tissues innervated by these nerves. (p. 170)

Malignant hyperthermia A genetically linked major adverse reaction to general anesthesia characterized by a rapid rise in body temperature, as well as tachycardia, tachypnea, and sweating. (p. 172)

Moderate sedation A milder form of general anesthesia that causes partial or complete loss of consciousness but does not generally reduce normal respiratory drive (also referred to as *conscious sedation*). (p. 173)

Overton-Meyer theory A theory that describes the relationship between the lipid solubility of anesthetic drugs and their potency. (p. 171)

Spinal anesthesia Local anesthesia induced by injection of an anesthetic drug near the spinal cord to anesthetize nerves that are distal to the site of injection (also called *intraspinal anesthesia*). (p. 174)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Anesthetics are drugs that reduce or eliminate pain by depressing nerve function in the central nervous system (CNS) and/or the peripheral nervous system (PNS). This state of reduced neurologic function is called **anesthesia.** Anesthesia is further classified as *general* or *local.* **General anesthesia** involves complete loss of consciousness, loss of body reflexes, elimination of pain and other sensations throughout the entire body, and skeletal and smooth muscle paralysis, including paralysis of respiratory muscles. This loss of normal respiratory function requires mechanical or manual ventilatory support to avoid brain damage and suffocation (death from respiratory arrest). **Local anesthesia** does not involve paralysis of respiratory function but does involve elimination of pain sensation in the tissues innervated by *anesthetized* nerves. Functions of the *autonomic nervous system,* which is a branch of the parasympathetic nervous system, may also be affected.

PHARMACOLOGY OVERVIEW

GENERAL ANESTHETICS

General anesthetics are drugs that induce general anesthesia and are most commonly used to induce anesthesia during surgical procedures. General anesthetics are given only under controlled situations by anesthesiologists or nurse anesthetists. General anesthesia is achieved by the use of one or more drugs. Often a synergistic combination of drugs is used, which allows for smaller doses of each drug and better control of the patient's anesthetized state. Inhalational anesthetics are volatile liquids or gases that are vaporized or mixed with oxygen to induce anesthesia. For a historical perspective on general anesthesia, see Box 11-1.

Parenteral anesthetics (Table 11-1) are given intravenously and are used for induction and/or maintenance of general anesthesia, induction of amnesia, and as adjuncts to inhalation-type anesthetics (Table 11-2). The specific goal varies with the drug. Common intravenous anesthetic drugs include drugs classified solely as general anesthetics, such as etomidate and propofol.

Adjunct anesthetics or simply adjuncts are also used. *Adjunct* is a general term for any drug that enhances clinical therapy when used simultaneously with another drug. Adjunct drugs can be thought of as "helper drugs" when their use complements the use of any other drug(s). They are used simultaneously with general anesthetics for anesthesia initiation (induction), sedation, reduction of anxiety, and amnesia. Adjuncts include neuromuscular blocking drugs (NMBDs; see Neuromuscular Blocking Drugs later in the chapter), sedative-hypnotics or anxiolytics (see Chapter 12) such as propofol (this chapter), benzodiazepines (e.g., diazepam, midazolam),

BOX 11-1 GENERAL ANESTHESIA: A HISTORICAL PERSPECTIVE

Until recently, general anesthesia was described as having several definitive stages. This was especially true with the use of many of the ether-based inhaled anesthetic drugs. Features of these distinctive stages were easily observable to the trained eye. They included specific physical and physiologic changes that progressed gradually and predictably with the depth of the patient's anesthetized state. Gradual changes in pupil size, progression from thoracic to diaphragmatic breathing, vital sign changes, and several other changes all characterized the various stages. Newer inhalational and intravenous general anesthetic drugs, however, often have a much more rapid onset of action and body distribution. As a result, the specific stages of anesthesia once observed with older drugs are no longer sufficiently well defined to be observable. Thus, the concept of stages of anesthesia is an outdated one in most modern surgical facilities. Registered nurses who pursue advanced training to become certified registered nurse anesthetists often find this to be a rewarding and interesting area of nursing practice. Some nurses also find that this type of work offers greater flexibility in their work schedule than do other practice areas.

TABLE 11-1 PARENTERAL GENERAL ANESTHETICS

GENERIC NAME	TRADE NAME
etomidate	Amidate
ketamine	Ketalar
methohexital	Brevital
propofol	Diprivan
thiopental	Pentothal

barbiturates (e.g., thiopental, methohexital; see Chapter 12), opioid analgesics (e.g., morphine, fentanyl, sufentanil; see Chapter 10), anticholinergics (e.g., atropine; see Chapter 21), and antiemetics (e.g., ondansetron; see Chapter 52). Note that propofol can be used as a general anesthetic and/or sedative-hypnotic, depending on the dose. The simultaneous use of both general anesthetics and adjuncts is called **balanced anesthesia.** Common adjunctive anesthetic drugs are listed in Table 11-3.

Mechanism of Action and Drug Effects

Many theories have been proposed to explain the actual mechanism of action of general anesthetics. The drugs vary widely in their chemical structures, and their mechanism of action is not easily explained by a structure-receptor relationship. The concentrations of various anesthetics required to produce a given state of anesthesia also differ greatly. The **Overton-Meyer theory** has been used to explain some of the properties of anesthetic drugs since the early days of anesthesiology. In general terms, it proposes that, for all anesthetics, potency varies directly with lipid solubility. In other words, across a continuum of drug potency, fat-soluble drugs are stronger anesthetics than water-soluble drugs. Nerve cell membranes have high lipid content, as does the blood-brain barrier (see Chapter 2). Lipid-soluble anesthetic drugs can therefore easily cross the blood-brain barrier to concentrate in nerve cell membranes.

The overall effect of general anesthetics is a progressive reduction of sensory and motor CNS functions. The degree and speed of this process varies with the anesthetics and adjuncts used along with their dosages and routes of administration. General anesthesia initially produces a loss of the senses of sight, touch, taste, smell, and hearing, along with loss of consciousness. Cardiac and pulmonary functions are usually the last to be interrupted, because they are controlled by the *medulla* of the *brainstem.* These are the classical "stages" of anesthesia. Mechanical ventilatory support is absolutely necessary. In more extensive surgical procedures, especially those involving the heart, pharmacologic cardiac support involving adrenergic drugs (see Chapter 18) and inotropic drugs (see Chapter 24) may also be required.

The reactions of various body systems to general anesthetics are further described in Table 11-4.

TABLE 11-2 INHALATIONAL GENERAL ANESTHETICS

GENERIC NAME	TRADE NAME
Inhaled Gas	
nitrous oxide (laughing gas)	
Inhaled Volatile Liquid	
desflurane	Suprane
enflurane	Ethrane
halothane	Fluothane
isoflurane	Forane
methoxyflurane	Penthrane
sevoflurane	Ultane

Indications

General anesthetics are used to produce unconsciousness as well as relaxation of skeletal and visceral smooth muscles for surgical procedures as well as in electroconvulsive therapy for severe depression (see Chapter 16).

Contraindications

Contraindications to the use of anesthetic drugs include known drug allergy. Depending on the drug type, contraindications may also include pregnancy, narrow-angle glaucoma, and known susceptibility to malignant hyperthermia (see Adverse Effects) from prior experience with anesthetics.

TABLE 11-3 ADJUNCTIVE ANESTHETIC DRUGS (ADULT DOSES)

DRUG	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
alfentanil (Alfenta)	Opioid analgesic	130-245 mcg/kg IV	Anesthesia induction
fentanyl (Sublimaze)		50-100 mcg/kg IV	
sufentanil (Sufenta)		8-30 mcg/kg IV	
diazepam (Valium)	Benzodiazepine	5-15 mg PO/IV/IM	Amnesia and anxiety reduction
midazolam (Versed)		1-5 mg IV	
atropine	Anticholinergic	0.2-1 mg IV/IM/subcut	Drying up of excessive secretions
glycopyrrolate (Robinul)		4 mcg/kg IM	
scopolamine		0.3-0.6 mg subcut/IM/IV	
meperidine (Demerol)	Opioid analgesic	50-100 mg IV/IM	Pain prevention and pain relief
morphine		5-20 mg IV/IM	
hydroxyzine (Atarax, Vistaril)	Antihistamine	25-100 mg IM	Sedation, prevention of nausea and vomiting, anxiety reduction
promethazine (Phenergan)		25-50 mg IM	
pentobarbital (Nembutal)	Sedative-hypnotic	150-200 mg IM	Amnesia and sedation
secobarbital (Seconal)		100 mg PO	
dexmedetomidine (Precedex)	Alpha$_2$ agonist	0.2-0.7 mcg/kg/hr IV (doses up to 1.4 mcg/kg/hr have been shown to be effective)	Sedation

IM, Intramuscularly; *IV,* intravenously; *PO,* orally; *subcut,* subcutaneously

TABLE 11-4 EFFECTS OF INHALED AND INTRAVENOUS GENERAL ANESTHETICS

ORGAN/SYSTEM	REACTION
Respiratory system	Depressed muscles and patterns of respiration; altered gas exchange and impaired oxygenation; depressed airway-protective mechanisms; airway irritation and possible laryngospasm
Cardiovascular system	Depressed myocardium; hypotension and tachycardia; bradycardia in response to vagal stimulation
Cerebrovascular system	Increased intracranial blood volume and increased intracranial pressure
Gastrointestinal system	Reduced hepatic blood flow and thus reduced hepatic clearance
Renal system	Decreased glomerular filtration
Skeletal muscles	Skeletal muscle relaxation
Cutaneous circulation	Vasodilation
Central nervous system (CNS)	CNS depression; blurred vision; nystagmus; progression of CNS depression to decreased alertness, sensorium, and decreased level of consciousness

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

Anesthesia

- The elderly patient is affected more adversely by anesthesia than the young or middle-aged adult. With aging comes organ system deterioration. Declining liver function results in decreased metabolism of drugs, and a decline in renal functioning leads to decreased drug excretion. Either of these can lead to drug toxicity, unsafe levels, and/or overdose. If both of these organs are not functioning properly, the risk of drug toxicity or overdose is even greater. In addition, the elderly are more sensitive to the effects of drugs affecting the central nervous system.
- Presence of cardiac and respiratory diseases places the elderly patient at higher risk for cardiac dysrhythmias, hypotension, respiratory depression, atelectasis, and/or pneumonia during the postanesthesia and postoperative phases.
- The practice of polypharmacy is yet another concern in the elderly with regard to administration of any type of anesthetic. Because of the presence of various age-related diseases, the older patient is generally taking more than one medication. The more drugs a patient is taking, the higher the risk of adverse reactions and drug-drug interactions, including interactions with anesthetics.

Adverse Effects

Adverse effects of general anesthetics are dose dependent and vary with the individual drug. The heart, peripheral circulation, liver, kidneys, and respiratory tract are the sites primarily affected. Myocardial depression is a common adverse effect. All of the halogenated anesthetics are capable of causing hepatotoxicity, and methoxyflurane can cause significant respiratory depression.

With the development of newer drugs, many of the unwanted adverse effects characteristic of the older drugs (such as hepatotoxicity and myocardial depression) are now a thing of the past. In addition, many of the bothersome adverse effects such as nausea, vomiting, and confusion are less common since balanced anesthesia is widely used. Substance abuse (e.g., alcohol abuse; see Chapter 17) can predispose a patient to anesthetic-induced complications (e.g., liver toxicity). A positive history of substance abuse may lead to dosage adjustments in one or more of the drugs used. A drug-abusing patient with a high tolerance for street drugs may require larger doses of anesthesia-related drugs (e.g., benzodiazepines, opioids) to achieve the desired sedative effects.

Malignant hyperthermia is an uncommon, but potentially fatal, genetically linked adverse metabolic reaction to general anesthesia. It is classically associated with the use of volatile inhalational anesthetics as well as the depolarizing NMBD succinylcholine (see Neuromuscular Blocking Drugs later in this chapter). Signs include rapid rise in body temperature, tachycardia, tachypnea, and muscular rigidity. Patients known to be at greater risk for malignant hyperthermia include children, adolescents, and individuals with muscular and/or skeletal abnormalities such as hernias, strabismus, ptosis, scoliosis, and muscular dystrophy. Malignant hyperthermia is treated with cardiorespiratory supportive care as needed to stabilize heart and lung function along with the skeletal muscle relaxant dantrolene (see Chapter 12). In fact, by law, all facilities that provide general anesthesia must maintain a certain amount of dantrolene on hand in case of malignant hyperthermia.

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

Anesthesia

- Premature infants, neonates, and pediatric patients are more adversely affected by anesthesia than the young or middle-aged adult patient. The reason for this difference in response is the increased sensitivity of the pediatric patient to anesthetics and related drugs because of immature functioning of the liver and kidneys, which leads to possible drug accumulation, toxicity, and subsequent complications. The central nervous system of pediatric patients is also more sensitive to the effects of anesthetics. Because of these risks of toxicity and complications with all forms of anesthesia, take every precaution to ensure that the patient remains safe and free from harm.
- Cardiac and respiratory systems are not fully developed in the neonate, premature infant, and newborn, which makes this age group more susceptible to problems with the metabolism and excretion of drugs. Some of the more common problems include central nervous system depression with subsequent respiratory and cardiac depression, development of atelectasis, pneumonia, and cardiac abnormalities.
- Neonates in particular (see age group definitions and further discussion in Chapter 3) are at higher risk of upper airway obstruction during general anesthesia. During the anesthetic process, the risk of laryngospasm related to the intubation process may be increased for neonates because of the specific physical characteristics of the larynx and respiratory structures in this age group. Their higher metabolic rate and small airway diameter also put neonates at greater risk of experiencing complications during general anesthesia.
- Before any medications are given to the pediatric patient, perform a careful check and double-check of mathematical drug calculations. In addition to weight, body surface area and laboratory test results that may indicate organ dysfunction should always be taken into consideration in the actual drug calculation.
- Resuscitative equipment should be readily available on any neonatal or pediatric nursing care unit.

Toxicity and Management of Overdose

In large doses, anesthetics are potentially life threatening, with cardiac and respiratory arrest as the ultimate causes of death. However, these drugs are almost exclusively administered in a very controlled environment by personnel trained in advanced cardiac life support. These drugs are also very quickly metabolized. In addition, the medullary center, which governs the vital functions, is the last area of the brain to be affected by anesthetics and the first to regain function. These factors combined make an anesthetic overdose rare and easily reversible.

Interactions

Some of the common drugs that interact with general anesthetics are antihypertensives and beta blockers, which have additive effects when combined with general anesthetics (i.e., increased hypotensive effects from antihypertensives, and increased myocardial depression with beta blockers). No significant laboratory test interactions have been reported.

DRUG PROFILES

The dose of any anesthetic depends on the complexity of the surgical procedure to be performed and the physical characteristics of the patient. All of the general anesthetics have a rapid onset of action along with rapid elimination upon discontinuation. Anesthesia is maintained intraoperatively by continuous administration of the drug.

isoflurane

Isoflurane (Forane) is a fluorinated ether that is a chemical isomer of the older fluorinated ether enflurane. It has a more rapid onset of action, causes less cardiovascular depression, and has little or no associated toxicity. This is in contrast to enflurane, which can cause seizures, and halothane, which is associated with liver toxicity.

sevoflurane

Sevoflurane (Ultane) is a fluorinated ether and is now widely used. Its pharmacokinetics, with rapid onset and rapid elimination, make it especially useful in outpatient surgery settings. It is also nonirritating to the airway, which greatly facilitates induction of an unconscious state, especially in pediatric patients.

ketamine

Ketamine is a unique drug with multiple properties. Given intravenously, it can be used for both general anesthesia and moderate sedation. It is commonly used in the emergency department for setting broken bones. It can also provide moderate sedation when given intravenously and by other routes, including subcutaneous, intramuscular, epidural, oral, intranasal, rectal, transdermal, and topical. It binds to receptors in both central and peripheral nervous systems, including opioid receptors. The most important receptors for the therapeutic activity of this drug, however, are the N-methyl-D-aspartate (NMDA) receptors located in the dorsal horn of the spinal cord. The drug is highly lipid soluble and penetrates the blood-brain barrier rapidly, which results in a rapid onset of action. It has a low incidence of reduction of cardiovascular, respiratory, and bowel function. Adverse effects can include disturbing psychomimetic effects, including hallucinations. However, these are less likely to occur when benzodiazepines (see Chapter 12) are coadministered with the drug. Interacting drugs include NMBDs (prolonged paralysis) and halothane (reduced cardiac output and blood pressure). The drug is contraindicated in cases of known drug allergy.

nitrous oxide

Nitrous oxide, also known as *laughing gas,* is the only inhaled gas currently used as a general anesthetic. It is the weakest of the general anesthetic drugs and is used primarily for dental procedures or as a supplement to other, more potent anesthetics.

◆ propofol

Propofol (Diprivan) is a parenteral general anesthetic used for the induction and maintenance of general anesthesia and also for sedation for mechanical ventilation in intensive care unit (ICU) settings. In lower doses, it can also be used as a sedative-hypnotic for moderate sedation. Some states allow nurses to administer propofol as part of a moderate sedation protocol. However, many state boards of nursing prohibit administration by nurses. Propofol also is typically well tolerated, producing few undesirable effects. Propofol is a lipid-based emulsion, and prolonged use, or if given in conjunction with total parenteral nutrition, requires serum lipids to be monitored.

dexmedetomidine

Dexmedetomidine (Precedex) is an alpha-2 adrenergic receptor agonist (see Chapter 13). It produces dose-dependent sedation, decreased anxiety, and analgesia without respiratory depression. It is used for procedural sedation and for surgeries of short duration. It has a short half-life, and the patient awakens quickly upon withdrawal of the drug. Dexmedetomidine is also used in the intensive care setting for sedation of mechanically ventilated patients. Lower doses may be needed with concurrent anesthetics, sedatives, or opioids. Side effects include hypotension, bradycardia, transient hypertension, and nausea. Doses are listed in Table 11-3. Although the prescribing information states that dexmedetomidine is to be used for only 24 hours, multiple studies have shown it to be safe and effective at longer durations.

DRUGS FOR MODERATE SEDATION

Moderate sedation, *conscious sedation,* and *procedural sedation* are synonymous terms for anesthesia that does not cause complete loss of consciousness and does not normally cause respiratory arrest. As more minor surgical procedures move from traditional operating room settings to outpatient surgery centers or office-based practices, the use of moderate sedation will continue to increase. Moderate sedation allows the patient to relax and have markedly reduced or no anxiety, yet still maintain his or her own open airway, and response to verbal commands. Standards must be followed when providing moderate sedation. Health care personnel who administer moderate sedation are required to have advanced cardiac life support training; one professional must have no duties other than to monitor the patient, and someone with the ability to intubate the patient

must be present in case the patient slips into a deeper state of sedation and is unable to maintain an open airway. The American Society of Anesthesiologists has published guidelines on moderate sedation, which can be found at www.asahq.org.

The most commonly used drugs for moderate sedation include a benzodiazepine, usually midazolam (see Chapter 12), with an opioid, usually fentanyl or morphine. Propofol is also a common agent used. Propofol is usually given by an anesthesiologist, although there is some debate among physician specialties as who should be allowed to administer propofol. The doses of midazolam used in moderate sedation are 0.02 to 0.1 mg over a 2-minute period, not to exceed 2.5 mg. If needed, a repeat dose of 25% of the initial dose may be used. If midazolam is combined with an opioid such as fentanyl or morphine, the dose should be reduced by 30% to 50%. The most common dose of fentanyl is 1 to 2 mcg/kg, which may be repeated every 30 minutes. The dose of morphine for moderate sedation is 2 mg IV. When these drugs are combined with a benzodiazepine, smaller doses should be used. The dose of propofol for moderate sedation is 0.5 to 1 mg/kg followed by 0.5 mg/kg every 3 to 5 minutes. Mild amnesia is also a common effect, due to the midazolam. This is often desirable for helping patients not to remember painful medical procedures. Moderate sedation is associated with a more rapid recovery time than general anesthesia as well as a better safety profile because of lower cardiopulmonary risks.

The oral route of drug administration is commonly used in pediatric patients. This often involves administering an oral syrup form of midazolam with or without concurrent use of injected medications such as opiates. This is especially helpful for pediatric patients who must undergo uncomfortable procedures such as wound suturing or diagnostic procedures requiring reduced movement such as computed tomography and magnetic resonance imaging. See the Patient-Centered Care: Lifespan Considerations for the Pediatric Patient box below for other considerations.

LOCAL ANESTHETICS

Local anesthetics are the second major class of anesthetics. They reduce pain sensations at the level of peripheral nerves, although this can involve *intraspinal anesthesia* (see later). They are also called *regional anesthetics* because they render a specific portion of the body insensitive to pain. They work by interfering with nerve transmission in specific areas of the body, blocking nerve conduction only in the area in which they are applied without causing loss of consciousness. They are most commonly used in clinical settings in which loss of consciousness is undesirable or unnecessary. These include childbirth and other situations in which **spinal anesthesia** is desired, dental procedures, suturing of skin lacerations, and diagnostic procedures (e.g., lumbar puncture, thoracentesis, biopsy).

Most local anesthetics belong to one of two major groups of organic compounds: esters and amides. They are classified as either *parenteral* (injectable) or *topical* anesthetics**.** Parenteral anesthetics are most commonly given intravenously but may also be administered by various spinal injection techniques (Box 11-2). Topical anesthetics are applied directly to the skin and mucous membranes. They are available in the form of solutions, ointments, gels, creams, powders, suppositories, and ophthalmic drops. Their dosage strengths are listed in Table 11-5.

The injection of parenteral anesthetic drugs into the area near the spinal cord is known as *spinal* or *intraspinal* anesthesia. This type of anesthesia is generally used to block all peripheral nerves that branch out distal to the injection site. The result is elimination of pain and paralysis of the skeletal and smooth muscles of the corresponding innervated tissues. Some of the medications used for spinal anesthesia include the opioids morphine, hydromorphone, fentanyl, and meperidine (see Chapter 10), and the local anesthetics lidocaine and bupivacaine. Because spinal anesthesia does not depress the CNS at a level that causes loss of consciousness, it can be thought of as

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

Moderate or Conscious Anesthesia

- The American Academy of Pediatrics recommends that moderate or conscious sedation (anesthesia) be used to reduce anxiety, pain, and fear in the pediatric patient. The use of moderate anesthesia in the pediatric patient allows a procedure to be performed restraint free in most situations while keeping the patient responsive.
- Pediatric dosing often conforms to the following guidelines:
  - Morphine—pediatric dosing may be at 0.05 to 0.1 mg/kg intravenously (IV) over a 2-minute period and is ideal for long procedures or cases in which pain is anticipated after the procedure.
  - Fentanyl—pediatric dosing may be at 0.5 to 1 mcg/kg with increments over 3 minutes to a maximum of three doses. Too rapid an IV injection may result in chest rigidity, which may need to be treated with muscle relaxants and possibly mechanical ventilation. Fentanyl is used often for short procedures.
  - Hydromorphone—pediatric dosing is at 0.015 to 0.02 mg/kg.
  - Meperidine—pediatric dosing is at 0.5 to 1 mg/kg over 2 minutes.
- Discharge status of the pediatric patient depends on the type of drugs and drug combinations used. Discharge after conscious or moderate sedation is based mainly on whether the following criteria are met:
  - Patient is alert and oriented compared with the baseline neurologic assessment.
  - Protective swallowing and gag reflexes are intact.
  - Vital signs are stable and consistent with baseline values for at least 30 minutes after the last dosing. Different health care facilities set different criteria that must be met and documented (blood pressure and pulse rate within normal limits or within 20 points of baseline, temperature lower than 101° F [38.3° C]).
  - Oxygen saturation is at least 95% on room air 30 minutes after the last dose.
  - Pain rating is at baseline levels or less.
  - Ambulation is at baseline level.
  - An adult is present to get the patient home and remain with the patient for at least two half-lives of the various drugs used for the anesthesia.
  - If a reversal drug was administered, there has been time for the drug to be excreted.

NOTE: Drugs given as anesthesia for moderate sedation procedures are given only under controlled situations by anesthesiologists or nurse anesthetists.

BOX 11-2 TYPES OF LOCAL ANESTHESIA

Central

- **Spinal or intraspinal anesthesia:** Anesthetic drugs are injected into the area near the spinal cord within the vertebral column. Intraspinal anesthesia is commonly accomplished by one of two injection techniques: intrathecal and epidural.
  - **Intrathecal anesthesia** involves injection of anesthetic into the subarachnoid space. Intrathecal anesthesia is commonly used for patients undergoing major abdominal or limb surgery for whom the risks of general anesthesia are too high or for patients who prefer this technique instead of complete loss of consciousness during their surgical procedure. More recently, intrathecal injection of anesthetics through implantable drug pumps is even being used on an outpatient basis in patients with severe chronic pain syndromes, such as those resulting from occupational injuries.
  - **Epidural anesthesia** involves injection of anesthetic via a small catheter into the epidural space without puncturing the dura. Epidural anesthesia is commonly used to reduce maternal discomfort during labor and delivery and to manage postoperative acute pain after major abdominal or pelvic surgery. This route is becoming more popular for the administration of opioids for pain management.

Peripheral

- **Infiltration:** Small amounts of anesthetic solution are injected into the tissue that surrounds the operative site. This approach to anesthesia is commonly used for such procedures as wound suturing and dental surgery. Often drugs that cause constriction of local blood vessels (e.g., epinephrine, cocaine) are also administered to limit the site of action to the local area.
- **Nerve block:** Anesthetic solution is injected at the site where a nerve innervates a specific area such as a tissue. This allows large amounts of anesthetic drug to be delivered to a very specific area without affecting the whole body. This method is often reserved for more difficult-to-treat pain syndromes such as cancer pain and chronic orthopedic pain.
- **Topical anesthesia:** The anesthetic drug is applied directly onto the surface of the skin, eye, or any mucous membrane to relieve pain or prevent it from being sensed. It is commonly used for diagnostic eye examinations and skin suturing.

TABLE 11-5 SELECTED TOPICAL ANESTHETICS

DRUG	ROUTE	DOSE STRENGTH
benzocaine (Dermoplast, Lanacane, Solarcaine)	Topical, aerosol, and spray	0.5%-20% ointment or cream
cocaine	Topical	4%-10% solution, jelly
dibucaine (Nupercainal)	Injection and topical	0.5%-1% solution, ointment, or cream
dibucaine	Topical	1% ointment
dyclonine (Dyclone, Sucrets)	Topical	0.5%-1% solution
ethyl chloride (Chloroethane)	Topical	Spray
lidocaine (Lidoderm)	Topical	5% patch
proparacaine (Alcaine, Ophthetic)	Ophthalmic	0.5% solution
prilocaine/lidocaine (EMLA)	Topical	2.5% prilocaine and 2.5% lidocaine cream
tetracaine (Pontocaine)	Injection, topical, and ophthalmic	0.5%-2% solution, ointment, or cream

TABLE 11-6 SELECTED PARENTERAL LOCAL ANESTHETIC DRUGS*

GENERIC NAME	TRADE NAME	POTENCY	ONSET	DURATION
lidocaine	Xylocaine	Moderate	Immediate	60-90 min
mepivacaine	Carbocaine	Moderate	Immediate	120-150 min
procaine	Novocain	Lowest	2-5 min	30-60 min
tetracaine	Pontocaine	Highest	5-10 min	90-120 min

*Other common parenteral anesthetic drugs include bupivacaine (Marcaine, Sensorcaine), chloroprocaine (Nesacaine), etidocaine (Duranest), propoxycaine (Ravocaine), and ropivacaine (Naropin).

a large-scale type of *local* rather than general anesthesia. Common types of local anesthesia are described in Box 11-2. The parenteral local anesthetic drugs and their pharmacokinetics are summarized in Table 11-6.

Local anesthesia of specific peripheral nerves is accomplished by *nerve block anesthesia* or *infiltration anesthesia*. Nerve block anesthesia involves relatively deep injections of drugs into locations adjacent to major nerve trunks or ganglia. It focuses on a relatively large body region but not necessarily as extensive as that affected by spinal anesthesia. In contrast, infiltration anesthesia involves multiple small injections (intradermal, subcutaneous, submucosal, or intramuscular) to produce a more limited or "local" anesthetic field. Another subtype of local anesthesia involves *topical* application of a drug (e.g., lidocaine) onto the surface of the skin, mucous membranes, or eye. A new method of administering local anesthetics is via a peripheral nerve catheter attached to a pump containing the local anesthetic. These pumps are designed to infuse local anesthetic around the nerves that innervate the surgical site for several days postoperatively. The catheter is implanted during surgery and is normally taken out by the patient at home once the anesthetic has been infused. Common trade names include Pain Buster and On-Q pump.

Mechanism of Action and Drug Effects

Local anesthetics work by rendering a specific portion of the body insensitive to pain by interfering with nerve transmission. Nerve conduction is blocked only in the area in which the anesthetic is applied, and there is no loss of consciousness. Local anesthetics block both the generation and conduction of impulses through all types of nerve fibers (sensory, motor, and autonomic) by blocking the movement of certain ions (sodium, potassium, and calcium) important to this process. They do this by making it more difficult for these ions to move in and out of the nerve fiber. For this reason, some of these drugs are also described as *membrane-stabilizing* because they alter the cell membrane of the nerve so that the free movement of ions is inhibited. The membrane-stabilizing effects occur first in the small fibers, then in the large fibers. In terms of paralysis, usually autonomic activity is affected first, and then pain and other sensory functions are lost. Motor activity is the last to be

lost. When the effects of the local anesthetic wear off, recovery occurs in reverse order: motor activity returns first, then sensory functions, and finally autonomic activity.

Possible systemic effects of local anesthetics include effects on circulatory and respiratory function. The systemic adverse effects depend on where and how the drug is administered (e.g., injection at a certain level in the spinal cord or topical application of a drug that gains access to the circulation). Such adverse effects are unlikely unless large quantities of a drug are injected. Local anesthetics also produce *sympathetic blockade;* that is, they block the action of the two *neurotransmitters* of the sympathetic nervous system: *norepinephrine* and *epinephrine* (see Chapter 18). The cardiac effects include a decrease in stroke volume, cardiac output, and peripheral resistance. The respiratory effects include reduced respiratory function and altered breathing patterns, but complete paralysis of respiratory function is unlikely.

Indications

Local anesthetics are used for surgical, dental, or diagnostic procedures, as well as for the treatment of various types of chronic pain. Spinal anesthesia is used to control pain during surgical procedures and childbirth. Nerve block anesthesia is used for surgical, dental, and diagnostic procedures and for the therapeutic management of chronic pain. Infiltration anesthesia is used for relatively minor surgical and dental procedures.

Contraindications

Contraindications for local anesthetics include known drug allergy. Only specially formulated dosage forms are intended for ophthalmic use (see Chapter 57).

Adverse Effects

The adverse effects of the local anesthetics are limited and of little clinical importance in most circumstances. The undesirable effects usually occur with high plasma concentrations of the drug, which result from inadvertent intravascular injection, an excessive dose or rate of injection, slow metabolic breakdown, or injection into a highly vascular tissue. One notable complication of spinal anesthesia is *spinal headache.* Spinal headache occurs in up to 70% of patients who either experience inadvertent dural puncture during epidural anesthesia or undergo intrathecal anesthesia. Spinal headache is most often self-limiting and is treated with bed rest and conventional analgesic medications. Oral or intravenous forms of the CNS stimulant caffeine (see Chapter 13) are also sometimes used. Severe cases of spinal headache may be treated by the anesthetist by injection of a small volume (roughly 15 mL) of venous sample of the patient's own blood into the patient's epidural space. The exact mechanism by which this *blood patch* provides relief is unknown, but it is effective in treating spinal headache in over 90% of cases. See Box 11-9 for more information on spinal headaches.

True allergic reactions to local anesthetics are rare. However, allergic reactions can occur, ranging from skin rash, urticaria, and edema to anaphylactic shock. Such allergic reactions are generally limited to a particular chemical class of anesthetics called the *ester type.* Box 11-3 categorizes the local anesthetic drugs into the ester and amide chemical families. Different enzymes are responsible for the breakdown of these two groups of anesthetics in the body. Anesthetics belonging to the ester family are metabolized by cholinesterase in the plasma and liver. They are converted into a para-aminobenzoic acid (PABA) compound. This compound is responsible for the allergic reactions. In contrast, the *amide type* of anesthetics is metabolized uneventfully to active and inactive metabolites in the liver by other enzymes. Often when an individual has an adverse reaction to one of the local anesthetics, using a drug from the alternate chemical class avoids this problem.

BOX 11-3 CHEMICAL GROUPS OF LOCAL ANESTHETICS

Ester Type	Amide Type
benzocaine	bupivacaine
chloroprocaine	dibucaine
cocaine	etidocaine
procaine	lidocaine
proparacaine	mepivacaine
propoxycaine	prilocaine
tetracaine	

Toxicity and Management of Overdose

Local anesthetics have little opportunity to cause toxicity under most circumstances. However, systemic reactions are possible if sufficiently large quantities are absorbed into the systemic circulation. To prevent this from occurring, a *vasoconstrictor* such as epinephrine is often coadministered with the local anesthetic to maintain localized drug activity (e.g., lidocaine/epinephrine or bupivacaine/epinephrine). This property of epinephrine also serves to reduce local blood loss during minor surgical procedures. If significant amounts of the locally administered anesthetic are absorbed systemically, cardiovascular and respiratory function may be compromised. In extreme cases, such as inadvertent injection of drug into a major blood vessel, symptomatic and supportive cardiovascular and/or respiratory therapy may be required until the drug is metabolized and eliminated.

Interactions

Few clinically significant drug interactions occur with the local anesthetics. When given with enflurane, halothane, or epinephrine, these drugs can lead to dysrhythmias.

DRUG PROFILES

Besides lidocaine, profiled here, local anesthetics include bupivacaine, chloroprocaine, etidocaine, mepivacaine, prilocaine, procaine, propoxycaine, ropivacaine, and tetracaine. There are two major types of local anesthetics as determined by chemical structure: amides and esters. These designations refer to the type of linkage between the aromatic ring and the amino group of the chemical structures of the drug molecules. These structural components give these drugs their anesthetic properties.

◆ lidocaine

Lidocaine belongs to the amide class of local anesthetics. Some patients may report that they have allergic or anaphylactic

reactions to the "caines," as they may refer to lidocaine and the other amide drugs. In these situations, it may be wise to try a local anesthetic of the ester type.

Lidocaine (Xylocaine) is one of the most commonly used local anesthetics. It is available in several strengths, both alone and in different concentrations with epinephrine, and is used for both infiltration and nerve block anesthesia. Lidocaine is also available in topical forms, including the unique product EMLA. This is a cream mixture of lidocaine and prilocaine that is applied to skin to ease the pain of needle punctures (e.g., starting an intravenous line). There is also a transdermal lidocaine patch for relief of *postherpetic neuralgia* (see Chapter 10). Parenteral lidocaine is also used to treat certain cardiac dysrhythmias (see Chapter 23). Contraindications include known drug allergy. Lidocaine is a pregnancy category B drug.

NEUROMUSCULAR BLOCKING DRUGS

Neuromuscular blocking drugs (NMBDs) prevent nerve transmission in skeletal and smooth muscles, leading to paralysis. They are often used as adjuncts with general anesthetics for surgical procedures. Neuromuscular blocking drugs also paralyze the skeletal muscles required for breathing: the *intercostal* muscles and the *diaphragm.* The patient is rendered unable to breathe on his or her own, and mechanical ventilation is required to prevent brain damage or death by suffocation. Deaths have been reported when an NMBD is accidentally mistaken for a different drug and given to a patient who is not mechanically ventilated. Most hospitals have taken extra precautions to keep NMBDs separated from other drugs, or at least marked with warning stickers. It is essential that the nurse ensure that the patient is ventilated before giving an NMBD and double-check that an NMBD is not inadvertently given. In the event of an error, the patient would experience a horrendous death, because the mind is alert but the patient cannot speak or move (see the Safety and Quality Improvement: Preventing Medication Errors box).

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Neuromuscular Blocking Drugs

Neuromuscular blocking drugs are considered high-alert drugs, because improper use may lead to severe injury or death. The Institute for Safe Medication Practices has reported several cases of patient death or injury as a result of medication errors involving neuromuscular blocking drugs. Because these drugs paralyze the respiratory muscles, incorrect administration without sufficient ventilator support has resulted in patient deaths. There have been medication errors due to "sound-alike" drug names as well (e.g., vancomycin and vecuronium). Most facilities have followed recommendations to restrict access to these drugs, provide warning labels and reminders, and increase staff awareness of the dangers of these drugs.

For more information, visit www.ismp.org/Newsletters/acutecare/articles/20050922.asp.

Historically, snakes and plants have played a role in the identification of substances that cause paralysis and to the discovery of related receptor proteins in animals and humans. The beginning steps involved study of the irreversible nerve transmission inhibition caused by toxins in the venoms of krait snake species and the venoms of certain varieties of cobra. *Curare,* a general term for various South American arrow poisons, has a long and intriguing history. It has been used for centuries by natives of the Amazon River region and other parts of South America to kill wild animals for food. Animals shot with arrows soaked in this plant substance normally die from paralysis of respiratory muscles. Once the receptor sites of action of these venoms and toxins were identified, pharmacologic drugs were developed that mimic these substances. Curare can be considered the grandfather of modern NMBDs. Several curare-like drugs are now used in clinical practice. The first drug derived from curare to be used medicinally was d-tubocurarine, which was introduced into anesthesia practice in 1940; it has now been replaced by newer drugs such as pancuronium. Pancuronium has a pharmacodynamic profile similar to that of curare but produces fewer adverse effects.

Mechanism of Action and Drug Effects

NMBDs are classified into two groups based on mechanism of action: depolarizing and nondepolarizing. Depolarizing NMBDs work similarly to the neurotransmitter acetylcholine (ACh). They bind in place of ACh to cholinergic receptors at the motor endplates of muscle nerves or neuromuscular junctions. Thus they are competitive agonists (see Chapter 2). There are two phases of depolarizing block. During phase I (depolarizing phase), the muscles fasciculate (twitch). Eventually, after continued depolarization has occurred, muscles are no longer responsive to the ACh released; thus muscle tone cannot be maintained and the muscle becomes paralyzed. This is phase II, or the desensitizing phase. Depolarizing NMBDs include d-tubocurarine and succinylcholine (see later). The duration of action of succinylcholine after a single dose to facilitate intubation is only about 5 to 9 minutes because of the rapid breakdown of the drug by cholinesterase, the enzyme responsible for metabolizing succinylcholine.

Nondepolarizing NMBDs also bind to ACh receptors at the neuromuscular junction, but instead of mimicking ACh, they block its actions. Therefore, these drugs are *competitive antagonists* (see Chapter 2) of ACh. Consequently, the nerve cell membrane is not depolarized, the muscle fibers are not stimulated, and skeletal muscle contraction does not occur. Nondepolarizing NMBDs include vecuronium and pancuronium and are typically classified into three groups based on their duration of action: short-acting, intermediate-acting, and long-acting drugs.

The typical time course of NMBD-induced paralysis during a surgical procedure is as follows: The first sensation that is typically felt is muscle weakness. This is usually followed by a total flaccid paralysis. Small, rapidly moving muscles such as those of the fingers and eyes are generally the first to be paralyzed. The next are those of the limbs, neck, and trunk. Finally, the intercostal muscles and the diaphragm are paralyzed, which causes respiratory arrest. The patient can no longer breathe on his or her own. It must be noted that NMBDs, when used alone, do *not* cause sedation or relieve pain or anxiety. Therefore, the patient needs to also receive appropriate medications

TABLE 11-7 EFFECTS OF GANGLIONIC BLOCKADE BY NEUROMUSCULAR BLOCKING DRUGS

SITE	PART OF NERVOUS SYSTEM BLOCKED	PHYSIOLOGIC EFFECT
Arterioles	Sympathetic	Vasodilation and hypotension
Veins	Sympathetic	Dilation
Heart	Parasympathetic	Tachycardia
Gastrointestinal tract	Parasympathetic	Reduced tone and tract motility; constipation
Urinary bladder	Parasympathetic	Urinary retention
Salivary glands	Parasympathetic	Dry mouth

to manage pain and/or anxiety. Neuromuscular blocking drugs temporarily inactivate the body's natural drive to control respirations. Recovery of muscular activity after discontinuation of anesthesia usually occurs in the reverse order of the paralysis, and thus the diaphragm is ordinarily the first to regain function.

Indications

The main therapeutic use of NMBDs is for maintaining skeletal muscle paralysis to facilitate controlled ventilation during surgical procedures. Shorter-acting NMBDs are often used to facilitate intubation with an endotracheal tube. This is commonly done for a variety of diagnostic procedures such as laryngoscopy, bronchoscopy, and esophagoscopy. When used for this purpose, NMBDs are frequently combined with anxiolytics, analgesics, and anesthetics. Additional nonsurgical applications include reduction of laryngeal or general muscle spasms, reduction of spasticity from tetanus and neurologic diseases such as multiple sclerosis, and prevention of bone fractures during electroconvulsive therapy (see Chapter 16). These drugs are also used for the diagnosis of *myasthenia gravis,* a disease characterized by chronic muscular weakness.

Contraindications

Contraindications to NMBDs include known drug allergy and also may include previous history of malignant hyperthermia, penetrating eye injuries, and narrow-angle glaucoma.

Adverse Effects

The muscle paralysis induced by depolarizing NMBDs (e.g., succinylcholine) is sometimes preceded by muscle spasms, which may damage muscles. These muscle spasms are termed *muscle fasciculations* and are most pronounced in the muscle groups of the hands, feet, and face. Injury to muscle cells may cause postoperative muscle pain and release potassium into the circulation, resulting in hyperkalemia, which is usually self-limiting and reversible. Small doses of nondepolarizing NMBDs are sometimes administered with succinylcholine to minimize these muscle fasciculations. In spite of these disadvantages, succinylcholine is still popular due to its rapid onset of action, its depth of neuromuscular blockade, and its short duration of action. For these reasons, it is often preferred to nondepolarizing NMBDs for *rapid-sequence induction* of anesthesia (e.g., for emergency intubation).

BOX 11-4 CONDITIONS THAT PREDISPOSE PATIENTS TO TOXIC EFFECTS FROM NEUROMUSCULAR BLOCKING DRUGS

- Acidosis
- Amyotrophic lateral sclerosis
- Hypermagnesemia
- Hypocalcemia
- Hypokalemia
- Hypothermia
- Myasthenia gravis
- Myasthenic syndrome
- Neonatal status
- Neurofibromatosis
- Paraplegia
- Poliomyelitis

BOX 11-5 CONDITIONS THAT OPPOSE THE EFFECTS OF NEUROMUSCULAR BLOCKING DRUGS

- Cirrhosis with ascites
- Clostridial infections
- Hemiplegia
- Hypercalcemia
- Hyperkalemia
- Peripheral nerve transection
- Peripheral neuropathies
- Thermal burns

The effects on the cardiovascular system vary depending on the NMBD used and the individual patient. Increases and decreases in blood pressure and heart rate have been seen. Some NMBDs cause a release of histamine, which can result in bronchospasm, hypotension, and excessive bronchial and salivary secretion. The gastrointestinal tract is seldom affected by NMBDs. When it is affected, decreased tone and motility typically result, which can lead to constipation or even ileus. Use of succinylcholine has been associated with hyperkalemia; dysrhythmias; fasciculations; muscle pain; myoglobinuria; increased intraocular, intragastric, and intracranial pressure; and malignant hyperthermia.

The key to limiting adverse effects with most NMBDs is to use only enough of the drug to block the neuromuscular receptors. If too much is used, the risk is increased that other ganglionic receptors will be affected. Blockade of these other ganglionic receptors leads to most of the undesirable effects of NMBDs. The effects of ganglionic blockade in various areas of the body are listed in Table 11-7.

Toxicity and Management of Overdose

The primary concern when NMBDs are overdosed is prolonged paralysis requiring prolonged mechanical ventilation (see the Safety and Quality Improvement: Preventing Medication Errors box on p. 177). Cardiovascular collapse may be seen and is thought to be the result of histamine release. Multiple medical conditions can predispose an individual to toxicity. These conditions increase the sensitivity of the individual to NMBDs and prolong their effects. These predisposing conditions are listed in Box 11-4. Some conditions make it more difficult for NMBDs to work, and therefore higher doses of NMBDs are required in these cases. Although these conditions do not necessarily lead to toxicity or overdose, they are worthy of mention and are listed in Box 11-5.

Anticholinesterase drugs such as neostigmine, pyridostigmine, and edrophonium are antidotes and are used to reverse muscle paralysis. They work by preventing the enzyme cholinesterase from breaking down ACh. This causes ACh to build up at the motor endplate, and it eventually displaces the nondepolarizing NMBD molecule, returning the nerve to its original

BOX 11-6 DRUGS THAT INTERACT WITH NEUROMUSCULAR BLOCKING DRUGS

Additive Effects
Aminoglycosides
Calcium channel blockers
clindamycin
cyclophosphamide
cyclosporine
dantrolene
furosemide
Inhalation anesthetics
Local anesthetics
magnesium
quinidine

Opposing Effects
carbamazepine
Corticosteroids
phenytoin

BOX 11-7 CLASSIFICATION OF NONDEPOLARIZING NEUROMUSCULAR BLOCKING DRUGS

Short-Acting Drug
mivacurium (Mivacron)

Intermediate-Acting Drugs
atracurium (Tracrium)
rocuronium (Zemuron)
vecuronium (Norcuron)

Long-Acting Drugs
doxacurium (Nuromax)
pancuronium (Pavulon)
tubocurarine (dTC)

DOSAGES

Selected Neuromuscular Blocking Drugs

DRUG	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
pancuronium (Pavulon)	Nondepolarizing NMBD (long-acting)	**Adults, children older than 1 month** IV: 60-100 mcg/kg **Neonates up to 1 month** Because neonates are very sensitive to nondepolarizing NMBDs, give a test dose of 20 mcg/kg IV **Adult** IV: 0.04-0.1 mg/kg Continuous infusion: 0.1 mg/kg/hr	Intubation Intubation Mechanical ventilation
♦ succinylcholine (Anectine, Quelicin)	Depolarizing NMBD (short-acting)	**Pediatric** IV: 1-2 mg/kg IM: 3-4 mg/kg **Adult** IV: 0.3-1.1 mg/kg IM: 3-4 mg/kg	Intubation Intubation
♦ vecuronium (Norcuron)	Nondepolarizing NMBD (intermediate-acting)	**Pediatric** IV: 0.08-0.1 mg/kg **Adult** IV: 0.08-0.1 mg/kg Continuous infusion: 0.1 mg/kg/hr	Intubation Intubation Mechanical ventilation

IM, Intramuscular; *IV,* intravenous; *NMBD,* neuromuscular blocking drug.

state. Dysmetabolic syndrome known as malignant hyperthermia (see General Anesthetics earlier in the chapter) can also occur with NMBDs, especially succinylcholine.

Interactions

Many drugs interact with NMBDs, which may lead to either synergistic or opposing effects. Aminoglycoside antibiotics, when given with an NMBD, can have additive effects. The tetracycline antibiotics can also produce neuromuscular blockade, possibly by chelation of calcium, and calcium channel blockers have also been shown to enhance neuromuscular blockade. Other notable drugs that interact with NMBDs are listed in Box 11-6.

Dosages

For dosage information of selected NMBDs, see the table on this page.

DRUG PROFILES

Neuromuscular blocking drugs are one of the most commonly used classes of drugs in the operating room. They are given primarily with general anesthetics to facilitate endotracheal intubation and to relax skeletal muscles during surgery. In addition to their use in the operating room, they are given in the ICU to paralyze mechanically ventilated patients. There are two basic types of NMBDs: depolarizing and nondepolarizing drugs. Nondepolarizing NMBDs are generally classified by their duration of action. Box 11-7 lists examples of currently used nondepolarizing drugs.

DEPOLARIZING NEUROMUSCULAR BLOCKING DRUGS

♦ succinylcholine

Succinylcholine is the only currently available drug in the *depolarizing* subclass of NMBDs. Succinylcholine (Anectine) has a

structure similar to that of the parasympathetic neurotransmitter ACh. It stimulates the same neurons as ACh and produces the same physiologic responses initially. Compared to ACh, however, succinylcholine is metabolized more slowly. Because of this slower metabolism, succinylcholine subjects the motor endplate to ongoing depolarizing stimulation. Repolarization cannot occur. As long as sufficient succinylcholine concentrations are present, the muscle loses its ability to contract, and flaccid muscle paralysis results. Because of its quick onset of action, succinylcholine is most commonly used to facilitate endotracheal intubation. It is seldom used over long periods because of its tendency to cause muscular fasciculations. It is contraindicated in patients with personal or familial history of malignant hyperthermia, skeletal muscle myopathies, and known hypersensitivity to the drug. It is available only in injectable form. For dosage information, see the table on p. 179.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Rapid, less than 1 min	60 sec	Less than 1 min	4-6 min

NONDEPOLARIZING NEUROMUSCULAR BLOCKING DRUGS

Nondepolarizing NMBDs are commonly used to facilitate endotracheal intubation, reduce muscle contraction, and facilitate a variety of diagnostic procedures. They are often combined with anxiolytics or anesthetics. They may also be used to induce respiratory arrest in patients on mechanical ventilation.

pancuronium

Pancuronium (Pavulon) is a long-acting nondepolarizing NMBD. It is used as an adjunct to general anesthesia to facilitate endotracheal intubation and to provide skeletal muscle relaxation during surgery or mechanical ventilation. It is most commonly employed for long surgical procedures that require prolonged muscle paralysis. Use of pancuronium is contraindicated in cases of known drug allergy. It is available only in injectable form. For dosage information, see the table on p. 179.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	3-5 min	5 min	100 min	45-60 min

◆ vecuronium

Vecuronium (Norcuron) is an intermediate-acting nondepolarizing NMBD. It is used as an adjunct to general anesthesia to facilitate tracheal intubation and to provide skeletal muscle relaxation during surgery or mechanical ventilation, and it is one of the most commonly used NMBDs. Long-term use in the ICU setting has resulted in prolonged paralysis and subsequent difficulty weaning from mechanical ventilation. This is believed to be due to an active metabolite, 3-desacetyl vecuronium, which tends to accumulate with prolonged use. Use of vecuronium is contraindicated in cases of known drug allergy. It is available only in injectable form. For dosage information, see the table on p. 179.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	2.5-3 min	3-5 min	65-76 min	25-40 min

TEAMWORK AND COLLABORATION: PHARMACOKINETIC BRIDGE TO NURSING PRACTICE

With moderate (conscious or procedural) sedation or anesthesia, it is always important to understand the pharmacokinetic properties of the drug(s) used. For example, the intravenous form of midazolam has an onset of action of 1 to 5 minutes, a peak plasma effect of 20 to 60 minutes, an elimination half-life of 1 to 4 hours (time it takes for 50% of the drug to be excreted), and a duration of action of 2 to 6 hours. Therefore, if midazolam is used for moderate sedation, you will begin to see the sedating properties within 1 to 5 minutes and peak effects on the patient between 20 to 60 minutes. Since the drug's action only lasts for 2 to 6 hours, midazolam is an attractive option for use in outpatient procedures because of fast onset and short duration of action. Therefore, as noted with this drug's pharmacokinetic properties, you may then be able to predict the drug's onset of action, peak effect, and duration of action.

NURSING PROCESS

ASSESSMENT

It is important to note that anesthetics are not drugs that are typically given by the registered nurse unless the nurse is a licensed nurse anesthetist. Exceptions to this statement are orders for topical forms, such as oral swish-and-swallow solutions that may be used during chemotherapy and lidocaine patches for pain relief. Associated with each drug used for general and local anesthesia are some very broad as well as specific assessment parameters. First, for any form of anesthesia and during any of the phases of anesthesia, the major parameters to assess are airway, breathing, and circulation (ABCs). Include in your assessment questions regarding allergies and use of prescription as well as over-the-counter drugs, herbals, supplements, and social and/or illegal drugs.

Another important area to assess is the patient's use of alcohol and nicotine. Excessive use of alcohol may alter the patient's response to general anesthesia, especially if there is liver impairment. Also, if the patient has a history of alcohol abuse, withdrawal symptoms may occur during the recovery from anesthesia and/or surgery. Perform a respiratory assessment (e.g., respiratory rate, rhythm, and depth; breath sounds; oxygen saturation level), especially if the patient has a history of smoking or is currently a smoker. The patient's history of smoking is important because nicotine has a paralyzing effect on the cilia within the respiratory tract. Once they are malfunctioning, these cilia cannot perform their main function of keeping foreign bodies out of the lungs and allowing mucus and secretions to be coughed up with ease. Malfunctioning of the cilia can

potentially lead to atelectasis or pneumonia. Other objective data include weight and height, because these parameters are often used in the dosing of anesthesia. Other studies that may be ordered by the anesthesiologist and/or surgeon include an electrocardiogram, chest radiograph, and tests of renal function (e.g., BUN level, creatinine level, urinalysis with specific gravity) and hepatic function (e.g., total protein and albumin levels; bilirubin level; ALP, AST, and ALT levels). Additional laboratory tests may include Hgb, Hct, WBC with differential, and tests that indicate clotting abilities, such as PT-INR, aPTT, and platelet count. Also assess results for serum electrolytes, specifically potassium, sodium, chloride, phosphorus, magnesium, and calcium, because abnormalities may lead to further complications from the anesthesia. You must assess the results of a pregnancy test in females of childbearing age, if ordered, because of the possibility of teratogenic effects (adverse effects on the fetus) related to the anesthetic drug.

CASE STUDY

Moderate (Conscious) Sedation

A 53-year-old woman is scheduled to have a colonoscopy this morning, and she is very anxious. The nurse anesthetist has explained the moderate (conscious) sedation that is planned, but the patient says after the anesthetist leaves the room, "I'm so afraid of feeling it during the test. Why don't they just put me to sleep?"

1. How does moderate sedation differ from general anesthesia?
2. What is the nurse's best answer to the patient's question?
3. What is important for the nurse to assess before this procedure is performed?

The certified registered nurse anesthetist prepares to administer morphine and midazolam (Versed) before the procedure.

4. Explain the purpose of these two medications during moderate sedation. How are the dosages adjusted when these are given together?

For answers, see http://evolve.elsevier.Lilley.

Neurologic assessment includes a thorough survey of the patient's mental status. Determine and document level of consciousness, alertness, and orientation to person, place, and time prior to the anesthesia. Additional neurologic assessment includes motor assessments, with left-right and upper extremity versus lower extremity comparisons of strength, reflexes, grasp, and ability to move on command. Sensory assessment focuses on the same anatomic areas, with comparisons of the response to various types of stimuli such as sharp, dull, soft, and cold versus warm. Swallowing ability and gag reflexes are also important to assess and document for baseline status and comparisons. When these motor, sensory, and cognitive parameters are within normal limits, there is proof of an intact neurologic system.

One very significant reaction to assess for in patients receiving *general anesthesia* is that of malignant hyperthermia. This is a rapid progression of hyperthermia that may be fatal if not promptly recognized and aggressively treated. The tendency is inherited, so questions about related signs and symptoms in the family's and patient's medical histories are important to document and report. A familial history of malignant hyperthermia would put the patient at risk. Signs and symptoms of malignant hyperthermia include a rapid rise in body temperature, tachycardia, tachypnea, muscle rigidity, cyanosis, irregular heartbeat, mottling of the skin, diaphoresis (profuse sweating), and an unstable blood pressure. If there is no documented problem with general anesthesia or if the patient is undergoing general anesthesia for the first time, perform an astute and careful examination of all medical and medication histories. With any type of anesthesia, it is often very slight changes in vital signs, other vital parameters, and laboratory test results that may provide nursing and other health care providers with a possible clue to the patient's reaction to anesthesia. Note that malignant hyperthermia occurs during the anesthesia process and in the surgical suite; nevertheless, close observation after anesthesia is still important and much needed. Intravenously administered anesthetic drugs are usually combined with adjuvant drugs (given at the same time) such as sedative-hypnotics, antianxiety drugs, opioid and nonopioid analgesics, antiemetics, and anticholinergics. These drugs are used to decrease some of the undesirable aftereffects of inhaled anesthetics. If they are used, perform a complete assessment for each of the drugs, including obtaining a medical history and medication profile. Liver and kidney function studies are important in these patients as well, so that any risks of toxicity and complications can be anticipated.

For patients about to undergo anesthesia with *neuromuscular blocking drugs (NMBDs)*, perform a complete head-to-toe assessment with a thorough medical and medication history. Which specific drug is being used and whether it is depolarizing or nondepolarizing will guide your assessment, because of the action of NMBDs on the patient's neuromuscular functioning (see pharmacology discussion). Assess all cautions, contraindications, and drug interactions. Another concern with the use of these drugs is that they are associated with an increase in intraocular pressure and intracranial pressure. Therefore, these anesthetic drugs should not be used or used with extreme caution (close monitoring of these pressures) in patients with glaucoma or closed head injuries.

Complete a thorough respiratory assessment in patients receiving NMBDs because of the effect of these drugs on the respiratory system. In particular, these drugs have a paralyzing effect on the muscles used for breathing and—for this very reason—are used to facilitate intubation for mechanical ventilation. Paralysis of respiratory muscles allows patient relaxation to the point where the patient will not fight against the breaths delivered by the ventilator. Also indicated with the use of NMBDs is careful assessment of serum electrolyte levels, specifically potassium and magnesium levels. Imbalances in these electrolytes may lead to increased action of the NMBD with exacerbation of the drug's actions and toxic effects. Allergic reactions to these drugs are most commonly characterized by rash, fever, respiratory distress, and pruritus. Drug interactions with herbal products are outlined in the Safety: Herbal Therapies and Dietary Supplements box on p. 182. For more specific information on the differences between depolarizing and nondepolarizing NMBDs, see the pharmacology section of this chapter.

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

Possible Effects of Popular Herbal Products When Combined with Anesthetics

Feverfew: Migraine headaches, insomnia, anxiety, joint stiffness, risk of increased bleeding times with increased risk of bleeding
Garlic: Changes in blood pressure, risk of increased bleeding
Ginger: Sedating effects; risk of bleeding, especially if taken with either aspirin or ginkgo
Ginseng: Irritability and insomnia, risk of cardiac adverse effects
Kava: Sedating effects, potential liver toxicity, risk of additive effects with medications
St. John's Wort: Sedation, blood pressure changes, risk of interaction with other medications that prolong the effects of anesthesia

For more information, see www.aana.com, www.anesthesiapatientsafety.com, www.herbalgram.com, and http://nccam.NIH.gov.

With the use of *conscious or moderate sedation,* as with any anesthesia technique, assessment for allergies, cautions, contraindications, and drug interactions is important. Because moderate sedation is commonly used across the lifespan, closely assess organ function and note diseases or conditions that could lead to excessive levels of the drug in the body, such as liver or kidney impairment. See Chapters 10 and 12 for more information about the assessment associated with the use of opioids and sedative-hypnotics/CNS depressants.

Use of *spinal anesthesia* requires thorough assessment with an emphasis on the ABCs, respiratory function, and vital signs, specifically blood pressure. Baseline respirations with attention to rate, rhythm, depth, and breath sounds are important to note, as are oxygen saturation levels obtained via pulse oximetry. Because of possible problems with vasodilatation from the spinal anesthetic, document baseline blood pressure levels and pulse rate. Record history of previous reactions to this form of anesthesia, allergies, and a listing of all medications, and report any abnormal reactions to the anesthesiologist and surgeon. Neurologic assessment with notation of sensory and motor intactness in the lower extremities, as well as documentation of any abnormalities, is important. The use of epidural anesthesia requires special attention to overall hemostasis through monitoring of vital signs and oxygen saturation levels. Assess baseline sensory and motor function in the extremities, and document an intact neurologic system (see Implementation for more detailed discussion). Spinal headaches may occur with either spinal anesthesia or epidural injections, and thus baseline assessment for the presence of headaches is important.

Local-topical anesthetics, such as lidocaine, used for either infiltration or nerve block anesthesia may be administered with or without a vasoconstrictor (e.g., epinephrine). The vasoconstrictors are used to help confine the local anesthetic to the injected area, prevent systemic absorption of the anesthetic, and reduce bleeding. If there is systemic absorption of the vasoconstrictor into the bloodstream, the patient's blood pressure could elevate to life-threatening levels, especially in patients who are at high risk (e.g., those with underlying arterial disease). Therefore, review the patient's medical history to assess for any preexisting illnesses, such as vascular disease, aneurysms, or hypertension, because these may be contraindications to the use of the vasoconstrictor with the anesthetic. In addition, with these local anesthetics, assess for allergies to the drug as well as baseline vital signs. Also assess for possible drug interactions, and note prescription medications, herbal products, supplements, and over-the-counter medications. In summary, it is important with any type of anesthesia to assess the patient's level of homeostasis prior to actual administration of the drug. This assessment may include taking vital signs as well as checking the ABCs. Other parameters of interest may be oxygen saturation levels measured by pulse oximetry, cardiovascular and respiratory function, and neurologic function.

NURSING DIAGNOSES

1. Impaired gas exchange related to the general anesthetic's CNS depressant effect with altered respiratory rate and effort (decreased rate, decreased depth)
2. Decreased cardiac output related to the systemic effects of anesthesia
3. Acute pain related to the adverse effect of spinal headache from epidural anesthesia
4. Deficient knowledge related to lack of information about anesthesia
5. Risk for injury related to the impact of any form of anesthesia on the CNS (e.g., CNS depression and decreased sensorium)

PLANNING

GOALS

1. Patient maintains normal and effective respiratory patterns and status.
   - Patient demonstrates an understanding about the potential complications of anesthesia related to the respiratory system.
2. Patient maintains blood pressure and pulse rate within normal limits.
   - Patient demonstrates an understanding about the potential complications of anesthesia related to cardiac functioning.
3. Patient fully understands the potential for the adverse effect of spinal headache associated with epidural anesthesia.
4. Patient demonstrates sound knowledge base about the action and adverse effects of anesthesia.
5. Patient states the potential complications of anesthesia and possible risks related to CNS depression, specifically decreased sensorium.

OUTCOME CRITERIA

1. Patient states measures to increase respiratory expansion through coughing, deep breathing, turning, and ambulating (when allowed).
2. Patient remains well hydrated with increase in fluids and remains ambulating to help increase circulation and minimize complications, unless contraindicated.

3. Patient states measures to help minimize and/or prevent acute pain from possible complication of spinal headache with bed rest, hydration, and following postanesthesia/post-epidural orders for up to 24 to 48 hours after procedure.
4. Patient experiences maximal effects of anesthesia as noted by following preanesthesia orders, such as remaining NPO, taking medications only as prescribed, as well as experiencing minimal adverse effects from an adequate knowledge about the postanesthesia period and ways to minimize problems (see all measures listed in outcome criteria 1 to 3 and 5).
5. Patient remains free of injury and/or falls by asking for assistance while ambulating or having assistance if at home and recovering alone as well as taking medications only as prescribed, sitting up for brief periods prior to ambulating, forcing fluids, and resuming adequate nutritional intake during the postanesthesia period.

IMPLEMENTATION

Regardless of the type of anesthesia used, one of the most important nursing considerations during the preanesthesia, intraanesthesia, and postanesthesia periods is close and frequent observation of all body systems. Begin with a focus on the ABCs of nursing care, vital signs, and oxygen saturation levels as measured by pulse oximetry as well as by the clinical presentation of the patient. Remember that the way a patient looks is very important at any point in time! Document the observations from these interventions, and repeat the interventions as needed, depending on the patient's status and in keeping with the standard of care for the type of anesthesia. Monitor vital signs frequently and as needed, and based on the patient's condition, including assessing the fifth vital sign of pain (see discussion later in this section and in Chapter 10).

For patients undergoing *general anesthesia,* assessing the patient's temperature is especially important because of the risk of malignant hyperthermia, and close monitoring is required if malignant hyperthermia occurred during the anesthesia process. This sudden elevation in the patient's body temperature (e.g., higher than 104° F [40° C]) not only requires critical care during and immediately after anesthesia but also calls for close monitoring even during regular postoperative care (see earlier discussion). When intravenous, inhaled, or other forms of anesthesia are used, resuscitative equipment and medications, including opioid antidotes, are readily available in the surgical and postsurgical areas in case of cardiorespiratory distress or arrest. The anesthesiologist keeps control of the anesthetic drug, and he or she is well prepared for any emergency—as is the entire group of individuals in the surgical suite and postanesthesia recovery area. Continual monitoring of the status of breath sounds is an important intervention, because hypoventilation may be a complication of general and other forms of anesthesia. Oxygen is administered after a patient has received general and/or other forms of anesthesia to compensate for the respiratory depression that may have occurred during the anesthesia and surgical process. Because oxygen is a drug, a doctor's order is needed for its administration. Continuous monitoring of oxygen saturation levels is therefore an important intervention. In addition, hypotension and orthostatic hypotension are possible problems after anesthesia, so postural blood pressure measurements (supine and standing), in addition to regular blood pressure monitoring, may be needed. Additional nursing interventions include monitoring of neurologic parameters such as reflexes, response to commands, level of consciousness or sedation, and pupil reaction to light. Monitor for changes in sensation and movement in the extremities, distal pulses, temperature, and color when nerve blocks and spinal anesthesia are used, because it is important to confirm that areas distal to the anesthetic site have remained intact.

Should the patient require pain management once the anesthesia has been terminated, remember that the anesthetic and any adjuvant drugs used continue to have an effect on the patient until the period of the drugs' action has passed. Therefore, administer sedative-hypnotics, opioids, nonopioids, and other CNS depressants for pain relief cautiously and *only* with close monitoring of vital signs. If the patient has received some of these medications during postanesthesia, document dosages of drugs used, and then pass them on during a report when the patient is transferred to another unit. Additional orders are usually provided by the physician/surgeon or anesthesiologist regarding doses of analgesics to administer once the patient has been transferred or if discharged to home. If such orders have not been provided, however, and the patient is experiencing pain, contact the appropriate prescriber. The concern here is that the patient may receive either too much or not enough analgesic.

Patients who receive *NMBDs* as part of an induction process for mechanical ventilation need to be monitored closely during and after initiation of mechanical ventilation. Patients receiving NMBDs and who are awake may need to receive other medications for sedation and/or pain. These patients are in intensive care or critical care units, and many protocols are provided regarding interventions after the intubation. These include measurement of vital signs and determination of neurologic status, including sensation and hand grasp strength. When mechanical ventilation is used, educate patients and family members about the purpose of the drug-induced paralysis while receiving mechanical ventilation (e.g., to prevent the patient from fighting against the ventilation provided by the machine, resisting the effects of the mechanical ventilatory assistance and possibly leading to hypoventilation). Inform the family and remember in the nursing care of these patients that they can still hear the spoken word. Knowing what to expect is key to helping decrease fears and anxiety—for both the patient and those visiting the patient.

Patients undergoing *moderate sedation* as the method of anesthesia should receive patient education before the procedure. As noted earlier in the chapter, recovery from this type of anesthesia is more rapid, and the safety profile is better than that of general anesthesia with its inherent cardiorespiratory risks. As with general anesthesia, however, monitor the ABCs of care, vital signs, pulse oximetry oxygen saturation levels, and level of consciousness or sedation. See Box 11-8 for more information on moderate sedation.

With *spinal anesthesia,* nursing interventions need to include constant monitoring for a return of sensation and motor

BOX 11-8 MODERATE OR CONSCIOUS SEDATION: WHAT TO EXPECT AND QUESTIONS TO ASK

1. What questions do the patient or caregiver need to ask about the technique of moderate or conscious sedation?
   - Who will be providing this type of anesthesia?
   - Who will be monitoring me or my loved one?
   - Will there be constant monitoring of blood pressure, pulse rate, respiratory rate, and temperature?
   - Will there be emergency equipment in the room, in case of need?
   - Are the personnel qualified to administer these drugs? To administer advanced cardiac life support?
   - What do I need to know about care at home? Will I need help? Can I drive after having the procedure?
2. What are the adverse effects of moderate or conscious sedation?
   - Brief periods of amnesia (loss of memory)
   - Headache
   - Hangover feeling
   - Nausea and vomiting
3. What is to be expected immediately following the procedure?
   - Frequent monitoring
   - Written postoperative instructions and care
   - If the patient is of driving age, no driving for at least 24 hours after undergoing moderate sedation
   - A follow-up contact by phone to check on the patient
4. Who administers the conscious sedation?
   - Moderate or conscious sedation is safe when administered by qualified providers. Certified registered nurse anesthetists, anesthesiologists, other physicians, dentists, and oral surgeons are qualified to administer conscious sedation.
5. Which procedures generally require moderate sedation?
   - Breast biopsy
   - Vasectomy
   - Minor foot surgery
   - Minor bone fracture repair
   - Plastic or reconstructive surgery
   - Dental prosthetic or reconstructive surgery
   - Endoscopy (such as diagnostic studies and treatment of stomach, colon, and bladder cancer)
6. What are the overall benefits of this type of anesthesia?
   - It is a safe and effective option for patients undergoing minor surgeries or diagnostic procedures.
   - It allows patients to recover quickly and resume normal activities in a relatively short period of time.
7. Are there any concerns about daily medications or herbals if undergoing conscious sedation?
   - As with any form of anesthesia, being open and honest with the nurse anesthetist or anesthesiologist is of significant importance to patient safety.
   - Be sure to follow instructions closely regarding the intake of all medications including herbals, food, or liquids before anesthesia as such substances may react negatively with the drugs being administered.
   - Inquire about any brochures or written pamphlets such as the AANA brochure titled "Before anesthesia: Your active role makes a difference."

Data from Brenman EK (editor): Pain management: spinal headaches, 2007, available at http://www.WebMD.com; American Association of Nurse Anesthetists (AANA), available at www.aana.com. Accessed February 25, 2011.

activity below the anesthetic insertion site. Because of the risk that the anesthetic drug may move upward in the spinal cord and breathing may be affected, continually monitor respiratory and breathing status. In addition, because positioning is important to the movement of the anesthetic drug, keep the head of the bed elevated. Remember, though, that this complication is usually identified and treated by the anesthesiologist, and patients will not return to their rooms on a nursing unit until all respiratory risks are identified and managed appropriately. Another major area of concern with spinal anesthesia is the risk for a sudden decrease in blood pressure. This drop in blood pressure is secondary to vasodilation caused by the anesthetic block to the sympathetic vasomotor nerves. Vital signs and oxygen saturation levels should return to normal before the patient is transferred out of postanesthesia care; however, continue to monitor these vital signs frequently after transfer.

Another adverse reaction to intraspinal anesthesia is the occurrence of spinal headaches. These may occur with both intrathecal and epidural injections but are actually more frequent with the latter. Because intrathecal spinal needle designs have been technologically improved, the occurrence of spinal headaches is rare. Larger-bore needles are used to deliver epidural anesthetics, however, and these are more likely to give rise to spinal headache if they are inadvertently passed through the dura mater (the covering of the spinal cord). Keep the patient hydrated and on bedrest as recommended by the anesthesiologist. See Box 11-9 for more information about these headaches and their treatment.

BOX 11-9 SPINAL HEADACHES: A BRIEF LOOK AT A TERRIBLE PAIN!

Why do spinal headaches occur? As a result of penetration into and through the dura mater of the spinal cord (the covering of the spinal cord), a leakage of cerebrospinal fluid occurs from the insertion site. If enough of the spinal fluid leaks out, a spinal headache results. These headaches are more likely to be associated with epidural anesthesia than with intrathecal anesthesia because of the larger needles used with epidurals.

What are the symptoms of a spinal headache? Patients say that these headaches are worse than any other type! They are more severe when the patient is in an upright position and improve upon lying down. They may occur up to 5 days after the procedure and may be prevented with bed rest after the epidural procedure.

How are spinal headaches treated? Adequate hydration using intravenous fluids is often tried to help increase cerebral spinal fluid pressure. Other recommendations include the drinking of a beverage high in caffeine and strict bed rest for 24 to 48 hours. If the headaches are intolerable, however, the anesthesiologist may create a "blood patch" to help close up or seal the leak. This requires insertion of a needle into the same space or right next to the area that was injected with the anesthesia. A small amount of blood is then taken from the patient and injected into the epidural space. The blood clots and forms a seal over the hole that caused the leak, and the headache is relieved.

Data from American Association of Nurse Anesthetists: Conscious sedation: what patients should expect, 2005, available at http://www.aana.com; Bezov D, Ashina S, Lipton R: Post-dural puncture headache: part II—prevention, management, and prognosis, *Headache* 50(9):1482-1498, 2010.

The use of epidural anesthesia (also called *regional anesthesia* in some textbooks) does not pose the same risk of respiratory complications as general anesthesia; however, monitoring is still needed to confirm overall homeostasis. You must measure vital signs and pulse oximetry to determine oxygen saturation levels. In addition, patients undergoing this form of anesthesia require monitoring for the return of motor function and tactile sensation. Check the patient frequently for the return of sensation bilaterally along the dermatome (area of the skin innervated by specific segments of the spinal cord); such monitoring is important to ensure patient safety as well as to maximize comfort. Assess touch sensation through hand pressure or a gentle pinch of the skin. You need to know the level at which the epidural anesthesia was given to monitor properly for return of sensation. This monitoring process generally occurs in a postanesthesia care unit, and the patient is not returned to a regular nursing unit until all sensation and/or voluntary movement of the lower extremities is regained.

With regard to the use of *topical or local anesthetics* (e.g., lidocaine with or without epinephrine), solutions that are not clear and appear cloudy or discolored are not to be used. Some anesthesiologists mix the solution with sodium bicarbonate to minimize local pain during infiltration, but this also causes a more rapid onset of action and a longer duration of sensory analgesia. If an anesthetic ointment or cream is used, the nurse will thoroughly cleanse and dry the area to be anesthetized before applying the drug. If a topical or local anesthetic is being used in the nose or throat, remember that it may cause paralysis and/or numbness of the structures of the upper respiratory tract, which can lead to aspiration. If the patient receives a solution form of anesthetic, exact amounts of the drug are used and at the exact dosing times or intervals. Local anesthetics are not to be swallowed unless the prescriber has so instructed. Should this occur, closely observe the patient, check for the gag reflex, and expect to withhold food or drink until the patient's sensation and/or gag reflex has returned.

Once the patient has recovered from the anesthesia and procedure and is ready for discharge, complete your patient teaching. Focus the patient education on the patient's needs and how these needs can be met at home. Home health care and/or rehabilitation services may be indicated, and arrangements should be made before the patient is discharged. If additional care or resources are needed at home (e.g., for a patient who lives alone), these arrangements should be completed in a timely fashion. Some examples of procedures for which help might be needed are wound care, dressing changes, surgical site care, drawing of blood for laboratory studies, and administration of various medications through the intravenous, intramuscular, or subcutaneous route. Some patients may also need assistance with taking oral medications at home. Pain management requires thorough and individualized patient teaching and also includes any necessary education for patients who will require home health care. See Chapter 10 for more information on analgesics. Provide simple instructions using age-appropriate teaching strategies (see Chapter 6). Sharing of information about community resources is also important, especially for patients who need transportation, assistance with meals, housekeeping during recovery, and/or the services of additional health care providers (e.g., physical therapists, occupational therapists) in the home setting. Some of these community resources may be agencies that are supported by city or state social service programs. Meals on Wheels, senior citizen support groups, and church-sponsored groups are just a few examples of important resource groups. Many of these resources are free or have income-based fees. Additional suggestions regarding patient education are provided in the Patient Teaching Tips.

EVALUATION

The therapeutic effects of any *general or local anesthesia* include the following: loss of consciousness and reflexes during general anesthesia and loss of sensation to a particular area during local anesthesia (e.g., loss of sensation to the eye during corneal transplantation). Constantly monitor the patient who has undergone general anesthesia for the occurrence of adverse effects of the anesthesia. These may include myocardial depression, convulsions, respiratory depression, allergic rhinitis, and decreased renal or liver function. Constantly monitor patients who have received a local anesthetic for the occurrence of adverse effects, including bradycardia, myocardial depression, hypotension, and dysrhythmias. In addition, as mentioned earlier in this chapter, significant overdoses of local anesthetic drugs or direct injection into a blood vessel may result in cardiovascular collapse or cardiac or respiratory depression. For those receiving spinal anesthesia, therapeutic effects include loss of sensation below the area of administration, and adverse effects include hypotension, hypoventilation, urinary retention, the possibility of a prolonged period of decreased sensation or motor ability, and infection at the site. With *epidural anesthesia,* therapeutic effects are similar to those seen with intrathecal anesthesia; however, adverse effects include possible spinal headache (often severe) and/or loss of motor function or sensation below the area of administration. *Moderate sedation* provides the therapeutic effect of a decreased sensorium but without the complications of general anesthesia; however, there are CNS depressant effects associated with the drugs used.

KEY POINTS

- Anesthesia is the loss of the ability to feel pain resulting from the administration of an anesthetic drug. General anesthesia is a drug-induced state in which the nerve impulses of the CNS are altered to reduce pain and other sensations throughout the entire body and normally involves complete loss of consciousness and respiratory drive depression.
- General anesthetics are drugs that induce general anesthesia, including the administration of specific parenteral anesthetics. Inhalational anesthetic drugs are also general anesthetics and include volatile liquids or gases.
- Local anesthetics are used to induce a state in which peripheral or spinal nerve impulses are altered to reduce or eliminate pain and other sensations. Spinal anesthesia, or regional anesthesia, is a form of local anesthesia.
- Conscious or moderate sedation is a form of general anesthesia resulting in partial or complete loss of consciousness but without reducing normal respiratory drive.
- Adjunct anesthetics are drugs that assist with the induction of general anesthesia and include neuromuscular blocking drugs (NMBDs), sedative-hypnotics, and/or anxiolytics and antiemetics.
- Nondepolarizing NMBDs are used as an adjunct to general anesthesia to provide skeletal muscle relaxation during surgery and/or mechanical ventilation.
- Nursing assessment is very important to patient safety during and after all forms of anesthesia. With general anesthesia, however, one major problem to be concerned with is that of malignant hyperthermia, which may be fatal if not promptly recognized and aggressively treated. Signs and symptoms include rapid rise in body temperature, increased pulse rate (tachycardia)/respiratory rate (tachypnea), muscle rigidity, and unstable blood pressure.

PATIENT TEACHING TIPS

- Whenever general anesthesia is used, emphasize the prescriber's recommendations/orders about whether any medications should be discontinued or tapered before anesthetic administration.
- Make sure information about the anesthetic, route of administration, adverse effects, and special precautions is included in preprocedure and surgical education.
- Openly discuss with the patient all fears and anxieties about anesthesia and related procedures/surgery.
- Share with the patient and family instructions about the postanesthesia process and the need for close monitoring of vital signs, breath sounds, and neurologic intactness. Patients should expect frequent turning, coughing, and deep breathing to prevent atelectasis or pneumonia.
- Encourage patients to ambulate with assistance as needed and as ordered. Mobility helps increase circulation and improve ventilation to the alveoli of the lungs; consequently, circulation to the legs will be improved (which helps to prevent stasis of blood and possible blood clot formation in the leg veins). Assistance is needed to prevent falls or injury until recovery from the anesthetic.
- Encourage the patient to request pain medication, if needed, before pain becomes moderate to severe. Inform the patient that, even though anesthesia has been administered, there may still be discomfort or pain from the procedure or surgery. The anesthesia will wear off, and adequate analgesia will be needed. Ask the patient to rate his or her pain on a scale of 0 to 10, with 0 being no pain and 10 being the worst possible pain. See Chapter 10 for more information on pain assessment and its management.
- Explain the rationale for any other treatments or procedures related to the anesthesia (e.g., epidural catheter placement; delivery of oxygen; administration of a gas; use of various tubes, catheters, or intravenous lines). Adequate patient education will help ease fears and anxieties and help in preventing adverse effects or complications.
- For a patient with diminished sensorium, the bed side rails should be up and a call button at the bedside. These actions are critical to patient safety. Note that bed alarms may be used instead of side rails. Everyone involved in the postanesthesia and postsurgical care (e.g., family members) should be educated about these safety measures.
- With local anesthesia, the patient should understand the purpose and action of the local anesthetic as well as adverse effects.
- Inform a patient receiving spinal anesthesia about the need for frequent assessments, measurement of vital signs, and system assessments during and after the procedure.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The physician has requested "lidocaine *with* epinephrine." The nurse recognizes that the most important reason for adding epinephrine is that it
   - **a** helps to calm the patient before the procedure.
   - **b** minimizes the risk of an allergic reaction.
   - **c** enhances the effect of the local lidocaine.
   - **d** reduces bleeding in the surgical area.

2 The surgical nurse is reviewing operative cases scheduled for the day. Which of these patients is more prone to complications from general anesthesia?
   - **a** A 79-year-old woman who is about to have her gallbladder removed
   - **b** A 49-year-old male athlete who quit heavy smoking 12 years ago
   - **c** A 30-year-old woman who is in perfect health but has never had anesthesia
   - **d** A 50-year-old woman scheduled for outpatient laser surgery for vision correction

NCLEX® EXAMINATION REVIEW QUESTIONS—cont'd

3 Which nursing diagnosis is possible for a patient who is now recovering after having been under general anesthesia for 3 to 4 hours during surgery?
- **a** Impaired urinary elimination related to the use of vasopressors as anesthetics
- **b** Increased cardiac output related to the effects of general anesthesia
- **c** Risk for falls related to decreased sensorium for 2 to 4 days postoperatively
- **d** Impaired gas exchange due to the CNS depressant effect of general anesthesia

4 A patient is recovering from general anesthesia. What is the nurse's main concern during the immediate postoperative period?
- **a** Airway
- **b** Pupillary reflexes
- **c** Return of sensations
- **d** Level of consciousness

5 A patient is about to undergo cardioversion, and the nurse is reviewing the procedure and explaining moderate sedation. The patient asks, "I am afraid of feeling it when they shock me?" What is the nurse's best response?
- **a** "You won't receive enough of a shock to feel anything."
- **b** "You will feel the shock but you won't remember any of the pain."
- **c** "The medications you receive will reduce any pain and help you not to remember the procedure."
- **d** "They will give you enough pain medication to prevent you from feeling it."

6 The nurse is administering an NMBD to a patient during a surgical procedure. Number the following phases of muscle paralysis in the order in which the patient will experience them. (Number 1 is the first step.)
- **a** Paralysis of intercostals and diaphragm muscles
- **b** Muscle weakness
- **c** Paralysis of muscles of the limbs, neck, and trunk
- **d** Paralysis of small rapidly moving muscles (fingers, eye)

7 During a patient's recovery from a lengthy surgery, the nurse monitors for signs of malignant hyperthermia. In addition to a rapid rise in body temperature, which assessment findings would indicate the possible presence of this condition? (Select all that apply.)
- **a** Respiratory depression
- **b** Tachypnea
- **c** Tachycardia
- **d** Seizure activity
- **e** Muscle rigidity

1. d, 2. a, 3. d, 4. a, 5. c, 6. a = 4, b = 1, c = 3, d = 2, 7. b, c, e

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Briefly describe the functions of the central nervous system.
2 Contrast the effects of central nervous system depressant drugs and central nervous system stimulant drugs (see Chapter 13) as relates to their basic actions.
3 Define the terms *hypnotic, rapid eye movement, rapid eye movement sleep interference, rapid eye movement rebound, sedative, sedative-hypnotic, sleep,* and *therapeutic index.*
4 Briefly discuss the problem of sleep disorders.
5 Identify the specific drugs within each of the following categories of central nervous system depressant drugs: benzodiazepines, nonbenzodiazepines, muscle relaxants, and miscellaneous drugs.
6 Contrast the mechanism of action, indications, adverse effects, toxic effects, cautions, contraindications, dosage forms, routes of administration, and drug interactions of the following medications: benzodiazepines, nonbenzodiazepines, muscle relaxants, and miscellaneous drugs.
7 Discuss the nursing process as it relates to the nursing care of a patient receiving any central nervous system depressants and/or muscle relaxant.
8 Develop a thorough nursing care plan related to the use of pharmacologic and nonpharmacologic approaches to the treatment of sleep disorders.

DRUG PROFILES

- ♦ **baclofen, p. 197**
- ♦ **cyclobenzaprine, p. 197**
- **diazepam, p. 192**
- **eszopiclone, p. 193**
- **midazolam, p. 192**
- **pentobarbital, p. 195**
- **phenobarbital, p. 195**
- **ramelteon, p. 193**
- ♦ **temazepam, p. 193**
- ♦ **zaleplon, p. 193**
- ♦ **zolpidem, p. 193**

♦ *Key drug*

KEY TERMS

Barbiturates A class of drugs that are chemical derivatives of barbituric acid. They are used to induce sedation. (p. 193)

Benzodiazepines A chemical category of drugs most frequently prescribed as anxiolytic drugs and less frequently as sedative-hypnotic agents. (p. 190)

Gamma-aminobutyric acid (GABA) The primary inhibitory neurotransmitter found in the brain. A key compound affected by sedative, anxiolytic, psychotropic, and muscle-relaxing medications. (p. 190)

KEY TERMS—cont'd

Hypnotics Drugs that, when given at low to moderate dosages, calm or soothe the central nervous system (CNS) without inducing sleep but when given at high dosages cause sleep. (p. 189)

Non–rapid eye movement (non-REM) sleep The largest portion of the sleep cycle. It has four stages and precedes REM sleep. Most of a normal sleep cycle consists of non-REM sleep. (p. 189)

Rapid eye movement (REM) sleep One of the stages of the sleep cycle. Some of the characteristics of REM sleep are rapid movement of the eyes, vivid dreams, and irregular breathing. (p. 189)

REM interference A drug-induced reduction of REM sleep time. (p. 189)

REM rebound Excessive REM sleep following discontinuation of a sleep-altering drug. (p. 189)

Sedatives Drugs that have an inhibitory effect on the CNS to the degree that they reduce nervousness, excitability, and irritability without causing sleep. (p. 189)

Sedative-hypnotics Drugs that can act in the body either as sedatives or as hypnotics. (p. 189)

Sleep A transient, reversible, and periodic state of rest in which there is a decrease in physical activity and consciousness. (p. 189)

Sleep architecture The structure of the various elements involved in the sleep cycle, including normal and abnormal patterns of sleep. (p. 189)

Therapeutic index The ratio between the toxic and therapeutic concentrations of a drug. If the index is low, the difference between the therapeutic and toxic drug concentrations is small, and use of the drug is more hazardous. (p. 193)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Sedatives and *hypnotics* are drugs that have a calming effect or that depress the central nervous system (CNS). A drug is classified as either a sedative or a hypnotic drug depending on the degree to which it inhibits the transmission of nerve impulses to the CNS. **Sedatives** reduce nervousness, excitability, and irritability without causing sleep, but a sedative can become a hypnotic if it is given in large enough doses. **Hypnotics** cause sleep and have a much more potent effect on the CNS than do sedatives. Many drugs can act as either a sedative or a hypnotic, depending on dose and patient responsiveness, and for this reason are called sedative-hypnotics. **Sedative-hypnotics** can be classified chemically into three main groups: barbiturates, benzodiazepines, and miscellaneous drugs.

PHYSIOLOGY OF SLEEP

Sleep is defined as a transient, reversible, and periodic state of rest in which there is a decrease in physical activity and consciousness. Normal sleep is cyclic and repetitive, and a person's responses to sensory stimuli are markedly reduced during sleep. During waking hours, the body is bombarded with stimuli that provoke the senses of sight, hearing, touch, smell, and taste. These stimuli elicit voluntary and involuntary movements or functions. During sleep, a person is no longer aware of the sensory stimuli within his or her immediate environment.

Sleep research involves study of the patterns of sleep, or what is sometimes referred to as **sleep architecture.** The architecture of sleep consists of two basic elements that occur cyclically: **rapid eye movement (REM) sleep** and **non–rapid eye movement (non-REM) sleep.** The normal cyclic progression of the stages of sleep is summarized in Table 12-1. Various sedative-hypnotic drugs affect different stages of the normal sleep pattern. Prolonged sedative-hypnotic use may reduce the cumulative amount of REM sleep; this is known as **REM interference.** This can result in daytime fatigue, because REM sleep provides a certain component of the "restfulness" of sleep. Upon discontinuance of a sedative-hypnotic drug, **REM rebound** can occur in which the patient has an abnormally large amount of REM sleep, often leading to frequent and vivid dreams. Abuse and misuse of sedative-hypnotic drugs is common and is discussed in Chapter 17.

TABLE 12-1 STAGES OF SLEEP

STAGE	CHARACTERISTICS	AVERAGE PERCENTAGE OF SLEEP TIME IN STAGES (FOR YOUNG ADULT)
Non-REM Sleep		
1	Dozing or feelings of drifting off to sleep; person can be easily awakened; insomniacs have longer stage 1 periods than normal.	2%-5%
2	Relaxation, but person can easily be awakened; person has occasional REMs and also slight eye movements.	50%
3	Deep sleep; difficult to wake person; respiratory rates, pulse, and blood pressure may decrease.	5%
4	Very difficult to wake person; person may be very groggy if awakened; dreaming occurs, especially about daily events; sleepwalking or bedwetting may occur.	10%-15%
REM Sleep		
	REMs occur; vivid dreams occur; breathing may be irregular.	25%-33%

Modified from McKenry LM, Tessier E, Hogan MA: *Mosby's pharmacology in nursing,* ed 22, St Louis, 2006, Mosby.
REM, Rapid eye movement.

PATIENT-CENTERED CARE: CULTURAL IMPLICATIONS

Understanding Your Patient's Sleep Needs

- Question the patient of another culture about his or her usual sleep patterns and habits and what is practiced to promote sleep.
- Collect a thorough health, medication, and diet history to identify food and herbal practices used to manage common everyday problems, such as insomnia.
- Asians, Pacific Islanders, Hispanics, and African Americans have a high incidence of lactose intolerance, so use of warm milk at bedtime to help with sleep may lead to GI distress, abdominal cramping, and bloating. Lactose-free milk may be used.
- Some Asian Americans believe in the yin and the yang and may practice meditation, herbology, nutritional interventions, and acupuncture for sleep.
- Chinese patients have been found to require lower doses of benzodiazepines (diazepam [Valium] and alprazolam [Xanax]).
- Some Hispanics believe that maintaining a balance in diet and physical activity are methods for preventing evil or poor health. Nondrug therapies and/or home remedies of vegetables and herbs may be used for sleep and other health issues.
- Jewish Americans may tend to be less accepting of therapeutic touch as compared to some cultures. Nurses must be sensitive to this and find alternatives to massage.

TABLE 12-2 SEDATIVE-HYPNOTIC BENZODIAZEPINES AND MISCELLANEOUS DRUGS

GENERIC NAME	TRADE NAME
Long Acting	
clonazepam	Klonopin
diazepam	Valium
flurazepam	Dalmane
Intermediate Acting	
alprazolam	Xanax
lorazepam	Ativan
temazepam	Restoril
Short Acting	
eszopiclone*	Lunesta
midazolam	Versed
ramelteon*	Rozerem
triazolam	Halcion
zaleplon*	Sonata
zolpidem*	Ambien

*These drugs share many characteristics with the benzodiazepines but are classified as miscellaneous hypnotic drugs.

PHARMACOLOGY OVERVIEW

BENZODIAZEPINES AND MISCELLANEOUS HYPNOTIC DRUGS

Historically, **benzodiazepines** were the most commonly prescribed sedative-hypnotic drugs; however, the nonbenzodiazepine drugs are now more frequently prescribed. Other drugs commonly used for sleep include the antihistamine diphenhydramine (see Chapter 36), trazodone, and amitriptyline (see Chapter 16). The benzodiazepines show favorable adverse effect profiles, efficacy, and safety when used appropriately. Benzodiazepines are classified as either sedative-hypnotics or anxiolytics depending on their primary usage. Anxiolytic drugs are used to reduce the intensity of feelings of anxiety. However, any of these drugs can function along a continuum as a sedative and/or hypnotic and/or anxiolytic depending on the dosage and patient sensitivity. See Chapter 16 for a further discussion of the anxiolytic use of benzodiazepines. There are five benzodiazepines commonly used as sedative-hypnotic drugs. In addition, there are several miscellaneous drugs that are used as hypnotics. They function much like benzodiazepines but are chemically distinct from them. All are listed in Table 12-2. Ramelteon is a hypnotic drug not related to any other hypnotics. It has a new mechanism of action and is profiled separately later in the chapter.

Mechanism of Action and Drug Effects

The sedative and hypnotic action of benzodiazepines is related to their ability to depress activity in the CNS. The specific areas that are affected include the hypothalamic, thalamic, and limbic systems of the brain. Although the mechanism of action is not certain, research suggests that there are specific receptors in the brain for benzodiazepines. These receptors are thought to be either **gamma-aminobutyric acid (GABA)** receptors or other adjacent receptors. GABA is the primary inhibitory neurotransmitter of the brain, and it serves to modulate CNS activity by inhibiting overstimulation. Like GABA itself, benzodiazepine activity appears to be related to their ability to inhibit stimulation of the brain. They have many favorable characteristics compared with the older drug class *barbiturates* (see the next section of this chapter). They do not suppress REM sleep to the same extent, nor do they induce hepatic microsomal enzyme activity as do the barbiturates. They are safe to administer to patients who are taking medications metabolized by this enzyme system.

Indications

Benzodiazepines have a variety of therapeutic applications. They are commonly used for sedation, relief of agitation or anxiety, treatment of anxiety-related depression, sleep induction, skeletal muscle relaxation, and treatment of acute seizure disorders. Benzodiazepines are often combined with anesthetics, analgesics, and neuromuscular blocking drugs in balanced anesthesia and also moderate sedation (see Chapter 11) for their amnesic properties to reduce memory of painful procedures. Finally, benzodiazepine receptors in the CNS are in the same area as those that play a role in alcohol addiction. Therefore, some benzodiazepines (e.g., diazepam, chlordiazepoxide) are used in the treatment and prevention of the symptoms of alcohol withdrawal (see Chapter 17). When benzodiazepines are used to treat insomnia, it is recommended that they be used short term if clinically feasible to avoid dependency. Two newer products that have been approved by the U.S. Food

and Drug Administration (FDA) for long-term use for insomnia include eszopiclone (Lunesta) and an extended-release form of zolpidem (Ambien CR). These two drugs are classified as nonbenzodiazepines.

Contraindications

Contraindications to the use of benzodiazepines include known drug allergy, narrow-angle glaucoma, and pregnancy.

Adverse Effects

As a class, benzodiazepines have a relatively favorable adverse effect profile; however, they can be harmful if given in excessive doses or when mixed with alcohol. Adverse effects associated with their use usually involve the CNS. Commonly reported undesirable effects are headache, drowsiness, paradoxical excitement or nervousness, dizziness or vertigo, cognitive impairment, and lethargy. Benzodiazepines can create a significant fall hazard in elderly patients, and the lowest effective dose must be used in this patient population. Although these drugs have comparatively less intense effects on the normal sleep cycle, a "hangover" effect is sometimes reported (e.g., daytime sleepiness). Withdrawal symptoms such as rebound insomnia (i.e., greater insomnia than pretreatment) may occur with abrupt discontinuation.

Toxicity and Management of Overdose

An overdose of benzodiazepines may result in one or all of the following symptoms: somnolence, confusion, coma, and diminished reflexes. Overdose of benzodiazepines alone rarely results in hypotension and respiratory depression. These effects are more commonly seen when benzodiazepines are taken with other CNS depressants such as alcohol or barbiturates. The same holds true for their lethal effects. In the absence of the concurrent ingestion of alcohol or other CNS depressants, benzodiazepine overdose rarely results in death.

Treatment of benzodiazepine intoxication is generally symptomatic and supportive. Flumazenil, a benzodiazepine antidote, can be used to acutely reverse the sedative effects of benzodiazepines. It antagonizes the action of benzodiazepines on the CNS by directly competing with the benzodiazepine for binding at the receptors. Flumazenil is used in cases of oral overdose or excessive intravenous sedation. The dosage regimens to be followed for the reversal of conscious sedation or general anesthesia induced by benzodiazepines and the management of suspected overdose are summarized in Table 12-3.

TABLE 12-3 FLUMAZENIL TREATMENT REGIMEN

INDICATION	RECOMMENDED REGIMEN	DURATION
Reversal of moderate sedation or general anesthesia	0.2 mg (2 mL) IV over 15 sec, then 0.2 mg if consciousness does not occur; may be repeated at 60-sec intervals prn up to 4 additional times (maximum total dose, 1 mg)	1-4 hr
Management of suspected benzodiazepine overdose	0.2 mg (2 mL) IV over 30 sec; wait 30 sec, then give 0.3 mg (3 mL) over 30 sec if consciousness does not occur; further doses of 0.5 mg (5 mL) can be given over 30 sec at intervals of 1 min up to a cumulative dose of 3 mg	1-4 hr

NOTE: Flumazenil has a relatively short half-life and a duration of effect of 1 to 4 hr; therefore, if flumazenil is used to reverse the effects of a long-acting benzodiazepine, the dose of the reversal drug may wear off and the patient may become sedated again, requiring more flumazenil. *IV,* Intravenously.

Interactions

Potential drug interactions with the benzodiazepines are significant because of their intensity, particularly when they involve other CNS depressants (e.g., alcohol, opioids, muscle relaxants). These drugs result in further CNS depressant effects, including reduced blood pressure, reduced respiratory rate, sedation, confusion, and diminished reflexes. This and other major drug interactions are listed in Table 12-4. Herbal remedies that interact with the benzodiazepines include kava and valerian, which may also lead to further CNS depression. Food-drug interactions include interactions with grapefruit and grapefruit juice, which alter drug metabolism via inhibition of the cytochrome P-450 system and can result in prolonged effect, increased effect, and toxicity.

TABLE 12-4 BENZODIAZEPINES: DRUG/FOOD INTERACTIONS

DRUG	MECHANISM	RESULT
Azole antifungals, verapamil, diltiazem, protease inhibitors, macrolide antibiotics, grapefruit juice	Decreased benzodiazepine metabolism	Prolonged benzodiazepine action
CNS depressants	Additive effects	Increased CNS depression
olanzapine	Unknown	Increased benzodiazepine effects
rifampin	Increased metabolism	Decreased benzodiazepine effects

CNS, Central nervous system; *MAOIs,* monoamine oxidase inhibitors.

Dosages

For dosage information, see the table on p. 192.

DRUG PROFILES

Benzodiazepines and miscellaneous sedative-hypnotic drugs are prescription-only drugs, and they are designated as Schedule IV controlled substances. Uses for benzodiazepines can vary,

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

Kava (Piper methysticum)

Overview
Kava consists of the dried rhizomes of *Piper methysticum.* The drug contains kava pyrones (kawain). Extended continuous intake can cause a temporary yellow discoloration of the skin, hair, and nails.

Common Uses
Relief of anxiety, stress, restlessness; promotion of sleep

Adverse Effects
Skin discoloration, possible accommodative disturbances and pupillary enlargement, scaly skin (with long-term use)

Potential Drug Interactions
Alcohol, barbiturates, psychoactive drugs

Contraindications
Contraindicated in patients with Parkinson's disease, liver disease, depression, or alcoholism; in those operating heavy machinery; and in pregnant and breastfeeding women

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

Valerian (Valeriana officinalis)

Overview
Valerian root, consisting of fresh underground plant parts, contains essential oil with monoterpenes and sesquiterpenes (valerianic acids).

Common Uses
Relief of anxiety, restlessness, sleep disorders

Adverse Effects
Central nervous system depression, hepatotoxicity, nausea, vomiting, anorexia, headache, restlessness, insomnia

Potential Drug Interactions
Central nervous system depressants, monamine oxidase inhibitors, phenytoin, warfarin; may have enhanced relative and adverse effects when taken with other drugs (including other herbal products) that have known sedative properties (including alcohol)

Contraindications
Contraindicated in patients with cardiac disease, liver disease, or those operating heavy machinery

including treatment of insomnia, moderate sedation (see Chapter 11), muscle relaxation, anticonvulsant therapy (see Chapter 14), and anxiety relief (see Chapter 16). The miscellaneous drugs are normally used only for their hypnotic purposes to treat insomnia. Dosage information appears in the Dosages table on this page.

BENZODIAZEPINES

diazepam

Diazepam (Valium) was the first clinically available benzodiazepine drug. It has varied uses, including treatment of anxiety, procedural sedation and anesthesia adjunct, anticonvulsant therapy, and skeletal muscle relaxation following orthopedic injury or surgery. It is available in oral, rectal, and injectable forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Immediate	8 min	20-50 hr	15-60 min
PO	30 min	1-2 hr	20-60 hr	12-24 hr

midazolam

Midazolam (Versed) is most commonly used preoperatively and for moderate sedation (see Chapter 11). It is useful for this indication due to its ability to cause amnesia and anxiolysis (reduced anxiety) as well as sedation. This helps patients to feel less anxious about, and avoid remembering, uncomfortable medical procedures. The drug is normally given by injection in adults. However, a liquid oral dosage form is also available for children. See Chapter 11 for dosage information.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	1-5 minutes	20-60 minutes	1-4 hours	2-6 hours

DOSAGES

Selected Benzodiazepine and Other Sedative-Hypnotic Drugs

DRUG (PREGNANCY CATEGORY)	ONSET AND DURATION	USUAL DOSAGE RANGE	INDICATIONS/ USES
diazepam (Valium) (D)	Long acting	**Adult** PO: 2-10 mg 3-4 times daily IV: 2-10 mg IV (supplied 5 mg/mL) IM: infrequent use	Muscle relaxation, preprocedure sedation, status epilepticus, acute anxiety/ agitation
♦ temazepam (Restoril) (D)	Intermediate acting	**Adult** PO: 7.5-30 mg at bedtime	Sleep induction
♦ zaleplon (Sonata) (C)	Short acting	**Adult** PO: 5-10 mg at bedtime	Sleep induction
♦ zolpidem* (Ambien) (C)	Short acting	**Adult** PO: 5-10 mg at bedtime	Sleep induction
eszopiclone* (Lunesta) (C)	Short acting	**Adult** PO: 1-3 mg at bedtime	Sleep induction
ramelteon* (Rozerem) (C)	Short acting	**Adult** PO: 8 mg at bedtime	Sleep induction

IM, Intramuscular; *IV,* intravenous; *N/A,* not applicable; *PO,* oral.
*Nonbenzodiazepine drugs.

temazepam

Temazepam (Restoril), an intermediate-acting benzodiazepine, is actually one of the metabolites of diazepam and normally induces sleep within 20 to 40 minutes. Temazepam has a long onset of action, so it is recommended that patients take it about 1 hour prior to going to bed. Although it is still an effective hypnotic, it has been replaced by the newer drugs.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-60 min	2-3 hr	9.5-12 hr	7-8 hr

NONBENZODIAZEPINES

zaleplon

Zaleplon (Sonata) is a short-acting nonbenzodiazepine hypnotic. A unique advantage of this drug stems from its very short half-life. Patients whose sleep difficulties include early awakenings can take a dose in the middle of the night as long as it is at least 4 hours before they must arise.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Rapid	1 hr	1 hr	6-8 hr

zolpidem

Zolpidem (Ambien) is also a short-acting nonbenzodiazepine hypnotic. Its relatively short half-life and its lack of active metabolites contribute to a lower incidence of daytime sleepiness compared with benzodiazepine hypnotics. A unique dosage form, Ambien CR, is a longer-acting form with two separate drug reservoirs. One releases zolpidem faster than the other to induce hypnosis (sleep) more rapidly. The second reservoir also releases zolpidem but does so more slowly throughout the night to help maintain sleep. One special concern with this particular dosage form is the possibility of *somnambulation* or sleepwalking, which has been reported with its use. Nevertheless, Ambien CR is currently one of only two hypnotics to be FDA-approved for long-term use; the other is eszopiclone (Lunesta; see next profile).

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30 min	1.6 hr	1.4-4.5 hr	6-8 hr

eszopiclone

Eszopiclone (Lunesta) is the first hypnotic to be FDA-approved for long-term use. It is designed to provide a full 8 hours of sleep. It is considered a short- to intermediate-acting agent. As with other hypnotics, patients should allot 8 hours of sleep time and should avoid taking hypnotics when they must awaken in less than 6 to 8 hours.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-60 min	1 hr	6 hr	8 hr

ramelteon

Ramelteon (Rozerem) is the first prescription hypnotic in 35 years with a new mechanism of action. This drug is structurally similar to the hormone melatonin, which is believed to regulate circadian rhythms (day-night sleep cycles) in the body. Over-the-counter dietary supplements containing melatonin have been available for several years. Ramelteon works as an agonist at melatonin receptors in the CNS. Technically it is not a CNS depressant, but it is included here because of its use as a hypnotic. It is also not classified as a controlled substance because of its lack of observed dependency risk. It has a shorter duration of action than other hypnotics and is therefore indicated primarily for patients who have difficulty with sleep *onset* rather than sleep maintenance. Its use is contraindicated in cases of severe liver dysfunction. It is best avoided in patients receiving fluvoxamine (see Chapter 16), fluconazole, or ketoconazole (see Chapter 42), all of which can impede its metabolism. Rifampin (see Chapter 41) can reduce the efficacy of ramelteon by speeding its metabolism via the induction of hepatic enzymes.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-60 min	45 min	1-2.5 hr	6-8 hr

BARBITURATES

Barbiturates were first introduced into clinical use in 1903 and were the standard drugs for treating insomnia and producing sedation. Chemically they are derivatives of barbituric acid. Although 50 different barbiturates are approved for clinical use in the United States, only a few are in clinical use today. This is due to the favorable safety profile and proven efficacy of the benzodiazepines. Barbiturates can produce many unwanted adverse effects. They are physiologically habit forming and have a low **therapeutic index** (i.e., there is only a narrow dosage range within which the drug is effective, and above that range it is rapidly toxic). Barbiturates can be classified into four groups based on their onset and duration of action. Table 12-5 lists the barbiturates in each category and summarizes their pharmacokinetic characteristics.

Mechanism of Action and Drug Effects

Barbiturates are CNS depressants that act primarily on the brainstem in an area called the *reticular formation.* Their sedative and hypnotic effects are dose related, and they act by reducing the nerve impulses traveling to the area of the brain called the *cerebral cortex.* Their ability to inhibit nerve impulse transmission is due in part to their ability to potentiate the action of the inhibitory neurotransmitter GABA, which is found in high

TABLE 12-5 SEDATIVE-HYPNOTIC BARBITURATES

GENERIC NAME	TRADE NAME
Ultrashort Acting	
methohexital	Brevital
thiopental	Pentothal
Short Acting	
pentobarbital	Nembutal
secobarbital	Seconal
Intermediate Acting	
butabarbital	Butisol
Long Acting	
phenobarbital	Generic
mephobarbital	Mebaral

concentrations in the CNS. Barbiturates also raise the seizure threshold and can be used to treat seizures (see Chapter 14).

Indications

All barbiturates have the same sedative-hypnotic effects but differ in their potency, time to onset of action, and duration of action. They can be used as hypnotics, sedatives, and anticonvulsants and also for anesthesia during surgical procedures. It is important to note that the use of barbiturates is no longer recommended for sleep induction. The various categories of barbiturates can be used for the following therapeutic purposes: (1) ultrashort acting: anesthesia for short surgical procedures, anesthesia induction, control of convulsions, and reduction of intracranial pressure in neurosurgical patients; (2) short acting: sedation and control of convulsive conditions; (3) intermediate acting: sedation and control of convulsive conditions; and (4) long acting: epileptic seizure prophylaxis.

Contraindications

Contraindications to barbiturate use include known drug allergy, pregnancy, significant respiratory difficulties, and severe kidney or liver disease. These drugs must be used with caution in elderly patients due to their sedative properties and increased fall risk.

Adverse Effects

Adverse effects of barbiturates relate to the CNS and include drowsiness, lethargy, dizziness, hangover (prolongation of drowsiness, lethargy, and dizziness), and paradoxical restlessness or excitement. Their long-term effects on normal sleep architecture can be detrimental. Sleep research has shown that adequate rest is obtained from the sleep process only when there are proper amounts of REM sleep, which is sometimes referred to as *dreaming sleep*. Barbiturates deprive people of REM sleep, which can result in agitation and an inability to deal with normal daily stress. When the barbiturate is stopped and REM sleep once again takes place, a rebound phenomenon can occur. During this rebound, the proportion of REM sleep is increased, dream time constitutes a larger percentage of total sleep, and nightmares often ensue. Common adverse effects of barbiturates are listed in Table 12-6. As is the case with most sedative drugs, barbiturates are also associated with an increased incidence of falls when used in the elderly. If they are recommended for older adults at all, the usual dose is reduced by half whenever possible.

TABLE 12-6 BARBITURATES: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Vasodilation and hypotension, especially if given too rapidly
Gastrointestinal	Nausea, vomiting, diarrhea, constipation
Hematologic	Agranulocytosis, thrombocytopenia
Nervous	Drowsiness; lethargy; vertigo
Respiratory	Respiratory depression, cough
Other	Hypersensitivity reactions: urticaria, angioedema, rash, fever, Stevens-Johnson syndrome

Toxicity and Management of Overdose

Phenobarbital is also used to treat status epilepticus (prolonged uncontrolled seizures). In extreme cases, patients may be intentionally overdosed to the extent of causing therapeutic phenobarbital or pentobarbital coma. Because of the inhibitory effects on nerve transmission in the brain (possibly GABA mediated), the uncontrollable seizures can be stopped until sufficient serum levels of anticonvulsant drugs are achieved. An overdose of barbiturates produces CNS depression ranging from sleep to profound coma and death. Respiratory depression progresses to Cheyne-Stokes respirations, hypoventilation, and cyanosis. Patients often have cold, clammy skin or are hypothermic, and later they can exhibit fever, areflexia, tachycardia, and hypotension.

Treatment of an overdose is mainly symptomatic and supportive. The mainstays of therapy are maintenance of an adequate airway, assisted ventilation, and oxygen administration if needed, along with fluid and pressor support as indicated. Barbiturates are highly metabolized by the liver, where they also induce enzyme activity. In an overdose, however, the amount of barbiturate may overwhelm the liver's ability to metabolize it. This is a situation in which administration of activated charcoal may be helpful. Activated charcoal adsorbs (binds to) drug molecules in the stomach. It also has the effect of drawing the drug from the circulation into the GI tract for elimination. Multiple-dose (every 4 hours) nasogastric administration of activated charcoal is a common regimen. Phenobarbital and mephobarbital are relatively acidic and can be eliminated more quickly by the kidneys when the urine is alkalized (pH is raised). This keeps the drug in the urine and prevents it from being resorbed back into the circulation. Alkalization, along with forced diuresis using diuretics (e.g., furosemide [see Chapter 28]), can hasten elimination of the barbiturate.

Interactions

Barbiturates as a class are notorious enzyme inducers. They stimulate the action of enzymes in the liver that are responsible for the metabolism or breakdown of many drugs. By stimulating the action of these enzymes, they cause many drugs to be

metabolized more quickly, which usually shortens their duration of action. Other drugs that are enzyme inducers are warfarin, rifampin, and phenytoin.

Additive CNS depression occurs with the coadministration of barbiturates with alcohol, antihistamines, benzodiazepines, opioids, and tranquilizers. Most of the drug-drug interactions are secondary to the effects of barbiturates on the hepatic enzyme system. Barbiturates increase the activity of hepatic microsomal or cytochrome P-450 enzymes (see Chapter 2). This process is called *enzyme induction.* Induction of this enzyme system results in increased drug metabolism and breakdown. However, if two drugs are competing for the same enzyme system, the result can be inhibited drug metabolism and possibly increased toxicity for the wide variety of drugs that are metabolized by these enzymes. Drugs most likely to have marked interactions with the barbiturates include monoamine oxidase inhibitors (MAOIs), tricyclic antidepressants (see Chapter 16), anticoagulants (see Chapter 26), glucocorticoids (see Chapter 30), and oral contraceptives (see Chapter 34) with barbiturates. Coadministration of MAOIs and barbiturates can result in prolonged barbiturate effects. Coadministration of anticoagulants with barbiturates can result in decreased anticoagulation response and possible clot formation. Coadministration of barbiturates with oral contraceptives can result in accelerated metabolism of the contraceptive drug and possible unintended pregnancy. Women taking both types of medication concurrently need to be advised to consider an additional method of contraception as a backup.

Dosages

Barbiturates can act as either sedatives or hypnotics depending on the dosage. For information on selected barbiturates and their recommended sedative and hypnotic dosages, see the table on this page.

DOSAGES

Selected Barbiturates

DRUG	ONSET AND DURATION	USUAL DOSAGE RANGE	INDICATIONS/ USES
pentobarbital (Nembutal)	Short acting	**Pediatric**	
		IM/IV/PO/PR: 2-6 mg/kg/day (max 100 mg)	Anticonvulsant, preoperative sedative, sedative
		Adult	
		IM: 150-200 mg IV: 100 mg	Preoperative sedative
phenobarbital	Long acting	**Pediatric**	
		PO: 6 mg/kg in 3 divided doses	Sedative
		IM/IV: 1-3 mg/kg	Preoperative sedative
		Adult	
		PO: 30-120 mg/day divided	Sedative
		IM/IV: 100-200 mg 60-90 min before surgery	Preoperative sedative

IM, Intramuscularly; *IV,* intravenously; *PO,* orally; *PR,* rectally.

TABLE 12-7 BARBITURATES: CONTROLLED SUBSTANCE SCHEDULE

SCHEDULE	BARBITURATES
C-II	pentobarbital, secobarbital
C-III	butabarbital, thiopental
C-IV	mephobarbital, methohexital, phenobarbital

DRUG PROFILES

Like benzodiazepines, barbiturates can also have varied uses, including preoperative sedation, anesthesia adjunct, and anticonvulsant therapy. All barbiturates are controlled substances, but not all are on the same schedule, as illustrated in Table 12-7. Dosage information appears in the Dosages table for barbiturates.

pentobarbital

Pentobarbital (Nembutal) is a short-acting barbiturate. Formerly prescribed as a sedative-hypnotic for insomnia, pentobarbital is now principally used preoperatively to relieve anxiety and provide sedation. In addition, it is used occasionally to control status epilepticus or acute seizure episodes resulting from meningitis, poisons, eclampsia, alcohol withdrawal, tetanus, and chorea. Pentobarbital may also be used to treat withdrawal symptoms in patients who are physically dependent on barbiturates or nonbarbiturate hypnotics. It is available in oral, injectable, and rectal dosage forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-60 min	1-2 hr	20-45 min	3-4 hr

phenobarbital

Phenobarbital is the most commonly prescribed barbiturate, either alone or in combination with other drugs. It is considered the prototypical barbiturate and is classified as a long-acting drug. Phenobarbital is used for the prevention of generalized tonic-clonic seizures and fever-induced convulsions. In addition, it has been useful in the treatment of hyperbilirubinemia in neonates. It is only rarely used today as a sedative and is no longer recommended to be used as a hypnotic drug. It is available in oral and injectable forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	5 min	30 min	50-120 hr	6-12 hr
PO	30 min	1-6 hr	50-120 hr	6-12 hr

OVER-THE-COUNTER HYPNOTICS

Nonprescription sleeping aids often contain antihistamines (see Chapter 36). These drugs have a CNS depressant effect. The

most common antihistamines contained in over-the-counter sleeping aids are doxylamine (Unisom) and diphenhydramine (Sominex). Analgesics (e.g., acetaminophen [see Chapter 10]) are sometimes added to offer some pain relief if pain is a component of the sleep disturbance (e.g., acetaminophen/diphenhydramine [Extra Strength Tylenol PM]). As with other CNS depressants, concurrent use of alcohol can cause respiratory depression or arrest.

MUSCLE RELAXANTS

A variety of conditions such as trauma, inflammation, anxiety, and pain can be associated with acute muscle spasms. Although there is no perfect therapy available for relief of skeletal muscle spasticity, muscle relaxant drugs are capable of providing some relief. The muscle relaxants are a group of compounds that act predominantly within the CNS to relieve pain associated with skeletal muscle spasms. Most muscle relaxants are known as *centrally acting* skeletal muscle relaxants because their site of action is the CNS. Centrally acting skeletal muscle relaxants are similar in structure and action to other CNS depressants such as diazepam. It is believed that the muscle relaxant effects are related to this CNS depressant activity. Only one of these compounds, dantrolene, acts directly on skeletal muscle. It belongs to a group of relaxants known as direct-acting skeletal muscle relaxants. It closely resembles GABA.

Muscle relaxants are most effective when they are used in conjunction with rest and physical therapy. When taken with alcohol, other CNS depressants, or opioid analgesics, enhanced CNS depressant effects are seen. In such cases, close monitoring and dosage reduction of one or both drugs need to be considered.

Mechanism of Action and Drug Effects

The majority of the muscle relaxants work within the CNS. Their beneficial effects are believed to come from their sedative effects rather than from direct muscle relaxation. Dantrolene acts directly on the excitation-contraction coupling of muscle fibers and not at the level of the CNS. It directly affects skeletal muscles by decreasing the response of the muscle to stimuli. It appears to exert its action by decreasing the amount of calcium released from storage sites in the sarcoplasmic reticula of muscle fibers. All other muscle relaxants have no direct effects on muscles, nerve conduction, or muscle-nerve junctions and have a depressant effect on the CNS. Their effects are the result of CNS depression in the brain primarily at the level of the brainstem, thalamus, and basal ganglia and also at the spinal cord. The effects of muscle relaxants are relaxation of striated muscles, mild weakness of skeletal muscles, decreased force of muscle contraction, and muscle stiffness. Other effects include generalized CNS depression manifested as sedation, somnolence, ataxia, and respiratory and cardiovascular depression. Baclofen is one of the more effective drugs in this class and is a derivative of GABA. It is believed to work by depressing nerve transmission in the spinal cord. The other drugs in this class are not derivatives of GABA but act by enhancing GABA's central inhibitory effects at the level of the spinal cord.

Indications

Muscle relaxants are primarily used for the relief of painful musculoskeletal conditions such as muscle spasms, often following injuries such as low back strain. They are most effective when used in conjunction with physical therapy. They may also be used in the management of spasticity associated with severe chronic disorders such as multiple sclerosis and other types of cerebral lesions, cerebral palsy, and rheumatic disorders. Some relaxants are used to reduce choreiform movement in patients with Huntington's chorea, to reduce rigidity in patients with parkinsonian syndrome, or to relieve the pain associated with trigeminal neuralgia. Intravenous dantrolene is used for the management of the hypermetabolic skeletal muscle spasms that accompany the crisis condition known as malignant hyperthermia (see Chapter 11). Baclofen has been shown to be effective in relieving hiccups.

Contraindications

The only usual contraindication to the use of muscle relaxants is known drug allergy, but contraindications for some drugs may include severe renal impairment.

Adverse Effects

The primary adverse effects of muscle relaxants are an extension of their effects on the CNS and skeletal muscles. Euphoria, lightheadedness, dizziness, drowsiness, fatigue, confusion, and muscle weakness are often experienced early in treatment. These adverse effects are generally short-lived, as patients grow tolerant to them over time. Less common adverse effects seen with muscle relaxants include diarrhea, GI upset, headache, slurred speech, muscle stiffness, constipation, sexual difficulties in males, hypotension, tachycardia, and weight gain.

Toxicity and Management of Overdose

The toxicities and consequences of an overdose of muscle relaxants primarily involve the CNS. There is no specific antidote (or reversal drug) for muscle relaxant overdoses. They are best treated with conservative supportive measures. More aggressive therapies are generally needed when muscle relaxants are taken along with other CNS depressant drugs in an overdose. An adequate airway must be maintained, and means of artificial respiration must be readily available. Electrocardiographic monitoring needs to be instituted, and large quantities of intravenous fluids are administered to avoid crystalluria.

Interactions

When muscle relaxants are administered along with other depressant drugs such as alcohol and benzodiazepines, caution needs to be used to avoid overdosage. Mental confusion, anxiety, tremors, and additive hypoglycemic activity have been reported with this combination as well. A dosage reduction and/or discontinuance of one or both drugs is recommended.

Dosages

For dosage information for commonly used muscle relaxants, see the table on p. 197.

DOSAGES

Selected Muscle Relaxants

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
♦ baclofen (Lioresal) (C)	Centrally acting	**Adult** PO: 5 mg three times daily (tid) for 3 days, then 10 mg tid for 3 days, then 20 mg tid, then titrated to response (max: 20 mg po qid)	Spasticity
♦ cyclobenzaprine (Flexeril) (B)	Centrally acting	**Adult** PO: 5-10 mg tid **Adults and adolescents 15 yrs and younger** 5 mg PO tid Dosage may be increased to 10 mg po tid if needed	Spasticity

PO, Orally.

DRUG PROFILES

With the exception of dantrolene (Dantrium), which acts directly on skeletal muscle tissues, muscle relaxants are classified as centrally acting drugs because of their site of action in the CNS. These include baclofen (Lioresal), carisoprodol (Soma), chlorzoxazone (Paraflex), cyclobenzaprine (Flexeril), metaxalone (Skelaxin), methocarbamol (Robaxin), and tizanidine (Zanaflex). Some evidence suggests that carisoprodol has abuse potential; however, it and other muscle relaxants are not controlled substances. Use of all muscle relaxants is contraindicated in patients who have shown a hypersensitivity reaction to them or have compromised pulmonary function, active hepatic disease, or impaired myocardial function. Dosage information appears in the Dosages table for muscle relaxants.

♦ baclofen

Baclofen (Lioresal) is available in both oral and injectable dosage forms. The injectable form is for use with an implantable baclofen pump device. This method is sometimes used to treat chronic spastic muscular conditions. With this route, a test dose needs to be administered initially to test for a positive response. The injection is diluted before infusion. Both oral and injectable doses are titrated to desired response.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	0.5-1 hr	2-3 hr	2.5-4 hr	8 hr or longer

♦ cyclobenzaprine

Cyclobenzaprine (Flexeril) is available in a 5-mg and 10-mg dose and an extended-release formulation (Amrix). Cyclobenzaprine is a centrally acting muscle relaxant that is structurally and pharmacologically related to the tricyclic antidepressants. It is the most commonly used drug in this class to reduce spasms following musculoskeletal injuries. It is very common for patients to exhibit marked sedation from its use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	3-8 hr	8-37 hr	12-24 hr

NURSING PROCESS

ASSESSMENT

Before administering any *CNS depressant drug,* such as a benzodiazepine, nonbenzodiazepine, miscellaneous drug, muscle relaxant, or barbiturate, perform an assessment focusing on some of the more common parameters and data, including the following: (1) complaints of any insomnia with attention to onset, duration, frequency, and pharmacologic as well as nonpharmacologic measures used; (2) any concerns by the patient or family of sleep disorders, sleep patterns, difficulty in sleeping, or frequent awakenings; (3) the time it takes to fall asleep and the energy level upon awakening; (4) vital signs with attention to blood pressure (both supine and standing measurements); pulse rate and rhythm; respiratory rate, rhythm, and depth; body temperature; and presence of pain; (5) thorough physical assessment/examination for baseline comparisons; (6) neurologic findings with a focus on any changes in mental status, memory, cognitive abilities, alertness, level of orientation (to person, place, and time) or level of sedation, mood changes, depression or other mental disorder, changes in sensations, anxiety, and panic attacks; and (7) miscellaneous information about medical history; allergies; use of alcohol; smoking history; caffeine intake; past and current medication profile, with notation of use of any prescription drugs, over-the-counter drugs, and herbals; alternative or folk practices; and any changes in health status, weight, nutrition, exercise, life stressors (including loss and grief), or lifestyle.

For patients taking *benzodiazepines* or *benzodiazepine-like drugs,* assessment needs to also the identification of disorders or conditions that represent cautions or contraindications to use of these drugs as well as drugs the patient is taking that might interact with benzodiazepines or benzodiazepine-like drugs (see pharmacology discussion). Closely

monitor those who are anemic, are suicidal, or have a history of abusing drugs, alcohol, or other substances. Other significant cautions pertain to use of these drugs in the elderly and the very young because of their increased sensitivity to these drugs, as well as in pregnant or lactating women. The elderly and very young may require lower dosages due to potential ataxia and excessive sedation. In addition, before initiating drug therapy with the benzodiazepines and other sedative-hypnotic drugs, including barbiturates, the prescriber may order blood studies such as CBC. Renal function studies (BUN or creatinine levels) and/or hepatic function studies (ALP level) may be ordered to rule out organ impairment and prevent potential toxicity or complications resulting from decreased excretion and/or metabolism. Potential drug interactions for benzodiazepines are presented in Table 12-4. Pay particular attention to the concurrent use of other CNS depressants (e.g., opioids), because this may lead to severe decreases in blood pressure, respiratory rate, reflexes, and level of consciousness.

With the *nonbenzodiazepines* such as zaleplon and zolpidem tartrate, include a head-to-toe physical assessment and a thorough medication history with measurement of vital signs and other parameters previously mentioned. Assess and document for allergies to these drugs and to aspirin. If the patient is allergic to aspirin, there is an associated risk of allergies to nonbenzodiazepines. Other considerations include the need for assessment of any confusion and lightheadedness, especially in the elderly because of their increased sensitivity. Do not use zaleplon and eszopiclone in those younger than 18 years of age, and use extreme caution if there is a history of compromised respiratory status or drug, alcohol, or other substance abuse. Drug interactions include other CNS depressants.

For *muscle relaxants,* always note drug allergies before use, and perform a complete head-to-toe assessment with focus on the neurologic system. In the elderly, there is increased risk of CNS toxicity with possible hallucinations, confusion, and excessive sedation. Assessment includes taking a thorough health/medication history and examining the complete patient profile with results of associated laboratory studies. See pharmacology discussion about cautions, contraindications, and drug interactions.

The *miscellaneous* drug ramelteon is a newer medication that is used for insomnia but is not associated with CNS depression, does not carry the potential for abuse or dependence, and does not lead to withdrawal symptoms when treatment stops. Therefore, this drug can be used for patients who are likely to be abusers of CNS depressants. Include inquiry into sleep patterns and habits in your assessment. Because this drug is not to be used in patients with liver impairment, liver function studies are needed prior to beginning the medication. Perform respiratory assessment and assessment of other vital signs as well. If the patient has a history of respiratory disorders such as chronic obstructive pulmonary disease or sleep apnea, or if the patient is a child, this medication would not be indicated.

Barbiturates are discussed further in Chapter 14 along with other antiepileptic drugs. However, a brief description is needed to emphasize the importance of conducting a thorough patient assessment as well as evaluating for cautions, contraindications, and drug interactions. Barbiturates are not to be used by pregnant or lactating women. These drugs cross the placenta and breast-blood barriers, posing the risk of respiratory depression in the fetus and neonate. Withdrawal symptoms may appear in neonates born to women who have taken barbiturates during their last trimester of pregnancy. Barbiturates may also produce paradoxical excitement in children and confusion and mental depression in the elderly, so baseline neurologic assessment is needed. Assessment of renal and liver function is also important in those with compromised organ function and in the elderly to help avoid toxicity.

NURSING DIAGNOSES

1. Impaired gas exchange related to the respiratory depression associated with CNS depressants
2. Deficient knowledge related to inadequate information about the various CNS drugs and their first-time use
3. Disturbed sleep patterns related to the drug's interference with REM sleep
4. Risk for injury and falls related to adverse effect of decreased sensorium
5. Risk for injury related to possible drug overdose or adverse reactions related to drug-drug interactions (e.g., combined use of the drug with alcohol, tranquilizers, and/or analgesics) and decreased level of alertness and an unsteady gait
6. Risk for injury and addiction related to physical or psychological dependence on CNS drugs

PLANNING

GOALS

1. Patient maintains normal gas exchange and is free of respiratory depression.
2. Patient demonstrates adequate knowledge about the drugs, how they work, and their adverse effects and interactions.
3. Patient remains free of further disturbed sleep patterns.
4. Patient remains free of self-injury and falls due to safety measures for decreased sensorium.
5. Patient remains free of injury due to adequate information about drug interactions that lead to further CNS depression.
6. Patient remains free of injury to self with no drug dependence.

OUTCOME CRITERIA

1. Patient states measures to maintain normal gas exchange such as coughing, deep breathing, taking only the prescribed amount of medication, and reporting any difficulty breathing to prescriber.
2. Patient demonstrates adequate knowledge about the medication(s) used including sedating/hypnotic properties, CNS depressant effects, and side effects of altered respirations, decreased depth/rate of respirations, altered cough, confusion, drowsiness, and interactions with other CNS depressants.

3. Patient states risk for REM interference from sedative-hypnotic drugs with associated sleep interference with most of these drugs as well as known hangover effects.
   - Patient states importance of trying nonpharmacologic measures for enhancing sleep as appropriate prior to drug therapy, such as massage, relaxation therapy, music, biofeedback.
4. Patient demonstrates understanding of safety measures to decrease risk of injury/falls while taking sedative/hypnotics, such as taking medication only as prescribed, removing all throw rugs from walking areas (especially at night), moving and changing positions slowly, ambulating with caution, and reporting any excessive drowsiness or sedation to prescriber.
5. Patient ably states common drug interactions associated with and to avoid with sedative/hypnotics, (i.e., other CNS depressants, opioids, herbals [kava, valerian], alcohol, and sedating products found over the counter [diphenydramine]).
6. Patient remains free of risk of drug dependence issues through appropriate use of sedative/hypnotics, taking medication only as prescribed, reporting any problems with increased resistance to drug's effects, as well as excessive sedation and the feeling that more medication is needed to get the same drug effect.
   - Patient tries nonpharmacologic measures to promote sleep, as needed.

IMPLEMENTATION

Patients taking *benzodiazepines* and other CNS depressants experience sedation and possible ataxia, thus the need for patient safety measures. Hospital or facility policies mandate the type of safety precautions to be taken, such as the use of side rails or bed alarms. Ambulation needs to occur safely and with assistance when patients are sedated or are experiencing the adverse effects of these drugs. In addition, dependence may be a problem with the benzodiazepines, but not to the same degree as with the barbiturates. While taking these drugs, patients need to avoid driving or participating in any activities that require mental alertness. It is recommended that these drugs be taken on an empty stomach for faster onset of action; however, this often results in GI upset so, practically speaking, they need to be taken with food, a light snack, or meals. Orally administered benzodiazepines have an onset of action of 30 minutes to 6 hours depending on the drug (see the Pharmacokinetics tables in the Drug Profiles section), and the appropriate timing and intervals of dosing will be determined by these characteristics. For example, if a patient takes a benzodiazepine or other CNS drug to induce sleep and the drug's onset of action is 30 to 60 minutes, then the drug needs to be dosed 60 minutes prior to bedtime. In addition, it is crucial to patient compliance and safety to understand that drug tolerance may develop to many of these drugs, and so the patient may require larger dosages to produce the same therapeutic effect at some point. Interrupting therapy helps to decrease drug tolerance.

Among the benzodiazepines, REM interference is less problematic with flurazepam, quazepam, and estazolam, primarily because they produce fewer active metabolites. Educate patients about the REM interference and rebound insomnia that may occur with just a 3- to 4-week regimen of drug therapy. To minimize REM interference, benzodiazepines and other drugs are only used when nonpharmacologic methods fail and must be used with caution in all patients with sleep disorders and for short periods of time. Zolpidem is also available in a sustained-release product used for long-term management of sleep disorders. Gradual weaning-off periods are recommended for benzodiazepines and all CNS depressants. Hangover effects are also associated with many of the CNS depressants but occur less frequently with benzodiazepines and nonbenzodiazepines than with barbiturates.

It is recommended that *nonbenzodiazepines* (e.g., zaleplon) be taken for the prescribed time. Take zaleplon as directed and immediately before bedtime due to its quick onset of action. Avoid consumption of very heavy and/or high-fat meals within 2 hours of taking this drug because of interference with the drug's action. Zolpidem has optimal absorption if taken at bedtime on an empty stomach with no crushing, chewing, or breaking of the oral dosage form. This drug may infrequently lead to temporary memory loss. To help avoid this adverse effect, it is important to encourage the patient to not take a dose of the drug without a full night's sleep (e.g., at least 7 to 8 hours) the previous night. As with any CNS depressant drug, avoid tasks requiring mental alertness until response to the drug is known. Tolerance and dependence are possible with prolonged use, and this drug is to be gradually weaned before discontinuation.

Muscle relaxants have different indications than the barbiturates and benzodiazepines and are not used to treat insomnia. They are generally indicated for some forms of spasticity (see Pharmacology Overview). However, when used they may lead to adverse effects and toxicities, so frequently monitor airway, breathing, and circulation. Early identification of toxicity is critical to provide prompt treatment and to prevent respiratory and other CNS depressant effects. Closely monitor all vital parameters, level of consciousness, and presence of sedation when these muscle relaxants are used. Encourage cautious ambulation. Recommend that the patient change positions purposefully and slowly to prevent syncope or dizziness. The greatest risk for hypotension associated with these drugs is usually within 1 hour of dosing, so the patient must be more cautious about activity during this time.

The *miscellaneous* drug ramelteon must be used with caution, with emphasis on the fact that the drug is not to be mixed with alcohol. In the patient education, include that the drug is to be taken 30 minutes before bedtime and is *not* to be taken along with or immediately following a high-fat meal.

Barbiturates are to be used with very close monitoring and extreme caution. Observe and document the patient's level of consciousness or sedation; orientation to person, place, and time; respiratory rate; oxygen saturation; and other vital signs. Advise the patient to take oral doses with food or a light snack,

and not to alter dosage forms. Use a bed alarm system or side rails and provide assistance with ambulation, as needed or indicated, to help prevent injury. Barbiturates also produce a hangover effect, and this residual drowsiness occurs upon awakening and results in impaired reaction times. The intermediate- and long-acting hypnotics are often the culprits for this adverse effect. Abrupt withdrawal of barbiturates after prolonged therapy may produce adverse effects ranging from nightmares, hallucinations, and delirium to seizures. In addition, while the patient is taking barbiturates, monitor the patient's red blood cell count and hemoglobin and hematocrit levels because of the possible adverse effect of anemia. Long-term use of barbiturates also requires monitoring of therapeutic blood levels of the drug. For example, the therapeutic level of phenobarbital must range between 10 and 40 mcg/mL. Patients with serum levels above 40 mcg/mL may experience toxicity manifested by cold and clammy skin, respiratory rate of less than 10 breaths/min, and other signs of severe CNS depression.

Intravenous use of barbiturates, as with some benzodiazepines (e.g., diazepam), requires dilution of the drug with normal saline or other recommended solutions. Recommendations regarding diluents and rates of intravenous administration must be strictly followed for safe use. Most of the drugs are not to be given any faster than 1 mg/kg per minute, and a maximum amount per minute may be specified. Consult authoritative drug sources (e.g., a current drug handbook/reference or the manufacturer's insert) for the recommended rate of infusion before giving any of these drugs. Too rapid an infusion of a barbiturate may produce profound hypotension and marked respiratory depression. If intravenous infiltration is present, the site may become swollen, erythematous, and tender. Tissue necrosis may occur with this infiltration, depending on the irritating qualities of the particular drug. There are antidote protocols for some of the intravenous barbiturates. For example, with phenobarbital intravenous infiltration, the solution must be discontinued, a 0.5% procaine solution injected into the affected area, and moist heat applied, as per institutional policy or procedure. Always check protocol for management of infiltration of an intravenous drug before intervening because, in certain situations, the intravenous catheter may be left in place until antidotes are administered. Another area of concern with intravenous drugs is incompatibilities with other intravenously administered medications, and barbiturates have several. Some intravenous drugs that are incompatible with barbiturates include amphotericin B, hydrocortisone, and hydromorphone. Only give these particular drugs after the intravenous line has been adequately flushed with normal saline. With intramuscular injection, give the solution deep into a large muscle mass to prevent tissue sloughing; however, avoid this route and use only when absolutely necessary.

In summary, before giving any CNS depressant, it is always important to try nonpharmacologic measures to induce sleep. However, if medication therapy is indicated, preventing respiratory depression and other problems associated with CNS depression is of prime importance, as is maintaining patient safety and preventing injury. Documentation must be timely, clear, and concise and reflect follow-up of the patient's response to the drug. It is also important to document the dose, route, time of administration, and safety measures taken after each dose is given.

CASE STUDY

Drugs for Sleep

P.S., a 68-year-old retired secretary, comes to the office complaining of feeling "so tired" during the day. She has had trouble sleeping off and on for years, and a few weeks ago received a prescription for the benzodiazepine alprazolam (Xanax) to take "as needed for nerves." Upon closer questioning, the nurse discovers that P.S. has been using alprazolam almost every night for 3 weeks to help her get to sleep. She says, "I just could not fall asleep before! I am sleeping very well, but I'm so tired during the day. I don't understand how I can get such good sleep and still feel tired!"

1. Can you explain the reason for her tiredness?
2. P.S.'s nurse practitioner prescribes a period of decreasing doses of the alprazolam each evening, then every other evening, until the medication is stopped. Explain the rationale behind the tapering dosage schedule.
3. P.S. receives a prescription for ramelteon (Rozerem). How is this drug different from alprazolam?
4. What nonpharmacologic measures can P.S. try to improve her sleep?

For answers, see http://evolve.elsevier.com/Lilley.

EVALUATION

Some of the criteria by which to confirm a patient's therapeutic response to a *CNS depressant* include the following: an increased ability to sleep at night, fewer awakenings, shorter sleep induction time, few adverse effects such as hangover effects, and an improved sense of well-being because of improved sleep. Therapeutic effects related to *muscle relaxants* include decreased spasticity, reduction of choreiform movements in Huntington's chorea, decreased rigidity in parkinsonian syndrome, and relief of pain from trigeminal neuralgia. Constantly watch for and document the occurrence of any of the adverse effects of benzodiazepines, barbiturates, and muscle relaxants. See the previous discussions of adverse effects for each type of drug. Evaluation for CNS depressant toxic effects includes monitoring for severe CNS depression of all body systems, especially respiratory and circulatory collapse, with decrease in respiratory rate/depth and decrease in blood pressure.

PATIENT TEACHING TIPS

- Encourage individuals to keep a journal recording sleep habits, sleep patterns, and response to both drug and nondrug therapy (Box 12-1).
- Implement nonpharmacologic measures first to enhance sleep. This is important because the use of CNS depressants for treatment of sleep deficit or insomnia often leads to interference with the REM stage of sleep, hangover effects, and/or tolerance, as well as other adverse effects.
- Always check with the prescriber or pharmacist before taking any over-the-counter medications because of the many drug interactions with CNS depressants.
- Keep these drugs and all medications out of the reach of children.
- Emphasize that medications are to be taken only as prescribed. The patient is usually told that if one dose does not work, not to double up on the dosage unless otherwise prescribed or directed.
- Educate about any time constraints related to driving, operation of heavy machinery or equipment, and participation in activities requiring mental alertness while the patient is taking these medications.
- Do not abruptly discontinue or withdraw these medications, if possible, to avoid rebound insomnia.
- Sedative-hypnotic drugs (for sleep promotion) are not intended for long-term use because of their adverse effects, interference with REM sleep, and addictive properties.
- Advise the patient that hangover effects may occur with most of these drugs and that this is more problematic in the elderly or in patients with altered renal and hepatic function.
- Provide the patient with thorough instructions about safety with these drugs, such as avoiding smoking in bed or when lounging.
- Teach the patient about significant drug/drug and drug/food interactions with all these medications.
- Educate patients about the effect of grapefruit and grapefruit juice on benzodiazepines. The grapefruit results in decreased drug metabolism via inhibition of the cytochrome P-450 system and may lead to a prolonged effect and possible toxicity (of the benzodiazepine).

BOX 12-1 SLEEP DIARIES AND NONPHARMACOLOGIC TREATMENT OF SLEEP DISORDERS

Information for a Sleep Diary

- What time do you usually go to bed and wake up?
- How long and how well do you sleep?
- When were you awake during the night, and for how long?
- How easy was it to go to sleep?
- How easy was it to wake up in the morning?
- How much caffeine or alcohol do you consume?
- What time did you last eat or drink (if after dinner)?
- Did you have any bedtime snacks?
- What emotions or stressors are present?
- What medications do you take daily?
- Do you smoke? If so, how much and for how long?
- Do you consume alcohol? If so, how much and for how long?
- Do you take any over-the-counter drugs? If so, what drug and for what reason? How much and for how long?
- Do you take any herbals? If so, which ones? For what and for how long?

Nonpharmacologic Sleep Interventions

- Establish a set sleep pattern with a time to go to bed at night and a regular time to get up in the morning, and stick to it. This will help to reset your internal clock.
- Sleep only as much as you need to feel refreshed and renewed. Too much sleep may lead to fragmented sleep patterns and shallow sleep.
- Keep bedroom temperatures moderate, if possible.
- Avoid caffeine-containing beverages and food within 6 hours of bedtime.
- Decrease exposure to loud noises.
- Avoid daytime napping.
- Avoid exercise late in the evening (i.e., not past 7 PM).
- Avoid alcohol in the evening. Rather than putting you to sleep, it actually results in fragmented sleep.
- Avoid tobacco at bedtime, because it disturbs sleep.
- Try to relax before bedtime with soft music, yoga, relaxation therapy, deep breathing, or light reading on a topic that is not intense or anxiety provoking.
- Drink a warm decaffeinated beverage, such as warm milk or chamomile tea, 30 minutes to 1 hour before bedtime.
- If you are still awake 20 minutes after going to bed, get up and engage in a relaxing activity (as noted previously) and go back to bed once you feel drowsy. Repeat as necessary.

KEY POINTS

- Nonpharmacologic measures to improve sleep need to be tried before resorting to treatment with medications.
- Recognize and understand the classification and pharmacokinetic properties of barbiturates. Short-acting barbiturates include pentobarbital and secobarbital. Intermediate-acting barbiturates include butabarbital. Long-acting barbiturates include phenobarbital and mephobarbital.
- The pharmacokinetics of each group of barbiturates lends specific characteristics to the drugs in that group. You need to understand how these drugs are absorbed orally and used parenterally, as well as their onset time, time until peak effect, and duration of action. You must understand the life-threatening potential of these drugs because too rapid an infusion may precipitate respiratory and/or cardiac arrest.
- Benzodiazepines are commonly used for sedation, relief of anxiety, skeletal muscle relaxation, and treatment of acute seizure disorders.
- Most sedative-hypnotic drugs suppress REM sleep and should be used only for the recommended period of time. This time frame varies, depending on the specific drug used.
- Long-acting benzodiazepines include clonazepam, diazepam, and flurazepam. Intermediate-acting benzodiazepines include alprazolam, lorazepam, and temazepam. Short-acting benzodiazepines include eszopiclone, midazolam, ramelteon, triazolam, zaleplon, and zolpidem.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A patient has been admitted to the emergency department because of an overdose of an oral benzodiazepine. He is very drowsy but still responsive. The nurse will prepare for which immediate intervention?
- **a** Hemodialysis to remove the medication
- **b** Administration of flumazenil
- **c** Administration of naloxone
- **d** Intubation and mechanical ventilation

2 An older adult has been given a benzodiazepine for sleep induction, but the night nurse noted that the patient was awake most of the night, watching television and reading in bed. The nurse documents that the patient has had which type of reaction to the medication?
- **a** Allergic
- **b** Teratogenic
- **c** Paradoxical
- **d** Idiopathic

3 The nurse is preparing to administer a medication for sleep. Which intervention applies to the administration of a non-benzodiazepine, such as zaleplon (Sonata)?
- **a** These drugs need to be taken about 1 hour before bedtime.
- **b** Because of their rapid onset, these drugs need to be taken just before bedtime.
- **c** The patient needs to be cautioned about the high incidence of morning drowsiness that may occur after taking these drugs.
- **d** These drugs are less likely to interact with alcohol.

4 The nurse will monitor the patient who is taking a muscle relaxant for which adverse effect?
- **a** CNS depression
- **b** Hypertension
- **c** Peripheral edema
- **d** Blurred vision

5 A hospitalized patient is complaining of having difficulty sleeping. Which action will the nurse take first to address this problem?
- **a** Administer a sedative-hypnotic drug if ordered.
- **b** Offer tea made with the herbal preparation valerian.
- **c** Encourage the patient to exercise by walking up and down the halls a few times if tolerated.
- **d** Provide an environment that is restful, and reduce loud noises.

6 Which considerations are important for the nurse to remember when administering a benzodiazepine as a sedative-hypnotic drug? (Select all that apply.)
- **a** These drugs are intended for long-term management of insomnia.
- **b** The drugs can be administered safely with other CNS depressants for insomnia.
- **c** The dose needs to be given about 1 hour before the patient's bedtime.
- **d** The drug is used as a first choice for treatment of sleeplessness.
- **e** The patient needs to be evaluated for the drowsiness that may occur the morning after a benzodiazepine is taken.

7 A child is to receive phenobarbital 2 mg/kg IV on call as a preoperative sedative. The child weighs 64 pounds. How many milligrams will the child receive for this dose?

1. b, 2. c, 3. b, 4. a, 5. d, 6. c, e, 7. 58.2 mg

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Briefly review the anatomy, physiology, and functions of the central nervous system with attention to the stimulant effects on its function.
2 Review the key terms as they relate to the central nervous system and stimulant drugs.
3 Identify the various central nervous system stimulant drugs.
4 Discuss the mechanisms of action, indications, dosages, routes of administration, contraindications, cautions, drug interactions, adverse effects, and any related toxicity for the various central nervous system stimulants and related drugs.
5 Develop a nursing care plan based on the nursing process for patients using central nervous system stimulants and related drugs.

DRUG PROFILES

- ♦ **amphetamines, p. 207**
- **atomoxetine, p. 208**
- ♦ **caffeine, p. 212**
- **doxapram, p. 213**
- ♦ **methylphenidate, p. 207**
- **modafinil, p. 208**
- **orlistat, p. 209**
- ♦ **phentermine, p. 209**
- ♦ **sumatriptan, p. 211**

♦ *Key drug*

KEY TERMS

Amphetamines A class of stimulant drugs that includes amphetamine sulfate and all of its drug derivatives. (p. 206)

Analeptics Central nervous system (CNS) stimulants that have generalized effects on the brainstem and spinal cord, which produce an increase in responsiveness to external stimuli and stimulate respiration. (p. 212)

Anorexiants Drugs used to control or suppress appetite. (p. 208)

Attention deficit hyperactivity disorder (ADHD) A syndrome characterized by difficulty in maintaining concentration on a given task and/or hyperactive behavior; may affect children, adolescents, and adults. The term *attention deficit disorder (ADD)* has been absorbed under this broader term. (p. 205)

Cataplexy A condition characterized by abrupt attacks of muscular weakness and hypotonia triggered by an emotional stimulus such as joy, laughter, anger, fear, or surprise. It is often associated with narcolepsy. (p. 205)

Central nervous system (CNS) stimulants Drugs that stimulate specific areas of the brain or spinal cord. (p. 204)

Ergot alkaloids Drugs that narrow or constrict blood vessels in the brain and provide relief of pain for certain migraine headaches. (p. 209)

KEY TERMS—cont'd

Migraine A common type of recurring painful headache characterized by a pulsatile or throbbing quality, incapacitating pain, and photophobia. (p. 205)

Narcolepsy A syndrome characterized by sudden sleep attacks, *cataplexy*, sleep paralysis, and visual or auditory hallucinations at the onset of sleep. (p. 205)

Serotonin receptor agonists A class of CNS stimulants used to treat migraine headaches; they work by stimulating 5-hydroxytryptamine 1 receptors in the brain and are sometimes referred to as *selective serotonin receptor agonists* or *triptans*. (p. 209)

Sympathomimetic drugs CNS stimulants such as noradrenergic drugs (and, to a lesser degree, dopaminergic drugs) whose actions resemble or mimic those of the sympathetic nervous system. (p. 204)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

The central nervous system (CNS) is a very complex system in the human body. Many therapeutic drugs either work in the CNS or cause adverse effects in the CNS. Activity of the CNS is regulated by a checks-and-balances system that consists of excitatory and inhibitory neurotransmitters and their corresponding receptors in the brain and spinal cord tissues. CNS stimulation results from either excessive stimulation of excitatory neurons or blockade of inhibitory neurons. **Central nervous system (CNS) stimulants** are a broad class of drugs that stimulate specific areas of the brain or spinal cord. Most CNS stimulant drugs act by stimulating the excitatory neurons in the brain. These neurons contain receptors for excitatory neurotransmitters, including dopamine (dopaminergic drugs), norepinephrine (adrenergic drugs), and serotonin (serotonergic drugs). Dopamine is a metabolic precursor of norepinephrine, which is also a neurotransmitter in the sympathetic nervous system. Actions of adrenergic drugs often resemble or mimic the actions of the sympathetic nervous system. For this reason, adrenergic drugs (and, to a lesser degree, dopaminergic drugs as well) are also called **sympathomimetic drugs.** Other sympathomimetic drugs are discussed further in Chapter 18.

CNS stimulant drugs are classified in three ways. The first is on the basis of chemical structural similarities. Major chemical classes of CNS stimulants include amphetamines, serotonin agonists, sympathomimetics, and xanthines (Table 13-1). Second, these drugs can be classified according to their site of therapeutic action in the CNS (Table 13-2). Finally, they can be categorized according to five major therapeutic usage categories for CNS stimulant drugs (Table 13-3). These include anti–attention deficit, antinarcoleptic, anorexiant, antimigraine, and analeptic drugs. Anorexiants are drugs used to control obesity by suppression of appetite. Analeptics are drugs used for specific CNS stimulation in certain clinical situations. Some therapeutic overlap exists among these drug categories.

TABLE 13-1 STRUCTURALLY RELATED CNS STIMULANTS

CHEMICAL CATEGORY	CNS STIMULANTS AND RELATED DRUGS
Amphetamines and related stimulants	dextroamphetamine, methamphetamine, benzphetamine, methylphenidate, dexmethylphenidate,
Serotonin agonists	almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, sumatriptan, zolmitriptan
Sympathomimetics	phentermine, phendimetrazine
Xanthines	caffeine, theophylline, aminophylline
Miscellaneous	modafinil, armodafinil, orlistat (lipase inhibitor), doxapram (analeptic)

CNS, Central nervous system.

TABLE 13-2 CNS STIMULANTS: SITE OF ACTION

PRIMARY SITE OF ACTION	CNS STIMULANTS
Cerebrovascular system, $5\text{-HT}_{1D/1B}$ receptors	Serotonin agonists
Cerebral cortex	Amphetamines, phenidates, modafinil, armodafinil
Hypothalamic and limbic regions	Anorexiants
Medulla and brainstem	Analeptics

CNS, Central nervous system.

TABLE 13-3 CNS STIMULANTS AND RELATED DRUGS: THERAPEUTIC CATEGORIES

CATEGORY	DRUGS
Anti-ADHD	dextroamphetamine, lisdexamfetamine, methamphetamine, methylphenidate, atomoxetine (norepinephrine reuptake inhibitor)
Antinarcoleptic	dextroamphetamine, methamphetamine, methylphenidate, modafinil, armodafinil
Anorexiant	methamphetamine, phentermine, phendimetrazine, diethylpropion, benzphetamine, orlistat (lipase inhibitor)
Antimigraine	almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, sumatriptan, zolmitriptan (serotonin agonists); dihydroergotamine mesylate, ergot-amine tartrate with caffeine (ergot alkaloids)
Analeptic	caffeine, doxapram, aminophylline, theophylline, modafinil, armodanafil (antinarcoleptic)

ADHD, Attention deficit hyperactivity disorder; *CNS,* central nervous system.

ATTENTION DEFICIT HYPERACTIVITY DISORDER

Attention deficit hyperactivity disorder (ADHD), formerly known as *attention deficit disorder (ADD),* is the most common psychiatric disorder in children, affecting 3% to 10% of school-age children. Boys are affected from two to nine times more often than girls, although the disorder may be underdiagnosed in girls. Primary symptoms of ADHD are a developmentally inappropriate ability to maintain attention span and/or the presence of hyperactivity and impulsivity. The disorder may involve predominantly attention deficit, predominantly hyperactivity or impulsivity, or a combination of both. It usually begins before 7 years of age, sometimes earlier than 4 years of age. It can officially be diagnosed when symptoms last at least 6 months and occur in at least two different settings (e.g., home and school), according to the *Diagnostic and Statistical Manual of Mental Disorders.* Many children outgrow ADHD, but adult ADHD is also common. Drug therapy for both childhood and adult ADHD is essentially the same. There is some social controversy regarding possible overdiagnosis of, and overmedication for this disorder. Studies in twins indicate a degree of genetic predisposition and familial heritability. The disorder is commonly associated with other forms of mental illness, including depression, bipolar disorder, anxiety, and learning difficulties.

NARCOLEPSY

Narcolepsy is an incurable neurologic condition in which patients unexpectedly fall asleep in the middle of normal daily activities. These "sleep attacks" are reported to cause car accidents or near-misses in 70% or more of patients. Another major symptom of the disease is dysfunctional *rapid eye movement sleep* (see Chapter 12). **Cataplexy** is an associated symptom in at least 70% of narcolepsy cases. It involves sudden acute skeletal muscle weakness. The condition is often associated with strong emotions (e.g., joy, anger), and commonly the knees buckle and the individual falls to the floor while still awake. Men and women are equally affected, with approximately 100,000 cases in the United States. Some genetic markers have been identified. Roughly half of patients with narcolepsy experience migraine headaches as well.

OBESITY

According to the National Institutes of Health and the Centers for Disease Control and Prevention, approximately 30% of Americans are obese and nearly two thirds (64.5%) are overweight. This translates into more than 72 million obese adults, with a higher incidence of obesity among women and minorities. Obesity was formerly defined as being 20% or more above one's ideal body weight based on population statistics for height, body frame, and gender. More recent data are based on a measurement known as the body mass index (BMI), defined as weight in kilograms divided by height in meters squared (i.e., BMI = weight [kg] ÷ [height (m)]^2). *Overweight* is now defined as a BMI of 25 to 29.9, whereas *obesity* is now defined as a BMI of 30 or higher. At any given time, one third of women and one quarter of men are trying to lose weight. Moreover, the incidence of obesity in young people 6 to 19 years of age has more than tripled since 1980. The pathophysiology of obesity is not fully understood, but calorie excess, disordered metabolism, and other factors are hypothesized. Obesity increases the risk for hypertension, dyslipidemia, coronary artery disease, stroke, type 2 diabetes mellitus, gallbladder disease, gout, osteoarthritis, sleep apnea, and certain types of cancer, including breast and colon cancer. An estimated 80% of diabetes risk in the United States can be attributed to excess weight. Some 112,000 deaths each year are linked to obesity. The related health care costs alone are currently estimated at more than $140 billion. Yet many people who attempt weight loss do so for cosmetic reasons rather than health reasons. Obese people are often stigmatized, at times even by the health care professionals treating them.

MIGRAINE

A **migraine** is a common type of recurring headache, usually lasting from 4 to 72 hours. Typical features include a pulsatile quality with pain that worsens with each pulse. The pain is most commonly unilateral but may occur on both sides of the head. Associated symptoms include nausea, vomiting, *photophobia* (avoidance of light), and *phonophobia* (avoidance of sounds). In addition, some migraines are accompanied by an *aura,* which is a predictive set of altered visual or other senses (formerly termed *classic migraine*). However, the majority of migraines are without an aura (formerly termed *common migraine*). Migraines affect about 30 million people in the United States, with a reported incidence in females roughly three times that in males. Migraine headaches have been classified by the World Health Organization as one of the 19 most disabling diseases worldwide, with approximately 64 to 150 million workdays lost annually. Migraines commonly begin after 10 years of age and peak between the mid-twenties and early forties. They often fade after 50 years of age. Familial inheritance of migraine is well recognized. Precipitating factors include stress, hypoglycemia, menses, endogenous estrogen (including oral contraceptives), exercise, and intake of alcohol, caffeine, cocaine, nitroglycerin, aspartame, and the food additive monosodium glutamate (MSG). Over 50% of patients with narcolepsy report nocturnal migraines. Historically, there have been several theories regarding the cause of migraines, including the "vascular hypothesis" and the "neurovascular hypothesis." Most recent evidence points to decreased serotonin levels. Thus, the majority of current investigations involve drugs that can increase the serotonin levels.

ANALEPTIC-RESPONSIVE RESPIRATORY DEPRESSION SYNDROMES

Neonatal apnea, or periodic cessation of breathing in newborn babies, is a common condition seen in neonatal intensive care units. It occurs in about 25% of premature infants whose pulmonary and CNS structures, including the medullary centers

that control breathing, have not completed their gestational development because of preterm birth. Infants undergoing prolonged mechanical ventilation, especially at high pressures, often develop a chronic lung disease known as *bronchopulmonary dysplasia,* for which caffeine can be helpful. *Postanesthetic respiratory depression* occurs when a patient's spontaneous respiratory drive does not resume adequately and in a timely manner after general anesthesia. Respiratory depression may also be secondary to abuse of some drugs. Hypercapnia, or elevated blood levels of carbon dioxide, is often associated with later stages of chronic obstructive pulmonary disease (COPD). Analeptic drugs such as theophylline, aminophylline, caffeine, and doxapram may be used to treat one or more of these conditions. Analeptic drugs are now used much less frequently than they were in the earlier days of general anesthesia. This is because of advances in intensive respiratory care, including mechanical ventilation and improved anesthetic techniques, as well as the availability of newer medications with less toxicity.

PHARMACOLOGY OVERVIEW

DRUGS FOR ATTENTION DEFICIT HYPERACTIVITY DISORDER AND NARCOLEPSY

CNS stimulants are the first-line drugs of choice for both ADHD and narcolepsy. They are potent drugs with a strong potential for tolerance and psychological dependence (addiction; see Chapter 17). They are classified as Schedule II drugs under the Controlled Substance Act. Although there has been some public controversy regarding their use in ADHD, these drugs have led to a 65% to 75% improvement in symptoms in treated patients compared with a placebo. In general, CNS stimulants elevate mood, produce a sense of increased energy and alertness, decrease appetite, and enhance task performance impaired by fatigue or boredom. Two of the oldest known stimulants are cocaine and amphetamine, which are prototypical drugs for this class. Caffeine, contained in coffee and tea, is another plant-derived CNS stimulant.

Amphetamine sulfate was first synthesized in the late 1800s. It was subsequently used to treat narcolepsy and then to prolong the alertness of soldiers during World War II. Later derivatives of this drug, which are still used clinically, include its d-isomer dextroamphetamine sulfate, methamphetamine hydrochloride, benzphetamine, and mixed amphetamine salts—salts of both amphetamine and dextroamphetamine. They are often collectively referred to simply as **amphetamines.** Methylphenidate, a synthetic amphetamine derivative, was first introduced for the treatment of hyperactivity in children in 1958. Its d-isomer is the drug dexmethylphenidate. The phenidates are also Schedule II drugs. All of these amphetamine-related drugs are used to treat ADHD and/or narcolepsy. Nonamphetamine stimulants include pemoline and modafinil. In 2005, pemoline was taken off the market because of reports of liver failure associated with its use.

Atomoxetine is a nonstimulant drug that is also used to treat ADHD. Atomoxetine is a norepinephrine reuptake inhibitor. Because it is not an amphetamine, it is associated with a low incidence of insomnia and has low abuse potential. Another advantage is that phone-in refills are allowed for this drug (as opposed to Schedule CII drugs, which require a written prescription). One of the newest drugs in the ADHD arsenal is lisdexamfetamine (Vyvanse). It is a prodrug for dextroamphetamine, meaning it is converted in the body to dextroamphetamine.

Mechanism of Action and Drug Effects

Amphetamines stimulate areas of the brain associated with mental alertness, such as the cerebral cortex and the thalamus. Pharmacologic actions of CNS stimulants are similar to the actions of the sympathetic nervous system in that the CNS and respiratory systems are the primary systems affected. CNS effects include mood elevation or euphoria, increased mental alertness and capacity for work, decreased fatigue and drowsiness, and prolonged wakefulness. The respiratory effects most commonly seen are relaxation of bronchial smooth muscle, increased respiration, and dilation of pulmonary arteries.

The amphetamines and phenidates increase the effects of norepinephrine and dopamine in CNS synapses by increasing their release and blocking their reuptake. As a result, both neurotransmitters are in contact with their receptors longer, which lengthens their duration of action. Modafinil is also classified as an analeptic. It promotes wakefulness like the amphetamines and phenidates. It lacks sympathomimetic properties, however, and appears to work primarily by reducing gamma-aminobutyric acid (GABA)–mediated neurotransmission in the brain. GABA is the principal inhibitory neurotransmitter in the brain. The nonstimulant drug atomoxetine is also being used to treat ADHD. It works in the CNS by selective inhibition of norepinephrine reuptake.

Indications

Various amphetamine derivatives, including methylphenidate, are currently used to treat both ADHD and narcolepsy. Dexmethylphenidate is currently indicated for ADHD alone. Amphetamine sulfate was also used to treat obesity in the early to mid twentieth century. However, the only amphetamines currently approved for this indication are benzphetamine and methamphetamine (see Anorexiants). The nonamphetamine stimulant modafinil is indicated for narcolepsy.

Specialists sometimes recommend periodic "drug holidays" (e.g., 1 day per week) without medication to diminish the addictive tendencies of the stimulant drugs. School-age children often do not take these drugs on weekends and school vacations.

Contraindications

Contraindications to the use of amphetamine and nonamphetamine stimulants include known drug allergy or cardiac structural abnormalities. These drugs can also exacerbate the following conditions: marked anxiety or agitation, Tourette's syndrome and other tic disorders (hyperstimulation), hypertension, and glaucoma (can increase intraocular pressure; see Chapter 57). The drugs must not be used in patients who have received therapy with any monoamine oxidase inhibitor (MAOI) in the preceding 14 days (see Chapter 16). Contraindications specific to atomoxetine include drug allergy, glaucoma, and recent MAOI use.

TABLE 13-4 CNS STIMULANTS: COMMON DRUG INTERACTIONS

DRUG	INTERACTING DRUGS	MECHANISM	RESULT
Amphetamine and Nonamphetamine Stimulants			
Amphetamines (various salts) methylphenidate	CNS stimulants	Additive toxicities	Cardiovascular adverse effects, nervousness, insomnia
	MAOIs	Increased release of catecholamines	Headaches, dysrhythmias, severe hypertension
Atomoxetine	Sympathomimetic drugs	Enhanced SNS effects	Cardiovascular adverse effects (dysrhythmias, tachycardia, hypertension)
	CYP2D6 inhibitors (MAOIs, paroxetine)	Reduced metabolism of atomoxetine	Enhanced atomoxetine toxicity
Anorexiants and Analeptics			
phentermine	CNS stimulants	Additive toxicities	Nervousness, insomnia, dysrhythmias, seizures
	MAOIs	Increased release of catecholamines	Headaches, dysrhythmias, severe hypertension
	Serotonergic drugs	Additive toxicity	Cardiovascular adverse effects, nervousness, insomnia, convulsions
Serotonin Agonists			
sumatriptan and others	Ergot alkaloids, SSRIs, MAOIs	Additive toxicity	Cardiovascular adverse effects, nervousness, insomnia, convulsions
Ergot Alkaloids			
D.H.E.45, Caffergot	Protease inhibitors, azole antifungals, macrolide antibiotics	Increased ergot levels	Acute ergot toxicity; nausea, vomiting, hypotension or hypertension, seizures, coma, death; use with ergot alkaloids is contraindicated

CNS, Central nervous system; *CYP2D6,* cytochrome P-450 enzyme 2D6; *MAOIs,* monoamine oxidase inhibitors; *SNS,* sympathetic nervous system; *SSRIs,* selective serotonin reuptake inhibitors.

Adverse Effects

Both amphetamine and nonamphetamine stimulants have a wide range of adverse effects that most often arise when these drugs are administered at high doses. These drugs tend to "speed up" body systems. For example, effects on the cardiovascular system include increased heart rate and blood pressure. Other adverse effects include angina, anxiety, insomnia, headache, tremor, blurred vision, increased metabolic rate (beneficial in treatment of obesity), gastrointestinal (GI) distress, dry mouth, and worsening of or new onset of psychiatric disorders, including mania, psychoses, or aggression. Common adverse effects associated with atomoxetine include headache, abdominal pain, vomiting, anorexia, and cough.

Interactions

Drug interactions associated with these drugs vary greatly from class to class. Table 13-4 summarizes some of the more common interactions for all drug classes in this chapter.

Dosages

For dosage information, see the table on p. 211.

DRUG PROFILES

AMPHETAMINES AND RELATED STIMULANTS

The principal drugs used to treat ADHD and narcolepsy are amphetamines and nonamphetamine stimulants. Atomoxetine, a nonstimulant drug, is also used for ADHD.

◆ amphetamines

The various amphetamine salts are the prototypical CNS stimulants used to treat ADHD and narcolepsy. Amphetamine is available in prescription form only for oral use, both as single-component dextroamphetamine sulfate (Dexedrine) and as a mixture of dextroamphetamine sulfate, dextroamphetamine saccharate, amphetamine sulfate, and amphetamine aspartate (Adderall).

Pharmacokinetics (dextroamphetamine)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-60 min	90-120 min	7-14 hr	10 hr

◆ methylphenidate

Methylphenidate (Ritalin) was the first prescription drug indicated for ADHD and continues to be the most widely prescribed drug for the treatment of ADHD and is also used for narcolepsy. Extended-release dosage forms include Ritalin SR, Concerta, and Metadate CD. There is some controversy regarding drug therapy for ADHD. Some parents may be understandably apprehensive regarding this type of drug therapy. However, with proper diagnosis of the disorder, proper dosing of the drug, and regular medical monitoring, many children can achieve significant improvement in school performance and social skills. Psychosocial problems within a child's family need to be ruled out

or addressed if they are contributing to the child's problems, regardless of whether the medication is prescribed.

Pharmacokinetics (immediate release)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-60 min	6-8 hr	1-3 hr	4-6 hr

atomoxetine

Atomoxetine (Strattera) is approved for treating ADHD in children older than 6 years of age and in adults. This medication is not a controlled substance because it lacks addictive properties, unlike amphetamines and phenidates. For this reason, it has rapidly gained popularity as a therapeutic option for treating ADHD. In September 2005, however, the FDA issued a warning describing cases of suicidal thinking and behavior in small numbers of adolescent patients receiving this medication, similar to its previous warnings regarding adolescent use of antidepressant medications (see Chapter 16). Prescribers are advised to work with parents in providing prudent monitoring of any young patients taking this medication and to promptly reevaluate patients showing any behavioral symptoms of concern.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	60 min	1-2 hr	5-24 hr	24-120 hr

modafinil

Modafinil (Provigil) is indicated for improvement of wakefulness in patients with excessive daytime sleepiness associated with narcolepsy and also with *shift work sleep disorder*. It has less abuse potential than amphetamines and methylphenidate and is a Schedule IV drug. A related drug is armodafinil (Nuvigil), which is similar to modafinil.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-2 months*	2-4 hr	8-15 hr	Unknown

*Therapeutic effects.

ANOREXIANTS

By definition, an *anorexiant* is any substance that suppresses appetite. Anorexiants are CNS stimulant drugs used to promote weight loss in obesity; however, their effectiveness has not been proved. These drugs include phentermine (Ionamin), benzphetamine (Didrex), methamphetamine (Desoxyn), and diethylpropion (Tenuate). In 2010, sibutramine (Meridia) was withdrawn from the market due to safety concerns. Benzphetamine and methamphetamine are the only amphetamines currently approved for treating obesity. Orlistat (Xenical) is a related nonstimulant drug used to treat obesity. It works locally in the small and large intestines where it inhibits absorption of caloric intake from fatty foods.

CASE STUDY

Methylphenidate for Attention Deficit Hyperactivity Disorder

Nina, a 13-year-old girl, has been diagnosed with attention deficit hyperactivity disorder. She is in the seventh grade at a local middle school and plays the clarinet in the school's after-school band. Her parents have noticed that she has had trouble focusing on assignments and music practice for the last year and have discussed her problems with Nina's pediatrician. The physician has prescribed methylphenidate (Ritalin), 5 mg, twice a day for 2 weeks, then increasing the dose to 10 mg twice a day if no improvement is noted.

1. What are the therapeutic effects of methylphenidate?
2. After 3 weeks, Nina's mother calls the physician's office to say that Nina has been doing better at school, as reported by her morning teacher, but the band teacher has reported that Nina gets restless during after-school rehearsals. Nina's mother also reports that Nina seems unable to get to sleep at night and has been staying up too late. What should the nurse suggest?
3. At the 2-month checkup, the physician suggests that Nina's mother hold the medication on weekends, giving the drug only during the weekdays while Nina is at school. In addition, careful height and weight measurements are taken. What is the reason for this "drug holiday," as described by the physician? What is the purpose of the height and weight measurements?
4. When it is time for a refill, Nina's mother calls the pharmacy. However, the pharmacist tells her, "I can't refill this medication by phone. You will need to bring in a new prescription." What is the reason for this?

For answers, see http://evolve.elsevier.com/Lilley.

Mechanism of Action and Drug Effects

Anorexiants are CNS stimulants that are believed to work by suppressing appetite control centers in the brain. Some evidence suggests that they also increase the body's basal metabolic rate, including mobilization of adipose tissue stores and enhanced cellular glucose uptake, as well as reduce dietary fat absorption.

There are some minor differences between these drugs in terms of their individual actions. Phentermine, diethylpropion, methamphetamine, and benzphetamine resemble amphetamine sulfate in their chemical structures and CNS effects. These drugs are classified as both anorexiants and adrenergic (sympathomimetic) drugs. However, all appear to suppress appetite centers in the CNS through dopamine- and norepinephrine-mediated pathways.

Orlistat differs from other antiobesity drugs in that it is not a CNS stimulant. It works by inhibiting the enzyme lipase. This results in reduced absorption of dietary fat from the intestinal tract and increased fat elimination in the feces.

Indications

Anorexiants are used for the treatment of obesity. However, their effects are often minimal without accompanying behavioral modifications involving diet and exercise. Current evidence-based guidelines for the treatment of obesity do not support the use of anorexiants as monotherapy. They are most commonly used in higher-risk patients. These include obese patients with a BMI of 30 or higher, or patients with a BMI of 27 who are also hypertensive or have high cholesterol or diabetes.

Contraindications

Contraindications to anorexiants include drug allergy, any severe cardiovascular disease, uncontrolled hypertension, hyperthyroidism, glaucoma, mental agitation, history of drug abuse, eating disorders (e.g., anorexia, bulimia), and use of MAOIs (see Chapter 16) within the previous 14 days. Orlistat is contraindicated in cases of chronic malabsorption syndrome (e.g. Crohn's disease, colitis, short bowel syndrome) or cholestasis.

Adverse Effects

With the exception of diethylpropion, anorexiants may raise blood pressure and cause heart palpitations and even dysrhythmias at higher dosages. Ironically, at therapeutic dosages, they may actually reflexively slow the heart rate. Diethylpropion, however, has little cardiovascular activity. These drugs may also cause anxiety, agitation, dizziness, and headache. The most common adverse effects of orlistat include headache, upper respiratory tract infection (mechanism uncertain), and GI distress, including fecal incontinence and oily stools.

Interactions

See Table 13-4.

Dosages

For dosage information, see the table on p. 211.

DRUG PROFILES

Amphetamine salts are no longer used for treatment of obesity because of their high abuse potential. The nonstimulant drug orlistat, a lipase inhibitor, is available over the counter.

◆ phentermine

Phentermine (Ionamin) is a sympathomimetic anorexiant that is structurally related to amphetamines but with much lower abuse potential. It is classified as a Schedule IV drug. This drug is not to be confused with several other drugs that were recalled by the FDA in the late 1990s (fenfluramine/dexfenfluramine [Phen-Fen]) and in 2000 (phenylpropanolamine) because of case reports of various adverse cardiovascular and/or pulmonary effects.

orlistat

Orlistat (Xenical) is unrelated to other drugs in its category. Allī is an over-the-counter (OTC) version released in 2007. It works by binding to gastric and pancreatic enzymes called *lipases.* Blocking these enzymes reduces fat absorption by roughly 30%. Restricting dietary intake of fat to less than 30% of total calories can help reduce some of the GI adverse effects, which include oily spotting, flatulence, and fecal incontinence in 20% to 40% of patients. Decreases in serum concentrations of vitamins A, D, and E and beta carotene are seen as a result of the blocking of fat absorption. Supplementation with fat-soluble vitamins corrects this deficiency.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	3 mo*	6-8 hr	1-2 hr	Unknown

*Therapeutic effects.

ANTIMIGRAINE DRUGS

Serotonin receptor agonists, first introduced in the 1990s, have revolutionized the treatment of migraine headache. They work by stimulating serotonin receptors in the brain. They include sumatriptan (Imitrex), almotriptan (Axert), eletriptan (Relpax), naratriptan (Amerge), rizatriptan (Maxalt), zolmitriptan (Zomig), and frovatriptan (Frova). Collectively, these drugs are referred to as *triptans.* They are to be used cautiously in patients with severe cardiovascular disease (especially angina pectoris). Historically, **ergot alkaloids** were the mainstay of treatment of migraine headaches but have been replaced by the triptans for first-line therapy. The ergot alkaloids are obtained from a fungus and cause vasoconstriction of dilated blood vessels in the brain and of the carotid arteries. They are contraindicated in patients with peripheral vascular disease, coronary artery disease, sepsis, impaired renal or hepatic function, and severe hypertension.

Mechanism of Action and Drug Effects

The chemical name for serotonin is 5-hydroxytryptamine, or 5-HT. Physiologists have further identified two 5-HT receptor subtypes on which these drugs have their greatest effect: 5-HT_{1B} and 5-HT_{1D}. Triptans stimulate these receptors in cerebral arteries, causing vasoconstriction and normally reducing or eliminating headache symptoms. They also reduce the production of inflammatory neuropeptides. This is known as *abortive* drug therapy because it treats a headache that has already started. Ergot alkaloids also narrow or constrict blood vessels in the brain. Although the cause of migraines is not fully understood, they are thought to be related to abnormal dilation of the blood vessels within the brain.

Indications

The triptan antimigraine drugs, also referred to as *selective serotonin receptor agonists (SSRAs),* are indicated for abortive therapy of an acute migraine headache. Although they may be taken during aura symptoms in patients who have auras with their headaches, these drugs are not indicated for *preventive* migraine therapy. Preventive therapy is indicated if migraine attacks occur one or more days per week. A variety of drugs

are used for preventive therapy; most of them are discussed in more detail in other chapters. First-line drugs for preventive therapy include propranolol (see Chapter 19), amitriptyline (see Chapter 16), valproic acid, and topiramate (see Chapter 15). Second-line therapies include the ergot alkaloid dihydroergotamine mesylate (D.H.E. 45); nonsteroidal antiinflammatory drugs, including naproxen (see Chapter 44), calcium channel blockers, and angiotensin receptor blockers (see Chapter 22). In many cases, preventive drug therapy is sufficient to prevent a full-blown migraine. However, when prevention fails, treatment is needed and the triptans are the most commonly prescribed drug class. Another frequently used product as abortive therapy is a combination of acetaminophen or aspirin plus the barbiturate butalbital plus the analeptic caffeine, with or without codeine (Fioricet). In addition to potentiating the effects of the analgesics, caffeine can also enhance intestinal absorption of the ergot alkaloids and has a vasoconstricting effect, which can reduce cerebral blood flow to ease headache pain. Caffeine also has a diuretic effect, which may ultimately also reduce cerebral blood flow owing to reduced vascular volume secondary to enhanced urinary output.

Contraindications

Contraindications to triptans include drug allergy and the presence of serious cardiovascular disease, because of the vasoconstrictive potential of these medications. Contraindications to the use of ergot alkaloids include uncontrolled hypertension; cerebral, cardiac, or peripheral vascular disease; dysrhythmias; glaucoma; and coronary or ischemic heart disease.

Adverse Effects

Triptans have potential vasoconstrictor effects, including effects on the coronary circulation. Injectable dosage forms may cause local irritation at the site of injection. Other adverse effects include feelings of tingling, flushing (skin warmth and redness), and a congested feeling in the head or chest. Ergot alkaloids are associated with the adverse effects of nausea, vomiting, cold or clammy hands and feet, muscle pain, dizziness, numbness, a vague feeling of anxiety, a bitter or foul taste in the mouth or throat, and irritation of the nose (with the nasal spray dosage form). Overuse of abortive therapy may result in rebound headaches.

EVIDENCE-BASED PRACTICE

Ibuprofen May Help Relieve Acute Migraine Headaches

Review

Migraine headache is a common, disabling condition that has a major impact on the individual, health care services, and society. Many migraine sufferers do not seek proper medical attention and often rely on the use of over-the-counter (OTC) analgesics/medications. The goal of this review of literature was to assess the effectiveness and tolerability of ibuprofen on migraine headaches in adults. Additionally, this review is to assess ibuprofen when given as monotherapy or together with an antiemetic as compared to placebo treatment or other drug treatment for the relief of acute migraines in adults.

Type of Evidence

The investigators searched the databases of Cochrane CENTRAL, MEDLINE, EMBASE and the Oxford Pain Relief Database. These sources were used to identify studies published through April 2010 about ibuprofen and migraines. Criteria used to determine inclusion included randomized, double-blind trials of self-given ibuprofen versus active comparators to treat a migraine episode with outcome data for at least 10 participants per treatment group. Once data were collected, two independent investigators performed a methodological trial from which nine studies comparing ibuprofen and placebo or other active drugs were identified. Over 4300 participants were studied for a total of over 5220 migraine attacks. Of these studies, none were representative of the protocol of using ibuprofen and an antiemetic. Single doses of medications were used to treat all the attacks. Relative risk and number needed to treat (NNT) or harm versus placebo or other active drug were calculated from the participants.

Results of Study

When comparing ibuprofen 400 mg with use of the placebo, the numbers needed to treat (NNTs) were 7.2 for 2 hours pain-free (26% versus 12%), 3.2 for 2 hours of headache relief (57% versus 25%), and 4.0 for 24-hour sustained headache relief (45% versus 19%). Ibuprofen 200 mg versus the placebo showed that the NNTs were 9.7 for 2 hours pain-free (20% versus 10%) and 6.3 for 2 hours of headache relief (52% versus 37%). The ibuprofen dose of 400 mg offered significantly better 2-hour headache relief than the 200-mg dose, and the soluble dosage forms of ibuprofen offered better 1 hour relief but not the 2-hour headache relief as compared to standard tablet dosage forms. Another set of symptoms that were looked at were those of nausea, vomiting, photophobia, phonophobia, and functional disability. These symptoms were reduced within 2 hours with the ibuprofen versus placebo. Additionally, fewer participants used rescue medication. Side effects were mostly mild and temporary and occurred similarly in participants across treatment groups. The major limitation of this review includes weaknesses inherent in the reviewed studies as well as the fact that a small number of events were used to calculate some of the results.

Link of Evidence to Nursing Practice

Over 30 million people in the United States suffer from migraines with significant impacts on quality of life. Migraine management remains a huge challenge for health care professionals and has a subsequent negative impact on health care costs. Migraines have been classified as one of the 19 most disabling diseases worldwide. Therefore, adequate management or treatment is crucial to patient quality of life and to helping trim the costs of health care. Ibuprofen has been identified as an effective treatment for acute migraine headaches leading to pain relief in about 50% of sufferers but only complete relief from pain (and other symptoms) in a minority of participants. This review is just one example of the need for more effective, larger sample-sized studies. Additionally, there is the need for further studies on migraines and looking at a variety of outcomes for pain relief, types of management, and multisymptom management. Dosage formulations and their advantages and effectiveness also need to be studied. Nurse researchers need to continue to take the lead in identifying patient problems as well as helping to identify a variety of medical, holistic and alternative approaches to their short and long-term treatment.

Interactions

See Table 13-4.

Dosages

For dosage information, see the table on this page.

DRUG PROFILES

SEROTONIN RECEPTOR AGONISTS

Serotonin receptor agonists are used to treat migraine headache. They can produce relief from moderate to severe migraines within 2 hours in 70% to 80% of patients. They work by stimulating 5-HT_1 receptors in the brain and are sometimes referred to as *SSRAs* or *triptans.* They are available in a variety of formulations, including oral tablets, sublingual tablets, subcutaneous self-injections, and nasal sprays. A common effect of migraines is nausea and vomiting. Orally administered medications are therefore not tolerated by some patients. Non-oral (including sublingual) forms are advantageous for this reason. They also often have a more rapid onset of action, producing relief in some patients in 10 to 15 minutes, compared with 1 to 2 hours for tablets taken orally. For dosage information, see the table on this page.

♦ sumatriptan

Sumatriptan (Imitrex) was the original prototype drug for this class. As noted earlier, there are now seven triptans. Slight pharmacokinetic differences exist between some of these products, but their effects are comparable overall.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	0.5-1 hr	2.5 hr	2.5 hr	4 hr

DOSAGES

Selected CNS Stimulants and Related Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
♦ amphetamine/dextroamphetamine (Adderall) (C)	CNS stimulant	**Pediatric 3-5 yr** PO: 2.5 mg/day, increased weekly until desired effect **Pediatric 6 yr and older and Adult** PO: 5 mg once or twice daily, increased weekly until desired effect to a daily max of 40 mg	ADHD, narcolepsy
atomoxetine (Strattera) (C)	Selective norepinephrine reuptake inhibitor	**Pediatric (less than 70 kg)** PO: 0.5-1.2 mg/kg/day divided once or twice daily **Adult** (70 kg or more) PO: 40-100 mg/day divided once or twice daily	ADHD
♦ caffeine (B)	Xanthine cerebral stimulant	**Adult** PO: 300-400 mg IV: 500 mg **Premature infants** IV (caffeine citrate only): 20 mg/kg load followed by 5 mg/kg once daily	Treatment of spinal headache Neonatal apnea, bronchopulmonary dysplasia
doxapram (Dopram) (B)	Respiratory stimulant (analeptic)	**Adult, pediatric older than 12 yr** IV: 0.5-1 mg/kg, may repeat up to 2 mg/kg Infusion of 1-2 mg/min for up to 2 hr	Drug-induced respiratory depression COPD-associated hypercapnia
♦ methylphenidate, extended release (Concerta) (C)	CNS stimulant	**Pediatric and adult** 18-72 mg/day in a single dose	ADHD, narcolepsy
♦ methylphenidate (Ritalin) (C)	CNS stimulant	**Pediatric 6 yr and older** PO: 5 mg bid before breakfast and lunch and increased weekly until desired effect to max of 60 mg/day **Adult** PO: 20-60 mg/day divided bid-tid	ADHD, narcolepsy
♦ methylphenidate, extended release (Ritalin-SR) (C)	CNS stimulant	**Pediatric and adult** 20-60 mg/day in a single dose	ADHD, narcolepsy
modafinil (Provigil) (C)	CNS stimulant	**Adult** PO: 200 mg q AM; if second dose needed, give at noon	Narcolepsy
orlistat (Xenical, Allī) (B)	Lipase inhibitor	**Adult** PO: 120 mg tid with each meal containing fat	Obesity
♦ sumatriptan (Imitrex) (C)	Serotonin receptor agonist	**Adult** PO: 25, 50, or 100 mg, can repeat after 2 hr (max 200 mg/day) Subcut: 4-6 mg, can repeat in 1 hr (max 2 injections/day) Nasal spray: 5, 10, or 20 mg, can repeat after 2 hr (max 40 mg/day)	Acute migraine with or without aura

ADHD, Attention deficit hyperactivity disorder; *CNS,* central nervous system; *COPD,* chronic obstructive pulmonary disease; *IM,* intramuscular; *IV,* intravenous; *PO,* oral; *subcut,* subcutaneous.

ERGOT ALKALOIDS

Ergot alkaloids, such as ergotamine, are still used in treatment and prevention of migraines but are rapidly being replaced by the triptans. Dihydroergotamine mesylate (D.H.E. 45) is available in injectable form and as a nasal spray (Migranal). Ergotamine tartrate with caffeine (Cafergot) is available in tablet form.

DRUGS FOR SPECIFIC RESPIRATORY DEPRESSION SYNDROMES: ANALEPTICS

Analeptics include doxapram (Dopram) and the methylxanthines aminophylline, theophylline, and caffeine. These drugs are sometimes used to treat neonatal and postoperative respiratory depression. Neonatal uses are more common. Postoperative respiratory depression is a less common problem today due to the design of newer anesthetic drugs with shorter durations of action.

Mechanism of Action and Drug Effects

Analeptics work by stimulating areas of the CNS that control respiration, mainly the medulla and spinal cord. Methylxanthine analeptics (caffeine, aminophylline, and theophylline) also inhibit the enzyme *phosphodiesterase.* This enzyme breaks down a substance called *cyclic adenosine monophosphate (cAMP).* When analeptics block this enzyme, cAMP accumulates. This results in relaxation of smooth muscle in the respiratory tract, dilation of pulmonary arterioles, and stimulation of the CNS in general. Aminophylline is a *prodrug* (a drug that is formulated for greater solubility to facilitate administration but must be metabolized to an active form); it is *hydrolyzed* to theophylline in the body. Theophylline, in turn, is metabolized to caffeine. Caffeine is inherently a stronger CNS stimulant, hence its popularity in coffee, tea, and soft drinks. It also helps to potentiate the effects of analgesics used for migraine therapy and has a diuretic effect. The stimulant effects of caffeine are attributed to its antagonism (blocking) of adenosine receptors in the brain. Adenosine is associated with sleep promotion. The mechanism of action of doxapram is similar to that of the methylxanthines, but it has a greater stimulant effect in the area of the brain that senses carbon dioxide content. When the carbon dioxide content of the blood is high, the respiratory center in the brain is stimulated to induce deeper and faster breathing in an attempt to exchange more carbon dioxide for inhaled oxygen.

Indications

Currently listed indications for analeptics include neonatal apnea, bronchopulmonary dysplasia, hypercapnia associated with COPD, postanesthetic respiratory depression, and respiratory depression secondary to drugs of abuse (e.g., opioids, alcohol, or barbiturates). In newborns, administration of caffeine is associated with less tachycardia, CNS stimulation, and feeding intolerance than administration of theophylline or aminophylline. The latter are also used to treat neonatal bradycardia and are infrequently used to treat asthma in older children and adults.

Contraindications

Contraindications to the use of analeptics include drug allergy, peptic ulcer disease (especially for caffeine), and serious cardiovascular conditions. Concurrent use of other phosphodiesterase-inhibiting drugs such as sildenafil and similar drugs is also not recommended.

Doxapram use is contraindicated in newborns because of the benzyl alcohol contained in the injectable formulation of the drug. Benzyl alcohol is associated with *gasping syndrome* in infants and may also displace bilirubin into the blood from albumin binding sites in the circulation. This, in turn, could cause or worsen hyperbilirubinemia, a common condition in high-risk infants.

Its use is also contraindicated in patients with epilepsy or other convulsive disorders, those who have shown a hypersensitivity reaction to it, those showing evidence of head injury, those suffering from cardiovascular impairment or severe hypertension, and patients who have experienced a stroke.

Adverse Effects

At higher dosages, analeptics stimulate the vagal, vasomotor, and respiratory centers of the medulla in the brainstem, as well as increasing blood flow to skeletal muscles. Vagal effects include stimulation of gastric secretions, diarrhea, and reflex tachycardia. Vasomotor effects include flushing (warmth, redness) and sweating of the skin. Respiratory effects include elevated respiratory rate (which is normally desired). Skeletal muscle effects include muscular tension and tremors. Neurologic effects include reduced deep tendon reflexes.

Interactions

See Table 13-4.

Dosages

For dosage information, see the table on p. 211.

DRUG PROFILES

Analeptic drugs include doxapram (Dopram), aminophylline, theophylline, and caffeine. The profiles for aminophylline and theophylline can be found in Chapter 37. The antinarcoleptic analeptic drug modafinil was discussed earlier in the narcolepsy section of this chapter. For dosage information, see the table on p. 211.

◆ caffeine

Caffeine is a CNS stimulant that can be found in OTC drugs (e.g., NoDoz) and combination prescription drugs (e.g., Fioricet, Fiorinal). It is also contained in many beverages and foods. A few of the many foods and drugs that contain caffeine are listed in Table 13-5. Caffeine is contraindicated in patients with a known hypersensitivity to it and is used with caution in patients who have a history of peptic ulcers or cardiac dysrhythmias or who have recently experienced a myocardial infarction. Caffeine is available in oral and injectable dosage forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	15-45 min	1 hr	3-4 hr	6 hr

There are two forms of intravenous caffeine: caffeine citrate and caffeine sodium benzoate. Caffeine citrate is recommended for neonatal apnea, including cases not responsive to other methylxanthines such as theophylline. Caffeine sodium

benzoate is used for respiratory depression in adults only, because it contains the preservative benzyl alcohol.

doxapram

Doxapram (Dopram) is an analeptic that is commonly used in conjunction with supportive measures in cases of respiratory depression that involve anesthetics or drugs of abuse and in COPD-associated hypercapnia. Deep tendon reflexes, in addition to vital signs and heart rhythm, are monitored to prevent overdosage of this drug.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Less than 30 sec	Less than 2 min	2-4 hr	5-12 min

NURSING PROCESS

ASSESSMENT

CNS stimulants are used for a variety of conditions and disorders. They have addictive potential, and so the following assessment data need to be collected before their use, regardless of indication: (1) a thorough medical history with attention to preexisting diseases or conditions, especially those of the cardiovascular, cerebrovascular, neurologic, renal, and liver systems; (2) past and current history of addictive or substance abuse behaviors; (3) complete medication profile with a listing of prescription, OTC, and herbal drugs and any use of alcohol, nicotine, and/or social or illegal drugs; and (4) a complete nutritional and dietary history. Assess all of these areas because of the mechanism of action of CNS stimulants, which increases pulse rate and blood pressure, and can lead to seizures, intracerebral bleeding, and toxicity (due to decreased drug metabolism and excretion). Stimulation of the respiratory system is actually desirable, and this action is beneficial in those patients suffering from CNS depression, such as postoperatively. Improvement of attention span is beneficial for those in need of the medication, but the possibility of adverse effects requires a thorough assessment to obtain baseline information. The anorexiant action may cause complications if the drugs are used or ordered inappropriately. When these drugs are taken for appetite suppression, assess and document baseline height, weight, and dietary intake. Measure vital signs with specific attention to blood pressure and pulse rate whenever these drugs are used.

To add to the thoroughness of the assessment, include in your nursing history the following information: inquiry about lifestyle, exercise, nutritional habits and patterns (e.g., a reduction in fat-soluble vitamins, history of any type of eating disorder), educational level, previous teaching and learning successes and failures, available support structures (e.g., family and friends), self-esteem, stress levels, mental status and mental health problems (drugs may exacerbate psychosis), presence of diabetes (diabetic patients need closer monitoring and tighter glucose control when taking stimulant medications due to increased glucogenolysis), and information related to contraindications, cautions, and drug interactions (see Table 13-4).

With *drugs used for the management of attention deficit hyperactivity disorder,* very cautiously and continuously assess the patient. For the pediatric patient, gather the following information during assessment: baseline weight, height, growth and development patterns, and vital signs. Complete blood counts may be ordered. Thoroughly document any changes in emotional status as well. Adults also require thorough assessment of baseline weight, height, and vital signs. Assess and document usual sleep habits and patterns so that sleep disturbances may be anticipated and managed appropriately. Atypical behavior, loss in attention span, and history of social problems or problems in school are also important to assess and document before and during therapy for baseline comparison. For children with ADHD, parental support is important to the success of treatment, and so a home assessment may be needed. Attention to and documentation of daily dietary intake before drug therapy is important because of the risk of drug-related weight loss. It is also important that the pediatric patient not experience too rapid or too much weight loss; a thorough nutritional and dietary assessment is needed. Cardiac assessment is important because of the CNS stimulation. Blood pressure, pulse rate, heart sounds, and any history of chest pain or palpitations must be noted. Other data to gather during assessment include possible contraindications, cautions, and drug interactions (see previous discussion). Document findings and note the patient's use of any prescription drugs, OTC drugs (e.g., nasal decongestants, which are also stimulants), and herbal preparations, specifically ginseng and caffeine (see the Safety: Herbal Therapies and Dietary Supplements box on p. 214).

TABLE 13-5 CAFFEINE-CONTAINING BEVERAGES AND DRUGS

MEDICATION OR BEVERAGE	AMOUNT OF CAFFEINE
Nonprescription Medications	
Analgesics	
Anacin	32 mg/tab
Excedrin, Excedrin Aspirin-Free, Excedrin Migraine	65 mg/tab
Stimulants	
NoDoz Maximum Strength	100 mg/tab
Vivarin	200 mg/tab
Zantrex-3 (marketed as anorexiant)	200 mg/tab
Prescription Medications (for Migraines)	
Fioricet, Fiorinal	40 mg/tab
Esgic	40 mg/tab
Cafergot	10 mg/suppository
Beverages	
Coffee (brewed, instant)	80-150 mg/5-oz cup
Coffee (decaffeinated)	2-20 mg/5-oz cup
Tea (brewed)	30-75 mg/5-oz cup
Soft drinks	35-60 mg/12-oz cup
Cocoa	5-40 mg/5-oz cup
Supplemented water (Red Bull, Propel, Vitamin Water)	~50 mg/12-oz cup
Coffee-flavored or chocolate ice cream	30-45 mg/0.5-oz cup

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

Selected Herbal Compounds Used for Nervous System Stimulation

COMMON NAME(S)	USES	POSSIBLE DRUG INTERACTIONS (AVOID CONCURRENT USE)
Ginkgo biloba, ginkgo	To enhance mental alertness; to improve memory or dementia	Warfarin, aspirin
Ginseng	To enhance impaired mental function and concentration	Drugs for diabetes that lower blood sugar (e.g., insulin, oral hypoglycemic drugs), monoamine oxidase inhibitors
Guarana	To stimulate nervous system, suppress appetite	Adenosine, disulfiram, quinolones, oral contraceptives, beta blockers, iron, lithium, phenylephrine (e.g., nasal spray), cimetidine, theophylline, tobacco

The *serotonin agonists* commonly used in the treatment of migraines are not without adverse reactions, contraindications, cautions, and drug interactions (see previous discussion). Include in your assessment a thorough cardiac history as well as measurement of blood pressure and pulse rate and rhythm. If a patient has a history of hypertension, there is risk of further increases in blood pressure to dangerous levels with use of these drugs, and thus the need for careful assessment and documentation. In fact, generally these drugs are not prescribed for patients with migraines who also have coronary artery disease unless a thorough cardiac evaluation has been performed. Conduct a careful assessment to identify other drugs the patient is taking that might lead to significant drug interactions, such as ergot alkaloids, selective serotonin receptor inhibitors, and MAOIs. If serotonin agonists are taken within 2 weeks of the use of these drugs, there is high risk for an additive toxicity. Such toxicity would be manifested by nervousness, insomnia, cardiovascular complications, and convulsions (serotonin syndrome).

Ergot alkaloids also have cautions, contraindications, and drug interactions (see previous discussion), which you need to assess for and document. Obtain a history of the migraines and their pattern, exacerbating factors, measures that provide relief, and previous treatments.

An *analeptic* such as doxapram is used as a central respiratory stimulant; therefore, it is most likely to be used in a hospital setting, specifically in intensive care units or postanesthesia units. The same concerns regarding contraindications, cautions, and drug interactions exist for this drug as for all CNS stimulants, and even closer attention must be paid to vital signs, especially heart rate and rhythm, and blood pressure. Any elevations in blood pressure and pulse rate may put the patient at a higher risk of complications. Perform a thorough neurologic assessment with specific attention to any possibility of seizures. Assess baseline deep tendon reflexes, and document for comparative purposes.

NURSING DIAGNOSES

1. Decreased cardiac output related to the adverse effects of CNS stimulants (e.g., palpitations and tachycardia)
2. Imbalanced nutrition, less than body requirements, related to adverse effects of CNS stimulants (e.g., amphetamines and anorexiants)
3. Chronic pain related to the experience of or a history of migraine headaches
4. Disturbed sleep patterns related to the action and adverse effects of CNS stimulants

PLANNING

GOALS

1. Patient remains free of cardiac symptoms and adverse effects.
2. Patient's nutritional status remains intact and without excess weight loss.
3. Patient regains adequate comfort level with adequate and efficient management of migraines.
4. Patient experiences minimal disturbed sleep patterns.

OUTCOME CRITERIA

1. Patient vital signs, especially blood pressure (120/80) and pulse rate (60 to 100) remain within normal limits and without major fluctuations or changes.
   - Patient states symptoms (e.g., palpitations, chest pain) that need to be reported to the prescriber immediately.
2. Patient maintains appropriate weight without too rapid losses during drug therapy regimen.
   - Patient regains or maintains near normal body weight and BMI during therapy.
   - Patient continues to undergo close to normal growth and development while taking medications.
3. Patient reports a decrease in headaches and improved activities of daily living and well being while taking medications as prescribed.
   - Patient reports minimal adverse effects from antimigraine medications.
   - Patient states improved quality of life with efficient and adequate self-administration of medication.
4. Patient experiences more restful sleep while experiencing efficient drug therapy.
   - Patient uses nonpharmacologic measures to enhance sleep such as massage, biofeedback, music therapy, relaxation breathing, and keeping the room quiet and at a comfortable temperature.

IMPLEMENTATION

With *drugs used for the treatment of attention deficit hyperactivity disorder,* some pediatric patients may respond better to certain dosage forms such as immediate release. However, dosing needs to be individualized and based on the patient's needs at different

times during the school day (e.g., a noon dose to help with music lessons later in the afternoon). Well-planned scheduling of these medications and close communication among the school, teachers, school nurse, and the family and patient is very important to successful treatment. It is also important to time the dosing of medications—but as ordered—for periods in which symptom control is most needed but without causing alterations in sleep patterns. Generally speaking, once-a-day dosing is used with extended-release or long-acting preparations. Adequate and proper dosing will be manifested by good control of inattentive/impulsive behavior during school time. If extended-release dosage forms lead to acceptable outcomes for the pediatric patient, taking medications at school may not be necessary. Many times a stigma is associated with taking medications at school. This may be preventable with use of long-acting preparations or other scheduling. To help decrease the occurrence of insomnia, it is recommended that the last daily dose be taken 4 to 6 hours before bedtime, as ordered. During therapy, monitor the patient for continued physical growth, with specific attention to weight and height. The prescriber may order medication-free times on weekends, holidays, and/or vacations; that is, the drug may be discontinued periodically so that the need for the medication can be reassessed and sensitivity increased.

Because *anorexiants* are generally used for a short period of time, emphasize to the patient and all members of the patient's support system that a suitable diet, appropriate independent and/or supervised exercise program, and behavioral modifications are necessary to support a favorable result and to help the patient cease overeating and experience healthy weight loss. With a drug regimen, medications are usually taken first thing in the morning, as ordered, to minimize interference with sleep. Therefore, it is recommended that these drugs not be taken within 4 to 6 hours of sleep. If the patient has been taking these drugs for a prolonged period, an interval period of weaning before discontinuation is needed to avoid withdrawal symptoms and to avoid any chance of a rebound increase in appetite. Weights must be assessed weekly or as ordered. Encourage journal keeping so that the patient can keep record of food intake as well as responses to the drug regimen, any adverse effects, socialization, exercise, and notes about how they are feeling day to day. Dry mouth may be managed with frequent mouth care and the use of sugar-free gum or hard candy. Sucking ice chips, as well as keeping a bottle of fresh water on hand at all times, may also be helpful. If headaches occur, acetaminophen will most likely be suggested. Caffeine in any form needs to be avoided including coffee, tea, sodas, and chocolate. Other products that may contain caffeine include some OTC analgesics; OTC compounds to treat menstrual symptoms; OTC products for cough, cold, flu, or congestion; and prescription drugs such as analgesics with ergotamine and caffeine, and butalbital with aspirin and caffeine. Supplementation with fat-soluble vitamins may be indicated with use of these drugs. It is also important to watch for tolerance to the anorexiant during the course of treatment. Other nursing considerations include emphasis on a holistic approach to treatment of obesity, including the possible use of hypnosis, biofeedback, and guided imagery, as ordered. Encourage patients to keep follow-up visits with their prescribers and others involved in their care.

SSRAs come in a variety of dosage forms. Rizatriptan is available in oral tablets as well as in a disintegrating tablet or wafer that dissolves on the tongue. The latter dosage form leads to a more rapid absorption. Use of the nasal spray or self-injectable forms of the serotonin agonists is especially desirable in patients experiencing the nausea and vomiting that may occur with migraine headaches. Self-injectable forms and nasal sprays also have the benefit of an onset of action of 10 to 15 minutes compared with 1 to 2 hours for tablet forms. Administration of a test dose of the injectable and all other dosage forms is usually recommended. If the injectable form is prescribed, provide instructions and demonstrations of the technique. See the Patient Teaching Tips for more information.

Ergot alkaloids are taken exactly as prescribed; for example, tablets need to be taken with 6 to 8 ounces of water or other fluid and work best when taken at the first sign of the migraine. This allows more successful treatment. With ergotamine tartrate and related drugs, the maximum dose is usually 6 tablets for a single headache and 10 tablets in any 7-day period. Dependence may occur with the ergots, and if they are withdrawn suddenly, rebound headaches may occur. Encourage the patient to report to the prescriber any headaches that are uncharacteristic or unusual, as well as any persistent headache, worsening of headaches, severe nausea, vomiting, dizziness, or restlessness. Any of the following also need to be reported immediately to the prescriber: slow, fast, or irregular heartbeat; tingling, pain, or coldness in the fingers or toes; loss of feeling in the fingers or toes; muscle pain or weakness; chest pain; severe stomach or abdominal pain; lower back pain; little or no urine. Emphasize that the patient must seek immediate medical attention if there is any chest pain, vision changes, confusion, or slurred speech. As mentioned previously, these medications are not to be taken with triptans.

The *analeptic* doxapram may be administered intravenously, but at different dosages depending on the purpose. (For dosage information, see the table on p. 211.) Give doxapram infusions using an intravenous pump, and closely monitor the patient. Because the patient's sensorium is generally diminished in this situation, place the patient in the Sims' or semi-Fowler's position to prevent aspiration. The patient's airway, breathing, and circulation (ABCs of care) are of highest priority. If adverse effects occur (see the pharmacology discussion), notify the prescriber.

EVALUATION

Therapeutic responses to *drugs for attention deficit hyperactivity disorder* include decreased hyperactivity, increased attention span and concentration, improved behavior, and, for adults, increased effectiveness at work. Adverse effects range from loss of appetite to increased irritability, insomnia, palpitations, nausea, and headaches. Therapeutic effects of *anorexiants* include appetite control and weight loss for the treatment of obesity. Adverse effects of these drugs include dry mouth, headache, insomnia, constipation, tachycardia, cardiac irregularities, hypertension, changes in mental status or sensorium, changes in mood or affect, alteration of sleep patterns, and seizures (all due to excess CNS stimulation). Evaluating for any increased irritability and withdrawal symptoms

TEAMWORK AND COLLABORATION: LEGAL AND ETHICAL PRINCIPLES

Handling of Prescription Drugs

It is important for the nurse to understand the following amendments to the federal laws that apply to the handling of all prescription drugs by the registered nurse. (NOTE: This is a summary and does not reflect the laws in their entirety.)

The registered nurse is prohibited from doing the following:

- Compounding or dispensing the designated drugs for legal distribution and administration.
- Distributing the drugs to any individuals who are not licensed or authorized by federal or state law to receive the drugs (e.g., those outside the health care provider–patient relationship); the penalties for such actions are generally severe.
- Making, selling, keeping, or concealing any counterfeit drug equipment.
- Possessing any type of stimulant or depressant drug unless authorized to do so by a legal prescription (as a patient); any unauthorized possession is illegal.

It is important to adhere to these legal guidelines in the practice of drug administration to avoid legal penalties, including possible loss of license or other severe penalties.

(e.g., headache, nausea and vomiting) is also important. If the anorexiant affects fat metabolism, then there may be adverse effects such as flatulence with an oily discharge, spotting, and fecal urgency. The patient also needs to be closely evaluated for decreased levels of fat-soluble vitamins (A, D, E, and K), because their levels may be affected by the decreased absorption of fats. For *drugs used to treat narcolepsy,* therapeutic responses include a decrease in daytime sleepiness. Adverse effects for which to monitor include headache, nausea, nervousness, insomnia, and anxiety. Therapeutic responses to the *serotonin agonists* include aborting of migraine headache with improved daily functioning and performance because of the reduction in headaches. Adverse effects for which to monitor include pain at the injection site (if a self-injectable form is used; such pain is temporary), flushing, chest tightness or pressure, weakness, sedation, dizziness, sweating, increase in blood pressure and pulse rate, and bad taste with the nasal spray formulation, which may precipitate nausea.

PATIENT TEACHING TIPS

General Information

- Serotonin agonists are to be taken as prescribed on a prn (as needed) basis at the onset of the migraine but within the frequency and dosage amount prescribed.
- Medications need to be taken exactly as prescribed without skipping, omitting, or adding doses.
- Alcohol, OTC cold products, cough syrups that contain alcohol, nicotine, and caffeine-containing food items and/or beverages must be avoided.
- Keeping a journal of daily activities and response to drug therapy and any adverse effects is encouraged. Medications or foods/beverages identified as triggers to a migraine may vary from person to person. Encourage the patient to track food/beverage intake as well as sleep habits and other practices/factors that may be identified as precipitators of migraines.
- Avoid any abrupt or sudden withdrawal of medications.

Drugs Used to Treat Attention Deficit Hyperactivity Disorder

- For maximal drug effects, medications are to be taken on an empty stomach 30 to 45 minutes before eating.
- Keeping all follow-up appointments is important to monitoring drug therapy.
- If the prescriber decides to discontinue the medication, a weaning process with careful supervision is recommended.
- Extended-release or long-acting preparations are to be taken in their original dosage form and only as directed. They are not to be crushed, chewed, broken, or altered in any way.
- Dosage amounts are not to be increased or decreased by the patient or family, because this may lead to drug-related complications. If there is any concern about the drug and its dosage amount or adverse effects, encourage parents or caregivers to contact the prescriber.

Anorexiants

- The patient must follow all prescriber instructions regarding medications, diet, and exercise.
- Some of these medications may impair alertness and the ability to think, so patients need to remain very cautious if engaging in activities that may be adversely affected until these impairments are resolved.
- An unpleasant taste of the medicine and/or dry mouth may be minimized by the use of mouth rinses, ice chips, sugarless chewing gum, and/or hard candies.

Antimigraine Drugs

- Encourage patients who experience migraines to avoid foods/beverages that are known triggers to severe or other forms of migraine headaches.
- Other triggers for some individuals may include food additives, preservatives (including MSG, nitrates, and nitrites), artificial sweeteners (especially aspartame when used for extended periods of time), and chocolate.
- Before using a nasal spray dosage form of an antimigraine drug, instruct the patient to first gently blow the nose to clear the nasal passages. With the head upright, the patient then closes one nostril and inserts the nozzle into the open nostril. While a breath is taken through the nose, the spray is released. The nozzle is removed, and then the patient gently breathes in through the nose and out through the mouth for 10 to 20 seconds. Some bad taste may be experienced.
- Until migraine is resolved, the patient may find comfort by avoiding doing things that require alertness and rapid skilled movements. It may be helpful to keep the room darkened and noise to a minimum. If the headache is not resolved and/or vomiting occurs, the patient may need further

PATIENT TEACHING TIPS—cont'd

medical attention to help avoid additional problems, such as dehydration.
- Encourage keeping a journal about the experience of all headaches, precipitators/relievers, and the rating of each headache on a scale of 0 to 10 (where 0 is no pain and 10 is the worst pain ever). Recording of other symptoms (e.g., photophobia, nausea, and vomiting) as well as their frequency and duration is recommended.
- When taking SSRAs, the patient must understand the importance of contacting the prescriber immediately if there are any problems with palpitations, chest pain, and/or pain or weakness in the extremities.
- Injectable forms of sumatriptan are to be given subcutaneously and as ordered. Have the patient practice administering injections (without the medication) with you at the prescriber's office so that proper technique is used and a moderate comfort level is achieved.
- Autoinjectors with prefilled syringes may be used. The syringe needs to be discarded in an appropriate container or receptacle after use and kept out of the reach of children.
- Administer no more than two injections of sumatriptan during a 24-hour period, and allow at least 1 hour between injections.
- When using injectable sumatriptan, contact the prescriber or emergency services immediately if there is swelling around the eyes, pain or tightness in the chest or throat, wheezing, and/or heart throbbing.
- Treatment for migraine headaches may relieve the pain and symptoms of a migraine attack as well as prevent further migraine attacks. Some abortive therapies, such as sumatriptan, may offer rapid relief if drugs are given as ordered and before the headache worsens. Drugs may be given orally, sublingually, or by subcutaneous injection in the thigh. When a triptan does not work, an ergot alkaloid (e.g., dihydroergotamine or ergotamine tartrate) may be ordered but is not to be used concurrently. Other drugs that may also be used to try to prevent migraine headache include antidepressants, antiseizure medications, and beta blockers.

KEY POINTS

- CNS stimulants are drugs that stimulate the brain or spinal cord.
- The actions of these stimulants mimic those of the neurotransmitters of the sympathetic nervous system (e.g., norepinephrine, dopamine, and serotonin).
- Included in the family of CNS stimulants are amphetamines, analeptics, and anorexiants with therapeutic uses for attention deficit hyperactivity disorder, narcolepsy, and appetite control. Adverse effects associated with CNS stimulants include changes in mental status or sensorium, changes in mood or affect, tachycardia, loss of appetite, nausea, altered sleep patterns (e.g., insomnia), physical dependency, irritability, and seizures.
- Serotonin agonists may be administered as a subcutaneous injection, as a nasal spray, and as oral tablets. Any chest pain or tightness, tremors, vomiting, or worsening symptoms needs to be reported to the prescriber immediately.
- Anorexiants control or suppress appetite. They are used to stimulate the CNS and result in suppression of appetite control centers in the brain.
- Contraindications to the use of anorexiants, as well as other CNS stimulants, include hypersensitivity, seizure activity, convulsive disorders, and liver dysfunction.
- The SSRAs are a newer class of CNS stimulants and are used to treat migraine headaches. They are not to be given to patients with coronary heart disease.
- Amphetamines elevate mood or produce euphoria, increase mental alertness and capacity for work, decrease fatigue and drowsiness, and prolong wakefulness.
- Journaling is helpful in evaluating the effects of all drugs used to treat attention deficit hyperactivity disorder, obesity, migraines, and narcolepsy.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A patient with narcolepsy will begin treatment with a CNS stimulant. The nurse expects to see which adverse effect?
- **a** Bradycardia
- **b** Nervousness
- **c** Mental clouding
- **d** Drowsiness at night

2 A patient at a weight management clinic who was given a prescription for orlistat (Xenical) calls the clinic hotline complaining of a "terrible side effect." The nurse suspects that the patient is referring to which problem?
- **a** Nausea
- **b** Sexual dysfunction
- **c** Urinary incontinence
- **d** Fecal incontinence

3 The nurse is developing a plan of care for a patient receiving an anorexiant. Which nursing diagnosis is most appropriate?
- **a** Deficient fluid volume
- **b** Sleep deprivation
- **c** Impaired memory
- **d** Imbalanced nutrition, less than body requirements

4 A patient has a new prescription for sumatriptan (Imitrex). The nurse providing patient teaching on self-administration will include which information?
- **a** Correct technique for intramuscular injections
- **b** Take the medication before the headache worsens.
- **c** Allow at least 30 minutes between injections.
- **d** Take no more than 4 doses in a 24-hour period.

NCLEX® EXAMINATION REVIEW QUESTIONS—cont'd

5 The nurse is reviewing the history of a patient who will be starting the triptan sumatriptan (Imitrex) as part of treatment for migraine headaches. Which condition, if present, may be a contraindication to triptan therapy?
- **a** Cardiovascular disease
- **b** Chronic bronchitis
- **c** History of renal calculi
- **d** Diabetes mellitus type 2

6 The nurse is reviewing medication therapy with the parents of an adolescent with ADHD. Which statement is correct? (Select all that apply.)
- **a** "Be sure to have your child blow his nose before administering the nasal spray."
- **b** "This medication is used only when symptoms of ADHD are severe."
- **c** "The last dose should be taken 4 to 6 hours before bedtime to avoid interference with sleep."
- **d** "Be sure to contact the physician right away if you notice expression of suicidal thoughts."
- **e** "We will need to check your child's height and weight periodically to monitor physical growth."
- **f** "If adverse effects become severe, stop the medication for 3 to 4 days."

7 The medication order reads: "Atomoxetine (Strattera) 1.2 mg/kg/day in 2 divided doses." The child weighs 66 lbs. How much will be given with each dose?

1. b, 2. d, 3. d, 4. b, 5. a, 6. c, d, e, 7. 18 mg per dose

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Briefly describe the pathophysiology of epilepsy.
2 Discuss the rationale for the use of the various classes of antiepileptic drugs (AEDs) in the management of the different forms of epilepsy.
3 Identify the various drugs in each of the following drug classes: iminostilbenes, benzodiazepines, barbiturates, hydantoins, and miscellaneous drugs.
4 Identify the mechanisms of action, indications, cautions, contraindications, dosages, routes of administration, adverse effects, toxic effects, therapeutic blood levels, and drug interactions for each antiepileptic drug.
5 Develop a nursing care plan, including patient education, based on the nursing process for patients receiving AEDs.

DRUG PROFILES

- ♦ **carbamazepine, p. 229**
  ethosuximide, p. 229
- ♦ **gabapentin, p. 229**
  lamotrigine, p. 230

KEY TERMS

Anticonvulsants Substances or procedures that prevent or reduce the severity of *epileptic* or other *convulsive* seizures. (p. 221)

Antiepileptic drugs Prescription drugs that prevent or reduce the severity of epilepsy and different types of epileptic seizures, not just convulsive seizures. (p. 221)

Autoinduction A metabolic process in which a drug stimulates the production of enzymes that enhance its own metabolism over time, which leads to a reduction in therapeutic drug concentrations. (p. 229)

Convulsion A type of seizure involving excessive stimulation of neurons in the brain and characterized by the spasmodic contraction of voluntary muscles. (See also *seizure*.) (p. 220)

Electroencephalogram (EEG) A recording of the electrical activity that arises from spontaneous currents in nerve cells in the brain, derived from electrodes placed on the outer skull. (p. 220)

KEY TERMS—cont'd

Epilepsy A general term for any of a group of neurologic disorders characterized by *recurrent* episodes of *convulsive seizures*, sensory disturbances, abnormal behavior, loss of consciousness, or any combination of these. (p. 220)

Generalized onset seizures Seizures originating simultaneously in both cerebral hemispheres. (p. 220)

Gingival hyperplasia Overgrowth of gum tissue and often a side effect of phenytoin. (p. 228)

Partial onset seizures Seizures originating in a more localized region of the brain (also called *focal* seizures). (p. 221)

Primary epilepsy Epilepsy in which there is no identifiable cause. Also known as *idiopathic*. (p. 220)

Seizure Excessive stimulation of neurons in the brain leading to a sudden burst of abnormal neuron activity that results in temporary changes in brain function, primarily affecting sensory and motor activity. (p. 220)

Status epilepticus A seizure disorder characterized by generalized tonic-clonic convulsions that occur repeatedly; considered a medical emergency. (p. 221)

Tonic-clonic seizures Seizures involving initial muscular contraction throughout the body (tonic phase), progressing to alternating contraction and relaxation (clonic phase). (p. 220)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

EPILEPSY

Epilepsy is a syndrome of central nervous system (CNS) dysfunction that can cause symptoms ranging from momentary sensory disturbances to convulsive seizures. It is the most common chronic neurologic illness, affecting 3 million people in the United States and 50 million people worldwide. It results from excessive electrical activity of neurons (nerve cells) located in the superficial area of the brain known as the *cerebral cortex* or *gray matter*. The terms *seizure, convulsion,* and *epilepsy* are often used interchangeably, but they do not have the same meaning. A **seizure** is a brief episode of abnormal electrical activity in the nerve cells of the brain, which may or may not lead to a convulsion. A **convulsion** is a more severe seizure characterized by involuntary spasmodic contractions of any or all voluntary muscles throughout the body, including skeletal, facial, and ocular muscles. Commonly reported symptoms include abnormal motor function, loss of consciousness, altered sensory awareness, and psychic changes. In contrast, **epilepsy** is a chronic, recurrent pattern of seizures. Excessive electrical discharges can often be detected by an **electroencephalogram (EEG),** which is obtained to help diagnose epilepsy. Fluctuations in the brain's electrical potential are seen in the form of waves. These waves correlate well with different neurologic conditions and are used as diagnostic indicators. In the case of epilepsy, they are used to identify specific seizure subtypes.

Up to 50% of patients with epilepsy have normal EEGs; therefore a careful history is very important for accurate diagnosis. Other applicable diagnostic tests include skull radiography, *computed tomography,* and *magnetic resonance imaging.* These procedures help to rule out structural causes of epilepsy, such as brain tumors. In particularly severe cases, patients may be observed in a hospital setting or sleep study laboratory. This allows for continuous EEG and video monitoring to identify detailed patterns of seizure activity and to allow tailoring of an effective treatment.

Epilepsy occurs most commonly in children and the elderly. Epilepsy without an identifiable cause is known as **primary epilepsy** or *idiopathic* epilepsy. Primary epilepsy accounts for roughly 50% of cases. Evidence indicates genetic predispositions, but these have yet to be clearly defined. Studies in the field of *pharmacogenomics* (see Chapter 8) are beginning to clarify genetic factors that can help optimize antiepileptic drug therapy. In other cases, epilepsy has a distinct cause, such as trauma, infection, cerebrovascular disorder, or other illness. This is known as *secondary* or *symptomatic* epilepsy. The chief causes of secondary epilepsy in children and infants are developmental defects, metabolic disease, and injury at birth. *Febrile seizures* occur in children 6 months to 5 years of age, and by definition are caused by fever. Children usually outgrow the tendency to have such seizures, and thus these seizures do not constitute a chronic illness. Antipyretic drugs (e.g., acetaminophen [see Chapter 10]) are normally adequate for acute treatment.

In adults, acquired brain disorder is the major cause of secondary epilepsy. Examples include head injury, disease or infection of the brain and spinal cord, stroke, metabolic disorders, adverse drug reactions (e.g., meperidine [see Chapter 10], theophylline [see Chapter 37]), primary or metastatic brain tumor, or other nonspecific neurologic diseases. The elderly have the highest incidence of new-onset epilepsy. Fortunately, seizures in the elderly are often well controlled with drug therapy.

Seizures are classified into different categories based on their presenting features. There are three major categories: *partial onset, generalized onset,* and *unclassified* seizures (Box 14-1). Evidence provided by EEG and other diagnostic techniques indicates that different types of seizures originate from disruptions of normal brain electrical activity in different regions or *lobes* of the brain.

Generalized onset seizures, formerly called *grand mal* seizures, are characterized by neuronal activity that originates simultaneously in the gray matter of both hemispheres. There are several subtypes of generalized seizures. **Tonic-clonic seizures** begin with muscular contraction throughout the body (tonic phase) and progress to alternating contraction and relaxation (clonic phase). *Tonic* seizures involve spasms of the upper trunk with flexion of the arms. *Clonic* seizures are the same as tonic-clonic seizures but without the tonic phase. *Atonic* seizures, also known as *drop attacks,* involve sudden global muscle weakness and syncope. *Myoclonic seizures* are characterized by brief muscular jerks, but not as extreme as in other subtypes. Finally, *absence* seizures involve a brief loss of awareness that commonly occurs

BOX 14-1 CLASSIFICATION OF SEIZURES

Partial Seizures

Description

Short alterations in consciousness, repetitive unusual movements (chewing or swallowing movements), psychologic changes, and confusion

Simple Seizures

- No impaired consciousness
- Motor symptoms (most commonly related to the face, arm, or leg)
- Hallucinations of sight, hearing, or taste along with somatosensory changes (tingling)
- Autonomic nervous system responses
- Personality changes

Complex Seizures

- Impaired consciousness
- Memory impairment
- Behavioral effects
- Purposeless behaviors
- Aura, chewing and swallowing movements, unreal feelings, and bizarre behavior
- Tonic, clonic, or tonic-clonic seizures

Generalized Seizures

Description

Most often seen in children and commonly characterized by temporary lapses in consciousness lasting a few seconds. Staring off into space, daydreaming, and inattentive look are common symptoms. Patients may exhibit rhythmic movements of their eyes, head, or hands but do not experience convulsions. Patients may have several attacks per day.

- Both cerebral hemispheres involved
- Tonic, clonic, myoclonic, atonic, or tonic-clonic seizures and infantile spasms possible
- Brief loss of consciousness for a few seconds with no confusion
- Head drop or falling-down symptoms

Unclassified Seizures

Description

Seizures that are not officially classified due to inadequate data, as well as seizures that do not fit into the above categories. These include neonatal seizures such as those manifested by rhythmic eye movements, chewing, and swimming movements.

with repetitive spasmodic eye blinking for up to 30 seconds. This type occurs primarily in childhood and rarely after 14 years of age.

Partial onset seizures originate in a localized or *focal* region (e.g., one lobe) of the brain. There are three types of partial onset seizures. *Simple partial onset seizure,* formerly called *petit mal* seizure, is characterized by brief loss of awareness (e.g., blank stare) but without loss of consciousness or spasmodic eye blinking as in absence seizures. In *complex partial onset seizure,* the level of consciousness is reduced but is not completely lost. Partial onset seizures can progress to generalized tonic-clonic seizures in up to 40% of patients. This third type is known as a *secondary generalized tonic-clonic seizure.* The latter two types are also associated with *postictal confusion,* a term for the confused mental state that follows seizure activity. *Unclassified seizures* are those that do not clearly fit into any of the other categories.

Seizure episodes can sometimes start off as partial and then become generalized. If the partial component is not noticed, the patient may be misdiagnosed and receive suboptimal drug therapy. Another important seizure condition is **status epilepticus.** In status epilepticus, multiple seizures occur with no recovery between them. If appropriate therapy is not started promptly, hypotension, hypoxia, brain damage, and death can quickly ensue. Thus, status epilepticus is considered a true medical emergency (see Table 14-3 for drugs used to treat status epilepticus). Febrile seizures can also sometimes progress to status epilepticus. In addition to the website of the International League Against Epilepsy, other helpful websites include www.epilepsyfoundation.org and www.epilepsy.com.

PHARMACOLOGY OVERVIEW

ANTIEPILEPTIC DRUGS

Antiepileptic drugs are also called *anticonvulsants.* **Antiepileptic drugs** is a more appropriate term, because many of these medications are indicated for the management of all types of epilepsy, and not necessarily just convulsions. **Anticonvulsants,** on the other hand, are medications that are used to prevent the *convulsive* seizures typically associated with epilepsy.

The goal of antiepileptic drug therapy is to control or prevent seizures while maintaining a reasonable quality of life. Approximately 70% of patients can expect to become seizure free while taking only one drug. The remaining 30% of cases are more complicated, and often require multiple medications. Antiepileptic drugs have many adverse effects, and it is often difficult to achieve seizure control while avoiding adverse effects. In most cases, the therapeutic goal is not to eliminate seizure activity but rather to maximally reduce the incidence of seizures while minimizing drug-induced toxicity. Many patients must take these drugs for their entire lives. Treatment may eventually be stopped in some, but others will experience repeated seizures if constant levels of antiepileptic drugs are not maintained in the blood. Abrupt discontinuation of these drugs can result in withdrawal seizures. In both children and adults, there is only a 40% chance of recurrence after the first partial or generalized seizure. Therefore, antiepileptic drug therapy is *not* recommended after a single isolated seizure event.

There are numerous antiepileptic drugs available. To optimize drug selection, neurologists must consider the known efficacy of a drug for a certain type of seizure, the adverse effects and drug interaction profile, the cost, ease of use, and the availability of pediatric dosage forms. Many antiepileptic drugs are also used to treat other types of illnesses, including psychiatric disorders (see Chapter 16), migraine headaches (see Chapter 13), and neuropathic pain syndromes (see Chapter 10).

It is sometimes difficult to control a patient's seizures using a single drug. Single-drug therapy must fail before multidrug therapy is attempted. Patients are normally started on a single antiepileptic drug, and the dosage is slowly increased until the seizures are controlled or until clinical toxicity occurs. If the

first antiepileptic drug is not effective, the drug is tapered slowly while a second drug is introduced. Antiepileptic drugs are never to be stopped abruptly unless a severe adverse effect occurs.

Therapeutic drug monitoring (see Chapter 2) of serum drug concentrations provides a useful guideline in assessing the effectiveness of and adherence to therapy. For example, if a patient has a very low serum level, it may mean the patient is not taking the medication as prescribed. This gives the nurse an opportunity to ask about why the patient may not be taking the medication. If the level is above normal, the nurse needs to contact the physician before giving the next dose. Maintaining serum drug levels within therapeutic ranges helps not only to control seizures but also to reduce adverse effects. Drugs that are routinely monitored in this way have a low *therapeutic index* (see Chapter 2). There are established normal therapeutic ranges for many antiepileptic drugs, but these are only guidelines (see Table 14-6). The serum concentrations of phenytoin, phenobarbital, carbamazepine, and primidone correlate better with seizure control and toxicity than do those of valproic acid, ethosuximide, and clonazepam. Each patient must be monitored and dosed based on the individual case. In many patients, maintenance is successful at levels below or above the usual therapeutic range. The goal is to slowly titrate to the lowest effective serum drug level that controls the seizure disorder. This reduces the risk for adverse drug effects and drug interactions. Successful control of a seizure disorder hinges on selection of the appropriate drug class and drug dosage, avoidance of drug toxicity, and patient compliance with the treatment regimen.

The antiepileptic drugs traditionally used to manage seizure disorders include barbiturates, hydantoins, and iminostilbenes, plus valproic acid. Second- and third-generation antiepileptics are also available (Table 14-1). The latter drugs may have fewer adverse effects and drug interactions than the more traditional drugs. This may benefit elderly patients, who are more likely to be taking multiple medications and, therefore, are more prone to drug interactions. However, there is currently debate in the neurologic literature as to whether patients actually benefit more from newer than from older drugs. It is now believed that the majority of pediatric and adult epilepsy patients who have been seizure free for 1 to 2 years while taking antiepileptic drugs can eventually stop taking them with medical supervision.

For many years, only the name-brand form of phenytoin, Dilantin, was available. However, generic dosage forms are also available now. Both name-brand and generic phenytoin are commonly prescribed. Phenobarbital and valproic acid are used almost exclusively in the generic forms. The remainder of the newer antiepileptic drugs is still available in brand-name forms only, with the exception of gabapentin and levetiracetam. All generic drug manufacturers are required to provide research data that demonstrate *bioequivalency* of their generic drugs to the corresponding original brand-name drugs. This means that the generic drug product must meet federal standards that include equality of absorption and distribution *(bioavailability)*, as well as equal clinical efficacy compared with the brand-name drug. In spite of the existence of these standards, both the American Academy of Neurology and the American Epilepsy Society are concerned that generic drug products may be less clinically efficacious than brand-name drug products. Of particular concern is the common requirement of health insurance companies that patients receive generic drugs when available. Increased monitoring of patients is necessary when switching from brand-name products to generics.

TABLE 14-1 CURRENTLY AVAILABLE ANTIEPILEPTIC DRUGS

GENERIC NAME	TRADE NAME	ROUTE
Traditional Antiepileptic Drugs		
Barbiturates		
phenobarbital	Generic	PO
	Generic	IV
primidone	Mysoline	PO
Hydantoins		
phenytoin	Dilantin	PO, IV
fosphenytoin	Cerebyx	IV, IM
Iminostilbenes		
carbamazepine	Tegretol, Carbatrol	PO
oxcarbazepine	Trileptal	PO
Miscellaneous Antiepileptic Drugs		
gabapentin	Neurontin	PO
lacosamide	Vimpat	PO, IV
lamotrigine	Lamictal	PO
levetiracetam	Keppra	PO
pregabalin	Lyrica	PO
tiagabine	Gabitril	PO
topiramate	Topamax	PO
valproic acid	Depakene, Depakote	PO
	Depacon	IV
zonisamide	Zonegran	PO

IM, Intramuscular; *IV,* intravenous; *PO,* oral.

Mechanism of Action and Drug Effects

As with many classes of drugs, the exact mechanism of action of the antiepileptic drugs is not known with certainty. However, evidence indicates that they alter the movement of sodium, potassium, calcium, and magnesium ions. The changes in the movement of these ions result in more stabilized and less excitable cell membranes.

The major pharmacologic effects of antiepileptics are threefold. First, they *increase the threshold* of activity in the area of the brain called the *motor cortex.* In other words, they make it more difficult for a nerve to be excited, or they reduce the nerve's response to incoming electrical or chemical stimulation. Second, they act to *limit the spread* of a seizure discharge from its origin. They do this by suppressing the transmission of impulses from one nerve to the next. Third, they can *decrease the speed* of nerve impulse conduction within a given neuron. Less well understood are mechanisms that involve drug effects outside the neuron. For example, some drugs may indirectly affect seizure *foci* (locations) in the brain by altering the blood supply to these areas. Some drugs

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

Antiepileptic Drugs

- If a skin rash develops in a child or infant taking phenytoin, discontinue the drug immediately and notify the prescriber.
- Chewable dosage forms of antiepileptic drugs are not recommended for once-a-day administration. Intramuscular injections of barbiturates or phenytoin must never be used.
- Encourage family members, parents, significant others, or caregivers to keep a journal with a record of the signs and symptoms before, during, and after a seizure and before, during, and after treatment with an antiepileptic drug.
- Encourage the wearing of a medical alert bracelet or necklace at all times with information about the diagnosis, drug therapy, and any drug allergies.
- Shake suspension dosage forms thoroughly before use. A graduated device or oral syringe may be used for more accurate dosing of this liquid.
- Pediatric patients are more sensitive to barbiturates and may respond to lower than expected dosages. They may also experience more profound central nervous system depressive effects related to the antiepileptic drug or show depression, confusion, or excitement (a paradoxical reaction).
- Any excessive sedation, confusion, lethargy, hypotension, bradypnea, tachycardia, and/or decreased movement in pediatric patients taking any antiepileptic drug must be reported to the prescriber immediately.
- Carbamazepine may be given with meals to reduce risk of gastrointestinal distress. All suspension forms are to be shaken and mixed thoroughly before use.
- Oral forms of valproic acid are not to be given with milk, because this may cause the drug to dissolve early and irritate the mucosa. Carbonated beverages must also be avoided.

TABLE 14-2 COMMON SEIZURE INDICATIONS FOR ANTIEPILEPTIC DRUGS

	PARTIAL	SECONDARY GENERAL	GENERALIZED TONIC CLONIC	ABSENCE	MYOCLONIC
First Line	carbamazepine phenobarbital primidone phenytoin fosphenytoin	carbamazepine phenobarbital primidone phenytoin fosphenytoin	carbamazepine phenobarbital primidone phenytoin fosphenytoin valproic acid	valproic acid	valproic acid
Adjunct Drugs	clonazepam clorazepate oxcarbazepine gabapentin pregabalin lamotrigine levetiracetam tiagabine topiramate zonisamide	clonazepam oxcarbazepine gabapentin lamotrigine levetiracetam tiagabine topiramate zonisamide	clonazepam lamotrigine topiramate zonisamide	acetazolamide ethosuximide zonisamide	clonazepam zonisamide

work by enhancing the effects of the inhibitory neurotransmitter gamma-aminobutyric acid (GABA). GABA plays a role in regulating neuron excitability in the brain. Low levels of GABA are associated with seizures. Many antiepileptic drugs increase GABA levels to the normal range, and thus reduce the potential for seizures. Regardless of the mechanism, the overall effect is that antiepileptics stabilize neurons and keep them from becoming hyperexcited and generating excessive nerve impulses to adjacent neurons.

Indications

Antiepileptic drugs are used to prevent or control seizure activity. As evidenced by the wide range of seizure disorders listed in Box 14-1, epilepsy is a very diverse disorder. As a result, specific indications vary among drugs. The most recent indications are noted, drug by drug, in Table 14-2, the Dosages table on p. 227, and specific drug profiles. It is important to have an accurate diagnosis of the seizure type, because some drugs may not be ideal for specific seizures. For example, it is known that carbamazepine may worsen myoclonic or absence seizures. Other evidence supports the following generalizations: Phenobarbital, phenytoin, primidone, carbamazepine, and valproic acid are equally effective for partial onset seizures. Lamotrigine, topiramate, gabapentin, oxcarbazepine, zonisamide, levetiracetam, and tiagabine are all effective as adjunctive therapy for refractory (not responsive to other therapy) partial onset seizures. Specific antiepileptic drugs and the seizure disorders they are used to treat are listed in Table 14-2.

Antiepileptics are used for the long-term maintenance treatment of epilepsy. However, they are also useful for the acute treatment of status epilepticus. In this case, diazepam or lorazepam are considered to be the drugs of choice. Other commonly used drugs in status epilepticus are listed in Table 14-3. Once status epilepticus is controlled, long-term drug therapy is begun with other drugs for the prevention of future seizures. Patients who undergo brain surgery or who have experienced severe head injuries may receive prophylactic antiepileptic therapy. These patients are at high risk for acquiring a seizure disorder, and often severe complications will arise if seizures are not controlled.

TABLE 14-3 ANTIEPILEPTIC DRUGS USED TO TREAT STATUS EPILEPTICUS

DRUG	IV DOSE	ONSET	DURATION	HALF-LIFE	ADVERSE EFFECTS
diazepam	**Pediatric:** 0.15-0.25 mg/kg* **Adult:** 5-30 mg	Immediate	15-60 min	20-50 hr	Apnea, hypotension, somnolence
fosphenytoin	15-20 phenytoin equivalents/kg	15-30 min	12-24 hr	10-60 hr	Comparable to those for phenytoin (see below)
lorazepam†	**Pediatric:** 0.05-0.1 mg/kg **Adult:** 4 mg	1-20 min	Hours	15 hr	Apnea, hypotension, somnolence
phenobarbital	15-20 mg/kg	5 min	6-12 hr	50-120 hr	Apnea, hypotension, somnolence
phenytoin	15-20 mg/kg	1-2 hr	12-24 hr	7-42 hr	Cardiac dysrhythmias, hypotension

IV, Intravenous.
*Rectal products are also available for emergency use for both adults and children of all ages.
†Off-label use (not a Food and Drug Administration–approved indication), but still sometimes used for this purpose.

Contraindications

The only usual contraindication to antiepileptics is known drug allergy. Pregnancy is also a common contraindication; however, the prescriber must consider the risks to mother and infant of untreated maternal epilepsy and the increased risk for seizure activity. Many women take antiepileptics throughout their pregnancy. The newer generation antiepileptic drugs appear to be safer in pregnancy than the traditional drugs.

Adverse Effects

Antiepileptic drugs are plagued by many adverse effects, which often limit their usefulness. Many patients cannot tolerate the adverse effects, and therapy must be withdrawn. Birth defects in infants of epileptic mothers are higher than normal, regardless of whether the mother was receiving drug therapy. Epileptic women need to be monitored closely during pregnancy by both an obstetrician and a neurologist. Each antiepileptic drug is associated with its own diverse set of adverse effects. The various antiepileptic drugs and their most common adverse effects are listed in Table 14-4.

In December 2008, the U.S. Food and Drug Administration (FDA) required black box warnings on all antiepileptic drugs regarding the risk of suicidal thoughts and behavior. Patients being treated with antiepileptic drugs for any indication need to be monitored for the emergence or worsening of depression, suicidal thoughts or behavior, or any unusual changes in mood or behavior. The FDA's action was based on a review of 199 clinical trials of 11 antiepileptic drugs, which showed that patients receiving antiepileptic drugs had almost twice the risk of suicidal behavior compared with those receiving a placebo.

Interactions

Drug interactions that can occur with antiepileptic drugs are numerous and are summarized in Table 14-5. Many of the antiepileptic drugs can interact with each other, requiring close monitoring of the patient. Since many of these drugs induce hepatic metabolism, the effects of other drugs may be reduced, including oral contraceptives. There is a prime opportunity to counsel the patient about need for alternative birth control methods due to reduced efficacy. Carbamazepine is not to be given with grapefruit because this leads to increased toxicity of the antiepileptic drug.

TABLE 14-4 ADVERSE EFFECTS OF SELECTED ANTIEPILEPTIC DRUGS

DRUG OR DRUG CLASS	ADVERSE EFFECTS
First-Line Drugs	
Barbiturates: phenobarbital, primidone	Dizziness, drowsiness, lethargy, paradoxical restlessness
Hydantoins: phenytoin, fosphenytoin	Nystagmus, ataxia, drowsiness, rash, gingival hyperplasia, thrombocytopenia, agranulocytosis, hepatitis
Iminostilbenes: carbamazepine, oxcarbazepine	Nausea, headache, dizziness, unusual eye movements, visual change, behavioral changes, rash, abdominal pain, abnormal gait
valproic acid and derivatives, including valproate sodium and divalproex sodium	Dizziness, drowsiness, GI upset, weight gain, hepatotoxicity, pancreatitis
Adjunct Drugs	
gabapentin	Dizziness, drowsiness, nausea, visual and speech changes, edema
pregabalin	Dizziness, drowsiness, peripheral edema, blurred vision
lamotrigine	Drowsiness, ataxia, headache, nausea, blurred or double vision
levetiracetam	Dizziness, drowsiness, hyperactivity, behavior changes such as anxiety, hostility, agitation, or suicidal ideation, uncoordination
Succinimides: ethosuximide	Nausea, abdominal pain, dizziness, drowsiness
tiagabine	Dizziness, drowsiness, agitation, asthenia, GI upset, abdominal pain, rash, tremor
topiramate	Dizziness, drowsiness, GI upset, ataxia
zonisamide	Drowsiness, anorexia, ataxia, confusion, agitation, cognitive impairment

GI, Gastrointestinal.

Dosages

For certain antiepileptic drugs, the safe and toxic levels are very close together; that is, they have a narrow therapeutic range. Table 14-6 lists the various drugs for which monitoring of therapeutic plasma levels is required and their corresponding therapeutic values. For dosage information see the table on p. 227.

TABLE 14-5 SIGNIFICANT DRUG INTERACTIONS OF ANTIEPILEPTIC DRUGS

AED DRUG OR DRUG CLASS	INTERACTING DRUG	MECHANISM	RESULTS
Barbiturates			
	Beta blockers, corticosteroids (e.g., prednisone), oral contraceptives, dihydropyridine, calcium channel blockers, metronidazole, quinidine, theophylline	Altered CYP450 enzyme metabolism	Reduced effects of listed drugs
	ethanol (alcohol)	Enhanced CNS depression	Can be fatal
Hydantoins			
phenytoin	amiodarone, benzodiazepines, azole antifungals, isoniazid, proton pump inhibitors, sulfonamide antibiotics, SSRIs	Altered CYP450 enzyme metabolism	Reduced hydantoin clearance and increased effects
	carbamazepine	Altered CYP450 enzyme metabolism	Increased hydantoin clearance and reduced effects
	cyclosporine, loop diuretics, meperidine, methadone, rifampin, quinidine, quetiapine, theophylline, zonisamide	Increased metabolism	Reduced effects of listed drugs
	warfarin	Displacement of warfarin from plasma protein binding sites	Increased free warfarin levels and bleeding risk
Iminostilbenes			
carbamazepine	Azole antifungals, diltiazem, isoniazid, macrolides, protease inhibitor antiretrovirals, SSRIs, valproic acid, verapamil	Altered CYP450 enzyme metabolism	Increased carbamazepine levels and toxicity risk
	Barbiturates, hydantoins, rifampin, succinimides, theophylline	Altered CYP450 enzyme metabolism	Reduced carbamazepine levels and efficacy
	acetaminophen	Altered CYP450 enzyme metabolism	Increased hepatic metabolism of acetaminophen and toxicity risk, and reduced efficacy
	Antipsychotics, antidepressants, benzodiazepines, cyclosporine, oral contraceptives	Altered CYP450 enzyme metabolism	Reduced efficacy; patient response must be monitored
	Monoamine oxidase inhibitors (MAOIs)	Altered CYP450 metabolism	Increased MAOI toxicity risk
oxcarbazepine	Barbiturates, hydantoins	Altered CYP450 enzyme metabolism	Increased barbiturate and hydantoin levels and reduced oxcarbazepine levels
	valproic acid, verapamil	Altered CYP450 enzyme metabolism	Reduced oxcarbazepine levels
	lamotrigine	Altered CYP450 enzyme metabolism	Reduced lamotrigine levels
	Oral contraceptives	Altered CYP450 enzyme metabolism	Reduced oral contraceptive levels and increased likelihood of pregnancy
Valproic Acid and Derivatives			
valproic acid valproate sodium and divalproex sodium	aspirin	Displacement of valproic acid from plasma protein binding sites	Increased free valproic acid levels and toxicity risk
	carbamazepine, oxcarbazepine, lamotrigine	Altered CYP450 enzyme metabolism	Reduced valproic acid efficacy; increased lamotrigine levels; increased or decreased carbamazepine levels
	lorazepam	Altered hepatic metabolism	Increased lorazepam toxicity risk
	rifampin	Altered CYP450 enzyme metabolism	Reduced valproic acid efficacy
	Tricyclic antidepressants	Altered CYP450 enzyme metabolism	Increased tricyclic antidepressant toxicity risk
Succinimides			
ethosuximide	Hydantoins, barbiturates, valproic acid	Altered CYP450 enzyme metabolism	Increased or reduced involved drug clearance
Miscellaneous AEDs			
gabapentin	Alcohol	Additive CNS depression	Increased CNS depression
pregabalin	None listed		
lamotrigine	Hydantoins, oral contraceptives, oxcarbazepine, rifampin	Altered CYP450 enzyme metabolism	Reduced lamotrigine levels and efficacy; may need dosage increase
lamotrigine	CNS depressants	Additive effects	Increased CNS depression

TABLE 14-6 THERAPEUTIC PLASMA LEVELS OF ANTIEPILEPTIC DRUGS WITH A NARROW THERAPEUTIC RANGE

ANTIEPILEPTIC DRUG	THERAPEUTIC PLASMA LEVEL (mcg/mL)
carbamazepine	4-12
phenobarbital	10-40
phenytoin	10-20
primidone	5-12
valproic acid	50-100

DRUG PROFILES

In most children and adults, epilepsy can be controlled with a first-line antiepileptic drug such as carbamazepine (Tegretol), phenobarbital, phenytoin (Dilantin), or valproic acid (Depakene). For patients who do not respond to these first-line drugs, there are a number of second-line or *adjunct* antiepileptic drugs that are used occasionally, such as ethosuximide (Zarontin), primidone (Mysoline), the benzodiazepines (see Chapter 16), diazepam (Valium), clonazepam (Klonopin), clorazepate (Tranxene), and the diuretic acetazolamide (Diamox [see Chapter 28]).

After valproic acid was introduced in 1978, no major new drugs for the treatment of epilepsy were introduced in the United States until the 1990s. Gabapentin (Neurontin), lamotrigine (Lamictal), and felbamate (Felbatol) all were approved during this decade. Although felbamate initially appeared to be a promising antiepileptic drug, there were several case reports of aplastic anemia and acute liver failure associated with its use. As a result, the FDA recommends that felbamate be given only to patients with seizures who do not respond to treatment with all other medications. Because of its rare clinical use, this drug is not discussed further in this book.

Antiepileptic drugs most recently approved include levetiracetam (Keppra), topiramate (Topamax), zonisamide (Zonegran), tiagabine (Gabitril), and pregabalin (Lyrica). These drugs fall into the miscellaneous category of antiepileptics and have greatly expanded the options currently available to treat patients with seizure disorders. Common adverse effects and drug interactions are listed in the individual drug profiles and/or in Tables 14-3 and 14-4. For dosage information, see the table on p. 227.

BARBITURATES

♦ phenobarbital and primidone

Historically, two of the most commonly used antiepileptic drugs were the barbiturates phenobarbital and primidone (Mysoline). Primidone is metabolized in the liver to phenobarbital and phenylethylmalonamide, both of which have anticonvulsant properties. Use of primidone can provide anticonvulsant activity with a lower serum level of phenobarbital than that attained with phenobarbital itself. This can reduce the likelihood of sedation and fatigue associated with phenobarbital. Phenobarbital is a Schedule IV controlled substance, whereas primidone is not controlled. Phenobarbital has been used since 1912, principally for controlling tonic-clonic and partial seizures. Phenobarbital is used for the management of status epilepticus and is an effective prophylactic drug for the control of febrile seizures. Although phenobarbital is still used to treat seizure emergencies, the use of oral phenobarbital for seizure prevention is much less common. In third-world countries, oral phenobarbital is often the drug of choice for routine seizure prophylaxis because of its low cost. The most common adverse effect of phenobarbital is sedation, although tolerance to this effect usually develops with continued therapy. Therapeutic effects are generally seen at serum drug levels of 10 to 40 mcg/mL. A major advantage of this drug is its long half-life, which allows once-a-day dosing. This can be a substantial advantage for patients who have a difficult time remembering to take their medication or for those who have erratic schedules. Even if a patient takes his or her dose 12 or even 24 hours late, therapeutic blood levels may still be maintained. Contraindications include known drug allergy, porphyria (a disorder of the synthesis of *heme,* a component of hemoglobin), liver or kidney impairment, and respiratory illness. Adverse effects include cardiovascular, CNS, gastrointestinal (GI), and dermatologic reactions (see Table 14-4). Phenobarbital interacts with many drugs because it is a major inducer of hepatic microsomal enzymes, including the cytochrome P-450 system enzymes (see Chapter 2), which causes more rapid clearance of some drugs (see Table 14-5). Phenobarbital is available in oral and injectable forms, whereas primidone is available only for oral use.

DOSAGES

*Selected Antiepileptic Drugs**

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	SEIZURE INDICATIONS
♦ carbamazepine (Tegretol, Tegretol XR) (D)	Iminostilbene	**Pediatric** PO: younger than 6 yr, 10-20 mg/kg/day PO: 6-12 yr, 200-1000 mg/day **Adult and pediatric older than 12 yr** PO: 400-1200 mg/day	Partial, secondary generalized, generalized tonic-clonic seizures
ethosuximide (Zarontin) (C)	Succinimide	**Pediatric** PO: 3-6 yr, 250 mg/day then adjust; older than 6 yr, 500 mg/day then adjust **Adult** PO: 500 mg/day then adjust	Absence seizures
♦ fosphenytoin (Cerebyx) (D)	Hydantoin	**Pediatric** IV: 10-20 PE† /kg loading dose; may begin maintenance dosing 8-12 hr later using pediatric phenytoin dosing guidelines (see below) **Adult** IV: 10-20 PE† /kg loading dose; maintenance dose 4-6 mg/kg/day	Partial, secondary generalized, generalized tonic-clonic seizures
♦ gabapentin (Neurontin) (C)	Miscellaneous	**Pediatric** PO: 10-15 mg/kg/day divided tid, then adjust **Adult** PO: Older than 18 yr, 900-1800 mg/day	Partial, secondary generalized seizures
lamotrigine (Lamictal) (C)	Miscellaneous	**Pediatric** PO: 2-12 yr, 5-15 mg/kg/day depending on other AEDs used **Adult** PO: 50-200 mg once daily or divided bid	Partial, secondary generalized, generalized tonic-clonic seizures; seizures associated with Lennox-Gastaut syndrome
levetiracetam (Keppra) (C)	Miscellaneous	**Pediatric** 20 mg/kg/day in two divided doses **Adult** PO: 500 mg bid to 3000 mg/day	Partial, secondary generalized seizures
oxcarbazepine (Trileptal) (C)	Iminostilbene	**Pediatric** PO: 8-10 mg/kg/day divided bid; max 600 mg/day **Adult** 300-600 mg bid	Partial, secondary generalized seizures
♦ phenobarbital (oral, injectable) (D)	Barbiturate	**Pediatric** PO: 3-6 mg/kg/day **Adult** PO: 1-3 mg/kg/day	Partial, secondary generalized, generalized tonic-clonic seizures, prophylaxis for febrile seizures, psychomotor seizures Partial, secondary generalized, generalized tonic-clonic seizures
♦ phenytoin (Dilantin) (D)	Hydantoin	**Pediatric** PO: 5-10 mg/kg/day, depending on age **Adult** PO: 300-600 mg/day	Partial, secondary generalized, generalized tonic-clonic seizures Generalized tonic-clonic seizures
pregabalin (Lyrica) (C)	Miscellaneous	**Adult** PO: 150-600 mg/day divided into 2 or 3 doses	Partial seizures
♦ primidone (Mysoline) (D)	Barbiturate	**Pediatric** PO: younger than 8 yr, 125-250 mg/tid; doses vary based on age **Adult and pediatric older than 8 yr** 250 mg orally 4-6 times/day; max 2 g/day	Partial, secondary generalized, generalized tonic-clonic seizures Partial, secondary generalized, generalized tonic-clonic seizures
tiagabine (Gabitril) (C)	Miscellaneous	**Pediatric** PO: 12-18 yr, 4-32 mg divided bid-qid **Adult** 4 mg daily to 56 mg divided bid-qid	Partial, secondary generalized seizures

DOSAGES—cont'd

Selected Antiepileptic Drugs*

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	SEIZURE INDICATIONS
topiramate (Topamax) (C)	Miscellaneous	**Pediatric** PO: Doses vary by type of seizure **Adult** PO: 25-1600 mg/day	Partial, secondary generalized, generalized tonic-clonic seizures
♦ valproic acid (Depacon, IV Depakote, Depakene oral) (D)	Miscellaneous	**Adult and pediatric** PO: 15-60 mg/kg/day divided bid-tid IV: 10-15 mg/kg/day as a 60-min infusion	Generalized tonic-clonic, absence, myoclonic seizures
zonisamide (Zonegran) (C)	Miscellaneous	**Pediatric** Older than 16 yr, 100-400 mg/day **Adult** 100-400 mg/day	Partial, secondary generalized, generalized tonic-clonic, absence, myoclonic seizures

AED, Antiepileptic drug; *IM,* intramuscular; *IV,* intravenous; *PE,* phenytoin equivalent; *PO,* oral.
†One PE = 1.5 mg fosphenytoin = 1 mg phenytoin. Therefore, 1.5 mg fosphenytoin is given for each milligram of phenytoin desired.
*See Table 14-3 for doses of drugs used for status epilepticus.

Pharmacokinetics (phenobarbital)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	20-60 min	8-12 hr	50-120 hr	6-12 hr
IV	5 min	30 min	50-120 hr	6-12 hr

Pharmacokinetics (primidone)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	3-4 hr	10-12 hr*	Unknown

*Longer for active metabolites, including phenobarbital.

HYDANTOINS

♦ phenytoin and fosphenytoin

Phenytoin (Dilantin) has been used as a first-line drug for many years and is the prototypical drug. It is indicated for the management of tonic-clonic and partial seizures. Contraindications include known drug allergy and heart conditions that involve bradycardia or blockage of electrocardiac function. Adverse effects and drug interactions both are numerous and are listed in Table 14-4 and 14-5, respectively. The most common adverse effects are lethargy, abnormal movements, mental confusion, and cognitive changes. **Gingival hyperplasia** is a well-known adverse effect of long-term oral phenytoin therapy. Scrupulous dental care can help prevent gingival hypertrophy. Long-term phenytoin therapy can cause gingival hyperplasia, acne, hirsutism, and hypertrophy of subcutaneous facial tissue resulting in an appearance known as *Dilantin facies.* Another long-term consequence of phenytoin therapy is osteoporosis. Vitamin D therapy may help to prevent this, particularly in women. Therapeutic drug levels are usually 10 to 20 mcg/mL. At toxic levels, phenytoin can cause nystagmus, ataxia, dysarthria, and encephalopathy. Phenytoin can interact with other medications for two main reasons. First, it is highly bound to plasma proteins and competes with other highly protein-bound medications for binding sites. Second, it induces hepatic microsomal enzymes, mainly cytochrome P-450 enzymes (see Chapter 2). This increases the metabolism of other drugs that are metabolized by these enzymes and reduces their blood levels.

Exaggerated phenytoin effects can be seen in patients with very low serum albumin concentrations. This most commonly occurs in patients who are malnourished or have chronic renal failure. In these patients, it may be necessary to maintain phenytoin levels well below 20 mcg/mL. With lower levels of albumin, more of the free, unbound, pharmacologically active phenytoin molecules will be present in the blood.

Phenytoin has many advantages for long-term therapy. It is usually well tolerated, highly effective, and relatively inexpensive. It can also be given intravenously if needed. Most often, however, phenytoin is taken orally. The long half-life of the drug allows for twice- or even once-daily dosing. This encourages patient adherence to drug therapy, which helps reduce seizure frequency.

Parenteral phenytoin is adjusted chemically to a pH of 12 for reasons of drug stability. It is very irritating to veins when injected and must be given by slow intravenous (IV) push (not exceeding 50 mg/min in adults) directly into a large vein through a large-gauge (20-gauge or larger) venous catheter. Phenytoin is only to be diluted in normal saline (NS) for IV infusion, and a filter must be used. Follow each dose by an injection of a saline flush to avoid local venous irritation. Soft-tissue irritation and inflammation can occur at the site of injection with or without extravasation. This can vary from slight tenderness to extensive necrosis and sloughing, and in rare instances can require amputation. Avoid improper administration, including subcutaneous or perivascular injection, to help prevent the possibility of such occurrences.

Fosphenytoin (Cerebyx) is an injectable prodrug of phenytoin that was developed in an attempt to overcome some of the chemical disadvantages of phenytoin injection. Fosphenytoin is a water-soluble phenytoin derivative that can be given intramuscularly or intravenously—by IV push or continuous

TABLE 14-7 COMPARISON OF PHENYTOIN SODIUM AND FOSPHENYTOIN SODIUM

	PHENYTOIN SODIUM (DILANTIN IV)	FOSPHENYTOIN SODIUM (CEREBYX IM/IV)
pH	12	8.6-9
Maximum infusion rate	50 mg/min	150 mg PE*/min
Admixtures	0.9% saline	0.9% saline or 5% dextrose

IM, Intramuscular; *IV,* intravenous; *PE,* phenytoin sodium equivalents.
*150 mg fosphenytoin sodium = 100 mg phenytoin sodium.

infusion—without causing burning on injection associated with phenytoin. Fosphenytoin is dosed in *phenytoin equivalents (PE)* as indicated in Table 14-7. Fosphenytoin is given at a rate of 150 mg PE/min or less to avoid hypotension or cardiorespiratory depression. If dysrhythmias or hypotension occur, discontinue the infusion. Implement fall prevention measures after infusion of either phenytoin or fosphenytoin because of possible ataxia and dizziness. Take vital signs up to 2 hours after infusion. Check available references and/or consult with a pharmacist before administering because there are numerous IV incompatibilities with both drugs.

Pharmacokinetics (phenytoin)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action

IV	1-2 hr	2-3 hr	7-42 hr	12-24 hr

IMINOSTILBENES

♦ carbamazepine

Carbamazepine (Tegretol) is the second most commonly prescribed antiepileptic drug in the United States, after phenytoin. It was marketed in the late 1960s for the treatment of epilepsy after its efficacy and safety were proven for the treatment of *trigeminal neuralgia* (a painful facial nerve condition). It is chemically related to the *tricyclic* antidepressants (see Chapter 16) and is considered a first-line treatment for partial seizures and generalized tonic-clonic seizures. It may actually worsen myoclonic or absence seizures. Therefore its use is contraindicated in both of these conditions as well as in cases of known drug allergy and bone marrow depression. Carbamazepine is associated with **autoinduction** of hepatic enzymes. Autoinduction is a process in which, over time, a drug stimulates the production of enzymes that enhance its own metabolism, which leads to lower than expected drug concentrations. With carbamazepine, this process usually occurs within the first 2 months after starting the drug. Carbamazepine has numerous adverse reactions and drug interactions; examples are given in Tables 14-4 and 14-5. It is available for oral use only.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Slow	4-8 hr	25-65 hr	12-24 hr

oxcarbazepine

Oxcarbazepine (Trileptal) is a chemical analogue of carbamazepine. Its precise mechanism of action has not been identified, although it is known to block voltage-sensitive sodium channels, which aids in stabilizing excited neuronal membranes. It is indicated for partial seizures and secondarily generalized seizures. Contraindications include known drug allergy. Common adverse reactions include headache, dizziness, and nausea (see also Table 14-4). Unlike carbamazepine, this drug is not a hepatic enzyme inducer. As a result, it is associated with far fewer common drug interactions than is carbamazepine (see Table 14-5). Oxcarbazepine is available for oral use only.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2-4 hr	2-3 days	2-9 hr	Unknown

SUCCINIMIDE

ethosuximide

Ethosuximide (Zarontin) is used in the treatment of uncomplicated absence seizures. It is not effective for secondary generalized tonic-clonic seizures. The only listed contraindication for either use is known allergy to succinimides. Adverse effects include GI and CNS effects (see Table 14-4). Drug interactions most commonly involve hepatic enzyme–inducing drugs (see Table 14-5). Succinimides are available for oral use only.

MISCELLANEOUS DRUGS

♦ gabapentin

Gabapentin (Neurontin) is a chemical analogue of *GABA,* a neurotransmitter that inhibits brain activity. The exact mechanism of action of gabapentin is unknown. Many believe that it works by increasing the synthesis and synaptic accumulation of GABA between neurons, hence, the drug name. It is indicated as an adjunct drug for the treatment of partial seizures and for prophylaxis of partial seizures. Evidence also shows gabapentin to be effective as single-drug therapy for new-onset epilepsy. It is most commonly used to treat neuropathic pain (see Chapter 10). Contraindications include known drug allergy. Adverse effects include CNS and GI symptoms (see Table 14-4). Drug interactions are listed in Table 14-5. Gabapentin is available for oral use only.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	Unknown	5-7 hr	Unknown

pregabalin

Pregabalin (Lyrica), like gabapentin, is structurally related to the inhibitory neurotransmitter GABA. However, it does not bind to GABA receptors but rather to the alpha$_2$-delta receptor sites, which affect calcium channels in CNS tissues. Its mechanism of action is still not fully understood. Pregabalin is a Schedule V controlled substance. The drug is indicated as adjunct therapy for partial seizures, although it is most commonly used for *neuropathic pain* (see Chapter 10), and *postherpetic neuralgia* (see Chapter 40). Contraindications include known drug allergy. Adverse drug reactions are primarily CNS related (see Table 14-4). No clinically significant drug interactions are listed to date; however, as with all antiepileptic drugs, the potential for additive CNS depression exists when other sedating drugs are used. Pregabalin is available for oral use only.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	1.5 hr	6 hr	Unknown

lamotrigine

Lamotrigine (Lamictal) is indicated for simple or complex partial seizures, for generalized seizures related to *Lennox-Gastaut syndrome* (an atypical form of absence epilepsy that may persist into adulthood), and, most recently, for primary generalized tonic-clonic seizures. It is also used for the treatment of bipolar disorder. It has no known contraindications other than drug allergy. Common adverse effects include relatively minor CNS and GI symptoms (see Table 14-4). One potentially serious adverse effect is a rash that can progress to the major dermatologic reaction known as *Stevens-Johnson syndrome.* This condition involves inflammation and sloughing of skin, potentially over the entire body, in a manner that resembles a third-degree burn. It is often reversible but can also be fatal. To avoid this condition, patients' doses are very slowly titrated over several weeks. Drug interactions chiefly involve other antiepileptic drugs as well as other CNS depressants and oral contraceptives (see Table 14-5). Lamotrigine is available for oral use only.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	1.4-2.3 hr	24 hr	Unknown

levetiracetam

Levetiracetam (Keppra) is indicated as adjunct therapy for partial seizures with and without secondary generalization. It is contraindicated in cases of known drug allergy. Its mechanism of action is unknown. It is generally well tolerated, with the most common adverse effects being CNS related (see Table 14-4). No drug interactions are currently listed; however, like all antiepileptic drugs, the potential for excessive CNS depression exists when it is used in combination with other sedating drugs. Levetiracetam is available in both oral and injectable forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Rapid	1 hr	6-8 hr	Unknown

tiagabine

Tiagabine (Gabitril) is indicated as adjunct therapy for partial seizures. Contraindications include known drug allergy. Its exact mechanism of action has not been identified, but is known to have beneficial effects by inhibiting the reuptake of GABA from the neuronal synapses (spaces between neurons) in the brain. In February 2005, the FDA issued a special warning regarding the use of tiagabine for "off-label" (non–FDA-approved) indications. Although tiagabine is effective in controlling epileptic seizures, there have been several case reports of *paradoxical* seizures (opposite of what would intuitively be expected) in nonepileptic patients who are treated with the drug for other indications. Most of these cases involved patients being treated for psychiatric disorders such as bipolar disorder. Of even greater concern is that in some of these cases the seizure episodes progressed to status epilepticus. For these reasons, prescribers are currently advised to avoid off-label use of tiagabine. Common adverse effects are CNS and GI symptoms (see Table 14-4). Drug interactions chiefly involve other CNS depressant drugs (see Table 14-5). Tiagabine is available for oral use only.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Rapid	45 min	7-9 hr	Unknown

topiramate

Topiramate (Topamax) is a structurally unique drug chemically related to fructose. It is indicated as adjunct therapy for partial and secondarily generalized seizures, for generalized tonic-clonic seizures, and for drop attacks in Lennox-Gastaut syndrome. Contraindications include known drug allergy. Its exact mechanism of action is unknown. Common adverse effects are primarily CNS related (see Table 14-4). Angle-closure glaucoma can also occur, and the patient must immediately report any visual changes. Common drug interactions involve chiefly other antiepileptic drugs and oral contraceptives (see Table 14-5). Topiramate is available for oral use only. In 2011, the FDA notified health care professionals about an increased

risk of cleft palate in children born to mothers who were taking topiramate during pregnancy.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	2-4 hr	21 hr	Unknown

♦ valproic acid

Valproic acid is used primarily in the treatment of generalized seizures (absence, myoclonic, and tonic-clonic). It is also used for bipolar disorder (see Chapter 16) and has been shown to be effective in controlling partial seizures. Contraindications include known drug allergy, liver impairment, and *urea cycle* disorders (genetic disorders of urea metabolism). Common adverse effects include drowsiness; nausea, vomiting, and other GI disturbances; tremor; weight gain; and transient hair loss (see Table 14-4). The most serious adverse effects are hepatotoxicity and pancreatitis. Valproic acid can interact with many medications (see Table 14-5). The main reasons for these interactions are protein binding and liver metabolism. It is highly bound to plasma proteins and competes with other highly protein-bound medications for binding sites. It also is metabolized by hepatic microsomal enzymes and competes for metabolism with other drugs. In contrast to phenobarbital and phenytoin, it is not a hepatic enzyme inducer. It is available in both oral and injectable forms. Valproic acid itself is chemically the simplest dosage form and is available as an oral liquid. Long-acting oral dosage forms are also available as divalproex sodium (Depakote), which comes in delayed- and extended-release tablets as well as capsules with long-acting granules (Depakote Sprinkles) that can be opened and sprinkled into food. The injectable form is the salt valproate sodium (Depacon).

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO, IV	15-30 min	1-4 hr	6-16 hr	4-6 hr

zonisamide

Zonisamide (Zonegran) is a sulfonamide derivative (see Chapter 38) indicated for a variety of seizure types, including partial and secondary generalized, primary generalized, absence, and myoclonic. It is contraindicated in patients with known drug allergy to the drug itself or to sulfa drugs (see Chapter 38). Common adverse effects include CNS and GI symptoms (see Table 14-4). Zonisamide interacts with a number of drugs metabolized by cytochrome P-450 enzymes, which increase or decrease clearance of zonisamide (see Table 14-5). Zonisamide is available for oral use only.

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Sound-Alike/Look-Alike Drugs: Cerebryx and Celebrex

Be careful with drug names! When using their trade names, Cerebryx and Celebrex sound and look very much alike. However, they are quite different. Cerebryx is a trade name for fosphenytoin, a hydantoin class antiepelieptic drug. It is used to treat a variety of seizure disorders. Celebrex is the trade name for celecoxib, a COX-2 inhibitor antiinflammatory drug used for pain and various disorders such as osteoarthritis and rheumatoid arthritis (see Chapter 44). Although the trade names are very similar, the indications are very different! These two drugs illustrate the importance of using both the trade name and generic name when ordering medications.

NURSING PROCESS

ASSESSMENT

With use of any of the *antiepileptic drugs,* perform a thorough physical assessment and obtain a comprehensive health and medication history, so that any possible allergies, drug interactions, adverse reactions, cautions, and contraindications can be identified. Thoroughly review the patient's medical history, and note any type of seizure disorder, precipitating events, and the duration, frequency, and intensity of the seizure activity. Other information to assess for includes the occurrence of any other problems or signs and symptoms occurring before, during, or after the seizure. Question the patient about the occurrence of panic attacks because of the possible association between high levels of anxiety or stress and the precipitation of seizures in those at risk. Assess the patient for signs and symptoms of autonomic nervous system responses associated with anxiety or stress such as cold, clammy hands, excessive sweating (diaphoresis), agitation, and trembling of the extremities. Additional assessment about other problems or symptoms is important because some antiepileptic medications may be indicated for other medical diagnoses, such as prevention of migraines or treatment of postherpetic neuralgia and neuropathic pain. A complete neurologic assessment with documentation of baseline CNS functioning is also important before administering antiepileptic drugs. This may include testing and grading the response of deep tendon reflexes, bilateral and upper and lower extremity sensory and motor testing, and questioning about the presence of any headaches, photosensitivity, occurrence of auras, or visual changes.

Before giving these drugs, review the laboratory test results, which may include the results of red blood cell and white blood cell counts, clotting studies, and renal and/or liver function studies. Knowing baseline levels of these laboratory values is important to help identify any initial abnormalities as well as to provide a comparison value when assessing for possible adverse effects, cautions, contraindications, and interactions. Assess urinary output (at least 30 mL/hr) and urine specific gravity. Conditions other than epilepsy or seizure disorders may also cause loss of or alterations in consciousness and are worthy of consideration during assessment. These conditions include

syncope, breath-holding practices, transient ischemic attacks, drug use, metabolic disorders, infections, head trauma, tumors, and psychogenic problems. Therefore, an attempt will most likely be made to rule out or eliminate many of these disorders or conditions during the diagnosing of epilepsy, and therein lies the importance of analyzing all available points of data. An EEG may also be ordered to provide more information related to the diagnosis of epilepsy. Another diagnostic procedure, magnetic resonance imaging, may be performed for neuroimaging and further data gathering.

The use of a *succinimide,* such as ethosuximide, requires assessment for the specific indication for this medication, that is, generalized absence seizures. In addition to performing a baseline neurologic assessment, other questions to pose to the patient include inquiring about any problems with nausea, abdominal pain, or dizziness. Always assess for any allergies to this drug.

Miscellaneous drugs such as tiagabine, topiramate, and zonisamide are some of the more recently available antiepileptic drugs and have significant contraindications, cautions, and drug interactions, which have been discussed previously in the Pharmacology Overview in this chapter and are summarized in Tables 14-4 and 14-5. Assess vital signs and mental status with attention to the patient's sensorium, level of alertness or consciousness, and any mental depression before, during, and after drug therapy and/or seizure activity. Document any of the following baseline problems if administering tiagabine or topiramate: dizziness, drowsiness, GI upset, ataxia, and/or agitation.

If *barbiturates* have been ordered, carefully assess not only the neurologic system but also vital signs because of the CNS depression associated with this class of drugs. Obtain and document all of the aforementioned general assessment data when barbiturates are prescribed. In addition, identify patients at high risk for excessive sedation for safety purposes. If the patient is in an acute care facility, assess the room and environment to ensure that safety measures are in place (e.g., side rails up or a bed alarm system in use depending on facility policy), noise level is controlled, and seizure precautions are available (oxygen, suctioning equipment, and airway devices nearby; padded side rails being used; and IV access obtained per facility policy). Note the patient's age, because the very young and the elderly react with more sensitivity to these drugs with paradoxical reactions, irritability, and hyperactivity (as compared to CNS depressant effects). Cautions, contraindications, and drug interactions have been previously discussed in the Pharmacology Overview.

With *hydantoins* like phenytoin, the previously mentioned assessment data are also appropriate. Perform a skin assessment and document intactness and the presence or absence of any rashes, because of the possibility of a measles-like rash. In addition, baseline dental hygiene habits and an oral assessment, such as the status of the patient's gums and teeth, are important because of the adverse effects of gingival hyperplasia. Assessment of baseline neurologic functioning is crucial with the use of these CNS-altering medications and needs to include the following: (1) a focus on vision with attention to any abnormalities, especially those related to eye movement; (2) baseline neuromuscular stability with attention to coordinated movements, gait, and reflexes; and (3) assessment of speech for clarity and ability to form and express words appropriately. In addition, when the phenytoins are taken, baseline liver function studies and complete blood counts are needed. Attention must also be given to specific drug-related cautions, contraindications, and drug interactions.

Before administering carbamazepine, an *iminostilbene,* a complete blood count is often ordered. Document these laboratory findings for baseline comparisons because of the possible adverse effect of drug-related anemias (e.g., aplastic anemia). Measure baseline vision and any abnormalities because of the potential visual changes. Significant contraindications include conditions involving bone marrow suppression because it is an adverse effect (though rare).

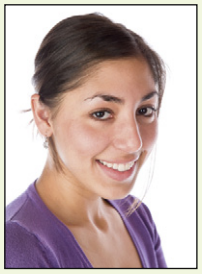
Gabapentin requires a thorough neurologic assessment with attention to baseline energy levels, visual intactness, sensory and motor functioning, and any changes in speech. It is also important to understand the rationale for gabapentin's use so that appropriate education and instructions can be shared with the patient and family. For example, gabapentin may be used for seizure therapy, but it is also used to treat postherpetic neuralgia and neuropathic pain and to prevent migraines. Thus, an individualized plan of care with proper education needs to be developed from the appropriate assessment data. Pregabalin is similar to gabapentin and requires the same assessment.

Valproic acid requires a careful assessment, as well. Gather and document information about the patient's medical history, medication profile, and neurologic system with information about seizure activity (see previous discussion). Assessment for drug allergies, cautions, contraindications, and drug interactions has been previously discussed. Other assessment areas include baseline weight, liver function studies, and notation of a history of pancreatitis.

Lamotrigine use requires a thorough neurologic assessment and documentation of baseline energy levels, vision acuity, and history of headaches for comparative purposes due to common adverse effects of headaches, vision changes, and drowsiness. Several newer *miscellaneous antiepileptic drugs* are available, such as levetiracetam, topiramate, zonisamide, tiagabine, and pregabalin. These miscellaneous drugs require the same thorough, general assessment as with other antiepileptic drugs. A few additional points must be kept in mind. For example, in patients taking levetiracetam, you must document the presence of any neuropsychiatric symptoms because of the potential for drug-related agitation, depression, anxiety, and other mood or behavioral changes. Although these adverse effects are rare, the assessment data must still be thorough. One interesting fact, as noted in the pharmacology section, is the lack of drug interactions with levetiracetam; however, because all antiepileptic drugs depress the CNS in some manner, assessment for the use of other CNS depressant drugs is important to note. In addition, assess liver and renal functioning before therapy is initiated. Topiramate is used not only for management of seizures but also for other indications such as cluster headaches and neuropathic pain. Therefore, include a thorough review of the medical and medication history in the assessment to understand the reason for the drug's use. Document energy levels as well.

CASE STUDY

Medications for Seizures



Devin, a 21-year-old patient, has been brought to the emergency department in status epilepticus. Measures are taken to ensure her safety and prevent injury, and an intravenous (IV) line is started. The emergency department physician has ordered diazepam (Valium) 8 mg IV push, STAT.

1. The diazepam is supplied in a vial of 5 mg/mL. How much medication will the nurse draw up into the syringe?

The IV diazepam is given at a rate of 2 mg/min. Soon after the IV diazepam is given, Devin's seizures stop, and she regains consciousness. She is admitted to a medical-surgical unit, and her mother goes to the room with her. The admitting orders call for an initial IV dose of phenytoin, followed by oral doses twice a day.

2. Why was the loading dose given intravenously?

After 2 days of observation, Devin is ready for discharge to her mother's home. Her phenytoin level is 16 mcg/mL. She is very concerned about how the phenytoin will affect her.

3. Evaluate the phenytoin level of 16 mcg/mL.
4. What teaching should the patient receive regarding self-care and the adverse effects of phenytoin?
5. After 4 months, the patient's mother calls to report that Devin has seemed "very sad lately" and has not wanted to join her friends for evenings out. "Devin just goes to work, then comes home and stays in her room." What is the priority in this situation?

For answers, see http:/evolve.elsevier.com/Lilley.

NURSING DIAGNOSES

1. Deficient knowledge related to lack of familiarity and minimal experience with and lack of information concerning the use of antiepileptic drugs
2. Noncompliance with the therapeutic regimen related to the patient's misuse of drugs or lack of understanding about the seizure disorder and its treatment
3. Chronic low self-esteem related to diagnosis of a lifelong disease and the adverse effects associated with antiepileptic drugs
4. Risk for injury related to decreased sensorium and CNS depression associated with the actions and adverse effects of antiepileptic drugs

PLANNING

GOALS

1. Patient demonstrates adequate knowledge about diagnosis and associated drug therapy.
2. Patient remains compliant with the therapy regimen, avoids adverse effects as much as possible, and experiences minimal problems with either overtreatment or undertreatment.
3. Patient maintains positive self-esteem and body image.
4. Patient remains free from injury during drug therapy.

OUTCOME CRITERIA

1. Patient states the therapeutic drug effects (e.g., minimal to no seizure activity) as well as adverse effects of antiepileptic drugs and measures to decrease drug-related sedation, confusion, ataxia, and drowsiness.
2. Patient and/or family states the importance of taking the medication exactly as prescribed, such as at the same time every day, to help maximize therapeutic effectiveness and minimize adverse effects.
   - Patient states the dangers associated with sudden withdrawal of the medication, such as rebound seizure activity.
3. Patient communicates openly and frequently about diagnosis-related and drug-related changes in self-esteem as well as increase in feelings of anxiety, stress, and/or altered body image.
4. Patient experiences a safe and protective environment while at home/work while implementing safety measures to minimize injury to self such as changing positions slowly and purposely, keeping throw rugs off the floor.
   - Patient reports symptoms of excessive sedation, confusion, lethargy, and dizziness to prescriber.

IMPLEMENTATION

For patients taking *antiepileptic* drugs, interventions are aimed at monitoring the patient while providing safety measures (see previous discussion) and securing the airway, breathing, and circulation. Airway maintenance is of critical importance for epileptic patients because the tongue relaxes during seizure activity, falling backward and subsequently blocking the airway. Maintain the patient's airway in the same way as during cardiopulmonary resuscitation, using the chin lift or jaw thrust method. Provide rescue breathing, if the patient is not breathing on his or her own, at a rate of 1 breath every 5 seconds. If the patient is breathing, keep the airway open through proper positioning (as just described). In addition to performing these critical components of care, maintain seizure precautions according to hospital policy. This may include making sure the patient is gently kept in bed or kept from falling, putting the side rails up, placing the patient in a side-lying position if needed. Avoid use of a tongue blade or other instrument to pry open the patient's mouth or clenched teeth, and ensure quick access to oxygen and suctioning equipment at all times.

With antiepileptic drug administration, adhere closely to the drug dose and frequency of dosing, as ordered. Close monitoring of dosing is important to attain therapeutic blood levels. For example, if an antiepileptic drug is ordered to be administered every 6 hours, it is crucial to dose the drug so that it is given around the clock to maintain blood levels. Administering the antiepileptic drug at the same time every day is also important to maintain blood levels. Educate patients on the importance of adhering to the medication regimen due to the impact one dose may have on maintaining steady states and therapeutic blood levels (see Chapter 2). If one or more doses of the antiepileptic drug is missed, the prescriber needs to be contacted immediately due to the increased risk of seizure activity. See Patient Teaching Tips for more information.

With oral dosing, it is recommended that these drugs be taken with at least 6 to 8 oz of fluid, preferably water, and with food, meals, or a snack to help decrease the risk of GI upset, a frequently encountered adverse effect. Juices, milk, and carbonated beverages are best avoided as the fluids of choice because of possible interactions with the drug. Oral suspensions are to be shaken and the solution mixed thoroughly. Capsules are *not* to be crushed, opened, or chewed—especially if extended- or long-release forms. Chewing or altering these long-release type formulations would allow for the entire dosage to be released at once versus over a period of time. Extended-release dosage forms are usually ordered once a day, and so checking and double-checking the dosage and frequency is critical to patient safety. These actions will help to prevent the patient from experiencing either too high or too low drug serum levels.

If there are any questions regarding the type of capsule, pill, or tablet or questions about other dosage forms and recommended administration guidelines, use appropriate authoritative sources. These sources would include a licensed pharmacist, manufacturer-package insert, and/or a current (within last 3 years) nursing drug handbook or pharmacology book. If there are any questions about the medication order or the medication prescribed, contact the prescriber immediately for clarification. *Topiramate* and *valproic acid* tablets and delayed- or extended-release dosage forms are not to be altered in any way and must be given as prescribed.

The following interventions are specific to drugs and/or drug classes:

- *Carbamazepine:* This drug is *not* to be given with grapefruit/grapefruit juice because this leads to increased toxicity of the antiepileptic drug. If the drug is to be replaced with another antiepileptic drug, a plan needs to be in place to decrease the dosages of the older drug before beginning low doses (at first) of the newer drug. Serum therapeutic levels are given in Table 14-6.
- *Hydantoins:* As a point of reference, 150 mg of fosphenytoin is the equivalent of 100 mg of phenytoin, and the dose, concentration solution, and infusion rate of fosphenytoin is expressed as a phenytoin equivalent (PE). With parenteral forms, the only dilutional fluid to use with these drugs is normal saline (NS). A filter must also be used. Rates of infusion must follow manufacturer's guidelines and are usually 150 mg PE/min or less to avoid hypotension and cardiorespiratory depression. If dysrhythmias or hypotension occur, discontinue the infusion immediately, monitor patient vital signs, and contact the prescriber immediately. Implement safety measures, such as assisting the patient with ambulation and having the patient move slowly and purposefully, when this drug (or any other antiepileptic drug) is given because of the adverse effects of ataxia and dizziness. IV dose administration requires even more cautious use because of the rapid onset of action. CNS depression is always a concern; thus, there is a need to frequently monitor the patient's vital signs. If existing IV lines contain D_5W or other solutions, the line must be flushed with normal saline before and after dosing to avoid precipitate formation. If infiltration of the IV site leads to subcutaneous tissue access, ischemia and sloughing may occur because of the high alkalinity of the drug. Review hospital or facility policy as well as manufacturer's guidelines regarding the use of possible antidotes. If infiltration occurs, discontinue infusion of the solution immediately, but leave the IV catheter/needle in place until all orders from the prescriber have been received. This practice allows any antidote medication to be administered through the IV catheter, if ordered. Sustained- or extended-release oral dosage forms are never to be opened, punctured, chewed, or broken in pieces. Other regular forms of the drug may be crushed, as needed. Gingival hyperplasia is an adverse effect and requires that the patient receive daily oral care as well as frequent dental visits. Complete blood counts are often monitored very closely within the first year of therapy (e.g., measured monthly for 1 year, then every 3 months).
- *Barbiturates* (e.g., phenobarbital): Abrupt withdrawal of these drugs, as well as of any antiepileptic drugs, must be avoided due to possible rebound seizure activity. Most of the oral dosage forms of this class of drugs are to be taken with water. Elixir dosage forms may be safely mixed with fruit juice, milk, or water. If IV infusions are indicated, calculate the dose carefully and use an IV infusion pump to administer the drug. Too rapid an infusion of IV dosage forms may lead to cardiovascular collapse and respiratory depression. In addition, frequently monitor vital signs and IV infusion rates and document in the patient's chart. If any signs or symptoms of cardiovascular or respiratory depression are noted, withhold the drug and contact the prescriber immediately while providing supportive care through maintenance of the airway, breathing, and circulation.
- *Gabapentin:* This is one of the antiepileptic drugs that can be taken without regard to meals. If discontinuation of the drug is indicated, taper the dosage, as ordered, over at least 1 week to avoid rebound seizures.
- *Lamotrigine:* The dosing regimen must be followed, as ordered. Checking for possible drug interactions is important to patient safety. If the patient shares any suicidal thoughts or actions, contact the prescriber immediately.
- *Levetiracetam:* The most common adverse effect is sleepiness. Contact the prescriber if any extreme adverse effects or any problems with moving, walking, or changes in mood/behavior occur. Any suicidal thoughts or psychotic symptoms must also be reported immediately. With the beginning of antiepileptic therapy, encourage the patient not to drive, operate heavy machinery, or make major decisions due to the sedation and CNS depression.
- *Oxcarbazepine:* This drug is to be taken as prescribed and is usually given in two divided doses. Always check for any potential drug interactions before administering (see previous discussion). The drug must be taken with food or snacks. Rash, abnormal walking or moving, or abdominal pain must also be reported, if present.
- *Pregabalin:* The daily dosage is usually given in two or three divided doses. Sudden or abrupt withdrawal is to be avoided.

Monitor the patient for any excessive dizziness, ocular or visual changes, or edema. If these are present, report immediately.
- *Tiagabine:* This drug is to be taken with food. Report any problems with tremors, rash, or abdominal pain.
- *Valproic acid:* Oral dosage forms are not to be taken with carbonated beverages. It is recommended that this drug be taken with at least 4 to 6 oz of water, food, or a snack to minimize GI upset.

EVALUATION

The occurrence of a therapeutic response to *antiepileptic drugs* does not mean that the patient has been cured of the seizures but only that seizure activity is decreased or absent. Thoroughly document any response to the medication in the nurse's notes. These classes of medications have other indications, such as management of chronic pain and migraines, so the existing problem or disorder would show improvement with minimal adverse effects. In addition, when monitoring and evaluating the effects of antiepileptic drugs, constantly assess the patient for changes in mental status/level of consciousness, affect, eye problems, or visual disorders. Monitoring CBC is also important because of the occurrence of blood dyscrasias. Measurements of serum levels of the specific antiepileptic drug are ordered at baseline or at the start of therapy and frequently thereafter to determine if subsequent serum levels are subtherapeutic, therapeutic, or toxic. Subtherapeutic levels indicate that the dosage may need to be increased (by the prescriber), and toxic levels require withholding or decreasing the dose—but only if prescribed! Serum therapeutic levels are found in Table 14-6.

PATIENT TEACHING TIPS

- Educate the patient about the sedating effects of drug therapy so that appropriate steps can be taken to ensure patient safety until a steady state is achieved (usually after four or five drug half-lives). The patient is not to drive, operate heavy machinery, or make major decisions until steady state is achieved.
- The patient needs to understand the importance of reporting any suicidal thoughts or ideas immediately. Alcohol, caffeine intake, and smoking are to be avoided.
- Antiepileptic drugs must never be abruptly discontinued as it may precipitate rebound seizure activity.
- The adverse effects most commonly associated with these drugs are drowsiness, GI upset, and CNS-depressing effects. Remind the patient that these adverse effects often decrease after the drug has been taken for several weeks. Taking the antiepileptic drug with food and/or 6 to 8 oz of fluids will help to minimize GI upset, unless otherwise noted.
- Advise the female patient contemplating pregnancy to seek education and medical advice from the prescriber due to the teratogenic effects of some of the medications.
- Educate the patient about drug interactions between antiepileptic drugs and beta blockers, corticosteroids, calcium channel blockers, ethanol (alcohol), and other CNS depressants.
- Inform the patient that a recurrence of seizure activity is usually due to a lack of compliance with the drug regimen. If a dose or doses of medication are missed, the prescriber needs to be contacted for further instructions. Adherence to medication regimen is critical to the prevention of seizure activity.
- Emphasize to the patient that treatment of epilepsy is lifelong and that compliance with the treatment regimen is important for effective therapy. Share information with the patient and family about community and other appropriate resources (e.g., national and local support groups).
- Discuss with the patient important ways to improve *safety* in day-to-day activities while taking antiepileptic drugs: *In the kitchen:* Use an electric stove with no open flame, wear oven mitts, and cook only on rear burners. Cook in the microwave—it is the safest option. Have a plumber install a heat-control device on faucets to avoid burns. Carpet floors to help cushion falls, and use plastic dishes and containers instead of glass when possible. *In the bathroom:* Use heat-control devices on faucets. Carpet floors instead of using tile. Do not put a lock on the bathroom door so that help can be obtained if needed. Bathe with only a few inches of water in the tub, and if seizure activity has not been fully controlled, bathe while someone else is present in the home. *During activities:* Always have someone along when engaging in sports, and make sure the person is knowledgeable about the management of airway and seizures. Bike riding with a helmet, swimming, and water sports are okay if an accompanying adult is present who knows how to manage seizure activity and its consequences.
- Each state has different driving regulations for individuals with epilepsy, and the Waiting Period for Drivers License Following Seizures provides specific requirements/guidelines. Contact each state's Division of Motor Vehicles for current and relevant information.
- Many people with epilepsy work at steady jobs and have successful careers. Some are unable to work, but epilepsy should not prevent the individual from getting a job; such discrimination has been outlawed by the Americans with Disabilities Act of 1990 (Public Law 101-336).
- Encourage the patient to wear a medical alert bracelet or necklace and to keep a medical alert card on his or her person at all times.
- Keeping a daily diary or journal is important and is a helpful tool for the patient, prescriber, and/or caregivers. Entries need to include the date and time of any seizure as well as any details such as omitted drug doses, illnesses, and so on.

KEY POINTS

- *Epilepsy* is a disorder of the brain manifested as a chronic, recurrent pattern of seizures. A *seizure* is abnormal electrical activity in the brain.
- Seizures are classified as follows: partial-onset seizures or those originating in a more localized region of the brain; status epilepticus, characterized by generalized tonic-clonic convulsions that occur repeatedly in succession; and tonic-clonic seizures involving initial muscular contraction throughout the body (tonic) and progressing to alternating contraction and relaxation (clonic phase).
- You must be able to distinguish between the different types of seizure, and assess/document all symptoms, events, and problems that occur before, during, and after any seizure activity. This information may aid in the diagnosis of the type of seizure the patient is experiencing.
- Noncompliance with the drug regimen is the most important factor leading to treatment failure.
- Monitor therapeutic blood levels at all times. Avoid abrupt withdrawal of the antiepileptic drug to prevent rebound seizure activity.
- IV infusions of antiepileptic drugs are very dangerous and must be managed cautiously, with adherence to hospital or facility policy and manufacturer's guidelines. Avoid rapid infusions because of the risk for cardiac and/or respiratory arrest.
- Elderly patients may experience paradoxical reactions to antiepileptic drugs, resulting in hyperactivity and irritability versus sedation.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is preparing to give medications. Which is the most appropriate nursing action for intravenous (IV) phenytoin (Dilantin)?
   - **a** Give IV doses via rapid IV push.
   - **b** Administer in normal saline solutions.
   - **c** Administer in dextrose solutions.
   - **d** Ensure continuous infusion of the drug.

2 The nurse is reviewing the drugs currently taken by a patient who will be starting drug therapy with carbamazepine (Tegretol). Which drug may raise a concern for interactions?
   - **a** digoxin (Lanoxin)
   - **b** acetaminophen (Tylenol)
   - **c** diazepam (Valium)
   - **d** warfarin (Coumadin)

3 Which response would the nurse expect to find in a patient with a phenytoin (Dilantin) level of 35 mcg/mL?
   - **a** Ataxia
   - **b** Hypertension
   - **c** Seizures
   - **d** No unusual response; this level is therapeutic.

4 A patient is taking pregabalin (Lyrica) but does not have a history of seizures. The nurse recognizes that this drug is also indicated for
   - **a** postherpetic neuralgia.
   - **b** viral infections.
   - **c** Parkinson's disease.
   - **d** depression.

5 The nurse is assessing a newly admitted patient who has a history of seizures. During the assessment, the patient has a generalized seizure that does not stop for several minutes. The nurse expects that which drug will be ordered for this condition?
   - **a** valproic acid (Depakote)
   - **b** neurontin (Gabapentin)
   - **c** carbamazepine (Tegretol)
   - **d** diazepam (Valium)

6 The nurse is administering an antiepileptic drug and will follow which guidelines? (Select all that apply.)
   - **a** Monitor the patient for drowsiness.
   - **b** Medications may be stopped if seizure activity disappears.
   - **c** Give the medication at the same time every day.
   - **d** Give the medication on an empty stomach.
   - **e** Notify the prescriber if the patient is unable to take the medication.

7 The nurse is preparing to administer valproic acid to a child. The order reads: "Give valproic acid, 15 mg/kg/day PO in three divided doses." The child weighs 33 pounds. How many milligrams will the child receive with each dose?

1. b, 2. b, 3. a, 4. a, 5. d, 6. a, c, e, 7. 75 mg per dose

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Briefly discuss the impact of acetylcholine and dopamine on the brain.
2 Describe the pathophysiology of Parkinson's disease.
3 Identify the different classes of medications used to manage Parkinson's disease, and list the drugs in each class.
4 Discuss the mechanisms of action, dosages, indications, routes of administration, contraindications, cautions, drug interactions, adverse effects, and toxic effects of antiparkinson drugs.
5 Develop a nursing care plan that includes all phases of the nursing process for patients taking antiparkinson drugs.

DRUG PROFILES

amantadine, p. 243
♦ **benztropine mesylate, p. 246**
bromocriptine, p. 244
♦ **carbidopa-levodopa, p. 246**
entacapone, p. 244
♦ **ropinirole, p. 245**
selegiline and rasagiline, p. 242

♦ *Key drug*

KEY TERMS

Adjunctive drugs Drugs that are added as a second drug for combined therapy with a primary drug and may have additive or independent properties. (p. 241)

Akinesia Classically defined as "without movement." Absence or poverty of movement that results in a masklike facial expression and impaired postural reflexes. (p. 239)

Bradykinesia Slowness of movement; a classic symptom of Parkinson's disease. (p. 239)

Chorea A condition characterized by involuntary, purposeless, rapid motions such as flexing and extending the fingers, raising and lowering the shoulders, or grimacing. (p. 239)

Dyskinesia Term for abnormal and distressing involuntary movements; inability to control movements, which often occurs as a side effect of levodopa therapy. (p. 239)

Dystonia Impaired or distorted voluntary movement, often involving the head, neck, or feet. (p. 239)

Exogenous A term describing any substance produced outside of the body that may be taken into the body (e.g., a medication, food, or environmental toxin). (p. 245)

On-off phenomenon A common experience of patients taking medication for Parkinson's disease in which they experience periods of greater symptomatic control ("on" time) alternating with periods of lesser symptomatic control ("off" time). (p. 239)

KEY TERMS—cont'd

Parkinson's disease A slowly progressive, degenerative neurologic disorder characterized by resting tremor, pill-rolling of the fingers, masklike facies, shuffling gait, forward flexion of the trunk, loss of postural reflexes, and muscle rigidity and weakness. (p. 238)

Postural instability A decrease or change in motor and muscle movements that leads to unsteadiness and hesitation in movement and gait when the individual starts or stops walking, or causes leaning to the left or right when sitting; occurs in Parkinson's disease. (p. 239)

Presynaptic Drugs that exert their antiparkinson effects before the nerve synapse. (p. 243)

Rigidity Resistance of the muscles to passive movement; leads to the "cogwheel" rigidity seen in Parkinson's disease. (p. 239)

TRAP (*T*remor, *r*igidity, *a*kinesia, *p*ostural instability); an acronym for symptoms of Parkinson's disease. (p. 239)

Tremor In Parkinson's disease, shakiness of the extremities seen mostly at rest. (p. 239)

Wearing-off phenomenon A gradual worsening of parkinsonian symptoms as a patient's medications begin to lose their effectiveness, despite maximal dosing with a variety of medications. (p. 239)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

PATHOPHYSIOLOGY OF PARKINSON'S DISEASE

Parkinson's disease is a chronic, progressive, neurodegenerative disorder affecting the dopamine-producing neurons in the brain. Other chronic central nervous system (CNS) neuromuscular disorders are myasthenia gravis and Alzheimer's disease. Parkinson's disease was initially recognized in 1817, at which time it was called *shaking palsy.* James Parkinson later described in more detail the symptoms of both the early and advanced stages of the disease. The underlying pathologic defect was not discovered until the1960s. It was then recognized that Parkinson's disease involves a dopamine deficit in the area of the cerebral cortex called the *substantia nigra,* which is contained within another brain structure known as the *basal ganglia.* Also relevant is the adjacent structure called the *globus pallidus.* All three structures are parts of the brain that make up the *extrapyramidal system,* which is involved in motor function, including posture, muscle tone, and smooth muscle activity. In addition, the *thalamus* serves as a relay station for brain impulses, whereas the *cerebellum* regulates muscle coordination (Figure 15-1).

Dopamine is an inhibitory neurotransmitter and *acetylcholine* is an excitatory neurotransmitter in this area of the brain. A correct balance between these two neurotransmitters is needed for the proper regulation of posture, muscle tone, and voluntary movement. Parkinson's disease results from an imbalance in these two neurotransmitters in the basal ganglia. This imbalance is caused by failure of the nerve terminals in the substantia nigra to produce dopamine. Dopamine acts in the basal ganglia to control movements. Destruction of the substantia nigra by Parkinson's disease leads to dopamine depletion. This often results in excessive, unopposed acetylcholine (cholinergic) activity due to the lack of a normal dopaminergic balancing effect. Figure 15-2 illustrates the difference in neurotransmitter concentrations in persons with normal balance and in patients with Parkinson's disease.

Some theorize that Parkinson's disease is the result of an earlier head injury or of excess iron in the substantia nigra, which undergoes oxidation and causes the generation of toxic free radicals. Another theory postulates that, because dopamine levels naturally decrease with age, Parkinson's disease represents a premature aging of the *nigrostriatal cells* of the substantia nigra resulting from environmental or intrinsic biochemical factors, or both. Evidence from animal studies suggests that environmental toxins, such as pesticides and metals, also may contribute to the development of Parkinson's disease.

Parkinson's disease affects at least 1 million Americans and 4 million people worldwide. It is the second most common neurodegenerative disease after Alzheimer's disease. Some patients may have symptoms of both conditions. In most patients, the disease becomes apparent between 45 and 65 years of age, with

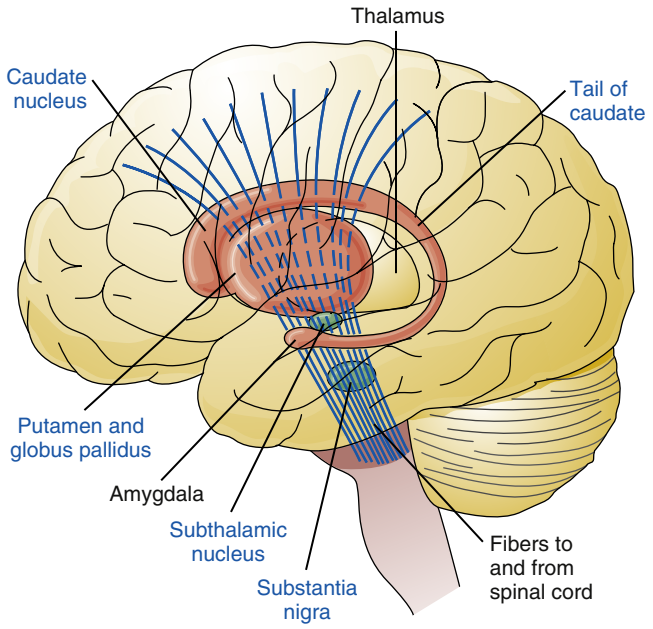

FIGURE 15-1 Basal ganglia and related structures of the brain. (From Copstead-Kirkhorn LC, Banasik JL: *Pathophysiology,* ed 4, St Louis, 2010, Saunders.)

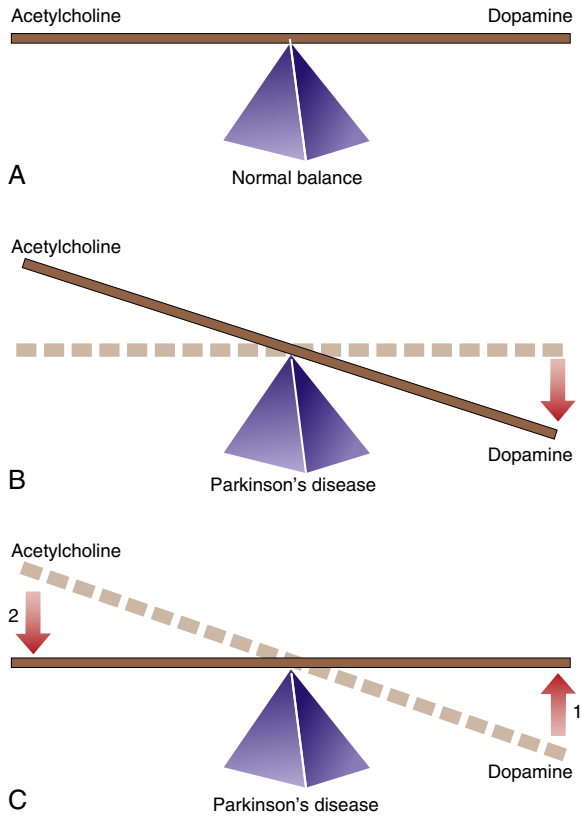
a mean age of onset of 56 years. The number of patients with Parkinson's disease is expected to continue to increase as our elderly population grows. The disease occasionally occurs in younger people, especially after acute encephalitis, or carbon monoxide or metallic poisoning. However, it is usually idiopathic (of no known cause). Overall, there is a 2% chance of developing the disease in one's lifetime. Men are affected more often than women in a ratio of up to 3:2. Evidence now suggests a possible genetic link, with up to 20% of patients having a family history of the disease.

There are no readily available laboratory tests that can detect or confirm Parkinson's disease. The diagnosis is usually made on the basis of the classic symptoms and physical findings. The classic symptoms of Parkinson's disease include **bradykinesia, postural instability, rigidity,** and **tremors** (**TRAP** [*T*remor, *r*igidity, *a*kinesia, *p*ostural instability] with **akinesia** really manifesting as bradykinesia) (see Table 15-1). Computed tomography (CT), magnetic resonance imaging (MRI), cerebrospinal fluid analysis, and electroencephalography (EEG) are usually normal and of little diagnostic value. Positron emission tomography (PET) may offer some additional information. CT, MRI, and PET may be useful tools for ruling out other possible diseases as causes of the symptoms, as well as for follow-up imaging after drug and surgical treatments.



A, Normal balance of acetylcholine and dopamine in the CNS.
B, In Parkinson's disease, a decrease in dopamine results in an imbalance.
C, Drug therapy in Parkinson's disease is aimed at correcting the imbalance between acetylcholine and dopamine. This can be accomplished by:
1. increasing the supply of dopamine
2. blocking or lowering acetylcholine levels

FIGURE 15-2 The neurotransmitter abnormality in Parkinson's disease.

Unfortunately, Parkinson's disease is a progressive condition. Over time, there is substantial reduction in the number of surviving dopaminergic terminals that can take up pharmacologically administered levodopa and convert it into dopamine. Rapid swings in the response to levodopa, called the **on-off phenomenon,** also occur. The result is worsening of the disease when too little dopamine is present, or dyskinesias when too much is present. In contrast, the **wearing-off phenomenon** occurs when anti–Parkinson's disease medications begin to lose their effectiveness, despite maximal dosing, as the disease progresses. **Dyskinesia** is the difficulty in performing voluntary movements and is commonly seen in the disease. The two dyskinesias most frequently associated with antiparkinson therapy are **chorea** (irregular, spasmodic, involuntary movements of the limbs or facial muscles) and **dystonia** (abnormal muscle tone leading to impaired or abnormal movements). Dystonia commonly involves the head, neck, or feet and is a symptom common to patients with Parkinson's disease. These motor complications make Parkinson's disease a prominent cause of disability. Dementia may also be a result of the disease and is referred to as *Parkinson's disease–associated dementia.*

Symptoms of Parkinson's disease do not appear until approximately 80% of the dopamine store in the substantia nigra has been depleted. This means that by the time the disease is diagnosed, only approximately 20% of the patient's original dopaminergic terminals are functioning normally.

TREATMENT OF PARKINSON'S DISEASE

The first step in the treatment of Parkinson's disease is to provide a full explanation of the disease to the patient and his or her family members or significant others. Physical therapy, speech therapy, and occupational therapy are almost always needed when the patient is in the later stages of the disease.

Treatment of the disease centers around drug therapy. However, physical activity is a must for these patients. Many experts believe that physical activity is as important as any drug

TABLE 15-1 CLASSIC PARKINSONIAN SYMPTOMS

SYMPTOM	DESCRIPTION
Akinesia	Absence of psychomotor activity resulting in mask-like facial expression
Bradykinesia	Slowness of movement
Rigidity	"Cogwheel" rigidity, resistance to passive movement
Tremor	Pill rolling: tremor of the thumb against the forefinger, seen mostly at rest and less severe during voluntary activity; usually starts on one side then progresses to the other; is the presenting sign in 70% of cases; also seen as tremor of the hand and extremities.
Postural instability	Unsteadiness (associated with bradykinesia and rigidity) that leads to danger of falling; leaning to one side, even when sitting

therapy, and together they greatly improve mobility. For severe cases, the surgical technique of *deep brain stimulation* may be used. This involves electrical stimulation of dopamine-deficient brain tissues in a way that helps to reduce Parkinson-associated dyskinesias. Surgical treatments are for the more severe cases, and the patient must still respond well to drug therapy.

PHARMACOLOGY OVERVIEW

Because Parkinson's disease is thought to be due to an imbalance of dopamine and acetylcholine, drug therapy is aimed at increasing the levels of dopamine and/or antagonizing the effects of acetylcholine. Unfortunately, current drug therapy does not slow the progression of the disease, but rather is used to slow the progression of symptoms. The drugs available for the treatment of Parkinson's disease are listed in Table 15-2.

Antiparkinson drug therapy is based upon the fact that nerve terminals can take up substances, store them, and release them for use when needed. As long as there are functioning nerve terminals that can take up dopamine, the symptoms of Parkinson's disease can be at least partially controlled. Since Parkinson's disease is essentially a deficiency of dopamine in certain areas of the brain, it seems logical that drug therapies focus primarily on restoring and enhancing dopaminergic activity in these neurons. A variety of both indirect- and direct-acting drugs are available for this purpose. The indirect-acting drugs are often administered first in the disease process.

INDIRECT-ACTING DOPAMINERGIC DRUGS

MONOAMINE OXIDASE INHIBITORS

The enzyme *monoamine oxidase (MAO)* causes the breakdown of *catecholamines* in the body, which include dopamine, norepinephrine, and epinephrine. There are two subclasses of MAO in the body: MAO-A and MAO-B. As early as 1965, nonselective monoamine oxidase inhibitors (MAOIs), which inhibit both MAO-A and MAO-B, were being used to improve the therapeutic effect of levodopa by preventing its metabolic breakdown. They were also among the first medications used to treat depression but have been replaced by newer drug

TABLE 15-2 REVIEW OF PHARMACOLOGIC THERAPY FOR PARKINSON'S DISEASE

GENERIC NAME	TRADE NAME	ROUTE	INDICATIONS
Indirect-Acting Dopamine Receptor Agonists (MAO-B Inhibitors)			
selegiline	Eldepryl, Zelapar*	PO	Used in conjunction with carbidopa-levodopa in early stages of disease; helpful with symptom fluctuations
rasagiline	Azilect	PO	
Dopamine Modulator			
amantadine	Symmetrel	PO	Used in early stages; can be effective in moderate or advanced stages; reduces tremor or muscle rigidity
COMT Inhibitors			
tolcapone	Tasmar	PO	Usually added to carbidopa-levodopa to treat symptom fluctuations; delays "off" periods; has levodopa dose-sparing effect
entacapone	Comtan	PO	
Direct-Acting Dopamine Receptor Agonists			
Ergot			
bromocriptine	Parlodel	PO	Usually used as drug of choice for young patients; first- or second-line therapy of choice for elderly; can be used as adjunct to levodopa for "off" periods; can be used to reduce dyskinesia associated with later stages
Nonergot			
pramipexole	Mirapex	PO	
ropinirole	Requip	PO	
Dopamine Replacement Drugs			
carbidopa-levodopa	Sinemet, Parcopa*	PO	Usually started as soon as patient becomes functionally impaired; drug of choice for most elderly patients
Anticholinergic Drugs†			
benztropine	Cogentin	PO, IV	Used as secondary drug for tremor/muscle rigidity
trihexyphenidyl	Generic only (formerly Artane)	PO	
Antihistamines‡			
diphenhydramine	Benadryl	PO, IV	Used as secondary drug for tremor/muscle rigidity

COMT, Catechol ortho-methyltransferase; *IV,* intravenous; *MAO-B,* monoamine oxidase type B; *PO,* oral.
*Orally disintegrating tablet (see Chapter 2).
†See Chapter 21.
‡See Chapter 36.

categories (see Chapter 16). A major adverse effect of the nonselective MAOIs is that they interact with tyramine-containing foods (cheese, red wine, beer, and yogurt) because of their inhibitory activity against MAO-A. This has been called the *cheese effect,* and can result in severe hypertension. Selegiline is a selective MAO-B inhibitor and is much less likely to elicit the classic cheese effect. It is approved for use in conjunction with levodopa therapy in the treatment of Parkinson's disease. There was earlier speculation that selegiline, as well as possibly vitamins E and C, might have antiparkinson effects due to "neuroprotective" activity at the neuronal (nerve cell) level. However, no studies to date have demonstrated this to be true. Nonetheless, this theoretical neuroprotective effect is still debated in the literature.

Rasagiline is the newest antiparkinson drug and received FDA approval in 2008. Like selegiline, rasagiline is a selective MAO-B inhibitor. It is approved to be given once a day as monotherapy in the early stages of the disease, as well as in combination with other drugs in advanced cases. Drug interactions and adverse effects are similar to those of selegiline.

Mechanism of Action and Drug Effects

The MAO enzymes are widely distributed throughout the body, with the highest concentrations found in the liver, kidney, stomach, intestinal wall, and brain. Most MAO-B occurs in the CNS, primarily in the brain. The primary role of MAO enzymes is the breakdown of catecholamines, such as dopamine, norepinephrine, and epinephrine, as well as serotonin. Giving an MAO-B inhibitor such as selegiline or rasagiline causes an increase in the levels of dopaminergic stimulation in the CNS. This helps to counter the dopaminergic deficiency seen in Parkinson's disease. Administration of selegiline can also allow the dose of levodopa (discussed later in this chapter) to be reduced. Improvement in functional ability and decreased severity of symptoms can occur; however, only approximately 50% to 60% of patients show a positive response.

Indications

Selegiline and rasagiline are currently approved for use in combination with carbidopa-levodopa. They are **adjunctive drugs** used when a patient's response to levodopa is fluctuating. They may also be somewhat beneficial as a prophylactic drug to delay reduction in a patient's response to levodopa. Studies have shown that selegiline-treated patients required levodopa therapy approximately 1.8 times later than control patients. As Parkinson's disease progresses, it becomes more difficult to manage it with levodopa. Ultimately, levodopa no longer controls the disease, and the patient is seriously debilitated. This generally occurs between 5 and 10 years after the start of levodopa therapy.

Contraindications

Selegiline and rasagiline are contraindicated in cases of known drug allergy. Concurrent use with the opioid analgesic meperidine (see Chapter 10) is also contraindicated due to well-documented drug interactions between MAOIs and meperidine.

Adverse Effects

The most common adverse effects associated with selegiline use are mild and are listed in Table 15-3. At recommended dosages of 10 mg/day, the drug maintains its selective MAO-B inhibition. However, at dosages that exceed 10 mg/day, selegiline becomes a nonselective MAOI, which contributes to the development of the cheese effect described earlier.

Interactions

Selegiline interacts with meperidine and has been associated with delirium, muscle rigidity, hyperpyrexia (high fever), and hyperirritability. Other reported reactions are listed in Table 15-4. Selegiline may safely be taken concurrently with catechol ortho-methyltransferase (COMT) inhibitors (see later drug section). Patients taking higher doses of selegiline need to avoid tyramine-containing foods such as aged cheese, sausages, and draft beer.

Dosages

For dosage information, see the table on p. 242. Also see the Safety and Quality Improvement: Preventing Medication Errors box on p. 243.

TABLE 15-3 ADVERSE EFFECTS OF SELECTED ANTIPARKINSON DRUGS

DRUG OR DRUG CLASS	ADVERSE EFFECTS
MAO-B inhibitor: selegiline	Dizziness, insomnia, hallucinations, ataxia, agitation, depression, paresthesia, somnolence, headache, dyskinesia, nausea, diarrhea, hypotension or hypertension, chest pain, weight loss, dermatologic reactions, rhinitis, pharyngitis
Dopamine modulator: amantadine	Dizziness, insomnia, agitation, anxiety, headache, hallucinations, nausea, orthostatic hypotension, peripheral edema, dry mouth
COMT inhibitors: entacapone, tolcapone	GI upset, dyskinesia, urine discoloration, orthostatic hypotension, syncope, dizziness, fatigue, hallucinations, anxiety, somnolence, rash, dyspnea, worsening of dyskinesia *tolcapone:* liver failure
Anticholinergic agent: benztropine	Tachycardia; confusion; memory impairment; rash; hyperthermia; constipation; dry throat, nose, or mouth; nausea; vomiting; urinary retention; blurred vision; fever
Ergot derivative: bromocriptine	Ataxia, dizziness, headache, depression, drowsiness, GI upset, visual changes
Nonergot derivatives: pramipexole, ropinirole	Edema, fatigue, syncope, dizziness, drowsiness, GI upset
Dopamine replacement drugs: levodopa, carbidopa-levodopa combination	Palpitations, hypotension, urinary retention, depression, dyskinesia

COMT, Catechol ortho-methyltransferase; *GI,* gastrointestinal; *MAO-B,* monoamine oxidase type B.

TABLE 15-4 SELECTED DRUG INTERACTIONS OF ANTIPARKINSON DRUGS

DRUG OR DRUG CLASS	INTERACTING DRUG	MECHANISM	RESULT
MAO-B inhibitor: selegiline	meperidine and other opioids, tramadol, cyclobenzaprine, dextromethorphan, other MAOIs, serotonergic antidepressants, oxcarbazepine	Additive CNS stimulation	Serotonin syndrome
	carbamazepine, oral contraceptives	Reduced selegiline clearance	Potential selegiline toxicity
	buspirone	Uncertain	Hypertension
Dopamine modulator: amantadine	Anticholinergics	Additive effects	Increased anticholinergic adverse effects
COMT inhibitor: entacapone	MAOIs, catecholamines	Reduced catecholamine metabolism	Tachycardia, cardiac dysrhythmias, hypertension
Ergot derivative: bromocriptine	erythromycin	Cytochrome P-450 interactions	Increased bromocriptine effects with risk of toxicity
	Sympathomimetics	Additive effects	Hypertension, cardiac dysrhythmias
	Antihypertensives	Additive effects	Hypotension
Nonergot: ropinirole	warfarin, ciprofloxacin	Cytochrome P-450 interactions	Reduced ropinirole clearance with risk of toxicity
	Antipsychotics	Antidopaminergic activity	Reduced efficacy of ropinirole
Dopamine replacement: levodopa, carbidopa	Nonselective MAOIs	Additive toxicity	Hypertensive reactions
	Benzodiazepines, antipsychotics	Reduced levodopa effects	Reduced therapeutic effects

CNS, Central nervous system; *COMT,* catechol ortho-methyltransferase; *ECG,* electrocardiogram; *MAO-B,* monoamine oxidase type B; *MAOI,* monoamine oxidase inhibitor.

DOSAGES

Selected Antiparkinson Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL ADULT DOSAGE RANGE	INDICATIONS
amantadine (Symmetrel) (C)	Dopamine modulator	PO: 100-400 mg/day divided q12h	Parkinson's disease
♦ benztropine (Cogentin) (C)	Anticholinergic	PO: 0.5-6 mg/day	
bromocriptine (Parlodel) (D)	Direct-acting dopamine agonist; ergot derivative	PO: 2.5-90 mg/day	
carbidopa-levodopa (Sinemet, Sinemet CR, Parcopa) (C)	Antiparkinson agent	PO: 10/100, 1 tab 3-8 times/day; 25/100, 1 tab 3-6 times/day; 25/250, 1 tab tid-qid CR: 1 tab bid; up to 2-8 tabs at 4- to 8-hr intervals PO (orally disintegrating tablet [Parcopa]): same as above	
entacapone (Comtan) (C)	COMT inhibitor	PO: 200 mg with each dosage of levodopa, up to 8 times/day	
♦ ropinirole (Requip) (C)	Direct-acting dopamine agonist; nonergot derivative	PO: 0.25 mg tid, slowly titrating to max dose of 24 mg/day	
selegiline (Eldepryl, Zelapar) (C)	Selective MAO-B inhibitor	PO: 5 mg bid with breakfast and lunch in combination with carbidopa-levodopa, or 10 mg q AM PO (orally disintegrating tablet [Zelapar]): 1.25-2.5 mg once daily	

CR, Controlled release; *MAOI,* monoamine oxidase inhibitor; *PO,* oral; *subcut,* subcutaneous.

DRUG PROFILES

selegiline and rasagiline

Selegiline (Eldepryl) is a selective MAO-B inhibitor which is indicated for Parkinson's disease. It is used as an adjunctive drug along with levodopa to reduce the dosage of levodopa needed for symptom control. Adverse effects increased with doses greater than 10 mg when it loses its selectivity for MAO-B are listed in Table 15-3. Drug interactions are listed in Table 15-4. Selegiline is available as an oral tablet and an orally disintegrating tablet for buccal use known as Zelapar, which can provide improved drug absorption. In addition, a transdermal form of the drug known as Emsam is available. Emsam is currently indicated only for major depressive disorder (see Chapter 16). Rasagiline (Azilect) is a newer selective MAO-B inhibitor comparable to selegiline. Its advantage is that it is approved as monotherapy for Parkinson's disease, whereas selegiline is normally used adjunctively with the dopamine replacement drug levodopa.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	0.5-2 hr	2 hr	1-3 days

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Look-Alike/Sound-Alike Drugs: Selegiline and Salagen

Be careful with look-alike/sound-alike drugs! Medication errors often occur when drug names are similar.

Selegiline is a monoamine oxidase inhibitor that is used to treat Parkinson's disease. Salagen, an oral form of pilocarpine hydrochloride, is prescribed for relief of dry mouth symptoms, also known as *xerostomia,* in patients who have Sjögren's syndrome or who have received radiation therapy. To make it more confusing, both drugs are available in 5-mg dosage forms. Be sure to double-check the name and use of these drugs when receiving orders, and instruct patients to check the drug names when getting these drugs filled at pharmacies.

For more information, visit www.ismp.org/Newsletters/acutecare/articles/20050922_1.asp.

DOPAMINE MODULATOR

Only one drug is currently known to function as a dopamine modulator. Amantadine (Symmetrel) was first recognized as an antiviral drug and was used for treating influenza virus infections. It is still used for this purpose (see Chapter 40) as well as for management of Parkinson's disease.

Mechanism of Action and Drug Effects

Amantadine appears to work by causing the release of dopamine and other catecholamines from their storage sites, or vesicles, in the **presynaptic** fibers of nerve cells within the basal ganglia that have not yet been destroyed by the disease process. Amantadine also blocks the reuptake of dopamine into the nerve fibers. This results in higher levels of dopamine in the synapses between nerves and improved dopamine neurotransmission between neurons. Because amantadine does not directly stimulate dopaminergic receptors, it is considered to be indirect acting. Amantadine also has some anticholinergic properties (see Chapter 21). This may further help by controlling symptoms of dyskinesia.

Indications

Amantadine is generally indicated in the early stages of Parkinson's disease while there are still some intact neurons in the basal ganglia. However, it can be used in the moderate to advanced stages. It is usually effective for only 6 to 12 months, after which it often fails to relieve hypokinesia and rigidity. Once it becomes ineffective, a dopamine agonist such as bromocriptine is usually tried next (see later drug section). It is often used to treat dyskinesia associated with carbidopa-levodopa. It is also indicated for influenza virus infection (see Chapter 40).

Contraindications

Amantadine is contraindicated in cases of known drug allergy.

Adverse Drug Effects

Common adverse effects associated with amantadine are relatively mild and include dizziness, insomnia, and nausea.

Drug Interactions

Amantadine causes increased anticholinergic adverse effects when given with anticholinergic drugs.

Dosage

For dosage information, see the table on p. 242.

DRUG PROFILE

amantadine

Amantadine (Symmetrel) is actually an antiviral drug that is used most often for influenza virus infection (see Chapter 40). It is also indicated for treatment of moderate Parkinson's disease, for which it helps to control symptoms of tremor, including motor rigidity, by virtue of both its dopaminergic and anticholinergic effects. Common adverse reactions include dizziness, insomnia, and nausea. Interacting drugs include anticholinergics (additive effects) (see Table 15-4). Amantadine is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	48 hr	2-4 hr	11-15 hr	6-12 wk

CATECHOL ORTHO-METHYLTRANSFERASE INHIBITORS

The third category of indirect-acting dopaminergic drugs is the *catechol ortho-methyltransferase (COMT)* inhibitors. There are currently two drugs in this category: tolcapone (Tasmar) and entacapone (Comtan).

Mechanism of Action and Drug Effects

Tolcapone and entacapone, like amantadine, work presynaptically. Both drugs block COMT. COMT is the enzyme that catalyzes the breakdown of the body's catecholamines. Tolcapone acts both centrally and peripherally, whereas entacapone cannot cross the blood-brain barrier and therefore can act only peripherally. The positive effect of these drugs is that they prolong the duration of action of levodopa. This is especially true when levodopa is given with carbidopa (see section on dopamine replacement drugs later in the chapter). This results in reduction of the wearing-off phenomenon.

Indications

COMT inhibitors are indicated for the treatment of Parkinson's disease.

Contraindications

Both COMT inhibitors (tolcapone and entacapone) are contraindicated in cases of known drug allergy. Tolcapone is also contraindicated in cases of liver failure.

Adverse Effects

Commonly reported adverse effects with both COMT inhibitors include gastrointestinal (GI) upset and urine discoloration. In addition, they also can worsen dyskinesia that may already

be present (see Table 15-3). Tolcapone has been associated with cases of severe liver failure. For this reason, the FDA announced in 1998 that this drug is to be considered only in patients who do not respond to other Parkinson's disease drug therapy.

Interactions

Neither tolcapone nor entacapone are to be taken with nonselective MAOIs because of cardiovascular risk due to reduced catecholamine metabolism. However, the selective MAO-B inhibitor selegiline may be safely taken concurrently with COMT inhibitors.

Dosages

For dosage information, see the table on p. 242.

DRUG PROFILE

Inhibition of the enzyme in the body known as COMT is a strategy for prolonging the duration of action of levodopa. Two compounds were developed for this purpose: tolcapone (Tasmar) and entacapone (Comtan). Both drugs are reversible inhibitors of COMT. Tolcapone has been associated with severe liver failure and is rarely used. To date, no similar pattern of adverse outcomes has been shown with entacapone.

entacapone

Entacapone (Comtan) is a COMT inhibitor indicated for the adjunctive treatment of Parkinson's disease. Entacapone is taken with levodopa and is effective from the first dose. A patient can feel the benefit of entacapone within a few days. Entacapone benefits patients who are experiencing wearing-off effects. When used with levodopa, it can also reduce on-off effects. The levodopa dosage can often be reduced. Adverse reactions include GI upset, dyskinesias, and urine discoloration (see Table 15-3). Entacapone is contraindicated in patients who have shown a hypersensitivity reaction to it and used with caution in patients with preexisting liver disease. Entacapone is available only for oral use. It is also available in combination tablets that contain various doses of entacapone, carbidopa, and levodopa (Stalevo).

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	0.5-1.5 hr	1-5.3.5 hr	6 hr

DIRECT-ACTING DOPAMINE RECEPTOR AGONISTS

Direct-acting dopamine receptor agonists are drugs used to treat Parkinson's disease, often as first-line agents used upon diagnosis. These drugs include two subclasses: *nondopamine dopamine receptor agonists (NDDRAs)* and *dopamine replacement drugs.* NDDRAs are further subdivided into the ergot derivatives bromocriptine (Parlodel) and the nonergot drugs pramipexole (Mirapex) and ropinirole (Requip). Pergolide was taken off the U.S. market after severe adverse effects were reported.

NONDOPAMINE DOPAMINE RECEPTOR AGONISTS

Mechanism of Action and Drug Effects

All of the NDDRAs work by direct stimulation of presynaptic and/or postsynaptic dopamine receptors in the brain. They may be used in early or late stages of the disease.

Chemically, bromocriptine is an ergot alkaloid similar to ergotamine (see Chapter 13). (*Ergot* is the name of a pathologic fungal growth on plants.) Bromocriptine works by activating presynaptic dopamine receptors to stimulate the production of more dopamine. It chief site of activity is the D_2 subclass of dopamine receptors. Pramipexole and ropinirole are two newer *nonergot* NDDRAs. Both are effective in early and late stages of Parkinson's disease.

Indications

Both ergot and nonergot NDDRAs are used to treat various stages of Parkinson's disease, either alone or in combination with other drugs. Bromocriptine also inhibits the production of the hormone *prolactin,* which stimulates normal lactation. For this reason, it is used to treat women with excessive or undesired breast milk production *(galactorrhea)* and is also used for treatment of prolactin-secreting tumors. Ropinirole is also used to treat a disorder known as *restless legs syndrome,* a nocturnal movement of the legs that disrupts sleep.

Contraindications

Known allergy is a contraindication to dopaminergic drug therapy. These drugs are not to be used concurrently with adrenergic drugs (see Chapter 18) due to the cardiovascular risks of excessive catecholamine activity.

Adverse Effects

Many potential adverse effects are associated with the dopaminergic drugs. They are listed in Table 15-3.

Interactions

Interactions vary among drugs and are listed in Table 15-4.

Dosages

For dosage information, see the table on p. 242.

DRUG PROFILES

The traditional role of the NDDRAs bromocriptine, pramipexole, and ropinirole has been as adjuncts to levodopa for management of motor fluctuations; however, they are now often used as first-line therapy. These drugs differ from levodopa in that they do not replace dopamine itself but act by stimulation of dopaminergic receptors in the brain. They have been used as initial monotherapy and as combination therapy with low-dose levodopa in an attempt to either delay levodopa therapy or reduce the dosage of levodopa and its associated motor complications (see drug profile for levodopa).

bromocriptine

Bromocriptine stimulates only the D_2 receptors and antagonizes the D_1 receptors. Eventually, carbidopa-levodopa is

needed to control the patient's symptoms. Using amantadine or a nondopamine agonist until it fails may postpone the need for levodopa therapy for up to 3 years. Bromocriptine may also be given with carbidopa-levodopa so that lower dosages of the levodopa are needed. This often results in prolonging the "on" periods and minimizing the "off" periods of the disease. Bromocriptine is indicated for Parkinson's disease as well as hyperprolactinemia. Bromocriptine is contraindicated in cases of known drug allergy to any ergot alkaloids. It is also contraindicated in patients with severe ischemic disease of any kind (e.g., peripheral vascular disease) due to the ability of bromocriptine to stimulate dopamine receptors in the peripheral tissues outside of the brain. This can result in vasoconstriction, which can worsen peripheral vascular disease. Adverse reactions include GI upset, dyskinesias, sleep disturbances, and others as listed in Table 15-3. Drug interactions occur with erythromycin (see Chapter 38) and adrenergic drugs (see Chapter 18). Drug interactions are listed in Table 15-4. Bromocriptine is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	0.5-1.5 hr	1-3 hr	3-5 hr	4-8 hr

♦ ropinirole

Ropinirole (Requip) is a nonergot NDDRA. A similar drug is pramipexole (Mirapex). These nonergot drugs have a better adverse effects profile (e.g., fewer dyskinesias) than bromocriptine. Ropinirole is more specific than bromocriptine for the D_2 subfamily of dopamine receptors (D_2, D_3, and D_4). This in turn results in more specific antiparkinson effects with fewer of the adverse effects associated with more generalized dopaminergic stimulation. Ropinirole can be effective in both early- and late-stage Parkinson's disease and appears to delay the need for levodopa therapy. Ropinirole is indicated for both monotherapy and adjunctive therapy with levodopa. It is also approved by the FDA for moderate to severe primary restless legs syndrome. The drug is contraindicated in patients with known drug allergy. Adverse effects include dizziness, GI upset, and somnolence (see Table 15-3). Drug interactions occur with any drug metabolized by cytochrome P-450 enzyme 1A2 (e.g., warfarin, ciprofloxacin) (see Table 15-4). Ropinirole is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30 min	1-2 hr	3-5 hr	6-10 hr

DOPAMINE REPLACEMENT DRUGS

The traditional cornerstone of therapy for Parkinson's disease has been with the drug levodopa. It is a biologic precursor of dopamine required by the brain for dopamine synthesis. However, levodopa cannot be used by itself in the brain and must be combined with another substance, carbidopa. The combination product carbidopa-levodopa provides **exogenous** sources of dopamine that directly replace dopamine in the substantia nigra. These drugs are thus classified as *dopamine replacement* drugs and are drugs of choice in the later stages of Parkinson's disease.

Mechanism of Action and Drug Effects

Dopamine replacement drugs stimulate presynaptic dopamine receptors to increase brain levels of dopamine. Dopamine must be administered orally as levodopa, because exogenously administered dopamine cannot pass through the blood-brain barrier. Levodopa is the biologic precursor of dopamine and can penetrate into the CNS.

Levodopa is given in combination with carbidopa. Very large oral doses of levodopa are required to obtain adequate dopamine replacement, because much of the levodopa administered is broken down outside the CNS by the enzyme dopa decarboxylase. Large doses result in high peripheral levels of dopamine and lead to many unwanted adverse effects (see Table 15-3). These adverse effects include confusion, involuntary movements, GI distress, hypotension, and even cardiac dysrhythmias. These problems may be avoided when levodopa is given with carbidopa. Carbidopa is a peripheral decarboxylase inhibitor with little or no pharmacologic activity when given alone. When given in combination with levodopa, carbidopa inhibits the breakdown of levodopa in the periphery and thus allows smaller doses of levodopa to be used. Lesser amounts of levodopa result in fewer unwanted adverse effects.

Indications

Dopamine replacement drugs are used to directly restore dopaminergic activity in Parkinson's disease. Dopamine itself is also given by injection in critical care settings (see Chapter 18) as a pressor drug to raise blood pressure and enhance renal perfusion.

Contraindications

Levodopa and carbidopa are both contraindicated in cases of angle-closure glaucoma, because they can raise intraocular pressure. However, they may be used cautiously in patients with open-angle glaucoma (see Chapter 57). Neither drug is to be used in patients with any undiagnosed skin condition, because both drugs can activate malignant melanoma.

Adverse Effects

Adverse effects of dopamine replacement drugs include cardiac dysrhythmias, hypotension, chorea, muscle cramps, and GI distress (see Table 15-3).

Interactions

A possible drug interaction can occur with pyridoxine (vitamin B_6). Other interactions are listed in Table 15-4.

DRUG PROFILE

♦ carbidopa-levodopa

Carbidopa-levodopa (Sinemet), available orally, is one of the most commonly used drugs for Parkinson's disease. Carbidopa (Lodosyn) alone is not used as therapy, rather as an adjunct to treat nausea associated with Sinemet. A variety of studies have shown that the controlled-release product Sinemet CR (or generic) increases "on" time and decreases "off" time. As with all sustained-release products, Sinemet CR must not be crushed; however, it can be split one time, unlike most other CR or XR drugs on the market. Drug interactions occur with tricyclic antidepressants and other drugs (see Table 15-4). A possible drug interaction may occur with pyridoxine (vitamin B_6). Pyridoxine reduces the effectiveness of carbidopa-levodopa; however, the dose can usually be adjusted to overcome this interaction. See the nursing implementation section for discussion of the possible interaction of carbidopa-levodopa with dietary protein. Carbidopa-levodopa is best taken on an empty stomach; however, to minimize GI side effects, it can be taken with food.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2-3 wk*	0.5-2 hr	1.5 hr	5 hr

*Therapeutic effect.

ANTICHOLINERGIC DRUGS

Anticholinergic drugs block the effects of the neurotransmitter acetylcholine at cholinergic receptors in the brain as well as in the rest of the body. They are discussed in greater detail in Chapter 21. Anticholinergics are used as adjunct drug therapy in Parkinson's disease due to their anti-tremor properties. The purpose of their use is to reduce excessive cholinergic activity in the brain. Accumulation of acetylcholine in Parkinson's disease causes an overstimulation of the cholinergic excitatory pathways, which results in tremors and muscle rigidity. Cogwheel rigidity is an example and is defined as resistance to passive movement. It can be observed when an arm that is flexed toward the body is then extended at the elbow. Muscle tremors are usually worse when the patient is at rest and consist of a pill-rolling movement and bobbing of the head. Anticholinergic drugs help to alleviate these bothersome and often disabling symptoms. However, anticholinergics do little to relieve the *bradykinesia* (extremely slow movements) that is also associated with Parkinson's disease.

Acetylcholine is responsible for causing increased *s*alivation, *l*acrimation (tearing of the eyes), *u*rination, *d*iarrhea, increased GI motility, and possibly *e*mesis (vomiting). The acronym *SLUDGE* is often used to describe these cholinergic effects. Anticholinergics have the opposite effects. They can cause dry mouth or decreased salivation, urinary retention, decreased GI motility (constipation), dilated pupils (mydriasis), and smooth muscle relaxation. Anticholinergic drugs readily cross the blood-brain barrier and therefore can get to the site of Parkinson's disease pathology in the brain, the substantia nigra.

Historically, the anticholinergic drugs atropine and scopolamine were used. However, the anticholinergic adverse effects of dry mouth, urinary retention, and blurred vision associated with these original anticholinergics can be excessive. Therefore, synthetic anticholinergics were developed that have better adverse effect profiles. The anticholinergics most commonly used include benztropine (Cogentin) and trihexyphenidyl (generic only; formerly Artane). Antihistamines (see Chapter 36) also have significant anticholinergic properties; they can also be used to manage cholinergic symptoms in Parkinson's disease. The most common choice is the drug diphenhydramine (Benadryl). Anticholinergics must be used cautiously in older adults because of significant potential adverse effects such as confusion, urinary retention, visual blurring, palpitations, and increased intraocular pressure.

DRUG PROFILE

♦ benztropine mesylate

Benztropine (Cogentin) is an anticholinergic drug used for Parkinson's disease and also for extrapyramidal symptoms from antipsychotic drugs (see Chapter 16). Benztropine is to be used with caution in hot weather or during exercise because it may cause hyperthermia. Other adverse effects include tachycardia, confusion, disorientation, toxic psychosis, urinary retention, dry throat, constipation, nausea, and vomiting. Anticholinergic syndrome can occur when it is given with other drugs such as amantadine, phenothiazine, or tricyclic antidepressants that are associated with a high incidence of anticholinergic effects. Alcohol is to be avoided. Benztropine is available as tablets and in injectable form. The normal dosage is 0.5 to 6 mg/day in one or two divided doses.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	2-4 hr	4-8 hr	6-10 hr

NURSING PROCESS

ASSESSMENT

After patients are confronted with the diagnosis of Parkinson's disease, they soon experience the impact of the disease with every movement and activity of daily living. Not only will their lives never be the same, they will soon learn that their quality of life depends on drug therapy and nondrug measures. Before medications for Parkinson's disease are given, assess and document vital signs (e.g., blood pressure, pulse, respirations, temperature, pain) and ABCs (airway, breathing, and circulation). In addition, obtain a complete nursing history with a thorough physical assessment, including compiling a comprehensive medication profile. Because it may take several weeks to see a therapeutic response to medication regimens, a keen assessment and careful patient monitoring are even more critical to quality nursing care. A thorough assessment includes a health history, review of systems, and determination of sensory and motor abilities. Also gather the following information: complaint(s) upon admission or the symptom(s)/event that led the patient to obtain medical treatment; past and current medical history with

a focus on the presence or absence of head injury, seizures, diabetes, hypertension, heart disease, and/or cancer; family history of any neuromuscular or neurologic disorders, heart disease, diabetes, cancer, seizures, cerebrovascular accident (stroke), and/or Parkinson's disease. Additionally, complete a thorough systems assessment with gathering of subjective and objective information in the following areas as related to the possible impact of Parkinson's disease:

- *Central nervous system*—Inquire about any headaches, fatigue, weakness, paralysis, dizziness, and/or syncope. Note any changes in walking or mobility, increase in rigidity or muscle movements, and/or changes in the ability to carry out activities of daily living. Also important are any changes in sensation in the extremities, changes in vision or hearing, loss of or changes in coordination, changes in gait and balance, and/or any changes in energy level. Also include questions about any changes in baseline levels of alertness; changes in memory (short-term or long-term); blackouts or seizures; numbness, tingling, or abnormal sensations in the extremities; changes in mood; changes in muscle movement or strength (e.g., paralysis) or voluntary versus involuntary motor control; and any muscle rigidity or tremors. Assess response to stimuli, and assess pupils with attention to size, shape, response to light, and symmetry (in reactions). Assess deep tendon reflexes with attention to strength bilaterally. Observe and document the patient's ability to walk, his or her gait, and upper/lower, left/right extremity strength. Also assess and document ability to feed self and carry out activities of daily living.
- *Genitourinary and gastrointestinal systems*—Perform a general survey of the abdominal area with inspection, auscultation of bowel sounds, and palpation for any distention or tenderness. Determine daily baseline urinary and bowel patterns with attention to any changes in or loss of control of bladder or bowel functioning as well as the patient's ability to engage in toileting activities. Inquire about the need for assistance with these daily functions. Ask the patient about any difficulty in swallowing (dysphagia) and any problems in feeding self or preparing meals. If such difficulties are identified, assess further for any subsequent nutritional excesses or deficits.
- *Skin and oral mucus membranes*—Assess the skin's color, texture, turgor, and fragility, and note any breaks in the skin, bruises, lesions, masses, and/or swelling. Also document color and moisture of the oral cavity and mucus membranes.
- *Respiratory system*—Focus attention on respiratory rate, rhythm, depth, effort, and breath sounds.
- *Psychological and emotional status*—Assess the patient for any recent or past changes in mood, affect, or personality. Also note any other disease-related concerns such as depression, emotional ups and downs, increase in irritability, social withdrawal, or changes in sexual functioning or intimacy.
- *Functional abilities*—Inquire about any changes in everyday function in the patient's personal and/or professional life. Assess and note any changes in daily task performance at the place of employment or need to take sick leave or sick days, as well as the patient's ability to exercise, drive, and/or shop for groceries and other necessities.

With *indirect-acting dopamine receptor agonists,* such as amantadine, and *direct-acting dopamine receptor agonists,* such as carbidopa-levodopa, and ropinirole, include in your assessment vital signs with supine and standing blood pressures (because of drug-related postural hypotension), height, weight, medication and medical history, and nursing history. Include family, significant others, and/or caregiver in the assessment and data collection process. Note contraindications, cautions, and drug interactions prior to administering these drugs (see previous pharmacology discussion). Assess motor skills, including abilities and deficiencies, and for the presence of akinesia, bradykinesia, postural instability, rigidity, tremors, staggering gait, or drooling (see Key Terms and Table 15-1). Assessment of urinary patterns is also important because of the possibility of drug-induced urinary retention. If BUN and creatinine measurements are ordered, the results need to be routinely examined because these values are indicators of renal function. Alkaline phosphatase levels are indicators of liver function and also need to be assessed, if ordered. These laboratory values are important to determine in patients with decreased renal or liver function so that dosage amounts of antiparkinson drugs may be altered by the prescriber.

As related to lifespan considerations, it is important to understand the gynecologic history of the patient and to know if the patient is pregnant and/or lactating. Some of the *dopamine replacement drugs* cross into the placenta and into breast milk and have unknown actions in the pediatric patient. Drug interactions related to these drugs are presented in Table 15-4. See Table 15-3 for a listing of selected antiparkinson drugs and their related classifications and subclassifications.

When *anticholinergic drugs* are prescribed, assess the patient carefully to determine gross level of organ functioning—especially in those systems most affected by Parkinson's disease, including the GI, genitourinary, visual, cardiac, and neurologic systems. Assess mental status, and pay close attention to any present or past changes as well as the presence of confusion, disorientation, or psychotic-like behavior. This is important to consider in elderly patients because of decline in liver function and a subsequent higher risk for adverse effects and possible toxicity (with antiparkinson drugs and drugs in general) and an overall increased sensitivity to the effects of drugs (see Chapter 3). Cautions, contraindications, and drug interactions have been previously discussed.

For the *indirect-acting dopamine receptor agonist drugs (subclass of presynaptic dopamine release enhancers)* that are also antiviral (e.g., amantadine), the previously discussed baseline and general assessment information is also applicable. The patient's knowledge of the drug's use for Parkinson's disease (versus its use as an antiviral) and awareness that its onset of action will be delayed for several days or longer needs to be confirmed. Continual assessment of the patient's status and improvement of disease-related symptoms is important, because a decline in this drug's effectiveness (specifically a failure in the ability to control hypokinesia and rigidity of Parkinson's) may occur within

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

Antiparkinson Drugs

- Carbidopa-levodopa must be used cautiously and with close monitoring in elderly patients, especially those with a history of cardiac, renal, hepatic, endocrine, pulmonary, ulcer, or psychiatric disease.
- Elderly patients taking carbidopa-levodopa are at an increased risk for experiencing adverse effects, especially confusion, loss of appetite, and orthostatic hypotension.
- Carbidopa-levodopa is often started at a low dose because of the increased sensitivity of older patients to these medications and the need to save higher dosages for a later time during treatment.
- Overheating is a problem in patients taking anticholinergics, and so elderly patients taking these drugs must avoid excessive exercise during warm weather and excessive heat exposure.
- One of the main problems with the long-term use of carbidopa-levodopa is that its duration of effectiveness decreases over time; this is even more problematic in elderly patients. Catechol ortho-methyltransferase (COMT) inhibitors hold much promise for elderly patients who are experiencing the wearing-off phenomenon; they help turn "off" times into "on" times so that the drug begins to work throughout the day.

6 to 12 months after initiation of therapy. If amantadine (also a prolactin inhibitor) is prescribed, the nurse must understand that this drug is also used for suppression of lactation and must assess for the appropriateness of its use. Patients taking these drugs also require additional CNS assessment because of the possible adverse effects of dizziness, headache, insomnia, and anxiety. Also, if the patient is taking this medication long term, assessment for orthostatic hypotension and dizziness is crucial to patient safety.

The antiparkinson drugs classified as *indirect-acting dopamine receptor agonists (subclass of MAO-B inhibitors),* such as selegiline, require assessment of many of the same parameters discussed earlier. In addition, however, cardiac status is important to assess and document because of the possible adverse effects of hypotension/hypertension and chest pain. Assessment of dosing is also important because, as with other antiparkinson drugs, a low dose is used initially with gradual increases over approximately a 3- to 4-week period. The lowest possible dose is recommended for initiation of therapy so that plenty of room exists for further increases in dosing as the disease progresses. These drugs also require careful neurologic assessment due to drug-adverse effects of depression, hallucinations, ataxia, and agitation (see Table 15-3).

For the *indirect-acting dopamine receptor agonist-COMT inhibitors* (e.g., entacapone and tolcapone), assessment of baseline vital signs is also required, with a focus on standing and supine blood pressure because of the adverse effects of orthostatic hypotension and syncope. In fact, these adverse effects occur more frequently with the COMT inhibitors than with the other antiparkinson drugs, and thus increased caution and concern is needed. Assessment of dosing time is also important because if these drugs are not given 1 hour before or 2 hours after meals, the bioavailability of the drug may be adversely affected. Assess serum transaminase levels before and during drug therapy with tolcapone due to the adverse effect of liver failure. If the patient's ALT level is elevated to the upper range of normal or higher, the prescriber will most likely discontinue the drug because of the increased risk of hepatic failure.

NURSING DIAGNOSES

1. Urinary retention related to the pathophysiologic effects of the disease process on the bladder with incomplete emptying
2. Constipation related to decreased GI peristalsis associated with the disease process
3. Imbalanced nutrition, less than body requirements, related to the disease process as well as adverse effects of drug therapy
4. Impaired physical mobility related to the disease process and adverse effects of the various antiparkinson medications
5. Disturbed body image related to changes in appearance and mobility due to the disease process
6. Deficient knowledge related to lack of exposure to and experience with a complex and long-term treatment regimen
7. Risk for injury related to the physical limitations and changes in mobility, gait, balance, and coordination produced by the disease process

PLANNING

GOALS

1. Patient regains as normal as possible bladder elimination patterns.
2. Patient maintains as normal as possible bowel elimination patterns.
3. Patient maintains adequate and balanced nutritional status.
4. Patient is able to maintain safe mobility and activities of daily living.
5. Patient maintains a positive self-image and body image.
6. Patient demonstrates adequate knowledge and comprehension about the illness, medication therapy, and drug-related adverse and toxic effects.
7. Patient remains free from injury and self harm.

OUTCOME CRITERIA

1. Patient discusses ways to minimize problems associated with drug-induced alterations in bladder elimination patterns (retention) such as forcing fluids, taking medications as prescribed, attempting to empty the bladder at regular intervals, and reporting any unresolved urinary problems.
2. Patient implements various measures to decrease constipation such as increasing bulk and fiber in the diet with fruits and vegetables, forcing fluids, and remaining as active as possible.
3. Patient states the importance and gives examples of daily menus for increased dietary protein, increased intake from the major food groups divided in six small frequent meals, and use of nutritional supplements and vitamins.

4. Patient participates in daily care with use of assistive devices, as appropriate, as well as walking/ambulating.
   - Patient removes any barriers to safe mobility in the home environment and uses handrails throughout the home
   - Patient maintains mobility with the use of active/passive range-of-motion exercises or through use of physical and/or occupational therapy resources at home.
5. Patient openly verbalizes fears, anxieties, and changes in self-image with members of the health care team, supportive staff, family, and support groups.
6. Patient (and family, significant others, and/or caregiver) openly discusses impact of the disease process on relationships, daily activities, future activities; the lifelong need for daily medication; and monitoring for adverse and toxic effects (e.g., dizziness, nausea, vomiting, GI upset, and palpitations).
   - Patient states purposes of medication therapy such as decrease in symptoms of Parkinson's, improved comfort, improved activities of daily living, increase in nutritional status.
   - Patient states information for point of contact with prescriber and symptoms to report such as dry mouth, unresolved nausea/vomiting, fainting, loss of appetite.
7. Patient (and family, significant others, and/or caregiver) describes ways of preventing self-injury, such as the use of assistive devices, removing throw rugs, use of night lights, and handrail placement throughout the home.

CASE STUDY

Drugs for Parkinson's Disease

Ben, a 62-year-old retired contractor, is undergoing surgery to repair an umbilical hernia. He has had Parkinson's disease for 5 years and is currently taking carbidopa-levodopa (Sinemet CR) and selegiline (Eldepryl). Other than the Parkinson's disease, he has no health problems. He has enjoyed fairly good control up until this week but is now experiencing more "bad times," as he calls them.

1. Patients who are taking long-term levodopa treatment often experience an "on-off" phenomenon in symptoms. Explain the physiology behind this phenomenon.
2. Explain the reason for giving selegiline along with the carbidopa-levodopa.

Ben undergoes the surgery without any difficulties, and the following medication orders are noted on the chart:

Continue previous orders for carbidopa-levodopa (Sinemet CR) 1 tablet bid and selegiline (Eldepryl) 5 mg bid (taken with the Sinemet CR)
Meperidine (Demerol) 10 mg IV every 4 hours as needed for pain
Ondansetron (Zofran) 4 mg IV one time if needed for nausea
Begin entacapone (Comtan) 200 mg bid with each dose of Sinemet

3. Are there any concerns regarding drug interactions? Explain your answer.
4. What is the purpose of the entacapone?
5. Before administering the entacapone, the nurse reviews Ben's history for any potential contraindications. What condition(s) would be a potential contraindication to entacapone?

IV, Intravenous.
For answers, see http://evolve.elsevier.com/Lilley.

IMPLEMENTATION

Nursing interventions associated with the various antiparkinson drugs will vary somewhat depending on the drug class, but close monitoring and comprehensive patient education are required for all of these drugs. With the onset of drug therapy, encourage patients, family, or caregivers to begin keeping a daily drug calendar or journal with entries including the drugs prescribed, dosage, frequency/timing, therapeutic changes, and adverse effects. During the start of *dopaminergic replacement drug* therapy, the patient will most likely need assistance when walking because of the dizziness and possible syncope caused by these drugs. Doses are given several hours before bedtime to decrease the incidence of insomnia, a known adverse effect of these drugs. Oral doses are given with food to help minimize GI upset. Interaction of vitamin B_6 (pyridoxine) with levodopa was once a major concern because this vitamin was found to block the uptake of plain levodopa. However, a majority of patients taking a carbidopa-levodopa combination drug were found to have no problems with vitamin B_6. The National Parkinson's Disease Foundation (available at www.pdf.org) reports that only patients who are very sensitive to the effects of any of these drugs will have problems with vitamin B_6. If it is a problem, the prescriber needs to be consulted for further instructions (see p. 246). In addition, amino acids from dietary protein may interfere with the uptake of levodopa in the brain. While taking carbidopa-levodopa, the patient may continue to eat high-protein foods (e.g., meat, fish, poultry, and dairy products) but use portion control (meat portion about the size of a deck of cards) and take the drug dose one-half hour before a protein-containing meal. Timing is the issue, not the quantity of protein consumed over the course of the day. A nutritional consult may be beneficial to assist the patient in menu planning. A nutritionist may also be helpful in teaching the patient about how to divide the total quantity of protein among small frequent meals so that minimal amounts of protein are ingested throughout the day and are consumed at the proper time. Consumption of well-balanced meals is important, as is increasing fluids. Patients need to aim at drinking at least 3000 mL/day unless contraindicated. Drinking water is important, even if the patient is not thirsty or in need of hydration, to prevent and manage the adverse effect of constipation. Encourage the intake of foods that are natural laxatives, such as prunes, vegetables, and other foods high in fiber. If the adverse effect of dry mouth is problematic, taking fluids and sucking on hard candy or lozenges may be helpful. If nausea or vomiting occurs or problems with edema are persistent (the patient gains 2 pounds or more in 24 hours or 5 pounds or more in 1 week), the prescriber needs to be contacted immediately.

With *anticholinergic drugs,* patients need to take the medication as prescribed, after meals or at bedtime and not at the same time as with other medications. Patients also need to know that it may take a few days to several weeks for the drugs to show their therapeutic effectiveness (e.g., improvement in tremors). Because of the risk of stomach upset (i.e., nausea, vomiting), it is recommended that these drugs be taken with a snack, such as ginger ale and crackers. These medications are generally taken

at night because of their sedating properties. Measures to help prevent and treat dry mouth are encouraged, such as increasing fluids and sucking on sugar-free hard candies. See Chapter 21 for further information about the use of these drugs, interventions, and adverse effects to report. *Bromocriptine* is to be taken as prescribed and not abruptly stopped. Because this drug may cause GI upset, it is best taken with a snack. Any severe dizziness, GI upset, ataxia, excess drowsiness, or visual changes must be reported immediately.

MAO-B inhibitors, such as selegiline, are to be given exactly as ordered. Selegiline is often given in upwardly titrated dosages while carbidopa-levodopa dose amounts are decreased. Place oral disintegrating dosage forms on the tongue, and do not swallow dosage form until it is completely melted. This dosage form is to be taken without liquids and given in the morning before breakfast. Foods and fluids are not to be consumed for 5 minutes before or after the drug is taken. Postural hypotension may be a transient problem, and so the patient needs to move and change positions slowly and purposely. If dizziness is severe or if the patient experiences hallucinations, the prescriber needs to be contacted for further instructions.

The newer *COMT inhibitors* have been shown to have greater efficacy in patients with advanced forms of Parkinson's disease. After treatment using the various dosage forms of levodopa or carbidopa-levodopa, a COMT inhibitor may then be added to the therapeutic regimen. Onset of therapeutic effects is rapid. These drugs are to be administered as prescribed and may be taken without regard to meals or food. These and other antiparkinson drugs are never to be discontinued abruptly and require a gradual weaning period to avoid worsening of Parkinson's disease or other dangerous effects. Emphasize to patients and caregivers that all appointments with the prescriber must be kept and all laboratory testing performed, as ordered. Patients need to also understand the importance of changing positions slowly and with purpose to avoid syncope due to drug-related orthostatic hypotension. Inform patients that entacapone may turn their urine brownish orange but that this is not harmful. As with all medications, patients must keep on their person a written list of prescription drugs, over-the-counter drugs, vitamins, minerals, and herbal therapies they are taking at all times. This list of medications needs updating frequently and should be taken each time the prescriber is visited and/or the patient is hospitalized. This allows continuity of information with health care providers and helps to prevent errors or omission of medications. Encourage patients to report to the prescriber any back and/or abdominal pain (especially in the right upper quadrant), bruising, or jaundice as these may be indicative of liver dysfunction associated with tolcapone (see Table 15-3).

It is most important in the care of patients with Parkinson's disease to be aware of all other forms of therapies that may be beneficial, such as support groups, water aerobics, and occupational and physical therapy. Some community resources that are available are community-wide recreation facilities, transportation services, and Meals on Wheels. Educational materials and emotional support resources need to be made available and shared with family members, caregivers, and significant others because of the long-term and progressive nature of the disease. Contacting research institutes about new treatment protocols may be a viable option for patients and family members during the course of the disease. See Patient Teaching Tips for more specific information.

EVALUATION

Monitoring the patient's response to any of the *antiparkinson drugs* is crucial to documenting treatment success or failure. Therapeutic responses to the antiparkinson drugs include an improved sense of well-being, improved mental status, increased appetite, ability to perform activities of daily living, improved concentration and ability to think more clearly, and a decrease in the intensity of parkinsonian symptoms (e.g., less tremor, shuffling of gait, and muscle rigidity, and fewer involuntary movements). In addition to monitoring for therapeutic responses, also monitor for adverse effects such as dizziness, hallucinations, nausea, insomnia (associated with *indirect-acting dopamine receptor agoninsts* such as selegiline, amantadine, entacapone, and tolcapone), ataxia, depression (associated with *direct-acting dopamine receptor agonists* such as bromocriptine and *dopamine replacement drugs* such as levodopa and carbidopa), palpitations, hypotension, and urinary retention. Patients need to understand the importance of immediately reporting to their prescriber any of the following signs and symptoms indicating possible overdose: excessive twitching, drooling, or eye spasms. Therapeutic effects of *COMT inhibitors* (e.g., entacapone) may be noticed within a few days, whereas therapeutic effects of other antiparkinson drugs may take weeks to manifest. Adverse effects for which to monitor with COMT inhibitors include those mentioned previously, but fewer dyskinesias are seen than with dopamine agonists.

PATIENT TEACHING TIPS

- All medications must be taken exactly as ordered. Around-the-clock dosing is usually prescribed to achieve steady blood levels, especially with dopamine agonists.
- Some patients will be allowed a certain amount of freedom in the dosing of their medications depending on their individual needs. An example is when a patient is traveling or attending a function where an extra dose of medication may be indicated/needed to help with movement disorder.
- Alcohol, over-the-counter drugs, and herbals are to be avoided unless approved by the prescriber.
- Emphasize the importance of taking the medication as prescribed and not quitting the medication. It is important for the patient/family/caregiver to understand that medication(s) must be taken at the dosage and time prescribed. Inability to adhere to or remain compliant may lead to exacerbation of symptoms and development of complications. Missing a dose by even 30 minutes may lead to an "off" period and last hours.

PATIENT TEACHING TIPS—cont'd

- If the patient misses a dose of medication, the prescriber must be notified for further instructions. Some prescribers tell patients initially that if they miss a dose to take it as soon as they remember, and if it is close to the next dose time, then to skip the missed dose and take the next dose.
- If experiencing postural hypotension, the patient needs to understand the rationale for changing positions slowly and the need to increase fluids and wear compression stockings, unless contraindicated. If the patient has a history of congestive heart failure, fluid intake must be done very cautiously.
- Sustained-released drug forms are not to be crushed, chewed, or altered in any way. The drug is to be taken in its whole form. The exception to this standard of care is with Sinemet CR, which may be split only once and is available in scored dosage form for this reason (see pharmacology discussion).
- With anticholinergics, warn the patient about the adverse effect of dry mouth. Use of artificial saliva drops/gum, frequent mouth care, fluids, and sucking on sugarless gum or hard candy may be helpful.
- Inform the patient that urine color may darken if taking entacapone and that this adverse effect is harmless.
- Encourage the patient to report any change in vision (e.g., blurring), decline in mental alertness, confusion, or lethargy experienced while taking any of the antiparkinson drugs. Any difficulty with urination, irregular pulse rate, or severe, uncontrolled movements of the arms or legs must also be reported.
- The patient and family must understand that some antiparkinson drugs are often titrated to the patient's response and that it may take 3 to 4 weeks for a therapeutic response to become evident.
- The nonergot drug ropinirole may result in drowsiness, fatigue, and syncope. Emphasis on safety and how to handle these adverse effects is important.
- Fluids and dietary fiber must be increased to help prevent constipation associated with the disease process. Constipation is also an adverse effect of drug therapy.
- Inform the patient that the COMT inhibitors entacapone and tolcapone need to be taken with food, meals, or a snack to minimize GI upset. Other instructions with the use of entacapone include reporting any signs and symptoms of possible liver dysfunction such as jaundice and back or abdominal pain.
- Any abnormal contractions of the head, neck, or trunk, as well as any syncope, falls, itching, and/or jaundice must be reported immediately to the prescriber.
- Educate the patient about the goal of therapy, especially if entacapone is being used to help manage the wearing-off phenomenon. The wearing-off phenomenon is a waning of the effects of a dose of levodopa before the scheduled time of the next dose, resulting in diminished motor ability and the experience of more disease symptoms. If a COMT inhibitor is added to carbidopa-levodopa, the wearing-off phenomenon is minimized, and the therapeutic effects of the regimen are maximized. The patient can then expect that the "off" time will be minimized and that the drugs will work throughout the day, which is the goal in the treatment of Parkinson's disease.

KEY POINTS

- The neurotransmission-related abnormalities in Parkinson's disease include the chronic, progressive degeneration of dopamine-producing neurons in the brain. Patients with this disease also have elevated acetylcholine levels and lowered dopamine levels.
- Signs and symptoms of this disease process include bradykinesia (slow movements), muscle rigidity (cogwheel rigidity), tremor (pill rolling), postural instability, and dystonias (abnormal muscle tone in any tissue).
- Dyskinesias occur as adverse effects of some of the antiparkinson drugs. Dyskinesias include motor difficulties while performing voluntary movements.
- Drugs used in the treatment of Parkinson's disease include amantadine, benztropine, bromocriptine, carbidopa-levodopa, entacapone, ropinirole, and selegiline.
- Patient considerations include providing individual and family support along with options for care of the family member with Parkinson's disease. The disease is long-term and lifelong, as well as debilitating. A holistic approach in which all aspects of the patient and family are considered and respected is the key to quality nursing care.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 Which condition will alert the nurse to a potential caution or contraindication regarding the use of a dopaminergic drug for treatment of mild Parkinson's disease?
- **a** Diarrhea
- **b** Tremors
- **c** Angle-closure glaucoma
- **d** Unstable gait

2 A patient is taking entacapone (Comtan) as part of the therapy for Parkinson's disease. Which intervention by the nurse is appropriate at this time?
- **a** Notify the patient that this drug causes discoloration of the urine.
- **b** Limit the patient's intake of tyramine-containing foods.
- **c** Monitor results of renal studies because this drug can seriously affect renal function.
- **d** Force fluids to prevent dehydration.

3 During a patient teaching session about antiparkinson drugs, the nurse will include which statement?
- **a** "The drug will be stopped when tremors and weakness are relieved."
- **b** "If a dose is missed, take two doses to avoid significant decreases in blood levels."
- **c** "Be sure to notify your physician if your urine turns brownish-orange in color."
- **d** "Take care to change positions slowly to prevent falling due to a drop in blood pressure."

4 A patient will be taking selegiline (Eldepryl), 10 mg daily, in addition to dopamine replacement therapy for Parkinson's disease. The nurse will implement which precautions regarding selegiline?
- **a** Teach the patient to avoid foods containing tyramine.
- **b** Monitor for dizziness.
- **c** Inform the patient that this drug may cause urine discoloration.
- **d** Monitor for tachycardia and palpitations.

5 A patient with Parkinson's disease will start taking entacapone (Comtan) along with the carbidopa-levodopa (Sinemet) he has been taking for a few years. The nurse recognizes that the advantage of taking entacapone is that
- **a** the entacapone can reduce on-off effects.
- **b** the levodopa may be stopped in a few days.
- **c** there is less GI upset with entacapone.
- **d** it does not cause the cheese effect.

6 The nurse is assessing a patient who has begun therapy with amantadine (Symmetrel) for Parkinson's disease. The nurse will look for which possible adverse effects? (Select all that apply.)
- **a** Nausea
- **b** Palpitations
- **c** Dizziness
- **d** Insomnia
- **e** Edema

7 The order reads: bromocriptine (Parlodel) 10 mg per day PO. The medication is available in 2.5-mg tablets. How many tablets will the nurse give per dose?

1. c, 2. a, 3. d, 4. b, 5. a, 6. a, c, d, 7. 4 tablets

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Briefly discuss the various mental illnesses.
2 Identify the various psychotherapeutic drug classes, such as anxiolytic drugs, antidepressants, mood-stabilizing drugs, and antipsychotics.
3 Discuss the mechanisms of action, indications, therapeutic effects, adverse effects, toxic effects, drug interactions, contraindications, and cautions associated with the various psychotherapeutic drugs.
4 Develop a nursing care plan that includes all phases of the nursing process for patients taking psychotherapeutic drugs.
5 Develop patient education guidelines for patients taking psychotherapeutic drugs.

KEY TERMS

Affective disorders Emotional disorders that are characterized by changes in mood. (p. 255)

Agoraphobia An anxiety disorder that involves an intense fear of being in unfamiliar situations or places that may be difficult to leave or in which help may not be available in the event of having an unexpected panic attack or panic-like symptoms. (p. 255)

Akathisia A movement disorder in which there is an inability to sit still; motor restlessness. It can occur as an adverse effect of psychotropic medications. (p. 268)

Anxiety The unpleasant state of mind in which real or imagined dangers are anticipated and/or exaggerated. (p. 255)

Biogenic amine hypothesis A theory suggesting that depression and mania are caused by alterations in the concentrations of dopamine and norepinephrine, and serotonin and histamine in the brain. (p. 260)

Bipolar disorder A major psychological disorder characterized by episodes of *mania* or *hypomania,* cycling with depression; formerly called *manic-depressive illness*. (p. 255)

KEY TERMS—cont'd

Depression An abnormal emotional state characterized by exaggerated feelings of sadness, melancholy, dejection, worthlessness, emptiness, and hopelessness that impact the patient's life and may be out of proportion to reality. Signs include withdrawal from social contact, loss of appetite, and insomnia. (p. 255)

Dopamine hypothesis A theory suggesting that dopamine dysregulation in certain parts of the brain is one of the primary contributing factors to the development of psychotic disorders (psychoses). (p. 256)

Dyskinesia Term for abnormal and distressing involuntary movements; inability to control movements. (p. 268)

Dysregulation hypothesis A theory that views depression and affective disorders as caused not simply by decreased or increased catecholamine and serotonin activity but by failure of the brain to *regulate* the levels of these neurotransmitters. (p. 260)

Dystonia A syndrome of abnormal muscle contraction that produces repetitive involuntary twisting movements and abnormal posturing of the neck, face, trunk, and extremities; often caused as an adverse reaction to psychotropic medications. (p. 268)

Extrapyramidal symptoms The term for signs and symptoms that resemble pathologic changes to the *pyramidal* portions of the brain. Such symptoms include various motion disorders similar to those seen in Parkinson's disease, and are an adverse effect associated with use of various antipsychotic drugs. (p. 268)

Gamma-aminobutyric acid An amino acid in the brain that functions to inhibit nerve transmission in the central nervous system. (p. 255)

Hypomania A less severe and less potentially hazardous form of mania. (p. 255)

Mania An acute illness characterized by an expansive emotional state, including extreme excitement, elation, hyperactivity, agitation, talkativeness, flight of ideas, reduced attention span, increased psychomotor activity, impulsivity, insomnia, anorexia, and sometimes violent, destructive, and self-destructive behavior. (p. 255)

Metabolic syndrome A cluster of conditions (increased glucose level, increased blood pressure, abnormal cholesterol levels, excess body fat around the waist) occurring together that increases the risk of heart disease, stroke, and diabetes. (p. 269)

Neuroleptic malignant syndrome An uncommon but serious adverse effect associated with the use of antipsychotic drugs and characterized by symptoms such as fever, cardiovascular instability, and myoglobinemia (presence in the blood of muscle breakdown proteins). (p. 268)

Neurotransmitters Endogenous chemicals in the body that serve to conduct nerve impulses between nerve cells (neurons). (p. 254)

Permissive hypothesis A theory postulating that reduced concentrations of serotonin (5-hydroxytriptamine) is the predisposing factor in individuals with affective disorders. (p. 260)

Psychosis (Plural: *psychoses*) A type of serious mental illness that can take several different forms and is associated with being out of touch with reality; that is, the individual is unable to distinguish imaginary from real circumstances and events. (p. 255)

Psychotherapeutics The treatment of emotional and mental disorders. (p. 255)

Psychotropic Capable of affecting mental processes; usually said of a medication. (p. 256)

Serotonin syndrome A rare collection of symptoms resulting from elevated levels of the neurotransmitter *serotonin;* may occur with the use of any psychotropic drug (e.g., antidepressants, buspirone, tramadol) that enhances brain serotonin activity (see Box 16-1). (p. 265)

Stigma Widespread negative perceptions of and prejudice toward a specific group of people such as those with mental illness. (p. 255)

Tardive dyskinesia A serious drug adverse effect characterized by abnormal and distressing involuntary body movements and muscle tension that is associated with the use of antipsychotic medications. (p. 268)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

From time to time, most people experience the normal emotions of anxiety, depression, excitement, and grief. Many times such emotions are simply situational. They arise because of a specific event and subside with time. Treatment, if any, is often limited to psychotherapy, and possibly short-term drug therapy. However, longer-term pharmacotherapy in conjunction with psychotherapy is usually recommended when a person's emotions or behaviors compromise his or her quality of life, ability to carry out normal activities of daily living, social functioning (interactions and relationships with others), or occupational functioning (e.g., employment, school) over a prolonged period (at least several months).

The exact causes of mental disorders are not fully understood. There are many theories that attempt to explain the etiology and pathophysiology of mental dysfunction. In the biochemical imbalance theory, mental disorders are thought to arise as the result of abnormal levels of endogenous chemicals in the brain known as **neurotransmitters.** The conduction of messages between neurons (nerve cells) by neurotransmitters is called *neurotransmission*. This occurs in both the central nervous system (CNS) and the peripheral nervous system. The proposed mechanisms of both the pathology of and drug therapy for mental illness center around neurotransmission

within the brain. There is evidence indicating that the brain levels of catecholamines (especially dopamine and norepinephrine; see Chapter 18) and indolamines (serotonin and histamine) play an important role in maintaining mental health. Other biochemical substances necessary for the maintenance of normal mental function are the inhibitory neurotransmitter **gamma-aminobutyric acid,** the cholinergic neurotransmitter acetylcholine (see Chapter 20), and some inorganic ions such as sodium, potassium, and magnesium. Drugs used to treat mental illnesses, including anxiety, affective disorders, and psychoses, work by blocking or stimulating the release of various endogenous neurotransmitters.

The symptoms of the different psychiatric disorders often overlap, which can make them difficult to accurately diagnose. Complicating this issue further is the subjectivity of patients' experience of their symptoms. The *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, Text Revision *(DSM-IV-TR)* is a widely used reference published by the American Psychiatric Association. It presents demographic information and diagnostic criteria for recognized psychiatric disorders. Often a patient has ongoing symptoms that meet the criteria for several mental disorders. Such patients may be said to have a spectrum disorder. For example, research shows that more than half of chronically depressed adults also have a comorbid personality disorder, and one third have a comorbid anxiety disorder and/or a substance abuse disorder. The problem of comorbid substance abuse is especially troublesome. Usually, a patient must discontinue use of the abused substance(s) to have a chance at significant success in treating the concurrent psychiatric disorder. Unfortunately, this does not happen in the majority of patients.

Patients with mental illness may be more susceptible to various physical health problems than the general population. Obesity and tobacco use is significantly more common in patients with certain mental disorders. These patients are at greater risk for physical illnesses associated with obesity, including diabetes, hypertension, and heart disease. Economic, educational, and psychosocial issues may preclude a mentally ill person from seeking psychiatric health care. Thus, many patients self-medicate with substances of abuse, including alcohol, tobacco, and illegal or unauthorized prescription drugs. This compounds the problem of their baseline psychiatric illness.

Despite the development of newer, more effective treatments for mental illness, a longstanding societal **stigma** continues to be an obstacle for diagnosed patients. The National Alliance on Mental Illness (NAMI) is an organization that works to reduce this stigma. NAMI seeks to promote consumer well-being and autonomy through public education, research funding, and legislative advocacy.

The treatment of mental disorders is called **psychotherapeutics.** Ideal mental health care involves many components, including a carefully detailed patient interview (to help ensure accurate and complete diagnosis) and carefully chosen and regularly monitored drug therapy. Nonpharmacologic treatments include psychotherapy, support groups, social and family support systems, and often spiritual support systems. Other practices that promote mental health include physical exercise, good nutrition, and mental exercises such as meditation and visualization. In extreme cases, such as refractory depression, electroconvulsive therapy may be used.

This chapter focuses on three common types of mental illness: anxiety, affective, and psychotic disorders. The drugs used to treat anxiety are anxiolytics. Mood stabilizers and antidepressants are used to treat affective disorders, while antipsychotics are used to treat psychotic disorders.

Anxiety is the unpleasant state of mind characterized by a sense of dread and fear. It may be based on anticipated or past experiences. It may also stem from exaggerated responses to imaginary negative situations or to common everyday experiences. Persistent anxiety is divided clinically into several distinct disorders, including the following:

- Obsessive-compulsive disorder
- Posttraumatic stress disorder
- Generalized anxiety disorder
- Panic disorder with or without agoraphobia
- Social phobia (also called social anxiety disorder)
- Simple phobia

Anxiety is a normal reaction to stress; however, results of epidemiologic studies show that 5% to 8% of adults suffer from generalized anxiety disorder, 2.7% from panic disorder, 6.8% to 12% from posttraumatic stress disorder, and 3.8% from **agoraphobia** (the fear of being in unfamiliar situations or places). Obsessive-compulsive disorder is twice as common as schizophrenia or panic disorder in the general population. Anxiety may occur as a result of medical illnesses (e.g., cardiovascular or pulmonary disease, hypothyroidism, hyperthyroidism, pheochromocytoma, Cushing syndrome, and hypoglycemia).

Affective disorders, also called *mood disorders,* are characterized by changes in mood and range from **mania** (exaggerated emotions) to **depression** (fewer emotions or emotional range). Some patients may exhibit both mania and depression, experiencing periodic swings in emotions between these two extremes. This is referred to as **bipolar disorder. Hypomania** is a form of mania that is less severe and less potentially dangerous (to patient and others).

Bipolar disorder occurs in an estimated 2% of the population. Depression is currently reported to have prevalence rates ranging from 8% to 12%. Major depressive disorders are expected to become the second leading cause of disability by the year 2020. Common depressive symptoms include feelings of worthlessness, loss of interest in normally pleasurable activities, reduced energy level, reduced motivation and ability to meet routine responsibilities, drastic increase or decrease in appetite, insomnia or hypersomnia, and recurrent thoughts of death or suicide. In addition to being associated with reductions in quality of life and occupational and social functioning, depression is also accompanied by the occurrence of major sleep disturbances in up to 80% of patients. Despite recent advances in pharmacotherapy for depression, it remains undertreated in many cases.

Psychosis is a severe mental disorder that often impairs mental function to the point of causing significant disability in performing the activities of daily living. A hallmark of psychosis is a loss of contact with reality. The primary psychotic disorders

are schizophrenia and depressive and drug-induced psychoses. Schizophrenia may trigger hallucinations, paranoia, and delusions (false beliefs), and it is estimated to affect 1% of the population. The **dopamine hypothesis** of psychotic illness grows out of the observation that psychotic patients often have excessive dopaminergic activity in the brain. Drug therapy is therefore aimed at reducing this activity. Note that this is in direct contrast to the treatment of Parkinson's disease (see Chapter 15), in which the therapeutic goal is to enhance brain dopaminergic activity.

PHARMACOLOGY OVERVIEW

Psychotropic drugs are among the most commonly prescribed drugs in the United States. Because of the inherent variability in the description of symptoms and the diagnoses, the effects of these drugs are less easily quantified than many other types of medications. For example, it is usually not known how long a given psychotropic drug works in the body (duration of action). Thus, the effectiveness of psychotropic drug therapy is often measured by verbal reports from patients regarding the level of improvement (if any) in their social and occupational functioning. Drug selection is often a trial-and-error process, which can be long and frustrating for both prescribers and patients.

It is hoped that the emerging field of pharmacogenomics (see Chapter 8) will eventually allow more proactive and improved customization of psychotropic drug therapy. Also, as more information is learned about a drug after initial marketing, it is common for the approved indications for a given drug to expand over time. For example, a drug initially approved to treat depression may later be approved to treat social anxiety disorder or additional conditions.

A common problem with psychotropic drug therapy, as with other types of drug therapy, is nonadherence to the prescribed regimen. Many people do not want to accept a psychiatric diagnosis because of the associated stigma. As a result, they may remain in denial about the reality of their mental illness, including the need to take psychotropic medications. They may also have legitimate fears about adverse effects, as well as fear of the unknown regarding their illness. For example, the weight gain that is associated with antipsychotics can be a reason for patient noncompliance. Finally, they may dread the prospect of having to remain on medication to control their symptoms. Such patients can often be helped by support groups and other social supports. As they adjust to their diagnosis, it is hoped they will see enough benefits of treatment to strengthen their own role in maintaining their mental health.

ANXIETY DISORDERS

ANXIOLYTIC DRUGS

Primary anxiolytic drugs include the benzodiazepine drug class and the miscellaneous drug buspirone (Table 16-1). The benzodiazepines are commonly used as first-line drug therapy for both acute and chronic anxiety disorders; they are the focus of this section. In addition, other drugs that are effective as anxiolytics include selective serotonin reuptake inhibitors (SSRIs), tricyclic antidepressants (TCAs), and monoamine oxidase inhibitors (MAOIs) (all discussed in the section on antidepressants), antipsychotics (see later section on antipsychotic drugs), and the antihistamine hydroxyzine (see Chapter 36).

Mechanism of Action and Drug Effects

All anxiolytic drugs decrease anxiety by reducing overactivity in the CNS. Benzodiazepines exert their effects by depressing activity in the areas of the brain called the *brainstem* and the *limbic system.* Benzodiazepines are believed to increase the action of gamma-aminobutyric acid (GABA), which is an inhibitory neurotransmitter in the brain that blocks nerve transmission in the CNS.

The drug buspirone is a miscellaneous anxiolytic in its own class and is described in further detail in its drug profile.

Indications

Benzodiazepines are the largest and most commonly prescribed anxiolytic drug class because they offer several advantages over the other drugs used to treat anxiety. Because of their wide range of therapeutic effects, they are sometimes used for other indications such as ethanol withdrawal (see Chapter 17), insomnia and muscle spasms (see Chapter 12), seizure disorders (see Chapter 14), and as adjuncts in anesthesia (see Chapter 11). They are also commonly used as adjunct therapy for depression because depressive and anxious symptoms often occur together.

Contraindications

Contraindications to benzodiazepines include known drug allergy; narrow-angle glaucoma, due to their ability to cause mydriasis; and pregnancy, due to their sedative properties and risk for teratogenic effects.

Adverse Effects

The most common undesirable effect of these drugs is an overexpression of their therapeutic effects, in particular CNS depression. Benzodiazepines can also cause hypotension. Of

TABLE 16-1 CURRENTLY AVAILABLE ANXIOLYTIC DRUGS

GENERIC NAME	TRADE NAME	ROUTE
Benzodiazepines		
alprazolam	Xanax	PO

buspirone	BuSpar	PO
meprobamate	Miltown	PO
hydroxyzine	Vistaril	PO, IM

particular note are paradoxical reactions (opposite of those that would normally be expected) to the benzodiazepines and antihistamines, including hyperactivity and aggressive behavior. Such reactions are relatively uncommon. They are more likely to occur in children, in adolescents, and in the elderly with dementia. Rebound disinhibition can occur in elderly patients upon tapering of doses or discontinuation of the benzodiazepines. In rebound disinhibition, an elderly patient experiences marked sedation for 1 to 2 hours, followed by marked agitation and confusion for several hours afterward. All benzodiazepines are potentially habit-forming and addictive (Schedule IV). Although they can provide significant symptom relief, they must be used judiciously and at the lowest effective doses needed for symptom control. See Table 16-2 for more information on adverse effects. Elderly patients tend to be more sensitive to the sedating effects of benzodiazepines, which can increase their risk for falls; thus lower doses are usually needed.

Toxicity and Management of Overdose

When benzodiazepines are taken alone, an overdose is generally not life threatening. When they are combined with alcohol or other CNS depressants, the outcome is much more severe. An overdose of benzodiazepines may result in any of the following symptoms: somnolence, confusion, coma, and respiratory depression. The treatment of benzodiazepine intoxication is generally symptomatic and supportive. Flumazenil (Romazicon) is a benzodiazepine receptor blocker (antagonist) that is used to reverse the effects of benzodiazepines. It is sometimes given to reverse benzodiazepine effects after procedures involving moderate sedation (see Chapter 11). The treatment regimen for the acute reversal of benzodiazepine effects is summarized in Chapter 12. Flumazenil may cause acute withdrawal syndrome, including seizures in patients taking long-term benzodiazepines or those with a history of substance abuse.

TABLE 16-2 ADVERSE EFFECTS OF SELECTED ANXIOLYTIC DRUGS*

DRUG OR DRUG CLASS	ADVERSE EFFECTS
Benzodiazepines	Amnesia, anorexia, sedation, lethargy, fatigue, confusion, drowsiness, dizziness, ataxia, headache, visual changes, hypotension, weight gain or loss, nausea, weakness
Miscellaneous	
buspirone	Paradoxical anxiety, dizziness, blurred vision, headache, nausea

*See also drug profiles for drug-specific information.

Interactions

Several notable drug interactions occur with the use of benzodiazepines. Alcohol and CNS depressants, when coadministered with benzodiazepines, can result in additive CNS depression and even death. This serious consequence is more likely to occur in patients with renal and/or hepatic compromise (e.g., the elderly). Other drug interactions are listed in Table 16-3.

Dosages

Recommended dosages of selected anxiolytic drugs are given in the table on this page.

DRUG PROFILES

BENZODIAZEPINES

Benzodiazepines are widely used anxiolytic drugs. Benzodiazepines are all classified as Schedule IV controlled substances. For dosage and indication information, see the table on this page.

♦ alprazolam

Alprazolam (Xanax) is most commonly used as an anxiolytic. It is also indicated for the specific anxiety disorder known as *panic disorder*. Adverse effects include confusion, ataxia, headache, and others listed in Table 16-2. Interacting drugs include alcohol, antacids, oral contraceptives, and others listed in Table 16-3. Alprazolam is available only for oral use, in both tablet and orally dissolving tablet forms. The orally dissolving tablet is indicated for the treatment of anxiety disorder, short-term relief of anxiety symptoms, treatment of anxiety associated with

DOSAGES

Selected Anxiolytic Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE*	CURRENT FDA-APPROVED INDICATIONS/USES
♦ alprazolam (Xanax) (D)	Benzodiazepine	**Adult** PO: 0.25-2 mg tid; do not exceed 4 mg/day	Anxiety
♦ diazepam (Valium) (D)	Benzodiazepine	**Adult** PO: 2-10 mg 2-3 times/day **Pediatric** PO: 1-2.5 mg 3-4 times/day	Anxiety
♦ lorazepam (Ativan) (D)	Benzodiazepine	**Adult** PO: 0.5-6 mg/day in 2-3 divided doses	Anxiety, alcohol withdrawal, agitation

*All dosages reflect usual adult dosage ranges. Pediatric dosages may be more variable and are best prescribed by a pediatric practitioner.

depression, and treatment of panic disorder with or without agoraphobia.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-60 min	1-2 hr	10-15 hr	6 hr

♦ diazepam

Diazepam (Valium) used to be the most commonly prescribed benzodiazepine; however, for treatment of anxiety, it has generally been replaced by the shorter-acting benzodiazepines alprazolam and lorazepam. Diazepam is indicated for the relief of anxiety, management of alcohol withdrawal, reversal of status epilepticus, preoperative sedation, and less frequently as an adjunct for the relief of skeletal muscle spasms. Diazepam has active metabolites that can accumulate in patients with hepatic dysfunction, because it is metabolized primarily in the liver. This can result in additive, cumulative effects that may be manifested as prolonged sedation, respiratory depression, or coma. For this reason, it is probably best avoided in patients with major hepatic compromise. Adverse drug effects include headache, confusion, slurred speech, and others listed in Table 16-2. Diazepam interacts with alcohol, oral contraceptives, and others as shown in Table 16-3. Diazepam is available in oral, rectal, and injectable dosage forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-60 min	1-2 hr	20-80 hr	12-24 hr

♦ lorazepam

Lorazepam (Ativan) is an intermediate-acting benzodiazepine. Of those mentioned here, alprazolam is the shortest acting, whereas diazepam is the longest acting. Lorazepam is available in oral and injectable forms. It may be given intravenously or intramuscularly. It has excellent absorption and bioavailability when given intramuscularly, but it is irritating to the muscle and must be diluted. The conversion between injectable and oral dosage forms is 1:1. Lorazepam can be given by intravenous push, which is useful in the treatment of an acutely agitated patient. It is often administered as a continuous infusion to agitated patients who are undergoing mechanical ventilation. It is also used to treat or prevent alcohol withdrawal (see Chapter 17). Indications, contraindications, and adverse effects are similar to those of alprazolam.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-60 min	2 hr	11-16 hr	8 hr

MISCELLANEOUS DRUG

buspirone

Buspirone (BuSpar) is an anxiolytic drug that is different both chemically and pharmacologically from the benzodiazepines. Its precise mechanism of action is unknown, but it appears to have agonist activity at both serotonin and dopamine receptors. It is indicated for the treatment of anxiety and is always administered on a scheduled (not "as-needed") basis, as opposed to the benzodiazepines that may be administered as needed or on a schedule. The only reported contraindication is drug allergy. Buspirone lacks the sedative properties and dependency potential of the benzodiazepines. Adverse effects include paradoxical anxiety, dizziness, blurred vision, headache, and nausea. Potential drug interactions include a risk for serotonin syndrome (see section on antidepressants). Patients receiving buspirone and antidepressants together need to be monitored carefully. It is recommended that monoamine oxidase inhibitors (MAOIs) not be used concurrently with buspirone due to

TABLE 16-3 DRUG INTERACTIONS OF SELECTED ANXIOLYTIC DRUGS*

DRUG CLASS	INTERACTING DRUG(S)	MECHANISM	RESULT
Benzodiazepines	CNS depressants (e.g., alcohol, opioids)	Additive effects	Enhanced CNS depression (e.g., sedation, confusion, ataxia)
	Oral contraceptives, azole antifungals, SSRIs, verapamil, diltiazem, opioids, valproic acid	Impaired hepatic elimination of benzodiazepine	Enhanced benzodiazepine effects (e.g., CNS depression)
	rifampin	Enhanced benzodiazepine clearance	Reduced therapeutic effects
	theophylline	Antagonistic effects	Reduced sedative effects
	phenytoin	Reduced clearance	Potential for digoxin toxicity and phenytoin toxicity
Miscellaneous			
buspirone	CYP3A4 inhibitors, azole antifungals, verapamil, diltiazem	Impaired hepatic metabolism of buspirone	Enhanced buspirone effects
	rifampin	Enhanced buspirone clearance	Reduced therapeutic effects
	MAOIs	Unknown	Increased blood pressure

CNS, Central nervous system; *CYP3A4,* cytochrome P-450 enzyme 3A4; *MAOIs,* monoamine oxidase inhibitors; *NSAIDs,* nonsteroidal antiinflammatory drugs; *SSRIs,* selective serotonin reuptake inhibitors.
*See also drug profiles for drug-specific information.

the risk of hypertension. A washout period of at least 14 days after discontinuation of MAOI therapy must be allowed before buspirone is started. Other drugs that interact with buspirone include *inhibitors* of the cytochrome P-450 enzyme system (see Chapter 2)—specifically with CYP3A4 (e.g., ketoconazole [see Chapter 42], clarithromycin [see Chapter 38])—which can reduce buspirone clearance; and *inducers* of these same enzymes, which can enhance buspirone clearance and decrease its therapeutic effect. In either case, the buspirone dosage may need to be adjusted. Other interactions are listed in Table 16-3. Buspirone is available only for oral use.

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2-3 wk	40-60 min	2-3 hr	Unknown

AFFECTIVE DISORDERS

Several classes of drugs are used in the treatment of the affective (emotional) disorders. The two main drug categories are mood-stabilizing drugs and antidepressant drugs.

MOOD-STABILIZING DRUGS

Mood stabilizers are drugs used to treat bipolar illness (cycles of mania, hypomania, and depression). Clinical evidence indicates that the catecholamines (dopamine and norepinephrine) play an important pathophysiologic role in the development of mania. Serotonin also appears to be involved. Lithium has been in use for many years and is still used to effectively alleviate the symptoms of acute mania. Lithium is available in two salt forms: lithium carbonate and lithium citrate. Lithium is also effective for the maintenance treatment of bipolar disorder. Lithium is thought to potentiate serotonergic neurotransmission. A variety of medications may be used in conjunction with lithium to regulate mood or achieve stability; they include benzodiazepines (described earlier), antipsychotic drugs (see later in the chapter), antiepileptic drugs (see Chapter 14), and dopamine receptor agonists (see Chapter 15). The antiepileptics valproic acid, lamotrigine, oxcarbazepine, and topiramate are preferred to lithium because lithium has a narrow therapeutic range and requires blood level monitoring. These drugs are often effective in treating mania, hypomania, and, to a lesser degree, depressive symptoms. Other evidence has shown that the atypical antipsychotic drugs risperidone, olanzapine, quetiapine, and ziprasidone (see later) can also be effective in treating mania and hypomania. Available mood-stabilizing drugs are listed in Table 16-4.

DRUG PROFILE

lithium

The antimanic effect of lithium is not fully understood. Research indicates that lithium ions alter sodium ion transport in nerve cells, which results in a shift in catecholamine metabolism. The levels of lithium required to produce a therapeutic effect are close to the toxic levels. For the management of acute mania, a lithium serum level of 1 to 1.5 mEq/L is usually required. Desirable long-term maintenance levels range between 0.6 and 1.2 mEq/L. Blood levels are best measured 8 to 12 hours after the last dose (roughly the midpoint of the drug half-life), because the half-life is usually between 18 and 24 hours. Both sodium and lithium are monovalent positive ions, and one can affect the other. Therefore, the patient's serum sodium levels require monitoring. Keeping the sodium level in the normal range (135 to 145 mEq/L) helps to maintain therapeutic lithium levels. Patients should be advised not to drastically change their sodium intake while taking lithium and to avoid overhydration as well as dehydration.

Lithium is indicated for the treatment of manic episodes in bipolar disorder as well as for maintenance therapy to prevent such episodes. Contraindications to lithium therapy are relative and include dehydration, known sodium imbalance, and major renal or cardiovascular disease, because all of these conditions increase the risk of lithium toxicity. Renal dysfunction of any degree can increase lithium levels. Elderly patients are particularly prone to this effect, because renal function normally declines with advancing age. Adverse effects tend to correlate with serum levels. Levels exceeding 1.5 to 2.5 mEq/L begin to produce toxicity, including gastrointestinal discomfort, tremor, confusion, somnolence, seizures, and possibly death. The most serious adverse effect is cardiac dysrhythmia. Other effects include drowsiness, slurred speech, epilepsy-type seizures, choreoathetotic movements (involuntary wavelike movements of the extremities), ataxia (generalized disturbance of muscular coordination), and hypotension. Long-term treatment may cause hypothyroidism. Potentially interacting drugs include the thiazide diuretics (see Chapter 28), angiotensin-converting enzyme inhibitors (see Chapter 22), and nonsteroidal antiinflammatory drugs (see Chapter 44), all of which can increase lithium toxicity. Lithium carbonate is available only for oral use.

*Information provided is for immediate-release lithium.
†Therapeutic benefit for maintenance control of mania.

ANTIDEPRESSANT DRUGS

Antidepressants are the pharmacologic treatment of choice for major depressive disorders. Not only are they very effective in treating depression, they are also useful in treating other disorders, such as dysthymia (chronic low-grade depression), schizophrenia (as an adjunctive drug), eating disorders, and personality disorders. Some of the antidepressants are also used in the treatment of various medical conditions, including migraine headaches, chronic pain syndromes, sleep disorders, premenstrual syndrome, and hot flashes associated with menopause. Available antidepressants are listed in Table 16-4.

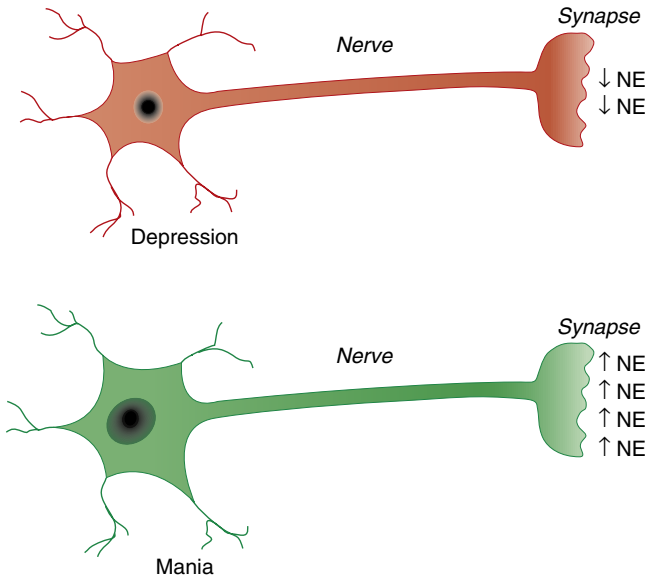

FIGURE 16-1 Biologic amine hypothesis. *NE,* Norepinephrine.

Many of the drugs used to treat affective disorders increase the levels of neurotransmitter concentrations in the CNS; these neurotransmitters include serotonin (also known as 5-hydroxytryptamine, or 5-HT), dopamine, and norepinephrine. This treatment is based on the belief that alterations in the levels of these neurotransmitters are responsible for causing depression. A widely held hypothesis advanced to explain depression in these terms is the **biogenic amine hypothesis.** It postulates that depression results from a deficiency of neuronal and synaptic catecholamines (primarily norepinephrine) and mania from an excess of amines at the adrenergic receptor sites in the brain. This hypothesis is illustrated in Figure 16-1.

Another hypothesis regarding the cause of depression is the **permissive hypothesis,** which led to the creation of the selective serotonin reuptake inhibitor (SSRI) drug class. The permissive theory postulates that reduced concentrations of serotonin are the predisposing factor in patients with affective disorders. Depression results from decreases in both the serotonin and catecholamine levels, whereas mania results from increased dopamine and norepinephrine levels but decreased serotonin levels. The permissive hypothesis is illustrated in Figure 16-2. The **dysregulation hypothesis** is essentially a reformulation of the biogenic amine hypothesis. This theory views depression and other affective disorders not simply in terms of decreased or increased catecholamine activity but as a failure of the regulation of these systems.

Research indicates that early and aggressive antidepressant treatment increases the chances for full remission. The first 6 to 8 weeks of therapy constitute the acute phase. The primary goals during this time are to obtain a response to drug therapy and to improve the patient's symptoms. It is currently recommended that antidepressant drug therapy be maintained at the effective dose for an additional 8 to 14 months after remission of depressive symptoms. In choosing an antidepressant, the patient's previous psychotropic drug response history (if any) needs to be considered. Family history of depression with known drug responses are also helpful. Therapeutic response is measured primarily by subjective patient feedback. In addition, a few measurement tools are available that attempt to quantify the patient's response to drug therapy, such as the Hamilton Rating Scale for Depression and the Symptom Checklist-90 anxiety factor scale.

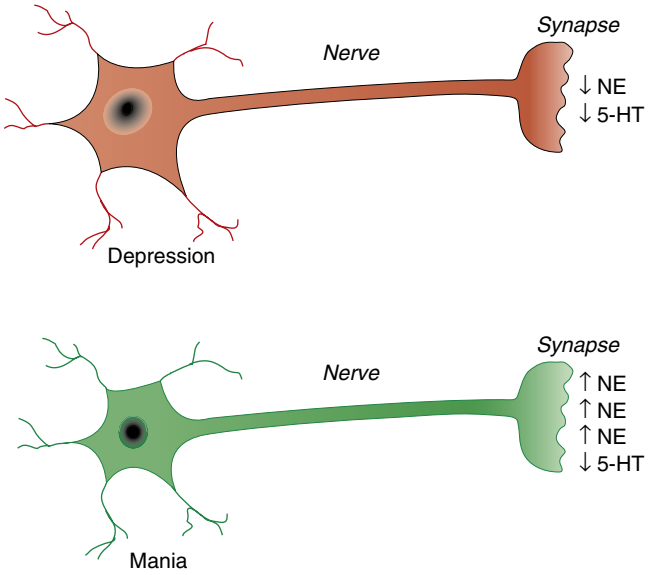

FIGURE 16-2 Permissive hypothesis. *NE,* Norepinephrine; *5-HT,* serotonin.

Anxiety and depression commonly occur together and reinforce each other. Similarly, there is much crossover in terms of symptom control between antidepressant and anxiolytic drugs. A nonresponse to antidepressant drug therapy is defined as failure to respond to at least 6 weeks of therapy with adequate drug dosages. Twenty percent to 30% of patients who do not respond to the usual dosage of an antidepressant will respond to higher dosages. Therefore, dosage optimization, which involves careful upward titration of dose for several weeks, is recommended before concluding that a given drug is ineffective. Often times a switch to a different pharmacologic class of antidepressant is necessary. Forty percent to 60% of patients will respond to the second drug class tried. Anxiolytic and antipsychotic drugs may also be used, either alone or as adjunct therapy. Evidence suggests that psychotherapy given with antidepressant medication is more effective than medication alone.

The most severe cases of refractory depression may warrant an attempt at treatment with electroconvulsive therapy. Electroconvulsive therapy treatment is generally carried out in a postanesthesia care unit setting under brief general anesthesia. Seizure activity is induced in the anesthetized patient via externally applied electric shocks to the brain.

Treatment failure in cases of depression may be due to a misdiagnosis or failure to treat comorbid mental illness (e.g., anxiety disorder, substance abuse) and/or comorbid nonpsychiatric illness (e.g., hypothyroidism). It may also be due to nonadherence to drug therapy. Careful choice of drug therapy to minimize adverse effects may improve patient compliance with treatment and therapeutic outcome. Another reason for treatment failure may be the discouragement associated with depression itself. This alone may cause patients to give up prematurely on their drug therapy, especially because antidepressants often take several weeks to reach their full effect. Effective psychotherapy and support groups can help encourage patients to be consistent with prescribed psychotropic drug therapy.

In 2005, the U.S. Food and Drug Administration (FDA) issued special black box warnings regarding the use of all classes of antidepressants in both adult and pediatric patient populations. Data from the FDA indicated a higher risk for suicide in patients receiving these medications (up to 4% of patients taking the drugs showed suicidal thoughts or behaviors compared with 2% receiving a placebo). As a result, current recommendations for all patients receiving antidepressants include regular monitoring for signs of worsening depressive symptoms, especially when the medication is started or the dosage is changed. Patients need immediate evaluation if they report, or others observe, signs of worsening depression or other emotional instability. Most patients do not experience severe adverse effects from these medications, and many patients obtain significant relief.

TRICYCLIC ANTIDEPRESSANTS

Tricyclic antidepressants (TCAs) were the original first-generation antidepressants. Their use has largely been replaced with the SSRIs and serotonin-norepinephrine reuptake inhibitors (SNRIs). The TCAs are considered second-line drug therapy in patients for whom the SSRIs are ineffective or as adjunct therapy with newer drugs. The TCAs are so named because of their characteristic three-ring chemical structure.

Mechanism of Action and Drug Effects

TCAs are believed to work by correcting imbalance in the neurotransmitter concentrations of serotonin and norepinephrine at the nerve endings in the CNS (the biogenic amine hypothesis). This is accomplished by blocking the presynaptic reuptake of the neurotransmitters, which makes them available for transmission of nerve impulses to adjacent neurons in the brain. Some also believe that these drugs may help regulate malfunctioning neurons (the dysregulation hypothesis).

Indications

Originally used to treat depression, currently TCAs are most commonly used to treat neuropathic pain syndromes and insomnia. With the advent of the newer-generation antidepressant classes, their use as antidepressants is rare. Some of the TCAs have additional specific indications. For example, imipramine is used as an adjunct in the treatment of childhood enuresis (bedwetting), and clomipramine is useful in the treatment of obsessive-compulsive disorder. Because TCAs tend to increase appetite leading to weight gain, they are sometimes used to treat anorexia nervosa.

Contraindications

Contraindications for TCAs include known drug allergy, use of MAOIs within the previous 14 days, and pregnancy. TCAs are also not recommended in patients with any acute or chronic cardiac problems or history of seizures, because both conditions are associated with a greater likelihood of death upon TCA overdose.

Adverse Effects

Undesirable effects of TCAs are a result of their effects on various receptors, especially the muscarinic receptors (a type of

TABLE 16-5 ADVERSE EFFECTS OF SELECTED MOOD STABILIZERS AND ANTIDEPRESSANTS*

DRUG OR DRUG CLASS	ADVERSE EFFECTS
Mood Stabilizers	
lithium salts	GI discomfort, tremor, confusion, sedation, seizures, cardiac dysrhythmia, drowsiness, slurred speech, slowed motor abilities, weight gain, ataxia, hypotension
Antiepileptic drugs	Dizziness, drowsiness, GI upset, weight gain, hepatotoxicity, pancreatitis, unusual eye movements, visual changes, behavioral changes, ataxia
Antidepressants	
First Generation	
Tricyclics	Anorexia, dry mouth, blurred vision, constipation, gynecomastia, sexual dysfunction, altered blood glucose level, urinary retention, agitation, anxiety, ataxia, cognitive impairment, sedation, headache, insomnia, skin rash, photosensitivity, weight changes, orthostatic hypotension, blood dyscrasias
MAOIs	Dizziness, dyskinesias, nausea, syncope, hypotension
Second Generation	
Tetracyclics	
mirtazapine, maprotiline	Drowsiness, abnormal dreams, dry mouth, constipation, increased appetite, asthenia (muscle weakness)
SSRIs	Anxiety, dizziness, drowsiness, headache, mild GI disturbance, sexual dysfunction, asthenia, tremor
SNRIs	Dizziness, drowsiness, headache, GI upset, anorexia, hepatotoxicity
Miscellaneous	
trazodone, bupropion	Dizziness, headache, sedation, nausea, blurred vision, tachycardia

*See also drug profiles for drug-specific information.

cholinergic receptor) and, to a lesser degree, adrenergic, histaminergic, dopaminergic, and serotonergic receptors. Blockade of cholinergic receptors results in undesirable anticholinergic adverse effects, the most common being constipation and urinary retention. Nortriptyline and desipramine have less anticholinergic activity, and they are preferred for use in the elderly. Adrenergic and dopaminergic receptor blockade can lead to disturbances in cardiac conduction and hypotension. Histaminergic blockade can cause sedation, and serotonergic blockade can alter the seizure threshold, and cause sexual dysfunction (see Table 16-5).

Toxicity and Management of Overdose

Tricyclic antidepressant overdoses are notoriously lethal. It is estimated that 70% to 80% of patients who die of TCA overdose do so before reaching the hospital, especially if the drugs are taken with alcohol. The primary organ systems affected are the CNS and cardiovascular system. Death usually results from either seizures or dysrhythmias. Historically it was taught that patients should not receive more than a 1-month supply of antidepressants because of the risk of suicide attempts. However, with the cost of drugs today, it is not uncommon to see a 3-month supply given with only one copay. This is a double-edged sword: the patient saves money, but now the depressed patient has more than enough drugs to cause death by overdose.

There is no specific antidote for TCA poisoning. Management efforts are aimed at reducing drug absorption by administering multiple doses of activated charcoal. Administration of sodium bicarbonate speeds up elimination of the TCA by alkalinizing the urine. CNS damage may be minimized by the administration of diazepam, and cardiovascular events may be minimized by giving antidysrhythmics. Other care includes basic life support in an intensive care setting to maintain vital organ functions. These interventions must continue until enough of the TCA is eliminated to permit restoration of normal organ function.

Interactions

Increased anticholinergic effects are seen when TCAs are taken with anticholinergics and phenothiazines. When MAOIs are taken with TCAs, the result may be increased therapeutic and toxic effects, including hyperpyretic crisis (excessive fever). Other drug interactions are listed in Table 16-6.

Dosages

Recommended dosages of selected TCA drugs are given in the table on p. 263.

DRUG PROFILE

TCAs are effective drugs in the treatment of various affective disorders, but they are associated with serious adverse effects. Therefore, patients taking them need to be monitored closely. For this reason, all antidepressants are available only with a prescription. Some herbal products used to treat depression, such as St. John's wort (see the Safety: Herbal Therapies and Dietary Supplements box on p. 264), are available over the counter but should not be taken with prescription antidepressants. Many drugs in this class are rated as pregnancy category D drugs, which makes their use by pregnant women relatively more hazardous than that of most of the newer drugs.

♦ amitriptyline

Amitriptyline (Elavil) is the oldest and most widely used of all the TCAs. Its original indication was depression, but it is now more commonly used to treat insomnia and neuropathic pain. Contraindications include known drug allergy, pregnancy, and recent myocardial infarction. It has very potent anticholinergic properties, which can lead to many adverse effects such as dry mouth, constipation, blurred vision, urinary retention, and dysrhythmias (see Table 16-5). Drug interactions are listed in Table 16-6. Amitriptyline is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

St. John's Wort (Hypericum perforatum)

Overview
St. John's wort herbal preparations consist of the dried above-ground parts of the plant species *Hypericum perforatum* gathered during flowering season. The herb is available over the counter in numerous oral dosage forms. St. John's wort is sometimes referred to as the *herbal Prozac.*

Common Uses
Depression, anxiety, sleep disorders, nervousness

Adverse Effects
Gastrointestinal upset, allergic reactions, fatigue, dizziness, confusion, dry mouth, possible photosensitization (especially in fair-skinned individuals)

Potential Drug Interactions
Monoamine oxidase inhibitors, selective serotonin reuptake inhibitors, cyclosporine, sympathomimetic amines, piroxicam, tetracycline, tyramine-containing foods, opioids, digoxin, estrogens, theophylline, warfarin

Contraindications
Contraindicated in patients with bipolar depression, schizophrenia, Alzheimer's disease, and dementia

MONOAMINE OXIDASE INHIBITORS

Monoamine oxidase inhibitors (MAOIs), along with TCAs, represent the first generation of antidepressant drug therapy; they are rarely used as antidepressants, but are used to treat Parkinson's disease. A serious disadvantage to MAOI use is their potential to cause a hypertensive crisis when taken with stimulant medications or with a substance containing tyramine, which is found in many common foods and beverages (Table 16-7).

Currently four MAOI antidepressants are available. Isocarboxazid, phenelzine, and tranylcypromine are nonselective inhibitors of both MAO type A and MAO type B. Selegiline is a selective MAO-B inhibitor that comes in a transdermal dosage form. An oral form of this drug is also used to treat Parkinson's disease (see Chapter 15). Because these drugs inhibit the MAO enzyme system in the CNS, amines such as dopamine, serotonin, and norepinephrine are not broken down, and therefore higher levels of these substances occur. This, in turn, alleviates the symptoms of depression.

Most adverse effects of MAOIs stem from their interactions with food and other medications. A variety of over-the-counter drugs (especially for cough and cold) also can interact with MAOIs to cause adverse cardiovascular effects. For example, MAOIs may increase the CNS depressant effects of diphenhydramine and cetirizine. Patients taking MAOIs need to read labels and/or consult the pharmacist when using any such products. Dosage information for selected MAOIs is given in the table on p. 263.

Sympathomimetic drugs can also interact with MAOIs, and together these drugs can cause a hypertensive crisis. MAOIs can markedly potentiate the effects of meperidine, and therefore their concurrent use is contraindicated. In addition, concurrent use of MAOIs with SSRIs carries the risk for serotonin syndrome. A washout period of 2 to 5 weeks between drugs is recommended.

TABLE 16-7 FOOD AND DRINK TO AVOID WHEN TAKING MONOAMINE OXIDASE INHIBITORS

FOOD/DRINK	EXAMPLES
High Tyramine Content (Not Permitted)	
Aged mature cheeses	Cheddar, blue, Swiss
Smoked or pickled meats	Herring, sausage, corned beef, smoked fish or poultry, salami, pepperoni
Aged or fermented meats	Chicken or beef liver pâté, game fish or poultry
Yeast extracts	Brewer's yeast
Red wines	Chianti, burgundy, sherry, vermouth
Italian broad beans	Fava beans
Moderate Tyramine Content (Limited Amounts Allowed)	
Meat extracts	Bouillon, consommé
Pasteurized light and pale beer	
Ripe avocado	
Low Tyramine Content (Permissible)	
Distilled spirits	Vodka, gin, rye, scotch (in moderation)
Non-aged cheeses	American cheese, mozzarella, cottage cheese, cream cheese
Chocolate and caffeinated beverages	
Fruit	Figs, bananas, raisins, grapes, pineapple, oranges
Soy sauce	
Yogurt, sour cream	

Toxicity and Management of Overdose

Clinical symptoms of MAOI overdose generally do not appear until about 12 hours after ingestion. The primary signs and symptoms are cardiovascular and neurologic. The most serious cardiovascular effects are tachycardia and circulatory collapse, and the neurologic symptoms of major concern are seizures and coma. Hyperthermia and miosis are also generally present in overdose. Treatment is aimed at eliminating the ingested toxin and protecting the organs at greatest risk for damage—the brain and the heart. Recommended treatments are urine acidification to a pH of 5 and hemodialysis. Treatment of hypertensive crisis resulting from consumption of tyramine-containing foods or beverages may require intravenous administration of hypotensive drugs along with careful monitoring in an intensive care setting.

DRUG PROFILE

selegiline transdermal patch

The selegiline transdermal patch (Emsam) is a selective MAO-B inhibitor. It is currently indicated for major depression. The lowest strength of the selegiline transdermal patch (6 mg/24 hr) can be used without dietary restrictions. However, to date there are insufficient data to permit the same dietary freedom with the 9- and 12-mg patch strengths. Contraindications include

known drug allergy. Adverse drug effects and drug interactions are the same as for the oral dosage form and can be found earlier in the discussion of MAOIs in general and in Chapter 15 for selegiline in particular. Patients need to avoid exposing the patch to external sources of heat, such as a heating pad, electric blanket, sauna, or even prolonged direct sunlight, as these heat sources speed absorption. Standard pharmacokinetic parameters for the transdermal dosage form are not known at this time.

SECOND-GENERATION ANTIDEPRESSANTS

The period from the 1980s to the present was one of much development in psychotropic pharmacotherapy. Several new antidepressants alone were introduced, including trazodone (Desyrel, Oleptro) and bupropion (Wellbutrin). Both are still commonly used. The selective serotonin reuptake inhibitors (SSRIs) were also introduced. These include fluoxetine (Prozac), sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (generic only; formerly Luvox), citalopram (Celexa), and escitalopram (Lexapro). The 1990s saw the introduction of still more antidepressants, including the serotonin-norepinephrine reuptake inhibitors (SNRIs) venlafaxine (Effexor) and miscellaneous drugs nefazodone (Serzone) and mirtazapine (Remeron). Two new SNRIs were introduced in the 2000s, including duloxetine (Cymbalta) and desvenlafaxine (Pristiq). Desvenlafaxine is the major active metabolite of venlafaxine. Currently available second-generation drugs are listed in Table 16-4. The second-generation antidepressants are generally considered superior to TCAs and MAOIs in terms of their adverse effect profiles. They are associated with significantly fewer and less severe systemic adverse effects, especially anticholinergic and cardiovascular adverse effects. It takes approximately the same amount of time to reach maximum clinical effectiveness with the second-generation antidepressants as it does with the TCAs and MAOIs, typically 4 to 6 weeks.

Mechanism of Action and Drug Effects

The inhibition of serotonin reuptake is the primary mechanism of action of the SSRIs, although SSRIs may also have weak effects on norepinephrine and dopamine reuptake (see individual drug profiles). SNRIs inhibit the reuptake of both serotonin and norepinephrine. Educate patients that antidepressant drugs commonly must be taken for several weeks before full therapeutic effects are realized. This requires some patience and faithful dosing on the part of patients.

Indications

Although depression is their primary indication, they have shown benefit in treating a variety of other mental and physical disorders. Examples include bipolar disorder, obesity, eating disorders, obsessive-compulsive disorder, panic attacks or disorders, social anxiety disorder, posttraumatic stress disorder, premenstrual dysphoric disorder, the neurologic disorder myoclonus, and various substance abuse problems such as alcoholism. This list is expanding with continued research on these drugs.

BOX 16-1 COMMON SYMPTOMS OF SEROTONIN SYNDROME

Common symptoms include:
- Delirium
- Agitation
- Tachycardia
- Sweating
- Myoclonus (muscle spasms)
- Hyperreflexia
- Shivering
- Coarse tremors
- Extensor plantar muscle (sole of foot) responses

In more severe cases, the following may occur:
- Hyperthermia
- Seizures
- Rhabdomyolysis
- Renal failure
- Cardiac dysrhythmias
- Disseminated intravascular coagulation

Contraindications

Contraindications include known drug allergy, use of MAOIs in the previous 14 days, and therapy with certain antipsychotic drugs such as thioridazine or mesoridazine. In addition, a significant history of cardiac disease or seizure may be a contraindication due to the relatively uncommon, but reported, cardiac effects and alterations in seizure threshold (see later discussion). Bupropion is also contraindicated in cases of eating disorders and seizure disorders because it can lower the seizure threshold.

Adverse Effects

The second-generation antidepressants offer advantages over TCAs and MAOIs due to their improved adverse effect profiles. However, up to two thirds of all depressed patients may still discontinue therapy due to drug adverse effects. Some of the most common adverse effects are insomnia (partly due to reduced rapid eye movement sleep), weight gain, and sexual dysfunction. Sexual dysfunction caused by the SSRIs is primarily related to inability to achieve orgasm. One potentially hazardous adverse effect of any drug or combination of drugs that have serotoninergic activity is known as **serotonin syndrome.** The symptoms of this condition are listed in Box 16-1. Fortunately, it is usually self-limiting on discontinuation of the causative drugs. (See also Table 16-5.)

Interactions

The second-generation antidepressants are highly bound to albumin. When given with other drugs that are also highly protein bound (e.g., warfarin and phenytoin), they compete for binding sites on the surface of albumin. This results in more free, unbound drug and therefore a more pronounced drug effect.

Some of the drugs may also inhibit cytochrome P-450 enzymes, although there is debate about this in the literature. The cytochrome P-450 system is an enzyme system in the liver that is responsible for the metabolism of several drugs (see Chapter 2). Inhibition of this enzyme system results in higher levels of these drugs with the potential for toxicity.

To prevent the potentially fatal pharmacodynamic interactions that can occur between these drugs and the MAOIs, a 2- to 5-week washout period is recommended between uses of these two classes of medications. Other drug interactions are listed in Table 16-6.

Dosages

Recommended dosages of selected newer-generation antidepressants are given in the table on p. 263.

DRUG PROFILES

The second-generation drugs have proved to be effective antidepressants. They also have generally better adverse effect profiles than first-generation antidepressants. They are now considered first-line drugs in the treatment of patients with depression, including patients with concurrent symptoms of anxiety and patients with depression with suicidal ideations.

trazodone

Trazodone (Desyrel, Oleptro) is in the triazolopyridine drug class. It was the first of the second-generation antidepressants that could selectively inhibit serotonin reuptake but minimally affect norepinephrine reuptake. Trazodone has minimal adverse effects on the cardiovascular system, which is an advantage over the TCAs. It is indicated for the treatment of depression, and it is also commonly used as a nonaddictive drug treatment for insomnia. Contraindications include known drug allergy. Adverse effects include strongly sedative qualities. These can be severe and can impair cognitive function in older adults. However, the sedating effect of trazodone is often advantageous in helping depressed patients, who commonly have comorbid anxiety and/or insomnia, obtain effective sleep. Trazodone also has been associated in rare cases with transient nonsexual *priapism.* This is a dangerously sustained penile erection that is reportedly the result of alpha-adrenergic blockade. Trazodone interacts with azole antifungals (see Chapter 42), phenothiazines (see later in the chapter), and protease inhibitors (see Chapter 40), all of which can increase the risk of trazodone toxicity; carbamazepine (see Chapter 14), which can reduce trazodone levels, while carbamazepine levels are increased; and CNS depressants (e.g., alcohol), whose effects can be potentiated by trazodone. It is also recommended that trazodone be started gradually after a patient has recently stopped MAOI therapy. Trazodone is available only for oral use. Vilazodone (Viibryd), marketed in 2011, is similar to trazodone in both structure and action. Vilazodone is a SSRI and a 5-HT_{1A} receptor agonist.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-2 wk	2-4 wk	6-9 hr	Several weeks

♦ fluoxetine

Fluoxetine (Prozac) was the first SSRI marketed for the treatment of depression and is considered the prototypical SSRI. Since that time, it has become the top-prescribed antidepressant in the United States and one of the most commonly prescribed of all drugs. Although it was initially indicated for the treatment of depression, the indications for fluoxetine have since expanded to include bulimia, obsessive-compulsive disorder, panic disorder, and premenstrual dysphoric disorder. Contraindications include known drug allergy and concurrent MAOI therapy. Adverse effects include anxiety, dizziness, drowsiness, insomnia, and others listed in Table 16-5. Interacting drugs include benzodiazepines (reduced benzodiazepine clearance) (see Chapter 12); buspirone (reduced buspirone effects) (see earlier in the chapter); antipsychotics (elevated antipsychotic levels); and propafenone (see Chapter 24). Other drug interactions are listed in Table 16-6. Fluoxetine is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-4 wk	6-8 hr	1-3 days*	2-4 wk

*Active metabolite has a half-life of 7 to 10 days.

♦ bupropion

Bupropion is a unique antidepressant in terms of both its structure and mechanism of action. It has relatively weak, but measurable, effects on brain serotonin activity, but little to no effect on monoamine oxidase. Its strongest therapeutic activity appears to be primarily dopaminergic and noradrenergic.

Bupropion was originally indicated for treatment of depression but is now also indicated as an aid in smoking cessation. It is sometimes added as an adjunct antidepressant for patients experiencing sexual adverse effects secondary to SSRI therapy. Although the mechanism is unclear, the drug is often effective in this situation. A sustained-release form of bupropion, Zyban, was approved for smoking cessation treatment. Sustained-release bupropion was an innovative new treatment because it was the first nicotine-free prescription medicine used to treat nicotine dependence. Its exact mechanism of action in treating nicotine dependence is unknown, but it is believed to be related to the drug's ability to modulate dopamine and norepinephrine levels in the brain. Both of these neurotransmitters are believed to play an important role in maintaining nicotine addiction. However, the newer smoking cessation drug varenicline (Chantix; see Chapter 17) is becoming popular for this purpose.

Bupropion is contraindicated in patients who have a known drug allergy, those with a seizure disorder (bupropion can lower the seizure threshold), those who currently have anorexia nervosa or bulimia or have had one of these disorders in the past, and those currently taking an MAOI. Common adverse effects include dizziness, confusion, tachycardia, agitation, tremor, and dry mouth. Drugs that interact with bupropion include the azole antifungals (see Chapter 42) as well as other drugs metabolized by the cytochrome P-450 enzyme system (see Chapter 2) and CNS depressants. Other drug interactions are listed in Table 16-6. Bupropion is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Up to 4 wk	3 hr	10-14 hr	Weeks to months

♦ mirtazapine

Mirtazapine (Remeron) is unique in that it promotes the presynaptic release of both serotonin and norepinephrine in the brain.

This is due to its antagonist activity in the presynaptic alpha$_2$-adrenergic receptors. It does not inhibit the reuptake of either of these neurotransmitters. It is strongly associated with sedation in more than 50% of patients due to its histamine 1 (H_1) receptor activity and therefore is usually dosed once daily at bedtime. Furthermore, although clearance of the drug may be somewhat reduced in elderly patients, no dosage adjustment is currently recommended. Mirtazapine is indicated for treatment of depression, including that associated with bipolar disorder. It is also sometimes helpful (mechanism unknown) in reducing the sexual adverse effects in male patients receiving SSRI therapy. Mirtazapine is known to be an appetite stimulant and thus can be helpful in underweight depressed patients or harmful in those who are already overweight. Mirtazapine is contraindicated in cases of drug allergy and concurrent use of MAOIs. Adverse effects include drowsiness, abnormal dreams, dry mouth, constipation, increased appetite, and asthenia. Drug interactions include additive CNS depressant effects with alcohol and CYP inhibitors (see Chapter 2). Mirtazapine is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-3 wk	2 hr	20-40 hr	Unknown

duloxetine

Duloxetine (Cymbalta), like venlafaxine, is a serotonin-norepinephrine reuptake inhibitor (SSNRI). It is indicated for depression and generalized anxiety disorder. It is also indicated for pain resulting from diabetic peripheral neuropathy or fibromyalgia. It is contraindicated in cases of known drug allergy and concurrent MAOI use, and it can worsen uncontrolled angle-closure glaucoma. Adverse effects include dizziness, drowsiness, headache, gastrointestinal upset, anorexia, and hepatotoxicity. Drugs with which duloxetine interacts include SSRIs and triptans (increased risk of serotonin syndrome) and alcohol (increased risk of liver injury). Duloxetine is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2-6 weeks	6 hr	12 hr	Unknown

PSYCHOTIC DISORDERS

ANTIPSYCHOTIC DRUGS

Antipsychotic drugs are used to treat serious mental illnesses such as drug-induced psychoses, schizophrenia, and autism. Antipsychotics are also used to treat extreme mania (as an adjunct to lithium), bipolar disorder, depression that is resistant to other therapy, certain movement disorders (e.g., Tourette's syndrome), and certain other medical conditions (e.g., nausea, intractable hiccups). Antipsychotics have also been referred to as *tranquilizers* or *neuroleptics* because they produce a state of tranquility and act on abnormally functioning nerves. However, these are both older terms that are now less commonly used.

Antipsychotic drugs represent a significant advance in the treatment of mental illnesses, as borne out by the fact that the early treatment of mental illnesses (before the 1950s) consisted of such extreme measures as isolation, physical restraint, shock therapy, and even lobotomy.

The phenothiazines are the largest chemical class of antipsychotic drugs, constituting about two thirds of all antipsychotics. They were also the original drugs in this category. Like many other drugs, phenothiazines were discovered by chance, in this case during research for new antihistamines. Chlorpromazine, isolated in 1951, was the first phenothiazine to be discovered in this way. The currently available antipsychotics are listed in Table 16-8.

Overall, there are few differences between conventional, or first-generation, antipsychotics in terms of mechanism of

TABLE 16-8 CURRENTLY AVAILABLE ANTIPSYCHOTIC DRUGS

action. Therefore, selection of an antipsychotic is based primarily on the patient's tolerance and the need to minimize adverse effects. Of the currently available antipsychotic drugs, no single drug stands out for all patients as either more or less effective in the treatment of psychotic symptoms. Antipsychotic drug therapy does not normally provide a cure for psychoses but is a way of chemically controlling the symptoms of the illness.

More recently, a new generation of antipsychotic medications has evolved. These are referred to as *atypical antipsychotics,* as opposed to the conventional drugs, which can also be thought of as older-generation antipsychotics. Atypical antipsychotics differ from conventional drugs in that they tend to have better adverse effect profiles. The atypical antipsychotics still have adverse effects, but they are usually not as severe as the conventional antipsychotic drugs.

Mechanism of Action and Drug Effects

All antipsychotics block dopamine receptors in the brain, which decreases the dopamine concentration in the CNS. Specifically, the conventional phenothiazines block the dopamine receptors postsynaptically in certain areas of the CNS, such as the limbic system and the basal ganglia. These are the areas associated with emotions, cognitive function, and motor function. This receptor blocking produces a tranquilizing effect in psychotic patients. Both the therapeutic and toxic effects of these drugs are the direct result of the dopamine blockade in these areas. The atypical antipsychotic drugs block specific dopamine receptors called dopamine 2 (D_2) receptors, as well as specific serotonin receptors in the brain known as serotonin 2 (5-HT_2) receptors. These more refined mechanisms of action of the atypicals are responsible for their improved efficacy and safety profiles, compared with older drugs (see Adverse Effects).

All antipsychotics show efficacy in improving the positive symptoms of schizophrenia, and these beneficial effects may even increase over time. So-called *positive symptoms* include hallucinations, delusions, and conceptual disorganization. Unfortunately, conventional drugs are less effective in managing negative symptoms. Negative symptoms are apathy, social withdrawal, blunted affect, poverty of speech, and catatonia. It is these negative symptoms that account for most of the social and vocational disability caused by schizophrenia. Fortunately, atypical antipsychotics have improved efficacy in treating both positive and negative symptoms.

Indications

Antipsychotic drugs are indicated for psychotic illness, most commonly schizophrenia. As more has been learned about these drugs, especially the atypical antipsychotic drugs, their indications have expanded to include anxiety and mood disorders as well. Certain antipsychotics (e.g., prochlorperazine) are used as antiemetics (see Chapter 52). They block serotonin receptors and dopamine receptors in the chemoreceptor trigger zone in the brain and inhibit neurotransmission in the vagus nerve in the gastrointestinal tract. Additional blocking of dopamine receptors in the brainstem reticular system also allows atypical drugs to have anxiolytic or antianxiety effects.

Contraindications

Contraindications to the use of antipsychotic drugs include known drug allergy, comatose state, and, possibly, significant CNS depression, brain damage, liver or kidney disease, blood dyscrasias, or uncontrolled epilepsy.

Adverse Effects

Common adverse effects caused by blockade of the alpha-adrenergic, dopamine, endocrine, histamine, and muscarinic (cholinergic) receptors are listed in Table 16-9. Possible severe hematologic effects include agranulocytosis (lack of granulocytes in the blood) and hemolytic anemia. CNS effects include drowsiness, **neuroleptic malignant syndrome, extrapyramidal symptoms,** and **tardive dyskinesia.** Neuroleptic malignant syndrome is a potentially life-threatening adverse effect that may include high fever, unstable blood pressure, and myoglobinemia. Extrapyramidal symptoms are involuntary motor symptoms similar to those associated with Parkinson's disease (see Chapter 15). This drug-induced state is known as *pseudoparkinsonism* and is characterized by symptoms such as **akathisia** (distressing motor restlessness) and acute **dystonia** (painful muscle spasms). Two anticholinergic medications, benztropine (Cogentin) and trihexyphenidyl (Artane), are commonly used to treat these symptoms (see Chapter 15). *Tardive* is a word that means "late appearing." Tardive **dyskinesia** is characterized by involuntary contractions of oral and facial muscles (e.g., involuntary tongue thrusting) and choreoathetosis (wavelike movements of the extremities) and usually appears only after continuous long-term antipsychotic therapy. Theoretically these effects are possible with atypical antipsychotics as well; however, evidence suggests that the incidence is lower.

Cardiovascular effects, caused by alpha receptor blockade, include postural hypotension. In addition, electrocardiogram (ECG) changes, notably prolonged QT interval, are associated with all classes of antipsychotic drugs. Baseline and periodic ECGs, as well as measurement of serum potassium and magnesium levels, can help to determine if a patient is at risk for such

TABLE 16-9 ANTIPSYCHOTICS: RECEPTOR-RELATED ADVERSE EFFECTS

RECEPTOR	ADVERSE EFFECTS	DRUG CATEGORY
Alpha-adrenergic	Postural hypotension, lightheadedness, reflex tachycardia	Conventional drugs
Dopamine	Extrapyramidal movement disorders, dystonia, parkinsonism, akathisia, tardive dyskinesia	Atypical drugs
Endocrine	Prolactin secretion (galactorrhea, gynecomastia), menstrual changes, sexual dysfunction	Conventional drugs
Histamine	Sedation, drowsiness, hypotension, weight gain	Conventional drugs
Muscarinic (cholinergic)	Blurred vision, worsening of angle-closure glaucoma, dry mouth, tachycardia, constipation, urinary retention, decreased sweating	Conventional drugs

effects or to diagnose newly acquired cardiac dysrhythmias. The conventional drugs such as the phenothiazines and haloperidol can also augment prolactin release, which can result in swelling of the breasts and milk secretion in women taking these drugs. Gynecomastia (breast tissue enlargement) can also be a distressing adverse effect in male patients (Table 16-10).

Adverse effects on the endocrine system associated with antipsychotics include insulin resistance, weight gain, and changes in serum lipid levels. Antipsychotics are associated with development of **metabolic syndrome,** which can cause serious long-term health problems.

In 2011, the FDA required manufacturers to change a product's labeling to include stronger wording regarding the use of antipsychotics in pregnant women. The new labeling includes more consistent information about the potential risk for abnormal muscle movements (extrapyramidal symptoms) and withdrawal symptoms in newborns whose mothers were treated with these drugs during the third trimester of pregnancy.

TABLE 16-10 ADVERSE EFFECTS OF SELECTED PSYCHOTROPIC DRUGS*

DRUG OR DRUG CLASS	ADVERSE EFFECTS
Conventional (e.g., haloperidol)	Akathisia, extrapyramidal symptoms, hypertension, neuroleptic malignant syndrome, confusion, headache, mild GI disturbance, dry mouth, amenorrhea, gynecomastia, visual disturbances, hyperpyrexia, edema, tardive dyskinesia, skin rash, photosensitivity, weight gain, urinary retention
Atypical (e.g., clozapine, risperidone)	Tachycardia, akathisia, agitation, asthenia, ataxia, seizures, dyskinesia, dizziness, drowsiness, headache, insomnia, dry mouth, dyspepsia, anxiety, increased appetite, weight gain

GI, Gastrointestinal; *MAOIs,* monoamine oxidase inhibitors; *SNRIs,* serotonin-norepinephrine reuptake inhibitors; *SSRIs,* selective serotonin reuptake inhibitors.
*See also drug profiles for drug-specific information.

Interactions

Major drug interactions are listed in Table 16-11. Antihypertensives may have additive hypotensive effects and CNS depressants may have additive CNS depressant effects when taken with antipsychotics. Grapefruit juice can enhance the effects of clozapine (by reducing its metabolism via the cytochrome P-450 enzyme system). Because grapefruit juice affects many enzymes in the P-450 system, it is wise to avoid this food for patients taking multiple medications.

Dosages

Recommended dosages of selected antipsychotic drugs are given in the table on this page.

DRUG PROFILES

The conventional antipsychotic drugs are currently still available on the U.S. market (see Table 16-8). However, much of their use in clinical practice has been replaced by the atypical antipsychotic drugs, which have better adverse effects profiles. All antipsychotics are prescription-only medications that are indicated for the treatment of various psychotic disorders. No single drug stands out as being either more or less effective in the treatment of the symptoms of psychosis. Some of the factors to be considered before selecting an antipsychotic are the patient's history of response to a drug and the possible adverse effects profile. Starting at a low dose with titration to the lowest effective dose helps achieve a balance between symptom relief and adverse effects. For dosage information on profiled drugs, see the table on this page.

BUTYROPHENONE

haloperidol

Haloperidol (Haldol) is structurally different from the thioxanthenes and the phenothiazines but has similar antipsychotic

DOSAGES

Selected Antipsychotic Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE*	CURRENT FDA-APPROVED INDICATIONS/USES
First Generation (Conventional)			
haloperidol (Haldol) (C)	Butyrophenone, phenylbutylpiperidine	**Adult** PO, IM/IV: 0.5-5 mg bid-tid **Pediatric** PO: 0.05-0.15 mg/kg/day IM/IV (acute care only): 1-3 mg q4-8h	Schizophrenia, Tourette's syndrome, severe refractory behavioral problems or hyperactivity
Second Generation (Atypical)			
clozapine (Clozaril) (B)	Dibenzodiazepine	PO: 12.5 mg bid, titrate up to maximum of 900 mg/day. Larger doses divided tid	Schizophrenia; recurrent suicidal behavior in patients with schizophrenia or schizoaffective disorder
♦ risperidone (Risperdal) (C)	Benzisoxazole	PO: 2-8 mg/day in either one or two doses IM depot form (Risperdal Consta): 25-50 mg every 2 wk	Schizophrenia, mania, irritability associated with autism

IM, intramuscular; *IV,* intravenous; *PO,* oral.
*All dosages reflect usual adult dosage ranges. Pediatric dosages may be more variable and are best prescribed by a pediatric practitioner.

properties. It is indicated primarily for the long-term treatment of psychosis. However, it has been largely replaced by the atypical antipsychotics because of its adverse effects (see later). Haloperidol is contraindicated in patients who have shown a hypersensitivity reaction to it, those in a comatose state, those taking large amounts of CNS depressants, and those with Parkinson's disease (due to its antidopaminergic effects). It is a high-potency neuroleptic drug that has a favorable cardiovascular, anticholinergic, and sedative adverse effect profile, but it can cause extrapyramidal symptoms as well as tardive dyskinesia. Haloperidol is available in three salt forms: base (for oral use), decanoate injection (for IM only), and lactate injection (IM or IV). Haloperidol decanoate has an extremely long duration of action, which has historically made it useful in treating patients with schizophrenia who were nonadherent with their drug regimen. The lactate formulation is commonly given intravenously in acute situations. It is important to note that, although the manufacturer states that it is not to be given intravenously, clinical experience and case reports have shown the intravenous route to be safe and effective. Other adverse effects are listed in Table 16-10. Drugs with which haloperidol interacts are listed in Table 16-11.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2 hr	2-6 hr	13-35 hr	8-12 hr
IM	Lactate: 20-30 min	Lactate: 30-45 min	13-35 hr	Lactate: 4-8 hr
	Decanoate: 3-9 days	Decanoate: unknown		Decanoate: 1 mo

ATYPICAL ANTIPSYCHOTICS

Between 1975 and 1990, not a single new antipsychotic drug was approved in the United States. In 1990, clozapine (Clozaril), the first of the atypical antipsychotics, was approved. Clozapine was followed by risperidone (Risperdal), olanzapine (Zyprexa), quetiapine (Seroquel), ziprasidone (Geodon), aripiprazole (Abilify), paliperidone (Invega), iloperidone (Fanapt), asenapine (Saphris), and lurasidone (Latuda).

The term *atypical antipsychotics* refers to the following advantageous properties of these drugs: reduced effect on prolactin levels compared with conventional drugs and improvement in the negative symptoms associated with schizophrenia. They also seem to show a lower risk for neuromuscular malignant syndrome, extrapyramidal adverse effects, and tardive dyskinesia. All ten of the currently available atypical drugs have several pharmacologic properties in common. Antagonist activity at the D_2 receptor is believed to be the mechanism of their antimanic activity. Serotonergic (serotonin agonist) activity at various 5-HT receptor subtypes and alpha$_2$-adrenergic (agonist) activity are associated with antidepressant activity. Alpha$_1$-adrenergic receptor antagonist activity is associated with orthostatic hypotension, and H_1 receptor antagonist activity is associated with both sedative and appetite-stimulating effects. This latter activity accounts for the common adverse effect of weight gain that is associated to various degrees with antipsychotic drugs. This can cause or worsen obesity and even lead to diabetes. Clozapine and olanzapine are associated with the most weight gain, risperidone and quetiapine with less, and ziprasidone is considered weight-neutral. Other atypical antipsychotics fall between the aforementioned drugs. Sedative effects may diminish over time and can actually be helpful for patients with insomnia. Although these drugs all have similar pharmacologic properties, they vary in the degree of affinity for the various types of receptors. These subtle pharmacologic differences, along with often unknown and unpredictable patient physiologic variation, help to explain why some patients respond better (or do not respond) to one medication versus another.

In April 2005, the FDA issued a special public health advisory concerning the use of atypical antipsychotic drugs in elderly patients for off-label (non–FDA-approved) uses. These medications are currently approved for the treatment of schizophrenia and mania. In practice, however, they are also commonly used to control behavioral symptoms of agitation in elderly patients with dementia, including dementia related to Alzheimer's disease. The FDA data found that elderly patients given atypical antipsychotics for this reason were up to 1.7 times more likely to die during treatment. The FDA recommends that patients so treated have their treatment plans reevaluated by their prescribers.

TABLE 16-11 DRUG INTERACTIONS OF SELECTED ANTIPSYCHOTICS*

DRUG CLASS	INTERACTING DRUG(S)	MECHANISM	RESULT
Conventional and Atypical	Alcohol, other CNS depressants	Additive drug effects	Enhanced CNS depression; dystonia with alcohol
	Antihypertensives	Enhanced antihypertensive effects	Potential for hypotension
Conventional: Phenothiazines	Anticholinergics	Additive and antagonistic drug effects	Reduced phenothiazine efficacy; enhanced anticholinergic effects
	Beta blockers	Additive drug effects	Potential toxicity of either drug
	Opioids	Additive drug effects	Excessive sedation, hypotension
	levodopa/carbidopa	Uncertain	Diminished antiparkinson effects
	phenytoin	Uncertain	Can increase or reduce phenytoin levels
	Thiazide diuretics	Reduced diuretic clearance	Potential for hypotension
Atypicals*	CYP3A4 inhibitors (e.g., ketoconazole)	Reduced antipsychotic clearance	Potential for antipsychotic toxicity
	carbamazepine	Enhanced antipsychotic clearance	Reduced therapeutic effects

CNS, Central nervous system; *CYP3A4,* cytochrome P-450 enzyme 3A4.
*See also drug profiles for drug-specific information.

Dosage information for atypical antipsychotics is given in the table on p. 269.

clozapine

Clozapine (Clozaril) was the first of the *atypical* antipsychotics. Compared to conventional antipsychotic drugs, it more selectively blocks the dopaminergic receptors in the *mesolimbic* region of the brain. Conventional antipsychotic drugs block dopamine receptors in an area of the brain called the *neostriatum,* but blockade in this area is believed to give rise to extrapyramidal adverse effects. Because clozapine has very weak dopamine-blocking abilities in this area of the brain, it is associated with minor or no extrapyramidal symptoms. This often makes clozapine the drug of choice for treatment of psychotic disorders in patients who also have Parkinson's disease, because it will not worsen motor symptoms.

Clozapine has been extremely useful for the treatment of patients for whom therapy with other antipsychotic drugs has failed, especially those with schizophrenia. In particular, it is indicated for schizophrenic patients who have shown high risk for suicidal behavior. Adverse effects include the potential for agranulocytosis, a dangerous disorder of white blood cell (WBC) underproduction that is drug induced. For this reason, patients beginning clozapine therapy require weekly monitoring of WBC counts for the first 6 months of therapy. The drug needs to be discontinued if the count falls below 3000/mm^3 and withheld until it rises above this value. It is also recommended that WBC counts be evaluated weekly for 4 weeks after discontinuation of the drug. Clozaril is available only through the Clozapine National Registry, with which the patient and prescriber must be registered. Other adverse effects are listed in Table 16-10. Clozapine is contraindicated in patients with known drug allergy; in those with myeloproliferative disorders, severe granulocytopenia, CNS depression, or angle-closure glaucoma; and in comatose patients. Interacting drugs include alcohol and other CNS depressants (increased CNS depression), levodopa (diminished therapeutic effects), antihypertensives (risk of hypotension), and others listed in Table 16-11. Clozapine is available only for oral use.

Other atypical antipsychotics have features comparable to those of clozapine but do not require extensive WBC monitoring. Risperidone is described in the following profile as an example of these drugs. Orally disintegrating tablets are available for clozapine and risperidone, and asenapine is available as a sublingual tablet. These dosage forms may improve compliance. The dosage is the same as that for regular tablets (see the Dosages table on p. 269).

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-6 hr	Weeks	6 hr	4-12 hr

♦ risperidone

Risperidone (Risperdal) is an atypical antipsychotic that was introduced a few years after clozapine. It is even more active than clozapine at the serotonin (5-HT_{2A} and 5-HT_{2C}) receptors. It also has a high affinity for alpha$_1$- and alpha$_2$-adrenergic receptors and histamine H_1 receptors. This drug is indicated for schizophrenia, including negative symptoms, and causes minimal extrapyramidal adverse effects at therapeutic dosages of 1 to 6 mg/day.

Risperidone is contraindicated in cases of known drug allergy. Adverse effects include elevated prolactin levels, abnormal dreams, insomnia, dizziness, headache, and others listed in Table 16-10. Drugs interacting with risperidone include CNS depressants, antihypertensives, and others listed in Table 16-11. Risperidone is available for oral and injectable use. The long-acting injectable form is called Risperdal Consta, and one intramuscular injection lasts approximately 2 weeks. This is at least one option for helping patients maintain adherence with the prescribed drug regimen. Patients must continue to take oral risperidone for 3 weeks after the first injection of the Consta dosage form to ensure adequate blood levels from the injection. Paliperidone also comes as a long-acting injection (Invega Sustenna), which lasts 1 month.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-2 wk	1-2 hr	20-30 hr	7 days
IM	3 wk	Unknown	20-30 hr	2 wk

NURSING PROCESS

ASSESSMENT

Before administering any of the psychotherapeutic drugs, perform a complete head-to-toe physical assessment and mental status examination. Document your findings. This data will serve as a comparative baseline for the patient during and after initiation of therapy.

Thoroughly assess the patient's neurologic functioning, including level of consciousness, mental alertness, and level of motor and cognitive functioning. The Mini-Mental State Examination (MMSE) is one tool that you may use to assess cognitive status and help identify impairments often found in mental illnesses. The MMSE is simple to use, is cost-effective, and may be completed in about 20 minutes. The MMSE is available in most nursing assessments, nursing fundamentals, and/or psychiatric or mental health nursing textbooks. Points are scored in the areas of level of orientation, attention and calculation ability, recall, and language skills. Other mental health assessment tools include the six-item Blessed Orientation-Memory-Concentration Test, clock-drawing tasks, and Functional Activities Questionnaire (for those with dementia), Alzheimer's Disease Assessment Scale, Mattis Dementia Rating Scale, Severe Impairment Battery, and the Hamilton Rating Scale for Depression. In addition to performing examinations such as these, note baseline levels of motor responses and reflexes as well as the presence of any tremors and/or personality changes. Assess for the presence of cold clammy hands, sweating, and/or pallor. These particular findings may be indicative of an altered autonomic nervous system response.

Constantly assess the patient for any suicidal ideations or tendencies, with attention not only to overt cues and behaviors but also to covert thoughts and ideation. This is important because

of the potential for suicide with the use of psychotherapeutic drugs, with or without the concurrent use of other medications or alcohol. Suicide assessment tools are available and may help you identify an individual's risk for suicidal behaviors. One such tool, the Suicide Assessment Scale, has been found to be valid, reliable, and easy to use. The following are some questions that may be helpful: "What brings you to the doctor's office today?" "How has life been treating you?" "What are some of your worries or concerns?" "How would you describe your mood?" "Tell me about your thoughts." If an assessment reveals any concerns and/or the patient acknowledges suicidal thoughts, make an appropriate referral for immediate assessment and/or treatment.

Remember that many of the patients who require psychotherapeutic drugs are depressed and, as such, suffer from insomnia and possibly from self-neglect. Deterioration in health status and weight loss or gain may also occur. Therefore, it is important to assess sleep habits and nutritional intake and to perform a head-to-toe physical examination for baseline and comparative purposes. Note any drug allergies as well as any contraindications, cautions, and potential drug interactions (see pharmacology discussion and Tables 16-3, 16-6, and 16-11). Assess and document blood pressure and pulse rate before, during, and after drug therapy. Postural blood pressures (i.e., blood pressure taken supine then standing) are particularly important to note because of the possible drug-related adverse effects of postural hypotension and dizziness. The more potent older drugs (e.g., MAOIs or TCAs) may lead to a significant drop in blood pressure and possible syncope, warranting even more skillful assessment and close monitoring (of blood pressure readings).

Review the results of any laboratory studies performed before and during the drug therapy. This is especially important for patients who are receiving long-term drug therapy to prevent or identify any early complications or other possible adverse effects or toxicity. Laboratory studies may include, but are not limited to, tests to confirm therapeutic serum levels of the specific drug and, if appropriate, a complete blood count, erythrocyte sedimentation rate, serum electrolyte and glucose levels, BUN, liver function studies, serum level of vitamin B_{12}, and thyroid studies. If the patient is experiencing forms of dementia, other types of testing may be needed, such as genetic studies, computed tomography, or magnetic resonance imaging.

With psychotherapeutic drug therapy, assess the patient's mouth and oral cavity to make sure the patient has swallowed the entire oral dosage. This helps to prevent hoarding or "cheeking" of medications, a form of noncompliance that may lead to drug toxicity or overdose. If the assessment shows that this is a potential risk, using liquid dosage forms, when available, may minimize such problems. Other areas to assess include the patient's appetite, sleeping patterns, addictive behaviors, elimination difficulties, and allergic reactions. Note any new symptoms or problems.

ANXIOLYTIC DRUGS

Anxiety disorders are treated with the anxiolytic drugs. *Anxiolytic drugs*, specifically the benzodiazepines, are associated with many contraindications, cautions, and drug interactions (see pharmacology discussion). When these drugs are used, the prescriber may order laboratory studies, such as complete blood counts, serum electrolyte levels, and hepatic/renal function studies (see earlier discussion). Blood pressure readings are also very important to assess because of drug-related postural hypotension. The baseline neurologic examination needs to include assessment of alertness, orientation, and sensory/motor functioning as well as any complaints of ataxia, headache, or other neurologic abnormalities. To complete a thorough medication profile, create a list of all medications taken along with any other psychotherapeutic

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

Psychotherapeutic Drugs

- Elderly patients show higher serum levels of psychotherapeutic drugs because they have age-related changes in drug distribution and metabolism, less serum albumin, decreased lean body mass, less water in tissues, and increased body fat. They also have decreased renal function. Because of these changes, elderly patients generally require lower dosages of antipsychotic and antidepressant drugs and are at greater risk for toxicity.
- Orthostatic hypotension, anticholinergic adverse effects, sedation, and extrapyramidal symptoms are more common in elderly patients taking psychotherapeutic drugs.
- Careful evaluation and documentation of baseline parameters, including neurologic findings, are important to the safe use of these drugs.
- Increased anxiety is often associated with the use of tricyclic antidepressants.
- Patients with a history of cardiac disease may be at a greater risk for experiencing dysrhythmias, tachycardia, stroke, myocardial infarction, or heart failure.
- Lithium toxicity is more common in elderly patients, and lower dosages are often necessary to achieve therapeutic levels. Close monitoring is important to its safe use in this age group. Central nervous system toxicity, lithium-induced goiter, and hypothyroidism are more common in elderly patients.

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

Psychotherapeutic Drugs

- Pediatric patients are more likely to experience adverse effects from psychotropic drugs, especially extrapyramidal effects.
- The incidence of Reye's syndrome and other adverse reactions is greater in pediatric patients who have had chickenpox, central nervous system infections, measles, acute illnesses, or dehydration and are taking psychotropic drugs.
- Lithium may lead to decreased bone density or bone formation in children; therefore, children receiving it need to be closely monitored for signs and symptoms of lithium toxicity and bone disorders. The safety and efficacy of lithium dosing for those younger than 6 years of age is not established.
- Tricyclic antidepressants generally are not prescribed for patients younger than 12 years of age. However, some antidepressants are used in children with enuresis, attention deficit disorders, and major depressive disorders, and may be associated with adverse reactions such as electrocardiographic changes, nervousness, sleep disorder, fatigue, elevated blood pressure, and gastrointestinal upset.
- Pediatric patients are generally more sensitive to the effects of most drugs, and psychotherapeutic drugs are no exception. Be aware of the risk of toxicity, which can be fatal. If confusion, lethargy, visual disturbances, insomnia, tremors, palpitations, constipation, or eye pain occur, contact the prescriber immediately.

drugs, all prescription drugs, over-the-counter drugs, vitamins, minerals, and herbal products. Diazepam, although one of the more commonly prescribed benzodiazepines, is generally used for seizure disorders and preoperative sedation and requires assessment related to these uses (see Chapters 11 and 14). Specific concerns for pediatric and elderly patients are presented in the boxes on p. 272. Closely observe and assess elderly patients for oversedation and/or profound CNS depression during drug therapy. The elderly are often more sensitive to drugs and therefore more likely to experience adverse effects; their safety needs to be a constant concern.

Since eye problems may occur with use of *benzodiazepines,* baseline visual testing using a Snellen chart or an eye examination conducted by the appropriate health care provider (e.g., an ophthalmologist or optometrist) is recommended. Allergic reactions to some of these medications (e.g., clonazepam) are characterized by a red raised rash. In addition, obese patients may experience toxicity in a shorter period of time than those who are not obese. This occurs because several anxiolytic drugs are lipid soluble and have greater affinity for fatty tissues; therefore, their half-life is increased in patients who are obese. Give lorazepam cautiously (under very close supervision) if the patient is suicidal, because its use may be associated with suicide attempts. Administer alprazolam only after very careful assessment of mental status, mood, sensorium, and sleep patterns.

Some benzodiazepines are also associated with medication errors because of the existence of sound-alike or look-alike drugs. Assessing the drug order for the right drug is important because of the possibility of such an error and the negative consequences to the patient. Benzodiazepine drugs and the sound-alike medications with which they could be confused include the following: Klonopin (clonazepam) and clonidine; diazepam and Ditropan (oxybutynin); lorazepam and alprazolam; and Versed (midazolam) and VePesid (etoposide) and Vistaril (hydroxyzine).

Buspirone is another anxiolytic drug that is not a benzodiazepine. It is used because it has fewer adverse effects, such as decreased sedation and lack of dependency potential. However, it is associated with many drug interactions, cautions, and contraindications (see pharmacology discussion). General assessment of the neurologic system and a mental health assessment are also important to complete.

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Sound-Alike Drugs: Bupropion and Buspirone

Is it bupropion or buspirone? Be careful—these two central nervous system drugs have sound-alike names but very different uses.

Bupropion (Wellbutrin) is an antidepressant that is used to relieve depression. The Zyban formulation of bupropion is given to treat nicotine withdrawal symptoms. Bupropion is available in various formulations ranging from 75- to 100-mg tablets to extended- or sustained-release formulations of 100-mg, 150-mg, 200-mg, and 300-mg tablets.

Buspirone hydrochloride (BuSpar) is an anxiolytic drug that is used for short-term treatment of anxiety symptoms or long-term management of anxiety disorders. It is available in tablets ranging from 5 mg to 30 mg.

MOOD-STABILIZING DRUGS

As previously discussed in the pharmacology section, affective disorders are treated with *mood-stabilizing drugs* and antidepressant drugs. Before antimanic drugs such as lithium are administered, perform a thorough neurologic examination. Also assess vital signs, especially blood pressure, hydration status, dietary intake, skin tone, and presence of edema. Baseline levels of consciousness and alertness, gait and mobility levels, and overall motor functioning are also important to assess. These are particularly important to assess because poor coordination, tremors, and weakness may be symptoms of toxic blood levels of antimanic drugs. Laboratory studies often ordered before and during drug therapy include serum sodium, albumin, and uric acid levels. Serum levels of sodium are important to know because lithium toxicity is potentiated by the presence of hyponatremia and hypovolemia. During the initial phase of therapy, serum lithium levels must be assessed every 3 to 4 days (therapeutic levels are 0.6 mEq/L to 1.2 mEq/L; toxic levels are above 1.5 mEq/L). A urinalysis with specific gravity may also be ordered to assess volume status.

ANTIDEPRESSANTS

You must assess for many cautions, contraindications, and drug interactions before giving *antidepressants* (see pharmacology discussion). Continuous assessment for any suicidal ideations or tendencies is important because indicators of suicide risk may be covert as well as overt. Suicide must always be considered a potential risk when any psychotherapeutic medication, whether an antidepressant or other CNS-altering drug, is taken alone or in combination with other drugs or alcohol.

The *second-generation antidepressants* are associated with fewer and less severe adverse effects as compared to the older TCA and MAOI antidepressants. These second-generation drugs include *SSRIs* (fluoxetine [Prozac]) and *SNRIs* (duloxetine [Cymbalta]). However, with SSRIs it is still important to assess and document neuromuscular and gastrointestinal systems. Cautious use in the elderly is recommended due to their increased risk for toxicity. Additionally, there is concern for the occurrence of serotonin syndrome. Serotonin syndrome (see Box 16-1) includes symptoms such as agitation, tachycardia, sweating, and muscle tremors. Contraindications include the use of these drugs within 14 days of use of MAOIs and with some antipsychotic drugs. Assess for significant drug interactions, such as warfarin and phenytoin, due to their increased protein binding. Do not give *SNRIs*, such as duloxetine (Cymbalta), to patients with closed-angle glaucoma or those taking MAOIs. Liver function studies may be ordered prior to use of this drug because of the risk of liver toxicity. The *miscellaneous antidepressant,* bupropion, may be preferred over some of the other antidepressants because of fewer anticholinergic, antiadrenergic, and cardiotoxic effects (see pharmacology discussion). Assess the patient's baseline neurologic, mental, and cardiac status before the drug is used. Because of delayed therapeutic effects, closely assess the patient for any suicidal tendencies or ideas. Assess the availability of family support systems as well as the need for any supportive resources.

TCAs, as an older class of antidepressants, are effective drugs but are associated with serious adverse effects. However, some patients do tolerate the TCAs. When patients are taking TCAs, monitor closely for potential adverse effects. Use with the herbal product, St. John's wort, is not recommended. Amitriptyline is not to be used in patients with recent myocardial infarction and is associated with potent anticholinergic properties leading to dry mouth, constipation, blurred vision, urinary retention, and alterations in cardiac rhythm.

Closely monitor patients receiving *MAOIs* who have a history of suicide attempts or suicidal ideations. Suicidal thoughts and suicide attempts are important to consider, because these drugs may be hoarded by the patient and then used to carry out suicide. These patients must be under the care of a health care professional (e.g., psychiatrist, physician, or nurse practitioner) so that they may be closely monitored for destructive behaviors. MAOIs are also known for their significant drug interactions (see Table 15-4) such as with meperidine, other opioids, other MAOIs, SSRIs, oral contraceptives, and buspirone. MAOIs, if taken with foods high in tyramine (see Table 16-7), are associated with a hypertensive crisis; therefore, closely monitor blood pressure readings, including postural blood pressure measurements. Postural hypotension, an adverse effect of MAOIs, may lead to a high risk of dizziness, fainting, and possible falls or injury. If the patient is hospitalized, monitor supine/standing or sitting blood pressures at least every 8 hours or more frequently, if needed. A period of 1 to 2 minutes needs to elapse after taking the supine blood pressure before measuring standing or sitting pressures and pulse rate. Laboratory tests that are often ordered for patients taking these drugs include complete blood counts and renal and liver function studies. In addition, it is crucial to understand that elderly patients be given these drugs only if it is deemed absolutely necessary by the prescriber and only with careful monitoring. The extrapyramidal adverse effects (e.g., tremors) are often worse in the elderly and may result in inability to perform activities of daily living. This extrapyramidal reaction may lead to progressive deterioration of motor activities; thus, there is a need for a thorough motor and neurologic assessment.

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

Ginseng

Overview
Comes from the *Panax quinquefolius* plant in North America (American ginseng), the *Panax ginseng* plant in Asia (Panax ginseng), and the *Acanthopanax senticosus* plant in Russia (Siberian ginseng). All three are different herbs, with Siberian ginseng being markedly different from the other two but often less expensive. Used for more than 5000 years.

Common Uses
Improvement of physical endurance and concentration, stress reduction (NOTE: This is a very abbreviated list of uses for these products.)

Adverse Effects
Elevated blood pressure, chest pain or palpitations, anxiety, insomnia, headache, nausea, vomiting, diarrhea

Potential Drug Interactions
May reduce the effectiveness of anticoagulants and immunosuppressants, but enhance the effectiveness of anticonvulsants and antidiabetic drugs

Contraindications
Contraindicated in children and pregnant women

ANTIPSYCHOTICS

The use of *antipsychotics* requires careful assessment of all body systems. Assessment of cardiovascular, cerebrovascular, neurologic, gastrointestinal, genitourinary, renal, hepatic, and hematologic functioning is important to safe and efficacious drug therapy. The presence of significant disease in one or several organ systems may lead to a more adverse response to a drug and may even be dose limiting; therefore, perform a careful and skillful assessment of the patient before and during drug therapy. Weight gain may occur, and if the patient is experiencing deleterious health effects because of this, another drug may be ordered. Suicidal ideations, orthostatic changes in blood pressure, extrapyramidal symptoms, confusion, headache, gastrointestinal upset, abnormal muscle movements, rashes, and dry mouth may be associated with many of these drugs; therefore, perform and document a thorough nursing history and mental status examination prior to the initiation of drug therapy. Identify possible drug interactions with any prescription drugs, over-the-counter medications, and/or herbals the patient is taking, as well as any conditions that represent cautions or contraindications to use of the antipsychotic drug (see pharmacology discussion). The phenothiazine antipsychotics may still be prescribed in some situations but are mentioned here mainly for historical purposes. These antipsychotics are associated with significant extrapyramidal adverse effects (see earlier discussion) as well as anticholinergic adverse effects such as dry mouth, urinary hesitancy, and constipation.

Haloperidol is similar to other high-potency antipsychotics because its sedating effects are low but the incidence of extrapyramidal symptoms is high. Assessment of baseline motor, sensory, and neurologic functioning is therefore very important to patient safety. With some of the antipsychotic drugs, patients may experience adverse effects of tremors and muscle twitching from the drug's blockade of dopamine receptors (dopamine generally has an inhibitory effect on specific motor activity in the musculoskeletal system). These extrapyramidal movements are like those in parkinsonism (see Chapter 15) and may be very bothersome and uncomfortable.

Atypical antipsychotics such as clozapine and risperidone have many contraindications, cautions, and drug interactions. Perform a thorough mental status examination, and document the findings prior to initiation of treatment with these and other antipsychotic drugs. An assessment of musculoskeletal functioning and monitoring for any extrapyramidal reaction is also important to patient safety. Monitor liver and renal function studies, complete blood count, and urinalysis before and during therapy. Make sure to document blood pressure readings with close attention to postural readings because of the potential for the adverse effect of postural hypotension. A drop of 20 mm Hg or more in the systolic blood pressure requires immediate

attention and implementation of safety precautions. In addition, for the elderly patient, the prescriber may order reduced dosages to help prevent toxicity. These drugs are also associated with a high degree of sedation and must be used only when absolutely necessary and with extreme caution (close monitoring) in the elderly and other patients who are at risk for falls or have limited motor and sensory capabilities. Carefully monitor heart sounds, and observe for any abnormal heart rhythms in patients taking these drugs.

NURSING DIAGNOSES

1. Imbalanced nutrition, less than body requirements, related to the consequences of the mental health disorder and/or the use of psychotherapeutic drugs
2. Urinary retention related to the adverse effects of psychotherapeutic drugs
3. Constipation related to the adverse effects of psychotherapeutic drugs
4. Sexual dysfunction related to the adverse effects associated with psychotherapeutic drugs
5. Sleep deprivation related to the mental health disorder and/or related drug therapy
6. Deficient knowledge related to lack of information about the specific psychotherapeutic drugs and their adverse effects
7. Impaired social interaction related to various inadequacies felt by the patient due to illness or isolation from others
8. Situational low self-esteem related to the mental health disorder and from the adverse effects of psychotherapeutic drugs, including sexual dysfunction
9. Risk for injury to self related to the mental health disorder and/or possible adverse effects of psychotherapeutic drugs

PLANNING

GOALS

1. Patient exhibits improved nutritional status and without weight loss.
2. Patient remains free from any alterations in urinary elimination patterns.
3. Patient regains/maintains normal bowel elimination patterns.
4. Patient remains free from or experiences minimal alterations in sexual function.
5. Patient implements measures to minimize sleep deprivation.
6. Patient is compliant to medication therapy, takes medication(s) as ordered, and is free from complications associated with drug therapy.
7. Patient regains/maintains social interaction and open communication with family, friends, significant others, and members of the health care team.
8. Patient exhibits more positive self-image, healthier thought processes, and interactive processes.
9. Patient maintains safety with drug therapeutic regimen and without injury to self.

OUTCOME CRITERIA

1. Patient shows healthy nutritional habits with appropriate weight gain and a diet that includes foods from the U.S. Department of Agriculture MyPlate (www.choosemyplate.gov/).
2. Patient reports any problems with urinary hesitancy, urgency, retention, or discomfort over the lower abdominal area.
3. Patient states measures to increase bowel elimination, such as increasing dietary bulk/fiber with fruits and vegetables, while also increasing fluid intake.
   - Patient reports any problems with bowel elimination, such as constipation or passing of hard stool.
4. Patient openly communicates with the prescriber and his or her partner about difficulty with sexual functioning as related to drug therapy.
   - Patient openly identifies/discusses with the prescriber options for improving sexual functioning to assist with any altered patterns of sexual behavior.
5. Patient reports measures to increase healthier sleeping habits through journaling, use of nondrug sleep enhancement measures such as going to bed at a regular time nightly, decreasing room noise/light, calming music, aromatherapy, and avoiding caffeine in the late afternoon/evening (see Chapter 12 for sleep hygiene nursing interventions).
6. Patient states reasoning for compliance to medication regimen, as well as the need to take the medication exactly as prescribed, and related drug safety measures.
   - Patient has assistance at home in the daily monitoring of self-administration of medication(s).
   - Patient states common adverse effects of psychotherapeutic drug therapy, such as confusion, sedation, constipation, nausea, dizziness, unsteady gait, dry mouth, changes in sexual performance, weight gain/loss, and loss or increase in appetite.
   - Patient states adverse effects that need reporting to the prescriber, such as unresolved constipation, urinary retention, increasing levels of sedation, and dizziness/fainting upon standing or changing of positions.
7. Patient demonstrates improved or no further deterioration in social integration with healthier patterns of communication and participation in activities.
   - Patient interacts openly and frequently with family, friends, significant others, and members of the health care team without suspicion or paranoia.
   - Patient participates daily or more frequently in social interactions/activities and plans to engage in more social activities, as appropriate.
8. Patient demonstrates improved self-concept/self-esteem in daily interactions with family/friends/significant others while experiencing fewer episodes of self-destructive and negative behaviors.
   - Patient feels more positive about self as seen with increased participation in activities of daily living, social activities, and family functions.
9. Patient demonstrates safety with activities of daily living and self-care measures by moving slowly, changing positions slowly, and reporting excess dizziness as well as fainting episodes.

IMPLEMENTATION

Regardless of the psychotherapeutic drug prescribed, several general nursing actions are important for safe administration. First and foremost, demonstrate a firm but patient attitude and use therapeutic communication if appropriate. Once the patient's reading level and effective means of teaching and learning are identified, provide the patient with simple explanations about the drug, its action, and the length of time before therapeutic effects can be expected. Always use a thorough psychosocial and holistic approach when caring for any patient with any illness. Monitor vital signs and document findings, especially during the initiation of therapy. Of great concern is administration of these medications to those who are elderly and to patients with a history of hypertension and cardiac disease. All of the psychotherapeutic drugs are to be taken exactly as prescribed and at the same time every day and without failure. If omission occurs, contact the prescriber immediately. Abrupt withdrawal may have negative effects on the patient's physical and mental status. Solicit help from family members or others providing support in the care of the patient so that there are options for assistance with drug administration. Adherence to the medication regimen is crucial to effective management; identify and utilize all support systems and resources to accomplish this.

ANXIOLYTIC DRUGS

Specific nursing interventions related to the use of *anxiolytic drugs* include frequent monitoring of vital signs with special attention to blood pressure and postural blood pressures. Encourage the use of elastic compression stockings and changing positions slowly to minimize dizziness and falls from orthostatic hypotension. Create a therapeutic environment for open communication—especially of all disturbing thoughts, including those of suicide. Check the patient's oral cavities for hoarding or cheeking of drugs. Dispense medications only as ordered to help minimize the risk for suicide attempts. Use intravenous routes of administration only as prescribed and give the drug over the recommended time with the proper diluent and at a rate indicated by the manufacturer and prescriber. Always administer intramuscular dosage forms in a large muscle mass and only as ordered or indicated (see Chapter 9 for more information on parenteral administration). See Patient Teaching Tips for more information.

MOOD-STABILIZING DRUGS

Safe use of the *mood-stabilizing drug lithium* depends on adequate hydration and electrolyte status, because lithium levels may become toxic with dehydration and hyponatremia. See Patient Teaching Tips for more information.

ANTIDEPRESSANTS

Administer all antidepressants carefully and exactly as ordered. With *second-generation antidepressants,* emphasize that it may take up to 4 to 6 weeks before therapeutic effects are evident. This 4- to 6-week time frame is also associated with the TCAs and MAOIs. Make sure the patient understands this and continues to take the medication as prescribed—even if the patient feels his or her condition is not improving. Carefully monitor the patient, be readily available, and provide supportive care during this time. The period before therapeutic effects are seen may be the time the patient is at highest risk for self-harm and/or suicide. Advise the patient to take the drug(s) with food and at least 4 to 6 oz of fluid. Assist with ambulation and other activities if the patient is weak, elderly, or dizzy (from postural hypotension). Counsel patients about potential sexual dysfunction (if appropriate) and if an adverse effect of the drug. If sexual dysfunction occurs, provide information to the patient about various options (e.g., waiting to see if the adverse effect resolves, reducing the current dosage of the drug as ordered, taking a "drug holiday" if ordered by the prescriber). A drug holiday, if indicated, generally occurs in a hospital setting, and the drug is removed but only under very close monitoring. See Patient Teaching Tips for more specific information regarding *SSRIs* and *SNRIs*.

With the use of *TCAs* and *MAOIs,* educate the patient on adverse effects and drug/food interactions. Emphasize the importance of keeping a list of all medications on their person at all times. Advise to change positions purposely and slowly. All health care providers need to be informed that the patient is taking these drugs and that weaning must occur when these drugs are to be discontinued. With TCAs, advise the patient to report any of the following to the prescriber if they occur: blurred vision, excessive drowsiness, sleepiness, urinary retention, constipation, and cognitive impairment. It is also important to inform patients that tolerance to sedation will occur with some second-generation antidepressants.

PATIENT-CENTERED CARE: CULTURAL IMPLICATIONS

Psychotherapeutic Drugs

Many racial and ethnic groups respond to drugs differently. For example, Asians have lower drug metabolism activity than whites related to lower levels of various enzymes. Asians often require lower dosages of benzodiazepines and tricyclic antidepressants because they have lower levels of the enzymes metabolizing these drugs (e.g., CY02D6) and are therefore more sensitive to the drugs.

Diazepam follows a different metabolic pathway in the Chinese and Japanese populations. These two groups are found to be poor metabolizers of this drug and its metabolite. Approximately 20% of Chinese and Japanese individuals metabolize diazepam poorly, which results in rapid drug accumulation. To prevent possible toxicity, lower dosages are generally required. Nurses need to be aware of this cultural variable and assess these patients for sedation, overdosage, and other adverse reactions.

Researchers have also identified genetic factors that help predict a response to antidepressants. A study of some 80 Mexican Americans with depression found that depressed and highly anxious patients with certain variant genes had a 70% higher reduction in anxiety and a 30% higher reduction in depression in response to treatment with fluoxetine than did other racial and ethnic groups without the specific gene variation.

ANTIPSYCHOTICS

Patients need to be aware that *antipsychotic drugs* are to be taken exactly as prescribed to be effective. Different levels of paranoia or delusions may lead the patient to mistrust you and

other members of the health care team, so maintain a sufficient level of trust through consistency, empathy, and the establishment of therapeutic communication to help ensure compliance. Adherence/compliance is always a critical issue for patients with psychotic illnesses, because these patients are at higher risk for not taking medications and not keeping follow-up appointments. Nonadherence to the medical and treatment regimen is of major concern because the serum levels of drugs such as haloperidol must be within a specified therapeutic range for the patient to feel better and be functional. If serum levels of haloperidol are less than 4 ng/mL, the patient may show symptoms of the mental disorder, whereas levels higher than 22 ng/mL may result in toxicity. Therefore, selection of an antipsychotic drug and its dosage, route of administration, risk for toxicity, and/or suicidal potential, as well as therapeutic communication and patient education, are all important factors for successful therapy. Because most antipsychotic drugs are quite potent, be sure that oral dosage forms have actually been swallowed and have not been intentionally hidden in the side of the mouth (see previous discussion on cheeking of medications). Oral forms of the antipsychotics are generally well absorbed and will cause less gastrointestinal upset if taken with food or a full glass of water. Sucking on hard candy or gum may help to relieve dry mouth. With any of the dosage forms, perspiration may be increased; therefore, encourage the patient to avoid engaging in excessive activity or being exposed to heat or humidity. Excessive sweating can lead to dehydration and subsequent drug toxicity.

Haloperidol may not necessarily be the best drug to use because of the risk for undermedication or overmedication and troubling adverse effects (see Table 16-10). Therefore, other antipsychotics (e.g., clozapine and risperidone) may be preferred, as previously discussed. Clozapine and risperidone are therapeutically effective and carry a minimal risk of tardive dyskinesia and extrapyramidal symptoms. In addition, they usually lead to improvement in cognitive behavior. Clozapine is to be taken as ordered and usually given in divided doses; proper dosing is very important to therapeutic effectiveness. If any changes in blood counts (e.g., leukopenia) are noted or if abnormal cardiac functioning (e.g., tachycardia) is identified, contact the prescriber immediately. In such a case, the medication may need to be discontinued, but only as ordered, and the patient monitored closely. Titration of doses of clozapine, either upward or downward, needs to be done very carefully with close monitoring of the patient for any exacerbation of the mental illness or suicidal tendencies.

Risperidone is to be given as ordered and administered by injection into a deep muscle mass. Always check hospital or facility policy and/or drug insert guidelines regarding the administration of this drug. Intramuscular injection dosage forms may be ordered along with oral doses of risperidone or possibly of another antipsychotic drug for several weeks, with maintenance doses of an intramuscular injection given every 2 to 4 weeks, as ordered. Always alternate intramuscular injection sites to maintain tissue integrity and muscle mass, and be sure that the site is not red, swollen, or irritated. Document and report any changes. Oral solution, tablets, and orally disintegrating tabs are other available dosage forms. Do not give oral solutions with cola or tea. Disintegrating tabs need to be dissolved under the tongue before swallowing with or without liquid. Always follow the prescriber's orders for administering this and all other drugs. The daily amount is usually given in two divided doses, with dosage decreased in the elderly and in those with impaired renal or hepatic function. Make sure you report any excess sedation, anxiety, extrapyramidal symptoms, tardive dyskinesia, seizures, or strokelike symptoms immediately. Measuring vital signs and monitoring for any postural hypotension is also important during treatment.

Once therapy with any of the antipsychotic drugs has been initiated, it is important for you and other health care providers involved in the patient's care to monitor drug therapy closely, including measuring serum drug levels during follow-up visits. If the patient is suspected of being nonadherent and serum drug levels are subtherapeutic, the patient needs to be reevaluated by the prescriber for a possible change of drug or dosage form. The parenteral dosage forms usually come in a depot (longer-releasing) dosage formulation that releases the drug over 2 to 4 weeks, leading to increased compliance and often a better therapeutic outcome.

Patient education (see Patient Teaching Tips) and patient adherence with the drug regimen are keys to successful treatment, regardless of the mental illness. Often it is the mental disorder itself that causes patient nonadherence. Keeping communication open with the patient, family, and/or caregiver is important to develop trust and a sense of empathy. Although patient education may have been thorough, emphasize that the patient may call the prescriber, clinic, or hotline 24 hours a day. Keep phone numbers continually updated. Make constant and ongoing professional counseling available with a mental health care provider (psychiatrist, nurse practitioner, or other licensed mental health professional) so that the patient's progress is consistently monitored. Group therapy and support groups are also available for the patient and significant others.

EVALUATION

Monitor the therapeutic effects of psychotherapeutic medications and the patient's progress before and during drug therapy. Mental alertness, cognition, affect, mood, ability to carry out activities of daily living, appetite, and sleep patterns are all areas that need to be closely monitored and documented. The patient must continue with other forms of therapy, in addition to drug therapy, with the goal of acquiring more effective coping skills. Other forms of treatment may include intense psychotherapy, relaxation therapy, stress reduction, and lifestyle changes. It is important to mention that blood levels of these drugs will be measured during follow-up visits to ensure that therapeutic levels are maintained. Such monitoring of serum drug levels helps identify both subtherapeutic and toxic levels.

The therapeutic effects of *anxiolytic drugs* are evidenced by improved mental alertness, cognition, and mood; fewer anxiety and panic attacks; improved sleep patterns and appetite; more interest in self and others; less tension and irritability; and fewer feelings of fear, impending doom, and stress. Watch for

CASE STUDY

Antidepressants

A 49-year-old patient comes to the clinic with a history of depression. He tells you that he was treated for it by a doctor in another country, but he "ran out of pills" a week ago and did not know how to get a refill. He could not remember the name of the medication but said it was for "depression." He has also been having trouble sleeping. After a psychiatric evaluation, he is given a 2-week prescription for fluoxetine (Prozac).

1. A few days later, his wife calls to describe "a terrible reaction" that he is having. She says that he is shaking and shivering, has a fever, and is somewhat confused and upset. She thinks he has a bad infection. What do you think has happened, and why?
2. What could have been done to prevent this problem?
3. After 2 weeks, the patient is given a prescription for trazodone (Desyrel) and is instructed to return to the office in 2 weeks. What advantage does this medication have for this patient?

For answers, see http://evolve.elsevier.com/Lilley.

the adverse effects of hypotension, lethargy, fatigue, drowsiness, and confusion in patients taking anxiolytic drugs. In general, adverse reactions to *antidepressants* consist of drowsiness, dry mouth, constipation, dizziness, postural hypotension, sedation, blood dyscrasias, sexual dysfunction, and dyskinesias. Overdose is evidenced by seizures or dysrhythmias.

Therapeutic effects of the *mood stabilizer lithium* are decreased mania and stabilization of the patient's mood. Lithium is usually better tolerated by the patient during the manic phase. Adverse reactions to lithium include dysrhythmias, hypotension, sedation, slurred speech, slowed motor abilities, and weight gain. Gastrointestinal adverse effects include GI discomfort.

When used as antidepressants, *SSRIs* and *SNRIs* may take up to 6 weeks to reach full therapeutic effect. A therapeutic response to these drugs includes improved depression or mental status, improved ability to carry out activities of daily living, less insomnia, and improved mood disorder with minimal adverse effects of weight gain, headache, gastrointestinal upset, insomnia, dizziness, drowsiness, and sexual dysfunction. Monitor the patient for symptoms of serotonin syndrome such as agitation, tachycardia, hyperreflexia, and tremors.

The therapeutic effects of the *antipsychotic drugs* include improvement in mood and affect, and alleviation or decrease in psychotic symptoms (decrease in hallucinations, paranoia, delusions, garbled speech) once the patient has been taking the medication for several weeks. Careful monitoring of the patient's potential to injure self or others during the delay between the start of therapy and symptomatic improvement is critical. Evaluation for adverse effects includes monitoring blood counts (clozapine) as well as tic-like trembling movements of the hands, face, neck, and head; hypotension; and dry mouth (haloperidol).

PATIENT TEACHING TIPS

Anxiolytic Drugs

- Encourage patients to avoid operating heavy machinery and driving until the adverse effects of sedation or drowsiness have resolved.
- Educate about the development of tolerance to the sedating properties of benzodiazepines with chronic use (see Chapter 12).
- Instruct patients not to take over-the-counter drugs or herbals without seeking advice from the prescriber.
- Keep these and all psychotherapeutic drugs out of the reach of children.
- Alcohol and other CNS depressants must be avoided.
- Advise patients to carry a medical alert or other identification bracelet/necklace with their diagnoses and a list of their drugs and allergies at all times. The drug list needs to be updated at least every 3 months.
- Medications must always be taken exactly as ordered. Avoid sudden withdrawal. If withdrawal of a drug is necessary, tapering/weaning of doses is needed.

Mood-Stabilizing Drugs

- Instruct the patient that lithium must be taken at the same time each day, and give specific instructions on how to handle missed doses. Make sure the patient understands the importance of adequate hydration.
- Inform the patient that the adverse effects of lithium are usually transient; however, excessive tremors, seizures, confusion, ataxia, and excessive sedation must be reported to the prescriber immediately.

Monoamine Oxidase Inhibitors and Tricyclic Antidepressants

- Advise the patient taking MAOIs to contact the prescriber immediately if any of the following signs and symptoms of overdosage or toxicity occur: tachycardia, hyperthermia, or seizures.
- If the patient is taking an MAOI, caution him or her about avoiding over-the-counter cold and flu products. Foods or beverages high in tyramine are to be avoided (see Table 16-7).
- When the patient is taking a TCA, any blurred vision, agitation, urinary retention, or ataxia needs to be reported to the prescriber immediately.
- Encourage wearing of a medical alert necklace or bracelet showing the diagnosis and a list of current drugs.

Selective Serotonin Reuptake Inhibitors and Serotonin-Norepinephrine Reuptake Inhibitors

- Consumption of fiber supplements must occur at least 2 hours before or after the dosing of medication to avoid interference with drug absorption; however, dietary fiber intake is appropriate.

PATIENT TEACHING TIPS—cont'd

- Encourage the patient to openly discuss any concerns about the medication and adverse effects such as gastrointestinal upset, sexual dysfunction, or tremors.
- Provide a listing of drug-drug interactions, such as the strong interaction between SSRIs and MAOIs, St. John's wort (an herbal product), and tryptophan (a serotonin precursor found in foods). Such interactions may pose a risk for serotonin syndrome (see earlier discussion). Cold products and over-the-counter medications must be approved by the prescriber.
- SSRIs must be taken carefully and as prescribed. Any increase in suicidal thoughts or extreme changes in mood needs to be reported immediately to the prescriber.
- Emphasize that all follow-up visits must be kept and prescriber contacted if there are any concerns. Educate that discontinuation of SSRIs and SNRIs requires a tapering period of up to 1 to 2 months, as ordered. Discontinuation syndrome may occur with or without a tapering period; this includes symptoms of dizziness, diarrhea, movement disorders, insomnia, irritability, visual disturbance, lethargy, anorexia, and lowered mood.
- If there is ever doubt that too much of an antidepressant has been taken, contact the prescriber and/or seek emergency medical treatment immediately.
- If transdermal patches are the dosage form used, emphasize the importance of rotating the patch site with each application and to place patch on a nonhairy, healthy, intact area. Any residue from the previous patch is to be gently cleansed off prior to application of a new patch.

Antipsychotics

- Advise patients to avoid hot baths, saunas, and hot climates with antipsychotics because of the risk of further drop in blood pressure, especially upon standing (postural hypotension). Injury to self may occur due to dizziness or fainting.
- Haloperidol and other antipsychotics must never be stopped abruptly because of the high risk of inducing a withdrawal psychosis.
- Drug interactions with clozapine include alcohol, CNS depressants, levodopa, and antihypertensives.
- Any sore throat, malaise, fever, or bleeding must be reported to the prescriber immediately because of the drop in WBC counts with clozapine.

KEY POINTS

- Psychosis is a major emotional disorder that impairs mental function. A person experiencing psychosis cannot participate in everyday life and shows the hallmark sign of loss of contact with reality.
- Affective disorders are emotional disorders characterized by changes in mood. They range from mania (abnormally elevated emotions) to depression (abnormally reduced emotions) and include anxiety, a normal emotion that may be a healthy reaction but becomes pathologic when it is life-altering.
- Situational anxiety arises in response to specific life events, and nursing assessment is key to identifying patients at risk.
- SSRIs and SNRIs are often prescribed because of their superiority to older antidepressants.
- Nursing considerations related to psychotherapeutic drugs include the need for skillful patient assessment with an emphasis on past and present medical history, physical examination, and a thorough medication history and profile.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 In caring for a patient experiencing ethanol withdrawal, the nurse expects to administer which medication or medication class as treatment for this condition?
   - **a** lithium (Eskalith)
   - **b** Benzodiazepines
   - **c** buspirone (BuSpar)
   - **d** Antidepressants

2 Patient teaching for a patient receiving an MAOI would include instructions to the patient to avoid which food product?
   - **a** Orange juice
   - **b** Milk
   - **c** Shrimp
   - **d** Swiss cheese

3 After a patient has been treated for depression for 4 weeks, the nurse calls the patient to schedule a follow-up visit. What concern will the nurse assess for during the conversation with the patient?
   - **a** Weakness
   - **b** Hallucinations
   - **c** Suicidal ideations
   - **d** Difficulty with urination

4 The nurse is caring for a patient who has been taking clozapine (Clozaril) for 2 months. Which laboratory test(s) should be performed regularly while the patient is taking this medication?
   - **a** Platelet count
   - **b** WBC count
   - **c** Liver function studies
   - **d** Renal function studies

5 The nurse is giving medications to a patient. Which drug or drug class, when administered with lithium, increases the risk for lithium toxicity?
   - **a** Thiazides
   - **b** levofloxacin
   - **c** calcium citrate
   - **d** Beta blockers

NCLEX® EXAMINATION REVIEW QUESTIONS—cont'd

6 The nurse is teaching a patient about treatment with an SSRI antidepressant. Which teaching considerations are appropriate? (Select all that apply.)

- **a** The patient should be told which foods contain tyramine and instructed to avoid these foods.
- **b** The patient should be instructed to use caution when standing up from a sitting position.
- **c** The patient should not take any products that contain the herbal product St. John's wort.
- **d** This medication should not be stopped abruptly.
- **e** Drug levels may become toxic if dehydration occurs.
- **f** The patient should be told to check with the prescriber before taking any over-the-counter medications.

7 A patient with a feeding tube will be receiving risperidone (Risperdal) 8 mg in 2 divided doses via the feeding tube. The medication is available in a 1 mg/mL solution. How many milliliters will the nurse administer for each dose?

1. b, 2. d, 3. c, 4. b, 5. a, 6. b, c, d, f, 7. 4 mL per dose

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss substance abuse and the significance of the problem in the United States.
2 Identify the drugs or chemicals that are most frequently abused.
3 Contrast the signs and symptoms of the most commonly abused drugs/chemicals.
4 Compare the treatments for drug withdrawal for the most commonly abused opioids (narcotics), central nervous system (CNS) depressants, amphetamines and other CNS stimulants, nicotine, and alcohol.
5 Describe alcohol abuse syndrome with a focus on signs and symptoms, mild to severe alcohol withdrawal symptoms, and associated treatment.
6 Describe other drug abuse syndromes, signs and symptoms, withdrawal symptoms, and treatment regimens.
7 Identify various assessment tools used in the nursing assessment of substance abuse.
8 Develop a nursing care plan encompassing all phases of the nursing process for a patient undergoing treatment for substance abuse and dependency.

KEY TERMS

Addiction Strong psychological or physical dependence on a drug or other psychoactive substance. (p. 282)

Amphetamine A drug that stimulates the central nervous system. (p. 284)

Detoxification A process of eliminating a toxic substance from the body; a medically supervised program for alcohol or opioid addiction (p. 284)

Enuresis Urinary incontinence. (p. 285)

Habituation Development of tolerance to a substance following prolonged medical use but without psychological or physical dependence (addiction). (p. 282)

Illicit drug use The use of a drug or substance in a way that it is not intended to be used or the use of a drug that is not legally approved for human administration. (p. 284)

Intoxication Stimulation, excitement, or stupefaction produced by a chemical substance. (p. 282)

Korsakoff's psychosis A syndrome of amnesia with confabulation (making up of stories) associated with chronic alcohol abuse; it often occurs together with *Wernicke's encephalopathy.* (p. 287)

Micturition Urination, the desire to urinate, or the frequency of urination. (p. 285)

Narcolepsy A sleep disorder characterized by sleeping during the day, disrupted nighttime sleep, cataplexy, sleep paralysis, and hallucinations. (p. 285)

Opioid analgesics Synthetic pain-relieving substances that were originally derived from the opium poppy. Naturally occurring opium derivatives are called *opiates.* (p. 283)

Physical dependence A condition characterized by physiologic reliance on a substance, usually indicated by tolerance to the effects of the substance and development of withdrawal symptoms when use of the substance is terminated. (p. 282)

KEY TERMS—cont'd

Psychoactive properties Drug properties that affect mood, behavior, cognitive processes, and mental status. (p. 284)

Psychological dependence A condition characterized by strong desires to obtain and use a substance. (p. 282)

Raves Increasingly popular all-night parties that typically involve dancing, drinking, and the use of various illicit drugs. (p. 285)

Roofies Pills that are classified as benzodiazepines. They have recently gained popularity as a recreational drug; chemically known as *flunitrazepam.* (p. 286)

Substance abuse The use of a mood- or behavior-altering substance in a maladaptive manner that often compromises health, safety, and social and occupational functioning, and causes legal problems. (p. 282)

Wernicke's encephalopathy A neurologic disorder characterized by apathy, drowsiness, ataxia, nystagmus, and ophthalmoplegia; it is caused by thiamine (vitamin B_1) deficiency secondary to chronic alcohol abuse. (p. 287)

Withdrawal A substance-specific mental disorder that follows the cessation or reduction in use of a psychoactive substance that has been taken regularly to induce a state of intoxication. (p. 282)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Substance abuse affects people of all ages, sexes, and ethnic and socioeconomic groups. **Physical dependence** and **psychological dependence** on a substance are chronic disorders with remissions and relapses, such as occur with any other chronic illness. Relapses are not to be seen as failures but as indications to intensify treatment. Recognizing physical or psychological dependence and understanding the various treatment guidelines are important skills for those caring for these patients. **Habituation** refers to situations in which a patient becomes accustomed to a certain drug (develops tolerance) and may have mild psychological dependence on it but does not show compulsive dose escalation, drug-seeking behavior, or major withdrawal symptoms on drug discontinuation. This might occur, for example, in a postsurgical patient who receives opioid pain therapy regularly for only a few weeks.

In 2010, the Office of Applied Studies of the U.S. Substance Abuse and Mental Health Services Administration conducted a survey indicating that some 22.6 million Americans 12 years of age or older were current illicit drug users; that is, they reported using an illicit drug during the month prior to the survey interview. This number represents 8.9% of the population 12 years of age and older. Marijuana was identified as the most commonly used illicit drug, followed by psychotherapeutic drugs, pain relievers, tranquilizers, stimulants, and sedatives used for nonmedical purposes.

Nearly 50% of the adult patients seen in many family practice clinics have an alcohol or drug disorder. Some 25% to 40% of hospital admissions are related to substance abuse and its sequelae. Of patients seen in a general medicine practice, 10% to 16% are seeking treatment for problems related to substance abuse. Substance abuse is strongly associated with many types of mental illness. Treatment of both disorders is often very difficult, in part because of the high risk of drug interactions with the abused substances. Assessment, intervention, use of certain medications, specific **addiction** treatment strategies, and monitoring of recovery are essential to the care of this patient population.

This chapter focuses on three major classes of commonly abused substances and two commonly abused individual drugs. A description of the category or the individual drug, possible effects, signs and symptoms of **intoxication** and **withdrawal,** peak period and duration of withdrawal symptoms, and drugs used to treat withdrawal are discussed. The list of substances of abuse in Box 17-1 is not all-inclusive, but it contains some of the substances most commonly abused at this time. Not all of these substances are discussed in this chapter. Refer to The National Institute on Drug Abuse, available at www.nida.nih.gov/nidahome.html for further information.

Specific drugs used to treat withdrawal symptoms are discussed in the sections covering the drug whose withdrawal symptoms they are intended to treat. Pharmacologic therapies are indicated for patients with addictive disorders to prevent life-threatening withdrawal complications, such as seizures and delirium tremens, and to increase compliance with psychosocial forms of addiction treatment.

BOX 17-1 COMMONLY ABUSED SUBSTANCES

Major Categories

Opioids
Stimulants
Depressants

Individual Drugs

Alcohol
Anabolic steroids (see Chapter 35)
Dextromethorphan
Lysergic acid diethylamide (LSD)
Marijuana
Methamphetamine
Methylenedioxymethamphetamine (MDMA, ecstasy)
Nicotine
Phencyclidine (PCP)

PHARMACOLOGY OVERVIEW

OPIOIDS

Opioid analgesics are synthetic versions of pain-relieving substances that were originally derived from the opium poppy plant (see Chapter 10). More than 20 different alkaloids are obtained from the unripe seed of the opium poppy plant, only a few of which are clinically useful, including morphine and codeine. The other opioid analgesics that are currently used in medical practice are synthetic or semisynthetic derivatives of these two drugs.

Diacetylmorphine (better known as *heroin*) and opium are classified as Schedule I drugs and are not available in the United States for therapeutic use. Heroin was banned in the United States in 1924 because of its high potential for abuse and the increasing number of heroin addicts. In Europe, heroin is available for medical treatment of pain, and governmental programs also exist to provide heroin to addicts with the goal of reducing crime.

Heroin is one of the most commonly abused opioids. Some of the other commonly abused substances in the opioid category are codeine, hydrocodone, hydromorphone, meperidine, morphine, and oxycodone. Currently heroin remains one of the top 10 most abused drugs in the United States and often is used in combination with the stimulant drug cocaine (discussed later in Stimulants). When heroin is injected (called *mainlining* or *skin popping*), sniffed (known as *snorting*), or smoked, it binds with opiate receptors found in many regions of the brain. The result is intense euphoria, often referred to as a *rush.* This rush lasts only briefly and is followed by a relaxed, contented state that persists for a couple of hours. In large doses, heroin, like other opioids, can reduce or stop respiration.

Mechanism of Action and Drug Effects

Opioids work by blocking receptors in the central nervous system (CNS). When these receptors are blocked, the perception of pain is blocked. There are three main receptor types to which opioids bind. These receptors and their physiologic effects when stimulated are discussed in Chapter 10. One of the reasons that opioids are abused is their ability to produce euphoria.

The drug effects of opioids are primarily centered in the CNS. However, these drugs also act outside the CNS, and many of their unwanted effects stem from these actions. In addition to analgesia, opioids produce drowsiness, euphoria, tranquility, and other alterations of mood. The mechanism by which opioids produce the latter effects is not entirely clear. The effects of opioids can be collectively referred to as *narcosis* or *stupor,* which involves reduced sensory response, especially to painful stimuli. For this reason, opioid analgesics are also referred to as *narcotics* (see Chapter 4), especially by law enforcement authorities.

Indications

The intended drug effects of opioids are to relieve pain, reduce cough, relieve diarrhea, and induce anesthesia. Many have a high potential for abuse and are therefore classified as Schedule II controlled substances. Relaxation and euphoria are the most common drug effects that lead to abuse and psychological dependence. Sustained-release oxycodone (e.g., OxyContin) is an example of an opioid narcotic that is controversial because it is often overprescribed, misused, and grossly abused. Numerous deaths have been reported when sustained-release oxycodone was crushed and the entire 12-hour supply was released at one time.

Certain opioid drugs are themselves used to treat opioid dependence. Historically, methadone has been used most commonly for this purpose. Its long half-life of up to 12 to 24 hours allows patients to be dosed once daily at federally approved methadone maintenance clinics. In theory, the goal of such programs is to reduce the patient's dosage gradually so that eventually the patient can live permanently drug free. Unfortunately, relapse rates are often high in these programs. However, patients who remain on long-term opioid maintenance therapy still benefit by avoiding the hazards associated with obtaining and using illegal "street" drugs.

Contraindications

Contraindications to the therapeutic use of opioid medications include known drug allergy, pregnancy (high dosage or prolonged use is contraindicated), respiratory depression or severe asthma when resuscitative equipment is not available, and *paralytic ileus* (bowel paralysis).

Adverse Effects

Adverse effects of opioids can be broken down into two groups: CNS and non-CNS. The primary adverse effects of opioids are related to their actions in the CNS. The major CNS-related adverse effects include diuresis, miosis, convulsions, nausea, vomiting, and respiratory depression. Many of the non-CNS adverse effects are secondary to the release of histamine. Histamine release can cause vasodilation leading to hypotension, spasms of the colon leading to constipation, increased spasms of the ureter resulting in urinary retention, and dilation of cutaneous blood vessels leading to flushing of the skin of the face, neck, and upper thorax. The release of histamine is also thought to cause sweating, urticaria, and pruritus.

Management of Withdrawal, Toxicity, and Overdose

Box 17-2 lists the signs and symptoms of opioid withdrawal. The box also indicates the time when these symptoms are most likely to occur and their duration. Many patients require a

BOX 17-2 SIGNS AND SYMPTOMS OF OPIOID WITHDRAWAL

Peak Period
1 to 3 days

Duration
5 to 7 days

Signs
Drug seeking, mydriasis, piloerection, diaphoresis, rhinorrhea, lacrimation, vomiting, diarrhea, insomnia, elevated blood pressure and pulse rate

Symptoms
Intense desire for drugs, muscle cramps, arthralgia, anxiety, nausea, malaise

formal **detoxification** program while withdrawal symptoms are occurring. See Chapter 10 for a detailed discussion of physical dependence and the management of acute intoxication, toxicity, and overdose. Withdrawal symptoms include nausea, dysphoria, muscle aches, lacrimation, rhinorrhea, pupillary dilation, piloerection (hair standing on end) or sweating, diarrhea, yawning, fever, and insomnia. Medications listed in Box 17-3 are intended to help decrease the desire for the abused opioid and reduce the severity of these withdrawal symptoms. The most serious adverse effect and the most common cause of death with opioids is respiratory depression.

Certain medications are used to prevent relapse use once an initial remission is achieved. They are useful only when concurrent counseling is provided and offer additional insurance against return to **illicit drug use.** For opioid abuse or dependence, naltrexone, an opioid antagonist, is administered. Naltrexone, which is also available as an injection called Vivitrol, works by blocking the opioid receptors so that use of opioid drugs does not produce euphoria. When euphoria is eliminated, the reinforcing effect of the drug is lost. The patient needs to be free from opioids for at least 1 week before beginning this medication, because naltrexone can produce withdrawal symptoms if given too soon. Naltrexone is also approved for use by alcohol-dependent patients to reduce cravings for alcohol and the likelihood of a full relapse if a slip occurs. Another opioid antagonist, naloxone, is used for opioid dependence. It is combined with buprenorphine (Subutrex) or used alone (Suboxone) (see Chapter 10).

STIMULANTS

The abuse of stimulants is related to their ability to cause elevation of mood, reduction of fatigue, a sense of increased alertness, and invigorating aggressiveness. **Amphetamine** is a stimulant drug that is commonly abused. Chemically, three classes of amphetamine exist: salts of racemic amphetamine, dextroamphetamine, and methamphetamine. These classes vary with respect to their potency and peripheral effects. Another stimulant drug of abuse is cocaine, which also produces strong CNS stimulation. Cocaine was originally classified as a narcotic. It is considered a narcotic by the penal system and has been treated as a narcotic in terms of secured storage in health care facilities. However, unlike the opioid analgesics, cocaine does not normally induce a state of narcosis or stupor and is therefore more correctly categorized as a stimulant drug. Other commonly abused substances in this category include methylphenidate, dextroamphetamine, phenmetrazine, and methamphetamine. Multiple slight chemical variants of amphetamine exist. They are commonly referred to as "designer drugs," which have **psychoactive properties** along with their stimulant properties, which further enhances their abuse potential. Table 17-1 lists commonly abused forms of amphetamine and cocaine with their street names.

Methamphetamine is a chemical class of amphetamine, but it has a much stronger effect on the CNS than the other two classes of amphetamine. Methamphetamine is generally used in pill form orally or in powder form by snorting or injecting. It has 15 to 20 times the potency of amphetamine sulfate, the original drug in this class. Crystallized methamphetamine, known as *ice, crystal,* or *crystal meth,* is a smokable and more powerful form of the drug. Methamphetamine users who inject the drug and share needles are at risk for acquiring human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS), as well as hepatitis B and C. Marijuana and alcohol are commonly listed as additional drugs of abuse in those admitted for treatment of methamphetamine abuse. Most of the recorded methamphetamine-related deaths involved the use of methamphetamine in combination with at least one other drug, such as alcohol, heroin, or cocaine. The over-the-counter (OTC) decongestant pseudoephedrine is commonly used to synthesize methamphetamine in secret drug laboratories, often in private homes. This practice has lead to dramatic increases in the abuse of this drug. In 2005, the Combat Methamphetamine Epidemic Act required restricted retail sales of all nonprescription drug products containing pseudoephedrine. Specific restrictions include allowing sales only from *behind* the pharmacy counter, requiring photo identification and electronic or paper record keeping of purchasers (which must remain on file for 2 years), and setting maximum allowable amount (in grams) of pseudoephedrine that can be sold per consumer per month.

BOX 17-3 MEDICATIONS FOR TREATMENT OF OPIOID WITHDRAWAL

Clonidine (Catapres) Substitution

Clonidine, 0.1 or 0.2 mg orally, is given every 4 to 6 hours as needed for signs and symptoms of withdrawal for 5 to 7 days. Days 2 to 4 are typically the most difficult days for the patient in detoxification. Check blood pressure before each dose, and do not give medication if patient is hypotensive.

Methadone Substitution

Methadone test dose of 10 mg is given orally in liquid form or as a crushed tablet. Additional 10- to 20-mg doses are given for signs and symptoms of withdrawal every 4 to 6 hours for 24 hours after initial dose. Range for total daily dose is 15 to 30 mg. Repeat total first-day dose in two divided doses (stabilization dose) for 2 to 3 days, then reduce dosage by 5 to 10 mg/day until medication is completely withdrawn.

TABLE 17-1 VARIOUS FORMS OF AMPHETAMINE AND COCAINE WITH STREET NAMES

CHEMICAL NAME	STREET NAMES
dimethoxymethylamphetamine	DOM, STP
methamphetamine (crystallized form)	Ice, crystal, glass
methamphetamine (powdered form)	Speed, meth, crank
methylenedioxyamphetamine	MDA, love drug
methylenedioxymethamphetamine	MDMA, ecstasy
cocaine (powdered form)	Coke, dust, snow, flake, blow, girl
cocaine (crystallized form)	Crack, crack cocaine, freebase rocks, rock

Another synthetic amphetamine derivative is methylenedioxymethamphetamine (MDMA, "ecstasy," or "E"), which is also usually prepared in secret home laboratories. This drug tends to have more calming effects than other amphetamine drugs. It is usually taken in pill form but can also be snorted or injected. Users often feel a strong sense of social bonding with and acceptance of other people, hence the nickname "love drug." The drug can also be very energizing, which makes it popular at **raves** (all-night dance parties). Originally synthesized by Merck Pharmaceuticals in 1914, it was studied by the U.S. Army as a "brainwashing" drug in the 1950s. Its popularity has grown widely since the Drug Enforcement Administration classified it as a Schedule I controlled substance in 1985.

Another illicit drug use problem is cocaine use. Cocaine is a white powder that is derived from the leaves of the South American coca plant. Cocaine is either snorted or injected intravenously. Cocaine tends to give a temporary illusion of limitless power and energy but afterward leaves the user feeling depressed, edgy, and craving more. Crack is a smokable form of cocaine that has been chemically altered. Cocaine and crack are highly addictive. The psychological and physical dependence can erode physical and mental health and can become so strong that these drugs dominate all aspects of the addict's life.

Mechanism of Action and Drug Effects

Stimulants work by releasing *biogenic amines* from their storage sites in the nerve terminals. The primary biogenic amine released is norepinephrine. Its release results in stimulation of the CNS, as well as cardiovascular stimulation, which results in increased blood pressure and heart rate and possibly cardiac dysrhythmias. The effect on smooth muscle is seen primarily in the urinary bladder and results in contraction of the sphincter. This is helpful in treating **enuresis** (urinary incontinence) but results in painful and difficult **micturition** (voiding or urination) otherwise.

Stimulants, particularly amphetamines, are very potent CNS stimulants. This CNS stimulation commonly results in wakefulness, alertness, and a decreased sense of fatigue; elevation of mood, with increased initiative, self-confidence, and ability to concentrate; often elation and euphoria; and an increase in motor and speech activity.

Indications

Many therapeutic uses for stimulants exist. Currently their most common use is in the treatment of attention deficit disorder or attention deficit hyperactivity disorder (see Chapter 13). Stimulants may be used to prevent or reverse fatigue and sleep, such as when they are used to treat **narcolepsy** (episodes of acute sleepiness). Another therapeutic effect of amphetamines is their ability to stimulate the respiratory center. Occasionally they are used after anesthesia to stimulate the respiration. Stimulants are also used to reduce food intake and treat obesity; however, this therapeutic effect is limited because of rapid development of tolerance.

Contraindications

Contraindications to the therapeutic use of stimulant medications include drug allergy, diabetes, cardiovascular disorders, states of agitation, hypertension, known history of drug abuse, and Tourette's syndrome.

Adverse Effects

Adverse effects of stimulants are commonly an extension of their therapeutic effects. The CNS-related adverse effects are restlessness, syncope (fainting), dizziness, tremor, hyperactive reflexes, talkativeness, tenseness, irritability, weakness, insomnia, fever, and sometimes euphoria. Confusion, aggression, increased libido, anxiety, delirium, paranoid hallucinations, panic states, and suicidal or homicidal tendencies occur, especially in mentally ill patients. Fatigue and depression usually follow the CNS stimulation. Cardiovascular effects are common and include headache, chilliness, pallor or flushing, palpitations, tachycardia, cardiac dysrhythmias, anginal pain, hypertension or hypotension, and circulatory collapse. Excessive sweating can also occur. Gastrointestinal (GI) effects include dry mouth, metallic taste, anorexia, nausea, vomiting, diarrhea, and abdominal cramps. A sometimes fatal hyperthermia can also occur, driven partly by excessive drug-induced muscular contractions.

Management of Withdrawal, Toxicity, and Overdose

Box 17-4 lists the signs and symptoms of withdrawal from stimulants, and also indicates the peak period when these symptoms are most likely to occur and their duration. Death due to poisoning or toxic levels is usually a result of convulsions, coma, or cerebral hemorrhage and may occur during periods of intoxication or withdrawal. Treatment of overdose is supportive and generally requires sedation of the patient.

DEPRESSANTS

Depressants are drugs that relieve anxiety, irritability, and tension when used as intended. They are also used to treat seizure disorders and induce anesthesia. The two main pharmacologic classes of depressant are benzodiazepines and barbiturates. Both of these drug classes are discussed further in Chapter 12.

Benzodiazepines are relatively safe. They offer many advantages over older drugs used to relieve anxiety and insomnia.

BOX 17-4 SIGNS AND SYMPTOMS OF STIMULANT WITHDRAWAL

Peak Period
1 to 3 days

Duration
5 to 7 days

Signs
Social withdrawal, psychomotor retardation, hypersomnia, hyperphagia

Symptoms
Depression, suicidal thoughts and behavior, paranoid delusions

Treatment
No specific pharmacologic treatments to reduce cravings or reverse acute toxicity and no known antidotes.

However, they are often intentionally and unintentionally misused. Ingestion of benzodiazepines together with alcohol can be lethal. Another depressant that is neither a benzodiazepine nor a barbiturate is marijuana. Derived from the cannabis plant, marijuana ("pot," "grass," "weed") is the most commonly abused drug worldwide. Marijuana is generally smoked as a cigarette ("joint") or in a pipe ("bong") but can be mixed in food or tea.

A benzodiazepine that has gained popularity as a recreational drug is flunitrazepam. Flunitrazepam is not legally available for prescription in the United States, but it is legally sold in over 60 countries for treatment of insomnia. The drug, known as **roofies** among young people, creates a sleepy, relaxed, drunken feeling that lasts 2 to 8 hours. Roofies are commonly used in combination with alcohol and other drugs. They are sometimes taken to enhance a heroin high or to mellow or ease the experience of coming down from a cocaine or crack high. Used with alcohol, roofies produce disinhibition and amnesia.

Roofies have recently gained a reputation as a "date rape" drug. Girls and women around the country have reported being raped after being involuntarily sedated with roofies, which were often slipped into their drinks by their attackers. The drug has no taste or odor, so the victims do not realize what is happening. About 10 minutes after ingesting the drug, the woman may feel dizzy and disoriented, simultaneously too hot and too cold, and nauseous. She may experience difficulty speaking and moving and then pass out. Such a victim will have no memories of what happened while under the influence of the drug. Another popular date rape drug used in similar fashion is gamma-hydroxybutyric acid (GHB). GHB works by mimicking the natural inhibitory brain neurotransmitter gamma-aminobutyric acid (GABA). It is also known as "liquid ecstasy." These drugs are also used simply for their depressant and hallucinogenic effects.

Mechanism of Action and Drug Effects

Benzodiazepines and barbiturates work by increasing the action of GABA. GABA is an amino acid in the brain that inhibits nerve transmission in the CNS. The alteration of GABA action in the CNS results in relief of anxiety, sedation, and muscle relaxation. The effects of depressants are primarily limited to the CNS. They can also cause amnesia and unconsciousness. They have moderate effects outside the CNS, causing slight blood pressure decreases.

The active ingredients of the marijuana plant are known as cannabinoids, the most active of which is delta-9-trans-tetrahydrocannabinol, abbreviated *THC*. THC exerts its effects on the body by chemically binding to and stimulating two cannabinoid receptors in the CNS (CB1 and CB2). Smoking the drug leads to acute sensorial changes that start within 3 minutes, peak in 20 to 30 minutes, and last for 2 to 3 hours. Effects are longer when the drug is taken via the oral route. Specific effects include mild euphoria, memory lapses, dry mouth, enhanced appetite, motor awkwardness, and distorted sense of time and space. THC also stimulates sympathetic receptors and inhibits parasympathetic receptors in cardiac tissue, which leads to tachycardia. Other effects include hallucinations, anxiety, paranoia, and unsteady gait.

Indications

Many therapeutic uses of depressants exist. Benzodiazepines are used primarily to relieve anxiety, to induce sleep, to sedate, and to prevent seizures. Barbiturates are used as sedatives and anticonvulsants and to induce anesthesia. Controversial medical uses for marijuana include treatment of chronic pain, reduction of nausea and vomiting associated with cancer treatment, and appetite stimulation in those with wasting syndromes, such as patients with cancer or AIDS. In 1996, California became the first state to legalize the medical use of marijuana. Since that time, 14 other states have legalized the use of marijuana for medical purposes, and others have legislation pending. Dronabinol is a synthetic THC prescription capsule approved by the Food and Drug Administration (FDA) for the previously mentioned indications (see Chapter 52 for further discussion of this drug). However, it is often not popular with those who claim that it is not as effective as inhaled marijuana.

Contraindications

Contraindications to the therapeutic use of depressant medications include known drug allergy, dyspnea or airway obstruction, narrow-angle glaucoma, and porphyria (a metabolic disorder).

Adverse Effects

The most common undesirable effect of benzodiazepines and barbiturates is an overexpression of their therapeutic effects. The CNS is the primary area of the body adversely affected by these drugs. Drowsiness, sedation, loss of coordination, dizziness, blurred vision, headaches, and paradoxical reactions (insomnia, increased excitability, hallucinations) are the primary CNS adverse effects. Occasional GI effects include nausea, vomiting, constipation, dry mouth, and abdominal cramping. Other possible adverse effects are pruritus and skin rash. Long-term use of marijuana may result in chronic respiratory symptoms (similar to those of tobacco abuse) and memory and attention deficit problems. A chronic depressive "amotivational" syndrome has also been observed, especially among younger users.

Management of Withdrawal, Toxicity, and Overdose

Box 17-5 lists the signs, symptoms, and treatment of withdrawal from depressants, and also indicates the peak periods when these symptoms are most likely to occur and their duration. Fatal poisoning is unusual with benzodiazepines when they are taken alone. When benzodiazepines are ingested with alcohol or barbiturates, however, the combination can be lethal. Death is typically due to respiratory arrest. Abrupt withdrawal of benzodiazepines when they have been taken for prolonged periods has resulted in autonomic withdrawal symptoms, seizures, delirium, rebound anxiety, myoclonus (involuntary muscle contractions), myalgia, and sleep disturbances.

Flumazenil is a benzodiazepine reversal agent. Flumazenil antagonizes the action of benzodiazepines on the CNS by directly competing with them for binding at the benzodiazepine receptor in the CNS and thus reversing sedation. The dosage regimen to be followed for the reversal of conscious sedation or general anesthesia induced by a benzodiazepine and the

BOX 17-5 SIGNS, SYMPTOMS, AND TREATMENT OF DEPRESSANT WITHDRAWAL

Peak Period
2 to 4 days for short-acting drugs
4 to 7 days for long-acting drugs

Duration
4 to 7 days for short-acting drugs
7 to 12 days for long-acting drugs

Signs
Increased psychomotor activity; agitation; muscular weakness; hyperthermia; diaphoresis; delirium; convulsions; elevated blood pressure, pulse rate, and temperature; tremors of eyelids, tongue, and hands

Symptoms
Anxiety; depression; euphoria; incoherent thoughts; hostility; grandiosity; disorientation; tactile, auditory, and visual hallucinations; suicidal thoughts

Treatment of Benzodiazepine Withdrawal
A 7- to 10-day taper (10- to 14-day taper with long-acting benzodiazepines). Treat with diazepam (Valium) 10 to 20 mg orally qid on day 1, then taper until the dosage is 5 to 10 mg orally on the last day. Avoid giving the drug "as needed." Adjustments in dosage according to the patient's clinical state may be indicated.

Treatment of Barbiturate Withdrawal
A 7- to 10-day taper or a 10- to 14-day taper. Calculate barbiturate equivalence, and give 50% of the original dosage (if actual dosage is known before detoxification); taper. Avoid giving the drug "as needed."

management of suspected benzodiazepine overdoses are summarized in Chapter 12 (Table 12-3).

Barbiturates and benzodiazepines are commonly implicated in suicides, especially in combination with alcohol. Generally speaking, depressants are not regularly prescribed over a long period. Relatively safe hypnotic drugs such as the benzodiazepines are preferred whenever possible, especially in emotionally disturbed patients. Combinations of sedative-hypnotic drugs or in combination with alcohol need to be avoided. Long-term use of hypnotic drugs leads to ineffective control of insomnia, decrease in rapid eye movement sleep, dependence, and drug withdrawal symptoms.

Effects of marijuana use are usually self-limiting and resolve within a few hours.

ALCOHOL

Alcoholic beverages have been used since the beginning of human civilization. Individuals of Arab descent introduced the technique of distillation to Europe in the Middle Ages. Alcohol has been called the "elixir of life" and has been touted as a remedy for practically all diseases, which led to the use of the term *whisky,* Gaelic for "water of life." Over time, it has been determined that the therapeutic value of alcohol is extremely limited, and long-term ingestion of excessive amounts is a major social and medical problem.

Mechanism of Action and Drug Effects

Alcohol, which is more accurately known as *ethanol* and abbreviated as *ETOH,* is a CNS depressant. It results in CNS depression by dissolving in the lipid membranes within the CNS. The latest hypothesis is that ethanol causes a local disordering in the lipid matrix of the brain. This has been termed *membrane fluidization.* Some also believe that ethanol may augment GABA-mediated synaptic inhibition and fluxes of chloride. This enhancement of the action of GABA, an inhibitory neurotransmitter in the brain, causes CNS depression. The CNS is continuously depressed in the presence of ethanol. Moderate amounts of ethanol may stimulate or depress respirations. Effects of ethanol on the circulation are relatively minor. In moderate doses, ethanol causes vasodilation, especially of the cutaneous vessels, and produces warm, flushed skin. Ingestion of ethanol causes a feeling of warmth because it enhances cutaneous and gastric blood flow. Increased sweating may also occur. Heat is therefore lost more rapidly, and the internal body temperature consequently falls. The short-term (versus long-term) ingestion of ethanol, even in intoxicating doses, produces little lasting change in hepatic function. Long-term ingestion of ethanol is one of the primary causes of liver failure. Ethanol exerts a diuretic effect by virtue of its inhibition of antidiuretic hormone secretion and the resultant decrease in renal tubular reabsorption of water.

Indications

Few legitimate uses of ethanol and alcoholic beverages exist. Ethanol is an excellent solvent for many drugs and is commonly employed as a vehicle for medicinal mixtures. When applied topically to the skin, ethanol acts as a coolant. Ethanol sponges are therefore used to treat fever. Ethanol may also be used in liniments (oily medications used on the skin). Applied topically, ethanol is the most popular skin disinfectant. More commonly, however, the type of alcohol used on the skin is isopropyl alcohol, which is similar in structure to ethanol but is more toxic and is not drinkable.

Systemic uses of ethanol are limited to the treatment of methyl alcohol and ethylene glycol intoxication (e.g., from drinking automotive antifreeze solution). However, small amounts of ethanol preparations (such as red wine) have been shown to have cardiovascular benefits.

Adverse Effects

Long-term excessive ingestion of ethanol is directly associated with serious neurologic and mental disorders. These neurologic disorders can result in seizures. Nutritional and vitamin deficiencies, especially of the B vitamins, can occur and can lead to **Wernicke's encephalopathy, Korsakoff's psychosis,** polyneuritis, and nicotinic acid deficiency encephalopathy.

Moderate amounts of ethanol may stimulate or depress respirations. Large amounts produce dangerous or lethal depression of respiration. Although circulatory effects of ethanol are relatively minor, acute severe alcoholic intoxication may cause cardiovascular depression. Long-term excessive use of ethanol has largely irreversible effects on the heart, such as cardiomyopathy.

When consumed on a regular basis in large quantities, ethanol produces a constellation of dose-related negative effects such as alcoholic hepatitis or its progression to cirrhosis. Teratogenic effects can be devastating and are caused by the direct action of ethanol, which inhibits embryonic cellular proliferation early in gestation. This often results in a condition known as *fetal alcohol syndrome,* which is characterized by craniofacial abnormalities, CNS dysfunction, and both prenatal and postnatal growth retardation in the infant. Pregnant women need to be strongly advised not to consume alcohol during pregnancy, and appropriate treatment and counseling need to be arranged for pregnant women addicted to alcohol or any other drug of abuse.

Interactions

Alcohol can intensify the sedative effects of any medications that work in the CNS (e.g., sedative-hypnotics, benzodiazepines, antidepressants, antipsychotics, opioids). It can interact with the antibiotic metronidazole, causing a disulfiram reaction. Alcohol can also cause severe hepatotoxicity when taken with acetaminophen. Acute ingestion of alcohol can increase the bioavailability of the blood thinner warfarin, which increases the chances of bleeding. Chronic ingestion can cause warfarin to be less effective, leading to increased risks of clots.

Management of Withdrawal, Toxicity, and Overdose

Box 17-6 lists the common signs and symptoms of ethanol withdrawal. Signs and symptoms may vary depending on the individual's usage pattern, the preferred type of ethanol, and the presence of comorbidities. Treatment of ethanol toxicity is supportive and strives to stabilize the patient and maintain the airway. Ethanol withdrawal can be life threatening.

One pharmacologic option for the treatment of alcoholism is disulfiram (Antabuse). Disulfiram works by altering the metabolism of alcohol. It is not a cure for alcoholism, but it helps patients who have a sincere desire to stop drinking. The rationale for its use is that patients know that if they are to avoid the devastating experience of *acetaldehyde syndrome,* they cannot drink for at least 3 or 4 days after taking disulfiram. Table 17-2 outlines acetaldehyde syndrome. These adverse effects are obviously very uncomfortable and potentially dangerous for someone with any other major illnesses. For this reason, disulfiram is usually reserved as the treatment of last resort for "hard core" alcoholic patients for whom other treatment options (e.g., Alcoholics Anonymous, psychotherapy) have failed but who still hope to avoid continued alcohol abuse. When ethanol is ingested by an individual previously treated with disulfiram, the blood acetaldehyde concentration rises 5 to 10 times higher than in an untreated individual. Within about 5 to 10 minutes of alcohol ingestion, the individual's face feels hot, and soon afterward it is flushed and scarlet. After this, throbbing in the head and neck, nausea, copious vomiting, diaphoresis, dyspnea, hyperventilation, vertigo, blurred vision, and confusion occur. As little as 7 mL of alcohol will cause mild symptoms in a sensitive person. The effects last from 30 minutes to several hours. After the symptoms wear off, the patient is exhausted and may sleep for several hours. Most of the signs and symptoms observed after the ingestion of disulfiram plus alcohol are attributable to the resulting increase in the concentration of acetaldehyde in the body. There have even been a few published reports of localized disulfiram-alcohol skin reactions when alcohol preparations—even beer-containing shampoo—were placed on the skin. The usual dosage of disulfiram is 250 mg/day, or 125 mg/day in patients who experience adverse effects such as sedation, sexual dysfunction, and elevated liver enzyme levels.

A less noxious drug therapy option is the use of naltrexone, as mentioned previously in the section on opioids earlier in

BOX 17-6 SIGNS, SYMPTOMS, AND TREATMENT OF ETHANOL WITHDRAWAL

Mild Withdrawal

Signs and Symptoms

Systolic blood pressure higher than 150 mm Hg, diastolic blood pressure higher than 90 mm Hg, pulse rate higher than 110 beats/min, temperature above 100° F (37.7° C), tremors, insomnia, agitation

Moderate Withdrawal

Signs and Symptoms

Systolic blood pressure 150 to 200 mm Hg, diastolic blood pressure 90 to 140 mm Hg, pulse rate 110 to 140 beats/min, temperature 100° to 101° F (37.7° to 38.3° C), tremors, insomnia, agitation

Severe Withdrawal (Delirium Tremens)

Signs and Symptoms

Systolic blood pressure higher than 200 mm Hg, diastolic blood pressure higher than 140 mm Hg, pulse rate higher than 140 beats/min, temperature above 101° F (38.3° C), tremors, insomnia, agitation

Treatment

Benzodiazepines are the treatment of choice for ethanol withdrawal. The dosages are variable and differ from institution to institution. Lower dosages are used for mild symptoms, and higher dosages are needed for severe withdrawal. The oral route is preferred; however, it is often necessary to use the intravenous route for patients experiencing severe withdrawal. Patients who are experiencing severe withdrawal often require monitoring in an intensive care unit for cardiac and respiratory function, fluid and nutrition replacement, vital signs, and mental status. Restraints are indicated for a patient who is confused or agitated to protect the patient from self and to protect others (delirium tremens can be a terrifying and life-threatening state). Thiamine administration, hydration, and magnesium replacement may be indicated depending on the severity of the withdrawal state.

TABLE 17-2 DISULFIRAM ADVERSE EFFECTS: ACETALDEHYDE SYNDROME

BODY SYSTEM AFFECTED	RESULT
Cardiovascular	Vasodilation over the entire body, hypotension, orthostatic syncope, chest pain
Central nervous	Intense throbbing of the head and neck leading to a pulsating headache, sweating, marked uneasiness, weakness, vertigo, blurred vision, confusion
Gastrointestinal	Nausea, copious vomiting, thirst
Respiratory	Difficulty breathing

the chapter. The newest drug treatment indicated for alcoholism is acamprosate. Approved in 2004, it is used to maintain abstinence from alcohol in patients who are abstinent when starting the drug and who have additional psychosocial support. Its mechanism of action is not completely understood, but it may interact with *glutamate* and *GABA* receptors in the brain. The usual dosage is two 333-mg tablets taken three times daily.

NICOTINE

Nicotine was first isolated from the leaves of tobacco in 1828. The medical significance of nicotine grows out of its toxicity, presence in tobacco, and propensity for eliciting dependence in its users. The long-term effects of nicotine and the untoward effects of the long-term use of tobacco are considerable. Although many people smoke because they believe cigarettes calm their nerves, smoking releases epinephrine, a hormone that creates physiologic stress in the smoker rather than relaxation. The apparent calming effects may be related to the increased deep breathing associated with smoking. The use of tobacco is addictive. Most users develop tolerance for nicotine and need greater amounts to produce the desired effect. Smokers become physically and psychologically dependent and will suffer withdrawal symptoms. Smoking is particularly dangerous in adolescents because their bodies are still developing and changing. The chemicals, including 200 known poisons, present in cigarette smoke can adversely affect this maturation. One third of young people who are "just experimenting" end up becoming addicted by the time they are 20 years of age.

Mechanism of Action and Drug Effects

Nicotine works by directly stimulating the autonomic ganglia of the nicotinic receptors (see Chapter 20). Its site of action is the ganglion itself rather than the preganglionic or postganglionic nerve fiber. The organs throughout the body that are innervated by nerves stimulated by nicotine actually contain nicotinic receptors. These receptors are so named because they were originally tested with nicotine to measure their responses. Nicotine can have multiple unpredictable and dramatic effects on the body because nicotinic receptors are found in several systems, including the adrenal glands, skeletal muscles, and CNS.

The major action of nicotine is transient stimulation, followed by more persistent depression of all autonomic ganglia. Small doses of nicotine stimulate the ganglion cells directly and facilitate the transmission of impulses. When larger doses of the drug are applied, the initial stimulation is followed quickly by a blockade of transmission.

Nicotine markedly stimulates the CNS, including respiratory stimulation. This stimulation of the CNS is followed by depression. Nicotine can have dramatic effects on the cardiovascular system as well, resulting in increases in heart rate and blood pressure. The GI system is generally stimulated by nicotine, which produces increased tone and activity in the bowel. This often leads to nausea and vomiting and occasionally to diarrhea.

Indications

The nicotine found in nature (i.e., tobacco plants) has no known therapeutic uses. It is medically significant because of its addictive and toxic properties. However, nicotine that is formulated into various drug products to reduce cravings and promote smoking cessation can be considered a therapeutic drug. It is available for this purpose as chewing gum, transdermal patches, and nasal spray.

Adverse Effects

Nicotine primarily affects the CNS. Large doses can produce tremors and even convulsions. Respiratory stimulation also commonly occurs. The initial stimulation of the CNS induced by nicotine is quickly followed by depression. Death can even result from respiratory failure, which is thought to be due to both central paralysis and peripheral blockade of respiratory muscles. The cardiovascular effects of nicotine are an increase in heart rate and blood pressure. The effects of nicotine on the GI system are largely due to parasympathetic stimulation, which results in increased tone and motor activity of the bowel. Nicotine induces vomiting by both central and peripheral actions. Centrally, nicotine's emetic effects are due to stimulation of the *chemoreceptor trigger zone* in the brain.

Management of Withdrawal, Toxicity, and Overdose

Acute nicotine toxicity generally occurs in children who accidentally ingest cigarettes. Treatment is supportive and may include treatment with activated charcoal. Smoking cessation is the primary cause of nicotine withdrawal, although discontinuation of any tobacco product can lead to this syndrome. An important and often overlooked problem in hospitalized patients is nicotine withdrawal, which manifests largely as cigarette craving. Irritability, restlessness, and a decrease in heart rate and blood pressure occur. Cardiac symptoms resolve over 3 to 4 weeks, but cigarette craving may persist for months or even years.

The nicotine transdermal system (patch), nicotine polacrilex (gum), and inhalers or nasal spray can be used to provide nicotine without the carcinogens in tobacco and are now available OTC. The patch system uses a stepwise reduction in subcutaneous delivery to gradually decrease the nicotine dose, and patient treatment compliance seems higher than with the gum. Acute relief from withdrawal symptoms is most easily achieved with the use of the gum, because rapid chewing releases an immediate dose of nicotine. The dose is approximately half the dose the average smoker receives in one cigarette, however, and the onset of action is 30 minutes versus 10 minutes or less from smoking. These pharmacologic changes in delivery minimize the immediate reinforcement and self-reward effects that are prominent with the rapid nicotine delivery of cigarette smoking.

A sustained-release form of the antidepressant bupropion (see Chapter 16) called *Zyban* has been approved as first-line therapy to aid in smoking cessation treatment. Sustained-release bupropion is an innovative treatment because it is the first nicotine-free prescription medicine to treat nicotine dependence. Table 17-3 lists the currently available drugs for nicotine withdrawal therapy.

Varenicline (Chantix) both activates and antagonizes the *alpha-4-beta-2* nicotinic receptors in the brain. This effect

TABLE 17-3 NICOTINE WITHDRAWAL THERAPIES

DRUG	DOSAGE	RECOMMENDED DURATION OF USE
Transdermal Nicotine Systems		
Habitrol, Nicoderm	7 mg/24 hr	2-4 wk
	14 mg/24 hr	2-4 wk
	21 mg/24 hr	4-8 wk
Nicotrol	5 mg/16 hr	2-4 wk
	10 mg/16 hr	2-4 wk
	15 mg/16 hr	4-12 wk
ProStep	11 mg/24 hr	2-4 wk
	22 mg/24 hr	4-8 wk
Nicotrol inhaler	10 mg/inhalation	6-12 wk
Nicotrol NS nasal spray	10 mg/spray	
nicotine gum (Resin)	When the patient has a strong urge to smoke, a stick of gum is chewed; use gradually reduced over a 2-3 mo period.	
Antidepressant		
bupropion (Zyban)	15-mg sustained-release tabs	15 mg on days 1-3, then 150 mg bid for 7-12 wk
Partial Nicotine Agonist		
varenicline (Chantix)	0.5 or 1 mg tabs	12-wk regimen, beginning with 0.5 mg orally bid, titrated to 1 mg daily by day 8.

provides some stimulation to nicotine receptors, while also reducing the pleasurable effects of nicotine from smoking. This drug has demonstrated greater efficacy than bupropion. The recommended 12-week treatment regimen begins with 0.5 mg orally twice daily, titrating up to 1 mg twice daily by day 8. An optional second 12-week regimen may be prescribed to help the patient maintain tobacco abstinence. The most common adverse effects are nausea, vomiting, headache, flatulence, insomnia, and taste disturbances. Drowsiness has also been reported, which prompted the FDA to recommend caution in driving and engaging in other potentially hazardous activities until the patient can determine how the drug affects his or her mental status. Although many highly addicted smokers are reporting significant success with varenicline, the FDA issued warnings in January 2008 regarding its use. Specifically, case reports of psychiatric symptoms including agitation, depression, and suicidality, as well as worsening of preexisting psychiatric illness while using the drug have emerged. The FDA recommends appropriate patient education and follow-up regarding these adverse effects. Varenicline is a pregnancy category C drug.

NURSING PROCESS

ASSESSMENT

The purpose of a substance abuse assessment is to determine whether substance abuse exists, to evaluate the relationship between the abuse and other health concerns, and to begin the implementation of an effective health promotion and health restoration plan. Because of the prevalence of substance abuse and the role played by the professional nurse in a variety of settings, the nurse may be the first one to identify the risky behavior in a patient. Indications of abuse problems in patients may also present themselves during an abuser's hospitalization for an injury, illness, or surgery. However, even when substance abuse is not suspected, include questions about use of alcohol, nicotine, opioids, and so on in the general nursing assessment and medication history (see Pharmacology Overview). Question all patients about the use and misuse of substances, because addiction is found across the lifespan, in all cultures and in all types of individuals, and may therefore be encountered in all clinical specialties. Additionally, abuse/misuse of substances/prescription medications may need to be assessed in family members because adolescents and other individuals in the home may be stealing their parents' prescription drugs.

The nurse's responsibilities relative to drug abuse and the nursing process must begin with the cultivation of excellent interpersonal communication skills. It is important for you to acknowledge and address your own individual beliefs about drug and alcohol use as well as any personal history of coping with addiction or dealing with addicted family members. This process will allow you to anticipate potential responses and behaviors toward this patient population and seek out resolution about these feelings. Acknowledging feelings and beliefs about this group of patients within a proper perspective and ethical framework will allow you to resolve any personal animosity, judgmental attitudes, rejection, and/or enabling behaviors. Once detrimental behaviors and possible barriers to responsible and nonjudgmental care have been dealt with, focus on the patient and avoid being drawn into the manipulative and other negative behaviors of the abuser.

A thorough patient assessment and history must include specific questions about the substance(s) being used, the duration of abuse, related physical and mental health concerns, and withdrawal potential. In patients with suspected or confirmed substance abuse, honesty—on the part of the patient as well as the family or significant other—may be problematic when it comes to answering questions about drug use. Therefore, establishing a more communicative environment is needed and may be possible through the use of open-ended questions during assessment. Additionally, be sure to maintain a nonjudgmental approach during the assessment phase as well as other phases of the nursing process. A medication history needs to include information about all drugs being used, including prescription drugs, OTC drugs, herbals, dietary supplements, and illegal or street drugs. Include the names of these drugs, doses, frequency, and duration of use. Be attentive to any clues the patient, family, or significant other may reveal, including behavioral and mood changes. A patient's reported use of multiple prescribed drugs as well as contact with multiple prescribers raises a red flag as a possible sign of drug abuse. In addition, laboratory findings are important to assess, including results of renal and liver function studies and any drug screening studies. Assess

BOX 17-7 DIAGNOSIS OF DEPENDENCE

The *Diagnostic and Statistical Manual of Mental Disorders IV, Text Revision* (American Psychiatric Association, 2000) identified criteria for the diagnosis of a dependence. The occurrence of at least *three* of the following symptoms within a 12-month period helps confirm a diagnosis of dependence:

- Tolerance or a marked need for increased amounts of the substance to achieve the desired effect
- Withdrawal symptoms
- Unsuccessful attempts to cut down or control use of the substance
- Abandonment or reduction of important social, occupational, or recreational activities due to substance use. The use continues regardless of recurrent physical/psychological problems.

Modified from Maurer FA, Smith CM: *Community/public health nursing practice: health for families and populations,* ed 4, Philadelphia, 2009, Saunders.

and monitor results of HIV and hepatitis laboratory tests, once ordered. Measure and document baseline vital signs.

A number of assessment tools with established validity and reliability are available to nurses and health care professionals for use with patients suspected of drug or substance. The goal of adequate screening for alcohol and other drug abuse or addiction is to identify patients who have or are at risk for developing alcohol or drug-related problems and to further engage them in discussion. This may help in further diagnosing and more accurately treating the patient's abuse problem. Laboratory tests are available to detect alcohol and other drugs in the blood and/or urine. These are used to identify more recent drug abuse rather than long-term use or dependence. However, there are other tests that are best used when assessing someone for confirmation of a diagnosis rather than screening (Box 17-7). The CAGE Questionnaire is available as a screening tool for alcohol use in adults and is used by many health care professionals in the field of alcohol addiction. Even though it is simple and brief (consisting of only four questions), it has a noted accuracy rate of 93%. The CAGE Questionnaire has also been adapted to include drug use in adults (CAGE-AID). Other available screening tools include the Substance Abuse Subtle Screening Inventory (SASSI), the Michigan Alcoholism Screening Test (MAST-G) for use in geriatric patients, and the Problem Oriented Screening Instrument for Teenagers (POSIT). If the findings of an assessment questionnaire are positive, the next step would be to explore the history of the patient's alcohol or drug use and problems. Further observation is needed to identify any physical, psychological, and social signs of dependence and dysfunction. Maintaining communication with family members may also provide useful information. If abuse is identified by a history-taking process, physical assessment, drug history profile, screening tests, or patient's confession of abuse, then confidentiality, privacy, and nonjudgmental behavior are keys to ethical nursing practice. Although the substance abuse must be reported to the necessary health care professionals, adhere to the American Nurses Association *Code of Ethics for Nurses* in making this report (see Chapter 4).

Assessment of *opioid* abuse includes, in addition to the assessment information above, determination of the route being used for drug delivery (e.g., oral versus intravenous use). The use of intravenous drugs may give rise to health concerns such as HIV/AIDS or hepatitis. Respiratory assessment with attention to rate and rhythm are important because of the risk for respiratory depression with opioid overdose or overuse. Other more specific signs and symptoms have been described earlier in the chapter.

Assessment of *CNS stimulant* abuse requires careful questioning about and observation for adverse effects, toxicity, and withdrawal signs and symptoms. Some of the more commonly abused CNS stimulants are dextroamphetamine, methamphetamine (crystallized and powdered forms), and cocaine (see Table 17-1). Signs and symptoms of CNS stimulant abuse have been previously discussed, such as changes in blood pressure and an increased heart rate. However, the following information needs to be assessed and documented: (1) frequent vital signs; (2) thorough head-to-toe physical examination; (3) assessment of neurologic functioning with attention to mydriasis (pupil dilation), hyperactive reflexes, headache, increased motor/speech activity, agitation, syncope, tremors, altered level of consciousness, and seizure activity; and (4) cardiac assessment with attention to increased heart rate (tachycardia), irregular heart rhythm (dysrhythmia), and hypertension or hypotension. Document and immediately report any abnormal assessment findings and/or the presence of an elevated temperature (hyperthermia which may be fatal), complaints of vomiting, headache or flushing of the face, and elevated temperature.

The most dangerous substances in terms of withdrawal are *CNS depressants* such as barbiturates, benzodiazepines, and cannabinoids. Abuse of CNS depressants is manifested by a decrease in vital signs and mental functioning (see previous discussion); therefore, frequent monitoring of vital signs and neurologic status is needed for safe and prudent care. As with any drug, obtain a comprehensive, thorough nursing history and medication profile. Additional signs and symptoms of abuse are tremors and agitation with possible progression to hallucinations and sometimes death with continued abuse. Early withdrawal (see Table 17-5) may be manifested by increased blood pressure and pulse rate and altered mental status. Because of the risk of respiratory and circulatory depression, always perform an assessment of the patient's ABCs (*a*irway, *b*reathing, and *c*irculation). See Pharmacology Overview for more specific information. Marijuana, as a depressant, may cause dizziness, disorientation, euphoria, and difficulty with speech and motor activities. Long-term use of marijuana may lead to a chronic, depressive, a motivational behavior. Be sure you always assess for any different or unusual behavioral changes. Assessment of marijuana use includes appraisal of cognitive and motor function and assessment for the inability to carry out minor tasks.

The signs and symptoms of ethanol (alcohol) withdrawal and toxicity are presented in Box 17-6. Include gathering data about possible drug interactions, especially the use of other CNS depressants such as opioids, sedatives, and hypnotics in the assessment. Blood alcohol levels are important to monitor, because the health issues and signs and symptoms that appear are directly related to the blood alcohol level.

Abuse of *nicotine* (a CNS stimulant) is associated with adverse effects such as increase in heart rate and blood pressure. It can also result in vomiting and increased bowel tone and motor activity. If the patient has a history of malnutrition, chronic lung disease, stroke, cancer, cardiac disease, or renal or liver dysfunction, relevant laboratory tests are generally ordered, and their results need to be examined by the nurse and those involved in the patient's care. Assessment needs to include vital signs, breath sounds, oxygen saturation levels, and monitoring for changes in neurologic functioning (e.g., level of consciousness, sensory/motor problems). Remember that smoking cessation and signs and symptoms of nicotine withdrawal may happen abruptly in hospitalized patients. Signs and symptoms of a craving for nicotine include irritability, restlessness, and decrease in pulse rate and blood pressure, which will help in early identification of more serious problems.

CASE STUDY

Substance Abuse and Adolescents

You are having a discussion with a neighbor who has a 14-year-old son. The neighbor expresses concern about his son and substance abuse problems he has heard about.

1. The neighbor describes his son's friend, who was a bright and motivated student but has become sullen and withdrawn, and lacks the motivation he once had. In addition, he has a chronic cough but denies that he smokes cigarettes. This behavior change may indicate abuse of what substance? Are there any long-term effects?
2. The neighbor mentions "huffing," which his son told him has happened at several parties this year. The neighbor says, "Huffing is not harmful, right?" What will you tell him?

A few weeks later, the neighbor calls you because his son is extremely drowsy and unable to speak. The neighbor notes that his bottle of alprazolam (Xanax) is almost empty and worries that his son has taken an overdose.

3. What will you do first? What treatment would you expect his son to receive?

For answers, see http://evolve.elsevier.com/Lilley.

NURSING DIAGNOSES

1. Ineffective health management of self related to perceived barriers of care due to substance abuse
2. Deficient knowledge related to lack of information about addictive behaviors and drugs being abused
3. Chronic low self-esteem related to the influence of substance abuse
4. Risk for injury and falls related to substance abuse and/or abrupt withdrawal

PLANNING

GOALS

1. Patient demonstrates patterns of more effective health maintenance.
2. Patient openly discusses his or her substance abuse and the benefits of a treatment regimen.
3. Patient gains improved self-esteem during treatment for substance abuse.
4. Patient remains free from injury during treatment for substance abuse and addictive disorder.

OUTCOME CRITERIA

1. Patient openly discusses individual, family, and other perceived barriers to his or her own effective health maintenance.
   - Patient exhibits a healthy participation and cooperation with therapeutic regimen for addictive and abusive disorders.
2. Patient demonstrates knowledge base about addictive and abusive behaviors through discussion of expectations of recovery, benefits, and short-/long-term effects of treatment as well as signs and symptoms of withdrawal regimen.
3. Patient verbalizes feelings of improved self-esteem as well as healthy adaptation and coping skills in an open and secure treatment environment.
4. Patient undergoes safe withdrawal from the abused substance with stabilization of the aggravated and dysfunctional physical and emotional state without injury to self or others.

IMPLEMENTATION

The nurse plays a vital role in the care of patients manifesting abuse behaviors, intoxication, and withdrawal. It is also the nurse who, through the nursing process, helps to meet the patient's basic needs after developing a therapeutic relationship and teaches the patient, family, and/or significant others about addiction and its effect on the entire family. Nursing strategies for meeting actual or potential health problems are implemented for nursing diagnoses generated from assessment data. Nurses working with substance abuse patients need their own sound knowledge base as well as special understanding and empathy. Participation in training, seminars, and education about the process of substance abuse and related lifestyles is encouraged to assist in understanding the patient and developing a comprehensive plan of care. In general, nursing interventions involve maximizing all of the therapeutic plans and minimizing those factors contributing to the abusive behaviors. Once a therapeutic rapport has been established and a patient-nurse-health care provider contract has been agreed upon, maximizing recovery is the plan. Interventions are based on the patient's specific physical and emotional problems and are carried out accordingly and in order of priority of basic needs. For example, if a patient is experiencing hallucinations (from either use of a substance or from its withdrawal), manage the ABCs of care and monitor vital signs and neurologic and mental status while providing a calm, quiet, nonjudgmental, and nonthreatening environment. Seizures may occur, so safety precautions are needed, including the use of protective measures such as attention to the airway, padding of side rails, and implementation of other seizure precautions (consult facility policies and procedures). For more information related to lifespan considerations (for adolescent and elderly patients), see the boxes on p. 293.

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

Alcohol and Substance Abuse

Alcohol and substance abuse among the elderly is a hidden national epidemic. A substantial number of older adults are drinking at higher than recommended levels; thus, alcohol abuse is becoming a growing problem in this population and is one that is often ignored and/or missed by many health care providers.

Alcohol abuse and alcoholism cut across gender, race, and nationality with some statistics showing 10% of the country's population identified as abusing alcohol. Additionally, in adults 18 years of age or older, individuals identified as current drinkers were at 52%. However, in a study of some 12,000 Medicare beneficiaries 65 years of age or older, 9% consumed more alcohol than recommended in health guidelines. Conversely, a study conducted at Brandeis University identified the fact that about two-thirds of Medicare beneficiaries did not drink at all, and some 25% drank within recommended guidelines; however, the remaining 9% were found to drink more than 30 drinks a month or more than four drinks in any one session during a month. Obviously, alcohol abuse is of major concern for the older population and renders the necessity of thorough assessment for drug/chemical abuse in this group of patients.

Abuse of other substances by older adults is also an overlooked and often ignored problem. Older drug abusers are often poor, frail, and hidden from health professionals and service providers. The stigma associated with these problems keeps them, as well as family members, from coming forward to report problems. Although the overall rate of substance abuse is lower in older adults than in younger people, substance abuse in the elderly is a significant and growing problem. Alcohol abuse in the elderly is complicated by the fact that many abusers in this age group also use prescription and OTC medications. OTC drugs may cause adverse effects even when taken alone, and serious consequences may result when they are taken with alcohol. The main problems are seen when the combining of alcohol with a drug results in intensification of the drug's action (e.g., heightened hypotensive effects when an antihypertensive drug is taken with alcohol); this can lead to increased adverse effects with significant negative consequences (such as dizziness and possible syncope due to the greater drop in blood pressure, which can result in falls and injury). Some of the signals indicating an alcohol- or alcohol and medication–related problem in the elderly include trouble with memory after having a drink or taking a medication; loss of coordination, unsteadiness in walking or frequent falls; changes in sleeping habits; unexplained bruises; and irritability, sadness, depression, and being unsure of oneself.

Data from Buddy T: Unhealthy drinking increasing among older adults, 2009, available at www.alcoholism.about.com/b/2009/03/19/unhealthy-drinking-increasing-among-older-adults.htm. PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

Abuse of Over-the-Counter Drugs and Huffing Practices in Adolescents

Adolescent patients are exposed to very real drug hazards connected with some everyday products within the home. Two major problems involving hazardous drug use are seen in this population. The first is the abuse of OTC cold products, specifically *dextromethorphan*-containing products. Dextromethorphan is the most commonly used and most effective nonprescription cough suppressant and is an ingredient in several OTC products, including Robitussin DM cough syrup and Mucinex DM tablets. Some adolescents have discovered that taking dextromethorphan in large amounts leads to a "high" that is accompanied by hallucinations. The hallucinations have been documented to be similar to those associated with the street drug phencyclidine (PCP) and the anesthetic ketamine (see Chapter 11). The incidence of abuse varies and has rapidly increased. In April 2005, the *Medical News Today* reported that 1 in 11 teens has abused dextromethorphan-containing medications (17th annual study; Partnership for a Drug-Free America). However, a 2008 study found that 1 in 10 American teenagers had abused products with dextromethorphan to get high, making this OTC cough medicine more popular in this age group than cocaine, ecstasy, LSD, and meth. DXM is found in almost half of all of the OTC drugs sold in the United States, and for teens experimenting with drugs, DXM is cheap, easily obtained, and legal!

Additionally, it has been found that teens who abuse dextromethorphan may also abuse other drugs such as lysergic acid diethylamide (LSD), PCP, ecstasy, and inhalants. The hazardous short- or long-term effects that may occur with these drugs include nausea, hot flashes, reduced mental status, dizziness, seizures, loss of coordination and balance, brain damage, and death. The second problem is that of "huffing" or the abuse of inhalants, including the following substances: (1) *volatile solvents*—nail polish and paint thinner, (2) *aerosols*—deodorants and cooking sprays, (3) *gases*—butane cigarette lighter fluid and nitrous oxide (laughing gas), and (4) *nitrites*—cyclohexyl nitrite (found in room deodorizers) and amyl nitrite and butyl nitrite (sold on the street in small sealed containers). While some studies reported an increase in inhalant abuse by teens in the past 10 years, a new report based upon the National Survey on Drug Use and Health found that fewer adolescents are using inhalants such as glue and lighter fluid, but that the number of inhalant abusers in U.S. teens has not declined. The Associated Press (2009) reported that the number of adolescents actually abusing inhalants, as compared to those just trying them, remained at a stable rate between 2002 and 2007. Inhalant use often results in a euphoric feeling, but brain damage and even death can occur with just one huff. While the rate may be "stable," there is still a tremendous need for continued prevention and treatment efforts. Education needs to begin early on in elementary school, so that children learn of the problem and the related damaging effects to the brain before actual exposure to the practice. Education and awareness are important to prevent abuse and abuse behaviors, and a child is never too young to learn about these types of dysfunctional and life-threatening behaviors. Parents, other family members and relatives, and caregivers need to be actively involved in any educational sessions about this specific practice, as well as about other drugs that are abused, and related signs and symptoms.

Data from Griffin MR: Teen drug abuse of cough and cold medicine, WebMD Feature in collaboration with Consumer Healthcare Products Association (CHPA), available at www.webmd.com/parenting/teen-abuse-cough-medicine-9/teens-and-dxm-drug-abuse. Accessed March 25, 2011; Werner, E: Fewer teens sniffing inhalants to get high, Associated Press, Washington, DC, March 16, 2009; Join Together: Inhalant use declines among U.S. teens, March 19, 2009, available at http://www.drugfree.org/join-together/drugs/inhalant-use-declines-among. Prescription for danger: A report on the troubling trend of prescription and over-the-counter drug abuse among the nation's teens, January 2008, available at http:// www.promoteprevent.org/resources/prescription-danger-report-prescription-and-over-counter-drug-abuse-among-nations-teens.; The Partnership for a Drug-Free America: Generation RX: National study reveals new category of substance abuse emerging: Teens abusing RX and OTC medications intentionally to get high, Robert Wood Johnson Foundation, April 21, 2005, Washington, D.C.

Substance withdrawal is treated with a multimodal approach that includes pharmacologic and nonpharmacologic interventions. You have the responsibility to remain nonjudgmental while assisting in the patient's recovery and rehabilitation. You need to remain current in your knowledge about the different substances being abused as well as the various treatment and rehabilitation protocols. Of all interventions, ensuring patient safety is of utmost importance. The patient's movement through the plan of care for withdrawal, recovery, and rehabilitation must be individualized and in a safe, secure, and nonthreatening environment. Patient education remains an essential part of patient care to help the patient, family, and/or significant others understand the need for long-term lifestyle changes. Whether it is disulfiram treatment for alcohol abuse or bupropion therapy for nicotine withdrawal, patients need careful instructions and information about their treatment regimen.

Substance abuse has a major impact on family members and significant others. The family will also be in need of treatment and therapeutic support. But it is the caring, empathic, supportive, and educative responses by the nurse that will convey acceptance to the patient and family and help in the overall process of recovery and rehabilitation. A nonjudgmental attitude, caring, empathy, and quality care must always be the center of Patient Rights as well as the American Nurses Association *Code of Ethics for Nurses* (see Chapter 4) regardless of the admitting diagnosis and/or the type of substance being abused. Lifelong treatment is often indicated; the need for support during the long-term process of recovery must be emphasized and support recommended from within the family unit and extending outward to the community. (See Box 17-8 for a listing of various organizations and resources.) Methods to encourage recovery and minimize relapse need to be individualized for each patient and draw on all available resources, whether private or public. Communication techniques must be reinforcing and firm, yet sensitive to the patient's values and beliefs. Family members must be an integral part of all treatment and must participate in all educational sessions.

BOX 17-8 ORGANIZATIONS AND AGENCIES CONCERNED WITH SUBSTANCE ABUSE

Alcoholics Anonymous
American Council for Drug Education
American Society of Addiction Medicine
International Nurses Society on Addictions
National Center on Addiction and Substance Abuse at Columbia University
National Clearinghouse for Alcohol and Drug Information
National Council on Alcoholism and Drug Dependence
National Inhalant Prevention Coalition
National Institute on Alcohol Abuse and Alcoholism
National Institute on Drug Abuse
Partnership for a Drug-Free America
Substance Abuse and Mental Health Services Administration
U.S. Drug Enforcement Administration

EVALUATION

Patient safety is of utmost importance at all times during patient care but especially when the patient is experiencing the signs and symptoms of withdrawal. Patients may go from mild withdrawal to severe withdrawal and enter into life-threatening situations within a period of a day or two, and therefore complete evaluation of the patient and environment must be ongoing. Evaluation of the recovery and rehabilitation process is important as well, with monitoring of the therapeutic effects of the treatment regimen and monitoring for any ill effects from the physiologic and/or psychological withdrawal of the substance. Part of this evaluation process also is appraisal of the support provided by others such as family members, as well as review of the availability of needed resources during and after hospitalization. In addition, report any abnormality in vital signs, laboratory test results, mental status, or other parameters immediately. An ongoing evaluation needs to also examine the availability of emotional, social, cultural, spiritual, and financial support, and revise the nursing care plan as needed.

PATIENT TEACHING TIPS

- Ensure that relevant, nondiscriminatory, current, and accurate information—at various reading levels—is available to the patient, family, or significant others regarding the specific abuse disorder, signs and symptoms, withdrawal, and treatment regimens. Making an informed decision is best for everyone involved in the process of recovery and rehabilitation.
- Educate the patient, family, and/or significant other about available support groups and community resources.
- Be sure that the patient understands the importance of having—on his or her person at all times—a current list of all medications, including treatment regimens for the abuse disorder. Include information about the drug, its action, why it is used and how, adverse effects, cautions, drug-drug and drug-food interactions, cautions, contraindications, dosing, and consequences of any missed doses.
- Patients must be educated about their rights to ethical and empathic treatment, regardless of the reason for treatment. One online resource available is at www.healthline.com/galecontent/center-for-substance-abuse-prevention. This site provides written information, resources, and video clips about drug/chemical abuse.

KEY POINTS

- Physical dependence is a condition characterized by physiologic reliance on a substance, usually indicated by tolerance to the effects of the substance and development of withdrawal symptoms when use of the substance is terminated.
- Psychological dependence is a condition characterized by strong desires to obtain and use a substance.
- Habituation refers to situations in which a patient becomes accustomed to a certain drug (develops tolerance) and may have mild psychological dependence on it but does not show compulsive dose escalation, drug-seeking behavior, or major withdrawal symptoms upon drug discontinuation.
- Acamprosate is used to maintain abstinence from alcohol in patients who are abstinent when starting the drug and who have additional psychosocial support. Its mechanism of action is not completely understood.
- A new medication for smoking cessation is varenicline, which has shown better efficacy than bupropion.
- Drug withdrawal symptoms vary with the class of drug and may even be the opposite of the drug's action. Signs and symptoms of *opioid withdrawal* include seeking the drug from more than one prescriber, mydriasis (pupil dilatation), rhinorrhea, diaphoresis, piloerection (goose bumps), lacrimation, diarrhea, insomnia, and elevated blood pressure and pulse rate. Signs and symptoms of *CNS stimulant withdrawal* include social isolation or withdrawal, psychomotor retardation, and hypersomnia. Signs and symptoms of *CNS depressant withdrawal* include increased psychomotor activity; agitation; muscular weakness; hyperthermia; diaphoresis; delirium; convulsions; elevated blood pressure, pulse rate, and temperature; and eyelid tremors. *Ethanol withdrawal* produces varying degrees of signs and symptoms depending on the specific blood alcohol level. Delirium tremens are characterized by hypertensive crisis, tachycardia, and hyperthermia and may be life threatening.
- Evaluation of the recovery and rehabilitation process is important, including monitoring of the therapeutic effects of the treatment regimen and monitoring for any physiologic and/or psychological ill effects from the withdrawal of the abused substance.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A patient is experiencing withdrawal from opioids. The nurse expects to see which assessment finding most commonly associated with acute opioid withdrawal?
   - **a** Elevated blood pressure
   - **b** Decreased pulse
   - **c** Lethargy
   - **d** Constipation

2 During treatment for withdrawal from opioids, the nurse expects which medication to be ordered?
   - **a** amphetamine (Dexedrine)
   - **b** clonidine (Catapres)
   - **c** diazepam (Valium)
   - **d** disulfiram (Antabuse)

3 The nurse is presenting a seminar on substance abuse. Which drug is the most commonly used illicit drug in the United States?
   - **a** Crack cocaine
   - **b** Heroin
   - **c** Marijuana
   - **d** Methamphetamine

4 A patient who is taking disulfiram as part of an alcohol treatment program accidentally takes a dose of cough syrup that contains a small percentage of alcohol. The nurse expects to see which symptom as a result of acetaldehyde syndrome?
   - **a** Lethargy
   - **b** Copious vomiting
   - **c** Hypertension
   - **d** No ill effect because of the small amount of alcohol in the cough syrup

5 The nurse is assessing a patient for possible substance abuse. Which assessment finding indicates possible use of amphetamines?
   - **a** Lethargy and fatigue
   - **b** Cardiovascular depression
   - **c** Talkativeness and euphoria
   - **d** Difficulty swallowing and constipation

6 A patient experiencing ethanol withdrawal is beginning to show severe manifestations of delirium tremens. The nurse will plan to implement which interventions for this patient? (Select all that apply.)
   - **a** Doses of an oral benzodiazepine
   - **b** Doses of an intravenous benzodiazepine
   - **c** Restraints if the patient becomes confused, agitated, or a threat to himself or others
   - **d** Thiamine supplementation
   - **e** Oral disulfiram (Antabuse) treatment
   - **f** Monitoring in the intensive care unit

7 A patient has been admitted to the emergency department after a suspected overdose of benzodiazepines mixed with alcohol. The patient is lethargic and cannot speak. The nurse expects which immediate measures to be implemented? (Select all that apply.)
   - **a** Prepare to administer naloxone (Narcan).
   - **b** Prepare to administer flumazenil.
   - **c** Monitor the patient for convulsions.
   - **d** Prepare for potential respiratory arrest.
   - **e** Apply restraints.

1. a, 2. b, 3. c, 4. b, 5. c, 6. b, c, d, f, 7. b, c, d

PART 3

Drugs Affecting the Autonomic Nervous System

STUDY SKILLS TIPS

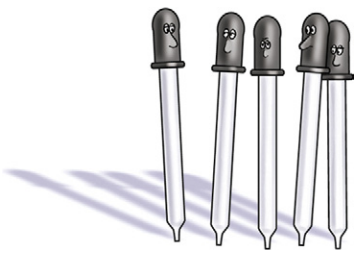
PURR Application • Study Groups

PURR APPLICATION

Planning for the Part

The basic explanation provided for the PURR model in the Study Skills Tips for Part 1 demonstrates the application process as it relates to individual chapters. There is another application for the PURR model that can be very useful. This application encourages the learner to take a broader view of the assignment. In the case of this text, you have noticed that the chapters are grouped together into multiple chapter blocks called *parts*. Part organization is not some random process applied by the author to further complicate the subject. Part organization is a carefully considered process to put content together in a fashion that is logical and meaningful. Since the authors have spent considerable time trying to link the chapters together in the most logical pattern, it is to your benefit as a student to learn to take advantage of the work already done for you.

Part Title



Begin the process of part planning by looking at the Part 3 title, "Drugs Affecting the Autonomic Nervous System." Then look at the part structure. There are four chapters contained in Part 3. All of these chapters must be concerned with the autonomic nervous system. Even before you have read any chapter, you are beginning to look for the links that will establish a relationship—not only the links among the ideas in individual chapters but also the broader links that connect the four chapters in this part with each other and with the ideas that have come in earlier parts and will follow in later parts.

There is a clear example here of the way in which parts relate to one another. Look back at Part 2, "Drugs Affecting the Central Nervous System." Clearly that part deals with some aspect of the nervous system, as does this part. One learning objective you should establish for yourself is determining the relationship between these two parts. You must be able to define and explain *central nervous system* and *autonomic nervous system*. However, just defining these terms and moving on limits the learning you can achieve. Ask yourself some additional questions that will help you establish a connection between these parts. What are the differences in function of the central and the autonomic nervous systems? Are there pharmacologic drugs that have application in both the central and autonomic nervous systems? The principle is to keep stressing the links that must exist throughout all the parts and chapters you are studying. The normal study pattern that most students apply is one that focuses on the individual chapters, but it is essential to remain aware of the broader scope of chapter and part.

Part Chapters

After considering the part title and looking for relationships between the new part and the previous parts, the next step in applying the *Plan* step of PURR is to spend a few minutes studying the chapter titles and looking for the relationships that must exist. Part 3 has four chapters, and there is a clear pattern in these chapters. Chapters 18 and 19 both contain the term *adrenergic.* Clearly the two chapters are dealing with the same broad topic. However, Chapter 18 covers adrenergic drugs and Chapter 19 covers adrenergic-blocking drugs. Apply questioning strategies at this point. What does *adrenergic* mean? What is an *adrenergic drug?* These two questions are essential in mastering the content of Chapter 18 and should be questions that you ask yourself almost without thinking.

The next step is one that can greatly enhance your understanding when you start to read the material. This is a step that is easily overlooked. Notice that Chapter 18 deals with drugs and Chapter 19 deals with blocking drugs. There must be a difference between a *drug* and a *blocking drug.* Focus now with a few questions that will keep you aware that the content in Chapter 18 has a direct relationship to the content in Chapter 19. What is the difference between a drug and a blocking drug? When is the pharmacologic application of a drug appropriate? Under what conditions should a blocking drug be chosen? Then ask a question to help maintain the focus on the concept of the entire part: What aspects of the autonomic nervous system are related to the adrenergic drugs and blocking drugs?

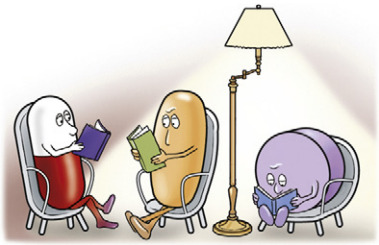
Once you begin to focus on the relationship of chapters within a part, certain things will begin to become apparent. Chapters 20 and 21 also cover drugs and blocking drugs. These two chapters develop the concept in relation to cholinergics rather than adrenergics. However, the same questions you used as a focus for Chapters 18 and 19 can be recycled in setting up the study of Chapters 20 and 21. Simply replace the term *adrenergic* with *cholinergic* and you are ready to begin reading these two chapters with a clear personal learning objective.

Active Questioning

Active questioning is the key concept to master in working through the process of planning your learning for an entire part rather than for single chapters. The idea is to view the part as a whole rather than seeing only the content of individual chapters. The preceding discussion has provided a number of sample questions to help you begin the process. These questions should not be seen as the only questions you should ask, but rather as examples to help you develop a questioning process.

Keep in mind that you may or may not ask questions that are useful and appropriate when you are using only the chapter titles as the question stimulus. Some of the questions you devise will prove to be very useful when reading the chapter. On the other hand, some of the initial questions you generate may have little or no application as you read and understand the content of an individual chapter. Do not worry about the quality of your questions when planning at the part level. Questions can (and sometimes should) be revised or discarded when the details of the chapter become clearer. The important point is that you begin the part with some questions to help you focus your own reading and learning. Also, you will find that the more you apply active questioning as a part of your learning strategy, the better your questions will become.

STUDY GROUPS



A significant part of the PURR approach to learning is active questioning and rehearsing. When we engage others in this process, we have access to their ideas and understanding. We must also think through our own thoughts and make them clear to others. The best way to learn is to teach others.

Study groups are particularly helpful when anticipating test questions. With several minds working, you increase your odds of being correct. In nursing, your textbook learning is of no value until you are able to apply the knowledge and skills you are learning. Study groups provide a discussion venue to stimulate thinking about the nursing process. Study group members can share lecture notes, which is of value if you need to be absent or if you have an instructor who talks too fast. Relating with a study group keeps you alert while you are studying. It is hard to fall asleep or daydream when you are in the middle of a discussion. There are many advantages to working with a study group; however, you must be careful when selecting the people to be in your group. Consider these four guidelines when establishing your study group:

1. Choose students who have **similar abilities and motivation** to yours. Socializing and gossiping can eat up valuable study time. Noncommitted and underprepared classmates can be a drain.
2. Look for students who have a **common time to meet.**
3. Select classmates who have learning styles **different** from yours. They might understand the reading material or lecture material better than you. They may be able to draw a diagram that will help your learning.
4. Find students that have **good communication skills;** that is, people who know how to listen, ask good questions, and explain concepts.

Study groups are not for everyone; however, they may be an alternative for you if you are having difficulty staying focused during your personal study time.

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Briefly describe the functions of the sympathetic nervous system and the specific effects of adrenergic stimulation.
2 List the various drugs classified as adrenergic agonists or sympathomimetics.
3 Discuss the mechanisms of action, therapeutic effects, indications, adverse and toxic effects, cautions, contraindications, drug interactions, and available antidotes to overdosage for the various adrenergic agonists or sympathomimetic drugs.
4 Develop a nursing care plan that includes all phases of the nursing process for patients taking adrenergic agonists.

DRUG PROFILES

- **dobutamine, p. 305**
- **dopamine, p. 305**
- **epinephrine, p. 305**
- **fenoldopam, p. 305**
- **midodrine, p. 305**
- **norepinephrine, p. 306**
- **phenylephrine, p. 306**

♦ *Key drug*

KEY TERMS

Adrenergic agonists Drugs that stimulate and mimic the actions of the sympathetic nervous system. Also called *sympathomimetics*. (p. 299)

Adrenergic receptors Receptor sites for the sympathetic neurotransmitters norepinephrine and epinephrine. (p. 299)

Alpha-adrenergic receptors A class of adrenergic receptors that are further subdivided into alpha$_1$- and alpha$_2$-adrenergic receptors. (p. 299)

Autonomic functions Bodily functions that are involuntary and result from the physiologic activity of the autonomic nervous system. The functions often occur in pairs of opposing actions between the sympathetic and parasympathetic divisions of the autonomic nervous system. (p. 299)

Autonomic nervous system A branch of the peripheral nervous system that controls autonomic bodily functions. It consists of the sympathetic nervous system and the parasympathetic nervous system. (p. 299)

Beta-adrenergic receptors Receptors located on postsynaptic cells that are stimulated by specific autonomic nerve fibers. Beta$_1$-adrenergic receptors are located primarily in the heart, whereas beta$_2$-adrenergic receptors are located in the smooth muscle fibers of the bronchioles, arterioles, and visceral organs. (p. 299)

Catecholamines Substances that can produce a sympathomimetic response. They are either endogenous catecholamines (such as epinephrine, norepinephrine, and dopamine) or synthetic catecholamine drugs (such as dobutamine). (p. 299)

KEY TERMS—cont'd

Dopaminergic receptor A third type of adrenergic receptor (in addition to alpha-adrenergic and beta-adrenergic receptors) located in various tissues and organs and activated by the binding of the neurotransmitter dopamine, which can be either endogenous or a synthetic drug form. (p. 300)

Mydriasis Pupillary dilation, whether natural (physiologic) or drug induced. (p. 303)

Ophthalmics Drugs that are used in the eye. (p. 302)

Positive chronotropic effect An increase in heart rate. (p. 302)

Positive dromotropic effect An increase in the conduction of cardiac electrical impulses through the atrioventricular node, which results in the transfer of nerve action potentials from the atria to the ventricles. This ultimately leads to a systolic heartbeat (ventricular contractions). (p. 302)

Positive inotropic effect An increase in the force of contraction of the heart muscle (myocardium). (p. 302)

Sympathomimetics Drugs used therapeutically that mimic the catecholamines epinephrine, norepinephrine, and dopamine. Also called *adrenergic agonists.* (p. 299)

Synaptic cleft The space either between two adjacent nerve cell membranes or between a nerve cell membrane and an effector organ cell membrane (also called *synapse*). (p. 300)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

The body's nervous system is divided into two major branches: the central nervous system and the peripheral nervous system (Figure 18-1). The central nervous system contains the brain and the spinal cord. The peripheral nervous system is further subdivided into somatic and autonomic. The autonomic nervous system is yet further subdivided into the parasympathetic (cholinergic) and the sympathetic (adrenergic). Understanding the autonomic nervous system and its subclasses is critical in the study of pharmacology, as numerous drugs act in these systems. This chapter will focus on the adrenergic nervous system and related compounds.

Adrenergic compounds include several exogenous (synthetic) and endogenous (produced in the body naturally) substances. They have a wide variety of therapeutic uses depending on their site of action and their effect on different types of adrenergic receptors. Adrenergics stimulate the sympathetic nervous system (SNS) and are also called **adrenergic agonists.** They are also known as **sympathomimetics,** because they mimic the effects of the SNS neurotransmitters norepinephrine, epinephrine, and dopamine. These three neurotransmitters are chemically classified as **catecholamines.** In considering the adrenergic class of medications, it is helpful to understand how the SNS operates in relation to the rest of the nervous system.

SYMPATHETIC NERVOUS SYSTEM

Figure 18-1 depicts the divisions of the nervous system and shows the relationship of the SNS to the entire nervous system. The SNS is the counterpart of the parasympathetic nervous system; together they make up the **autonomic nervous system**. They provide a checks-and-balances system for maintaining the normal homeostasis of the **autonomic functions** of the human body.

There are receptor sites for the catecholamines norepinephrine and epinephrine throughout the body. These are referred to as **adrenergic receptors.** It is at these receptor sites that adrenergic drugs bind and produce their effects. Many physiologic responses are produced when they are stimulated or blocked. Adrenergic receptors are further divided into **alpha-adrenergic receptors** and **beta-adrenergic receptors,** depending on the specific physiologic responses caused by their stimulation. Both types of adrenergic receptors have subtypes (designated 1 and 2), which provide a further means of checks and balances that control stimulation and blockade, vasoconstriction and vasodilation of blood vessels, and the increased and decreased production of various substances. The alpha$_1$- and alpha$_2$-adrenergic receptors are differentiated by their location relative to nerves. The alpha$_1$-adrenergic receptors are located on postsynaptic effector cells (the tissue, muscle, or organ that the nerve stimulates). The alpha$_2$-adrenergic receptors are located on the presynaptic nerve terminals. They control the release of neurotransmitters. The predominant alpha-adrenergic agonist response is vasoconstriction and central nervous system (CNS) stimulation.

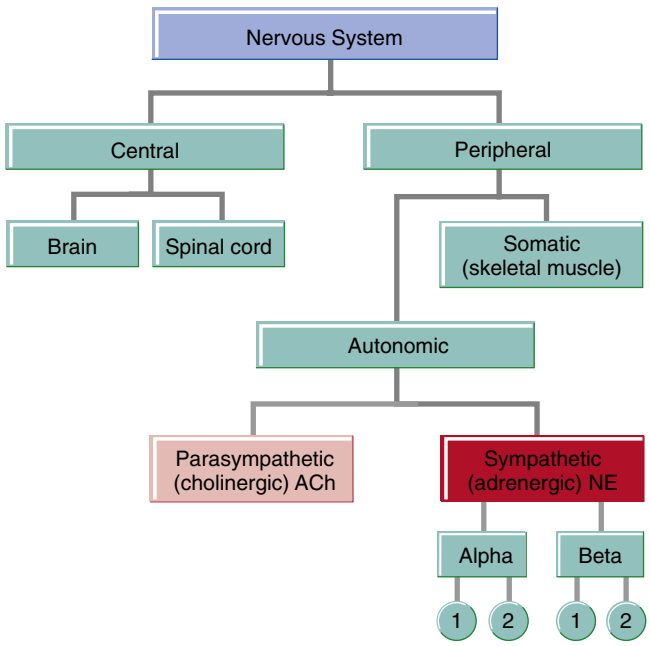

FIGURE 18-1 Sympathetic nervous system in relation to the entire nervous system. *ACh,* Acetylcholine; *NE,* norepinephrine.

TABLE 18-1 ADRENERGIC RECEPTOR RESPONSES TO STIMULATION

LOCATION	RECEPTOR	RESPONSE
Cardiovascular		
Blood vessels	Alpha$_1$	Vasoconstriction
	Beta$_2$	Vasodilation
Cardiac muscle	Beta$_1$	Increased contractility
Atrioventricular node	Beta$_1$	Increased heart rate
Sinoatrial node	Beta$_1$	Increased heart rate
Endocrine		
Liver	Alpha$_1$, beta$_2$	Glycogenolysis
Kidney	Beta$_1$	Increased renin secretion
Gastrointestinal		
Muscle	Alpha$_1$, beta$_2$	Decreased motility (relaxation of gastrointestinal smooth muscle)
Genitourinary		
Bladder sphincter	Alpha$_1$	Constriction
Penis	Alpha$_1$	Ejaculation
Uterus	Alpha$_1$	Contraction
	Beta$_2$	Relaxation
Respiratory		
Bronchial muscles	Beta$_2$	Dilation (relaxation of bronchial smooth muscles)
Ocular		
Pupillary muscles of the iris	Alpha$_1$	Mydriasis (dilated pupils)

The beta-adrenergic receptors are all located on postsynaptic effector cells. The beta$_1$-adrenergic receptors are primarily located in the heart, whereas the beta$_2$-adrenergic receptors are located in the smooth muscle fibers of the bronchioles, arterioles, and visceral organs. A beta-adrenergic agonist response results in bronchial, gastrointestinal (GI), and uterine smooth muscle relaxation; glycogenolysis; and cardiac stimulation. Table 18-1 provides a more detailed listing of the adrenergic receptors and the responses elicited when they are stimulated by a neurotransmitter or a drug that acts like a neurotransmitter (Figure 18-2).

Another type of adrenergic receptor is the **dopaminergic receptor.** When stimulated by dopamine, these receptors cause the vessels of the renal, mesenteric, coronary, and cerebral arteries to dilate, which increases blood flow to these tissues. Dopamine is the only substance that can stimulate these receptors.

Catecholamine neurotransmitters are produced by the SNS and are stored in vesicles or granules located in the ends of nerves. Here the transmitter waits until the nerve is stimulated, then the vesicles move to the walls of nerve endings and release their contents into the space between the nerve ending and the effector organ, known as the **synaptic cleft** or *synapse.* The released contents of the vesicles (catecholamines) then have the opportunity to bind to the receptor sites located all along the effector organ (see Figure 18-2). Once the neurotransmitter binds to the receptors, the effector organ responds. Depending on the function of the particular organ, this response may involve smooth muscle contraction (e.g., skeletal muscles) or relaxation (e.g., GI and airway smooth muscles), an increased heart rate, the increased production of one or more substances (e.g., stress hormones), or constriction of a blood vessel.

This process is halted by the action of specific enzymes and by reuptake of the neurotransmitter molecules back into the nerve cell (neuron). Catecholamines are metabolized by two enzymes, monoamine oxidase (MAO) and catechol orthomethyltransferase (COMT). Each enzyme breaks down catecholamines but is responsible for doing it in different areas. MAO breaks down the catecholamines that are in the nerve ending, whereas COMT breaks down the catecholamines that are outside the nerve ending at the synaptic cleft (see Figure 18-2). Neurotransmitter molecules may also be taken back up into the presynaptic nerve fiber by various protein pumps within the cell membrane. This phenomenon is known as *active transport.* This restores the catecholamine to the vesicle and provides another means of maintaining an adequate supply of the substance for future sympathetic nerve impulses. This process is illustrated in Figure 18-2. The sympathetic branch of the autonomic nervous system is often described as having a "fight-or-flight" function, because it allows the body to respond in a self-protective manner to dangerous situations.

PHARMACOLOGY OVERVIEW

ADRENERGIC DRUGS

Adrenergics are drugs with effects that are similar to or mimic the effects of the SNS neurotransmitters norepinephrine, epinephrine, and dopamine. These neurotransmitters are known as *catecholamines.* Catecholamines produce a sympathomimetic response. They are either endogenous substances such as epinephrine, norepinephrine, and dopamine or synthetic substances such as dobutamine and phenylephrine. The three endogenous catecholamines, (epinephrine, norepinephrine, and dopamine) are also available in synthetic drug form.

Catecholamine drugs that are used therapeutically produce the same result as endogenous catecholamines. When any of the adrenergic drugs is given, it bathes the area between the nerve and the effector cell (i.e., the synaptic cleft). Once there, the drug has the opportunity to induce a response. This can be accomplished in one of three ways: by direct stimulation, by indirect stimulation, or by a combination of the two (mixed-acting).

A direct-acting sympathomimetic binds directly to the receptor and causes a physiologic response (Figure 18-3). Epinephrine is an example of such a drug. An indirect-acting sympathomimetic causes the release of the catecholamine from the storage sites (vesicles) in the nerve endings; it then binds to the receptors and causes a physiologic response (Figure 18-4). Amphetamine and other related anorexiants (see Chapter 13) are examples of such drugs. A mixed-acting sympathomimetic both directly stimulates the receptor by binding to it and indirectly stimulates

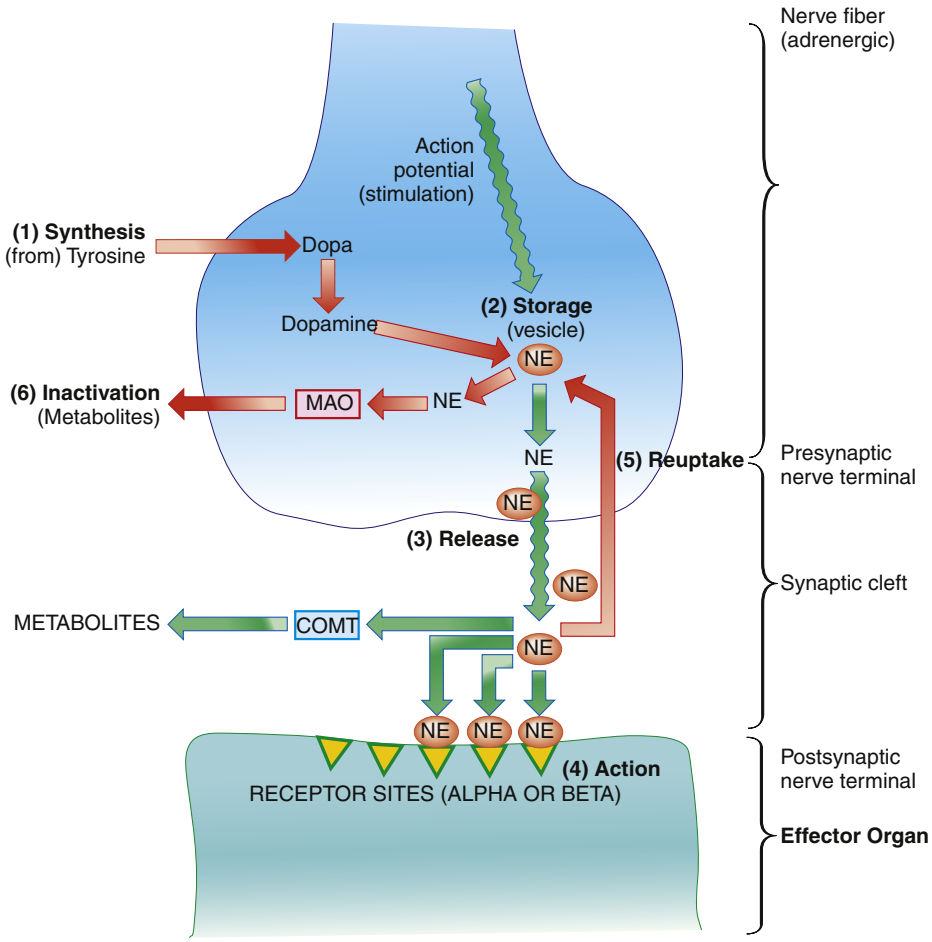

FIGURE 18-2 Mechanism by which stimulation of a nerve fiber results in a physiologic process; adrenergic drugs mimic this same process. *COMT,* Catechol ortho-methyltransferase; *MAO,* monoamine oxidase; *NE,* norepinephrine.

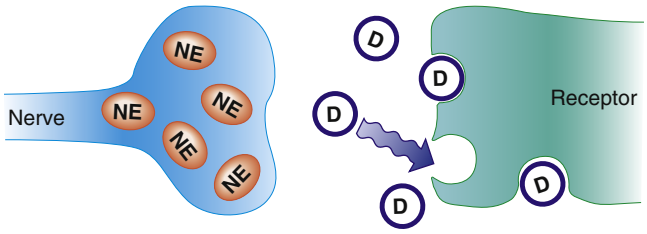

FIGURE 18-3 Mechanism of physiologic response to direct-acting sympathomimetics. *D,* Drug; *NE,* norepinephrine.

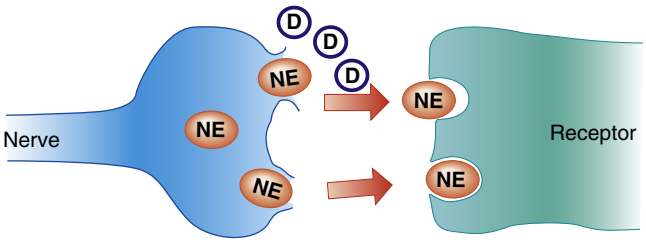

FIGURE 18-4 Mechanism of physiologic response to indirect-acting sympathomimetics. *D,* Drug; *NE,* norepinephrine.

the receptor by causing the release of the neurotransmitter stored in vesicles at the nerve endings (Figure 18-5). Ephedrine is an example of a mixed-acting adrenergic drug.

There are also noncatecholamine adrenergic drugs such as phenylephrine, metaproterenol, and albuterol. These are structurally dissimilar to the endogenous catecholamines and have a longer duration of action than either the endogenous or synthetic catecholamines. The noncatecholamine drugs show similar patterns of activity.

Adrenergic agents can also be classified as either selective or nonselective in their actions. For example, phenylephrine and

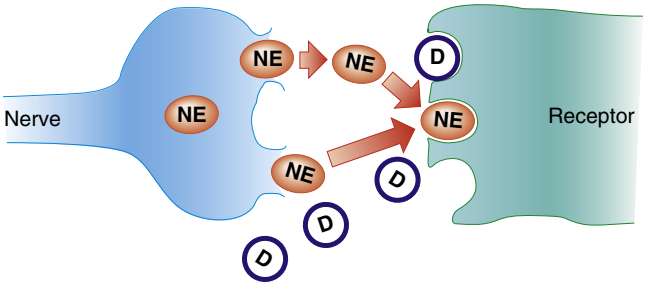

FIGURE 18-5 Mechanism of physiologic response to mixed-acting sympathomimetics. *D,* Drug; *NE,* norepinephrine.

TABLE 18-2 CATECHOLAMINES AND THEIR DOSE-RESPONSE RELATIONSHIP

DRUG	DOSAGE	RECEPTOR
dobutamine (Dobutrex)	Maintenance: 2-15 mcg/kg/min	Beta$_1$ more than beta$_2$
	High: 40 mcg/kg/min	Beta$_2$ more than alpha$_1$
dopamine (Intropin)	Low: 0.5-2 mcg/kg/min	Dopaminergic
	Moderate: 2-4 or less than 10 mcg/kg/min	Beta$_1$
	High: 20-30 mcg/kg/min	Alpha$_1$
epinephrine (Adrenalin)	Low: 1-4 mcg/min	Beta$_1$ more than beta$_2$ more than alpha$_1$
	High: 4-40 mcg/min	Alpha$_1$ more than/equal to beta$_1$

clonidine are considered selective agonists, meaning they only affect one receptor subtype. Epinephrine and norepinephrine are considered nonselective agonists, because they have action at both alpha and beta receptors. Adrenergic drugs can also act at different types of adrenergic receptors depending on the amount of drug administered. For example, dopamine may produce dopaminergic, beta$_1$, or alpha$_1$ effects, depending on the dose given. See Table 18-2 for other examples of catecholamines and the dose-specific selectivity.

Although adrenergics work primarily at postganglionic receptors (the receptors that immediately innervate the effector organ, gland, or muscle) peripherally, they may also work more centrally in the nervous system at the preganglionic sympathetic nerve trunks. The ability to do so depends on the potency of the specific drug and the dose used.

Adrenergic drugs are classified most technically by their specific receptor activities; they may also be categorized in terms of their clinical effects. For example, phenylephrine is both an alpha$_1$ agonist and a vasopressive drug (pressor), whereas albuterol is both an alpha$_2$ agonist and a bronchodilator. Both classifications are suitable for most clinical purposes. Clinically, it may be necessary to carefully choose an adrenergic drug with greater selectivity for a particular receptor type to avoid undesired clinical effects. In such a situation, detailed knowledge of the type and degree of receptor selectivity of different drugs becomes important.

Mechanism of Action and Drug Effects

To fully understand the mechanism of action of adrenergics, one must have a working knowledge of normal adrenergic transmission. This transmission takes place at the junction between the nerve (postganglionic sympathetic neuron) and the receptor site of the innervated organ or tissue (effector). The process of SNS stimulation is illustrated in Figure 18-2 and was discussed earlier in this chapter. When adrenergic drugs stimulate alpha$_1$-adrenergic receptor sites located on smooth muscles, vasoconstriction usually occurs. Binding to these alpha$_1$ receptors can also cause the relaxation of GI smooth muscle, contraction of the uterus and bladder, male ejaculation, and contraction of the pupillary muscles of the eye, which causes the pupils to dilate (see Table 18-1). Stimulation of alpha$_2$-adrenergic receptors, on the other hand, actually tends to reverse sympathetic activity but is not of great significance either physiologically or pharmacologically.

There are beta$_1$-adrenergic receptors on the myocardium and in the conduction system of the heart, including the sinoatrial node and the atrioventricular node. When these beta$_1$-adrenergic receptors are stimulated by an adrenergic drug, three things result: (1) an increase in the force of contraction **(positive inotropic effect),** (2) an increase in heart rate **(positive chronotropic effect),** and (3) an increase in the conduction of cardiac electrical nerve impulses through the atrioventricular node **(positive dromotropic effect).** In addition, stimulation of beta$_1$ receptors in the kidney causes an increase in renin secretion. Activation of beta$_2$-adrenergic receptors produces relaxation of the bronchi (bronchodilation) and uterus, and also causes increased glycogenolysis (glucose release) from the liver (see Table 18-1).

Indications

Adrenergics, or sympathomimetics, are used in the treatment of a wide variety of illnesses and conditions. Their selectivity for either alpha- or beta-adrenergic receptors and their affinity for certain tissues or organs determine the settings in which they are most commonly used. Some adrenergics are used as adjuncts to dietary changes in the short-term treatment of obesity. These drugs are discussed in more detail in Chapter 13.

Respiratory Indications

Bronchodilators are adrenergic drugs that have an affinity for the adrenergic receptors located in the respiratory system. They tend to preferentially stimulate the beta$_2$-adrenergic receptors and cause bronchodilation. Of the two subtypes of beta-adrenergic receptors, these drugs are attracted more to the beta$_2$-adrenergic receptors located on the bronchial, uterine, and vascular smooth muscles as opposed to the beta$_1$-adrenergic receptors located on the heart. The beta$_2$ agonists are helpful in treating conditions such as asthma and bronchitis. Common bronchodilators that are classified as predominantly beta$_2$-selective adrenergic drugs include albuterol, ephedrine, formoterol, levalbuterol, metaproterenol, pirbuterol, salmeterol, and terbutaline. These drugs are discussed in more detail in Chapter 37.

Indications for Topical Nasal Decongestants

The intranasal application of certain adrenergics can cause the constriction of dilated arterioles and a reduction in nasal blood flow, which thus decreases congestion. These adrenergic drugs work by stimulating alpha$_1$-adrenergic receptors and have little or no effect on beta-adrenergic receptors. The nasal decongestants include ephedrine, naphazoline, oxymetazoline, phenylephrine, and tetrahydrozoline. They are discussed in more detail in Chapter 36.

Ophthalmic Indications

Some adrenergics are applied to the surface of the eye. These drugs are called **ophthalmics.** They work in much the same way

as nasal decongestants except that they affect the vasculature of the eye. They stimulate alpha-adrenergic receptors located on small arterioles in the eye and temporarily relieve conjunctival congestion by causing arteriolar vasoconstriction. The ophthalmic adrenergics include epinephrine, naphazoline, phenylephrine, and tetrahydrozoline.

Adrenergics can also be used to reduce intraocular pressure, which makes them useful in the treatment of open-angle glaucoma. They can also dilate the pupils **(mydriasis),** which makes them useful for diagnostic eye examinations. They produce these effects by stimulating alpha- or beta$_2$-adrenergic receptors, or both. The two adrenergics used for this purpose are epinephrine and dipivefrin. Ocular adrenergic drugs are discussed in more detail in Chapter 57.

Cardiovascular Indications

The final group of adrenergic agents is used to support the cardiovascular system during cardiac failure or shock. These drugs are referred to as *vasoactive sympathomimetics, vasoconstrictive drugs* (also known as *vasopressive drugs, pressor drugs,* or *pressors), inotropes,* or *cardioselective sympathomimetics.* They have a variety of effects on the various alpha- and beta-adrenergic receptors, and the effects can be related to the specific dose of the adrenergic drug. Common vasoactive adrenergic drugs include dobutamine, dopamine, ephedrine, epinephrine, fenoldopam, midodrine, norepinephrine, and phenylephrine.

It is important to note that a common medication error is confusion between norepinephrine and the brand name for phenylephrine, which is Neo-Synephrine. These drugs are often both ordered for a patient at the same time, and, because the names sound alike, the wrong drug may be given. To avoid this confusion, many pharmacies list these drugs by their trade names as well: norepinephrine is called *Levophed,* and phenylephrine is called *Neo-Synephrine.*

Contraindications

The only usual contraindications to the use of adrenergic drugs are known drug allergy and severe hypertension.

Adverse Effects

Unwanted CNS effects of the alpha-adrenergic drugs include headache, restlessness, excitement, insomnia, and euphoria. Possible cardiovascular adverse effects of the alpha-adrenergic drugs include chest pain, vasoconstriction, hypertension, tachycardia, and palpitations or dysrhythmias. Effects on other body systems include anorexia (loss of appetite), dry mouth, nausea, vomiting, and, rarely, taste changes.

The beta-adrenergic drugs can adversely stimulate the CNS, causing mild tremors, headache, nervousness, and dizziness. These drugs can also have unwanted effects on the cardiovascular system, including increased heart rate (positive chronotropy), palpitations (dysrhythmias), and fluctuations in blood pressure. Other significant effects include sweating, nausea, vomiting, and muscle cramps. See the Patient-Centered Care: Lifespan Considerations for the Elderly Patient box on this page for additional information.

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

Use of Beta-Adrenergic Agonists

- Several physiologic changes occur in the cardiovascular system of the older adult, including a decline in the efficiency and contractile ability of the heart muscle, decrease in cardiac output, and diminished stroke volume. In most cases, the older adult adjusts to these changes without too much difficulty, but if unusual demands are placed on the aging heart, problems and complications may arise. Examples of unusual demands include strenuous activities, excess stress, heat, and medication use. For instance, stress, heat, and use of beta-adrenergic agonists may lead to significant increases in blood pressure and pulse rate. The older adult may then react negatively with a diminished ability to compensate adequately for these changes.
- Baroreceptors do not work as effectively in the elderly patient. Reduced baroreceptor activity may lead to orthostatic hypotension, even without the impact of certain medications and their associated mechanism of action and/or adverse effects.
- Because of the possible presence of concurrent medical conditions (e.g., hypertension, peripheral vascular disease, cardiovascular disease, and/or cerebrovascular disease), monitor the elderly patient carefully before, during, and after administration of adrenergic drugs.
- Advise patients that any occurrence of chest pain, palpitations, headache, or seizures must be reported immediately to the prescriber and/or emergency care accessed.
- Caution patients about the use of over-the-counter drugs, herbals, supplements, and other medications. This caution is due to possible drug-drug interactions as well as the elderly person's increased sensitivity to many drugs and other chemicals.
- Frequently monitor vital signs, especially blood pressure and pulse rate, when the patient is taking any of the adrenergic drugs because of their cardiovascular and cerebrovascular effects.
- The elderly often have decreased motor and cognitive functioning. Therefore, use additional equipment and certain facilitating aids, and provide special instructions to help ensure proper dosing of medications.

Toxicity and Management of Overdose

The toxic effects of adrenergic drugs are an extension of their common adverse effects (e.g., seizures from excessive CNS stimulation, hypotension or hypertension, dysrhythmias, palpitations, nervousness, dizziness, fatigue, malaise, insomnia, headache, tremor, dry mouth, and nausea). The two most life-threatening effects involve the CNS and cardiovascular system. In the acute setting, seizures can be effectively managed with diazepam. Intracranial bleeding can also occur, often as the result of an extreme elevation in blood pressure. Such elevated blood pressure poses the risk of hemorrhage not only in the brain but elsewhere in the body as well. The best and most effective treatment in this situation is to lower the blood pressure using a rapid-acting sympatholytic drug (e.g., esmolol; see Chapter 19). This can directly reverse the adrenergic-induced state.

The majority of the adrenergic compounds have very short half-lives, and thus their effects are short-lived. Therefore, when these drugs are taken in overdose or toxicity develops, stopping the drug causes the toxic symptoms to subside in a relatively short period of time. The recommended treatment for overdose is often to manage the symptoms and support the patient. If

DOSAGES

Selected Vasoactive Adrenergics

DRUG	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ dobutamine (Dobutrex) (D)	$Beta_1$-adrenergic	**Pediatric** IV infusion: 2.5-20 mcg/kg/min **Adult** IV infusion: 2.5-40 mcg/kg/min	Cardiac decompensation
♦ dopamine (Intropin) (C)	$Beta_1$-adrenergic	**Adult and pediatric** IV infusion: 1-50 mcg/kg/min	Shock syndrome, cardiopulmonary arrest
♦ epinephrine (Adrenalin) (C)	Alpha- and beta-adrenergic	**Pediatric** Subcut: 10 mcg/kg repeated q15min ×2 then q4h prn **Adult** Subcut: 0.3-0.5 mg repeated q10-15min if required	Anaphylaxis
		Neonatal IV: 10-30 mcg/kg q3-5min if required **Pediatric** IV: 10 mcg/kg q3-5min if required **Adult** IV: 1 mg q3-5min if required	Cardiopulmonary arrest
fenoldopam (Corlopam) (C)	Dopamine 1 agonist	**Adult only** IV: 0.1-1.6 mcg/kg/min for up to 48 hr	Hypertensive emergency in hospital setting
midodrine (ProAmatine) (C)	$Alpha_1$-adrenergic	**Adult only** PO: 10 mg tid, max 40 mg/day	Orthostatic hypotension
♦ norepinephrine (Levophed) (C)	Alpha- and beta-adrenergic	**Pediatric** IV infusion: 0.1-0.2 mcg/kg/min **Adult** IV infusion: 2-30 mcg/min	Hypotensive states
phenylephrine (Neo-Synephrine) (C)	Alpha-adrenergic	**Pediatric (for hypotension during spinal anesthesia)** Subcut/IM: 0.1 mg/kg/dose **Adult** IV infusion: 10 mg/250 or 500 mL IV solution, start at 100-180 mcg/min and titrate down to 40-60 mcg/min IM/subcut: 2-5 mg IV: 0.1-0.5 mg	Hypotension or shock

IM, Intramuscular; *IV,* intravenous; *PO,* oral; *subcut,* subcutaneous.

death occurs, it is usually the result of either respiratory failure or cardiac arrest. The treatment of overdose is therefore aimed at supporting the respiratory and cardiac systems.

Interactions

Numerous drug interactions can occur with adrenergic drugs. Although many of the interactions result only in a diminished effect because of direct antagonism at and competition for receptor sites, some reactions can be life-threatening. The following are some of the more serious drug-drug interactions involving adrenergic drugs: When alpha- and beta-adrenergic drugs are given with adrenergic antagonists (e.g., some classes of antihypertensive drugs), the drugs directly antagonize each other, which results in reduced therapeutic effects. Administration of adrenergics with anesthetic drugs (see Chapter 11) can increase the risk of cardiac dysrhythmias. Tricyclic antidepressants (see Chapter 16), when given with adrenergics, can cause increased vasopressor effects, acute hypertensive crisis. Administration of adrenergic drugs with monoamine oxidase inhibitors (MAOIs) may cause a possibly life-threatening hypertensive crisis (see Chapter 16). Antihistamines (see Chapter 36) and thyroid preparations (see Chapter 31) can also increase the effects of adrenergic drugs.

Laboratory Test Interactions

Alpha-adrenergic drugs can cause an increase in serum levels of endogenous corticotropin (i.e., adrenocorticotropic hormone), corticosteroids, and glucose. Therefore, the results of laboratory tests for these substances need to be interpreted with caution in patients receiving any of these medications.

Dosages

For dosage information on various adrenergic drugs, see the table on this page.

DRUG PROFILES

The four frequently used classes of adrenergic drugs are bronchodilators (see Chapter 37), ophthalmic drugs (see Chapter 57), nasal decongestants (see Chapter 36), and vasoactive drugs, which are emphasized in this chapter (see

Drug Profiles) and in Chapter 24. The receptor selectivity for the alpha$_1$, beta$_1$, and beta$_2$ receptor subtypes is *relative* (as opposed to *absolute*). Thus, there may be some overlap of drug effects between the different adrenergic classes of drugs, especially at higher dosages. In contrast, dopamine receptors are more specific for dopamine itself and/or specific dopaminergic drugs.

VASOACTIVE ADRENERGICS

Adrenergics that have primarily cardioselective effects are referred to as *vasoactive adrenergics.* They are used to support a failing heart or to treat shock. They may also be used to treat orthostatic hypotension. These drugs have a wide range of effects on alpha- and beta-adrenergic receptors, depending on the dosage. The vasoactive adrenergics are very potent, quick-acting, injectable drugs. Although dosage recommendations are given in the table on p. 304, all of these drugs are titrated to the desired physiologic response. All of the vasoactive adrenergics (with the exception of midodrine) are rapid in onset, and their effects very quickly cease when administration is stopped. Therefore, careful titration and monitoring of vital signs and electrocardiogram (ECG) are required.

◆ dobutamine

Dobutamine (Dobutrex) is a beta$_1$-selective vasoactive adrenergic drug that is structurally similar to the naturally occurring catecholamine dopamine. Through stimulation of the beta$_1$ receptors on heart muscle (myocardium), it increases cardiac output by increasing contractility (positive inotropy), which increases the stroke volume, especially in patients with heart failure. Dobutamine is available only as an intravenous drug and is given by continuous infusion. (See Dosages table on p. 304.)

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Less than 2 min	Less than 10 min	2-5 min	Less than 10 min

◆ dopamine

Dopamine (Intropin) is a naturally occurring catecholamine neurotransmitter. It has potent dopaminergic as well as beta$_1$- and alpha$_1$-adrenergic receptor activity, depending on the dosage. Dopamine, when used at low dosages, can dilate blood vessels in the brain, heart, kidneys, and mesentery, which increases blood flow to these areas (dopaminergic receptor activity). At higher infusion rates, dopamine can improve cardiac contractility and output (beta$_1$-adrenergic receptor activity). At highest doses, dopamine causes vasoconstriction (alpha$_1$-adrenergic receptor activity). Use of dopamine is contraindicated in patients who have a catecholamine-secreting tumor of the adrenal gland known as a *pheochromocytoma.* The drug is available only as an intravenous injectable drug and is given by continuous infusion. (See Dosages table on p. 304.)

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	2-5 min	Rapid	Less than 2 min	10 min

◆ epinephrine

Epinephrine (Adrenalin) is an endogenous vasoactive catecholamine. It acts directly on both the alpha- and beta-adrenergic receptors of tissues innervated by the SNS. It is considered the prototypical nonselective adrenergic agonist. Epinephrine is administered in emergency situations and is one of the primary vasoactive drugs used in many advanced cardiac life support protocols. The physiologic response it elicits is dose related. At low dosages, it stimulates mostly beta$_1$-adrenergic receptors, increasing the force of contraction and heart rate. It is also used to treat acute asthma (see Chapter 37) and anaphylactic shock at these dosages because it has significant bronchodilatory effects via the beta$_2$-adrenergic receptors in the lungs. At high dosages (e.g., intravenous drip), it stimulates mostly alpha-adrenergic receptors, causing vasoconstriction, which elevates the blood pressure. (See Dosages table on p. 304.) Epinephrine is available in two strengths for IV use, which has led to many medication errors. It is available as 1:1000 (1 mg/mL) and also as 1:10,000 (0.1 mg/mL). Be aware of these differences in strength and associated indications. Reading the label carefully before administering the drug is critical to patient safety.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Subcut	5-10 min	20 min	Variable	Unknown
IV	Less than 2 min	Rapid	Less than 5 min	5-30 min

◆ fenoldopam

Fenoldopam (Corlopam) is a peripheral dopamine 1 (D_1) agonist indicated for parenteral use in lowering blood pressure. Fenoldopam produces its blood pressure–lowering effects by inducing arteriolar vasodilation mainly through stimulation of D_1 receptors. It appears to be as effective as sodium nitroprusside for short-term treatment of severe hypertension and may have beneficial effects on renal function because it increases renal blood flow. It is available as a 10-mg/mL injection. (See Dosages table on p. 304.)

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	5 min	20 min	More than 5 min	10 min

◆ midodrine

Midodrine (ProAmatine) is a prodrug that is converted in the liver to its active form, desglymidodrine. This active metabolite is responsible for the primary pharmacologic action of midodrine, which is alpha$_1$-adrenergic receptor stimulation. This

alpha$_1$ stimulation causes constriction of both arterioles and veins, resulting in peripheral vasoconstriction. Midodrine is primarily indicated for the treatment of symptomatic orthostatic hypotension. Midodrine is available as 2.5- and 5-mg tablets (see Dosages table on p. 304.) Midodrine is usually given two to three times per day. The last dose of the day should not be given after 6 PM.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	45-90 min	1 hr	More than 3-4 hr	6-8 hr

◆ norepinephrine

Norepinephrine (Levophed) acts predominantly by directly stimulating alpha-adrenergic receptors, which leads to vasoconstriction. It also has some direct-stimulating beta-adrenergic effects on the heart (beta$_1$-adrenergic receptors) but none on the lung (beta$_2$-adrenergic receptors). Norepinephrine is directly metabolized to dopamine and is used primarily in the treatment of hypotension and shock. It is given only by continuous infusion. (See Dosages table on p. 304.)

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Rapid	1-2 min	Less than 5 min	1-2 min

◆ phenylephrine

Phenylephrine (Neo-Synephrine) works almost exclusively on the alpha-adrenergic receptors. It is used primarily for short-term treatment to raise blood pressure in patients in shock, to control some dysrhythmias (supraventricular tachycardias), and to produce vasoconstriction in regional anesthesia. It is also administered topically as an ophthalmic drug (see Chapter 57) and as a nasal decongestant (see Chapter 36). (See Dosages table on p. 304.)

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Rapid	Rapid	Less than 5 min	15-20 min

NURSING PROCESS

ASSESSMENT

Adrenergic agonist drugs have a variety of effects depending on the receptors they stimulate. Stimulation of the alpha-adrenergic receptors results in vasoconstriction of blood vessels. Stimulation of beta$_1$-adrenergic receptors produces cardiac stimulation, and beta$_2$-adrenergic receptor stimulation results in bronchodilation. Because of these sympathomimetic properties, use of adrenergic agonists requires careful patient assessment and monitoring to maximize therapeutic effects and minimize possible adverse effects. Focus assessment on a comprehensive health history with past and present medical history, and obtain a past/present medication history. Also include specific system-based questions, and identify cautions, contraindications, and drug interactions. Include the following health history questions in your assessment: (1) Medication history and allergies: What prescription medications are taken regularly? What about the self-administration of over-the-counter medications and herbals? Are there allergies to any medications, over-the-counter drugs, herbals, foods, topical products, and/or environmental pollutants/products? (2) Respiratory: Is there a history of asthma, and, if present, how frequent and severe are the acute episodes? What factors exacerbate or help to alleviate asthma? Any other asthma-related symptoms such as dyspnea, chest pain? Treatments used for asthma and associated successes or failures? (3) Cardiovascular: Is there a history of transient ischemic attacks or any history of cerebrovascular accident or stroke? Is there a history of hypertension, hypotension, cardiac irregularities, or other cardiovascular disease? (4) Renal/liver: Is there a history of kidney problems? Has anyone ever reported that kidney/liver function studies are abnormal? History of chronic kidney infections? Any jaundice? With altered renal/liver function, there is the risk for altered excretion/metabolism of drugs thus leading to possible toxicity.

Performing a thorough head-to-toe physical assessment is also a very important part of data collection with these drugs. Thorough assessment of the cardiac system is important because the adrenergic agonist drugs may exacerbate preexisting cardiac disorders. Other parameters that need to be thoroughly assessed with the adrenergic drugs include baseline vital signs. Assess and document breath sounds, heart sounds, peripheral pulses, skin color, and capillary refill. Specifically with the use of midodrine, assess postural blood pressures and pulse rates in supine, sitting, and standing positions before and during drug administration. In addition to measurement of postural blood pressures and pulse rates, inquire about other significant symptoms such as dizziness, lightheadedness, and syncope. Assessment of the patient's symptoms and the patient's perception of either disease progression or a decrease in symptoms is very important for effective and successful treatment.

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Ratio Solutions: Which Strength Is Stronger?

- When giving epinephrine, it is important to choose the correct dosage form. Ratio solutions indicate the number of grams of the medication per total milliliters of solution. Be sure you know what the numbers mean!
- A medication that is designated 1:1000 has 1 gram of medication per 1000 mL of solution.
- A medication that is designated 1:10,000 has 1 gram of medication per 10,000 mL of solution.
- Which is the more potent dose? 1:1000 or 1:10,000? 1:10,000 strength contains 0.1 mg/mL of medication; 1:1000 strength contains 1 mg/mL of medication, which is *ten times* stronger than the 1:10,000 strength. Therefore, the solution with the smaller number of milliliters is actually the more potent dose!

With other adrenergic drugs, such as those used for bronchodilating effects, perform a thorough respiratory assessment and document the patient's respiratory rate, rhythm, and depth as well as the presence of normal and/or adventitious (abnormal) breath sounds. Asking questions about any complaints of difficulty in breathing and activity/exercise intolerance is also important. Assess and document pulse oximetry readings for oxygen saturation levels. Include in the assessment measurement of respiratory peak flow using a flow meter as well as measurement of the anterior-posterior diameter of the chest wall. A decrease in peak flow readings may indicate bronchospasms, whereas an increased anterior-posterior chest wall diameter is seen in chronic lung disorders such as emphysema. Prescribers may also order additional respiratory function studies such as measurement of arterial blood gas levels.

Elderly and very young patients may react with increased sensitivity to these drugs. In addition, some of these drugs are used only for acute episodes of asthma, whereas other drugs are used year-round as preventative drugs. For example, the drugs salmeterol (see Chapter 37) and formoterol are *not* used to treat acute asthmatic episodes, whereas albuterol is indicated for treatment of acute episodes.

Epinephrine and similar drugs are used for their cardiac, bronchial, antiallergic, ophthalmic, and vasopressor effects. Focus assessment on vital signs, breath sounds, arterial blood gas levels, and ECG findings, if ordered. Assess and document liver and renal function test results. In addition, assess each system related to the specific action of the drug.

Overall, adrenergic drugs work in similar ways, but individual drugs may have some differences with regard to action, indications, and overall considerations. If the general class of drugs and the way in which they work is known, then the relevant assessment parameters, cautions, contraindications, drug interactions, and lifespan considerations are easy to determine. If the drug is a pure adrenergic agonist, the net effect is stimulation of alpha-adrenergic receptors with vasoconstriction of blood vessels and subsequent elevation of blood pressure and heart rate. You would then know to expect specific actions from the drug as well as to anticipate certain adverse effects. The drug may be used for the therapeutic effect of increased blood pressure, but an unwanted adverse effect could then be a hypertensive crisis. If the drug is a beta-adrenergic agonist, it will stimulate both $beta_1$ and $beta_2$ receptors, which will lead to cardiac stimulation and bronchodilation. This $beta_1$ action can also result in too much stimulation with severe tachycardia and possibly chest pain, if coronary artery disease is present. Thus, by knowing the actions of a given drug, you may draw conclusions about, anticipate, and be very alert to the drug's therapeutic action, adverse effects, cautions, contraindications, drug interactions, and toxicity.

NURSING DIAGNOSES

1. Impaired gas exchange related to asthma-induced bronchospasms
2. Decreased cardiac output related to cardiovascular adverse effects of adrenergic agonist drugs
3. Ineffective peripheral tissue perfusion related to intense vasoconstrictive actions of medications
4. Acute pain related to adverse effects of tachycardia and palpitations
5. Disturbed sleep patterns related to CNS stimulation caused by adrenergic drugs
6. Deficient knowledge of the therapeutic regimen, adverse effects, drug interactions, and precautions related to the use of adrenergic drugs
7. Noncompliance with drug therapy related to lack of information about the importance of taking the medication as ordered
8. Risk for injury related to possible adverse effects (nervousness, vertigo, hypertension, or tremors) or to potential drug interactions

PLANNING

GOALS

1. Patient experiences normal patterns of gas exchange and open airways.
2. Patient maintains normal cardiac output status.
3. Patient displays adequate peripheral vascular/tissue perfusion.
4. Patient experiences relief of pain and increased levels of comfort.
5. Patient experiences improved sleep patterns.
6. Patient demonstrates adequate knowledge about the use of specific medication.
7. Patient remains adherent to the drug therapy regimen and without drug-related complications.
8. Patient remains free from injury related to drug therapy.

OUTCOME CRITERIA

1. Patient shows improvement in gas exchange and respiratory status with normal respiratory rate (12 to 20 breaths/minute), regular rhythm and depth, clearing breath sounds, and pulse oximetry reading above 90%.
2. Patient's blood pressure and pulse rate remain within normal limits (BP 120/80; pulse 60 to 100 beats/min).
   - Patient's capillary refill is less than 5 seconds in fingers and toes.
3. Patient's circulation in extremities remains intact.
   - Patient's capillary refill is intact, with skin color pink and extremities warm to touch.
   - Patient's pedal pulses intact and strong to palpation.
4. Patient remains comfortable during drug therapy and takes medications exactly as prescribed.
   - Patient remains free of increased heart rate and irregular heart rhythm.
5. Patient uses relaxation therapy, massage, and maintains healthy sleep patterns in a quiet, temperate room environment.
   - Patient demonstrates proper use of drug therapy regimen and avoids overuse of medication to decrease adverse effects.
6. Patient states rationale for use of medications as well as timing/dosing and scheduling of drug therapy.

- Patient states most common adverse effects of drug therapy.
- Patient states adverse effects to report if they occur, such as increased occurrence of palpitations, chest pain, irregular heart rhythm, dizziness, and overall feeling of discomfort, anxiety, and restlessness.

7. Patient reports taking medication exactly as prescribed for maintenance and/or acute use and without adverse and/or toxic reactions.
8. Patient remains free from self-injury as related to safe and as-prescribed self-administration of drug therapy.

CASE STUDY

Dopamine Infusion

Mr. P., age 82 years, is receiving dopamine at a dose of 5 mcg/kg/min for heart failure. He has a history of hypothyroidism and takes a daily dose of thyroid replacement hormone. Yesterday, Mr. P's vital signs were as follows:

Blood pressure: 150/88 mm Hg
Pulse rate: 92 beats/min
Respiration rate: 16 breaths/min

His heart rhythm showed sinus rhythm with rare ectopic beats. While at rest, he had no shortness of breath but did experience some dyspnea when getting up to the bedside commode. He has edema in his lower legs rated as 2+ edema.

1. Explain how this dose of dopamine works to help treat Mr. P's heart failure.
2. What would you expect to happen if the dose were set to 1 mcg/kg/min? 20 mcg/kg/min?

This morning, you make rounds and find that Mr. P's vital signs are as follows:

Blood pressure: 170/94 mm Hg
Pulse rate: 120 beats/min
Respiration rate: 22 breaths/min

The heart monitor shows sinus tachycardia with two to three ectopic beats per minute. Mr. P. is complaining of palpitations and some shortness of breath at rest but says, "I've felt this before when I've had bad spells with my heart. I'm sure it will pass."

3. Do you think there is a concern at this time? Explain your reasoning and what should be done.

The physician decides to titrate the dopamine infusion to 3 mcg/kg/min, which you do immediately.

4. How quickly should you see a response from the patient to this decrease in dosage?

For answers, see http://evolve.elsevier.com/Lilley.

IMPLEMENTATION

There are several nursing interventions that may maximize the therapeutic effects of *adrenergic drugs* and minimize their adverse effects. These interventions include checking package inserts for the types and amounts of dilutional solutions to use with parenteral dosage forms (and for all dosage forms). For example, subcutaneous administration of the adrenergic agonist epinephrine to patients with asthma requires safe calculations and accurate dosing. A tuberculin syringe may be used for subcutaneous administration of epinephrine to help in accurate dosing for both adult and pediatric patients.

Use of epinephrine and some of the other pure *alpha-adrenergics* may not be indicated for shock-related symptoms because these drugs lead to vasoconstriction of the renal vessels and subsequent renal damage or shutdown. Therefore, when a patient is in shock and requires medications, dopamine is generally the drug of choice (rather than epinephrine). Dopamine is used because in specific dosage ranges it helps treat a shock-related syndrome through its ability to produce vasoconstriction of peripheral blood vessels and increase blood pressure, but without vasoconstriction of the renal vasculature. This lack of renal vasculature vasoconstriction helps improve perfusion through the kidneys and thus salvages the kidneys (while increasing blood pressure). With administration of dopamine and similar drugs, check the intravenous site frequently for infiltration (e.g., every hour, as needed) to be sure that the site remains intact and that the drug is being infused at the proper rate. Infiltration of an intravenous solution containing an adrenergic drug may lead to tissue necrosis from excessive vasoconstriction around the intravenous site. Phentolamine is often used for the treatment of infiltration (see Chapter 19). Also, with intravenous infusions, use only clear solutions and a proper dilutional fluid, always administer the drug with an intravenous infusion pump, and closely monitor the cardiac system (e.g., vital signs, heart sounds, and/or ECG monitoring). Give all of these drugs per the manufacturer's instructions and suggested infusion rates to avoid precipitating dangerously high blood pressure and pulse rate and subsequent complications.

When these drugs are given via an inhaler or nebulizer, provide the patient with complete, thorough, and age-appropriate instructions about correct use, storage, and care of equipment. Instruct the patient on how to use a spacer correctly, because use of this device with the inhaler is often ordered. A spacer provides more effective delivery of inhaled doses of drug (see Patient Teaching Tips, as well as Chapter 9). When the adrenergics are dosed for bronchodilating effects, often two adrenergics are prescribed. This is because different medications are associated with different pharmacokinetics and actions. One inhaler may be for use in *acute* situations, and the other may be for *long-term* and/or *preventative* use. With this type of treatment regimen, the patient needs to receive thorough, simple, and complete instructions and explanations about the method of delivery as well as the drugs used. This will help to minimize overdosage and reduce the risk of severe adverse effects such as hypertension, severe tachycardia, tremors, and CNS overstimulation.

Emphasize in patient teaching that these medications are to be used only as prescribed with regard to amount, timing, and spacing of doses. Because of their synergistic effects, when these medications (especially asthmatics) are used in combination with other types of bronchodilators, the patient must be very clear about what to do before, during, and after the dose is delivered. If the patient is taking an inhaled dosage form, he or she may also be taking an oral or parenteral form of the same or a similar drug. The reason for the use of more than one drug of the same drug class and the use of more than one route of administration is to achieve combined therapeutic effects. In educating the patient, pay extremely close attention to

these regimens because of the need to prevent exacerbation of adverse effects, minimize drug interactions, and prevent severe vascular and cardiovascular adverse effects. Advise the patient to immediately report any complaints of chest pain, palpitations, headache, or seizures.

Patients with chronic lung disease who are receiving adrenergic drugs also need to avoid anything that may exacerbate their respiratory condition (e.g., food or other allergens, cigarette smoking) and implement measures that may help diminish the risk of respiratory infection. These measures may include avoiding those who are ill with colds or flu, avoiding crowded areas, remaining well nourished and rested, and maintaining fluid intake of up to 3000 mL/day to ensure adequate hydration (unless contraindicated). Keeping a journal of symptoms and noting any improvement or worsening in the treated condition while taking the medications may also be very helpful.

Salmeterol is not to be used for relief of acute symptoms, and education about its dosing is important. The dosage of salmeterol is usually 1 puff twice daily, 12 hours apart. Always recheck these orders and directions. If another type of inhalant is used, such as a corticosteroid, instruct the patient to use the bronchodilator first, with a 5-minute waiting period prior to taking the second drug. All equipment must be rinsed after use. Provide patients with instructions about the importance of rinsing their mouth thoroughly after the use of any inhalant form of medication. Oral rinsing and mouth care after use of the inhaled drug is needed to prevent irritation and infection. See Chapter 37 for further discussion of salmeterol.

If ophthalmic forms of these drugs are used, make sure that the medication has not expired and is a clear solution. Do not allow the eyedropper to touch the eye when the drug is applied to help prevent contamination of the remaining solution. With ophthalmic administration, apply drops and ointments into the conjunctival sac—not directly onto the eye (cornea) itself.

Oral midodrine is to be taken exactly as prescribed. This medication is usually ordered to be given with forcing of fluids before the patient gets out of bed in the morning. Doses of the drug are often front-loaded in their dosing schedule so that most of the doses occur in the morning when patients with orthostatic intolerance are usually more symptomatic. Patients need to avoid taking this medication after 6 PM *if at all possible* to prevent insomnia and possible supine hypertension.

TEAMWORK AND COLLABORATION: LEGAL AND ETHICAL PRINCIPLES

Infiltrating Intravenous Infusions

Nurses often encounter infiltrating intravenous (IV) infusions in the routine care of many of their patients. Every action taken is very important in meeting the standard of care for the patient and in ensuring that the nurse has acted as any prudent nurse would. The assessment and action of the nurse can be important for the patient, as in the case of *Macon-Bibb County Hospital Authority v. Ross* (335 SE2d 633-GA).

Situation and Outcome

At approximately 2:52 PM, Ms. Ross arrived at the emergency department with dyspnea, bradycardia, and a blood pressure (BP) of 250/150 mm Hg. She became unresponsive, and at 2:55 PM went into respiratory arrest. She was intubated by a respiratory therapist. At approximately 2:58 PM, she received intravenous (IV) Nipride in an IV site in her right wrist. Nipride was used to decrease the severely elevated blood pressure. By 3:13 PM, the patient's blood pressure was 120/90 and the Nipride was discontinued as prescribed by the physician. Actual events are documented as follows: At 3:28 PM, the patient had no blood pressure at all and the physician had prescribed IV administration of dopamine to elevate her blood pressure; dopamine was actually administered at 3:31 PM to increase the then nonexistent blood pressure. She was then transferred to the cardiac care unit at approximately 4:30 PM after her blood pressure had stabilized. At midnight, a nurse noted that the IV catheter site had a "bruise bluish in color." The next notation was at 11:00 AM that morning. The patient's right arm was noted to be swollen, sore, and with a large blistered area located around the IV catheter site. The same description was noted again at 4:00 PM. There was no evidence that a physician was consulted or informed until 6:50 PM. At this time, the blistered area was shown to a physician but it wasn't until later in the evening that another physician cleansed the blistered area and treated it as a burn. The patient's lower right arm was permanently scarred and, it was undisputed, that the injury was a result of the infiltration of the dopamine. A nurse expert testified that she believed that the hospital personnel had been negligent in inserting the IV in the smaller vein at the patient's wrist or at least in the failure to document why it was not placed in the recommended vein initially or subsequently. However, most significant was the fact that there was a failure to notify the physician of the swollen and blistered arm. On a jury verdict, the court entered judgment for the patient. The hospital appealed.

The court of appeals affirmed the judgment of the lower court. It was noted that, although an infiltration may result from an improper technique, it may also be due to the size of the needle, the status of the patient's veins, or specific intolerance to an IV catheter. However, according to the expert nurse's testimony, supported by suitable references, dopamine must be infused into a large vein such as a vein in the antecubital fossa, to minimize the risk for extravasation. In addition, a dopamine infusion needs to be monitored continuously and the infusion very closely regulated. The antidote to counter the effects of dopamine extravasation is phentolamine (Regitine), and damage may be decreased or reversed if given within a specified time period. The nurses were criticized for not being sufficiently knowledgeable regarding dopamine, which resulted in their failure to notify a physician of the patient's impaired tissue integrity.

Data from *Macon-Bibb County Hospital Authority v Ross,* 70785 (176 Ga. App. 221) (335 SE2d 633), 1985, available at www.lawskills.com/case/ga/id/427/29/index.html. Accessed November 2, 2011.

EVALUATION

Therapeutic effects of *adrenergic drugs* include the following: For vasoactive drugs, therapeutic effects include improved cardiac output (with increased urinary output), return to normal vital signs (e.g., blood pressure of 120/80 mm Hg or higher or gradual increases in blood pressure as indicated, pulse rate greater than 60 but less than 100 beats/min), improved skin color (pallor to pink) and temperature (cool to warm) in the extremities, improved peripheral pulses, and increased level of consciousness. Therapeutic effects of drugs given for bronchial indications include a return to normal respiratory rate (more than 12 but fewer than 20 breaths/min), improved breath sounds throughout the lung field with fewer adventitious (abnormal) sounds, increased air exchange in all areas of the lungs, decreased to no coughing, less dyspnea, improved partial pressure of oxygen and pulse oximeter readings, and tolerance of slowly increasing levels of activity. Therapeutic effects of midodrine include improved level of functioning and improved performance of the activities of daily living, fewer episodes of postural intolerance (dizziness, lightheadedness, and syncopal episodes), and more energy.

To evaluate for the occurrence of adverse effects with *adrenergic drugs,* monitor for stimulation of the systems that are affected, such as the cardiac system and the CNS. Adverse effects such as cardiac irregularities, hypertension, and tachycardia may occur. Be sure to monitor for chest pain.

PATIENT TEACHING TIPS

- Medications must always be taken as prescribed. Excessive dosing may cause CNS and cardiovascular stimulation with tremors, nervousness, tachycardia, and palpitations.
- Instructions must be clear and concise for use of inhaled forms of medication, including nebulizers, inhalers, and metered-dose inhalers (see Chapter 9).
- Instruct the patient to report to the prescriber immediately any worsening of respiratory symptoms, dyspnea, distress, chest pain, and/or cardiac palpitations.
- Over-the-counter medications and herbal supplements are to be avoided unless the prescriber's approval is obtained.
- Midodrine requires careful dosing, as ordered. Encourage the patient to keep a journal to record adverse effects, improvements in symptoms, and any worsening of symptoms.

KEY POINTS

- Catecholamines are substances that produce a sympathomimetic response (stimulate the SNS). The naturally occurring or endogenous catecholamines include epinephrine, norepinephrine, and dopamine. An example of an exogenous catecholamine is dobutamine.
- If the patient has a chronic respiratory disease, such as emphysema or chronic asthma or bronchitis, it is important for the patient to avoid contact with individuals who may have infections to help minimize situations that would exacerbate the original problem. Respiratory irritants must be avoided.
- Midodrine use requires careful blood pressure monitoring, so patient education about supine blood pressure measurement and journaling of measured blood pressure values is very important to the effective use of the drug.
- Inhaled forms of beta$_2$ agonists are used for their bronchodilating action and must be taken only as prescribed, with caution to avoid any overuse of the drug. Overdosage of these drugs may lead to severe cardiovascular, CNS, and cerebrovascular adverse effects and stimulation.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse caring for a patient who is receiving beta$_1$ agonist drug therapy needs to be aware that these drugs cause which effect?
   - **a** Increased cardiac contractility
   - **b** Decreased heart rate
   - **c** Bronchoconstriction
   - **d** Increased GI tract motility

2 During a teaching session for a patient who is receiving inhaled salmeterol, the nurse emphasizes that the drug is indicated for which condition?
   - **a** Rescue treatment of acute bronchospasms
   - **b** Prevention of bronchospasms
   - **c** Reduction of airway inflammation
   - **d** Long-term treatment of sinus congestion

3 For a patient receiving a vasoactive drug such as intravenous dopamine, which action by the nurse is most appropriate?
   - **a** Monitor the gravity drip infusion closely, and adjust as needed.
   - **b** Assess the patient's cardiac function by checking the radial pulse.
   - **c** Assess the intravenous site hourly for possible infiltration.
   - **d** Administer the drug by intravenous boluses according to the patient's blood pressure.

NCLEX® EXAMINATION REVIEW QUESTIONS—cont'd

4 A patient is receiving dobutamine for shock and is complaining of feeling more "skipping beats" than yesterday. What will the nurse do next?
- **a** Monitor for other signs of a therapeutic response to the drug.
- **b** Titrate the drug to a higher dose to reduce the palpitations.
- **c** Discontinue the dobutamine immediately.
- **d** Assess the patient's vital signs and cardiac rhythm.

5 When a drug is characterized as having a negative chronotropic effect, the nurse knows to expect which effect?
- **a** Reduced blood pressure
- **b** Decreased heart rate
- **c** Decreased ectopic beats
- **d** Increased force of cardiac contractions

6 The nurse is monitoring a patient who is receiving an infusion of a beta-adrenergic agonist. Which adverse effects may occur with this infusion? (Select all that apply.)
- **a** Mild tremors
- **b** Bradycardia
- **c** Tachycardia
- **d** Palpitations
- **e** Drowsiness
- **f** Nervousness

7 The order reads: "Dopamine 3 mcg/kg/min IV." The solution available is 400 mg in 250 mL D_5W, and the patient weighs 176 pounds. The nurse will set the IV infusion pump to run at how many mL/hour?

1. a, 2. b, 3. c, 4. d, 5. b, 6. a, c, d, f, 7. 9 mL/hr

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Briefly review the functions of the sympathetic nervous system and the specific effects of adrenergic-blocking drugs.
2 List the various drugs classified as adrenergic antagonists (blockers) or sympatholytics.
3 Discuss the mechanisms of action, therapeutic effects, indications, adverse and toxic effects, cautions, contraindications, drug interactions, dosages, routes of administration, and any antidotal management for the various alpha antagonists (blockers), beta nonselective blockers, and the $beta_1$- and $beta_2$-blockers.
4 Develop a nursing care plan that includes all phases of the nursing process for patients taking adrenergic antagonists.

KEY TERMS

Acrocyanosis Decreased amount of oxygen delivered to the extremities, causing the feet or hands to turn blue. (p. 313)

Adrenergic receptors Specific receptor sites located throughout the body for the endogenous sympathetic neurotransmitters norepinephrine and epinephrine. (p. 313)

Agonists Drugs with a specific receptor affinity that mimic the body's natural chemicals (e.g., hormones, neurotransmitters). (p. 313)

Angina Paroxysmal (sudden) chest pain caused by myocardial ischemia. (p. 317)

Antagonists Drugs that bind to specific receptors and inhibit or block the response of the receptors. (p. 313)

Dysrhythmias Irregular heart rhythms; almost always called *arrhythmias* in clinical practice. (p. 317)

Extravasation The leaking of fluid from a blood vessel into the surrounding tissues, as in the case of an infiltrated intravenous infusion. (p. 314)

First-dose phenomenon Severe and sudden drop in blood pressure after the administration of the first dose of an alpha-adrenergic blocker. (p. 314)

Intrinsic sympathomimetic activity The paradoxical action of some beta-blocking drugs (e.g., acebutolol) that mimics the action of the sympathetic nervous system. (p. 316)

KEY TERMS—cont'd

Lipophilicity The chemical attraction of a substance (e.g., drug molecule) to lipid or fat molecules. (p. 317)

Orthostatic hypotension A sudden drop in blood pressure when a person stands up. Also referred to as *postural hypotension* or *orthostasis.* (p. 314)

Pheochromocytoma A vascular adrenal gland tumor that is usually benign but secretes epinephrine and norepinephrine and thus often causes central nervous system stimulation and substantial blood pressure elevation. (p. 313)

Raynaud's disease A narrowing of small arteries that limits the amount of blood circulation to the extremities, causing numbness of the nose, fingers, toes, and ears in response to cold temperatures or stress. (p. 313)

Sympatholytics Drugs that inhibit the postganglionic functioning of the sympathetic nervous system. (p. 313)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

The autonomic nervous system consists of the parasympathetic and sympathetic nervous systems. The class of drugs discussed in this chapter works primarily on the sympathetic nervous system (SNS). As discussed in Chapter 18, the adrenergic agonist drugs stimulate the SNS. Those drugs are called **agonists** because they bind to receptors and cause a response. Adrenergic blockers have the opposite effect and are therefore referred to as **antagonists.** They bind to adrenergic receptors, but in doing so inhibit or block stimulation by the SNS. They are also referred to as **sympatholytics** because they "lyse," or inhibit, SNS stimulation.

Throughout the body, there are receptor sites for the endogenous sympathetic neurotransmitters norepinephrine and epinephrine. Such receptors are known as **adrenergic receptors,** and two basic types are found: alpha and beta. There are subtypes of the alpha- and beta-adrenergic receptors, designated 1 and 2. The $alpha_1$- and $alpha_2$-adrenergic receptors are differentiated by their location on nerves. The $alpha_1$-adrenergic receptors are located on the tissue, muscle, or organ that the nerve is stimulating (postsynaptic effector cells). The $alpha_2$-adrenergic receptors are located on the actual nerves that stimulate the presynaptic effector cells. The $alpha_2$ receptors are inhibitory in nature. Thus, it is actually the stimulation of $alpha_2$ receptors that causes the inhibitory effects of the SNS. $Alpha_2$–active drugs (e.g., clonidine) are discussed in Chapter 22. The $beta_1$-adrenergic receptors are located primarily in the heart. The $beta_2$-adrenergic receptors are located primarily on the smooth muscles of the bronchioles and blood vessels. It is at these various receptors that adrenergic blockers act. They are classified by the type of adrenergic receptor they block—alpha or beta or, in a few cases, both. Hence, they are called *alpha blockers, beta blockers,* or *alpha/beta blockers.*

PHARMACOLOGY OVERVIEW

ALPHA BLOCKERS

Mechanism of Action and Drug Effects

The alpha-adrenergic–blocking drugs, or alpha blockers, interrupt stimulation of the SNS at the $alpha_1$-adrenergic receptors. More specifically, alpha blockers work either by direct competition with norepinephrine or by a noncompetitive process. Figure 19-1 illustrates these two mechanisms. Alpha blockers have a greater affinity for the alpha-adrenergic receptor than norepinephrine does and therefore can chemically displace norepinephrine molecules from the receptor. Adrenergic blockade at these receptors leads to effects such as vasodilation, reduced blood pressure, miosis (pupillary constriction), and reduced smooth muscle tone in organs such as the bladder and prostate. Currently available alpha blockers are listed in Table 19-1.

Indications

The alpha blockers such as doxazosin, prazosin, and terazosin cause both arterial and venous dilation, which reduces peripheral vascular resistance and blood pressure. These drugs are used to treat hypertension (see Chapter 22). There are also alpha-adrenergic receptors in the prostate and bladder. By blocking stimulation of $alpha_1$ receptors, these drugs reduce smooth muscle contraction of the bladder neck and the prostatic portion of the urethra. For this reason, alpha blockers are given to patients with benign prostatic hyperplasia (BPH) to decrease resistance to urinary outflow. This reduces urinary obstruction and relieves some of the effects of BPH. Tamsulosin and alfuzosin are used exclusively for treating BPH, whereas terazosin and doxazosin can be used for both hypertension and BPH.

Other alpha blockers can inhibit responses to adrenergic stimulation. These drugs noncompetitively block alpha-adrenergic receptors on smooth muscle and various exocrine glands. Because of this action, they are very useful in controlling or preventing hypertension in patients who have a **pheochromocytoma,** a tumor that forms on the adrenal gland on top of the kidney and secretes norepinephrine, thus causing SNS stimulation. The alpha blockers are also useful in the treatment of patients who have increased endogenous alpha-adrenergic agonist activity, which results in vasoconstriction. Three conditions in which this occurs are **Raynaud's disease, acrocyanosis,** and frostbite. Phenoxybenzamine, in particular, is an alpha blocker that is beneficial in the treatment of these syndromes, although its use is uncommon.

Still other alpha blockers (e.g., phentolamine) are effective at counteracting the effects of injected epinephrine and norepinephrine. They do this by causing peripheral vasodilation and reducing peripheral resistance by blocking catecholamine-stimulated vasoconstriction. Because of their potent vasodilating properties and their fast onset of action, they are used to prevent skin necrosis and sloughing after the

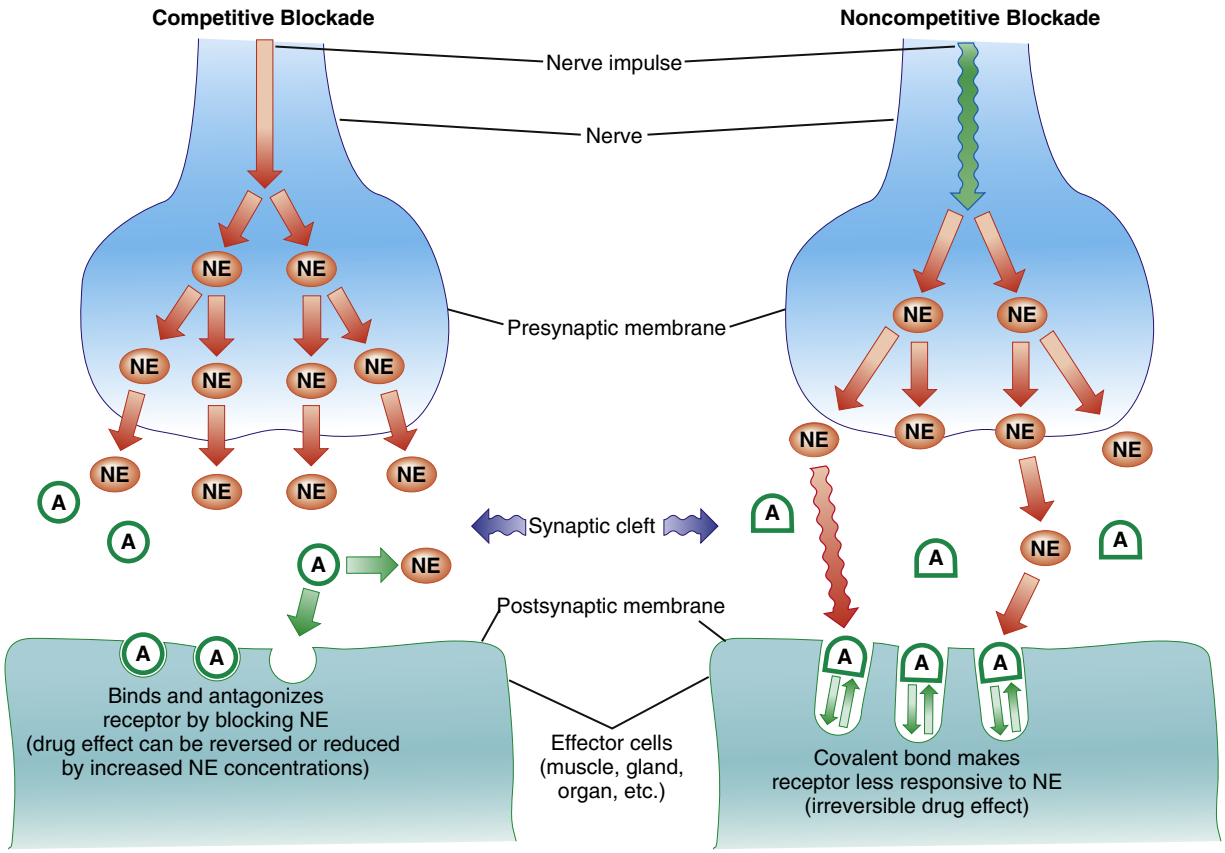

FIGURE 19-1 Mechanisms for alpha-adrenergic competitive and noncompetitive blockade by alpha blocker drugs. *A,* Alpha blocker; *NE,* norepinephrine.

extravasation of vasopressors such as norepinephrine or epinephrine. When these drugs extravasate (leak out of the blood vessel into the surrounding tissue), they cause vasoconstriction and ultimately tissue death, or necrosis. If the vasoconstriction is not reversed quickly, the entire limb can be lost. Phentolamine, in particular, can reverse this potent vasoconstriction and restore blood flow to the ischemic tissue.

Contraindications

Contraindications to the use of alpha-blocking drugs include known drug allergy and peripheral vascular disease and may include hepatic and renal disease, coronary artery disease, peptic ulcer, and sepsis.

Adverse Effects

The primary adverse effects of alpha blockers are those related to their effects on the vasculature. **First-dose phenomenon,** which is a severe and sudden drop in blood pressure after the administration of the first dose of an alpha-adrenergic blocker, can cause patients to fall or pass out. All patients must be warned about this adverse effect before they take their first dose of an alpha blocker. **Orthostatic hypotension** can occur with any dose of an alpha blocker, and patients must be warned to get up slowly from a supine position. The primary adverse effects of the alpha blockers are listed by body system in Table 19-2.

Toxicity and Management of Overdose

In an acute oral overdose, activated charcoal is administered to bind the drug and remove it from the stomach and the circulation. With overdoses of both oral and injectable forms, symptomatic and supportive measures are to be instituted as needed. Blood pressure support with the administration of fluids, volume expanders, and vasopressor drugs and the administration of anticonvulsants such as diazepam for the control of seizures are examples of such measures.

Interactions

The most severe drug interactions with alpha blockers are the ones that potentiate the effects of the alpha blockers. The alpha blockers are very highly protein bound and compete for binding sites with other drugs that are highly protein bound (see Chapter 2). Because of the limited sites for binding on proteins and the increased competition for these sites, more free alpha blocker molecules circulate in the bloodstream. More active drug results in a more pronounced drug effect. Some of the common drugs that interact with alpha blockers and the results of these interactions are listed in Table 19-3.

Dosages

For dosage information on alpha blockers, see the table on p. 315.

TABLE 19-1 CURRENTLY AVAILABLE ADRENERGIC-BLOCKING DRUGS

GENERIC NAME	TRADE NAME	ROUTE
Alpha$_1$ Blockers		
alfuzosin	Uroxatral	PO
doxazosin	Cardura	PO
phenoxybenzamine	Dibenzyline	PO
phentolamine	Generic	IV, IM, IM/subcut/intradermal (for extravasation wounds)
prazosin	Minipress	PO
terazosin	Hytrin	PO
tamsulosin	Flomax	PO
Beta Blockers		
Nonselective		
carvedilol*	Coreg, Coreg CR	PO
labetalol*	Normodyne, Trandate	PO, IV
nadolol	Corgard	PO
penbutolol	Levatol	PO
pindolol	Visken	PO
propranolol*	Inderal	PO, IV
sotalol	Betapace	PO
timolol	Blocadren, Timoptic	PO, IV, ophthalmic
Cardioselective		
acebutolol	Sectral	PO
atenolol	Tenormin	PO
betaxolol	Kerlone	PO
bisoprolol	Zebeta	PO
esmolol	Brevibloc	IV
nebivolol	Bystolic	PO
metoprolol	Lopressor, Toprol-XL	PO, IV

IM, Intramuscular; *IV,* intravenous; *PO,* oral; *subcut,* subcutaneous.
*Has antagonist activity at alpha$_1$, beta$_1$, and beta$_2$ receptors.

TABLE 19-2 ALPHA BLOCKERS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Palpitations, orthostatic hypotension, tachycardia, edema, chest pain
Central nervous	Dizziness, headache, anxiety, depression, weakness, numbness, fatigue
Gastrointestinal	Nausea, vomiting, diarrhea, constipation, abdominal pain
Other	Incontinence, dry mouth, pharyngitis

TABLE 19-3 ALPHA BLOCKERS: COMMON DRUG INTERACTIONS

DRUG	INTERACTING DRUG	MECHANISM	RESULT
phentolamine	Beta blockers, alcohol Erectile dysfunction drugs	Additive effects	Profound hypotension
	Epinephrine	Antagonism	Reduced phentolamine effects
tamsulosin	Warfarin	Competition for plasma protein-binding sites	Risk of bleeding
	Antihypertensives Erectile dysfunction drugs, alcohol	Additive effects	Risk of hypotension

DOSAGES

Selected Alpha-Adrenergic–Blocking Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ phentolamine (Regitine) (C)	Alpha blocker	**Adult** IM/IV: 5 mg; repeat if necessary	Hypertensive episodes with pheochromocytoma
		Adult 5-10 mg diluted in 10 mL NS injected into extravasation site	Alpha-adrenergic drug extravasation
		Pediatric 0.1-0.2 mg/kg into extravasation site	
tamsulosin (Flomax) (B)*	Alpha$_1$ blocker	**Adult** PO: 0.4 mg once daily; max dose 0.8 mg	Benign prostatic hyperplasia

IM, Intramuscular; *IV,* intravenous; *NS,* normal saline; *PO,* oral.
*Not indicated for use in women; however, it is sometimes used for kidney stones.

DRUG PROFILES

The alpha blockers are commonly used to treat hypertension and/or benign prostatic hyperplasia. They include phentolamine, phenoxybenzamine, terazosin, alfuzosin, tamsulosin, silodosin, and prazosin. Prazosin is discussed in Chapter 22.

♦ phentolamine

Phentolamine (Regitine) is an alpha blocker that reduces peripheral vascular resistance and is also used to treat hypertension. Like phenoxybenzamine, it is used to treat the high blood pressure caused by pheochromocytoma, but phentolamine can also be used in the diagnosis of this catecholamine-secreting tumor. To help establish a diagnosis of pheochromocytoma, a single intravenous dose of phentolamine is given to the hypertensive patient. If the blood pressure declines rapidly, it is highly likely that the patient has a pheochromocytoma. Phentolamine is available only as an injectable preparation. It is most commonly used to treat the extravasation of vasoconstricting drugs such as norepinephrine, epinephrine, and dopamine, which when given intravenously can leak out of the vein, especially if the intravenous tube is not correctly positioned. If such a drug is allowed to extravasate into the surrounding tissue, the result is intense vasoconstriction, decreased blood flow, necrosis, and potential loss of the limb. When phentolamine is injected subcutaneously in a circular fashion around the extravasation site, it causes alpha-adrenergic receptor blockade and vasodilation, which in turn increases blood flow to the ischemic tissue and thus prevents permanent damage. Its use is contraindicated in patients who have shown a hypersensitivity to it, those who have experienced a myocardial infarction (MI), and those with coronary artery disease. Adverse effects include tachycardia, dizziness, gastrointestinal upset, and others listed in Table 19-2. Drugs with which phentolamine interacts include alcohol (a disulfiram-like reaction; see Chapter 17) and erectile dysfunction medications such as sildenafil (additive hypotensive effects; see Chapter 35). Epinephrine and ephedrine can counteract the desired effects of phentolamine. The recommended dosages are given in the table on p. 315.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	1 hr	4-6 hr	24 hr	3-4 days

tamsulosin

Tamsulosin (Flomax) is an alpha blocker used primarily to treat BPH and is exclusively indicated for male patients. Similar drugs with the same indication are alfuzosin and silodosin. These drugs block alpha-adrenergic receptors on smooth muscle within the prostate and bladder. This results in relaxation of these smooth muscle fibers and improved urinary flow. Other similar drugs include terazosin and doxazosin, which can be used to treat both BPH and hypertension. Contraindications to tamsulosin include known drug allergy and concurrent use of erectile dysfunction drugs such as sildenafil. Adverse effects include headache, abnormal ejaculation, rhinitis, and others listed in Table 19-2. Interacting drugs include other alpha blockers, calcium channel blockers, and erectile dysfunction drugs (additive hypotensive effects); drugs that induce or inhibit hepatic enzymes may reduce or enhance the effects of tamsulosin. It is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	4-7 hr	15 hr	Unknown

BETA BLOCKERS

Mechanism of Action and Drug Effects

The beta-adrenergic–blocking drugs (beta blockers) block SNS stimulation of the beta-adrenergic receptors by competing with norepinephrine and epinephrine. The beta blockers can be either selective or nonselective, depending on the type of beta-adrenergic receptors they antagonize. $Beta_1$-adrenergic receptors are located primarily in the heart. Beta blockers that are selective for these receptors are called *cardioselective beta blockers* or *$beta_1$-blocking drugs.* Other beta blockers block both $beta_1$- and $beta_2$-adrenergic receptors and are referred to as *nonselective beta blockers.* $Beta_2$ receptors are located primarily on the smooth muscles of the bronchioles and blood vessels. In addition, beta blockers can be further categorized according to whether or not they have **intrinsic sympathomimetic activity.** Drugs with intrinsic sympathomimetic activity (acebutolol, penbutolol, pindolol) not only block beta-adrenergic receptors but also partially stimulate them. This was initially believed to be an advantageous characteristic, but clinical experience has not borne this out. Two beta blockers, carvedilol and labetalol, also have an alpha-receptor–blocking activity, especially at higher dosages. Table 19-1 lists the currently available beta blockers.

Cardioselective $beta_1$-blockers block the $beta_1$ receptors on the surface of the heart. This reduces myocardial stimulation, which in turn reduces heart rate, slows conduction through the atrioventricular (AV) node, prolongs sinoatrial (SA) node recovery, and decreases myocardial oxygen demand by decreasing myocardial contractile force (contractility). Nonselective beta blockers not only have these cardiac effects, but they block $beta_2$ receptors on the smooth muscle of the bronchioles and blood vessels as well.

Smooth muscle that surrounds the airways in the lungs is called the *bronchioles.* When the $beta_2$ receptors in the bronchioles are blocked, the end result is bronchial smooth muscle contraction and narrowing of the airways. This may lead to shortness of breath. In addition, the smooth muscle that surrounds blood vessels can cause dilation or constriction, depending on whether the $beta_1$ or $beta_2$ receptors are stimulated. When this $beta_2$ stimulation is blocked, the muscles are then stimulated by unopposed sympathetic activity at the $beta_1$ receptors, which causes them to contract. This causes increased peripheral vascular resistance. Furthermore, catecholamines promote *glycogenolysis* (the production of glucose from glycogen) and

mobilize glucose in response to hypoglycemia. Nonselective beta blockers impair this process and also impede the secretion of insulin from the pancreas, which causes elevation of blood glucose level.

Finally, beta blockers can cause the release of free fatty acids from adipose tissue. This may result in moderately elevated blood levels of triglycerides and reduced levels of the "good cholesterol" known as *high-density lipoprotein (HDL)*.

Indications

Indications for beta blockers include angina, MI, cardiac dysrhythmias, hypertension, and heart failure.

Beta blockers are commonly used in the treatment of **angina,** or chest pain (see Chapter 23). These drugs work by decreasing the demand for myocardial energy and oxygen consumption, which helps shift the supply/demand ratio to the supply side and allows more oxygen to get to the heart muscle. This in turn helps to relieve the pain in the heart muscle caused by the lack of oxygen.

Beta blockers are also considered to be *cardioprotective* because they inhibit stimulation of the myocardium by circulating catecholamines. Myocardial infarction causes catecholamines to be released. Unopposed stimulation by catecholamines would further increase the heart rate and the contractile force and thereby increase myocardial oxygen demand. When a beta blocker occupies myocardial $beta_1$ receptors, circulating catecholamine molecules are prevented from binding to the receptors. Thus, the beta blockers protect the heart from being stimulated by these catecholamines. Because of this characteristic, beta blockers are commonly given to patients after they have experienced an MI to protect the heart.

Beta blockers also have a profound effect on the conduction system of the heart. The AV node normally receives impulse stimulation from the SA node and slows it down so that the ventricles have time to fill before they are stimulated to contract. Conduction in the SA node is slowed by beta blockers, which results in a decreased heart rate. These drugs also slow conduction through the AV node. These effects of the beta blockers on the conduction system of the heart make them useful in the treatment of various types of irregular heart rhythms called **dysrhythmias** (see Chapter 25).

Beta blockers are useful in treating hypertension because of their ability to reduce SNS stimulation of the heart, including reducing heart rate and the force of myocardial contraction (systole). Traditionally beta blockers were thought to worsen heart failure. However, recent studies have shown benefit to the use of beta blockers. Certain beta blockers such as carvedilol and metoprolol have produced the best results to date. The form of heart failure that includes a component of diastolic dysfunction responds especially favorably to beta blockers.

Because of their **lipophilicity** (attraction to lipid or fat), some beta blockers (e.g., propranolol) can easily gain entry into the central nervous system and are used to treat migraine headaches. In addition, the topical application of timolol to the eye has been very effective in treating ocular disorders such as glaucoma (see Chapter 57).

TABLE 19-4 BETA BLOCKERS: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Atrioventricular block, bradycardia, heart failure
Central nervous	Dizziness, fatigue, depression, drowsiness, unusual dreams
Gastrointestinal	Nausea, vomiting, constipation, diarrhea
Hematologic	Agranulocytosis, thrombocytopenia
Metabolic	Hyperglycemia and/or hypoglycemia, hyperlipidemia
Other	Impotence, alopecia, bronchospasm, wheezing, dry mouth

Contraindications

Contraindications to the use of beta blockers include known drug allergies and may include uncompensated heart failure, cardiogenic shock, heart block or bradycardia, pregnancy, severe pulmonary disease, and Raynaud's disease.

Adverse Effects

The adverse effects of beta blockers are primarily extensions of their pharmacologic activity. Most such effects are mild and diminish with time. Some of the most serious undesirable effects can be caused by acute withdrawal of the drug. For example, such sudden withdrawal may exacerbate underlying angina, precipitate an MI, or cause rebound hypertension. Beta blockers also delay the recovery from hypoglycemia in patients with type 1 diabetes (rarely in those with type 2). In addition, the nonselective beta blockers can interfere with the normal responses to hypoglycemia, such as tremor, tachycardia, and nervousness, in essence masking the signs and symptoms of hypoglycemia. Adverse effects induced by beta blockers are listed by body system in Table 19-4.

Toxicity and Management of Overdose

For overdoses of both oral and injectable dosage forms, treatment consists primarily of symptomatic and supportive care. Atropine may be given intravenously for the management of bradycardia. If the bradycardia still persists, placement of a transvenous cardiac pacemaker may be considered. For the treatment of severe hypotension, vasopressors are titrated until the desired blood pressure and heart rate are achieved. Intravenously administered diazepam may be useful for the treatment of seizures. Most beta blockers are dialyzable; therefore, hemodialysis may be useful in enhancing elimination in the event of severe overdose.

Interactions

Most of the drug interactions with beta blockers result from either the additive effects of coadministered medications with similar mechanisms of action or the antagonistic effects of various drugs. Nonselective beta blockers may mask the tachycardia from hypoglycemia caused by insulin and sulfonylureas, and the hypoglycemic effect of insulin and sulfonylureas may be enhanced (see Chapter 32). Some of the common drugs that

DOSAGES

Selected Beta-Adrenergic–Blocking Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ atenolol (Tenormin) (C)	$Beta_1$ blocker	**Adult** PO: 50-200 mg/day daily or divided bid, (max 200 mg/day)	Hypertension, angina
carvedilol (Coreg) (C)	Alpha and beta blocker	**Adult** PO: 3.125 mg bid; may double dose every 2 wk to highest tolerated dose, max 50 mg/day (100 mg/day for patients with heart failure who weigh over 85 kg)	Heart failure, angina, hypertension
♦ esmolol (Brevibloc) (C)	$Beta_1$ blocker	**Adult** IV: Bolus of 500 mcg/kg over 1 min, followed by 50 mcg/kg/min for 4 minutes and evaluate	Supraventricular tachydysrhythmias
labetalol (Normodyne, Trandate) (C)	$Alpha_1$ and beta blocker	**Adult** PO: 200-800 mg/day divided bid IV: 20 mg with additional doses of 40-80 mg at 10-min intervals until desired effect or a total dose of 300 mg is injected; maintenance infusion of 2 mg/min initially and titrated to response	 Hypertension Severe hypertension
♦ metoprolol (Lopressor, Toprol XL) (C)	$Beta_1$ blocker	**Adult** PO: 100-400 mg/day divided bid-tid IV/PO: 3 bolus injections of 5 mg at 2-min intervals followed in 15 min by 50 mg PO q6h for 48 hr; thereafter 100 mg PO bid	 Hypertension, late MI Early MI
♦ propranolol (Inderal) (C)	Beta blocker	**Adult** PO: 80-320 mg/day divided bid-qid 120-640 mg/day divided bid-tid 10-30 mg tid-qid 180-240 mg divided tid-qid 160-240 mg/day divided	 Angina Hypertension Dysrhythmias Post-MI Migraine
sotalol (Betapace) (B)	Beta blocker	**Adult** PO: 160-320 mg/day divided	Life-threatening ventricular dysrhythmias

IV, Intravenous; *MI,* myocardial infarction; *PO,* oral.

TABLE 19-5 BETA BLOCKERS: DRUG INTERACTIONS

INTERACTING DRUG	MECHANISM	RESULT
Antacids (aluminum hydroxide type)	Decrease absorption	Decreased beta blocker activity
Antimuscarinics, anticholinergics	Antagonism	Reduced beta blocker effects
digoxin	Additive effect	Enhanced bradycardic effects of digoxin
Diuretics, cardiovascular drugs, alcohol	Additive effect	Additive hypotensive effects
Neuromuscular blocking drugs	Additive effect	Prolonged neuromuscular blockade
Oral hypoglycemic drugs, insulin	Mask signs of hypoglycemia	Delayed recovery from hypoglycemia

interact with beta blockers and the resulting effects are given in Table 19-5.

Dosages

For dosage information on selected beta blockers, see the table on this page.

DRUG PROFILES

Numerous beta blockers currently available are listed in Table 19-1. Several beta blockers are profiled in the following sections. Contraindications, adverse reactions, and drug interactions are comparable for these drugs and are listed in the previous text, Table 19-4, and Table 19-5, respectively.

♦ atenolol

Atenolol (Tenormin) is a cardioselective beta blocker that is commonly used to prevent future heart attacks in patients who have had one. It is also used in the treatment of hypertension and angina and in the management of thyrotoxicosis to help block the symptoms of excessive thyroid activity. Atenolol is available for oral use. Recommended dosages are given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	2-4 hr	6-7 hr	24 hr

carvedilol

Carvedilol (Coreg) has many effects, including acting as a nonselective beta blocker, an $alpha_1$-blocker, a calcium channel

blocker, and possibly an antioxidant. It is used primarily in the treatment of heart failure but is also beneficial for hypertension and angina. It has been shown to slow the progression of heart failure and to decrease the frequency of hospitalization in patients with mild to moderate (class II or III) heart failure. Carvedilol is most commonly added to digoxin, furosemide, and angiotensin-converting enzyme inhibitors when used to treat heart failure. Carvedilol is available only for oral use. A controlled-release formulation, Coreg CR, was recently approved. The dosages are different from those for immediate-release Coreg, and the two cannot be interchanged. Recommended dosages are given in the table on p. 318.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	20-120 min	1-4 hr	6-8 hr	8-24 hr

♦ esmolol

Esmolol (Brevibloc) is a very strong short-acting $beta_1$-blocker. It is primarily used in acute situations to provide rapid temporary control of the ventricular rate in patients with supraventricular tachydysrhythmias. Because of its very short half-life, it is given only as an intravenous infusion and is titrated to achieve the serum levels that control the patient's symptoms. Recommended dosages are given in the table on p. 318.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Immediate	6 min	9 min	15-20 min

labetalol

Labetalol (Normodyne) is unusual in that it can block both alpha- and beta-adrenergic receptors. It is used in the treatment of severe hypertension and hypertensive emergencies to quickly lower the blood pressure before permanent damage is done. Labetalol is available for oral and injectable use. Recommended dosages are given in the table on p. 318.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	2-5 min	5-15 min	2.5-8 hr	2-4 hr
PO	20-120 min	1-4 hr	2.5-8 hr	8-24 hr

♦ metoprolol

Metoprolol (Lopressor) is a $beta_1$-blocker that has become a favorite of cardiologists for use in patients after MI. Recent studies of metoprolol have shown increased survival in patients given the drug after they have experienced an MI. Metoprolol is available for oral and injectable use. Recommended dosages are given in the table on p. 318.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	1 min	20 min	3-8 hr	5-8 hr
PO	1 hr	2-4 hr	3-8 hr	10-20 hr

♦ propranolol

Propranolol (Inderal) is the prototypical nonselective $beta_1$- and $beta_2$-blocking drug. It was one of the very first beta blockers to be used. Lengthy experience with it has revealed many uses for it. In addition to the indications mentioned for metoprolol, propranolol has been used for the treatment of tachydysrhythmias associated with cardiac glycoside intoxication and for the treatment of hypertrophic subaortic stenosis, pheochromocytoma, thyrotoxicosis, migraine headache, essential tremor, and many other conditions. The same contraindications that apply to the cardioselective beta blockers discussed earlier hold for propranolol as well. In addition, its use is contraindicated in patients with bronchial asthma. Propranolol is available for oral and injectable use. Recommended dosages are given in the table on p. 318.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	2 min	1-4 hr	3-5 hr	3-6 hr
PO	1-2 hr	1-4 hr	3-5 hr	6-12 hr

sotalol

Sotalol (Betapace) is a nonselective beta blocker that has very potent antidysrhythmic properties. It is commonly used for the management of difficult-to-treat dysrhythmias. Often these dysrhythmias are life-threatening ventricular dysrhythmias such as sustained ventricular tachycardia. It has properties characteristic of both a class II and class III antidysrhythmic drug (see Chapter 25). Because it is a nonselective beta blocker, it causes some of the unwanted adverse effects typical of these drugs (e.g., hypotension). Sotalol is available only for oral use. Recommended dosages are given in the table on p. 318.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-2 hr	2.5-4 hr	12 hr	8-16 hr

NURSING PROCESS

ASSESSMENT

Adrenergic-blocking drugs, or sympatholytics, produce a variety of effects on the patient, depending on the type of receptor(s) blocked. Because of the impact of these drugs, primarily on the cardiac and respiratory systems, their use requires careful assessment to help minimize the adverse effects and maximize the therapeutic effects. Understanding the basic anatomy and

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Look-Alike Drugs: Toprol-XL, Topamax, and Tegretol

Be careful about look-alike drugs! Medication errors often occur when drug names are similar. The Food and Drug Administration has reported errors in prescribing and dispensing involving a mix-up between Topamax (topiramate), which is indicated for the treatment of epilepsy and prophylaxis of migraines, and Toprol-XL (metoprolol succinate), which is used for the treatment of hypertension and heart failure as well as the long-term treatment of angina pectoris. Other errors have occurred when Toprol-XL and Tegretol (carbamazepine), a drug used for various types of seizures and trigeminal neuralgia, have been confused. Consider what would happen if a patient with a history of seizures receives a beta blocker instead of the prescribed antiepileptic drug! These cases reinforce the importance of checking the drug name carefully (using both trade and generic names).

For more information, go to http://www.fda.gov/Safety/MedWatch/SafetyInformation/SafetyAlertsforHumanMedicalProducts/default.htm.

physiology of adrenergic receptors and their subsequent actions if stimulated or blocked is also critical in carrying out assessment and other aspects of the nursing process and drug therapy. If an adrenergic-blocking drug is nonselective, it blocks both alpha and beta ($beta_1$ and $beta_2$) receptors. Alpha receptor blocking affects blood vessels, whereas $beta_1$ receptor blocking affects heart rate and $beta_2$ blocking affects bronchial smooth muscle. Therefore, a nonselective adrenergic blocker will have the following actions: (1) alpha blocking leading to blockade of the sympathetic stimulation of blood vessels (i.e., vasoconstriction) and resulting in vasodilation and a subsequent decrease in blood pressure; (2) $beta_1$ blocking leading to blockade of the sympathetic effects on heart rate, contractility, and conduction with resulting bradycardia, negative inotropic effects (i.e., decrease in contractility), and a decrease in conduction; and (3) $beta_2$ blocking leading to blockade of the sympathetic effects on bronchial smooth muscle with the net effect of bronchoconstriction. However, if the drug is only an alpha-, $beta_1$-, or $beta_2$-blocker, the resulting effect will be related to the specific receptor being blocked (or combination of receptors, depending on the drug). An understanding of these basic physiologic concepts is necessary to critical thinking and decision making in the administration of these drugs.

Begin a thorough assessment by gathering information about the patient's allergies and past and present medical conditions. Conducting a system overview and taking a thorough medication history is also a part of this process. Pose the following questions and document the findings: Are there any allergies to medications and/or foods? Is there a history of chronic obstructive pulmonary disease (e.g., emphysema, asthma, chronic bronchitis), other respiratory diseases, hypertension or hypotension, cardiac disease, bradycardia, congestive heart failure, and/or cardiac dysrhythmias? This information is crucial because the action and adverse effects of alpha and beta blockers may pose additional health risks to individuals with these problems. For example, alpha blockers may precipitate hypotension, thus patients with baseline low blood pressure readings need more frequent blood pressure monitoring, or they may not tolerate the drug at all. Beta-blocking drugs may precipitate bradycardia, hypotension, heart block, heart failure, bronchoconstriction, and/or increased airway resistance. Therefore, any preexisting condition that might be worsened by the concurrent use of any of these medications may then represent a contraindication or caution. More specifically, with $beta_1$-blocking drugs, patients with preexisting bradycardia, decreased cardiac contractility, heart failure, and/or decreased conduction with heart block cannot take these drugs without exacerbation of these conditions. As another example, patients with a history of asthma, emphysema, bronchitis, or any condition with increased airway resistance or bronchoconstriction cannot take $beta_2$-blocking drugs without experiencing further bronchoconstriction and negative effects on their underlying disease condition. Given the actions and adverse effects of the drug, it is also important, to assess intake and output, daily weights, breath sounds, and blood glucose levels, especially if the patient has diabetes. For a complete listing of drug interactions, see Tables 19-3 and 19-5.

NURSING DIAGNOSES

1. Ineffective airway clearance related to the adverse effect of bronchoconstriction caused by beta-adrenergic drugs as well as any underlying restrictive airway conditions
2. Ineffective peripheral tissue perfusion related to the adverse effects of the disease of hypertension and the adverse effects of the adrenergic-blocking drugs (hypotension)
3. Imbalanced nutrition, less than body requirements, due to nausea and vomiting related to the adverse effects of the adrenergic blockers
4. Deficient knowledge related to lack of information about the therapeutic regimen, drug adverse effects, drug interactions, and precautions to be taken during drug treatment
5. Risk for injury related to possible adverse effects of the adrenergic-blocking drugs (e.g., postural hypotension, dizziness, syncope, numbness and tingling of the fingers and toes)

PLANNING

GOALS

1. Patient maintains/regains effective airway clearance and airway exchange.
2. Patient maintains/regains adequate peripheral tissue perfusion.
3. Patient experiences improved nutritional status.
4. Patient demonstrates adequate knowledge about use of the specific medications, their adverse effects, and the appropriate dosing routine to be followed at home.
5. Patient remains free from injury related to minimal problems with adverse effects of the medications.

OUTCOME CRITERIA

1. Patient states that respirations are performed with ease and in a regular rhythm, and without any bronchospasm, wheezing, or difficulty.
2. Patient states that blood pressure readings are within normal ranges.

- Patient experiences minimal adverse effects of drug therapy, specifically hypotension.

3. Patient states adequate dietary intake of the following: grains, vegetables, fruits, dairy, and protein foods (see www.choosemyplate.gov/).
4. Patient states the rationale for both pharmacologic and nonpharmacologic treatment of hypertension or other indications for drug therapy.
   - Patient states importance of adhering with the medication therapy regimen and taking medication as prescribed.
   - Patient reports effective blood pressure lowering or other treatment with an adrenergic blocker without risks and complications such as syncope, dizziness, and hypotension.
   - Patient demonstrates the correct method of self-measurement of blood pressure using a digital cuff device.
   - Patient states the conditions that may occur of which the prescriber must be informed immediately, such as palpitations, chest pain, insomnia, and excessive agitation.
5. Patient remains free from injury due to taking medication as prescribed and preventing/managing adverse reactions.
   - Patient keeps all follow-up appointments with the prescriber to maintain safe therapy.
   - Patient follows instructions to avoid sudden withdrawal of hypertensive drugs to prevent rebound hypertensive crises and experiences minimal complications/injury to self.

IMPLEMENTATION

Several nursing interventions may help maximize therapeutic effects of *adrenergic-blocking drugs* and minimize their adverse effects. To help minimize dry mouth, encourage intake of water within any restrictions and frequent rinsing/spraying of mouth with over-the-counter dental products indicated for dry mouth. Sugarless gum/candy may also be helpful with dry mouth. If any of the medications are given intravenously, an ECG monitor/cardiac monitoring is usually recommended. Encourage patients taking alpha blockers to change positions slowly and with purpose to prevent or minimize postural hypotension with subsequent dizziness and/or syncope. Alpha blockers and their indications in treatment of hypertensive disease and/or hypertensive crises are discussed further in Chapter 22. Use of the newer alpha blocker tamsulosin in patients with BPH is quite common, and patients taking this drug need to inform all health care providers—including dentists—that this is part of their medical regimen, especially before any type of surgery. In addition, anything leading to vasodilation needs to be avoided to prevent postural hypotension with resultant dizziness, lightheadedness, and syncope. This includes alcohol intake, excessive exercise, exposure to hot climates, and use of saunas, hot tubs, and heated showers or baths. See Patient Teaching Tips for more information.

When either an alpha blocker or beta blocker is used, count the apical pulse for 1 full minute. Measure and document both supine and standing blood pressures. Contact the prescriber immediately if the patient has any problems with dizziness, fainting, or lightheadedness, or if the systolic blood pressure is lower than 100 mm Hg or the pulse rate is lower than 60 beats/min. Daily weight measurement is important to monitor the progress of therapy and check for the adverse effect of edema. A good rule of thumb is to contact the prescriber if the patient shows an increase of 2 pounds or more over a 24-hour period or 5 pounds or more within 1 week. Keeping a daily journal documenting daily weights, blood pressure readings, pulse rates, adverse effects, and overall feelings of wellness or lack thereof will be important to the monitoring of the therapeutic regimen. Other symptoms to report to the prescriber include muscle weakness, shortness of breath, and collection of fluid in the lower extremities as manifested by difficulty in putting on shoes or socks and weight gain. Patients taking any of these medications must be weaned off the drug slowly because an abrupt discontinuation could lead to rebound hypertension or chest pain. The prescriber will designate a period of time for weaning; however, it is generally over a period of 1 to 2 weeks. Understanding basic anatomy and physiology and how receptors work will help guide nursing actions related to these drugs. See Patient Teaching Tips for more specific information.

CASE STUDY

Beta Blockers

Frank, a 58-year-old high school orchestra teacher, has been hospitalized after experiencing a myocardial infarction. He is married with two teenage children. His physician told him that his myocardial infarction was "mild" but that Frank must make some lifestyle changes, including exercise and dietary changes. Frank has a history of asthma; he had stopped smoking 5 years earlier and has had no recent problems. His history also includes gallbladder removal at 50 years of age. Frank's pulse rate has ranged from 78 to 112 beats/min; his blood pressure has been within normal range, 118/74 to 122/80 mm Hg. He is preparing for discharge and has the following prescriptions:

Aspirin, enteric-coated, 81 mg once a day, PO

Propranolol (Inderal) 60 mg three times a day, PO

1. Explain the purpose of the propranolol order for Frank.

After Frank has been home for a week, the home health nurse calls Frank to check on how he is doing. Frank tells the nurse that he was "about to call the doctor" because he has been feeling more and more short of breath, even though he has been resting at home.

2. What could be causing this problem? What do you expect will happen as a result?

Two months later, Frank is in the office for a follow-up visit. He seems upset, even though his blood pressure is within normal range, his cardiac function is stable, and he has had no further breathing problems. He tells the nurse, "I don't care what the doctor tells me, I'm going to stop that new pill. I'm having a terrible problem and I know it's because of that medicine."

3. What do you suspect is causing Frank to be so upset, and what will be done about it? Will the beta blocker be discontinued today? Explain your answer.

For answers, see http://evolve.elsevier.com/Lilley.

EVALUATION

Therapeutic effects for which to monitor in patients receiving *adrenergic-blocking drugs* include, but are not limited to, a decrease in blood pressure, pulse rate, and palpitations (in patients with these specific problems before drug therapy); alleviation of the symptoms of the disorder for which the drug was indicated; a return to normal blood pressure and pulse with lowering of the blood pressure toward 120/80 mm Hg and the pulse toward 60 beats/min in patients with diagnosed hypertension; and a decrease in chest pain in patients with angina. Also monitor patients for adverse effects associated with these medications, including bradycardia, depression, fatigue, and hypotension. See Tables 19-2 and 19-4 for other potential adverse effects.

PATIENT TEACHING TIPS

- Give patients written and verbal information about drug indications, actions, adverse effects, cautions, contraindications, and drug interactions. This information needs to be age-specific and tailored to the specific learning needs of the patient.
- Emphasize the need to wear a medical alert bracelet or necklace identifying the specific medical diagnoses and provide a list of all medications. The patient needs to understand the importance of carrying this information in written form on his or her person at all times and update the information at least every few months or whenever there are major changes in the diagnosis and treatment regimen. Recommend to the patient that he or she also keep a card in his or her wallet or purse to record blood pressure readings by date and time. This information may then be shared with other health care professionals.
- Caution the patient to take medications exactly as prescribed and to never abruptly discontinue them due to the risk of rebound hypertension. If there is concern about omitted or skipped doses, the patient needs to contact the prescriber immediately.
- Caffeine and other central nervous system stimulants must be avoided while taking adrenergic-blocking drugs to prevent further irritability of the cardiac and central nervous systems and subsequent negative effects on health status.
- Alcohol ingestion is to be avoided because it causes vasodilation, which increases the risk of hypotension and postural blood pressure changes.
- Encourage the patient to contact the prescriber if he or she experiences palpitations, chest pain, confusion, weight gain (2 pounds or more in 24 hours or 5 pounds or more in 1 week), dyspnea, nausea, or vomiting. Other problems to report include swelling in the feet and ankles, shortness of breath, excessive fatigue, dizziness, and syncope.
- The alpha blocker tamsulosin must be taken as directed and with caution in patients with blood pressure problems (e.g., hypotension). The drug must also be used with caution by the elderly and while driving or engaging in other activities requiring alertness, because the adverse effects of this drug include blurred vision, dizziness, and drowsiness.
- Caution patients to change positions slowly to avoid dizziness and/or syncope. Excessive exercise, exposure to hot climates, use of a sauna or tanning bed, and alcohol consumption exacerbate vasodilation from the adrenergic-blocking drugs and lead to a greater drop in blood pressure with even more risk of dizziness and syncope.
- Constipation may develop as an adverse effect. Increasing fluids as well as fiber may help to prevent constipation.

KEY POINTS

- Adrenergic-blocking drugs block the stimulation of the alpha-, $beta_1$-, and/or $beta_2$-adrenergic receptors, with the net result of blocking the effects of either norepinephrine or epinephrine on the receptors. This blocking action leads to a variety of physiologic responses depending on which receptors are blocked. Knowing how these receptors work allows the nurse to understand and predict the expected therapeutic effects of the drugs as well as the expected adverse effects.
- With alpha blockers, the predominant response is vasodilation. This is due to blocking of the alpha-adrenergic effect of vasoconstriction, which results in blood vessel relaxation.
- Vasodilation of blood vessels with the alpha blockers results in a drop in blood pressure and a reduction in urinary obstruction, which may lead to increased urinary flow rates. Monitor for these effects in patients taking alpha blockers.
- Beta blockers inhibit the stimulation of beta-adrenergic receptors by blocking the effects of the SNS neurotransmitters norepinephrine, epinephrine, and dopamine. Stimulation of $beta_1$ receptors leads to an increase in heart rate, conduction, and contractility. Stimulation of $beta_2$ receptors results in bronchial smooth muscle relaxation or bronchodilation. Blocking of $beta_1$ receptors results in a *decrease* in heart rate, conduction, and contractility. Blocking of $beta_2$ receptors leads to a *decrease* in bronchial smooth muscle relaxation, or bronchoconstriction.
- Beta blockers are classified as either selective or nonselective. Selective beta blockers are also called *cardioselective beta blockers* and block only the beta-adrenergic receptors in the heart that are located on the postsynaptic effector cells (i.e., the cells that nerves stimulate). The beneficial effects of the cardioselective beta blockers include decreased heart rate, reduced cardiac conduction, and

KEY POINTS—cont'd

decreased myocardial contractility with no bronchoconstriction. These drugs are a good choice for patients with hypertension who also have bronchospastic airway disease or other pulmonary disease.

- Nonselective beta blockers block both $beta_1$- and $beta_2$-adrenergic receptors and affect the heart and bronchial smooth muscle. These drugs are used to treat patients with hypertension who do not have a problem with bronchospasm or pulmonary airway disease.
- Nursing considerations for patients taking alpha and beta blockers include teaching patients that they must weigh themselves daily, avoid sudden changes in position, and increase intake of fluids and fiber. Weight gain, dizziness, fainting, and/or a decrease in heart rate below 60 beats/min or a blood pressure of less than 100 mm Hg systolic or less than 80 mm Hg diastolic need to be reported immediately.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 When a patient has experienced extravasation of a peripheral infusion of dopamine, the nurse will inject the alpha blocker phentolamine (Regitine) into the area of extravasation and expect which effect?
- **a** Vasoconstriction
- **b** Vasodilation
- **c** Analgesia
- **d** Hypotension

2 When administering beta blockers, the nurse will follow which guideline for administration and monitoring?
- **a** The drug may be discontinued at any time.
- **b** Postural hypotension rarely occurs with this drug.
- **c** Tapering off the medication is necessary to prevent rebound hypertension.
- **d** The patient needs to stop taking the medication at once if he or she gains 3 to 4 pounds in a week.

3 The nurse providing teaching for a patient who has a new prescription for $beta_1$ blockers will keep in mind that these drugs may result in which effect?
- **a** Tachycardia
- **b** Tachypnea
- **c** Bradycardia
- **d** Bradypnea

4 A patient who has recently had a myocardial infarction (MI) has started therapy with a beta blocker. The nurse explains that the main purpose of the beta blocker for this patient is to
- **a** cause vasodilation of the coronary arteries.
- **b** prevent hypertension.
- **c** increase conduction through the SA node.
- **d** protect the heart from circulating catecholamines.

5 Before initiating therapy with a nonselective beta blocker, the nurse will assess the patient for a history of which condition?
- **a** Hypertension
- **b** Liver disease
- **c** Pancreatitis
- **d** Asthma

6 A patient is taking an alpha blocker as treatment for benign prostatic hyperplasia. The nurse will monitor for which potential drug effects? (Select all that apply.)
- **a** Orthostatic hypotension
- **b** Increased blood pressure
- **c** Increased urine flow
- **d** Headaches
- **e** Bradycardia

7 A child in the pediatric ICU has been receiving a dopamine infusion. This morning while on rounds, the nurse noted that the IV has infiltrated. After stopping the infusion, the nurse prepares to administer phentolamine (Regitine). The ordered dose is 0.2 mg/kg, to be injected into the area of extravasation. The child weighs 39 lb. How many milligrams will the nurse administer? (Round to tenths.)

1. b, 2. c, 3. c, 4. d, 5. d, 6. a, c, d, 7. 3.5 mg

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Briefly review the functions of the autonomic nervous system and the impact of the parasympathetic division.
2 List the various drugs classified as cholinergic agonists (also called *parasympathomimetics*).
3 Discuss the mechanisms of action, therapeutic effects, indications, adverse and toxic effects, drug interactions, cautions, contraindications, dosages, routes of administration, and any antidotal management for the various cholinergic agonists (or parasympathomimetics).
4 Develop a nursing care plan that includes all phases of the nursing process for patients taking cholinergic agonists.

DRUG PROFILES

- **bethanechol, p. 327**
- **donepezil, p. 328**
- **memantine, p. 328**
- **pyridostigmine, p. 329**

- ***Key drug***

KEY TERMS

Acetylcholine The neurotransmitter responsible for transmission of nerve impulses to effector cells in the parasympathetic nervous system. (p. 325)

Acetylcholinesterase The enzyme responsible for the breakdown of acetylcholine (also referred to simply as *cholinesterase*). (p. 325)

Alzheimer's disease A disease of the brain that is characterized by progressive mental deterioration manifested by confusion, disorientation, and loss of memory, ability to calculate, and visual-spatial orientation. (p. 327)

Atony A lack of normal muscle tone (p. 326)

Cholinergic crisis Severe muscle weakness and respiratory paralysis due to excessive acetylcholine; often seen in patients with myasthenia gravis as an adverse effect of drugs used to treat the disorder (p. 327)

Cholinergic receptor A nerve receptor that is stimulated by acetylcholine. (p. 325)

Miosis The contraction of the pupil. (p. 326)

Muscarinic receptors Cholinergic receptors that are located postsynaptically in the *effector organs* such as smooth muscle, cardiac muscle, and glands supplied by parasympathetic fibers. (p. 325)

Nicotinic receptors Cholinergic receptors located in the *ganglia* (where presynaptic and postsynaptic nerve fibers meet) of both the parasympathetic nervous system and the sympathetic nervous system; so named because they can be stimulated by the alkaloid nicotine. (p. 325)

Parasympathomimetics Drugs that mimic the parasympathetic nervous system; also referred to as *cholinergic agonist drugs*. (p. 325)

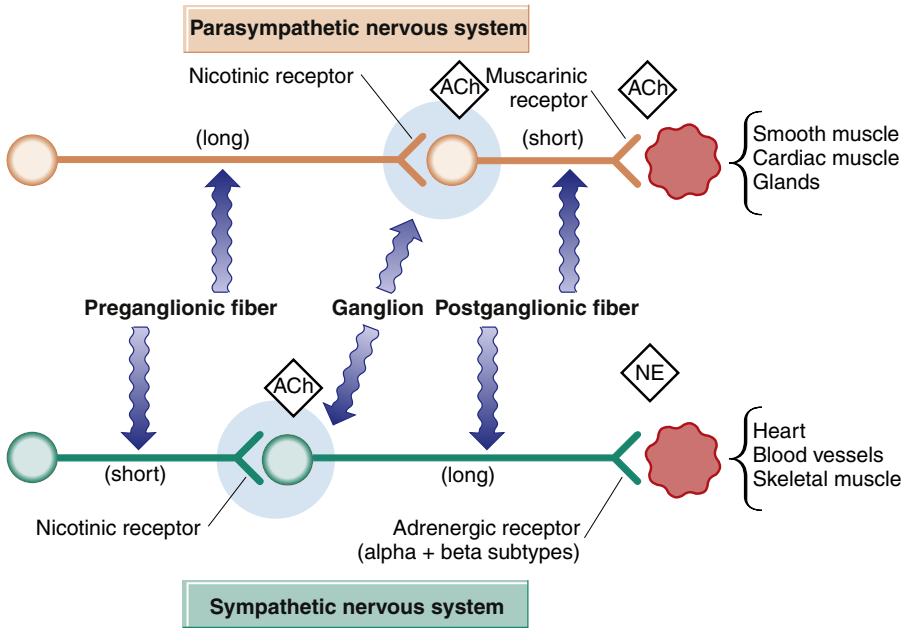

FIGURE 20-1 Parasympathetic and sympathetic nervous systems and their relationship to one another. *ACh,* Acetylcholine; *NE,* norepinephrine.

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Cholinergic drugs, cholinergic agonists, and *parasympathomimetics* are all terms that refer to the class of drugs that stimulate the parasympathetic nervous system.

PARASYMPATHETIC NERVOUS SYSTEM

The parasympathetic nervous system (PNS) is the branch of the autonomic nervous system with functions opposite those of the sympathetic nervous system (Figure 20-1). **Acetylcholine** is the neurotransmitter responsible for the transmission of nerve impulses to effector cells in the parasympathetic nervous system. A **cholinergic receptor** is a receptor that binds acetylcholine and mediates its actions. There are two types of cholinergic receptors, as determined by their location and their action. **Nicotinic receptors** are located in the ganglia of both the parasympathetic nervous system and sympathetic nervous system. They are called *nicotinic* because they can also be stimulated by nicotine. The other type of cholinergic receptor is the muscarinic receptor. **Muscarinic receptors** are located postsynaptically in the effector organs (i.e., smooth muscle, cardiac muscle, and glands) supplied by the parasympathetic fibers. They are called *muscarinic* because they are stimulated by the alkaloid muscarine, a substance isolated from mushrooms. Figure 20-2 shows how the nicotinic and muscarinic receptors are arranged in the parasympathetic nervous system.

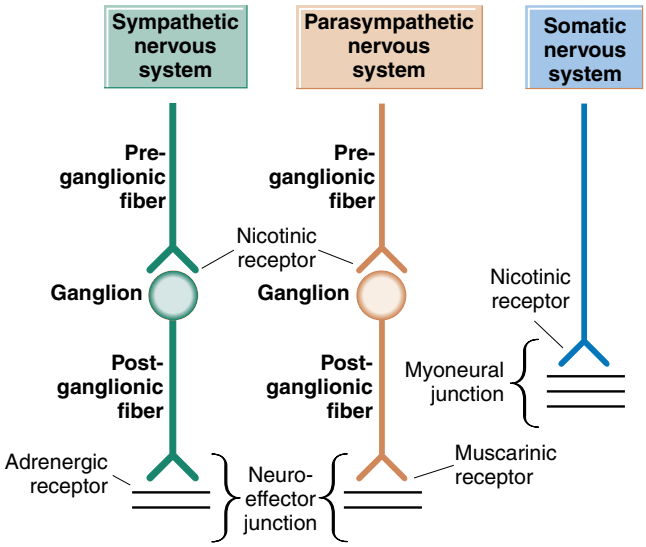

FIGURE 20-2 Sympathetic, parasympathetic, and somatic nervous systems. Note the location of the nicotinic and muscarinic receptors in the parasympathetic nervous system.

PHARMACOLOGY OVERVIEW

CHOLINERGIC DRUGS

Cholinergic drugs, also known as cholinergic *agonists* or **parasympathomimetics,** mimic the effects of acetylcholine. These drugs can stimulate cholinergic receptors either directly or indirectly. *Direct-acting* cholinergic agonists bind directly to cholinergic receptors and activate them. *Indirect-acting* cholinergic agonists stimulate the postsynaptic release of acetylcholine at the receptor site. This then allows acetylcholine to bind to and stimulate the receptor. Indirect-acting cholinergic drugs (also known as *cholinesterase inhibitors*) work by inhibiting the action of **acetylcholinesterase,** the enzyme responsible for breaking down acetylcholine. Acetylcholinesterase is also referred to as *cholinesterase.* There are two categories of cholinesterase inhibitors: reversible inhibitors and irreversible inhibitors. *Reversible* cholinesterase inhibitors bind to cholinesterase for a short period of time, whereas *irreversible* cholinesterase inhibitors

BOX 20-1 CHOLINERGIC DRUGS

Direct-Acting Drugs
bethanechol (Urecholine)
carbachol (Carboptic, others)
pilocarpine (Salagen, Pilocar [see Chapter 57], others)
succinylcholine (Anectine, Quelicin; see Chapter 11)

Indirect-Acting Drugs
donepezil (Aricept)
echothiophate (Phospholine Iodide; see Chapter 57)
edrophonium (Tensilon, others)
galantamine (Razadyne)
neostigmine (Prostigmin)
physostigmine (Antilirium)
pyridostigmine (Mestinon)
rivastigmine (Exelon)
tacrine (Cognex)

have a long duration of activity, and the body must generate new cholinesterase enzymes to override the effects of the irreversible drugs. Box 20-1 lists the direct- and indirect-acting cholinergics.

Mechanism of Action and Drug Effects

When acetylcholine directly binds to its receptor, stimulation occurs. Once binding takes place on the membranes of an effector cell (cell of the target tissue or organ), the permeability of the cell changes, and calcium and sodium are permitted to flow into the cell. This then depolarizes the cell membrane and stimulates the effector organ.

The effects of direct- and indirect-acting cholinergic drugs are seen when the parasympathetic nervous system is stimulated. There are many mnemonics to aid in remembering these effects. One is to think of the parasympathetic nervous system as the "rest and digest" system, in contrast to the "flight or fight" sympathetic nervous system.

Cholinergic drugs are used primarily for their effects on the gastrointestinal tract, bladder, and eye. These drugs stimulate the intestine and bladder, which results in increased gastric secretions, gastrointestinal (GI) motility, and urinary frequency. They also stimulate constriction of the pupil, termed **miosis.** This helps decrease intraocular pressure. In addition, cholinergic drugs cause increased salivation and sweating. Cardiovascular effects include reduced heart rate and vasodilation. Pulmonary effects include causing the bronchi of the lungs to constrict and the airways to narrow.

At recommended dosages, cholinergic drugs primarily affect the muscarinic receptors, but at high dosages the nicotinic receptors can also be stimulated. The desired effects come from muscarinic receptor stimulation; many of the undesirable adverse effects are due to nicotinic receptor stimulation. The various effects of the cholinergic drugs are listed in Table 20-1 according to the receptors stimulated.

TABLE 20-1 CHOLINERGIC AGONISTS: DRUG EFFECTS

	RESPONSE TO STIMULATION	
BODY TISSUE/ ORGAN	**MUSCARINIC**	**NICOTINIC**
Bronchi (lung)	Increased secretions, constriction	None
Cardiovascular		
Blood vessels	Dilation	Constriction
Heart rate	Slowed	Increased
Blood pressure	Decreased	Increased
Eye	Miosis (pupil constriction), decreased accommodation	Miosis (pupil constriction), decreased accommodation
Gastrointestinal		
Tone	Increased	Increased
Motility	Increased	Increased
Sphincters	Relaxed	None
Genitourinary		
Tone	Increased	Increased
Motility	Increased	Increased
Sphincter	Relaxed	Relaxed
Glandular secretions	Increased intestinal, lacrimal, salivary, and sweat gland secretion	—
Skeletal muscle	—	Increased contraction

Indications

Direct-Acting Drugs

Direct-acting drugs, such as carbachol, pilocarpine, and echothiophate, are used topically to reduce intraocular pressure in patients with glaucoma or in those undergoing ocular surgery (see Chapter 57). They are poorly absorbed orally, which limits their use mostly to topical application. One exception is the direct-acting cholinergic drug bethanechol, which is administered orally. Bethanechol affects the detrusor muscle of the urinary bladder and also the smooth muscle of the GI tract. It causes increased bladder and GI tract tone and motility, which increases the movement of contents through these areas. It also causes the sphincters in the bladder and the GI tract to relax, allowing them to empty. Bethanechol is also used to treat **atony** of the bladder and GI tract. Atony can occur after a surgical procedure. The direct-acting drug, cevimeline, is used to treat excessively dry mouth (xerostomia) resulting from a disorder known as *Sjögren's syndrome.* Oral pilocarpine can also be used for this purpose. Another direct-acting cholinergic is succinylcholine, which is used as a neuromuscular blocker in general anesthesia (see Chapter 11).

Indirect-Acting Drugs

Indirect-acting drugs work by increasing acetylcholine concentrations at the receptor sites, which leads to stimulation of the effector cells. Indirect-acting drugs cause skeletal muscle contraction and are used for the diagnosis and treatment of myasthenia gravis. Their ability to inhibit acetylcholinesterase also makes them useful for the reversal of neuromuscular blockade produced either by neuromuscular blocking drugs or by anticholinergic poisoning. For this reason, the indirect-acting drug physostigmine is considered the antidote for anticholinergic poisoning as well as poisoning by irreversible cholinesterase

inhibitors such as the organophosphates and carbonates, common classes of insecticides.

Indirect-acting drugs are also used to treat **Alzheimer's disease,** which is a neurologic disorder in which patients have decreased levels of acetylcholine. In the treatment of Alzheimer's disease, cholinergic drugs increase concentrations of acetylcholine in the brain by inhibiting cholinesterase. This increase in acetylcholine levels helps to enhance and maintain memory and learning capabilities. There are three cholinesterase inhibitors used to treat Alzheimer's disease, including donepezil (Aricept), galantamine (Razadyne), and rivastigmine (Exelon); all are indirect-acting cholinergic drugs. Although their therapeutic efficacy is often limited (it has been reported that only 15% to 30% of patients treated actually see benefits), these drugs may enhance a patient's mental status enough to cause a noticeable, if temporary, improvement in the quality of life for patients as well as caregivers and family members. The most commonly used of these medications at this time is donepezil. Patient response to these drugs is highly variable. For this reason, failure to respond to maximally titrated dosages of one of these drugs does not necessarily rule out an attempt at therapy with another drug in this same class. Memantine (Namenda) is also used to treat Alzheimer's disease, but it is not a cholinesterase inhibitor. For dosage information on all of these drugs, see the table on p. 328.

Contraindications

Contraindications to the use of cholinergic drugs include known drug allergy, GI or genitourinary (GU) tract obstruction, bradycardia, defects in cardiac impulse conduction, hyperthyroidism, epilepsy, hypotension, or chronic obstructive pulmonary disease. Parkinson's disease (see Chapter 15) is listed as a precaution to these drugs; however, rivastigmine (Exelon) is used in patients with Parkinson's disease who also have dementia.

Adverse Effects

The primary adverse effects of cholinergic drugs are the consequence of overstimulation of the parasympathetic nervous system. They are extensions of the cholinergic reactions that affect many body functions. The major effects are listed by body system in Table 20-2. The effects on the cardiovascular system are complex and may include syncope, hypotension with reflex tachycardia, hypertension, or bradycardia, depending on if the muscarinic or nicotinic receptors are stimulated.

Toxicity and Management of Overdose

There is little systemic absorption of the topically administered drugs and therefore little systemic toxicity. When administered locally in the eye, they can cause temporary ocular changes such as transient blurring and dimming of vision. Systemic toxicity with topically applied cholinergics is seen most commonly when longer-acting drugs are given repeatedly over a long period. This can result in overstimulation of the parasympathetic nervous system and all the attendant responses. Treatment is generally symptomatic and supportive, and the administration of a reversal drug (e.g., atropine) is rarely required.

TABLE 20-2 CHOLINERGIC AGONISTS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Bradycardia or tachycardia, hypotension or hypertension, syncope, conduction abnormalities (atrioventricular block and cardiac arrest)
Central nervous	Headache, dizziness, convulsions, ataxia
Gastrointestinal	Abdominal cramps, increased secretions, nausea, vomiting, diarrhea
Respiratory	Increased bronchial secretions, bronchospasm
Other	Lacrimation, sweating, salivation, miosis

The likelihood of toxicity is greater for cholinergics that are given orally or intravenously. The most severe consequence of an overdose of a cholinergic drug is a **cholinergic crisis.** Symptoms include circulatory collapse, hypotension, bloody diarrhea, shock, and cardiac arrest. Early signs include abdominal cramps, salivation, flushing of the skin, nausea, and vomiting. Transient syncope, transient complete heart block, dyspnea, and orthostatic hypotension may also occur. These can be reversed promptly by the administration of atropine, a cholinergic antagonist. Severe cardiovascular reactions or bronchoconstriction may be alleviated by epinephrine, an adrenergic agonist. One way of remembering the effects of cholinergic poisoning is to use the acronym *SLUDGE,* which stands for *s*alivation, *l*acrimation, *u*rinary incontinence, *d*iarrhea, *G*I cramps, and *e*mesis.

Interactions

Anticholinergics (such as atropine), antihistamines, and sympathomimetics may antagonize cholinergic drugs and lead to a reduced response to them. Other cholinergic drugs may have additive effects.

Dosages

For the recommended dosages of the cholinergic drugs, see the Dosages table on p. 328.

DRUG PROFILES

♦ bethanechol

Bethanechol (Urecholine) is a direct-acting cholinergic agonist. It is used in the treatment of acute postoperative and postpartum nonobstructive urinary retention and for the management of urinary retention associated with neurogenic atony of the bladder. It has also been used to prevent and treat bladder dysfunction induced by phenothiazine and tricyclic antidepressants (see Chapter 16). In addition, it is used in the treatment of postoperative GI atony and gastric retention, chronic refractory heartburn, as well as in diagnostic testing for infantile cystic fibrosis. Bethanechol is available orally and subcutaneously. Contraindications include known drug allergy, hyperthyroidism, peptic ulcer, active bronchial asthma, cardiac disease or coronary artery disease, epilepsy, and Parkinsonism. The drug is to be avoided in patients in whom the strength or integrity of the GI tract or bladder wall is questionable or with conditions

DOSAGES

Selected Cholinergic Agonist Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
♦ bethanechol (Urecholine) (C)	Muscarinic (direct-acting)	**Adult** PO: 10-50 mg tid-qid (usually start with 5-10 mg, repeating hourly until urination, max 50 mg/cycle)	Postoperative and postpartum functional urinary retention
♦ donepezil (Aricept) (C)	Anticholinesterase (indirect-acting)	**Adult** PO: 5-10 mg/day as a single dose	Alzheimer's dementia
♦ memantine (Namenda) (B)	NMDA-receptor antagonist	**Adult only** PO: Initial dose is 5 mg/day; titrate by 5 mg/wk up to a target dose of 10 mg/bid (20 mg/day). Maximum dose in renal impairment is 10 mg/day.	Alzheimer's dementia
physostigmine (Antilirium) (C)	Anticholinesterase (indirect-acting)	**Pediatric** IM/IV: 0.01-0.03 mg/kg repeated at 5-10 min intervals until desired effect or 2 mg is reached **Adult** IM/IV; 0.5-2 mg repeated q20 min if needed	Reversal of anticholinergic drug effects and tricyclic antidepressant overdose
♦ pyridostigmine (Mestinon) (C)	Anticholinesterase (indirect-acting)	**Adult** PO: 600 mg/day in divided doses IV: 0.1-0.25 mg/kg	Myasthenia gravis Antidote for neuromuscular blocker toxicity

IM, Intramuscular; *IV,* intravenous; *NMDA,* N-methyl-D-aspartate; *PO,* oral.

in which increased muscular activity could prove harmful, such as known or suspected mechanical obstruction.

Adverse effects include syncope, hypotension with reflex tachycardia, headache, seizure, GI upset, and asthmatic attacks. Drugs that interact with bethanechol include acetylcholinesterase inhibitors (i.e., indirect-acting cholinergics), which can enhance the adverse effects of bethanechol. Recommended dosages are given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO/injection	30-90 min	Less than 30 min	Unknown	1-6 hr

♦ donepezil

Donepezil (Aricept) is a cholinesterase inhibitor drug that works centrally in the brain to increase levels of acetylcholine by inhibiting acetylcholinesterase. It is used in the treatment of mild to moderate Alzheimer's disease. Similar cholinesterase inhibitors include tacrine, galantamine, and rivastigmine. Rivastigmine is also approved for treating dementia associated with Parkinson's disease. Contraindications for donepezil include known drug allergy. Adverse effects are normally mild and resolve on their own. They can often be avoided by careful dose titration. They include GI upset (including ulcer risk due to increased gastric secretions), drowsiness, dizziness, insomnia, and muscle cramps. The effects on the cardiovascular system are complex and may include bradycardia, syncope, hypotension with reflex tachycardia, or hypertension. Interacting drugs include anticholinergics (counteract donepezil effects) and nonsteroidal antiinflammatory drugs (see Chapter 44). Donepezil is available only for oral use as both a tablet and a rapid-acting, orally disintegrating tablet. Recommended dosages are given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	3 wk	3-4 hr	70 hr	2 wk

♦ memantine

Memantine (Namenda) is not a cholinergic drug, but is being included here in the discussion of drugs for Alzheimer's dementia. It is classified as an N-methyl-D-aspartate (NMDA) receptor antagonist owing to its inhibitory activity at the NMDA receptors in the central nervous system. Stimulation of these receptors is believed to be part of the Alzheimer's disease process. Memantine blocks this stimulation and thereby helps to reduce or arrest the patient's degenerative cognitive symptoms. As with all other currently available medications for this debilitating illness, the effects of this drug are likely to be temporary but may still afford some improvement in quality of life and general functioning for some patients. Its only current contraindication is known drug allergy. Reported adverse effects are relatively uncommon but include hypotension, headache, GI upset, musculoskeletal pain, dyspnea, ataxia, and fatigue. No clearly defined drug interactions are listed. Memantine is available only for oral use. The recommended dosage is given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	5 hr	70 hr	Unknown

♦ pyridostigmine

Pyridostigmine (Mestinon) is a synthetic quaternary ammonium compound that is similar in structure to other drugs in this class, including edrophonium, physostigmine, and neostigmine. All are indirect-acting cholinergic drugs that work to increase acetylcholine by inhibiting acetylcholinesterase. Pyridostigmine has been shown to improve muscle strength and is used to relieve the symptoms of myasthenia gravis, and it is the most commonly used drug for symptomatic treatment of myasthenia gravis. Edrophonium (Tensilon) is an indirect-acting cholinergic drug that is commonly used to diagnose myasthenia gravis. It can also be used to differentiate between myasthenia gravis and cholinergic crisis. Neostigmine, pyridostigmine, and physostigmine are also useful for reversing the effects of nondepolarizing neuromuscular blocking drugs (see Chapter 11) after surgery. They are also used in the treatment of severe overdoses of tricyclic antidepressants because of the significant anticholinergic effects associated with the tricyclic antidepressants. Physostigmine, neostigmine, and pyridostigmine are also used as an antidote after toxic exposure to nondrug anticholinergic agents, including those used in chemical warfare. Contraindications to these drugs include known drug allergy, prior severe cholinergic reactions, asthma, gangrene, hyperthyroidism, cardiovascular disease, and mechanical obstruction of the GI or GU tracts. Adverse effects include GI upset and excessive salivation. Interacting drugs include the anticholinergic drugs, which counteract the therapeutic effects of indirect-acting cholinergic drugs. Pyridostigmine is available in oral and injectable forms. Recommended dosages are given in the table on p. 328.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Oral/IM	15-45 min	1-2 hours	3-4 hr	Up to 6 hr
IV	2-5 min	Immediate	1-2 hr	2-3 hr

NURSING PROCESS

ASSESSMENT

Cholinergic drugs, or parasympathomimetics, produce a variety of effects stemming from their ability to stimulate the parasympathetic nervous system and mimic the action of acetylcholine. These effects include a decrease in heart rate, increase in GI and GU tone through increased contractility of the smooth muscle of the bowel and bladder, increase in the contractility and tone of bronchial smooth muscle, increased respiratory secretions, and miosis or pupillary constriction. Therefore, if the patient has any preexisting conditions, such as heart block, or the patient is taking other drugs that mimic the actions of the parasympathetic nervous system, adverse effects or toxicity may be increased. Before cholinergic drugs are given, perform a thorough head-to-toe physical examination, and obtain a nursing history and medication history (including prescription drugs, over-the-counter drugs, and herbals). Document drug allergies and past and present medical conditions as well. Identify cautions, contraindications, and drug interactions. Assess vital signs and document with special attention to baseline blood pressure readings because of the potential for orthostatic hypotension.

Before a drug for Alzheimer's disease, such as donepezil or memantine, is used, assess the patient for allergies, cautions, contraindications, and drug interactions. Perform a close assessment and documentation of the patient's neurologic status with attention to short- and long-term memory; level of alertness; motor, cognitive, and sensory functioning; any suicidal tendencies or thoughts; musculoskeletal intactness; and GI, GU, and cardiovascular functioning. Assess urinary patterns so that any problems with urinary retention may be identified. Report any abnormalities and/or complaints to the prescriber immediately. Presence or absence of family support systems is important to note because of the chronic nature of this illness. Once the patient has begun taking medication, it is critical for you to continue to assess the patient's response to the drug. Especially note any changes in symptoms within the first 6 weeks of therapy. Journaling may be helpful to the prescriber to assess any positive changes and any adverse effects and/or lack of improvement. Ginkgo may be used by some health care providers for organic brain syndrome (see the Safety: Herbal Therapies and Dietary Supplements box on p. 328).

CASE STUDY

Donepezil (Aricept) for Alzheimer's Disease

E. is a 72-year-old woman married to F., age 73 years. F. has noticed that E. is becoming more forgetful but did not worry about it until she got lost while driving home from the grocery store. F. makes an appointment for E. to see their primary care physician, Dr. S. After the examination, Dr. S. tells F., in private, that she thinks that E. is in the early stages of Alzheimer's disease but will order some tests to rule out other problems. F. then accompanies Dr. S. while she tells E. of the tentative diagnosis. Understandably, E. is upset to hear this news.

1. In her discussion with E. and her husband, Dr. S. mentioned a drug called donepezil (Aricept) that can be used in the early stages of Alzheimer's disease. It may be started after a few diagnostic tests are performed. After Dr. S. leaves the room, E. asks the nurse, "What will this drug do for me? Will it stop the Alzheimer's disease?" How will the nurse reply?

Several diagnostic tests are performed, including a complete blood count, serum electrolyte levels, vitamin B_{12} levels, liver and thyroid function tests, and a magnetic resonance imaging scan to rule out other neurologic disease. Results of all tests are within normal limits. Dr. S. decides to prescribe donepezil, 5 mg, daily, for E.

2. After a week, F. calls the nurse to ask about giving E. an over-the-counter antihistamine for her allergies. "She always needs an allergy pill this time of year." He also says that she needs to take a pain pill for her mild arthritis but is not sure whether to use acetaminophen or ibuprofen. What will the nurse tell F.?
3. After 6 weeks, F. brings E. back to the doctor's office for a follow-up appointment. F. privately tells Dr. S. that he is "upset" because he has noticed very little improvement. E. tells Dr. S. that she feels "fine" and has not noticed any problems. What do you think will be Dr. S.'s next order at this time? Is E.'s response to the donepezil typical? Explain your answer.

For answers, see http://evolve.elsevier.com/Lilley.

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

***Ginkgo* (Ginkgo biloba)**

Overview
The dried leaf of the ginkgo plant contains flavonoids, terpenoids, and organic acids that help ginkgo preparations exert their positive effects as an antioxidant and inhibitor of platelet aggregation.

Common Uses
To prevent memory loss, peripheral arterial occlusive disease, vertigo, tinnitus

Adverse Effects
Stomach or intestinal upset, headache, bleeding, allergic skin reaction

Potential Drug Interactions
Aspirin, nonsteroidal antiinflammatory drugs, warfarin, heparin, anticonvulsants, ticlopidine, clopidogrel, dipyridamole, tricyclic antidepressants

Contraindications
None

NURSING DIAGNOSES

1. Decreased cardiac output related to adverse cardiovascular effects of hypotension and bradycardia
2. Deficient knowledge of the therapeutic regimen, adverse effects, drug interactions, and precautions for cholinergic drugs related to lack of experience with drug therapies
3. Risk for injury related to the possible adverse effects of cholinergic drugs, such as bradycardia and hypotension, with subsequent risk for falls or syncope

PLANNING

GOALS

1. Patient maintains normal cardiac output/status due to proper taking of medication as prescribed.
2. Patient demonstrates adequate knowledge about the safe use of prescribed medication, its adverse effects, and the appropriate dosing at home.
3. Patient remains free from injury resulting from the adverse effects of the medication.

OUTCOME CRITERIA

1. Patient, caregiver, or family member states symptoms to report to the prescriber immediately such as the occurrence of dizziness, syncope, excess fatigue, and lightheadedness with heart rate changes.
   - Patient has blood pressure and pulse rate monitored and recorded daily.
   - Patient's blood pressure and pulse rate stay within normal ranges or without significant drops while on medication.
2. Patient, caregiver, or family member states the importance of scheduling and keeping follow-up appointments with the prescriber related to the management of the disorder for which medication has been prescribed and the monitoring for therapeutic or adverse effects.
   - Patient, caregiver, or family member demonstrates understanding that medications are not curative but are for symptomatic control.
   - Patient, caregiver, or family member demonstrates understanding that it may take several weeks for medications (i.e., medications for Alzheimer's disease) to have therapeutic effects.
3. Patient, caregiver, or family member demonstrates an understanding about the need to implement safety measures to avoid falls such as taking time to move slowly from lying/sitting to standing, taking purposeful movements, and using compression stockings.

IMPLEMENTATION

Several nursing interventions may help to maximize the therapeutic effects of cholinergic drugs and minimize their adverse effects. If the patient has undergone surgery and cholinergic drugs are indicated, encourage ambulation and increased intake of fluids and fiber, unless contraindicated. Early ambulation helps to increase GI peristalsis and possibly prevent the need for drugs such as bethanechol, which is used to treat decreased or absent peristalsis related to the surgery and/or anesthesia. However, do not administer these drugs if a mechanical obstruction is suspected. Use of these drugs in such a situation may possibly result in bowel perforation. Subcutaneous injections of bethanechol need to be administered as ordered (see Chapter 9 for information on injection techniques) and sites rotated if injections are frequent. It is always preferable to use nonpharmacologic measures rather than pharmacologic regimens to treat the anticipated postoperative problems of decreased peristalsis and/or urinary retention. For drugs used to treat myasthenia gravis, give the oral medication about 30 minutes before meals to allow for onset of action and therapeutic effects (e.g., decreased dysphagia or decreased difficulty swallowing). Atropine is the antidote to a cholinergic overdose; therefore, this medication needs to be readily available and given per the prescriber's order.

None of the drugs used for treatment of Alzheimer's disease provide a cure, but these drugs do improve function and cognition to some degree. It is crucial to discuss, with empathy and compassion, the fact that the disease has no cure. The diagnosis of Alzheimer's disease and/or dementia is shocking, at best. Those involved in the care of the patient need to be honest in sharing information with the patient, family, significant others, and caregivers. Always follow ethical standards of practice when working with patients, and adhere to the American Nurses Association *Code of Ethics for Nurses.* This code outlines behaviors required to maintain a high level of professionalism and specific actions that demonstrate respect for patient rights in any patient care situation. However, any sharing of information with the patient, family, significant others, and caregivers must be done with the approval of the prescriber, with good intent, in compliance with any research protocol, and/or with the goal of being a patient advocate. When beginning any of

these medications, the patient will most likely need continued assistance and help with activities of daily living (ADLs) and ambulation (because the medication may increase dizziness and subsequent gait imbalances at the initiation of treatment). The patient, family members, and caregivers also need to understand the importance of taking the medication exactly as ordered. Dosages and exact scheduling of medications is critical for the patient and family/caregiver to understand in order to achieve the drug's maximum therapeutic effects. In addition, instruct the patient and anyone involved in the patient's daily care about how to take the medication (e.g., taking the drug with food to decrease GI upset). Encourage the patient and family/caregiver to educate themselves about the use of the drug, its adverse effects, possible interactions, and potential for harm, and emphasize the importance of *not* withdrawing the medication abruptly. The patient must be weaned off all drugs over a period of time designated by the prescriber, because of the potential for a rapid decline in cognitive functioning.

Most of the cholinergic agonists have dose-limiting adverse effects that include severe GI disturbances such as nausea and vomiting. Blood pressure readings and pulse rates need to be taken and recorded before, during, and after initiation of drug therapy. Dizziness may occur with therapy, resulting in the need for assistance with ambulation and other ADLs. Maintenance of a journal that records daily doses of drugs, ability of the patient to participate in ADLs, motor ability, gait, mental status, cognition, and any adverse effects will provide valuable information to any health care provider or caregiver involved in the patient's day-to-day care.

Dosages of these medications may be changed by the prescriber after about 6 weeks if no therapeutic response occurs. For patient safety, blood pressure, pulse rate, and electrocardiogram need to be carefully monitored throughout therapy. Instruct the patient, family, or caregiver to report any cardiac problems such as decrease in pulse rate (less than 60 beats/min) and/or drop in blood pressure. A cholinergic crisis, resulting from overdosage of medication, may be manifested by abdominal cramps, flushing of the skin, nausea and vomiting (early signs and symptoms) progressing to circulatory collapse, hypotension, and cardiac arrest. Dissolving forms of the medication donepezil are to be placed on the tongue and allowed to dissolve before the patient drinks fluids or swallows.

In summary, because most of the cholinergic drugs are used to treat patients diagnosed with Alzheimer's disease, monitor the patient's family and other support personnel closely, and be sure that their questions are answered fully and completely and their needs met. Often family members, significant others, and caregivers have many questions as well as short- and long-term concerns. Preplanning education addressing these concerns is an important part of a holistic approach to patient care and to the meeting of patient needs. Often the best place to begin in terms of education is to prepare answers to the following questions that are often posed: What should we expect for our loved one? What will happen to the person emotionally and physically? What treatments are available, and what drugs are deemed safe? What are the common adverse effects of drug therapy, and how can they be minimized? What about diet, fluids, and exercise for our loved one? Are there herbals or any supplements or over-the-counter drugs that would help with the disease, or should they be avoided? What will we need to do for long-term care or other living situations for our loved one? What are the expected costs of our lived one's care now and in the future? What are the costs of drug therapy? Other costs? What kind of help can we all receive emotionally? What about emotional support for our loved one? How can this disease affect intimate relationships? What type of attorney should we seek out? What about durable power of attorney and living wills? Other types of wills? Are these needed right away if we don't have these legal documents already? How do we all go on with our lives when our loved one is changing so drastically? Will life ever be normal again? What about research and clinical trials for treatment regimens? Should we pursue other treatments or do nothing new? What about drugs that are not yet FDA-approved? How long will this process take? Just what can we expect over time?

EVALUATION

Monitor patients for the following therapeutic effects: (1) in patients with myasthenia gravis, a decrease in the signs and symptoms of the disease; (2) in patients experiencing a decrease in GI peristalsis postoperatively, an increase in bowel sounds, the passage of flatus, and the occurrence of bowel movements (all indicating an increase in peristalsis); and (3) in patients who have a hypotonic bladder with urinary retention, micturition (voiding) within about 60 minutes of the administration of bethanechol. Also monitor for adverse effects of these medications, including increased respiratory secretions, bronchospasm, nausea, vomiting, diarrhea, hypotension, bradycardia, and conduction abnormalities. For other adverse effects, see Table 20-2.

Therapeutic effects of the drugs used to manage Alzheimer's disease–related dementia or cognitive impairment include an improvement of the symptoms of the disease, but in most cases it takes up to 6 weeks for these effects to become apparent. Varying degrees of improvement in mood and a decrease in confusion usually occur. Adverse effects include nausea, vomiting, dizziness, and others (see individual drug profiles for specific information).

EVIDENCE-BASED PRACTICE

Exercise and Improved Cognition

Review

As the average age of the population in the United States and elsewhere continues to increase, the number of people living with Alzheimer's disease is expected to rise from the current 26.6 million to more than 106 million by 2050. It has been estimated that if the onset of dementia could be delayed by about 12 months, there would be approximately 9.2 million fewer cases worldwide. Several clinical trials have examined the ability of pharmacologic therapies such as cholinesterase inhibitors (e.g., donepezil), vitamin E, and rofecoxib to prevent progression to dementia in those at risk for Alzheimer's disease, but outcomes have been largely negative. However, many observational studies have suggested that physical activity may reduce the risk for cognitive decline. Because the evidence supporting a preventative effect of exercise is sparse, a randomized trial was designed to determine whether a program of regular exercise could slow the rate of cognitive decline in older adults at risk. This study is one of the first to demonstrate that exercise improves cognitive functioning in older adults experiencing subjective and objective mild cognitive impairment.

Type of Evidence

This study was a randomized, controlled trial in which one group of patients participated in a 24-week home-based program of physical activity consisting mainly of walking, whereas a second control group received only education and the usual care. Study participants were individuals who reported memory problems but did not meet the criteria for dementia. A total of 170 participants were randomly assigned to the two study groups, but only 138 actually completed the 18-month assessment. Those participating in the exercise program increased their physical activity by the relatively modest amount of about 20 minutes per day. Cognitive function was measured over a period of 18 months using the Alzheimer's Disease Assessment Scale—Cognitive Subscale (ADAS-Cog).

Results of Study

In an intent-to-treat analysis, participants in the physical activity group showed an average improvement of 0.26 points in their ADAS-Cog scores at the end of the 6-month intervention, while those in the usual care group showed deterioration by an average of 1.04 points; thus, the absolute improvement of the physical activity group over the usual care group was 1.3 points. The researchers noted that this result compares favorably with the reported improvement of 0.5 points associated with the use of donepezil. After the 6-month intervention period, patients in the physical activity group were encouraged to remain active, and a newsletter was sent out periodically to reinforce the goals of the program. No further intervention was offered. By 18 months, those in the physical activity group had improved by an average of 0.73 points in ADAS-Cog score, compared with an improvement of 0.04 points for those in the usual care group. Modest improvements were also seen in scores on some other tests, including word list delayed recall and Clinical Dementia Rating sum of boxes, but no significant changes were seen in scores on tests of word list total immediate recall, digit symbol coding, or verbal fluency. Beck Depression Inventory scores and scores on the Medical Outcomes 36-Item Short Form Health Survey physical and mental component summaries also improved in the physical activity group.

Link of Evidence to Nursing Practice

A very important achievement of this study is its demonstration of the potential benefit of the simple, nonpharmacologic intervention of exercise, which is almost universally available, in the prevention of cognitive decline. For these participants as well as many other patients with physical and/or mental disease, the benefits of exercise go beyond improvement in cognition and include a positive impact on depression, quality of life, and cardiovascular function, as well as a decrease in falls and disability. Although advances are being made in health and technology and people are living longer, there is a need to find alternative therapies as well as therapies that are nonpharmacologic and simple to implement to prevent and treat diseases such as Alzheimer's dementia and other catastrophic brain disorders. Nurses can educate patients and family members on the importance of habitual exercise as well as encourage the provision of consistent medical care, a suitable environment, adequate nutritional intake, and social interaction to help prevent mental and physical deterioration associated with certain disease states. These simple measures are easy to implement and may contribute significantly to the improvement of the individual's well-being in later life.

PATIENT TEACHING TIPS

- Medications must be taken exactly as ordered and with meals to minimize GI upset. Medications are never to be increased except on the advice of the prescriber. Give specific instructions on what to do if a medication dose has been omitted.
- Intervals between doses of medication need to be timed consistently to optimize therapeutic effects and minimize adverse effects and toxicity.
- Encourage patients, family, significant others, and/or caregivers to call the prescriber or other health care provider if there is any increased muscle weakness, abdominal cramps, diarrhea, dizziness, ataxia, and/or difficulty breathing.
- Share information about community resources with patients, caregiver(s), family, and significant others. Such resources may include, but are not be limited to, Meals on Wheels; local, state, and national chapters of the Alzheimer's Association; adult day care and/or alternate care resources; special prescription services (e.g., Nationwide Prescription Assistance at the toll-free number 888-812-5152 or online at www.freemedicinefoundation.com); and respite care and/or home health care services.
- Signs and symptoms of improvement of myasthenia gravis include a decrease in or absence of ptosis (eyelid drooping) and diplopia (double vision), less difficulty swallowing and chewing, and an improvement in muscle weakness. If the medication is being taken for myasthenia gravis, the patient needs to take it 30 minutes before meals so that the drug begins to work before the patient chews and swallows. This will help strengthen the muscles for chewing and eating.
- Sustained-released or extended-release dosage forms must be taken in their entirety and should not be crushed, chewed, or broken in any way.
- The patient needs to wear a medical alert bracelet or necklace or carry a medical alert card on his or her person at all times that gives the medical diagnoses and provides access to a list of medications and allergies, and any special requirements regarding emergency treatment.

KEY POINTS

- *Cholinergics, cholinergic agonists,* and *parasympathomimetics* are all appropriate terms for the class of drugs that stimulate the parasympathetic nervous system, which is the branch of the autonomic nervous system that opposes the sympathetic nervous system.
- The primary neurotransmitter of the parasympathetic nervous system is acetylcholine, and there are two types of cholinergic receptors: nicotinic and muscarinic.
- Nursing considerations for the administration of cholinergic drugs include giving the drug as directed and monitoring the patient carefully for the occurrence of bradycardia, hypotension, headache, dizziness, respiratory depression, and bronchospasms. If these occur in a patient taking cholinergics, the prescriber must be contacted immediately.
- It may take up to 6 weeks for a therapeutic response to occur with some of the medications used with Alzheimer's disease.
- Patients taking cholinergics need to change positions slowly to avoid dizziness and fainting that may result from the adverse effect of postural hypotension.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is reviewing the use of bethanechol (Urecholine) in a patient who is experiencing postoperative urinary retention. Which statement best describes the mechanism of action of bethanechol?
   - **a** It causes decreased bladder tone and motility.
   - **b** It causes increased bladder tone and motility.
   - **c** It increases the sensation of a full bladder.
   - **d** It causes the sphincters in the bladder to become tighter.

2 The family of a patient who has recently been diagnosed with Alzheimer's disease is asking about the new drug prescribed to treat this disease. The patient's wife says, "I'm so excited that there are drugs that can cure this disease! I can't wait for him to start treatment." Which reply from the nurse is appropriate?
   - **a** "The sooner he starts the medicine, the sooner it can have this effect."
   - **b** "These effects won't be seen for a few months."
   - **c** "These drugs do not cure Alzheimer's disease. Let's talk about what the physician said to expect with this drug therapy."
   - **d** "His response to this drug therapy will depend on how far along he is in the disease process."

3 The nurse is giving a dose of bethanechol (Urecholine) to a postoperative patient. The nurse is aware that contraindications to bethanechol include:
   - **a** bladder atony.
   - **b** peptic ulcer.
   - **c** urinary retention.
   - **d** hypothyroidism.

4 A patient took an accidental overdose of a cholinergic drug while at home. He comes to the emergency department with severe abdominal cramping and bloody diarrhea. The nurse expects that which drug will be used to treat this patient?
   - **a** atropine (generic)
   - **b** physostigmine (Antilirium)
   - **c** bethanechol (Urecholine)
   - **d** phentolamine (Regitine)

5 The nurse is reviewing the orders for a newly admitted patient and sees an order for edrophonium (Tensilon). The nurse expects that this drug is ordered for which reason?
   - **a** To reduce symptoms and delay the onset of Alzheimer's disease
   - **b** To treat the symptoms of myasthenia gravis
   - **c** To aid in the diagnosis of myasthenia gravis
   - **d** To reverse the effects of nondepolarizing neuromuscular blocking drugs after surgery

6 When giving intravenous cholinergic drugs, the nurse must watch for symptoms of a cholinergic crisis, such as: (Select all that apply.)
   - **a** peripheral tingling.
   - **b** hypotension.
   - **c** dry mouth.
   - **d** syncope.
   - **e** dyspnea.
   - **f** tinnitus.

7. A patient who has had an accidental overdose of tricyclic antidepressants is to receive physostigmine (Antilirium), 1.5 mg IM stat. The medication is available in a vial that contains 2 mL, with a concentration of 1 mg/mL. How much medication will the nurse draw up into the syringe for this dose?

1.5 mL. 7. e, 6. b, d, 5. c, 4. a, 3. b, 2. c, 1. b

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Briefly review the functions of the sympathetic nervous system and the specific effects of blocking cholinergic receptors (parasympatholytic effects).
2 List the various drugs classified as cholinergic antagonists (blocking) or sympatholytics.
3 Discuss the mechanisms of action, therapeutic effects, indications, adverse and toxic effects, drug interactions, cautions, contraindications, dosages, routes of administration, and any antidotal management for the various cholinergic antagonists (blockers).
4 Develop a nursing care plan that includes all phases of the nursing process for patients taking cholinergic antagonists.

- ♦ **tolterodine, p. 339**

♦ *Key drug*

KEY TERMS

Cholinergic-blocking drugs Drugs that block the action of acetylcholine and substances similar to acetylcholine at receptor sites in the synapse. (p. 335)

Mydriasis Dilation of the pupil of the eye caused by contraction of the dilator muscle of the iris. (p. 336)

Parasympatholytics Drugs that reduce the activity of the parasympathetic nervous system; also called *anticholinergics*. (p. 335)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

PARASYMPATHETIC NERVOUS SYSTEM

The parasympathetic nervous system is the branch of the autonomic nervous system with nerve functions generally opposite those of the sympathetic nervous system (see Chapters 18 and 19 for a discussion of the sympathetic nervous system). Acetylcholine is the neurotransmitter responsible for the transmission of nerve impulses to effector cells in the parasympathetic nervous system. A cholinergic receptor is one that binds acetylcholine and mediates its actions. This chapter focuses on cholinergic-blocking drugs, which inhibit the effects of the parasympathetic nervous system.

PHARMACOLOGY OVERVIEW

CHOLINERGIC-BLOCKING DRUGS

Cholinergic blockers, anticholinergics, **parasympatholytics,** and *antimuscarinic drugs* are all terms that refer to the class of drugs that block or inhibit the actions of acetylcholine in the parasympathetic nervous system. These drugs were first discussed in Chapter 15 in relation to treatment of Parkinson's disease.

Cholinergic blockers have many therapeutic uses and are one of the oldest groups of therapeutic drugs. Originally they were derived from various plant sources, but today they are only part of a larger group of cholinergic blockers that also include synthetic and semisynthetic drugs. Box 21-1 lists the currently available cholinergic blockers.

Mechanism of Action and Drug Effects

Cholinergic-blocking drugs block the action of the neurotransmitter acetylcholine at the muscarinic receptors in the parasympathetic nervous system (PNS). Acetylcholine that is released from a stimulated nerve fiber is then unable to bind to the receptor site and fails to produce a cholinergic effect. This is why the cholinergic blockers are also referred to as *anticholinergics.* Blocking the parasympathetic nerves allows the sympathetic (adrenergic) nervous system to dominate. Because of this, cholinergic blockers have many of the same effects as the adrenergics (see Chapter 18). Figure 21-1 illustrates the site of action of the cholinergic blockers in the parasympathetic nervous system.

Cholinergic blockers are *competitive antagonists.* They compete with acetylcholine for binding at the muscarinic receptors of the parasympathetic nervous system. Once they have bound to the receptor, they inhibit cholinergic nerve transmission. This generally occurs at the neuroeffector junction, or the point where the nerve ending reaches the effector organs such as smooth muscle, cardiac muscle, and glands. Cholinergic blockers have little effect at the nicotinic receptors, although at high doses they can have partial blocking effects.

The major sites of action of the anticholinergics are the heart, respiratory tract, gastrointestinal (GI) tract, urinary bladder, eye, and exocrine glands (sweat gland, salivary gland). Anticholinergics have the opposite effects of the cholinergics

BOX 21-1 CHOLINERGIC BLOCKERS GROUPED ACCORDING TO CHEMICAL CLASS

Natural Plant Alkaloids

atropine (generic)
belladonna (Belladonna tincture)
hyoscyamine (Levsin)
scopolamine (Transderm-Scōp)

Synthetic and Semisynthetic Drugs

benztropine (Cogentin; see Chapter 16)
biperiden (Akineton)
darifenacin (Enablex)
dicyclomine (Bentyl)
fesoterodine (Toviaz)
glycopyrrolate (Robinul)
homatropine (Isopto Homatropine; see Chapter 57)
ipratropium (Atrovent; see Chapter 37)
mepenzolate (Cantil)
methscopolamine (Pamine)
oxybutynin (Ditropan)
procyclidine (Kemadrin)
propantheline (Pro-Banthine)
solifenacin (Vesicare)
tolterodine (Detrol)
trihexyphenidyl (generic; see Chapter 15)
trospium (Sanctura)

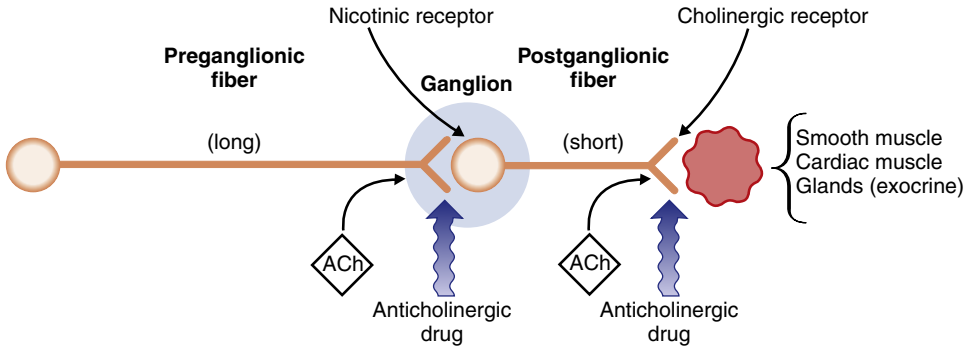

FIGURE 21-1 Site of action of cholinergic blockers in the parasympathetic nervous system. *ACh,* Acetylcholine.

TABLE 21-1 CHOLINERGIC BLOCKERS: DRUG EFFECTS

BODY SYSTEM	CHOLINERGIC-BLOCKING EFFECTS
Cardiovascular	Small doses: decrease heart rate Large doses: increase heart rate
Central nervous	Small doses: decrease muscle rigidity and tremors Large doses: cause drowsiness, disorientation, hallucinations
Eye	Dilate pupils (mydriasis), decrease accommodation by paralyzing ciliary muscles (cycloplegia)
Gastrointestinal	Relax smooth muscle tone of gastrointestinal tract, decrease intestinal and gastric secretions, decrease motility and peristalsis
Genitourinary	Relax detrusor muscle of bladder, increase constriction of internal sphincter; these two effects may result in urinary retention
Glandular	Decrease bronchial secretions, salivation, and sweating
Respiratory	Decrease bronchial secretions, dilate bronchial airways

(see Chapter 20) at these sites of action. Anticholinergic effects on the cardiovascular system are seen as an increase in heart rate. Respiratory system effects are dry mucous membranes and bronchial dilation. In the GI tract, cholinergic blockers cause a decrease in GI motility, GI secretions, and salivation. In the genitourinary (GU) system, they lead to decreased bladder contraction, which can result in urinary retention. In the skin they reduce sweating, and finally, anticholinergics cause the pupils to dilate and increase intraocular pressure. This occurs because the ciliary muscles and the sphincter muscle of the iris are innervated by cholinergic nerve fibers. Cholinergic blockers keep the sphincter muscle of the iris from contracting. The result is dilation of the pupil **(mydriasis)** and paralysis of the ocular lens (cycloplegia). This can be detrimental to patients with glaucoma because it results in increased intraocular pressure (see Chapter 57). These and other effects are listed by body system in Table 21-1. Many of the cholinergic-blocking drugs are available in a variety of forms, including intravenous, intramuscular, oral, and subcutaneous preparations.

Indications

In the central nervous system, cholinergic blockers have the therapeutic effect of decreasing muscle rigidity and diminishing tremors. This is of benefit in the treatment of both Parkinson's disease (see Chapter 15) and drug-induced extrapyramidal reactions such as those associated with antipsychotic drugs (see Chapter 16). These conditions involve dysfunction of the extrapyramidal parts of the brain and include motor dysfunctions such as chorea, dystonia, and dyskinesia.

Cardiovascular effects of anticholinergics are related to their cholinergic-blocking actions on the heart's conduction system. At low dosages, the anticholinergics may actually slow the heart rate through their effects on the cardiac center in the portion of the brain called the *medulla.* At high dosages, cholinergic blockers block the inhibitory vagal (i.e., parasympathetic or cholinergic) effects on the pacemaker cells of the sinoatrial and atrioventricular nodes, which leads to acceleration of the heart rate due to unopposed sympathetic activity. Atropine is used primarily in the management of cardiovascular disorders, such as in the diagnosis of sinus node dysfunction, the treatment of patients with symptomatic second-degree atrioventricular block, and provision of advanced life support in the treatment of sinus bradycardia that is accompanied by hemodynamic compromise. It also has ophthalmic uses (see Chapter 57).

When the cholinergic stimulation of the parasympathetic nervous system is blocked by cholinergic blockers, the sympathetic nervous system effects go unopposed. In the respiratory tract, this results in decreased secretions from the nose, mouth, pharynx, and bronchi. It also causes relaxation of the smooth muscles in the bronchi and bronchioles, which results in decreased airway resistance and bronchodilation. Because of this, the cholinergic blockers have proved beneficial in treating exercise-induced bronchospasm, chronic bronchitis, asthma, and chronic obstructive pulmonary disease. They are also used preoperatively to reduce salivary secretions, which aids in intubation and other procedures (e.g., endoscopy) involving the oral cavity.

Gastric secretions and the smooth muscles responsible for producing gastric motility are both controlled by the parasympathetic nervous system, which is primarily under the control of muscarinic receptors. Cholinergic blockers antagonize these receptors, causing reduced secretions, relaxation of smooth muscle, and reduced GI motility and peristalsis. For these reasons, cholinergic blockers are commonly used in the treatment of irritable bowel disease and GI hypersecretory states.

Anticholinergics are useful in the treatment of such GU tract disorders as reflex neurogenic bladder and incontinence. They relax the detrusor muscles of the bladder and increase constriction of the internal sphincter. The ability of cholinergic blockers to decrease glandular secretions also makes them potentially useful drugs for reducing gastric and pancreatic secretions in patients with acute pancreatitis.

Contraindications

Contraindications to the use of anticholinergic drugs include known drug allergy, angle-closure glaucoma, acute asthma or other respiratory distress, myasthenia gravis, acute cardiovascular instability (some exceptions were listed previously), and GI or GU tract obstruction (e.g., benign prostatic hyperplasia) or other acute GI or GU illness.

Adverse Effects

Anticholinergic drugs cause widely varied adverse effects, with many body systems affected. The various adverse effects of cholinergic blockers are listed by body system in Table 21-2. Certain patient populations are more susceptible to the effects of the anticholinergics. These populations include infants, children with Down syndrome, those with spastic paralysis or brain damage, and the elderly. The elderly are extremely sensitive to the CNS effects of anticholinergics, and it is not uncommon for elderly patients to develop delirium due to anticholinergic effects.

TABLE 21-2 CHOLINERGIC BLOCKERS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Increased heart rate, dysrhythmias (tachycardia, palpitations)
Central nervous	Excitation, restlessness, irritability, disorientation, hallucinations, delirium, ataxia, drowsiness, sedation, confusion
Eye	Dilated pupils (causing blurred vision), increased intraocular pressure
Gastrointestinal	Decreased salivation, gastric secretions, and motility (causing constipation)
Genitourinary	Urinary retention
Glandular	Decreased sweating
Respiratory	Decreased bronchial secretions

Toxicity and Management of Overdose

The dosage of cholinergic blockers is particularly important, because there is a very small difference between therapeutic and toxic dosages. Drugs with this characteristic are commonly referred to as having a *low therapeutic index* (see Chapter 2). The treatment of cholinergic blocker overdose consists of symptomatic and supportive therapy. The patient should be hospitalized, with continuous monitoring, including continuous electrocardiographic monitoring. Activated charcoal has proven very effective in removing from the GI tract any drug that has not yet been absorbed.

Fluid therapy and other standard measures used for the treatment of shock are instituted as needed. Delirium, hallucinations, coma, and cardiac dysrhythmias respond favorably to treatment with the cholinergic drug physostigmine. Its routine use as an antidote for cholinergic blocker overdose is controversial because it has the potential to produce severe adverse effects (e.g., seizures and cardiac asystole) and is usually reserved for the treatment of patients who show extreme delirium or agitation or who could inflict injury upon themselves.

Interactions

Drug interactions most commonly reported for the anticholinergics are additive anticholinergic effects when taken with other drugs that possess anticholinergic side effects such as amantadine (see Chapter 15), antihistamines (see Chapter 36), and tricyclic antidepressants (see Chapter 16). Reduced antipsychotic effects of phenothiazines (see Chapter 16) are seen when taken with anticholinergic drugs, and increased effects of digoxin (see Chapter 24) are seen when combined with anticholinergics.

Dosages

For dosage information on selected cholinergic blockers, see the table on p. 338.

DRUG PROFILES

Among the oldest and best known naturally occurring cholinergic blockers are the belladonna alkaloids. Of these, atropine is the prototypical drug. It has been in use for hundreds of years and continues to be widely administered because of its effectiveness. Besides atropine, scopolamine and hyoscyamine are the other major naturally occurring drugs. These drugs come from a variety of plants in the potato family.

Cholinergic blockers are used in the treatment of a variety of illnesses and conditions ranging from irritable bowel syndrome to the symptoms of the common cold and are also administered preoperatively to dry up secretions. They are the synthetic counterparts of the plant-derived belladonna alkaloids and are more specific in binding predominantly with muscarinic receptors. They are also associated with fewer adverse effects. Adverse effects and drug interactions are comparable for the different anticholinergic drugs and are detailed in Table 21-2 and previous text, respectively, unless otherwise noted.

♦ atropine

Atropine is a naturally occurring antimuscarinic. Atropine is more potent than scopolamine in its cholinergic-blocking effects on the heart and in its effects on the smooth muscles of the bronchi and intestines. Atropine is effective in the treatment of many of the conditions that are previously listed in the Indications section. Because atropine causes increased heart rate, it is used to treat bradycardia and ventricular asystole. Atropine is also used as an antidote for anticholinesterase inhibitor toxicity or poisoning. It is also used preoperatively to reduce salivation and GI secretions, as is glycopyrrolate. Atropine is contraindicated in patients with angle-closure glaucoma, adhesions between the iris and lens, certain types of asthma (not cholinergic associated), advanced hepatic and renal dysfunction, hiatal hernia associated with reflux esophagitis, intestinal atony, obstructive GI or GU conditions, and severe ulcerative colitis. Use with caution in patients with dysrhythmias (see Chapter 25). It is available in injectable, oral, and ophthalmic forms (see Chapter 57). It is also combined with the opiate diphenoxylate to make Lomotil tablets, a common antidiarrheal preparation. Overdose of atropine (usually from taking excessive Lomotil) is associated with flushing, dry skin and mucous membranes, mydriasis, altered mental status, and fever. Other serious effects include sinus tachycardia, urinary retention, hypertension, hallucinations, respiratory depression, and cardiovascular collapse. Activated charcoal is usually given along with supportive care. The reversible anticholinesterase inhibitor, physostigmine (see Chapter 20) is the antidote for atropine overdose. Recommended dosages are given in the table on p. xxx.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Immediate	2-4 min	2.5 hr	4-6 hr

♦ dicyclomine

Dicyclomine (Bentyl) is a synthetic antispasmodic cholinergic blocker used primarily in the treatment of functional disturbances of GI motility such as irritable bowel syndrome. It has

DOSAGES

Selected Cholinergic Antagonist (Anticholinergic) Drugs

DRUG (PREGNANCY CATEGORY)	USUAL DOSAGE RANGE	INDICATIONS/USES
♦ atropine (generic) (C)	**Pediatric**	
	0.02 mg/kg, max 0.5 mg	Treatment of bradycardia
	0.05 mg/kg initial dose, repeat q10-30min prn	Anticholinesterase effect for organophosphate or carbamate poisoning (e.g., insecticides)
	Adult	
	IV: 0.5-1 mg (max 3 mg)	Treatment of bradycardia, cardiopulmonary resuscitation
	IV: 1-3 mg/dose, repeat prn until signs of atropine intoxication appear (e.g., tachycardia)	Anticholinesterase effect for organophosphate or carbamate poisoning (e.g., insecticides)
♦ dicyclomine (Bentyl) (B)	**Pediatric**	Treatment of irritable bowel syndrome
	PO: 5-10 mg tid-qid	
	Adult	
	PO: 80-160 mg/day divided qid	
glycopyrrolate (Robinul) (B)	**Pediatric**	Preoperative control of secretions
	IM/IV: 4-9 mcg/kg/dose	
	Adult and pediatric 12 yr and older	Preoperative control of secretions
	IM: 4 mcg/kg 30-60 min preoperative	
	Adult and pediatric	Reversal of neuromuscular blockade
	0.2 mg for each 1 mg of neostigmine or 5 mg of pyridostigmine	
oxybutynin (Ditropan, Ditropan XL, Oxytrol [transdermal patch])	**Pediatric 1-5 yr**	Antispasmodic for neurogenic bladder (e.g., following spinal cord injury), overactive bladder
	PO: 0.2 mg/kg/dose bid-qid	
	Adult and pediatric older than 5 yr	
	PO: 5 mg bid-qid	
	Adult only	
	PO ER tab: 5-30 mg/day in single or divided doses	
	Adult	
	Transdermal patch: 1 patch (3.9 mg/day) applied twice weekly (every 3-4 days) (for overactive bladder)	
scopolamine (generic injection; Transderm-Scōp patch) (C)	**Pediatric**	Preoperative control of secretions
	6 mcg/kg/dose, max 0.3 mg/dose; may repeat q6-8h	
	Adult	
	IM/IV/subcut: 0.3-0.65 mg	Preoperative control of secretions
	Transdermal patch: 1.5 mg patch behind ear every 3 days (delivers approx 1 mg scopolamine over 3 days); apply at least 4 hr before transportation	Motion sickness prevention
♦ tolterodine (Detrol, Detrol XL) (C)	**Adult only**	Treatment of overactive bladder
	PO: 1-2 mg bid	
	PO ER cap: 2-4 mg daily	

ER, Extended release; *IM,* intramuscular; *IV,* intravenous; *PO,* oral; *subcut,* subcutaneous.

also been used alone and in combination with phenobarbital for the treatment of colic and enterocolitis in infants. It is contraindicated in patients who have a known hypersensitivity to anticholinergics and in those with angle-closure glaucoma, GI tract obstruction, myasthenia gravis, paralytic ileus, GI atony, or toxic megacolon. It is available in injectable and oral form. Recommended dosages are given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-2 hr	60-90 min	9-10 hr	3-4 hr

glycopyrrolate

Glycopyrrolate (Robinul) is a synthetic antimuscarinic drug that blocks receptor sites in the autonomic nervous system that control the production of secretions and the concentration of free acids in the stomach. It is most commonly used preoperatively to reduce salivation and excessive secretions in the respiratory and GI tracts. It is contraindicated in patients who are hypersensitive to it and in those with angle-closure glaucoma, myasthenia gravis, GI or GU tract obstruction, tachycardia, myocardial ischemia, hepatic disease, ulcerative colitis, or toxic megacolon. Glycopyrrolate is available in injectable and oral form. Recommended dosages are given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	1 min	10-15 min	Variable	4 hr
PO	Up to 45 min	1 hr	Variable	6 hr

oxybutynin

Oxybutynin (Ditropan) is a synthetic antimuscarinic drug used for the treatment of overactive bladder. It is also used as an antispasmodic for neurogenic bladder associated with spinal cord injuries and congenital conditions such as spina bifida. Contraindications include drug allergy, urinary or gastric retention, and uncontrolled angle-closure glaucoma. Oxybutynin is available for oral use. A transdermal patch (Oxytrol) is also available and approved for treatment of overactive bladder. Recommended dosages are given in the table on p. 338.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	1 hr	2-3 hr	Unknown

scopolamine

Scopolamine is a naturally occurring cholinergic blocker and one of the principal belladonna alkaloids. It is the most potent antimuscarinic for the prevention of motion sickness. It works by correcting the imbalance between acetylcholine and norepinephrine in the higher centers in the brain, particularly in the vomiting center. Ipratropium, a derivative of scopolamine, has potent therapeutic effects on the lungs and is discussed in Chapter 37. Scopolamine is available in several different delivery systems. For the prevention of motion sickness, it is available in a transdermal delivery system (Transderm-Scōp), a patch that can be applied just behind the ear 4 to 5 hours before travel (see Chapter 52). Transdermal scopolamine may cause drowsiness, dry mouth, and blurred vision. Using scopolamine with central nervous system depressants or alcohol may increase sedation. Scopolamine is also available in parenteral formulations for injection by various routes: intravenous, intramuscular, and subcutaneous. Scopolamine is available for ocular indications and in oral form. The contraindications that apply to atropine apply to scopolamine as well. Recommended dosages are given in the table on p. 338.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	30-60 min	30-45 min	Variable	4 hr
Transdermal	4-5 hr	6 hr	Variable	72 hr

♦ tolterodine

Tolterodine (Detrol) is a muscarinic receptor blocker used for the treatment of urinary frequency, urgency, and urge incontinence caused by bladder (detrusor) overactivity. Another drug that is commonly used to treat these conditions is oxybutynin (profiled previously). Other older-generation drugs include propantheline, hyoscyamine, and the tricyclic antidepressant imipramine. These drugs are less commonly used today because of their antimuscarinic adverse effects, particularly dry mouth. Newer drugs for this purpose include solifenacin (Vesicare), darifenacin (Enablex), trospium (Sanctura), and fesoterodine (Toviaz). The newer drugs are associated with a much lower incidence of dry mouth, in part because of their pharmacologic specificity for the bladder as opposed to the salivary glands.

Tolterodine is to be avoided in patients with angle-closure glaucoma or urinary retention. In patients with markedly decreased hepatic function or poor metabolizers taking drugs that inhibit cytochrome P-450 enzyme 3A4 (e.g., erythromycin or ketoconazole), the dose is reduced to 1 mg twice a day instead of the normal recommended dose of 2 mg twice a day. Tolterodine is available only for oral use. Recommended dosages are given in the table on p. 338.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	1-2 hr	2-4 hr	5 hr

NURSING PROCESS

ASSESSMENT

The drugs known as *parasympatholytics, cholinergic blockers, cholinergic antagonists,* or *anticholinergics* (an older term) produce a number of physiologic effects that result from the blocking of cholinergic receptors. These effects include smooth muscle relaxation, decreased glandular secretion, and mydriasis (pupil dilation). Knowing the way these drugs work and the related physiology will assist you in the safe assessment and nursing care of patients taking these drugs. A thorough medical history; complete medication history with a listing of prescription drugs, over-the counter drugs, and herbals; as well as a thorough head-to-toe examination will help you identify the presence of any contraindications, cautions, and/or potential drug interactions associated with the cholinergic blocking drugs (see Pharmacology Overview). The assessment data will help you document baseline findings and provide information for evaluating drug effectiveness. Lifespan considerations for the very young and/or elderly patient include the need for close assessment and monitoring because of the increased susceptibility of these groups to the adverse effects of restlessness, irritability, disorientation, constipation, urinary retention, blurred vision (from pupil dilation), and tachycardia.

In your assessment associated with atropine and other cholinergic blockers, check for allergies, glaucoma, certain eye conditions (e.g., adhesions in the iris and lens of the eye), gastroesophageal reflux disease, poor intestinal motility, obstructions of the GI and GU systems, and severe ulcerative colitis. These conditions and others may be exacerbated

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

Overactive Bladder

- Overactive bladder affects more than 12 million American adults, and the incidence of this disorder increases with age.
- Some questions to pose to the elderly patient regarding this condition are as follows:
  - Do you ever have a sudden and strong urge to urinate?
  - Do you urinate more than eight times in a 24-hour period?
  - Do you have to get up more than two times during the night to urinate?
  - Do you have "wetting" accidents?
  - Are these "wetting" accidents related to the uncontrollable urge to urinate?

NOTE: If the patient answers yes to some of these questions, the patient needs to be encouraged to contact his or her primary health care provider. Referral to a urologist may or may not be necessary.

- Various treatments for overactive bladder are available nationwide in the United States including the use of solifenacin succinate (Vesicare), which is to be taken once daily and treats all of the major symptoms of overactive bladder, including urgency, frequency, and urge-related incontinence.
- Solifenacin succinate was found to reduce the number of incontinence episodes over 12 weeks in studies of the drug involving more than 3000 patients with overactive bladder symptoms. Five- to 10-mg dosing of the drug produced improvement in all of the major symptoms. Use of this drug is contraindicated in patients with glaucoma, certain gastrointestinal or genitourinary tract problems, severe constipation, and/or urinary retention. Adverse effects include dry mouth, constipation, and blurred vision. If a patient experiences severe abdominal pain or is constipated for 3 or more days, the patient needs to contact the prescriber immediately.

Data from WebMD: Overactive bladder health check, 2011, available at www.webmd.com/urinary-incontinence-oab/overactive-bladder-health-check/default.htm. Accessed November 16, 2011; Vesicare (solifenacin succinate) website, 2011, available at www.vesicare.com.

by the cholinergic blockers (see Pharmacology Overview in this chapter and in Chapters 18 to 20) and would be considered contraindications. Address the associated cautions, contraindications, and drug interactions with dicyclomine, glycopyrrolate, and oxybutynin. Also, note any disorders of the bladder or GI tract. Apply the transdermal dosage form of scopolamine only after the order has been reviewed and the skin assessed.

NURSING DIAGNOSES

1. Constipation related to adverse effects of cholinergic-blocking drugs
2. Deficient knowledge related to lack of information about the therapeutic regimen, adverse effects, drug interactions, and precautions related to the use of cholinergic-blocking drugs
3. Risk for injury related to decreased sweating and loss of normal heat-regulating mechanisms due to the impact of the drug on the temperature-regulating mechanisms

PLANNING

GOALS

1. Patient experiences minimal adverse effects such as constipation.
2. Patient demonstrates adequate knowledge about the use of the specific medication, adverse effects, and appropriate dosing at home.
3. Patient is free from injury resulting from the adverse effect of inability to regulate sweating.

OUTCOME CRITERIA

1. Patient states various measures to regain normal bowel patterns and avoids constipation by forcing fluids and increasing fiber in daily dietary intake.
   - Patient increases fluids up to 8 glasses (preferably of water) per day.
   - Patient starts foods high in fiber, such as generous amounts of vegetables, fruits and legumes, to help take in approximately 40 g/day.
   - Patient uses a natural fiber supplement, if not contraindicated, such as a psyllium-based fiber product.
2. Patient states the rationale for the use of cholinergic blockers, such preoperative preparation, decreasing side effects associated with drugs used for Alzheimer's disease, and irritable bowel syndrome.
   - Patient states the more common adverse effects associated with cholinergic blockers, such as dry mouth, constipation, and urinary retention.
   - Patient states those adverse effects that need to be reported immediately to the prescriber if they occur, such as unresolved constipation, pain over the bladder region and inability to urinate, and/or chest pain.
3. Patient states measures to help decrease impact of decreased ability to sweat such as avoiding hot climates, vigorous exercising (especially in heated or hot environments), saunas, and hot tubs.
   - Patients who are elderly identify their increased risk to being overwhelmed by the decreased ability to sweat and the need for adherence to the above situations.

IMPLEMENTATION

A preventative focus for nursing care is important to the effective use of *cholinergic-blocking drugs,* especially with regard to patient teaching about how to decrease the need for these medications. There are several nursing interventions that may maximize the therapeutic effects of these drugs and minimize the adverse effects. Some important nursing interventions include giving the drug at the same time each day and per the prescriber's orders, and giving the medication with adequate fluid intake (6 to 8 glasses of water daily).

Because drugs such as atropine and glycopyrrolate are compatible with some of the commonly used opioids (e.g., meperidine and morphine), they may be used in combination with

these drugs and mixed in the same syringe for parenteral dosing. Checking for the compatibility of drugs combined in the same syringe is important with any medication. Always double-check compatibility for patient safety. If a cholinergic-blocking drug is given via the ophthalmic route, always check the concentration of the drug and, once it is given, apply light pressure with a tissue to the inner canthus of the eye for approximately 30 to 60 seconds. This helps to minimize the possibility of systemic absorption of the drug.

Atropine may be combined with other cholinergic-blocking drugs (e.g., hyoscyamine) for treatment of lower urinary tract discomfort or to help decrease GI and GU hypermotility, but give the drug via the correct route and with proper dosing as prescribed. The anticholinergic adverse effect of dry mouth may be managed with frequent mouth care, oral rinses, increase in fluids, and use of sugar-free gum or hard candy. Oxybutynin needs to be taken as directed either 1 hour before or 2 hours after meals, if tolerated. Tolterodine must be taken as directed and with food. Transdermal forms of these medications (e.g., scopolamine, oxybutynin) are to be applied to the skin only after the previous dosage form has been removed and the area gently cleansed of residual medication. Transdermal patches may be applied to any dry, nonhairy, nonirritated area. Rotation of transdermal sites is recommended to decrease skin irritation. Also associated with the cholinergic-blocking drugs are the adverse effects of constipation and inability to sweat or perspire. Because these may be significant to patients, include education on how to minimize these adverse effects. See the Patient Teaching Tips below for more information on these specific drugs.

CASE STUDY

Transdermal Scopolamine

Jan, a 53-year-old schoolteacher, is going on a cruise to Alaska with her husband, Jake, for their thirtieth anniversary. She is very excited about the trip but is also worried because she gets "very seasick" whenever she is on a boat. She calls her doctor's office for a prescription for a medicine for motion sickness. Her physician prescribes transdermal scopolamine (Transderm-Scōp).

1. Before Jan picks up the prescription, the nurse assesses for contraindications to scopolamine. What are the contraindications to the use of the scopolamine patch?

The nurse provides patient education, and Jan indicates that she understands how to use the patch. On the first day of the cruise, she applies the patch 4 hours before they board the ship.

2. That evening, Jan and Jake go to dinner. Jan is feeling somewhat drowsy, but thirsty. The waiter asks if they would like to have champagne as part of the first-night-of-the-cruise celebration. How should Jan respond?
3. The next morning, while out on the deck, Jake and Jan are taking pictures of the bright, snow-covered shoreline views. Jake looks at Jan and exclaims, "Look at your eyes! Is that a side effect of that patch?" What has Jake noticed about Jan's blue eyes? What would you suggest for Jan because of what Jake has noticed?
4. Later that day, Jan tells Jake, "I'm feeling great! I don't think I need this patch. I'm going to take it off, but I'll save it for later in case I get nauseated." Is this a good idea? Explain your answer.

For answers, see http://evolve.elsevier.com/Lilley.

EVALUATION

Monitoring of goals and outcome criteria is a starting place for effective evaluation of therapy with these medications. In particular, therapeutic effects of cholinergic-blocking drugs include the following: (1) improved ability to carry out activities of daily living and fewer problems with tremors, salivation, and drooling in patients with Parkinson's disease; (2) decreased GI symptoms, such as hyperacidity, abdominal pain, and nausea and vomiting, with improved comfort; (3) decreased GU hypermotility, with increased comfort and improved patterns of voiding with an increase in time between voidings; and (4) fewer bronchospasms with induction of anesthesia and fewer problems with thickened, viscous secretions in patients before, during, and after surgery. Monitor the patient for the occurrence of adverse effects such as constipation, tachycardia, palpitations, confusion, sedation, drowsiness, hallucinations, urinary retention, and decreased sweating leading to hot, dry skin. Toxic effects of anticholinergics include delirium, hallucinations, and cardiac dysrhythmias.

PATIENT TEACHING TIPS

- Medications need to be taken exactly as prescribed. Overdosage of anticholinergics may cause life-threatening problems, especially in the cardiovascular and central nervous systems.
- Anticholinergics may lead to dry mouth. Regular and thorough oral hygiene is required with brushing of teeth twice daily and dental flossing. Dry mouth may be minimized by forcing fluids, if not contraindicated, use of artificial saliva drops/gum, or sucking on sugar-free hard candy, as needed. Encourage regularly scheduled dental visits because of the risk of dental caries and gum disease with dry mouth. The use of water pick devices may stimulate gums and help prevent gum disease.
- Exercise must be done with caution and excessive sweating avoided because of drug-induced altered sweating. This may cause hyperthermia in the elderly or those with already altered sweating mechanisms.
- If there is sedation and/or blurred vision, the patient needs to avoid driving or engaging in activities that require quick decision making, alertness, or clear vision, such as operating heavy machinery, taking tests, and making important decisions. The adverse effects of sedation will decrease over time.
- Encourage the patient to wear dark or tinted glasses or sunglasses because of the increased sensitivity to light associated with these medications.

PATIENT TEACHING TIPS—cont'd

- The patient must understand the importance of always consulting the prescriber or other health care provider before taking any other medications, including prescription drugs, over-the-counter medications, herbals, and supplements.
- The elderly patient has existing age-related changes in body temperature–regulating mechanisms. With these medications, especially at high dosages, there is an increased risk of heat stroke or hyperthermia because of the drug's interference with the body's heat-regulating mechanisms. To prevent hyperthermia in the elderly, they need to stay in shaded areas or inside in an air-conditioned or cooled environment when external temperatures are warm; remain well hydrated with cool fluids; wear protective clothing and hats; avoid saunas, hot tubs, excessive heat, and strenuous exercise in warm environments; and keep portable fans on hand and maintain adequate ventilation in heated environments.
- All health care providers need to be informed about the treatment regimen, and a list of the patient's drugs must be given to all involved in the care of a patient taking anticholinergics or cholinergic blockers. The prescriber needs to be contacted if there is any unresolved constipation, palpitations, alterations in gait or balance, excessive dizziness, or inability to void.
- Constipation may be managed by the increased dietary intake of fluids and fiber and/or the use of over-the-counter fiber-containing supplements, such as psyllium products.

KEY POINTS

- *Cholinergic blockers, parasympatholytics, anticholinergics,* and *antimuscarinics* are all terms that refer to the drugs that block or inhibit the actions of acetylcholine in the parasympathetic nervous system.
- The use of these cholinergic blockers allows the sympathetic nervous system to dominate. These drugs are classified chemically as natural, semisynthetic, and synthetic cholinergic blockers. These drugs may be competitive antagonists (blockers) and compete with acetylcholine at the muscarinic receptors. In high dosages, they result in partial blocking actions at the nicotinic receptors.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is providing education about cholinergic-blocking drug therapy to an elderly patient. Which is an important point to emphasize for this patient?
- **a** Avoid exposure to high temperatures.
- **b** Limit liquid intake to avoid fluid overload.
- **c** Begin an exercise program to avoid adverse effects.
- **d** Stop the medication if excessive mouth dryness occurs.

2 The nurse is giving a cholinergic-blocking drug and will assess the patient for which contraindications to these drugs?
- **a** Chronic bronchitis
- **b** Peptic ulcer disease
- **c** Irritable bowel syndrome
- **d** Benign prostatic hyperplasia

3 When assessing for adverse effects of cholinergic-blocking drug therapy, the nurse would expect to find that the patient complains of which drug effect?
- **a** Diaphoresis
- **b** Dry mouth
- **c** Diarrhea
- **d** Urinary frequency

4 The nurse administering a cholinergic-blocking drug to a patient who is experiencing drug-induced extrapyramidal effects would assess for which therapeutic effect?
- **a** Decreased muscle rigidity and tremors
- **b** Increased heart rate
- **c** Decreased bronchial secretions
- **d** Decreased GI motility and peristalsis

5 During the assessment of a patient about to receive a cholinergic-blocking drug, the nurse will determine whether the patient is taking any drugs that may potentially interact with the anticholinergic, including:
- **a** opioids, such as morphine sulfate.
- **b** antibiotics, such as penicillin.
- **c** tricyclic antidepressants, such as amitriptyline.
- **d** anticonvulsants, such as phenobarbital.

6 A patient has been given a prescription for transdermal scopolamine patches (Transderm-Scōp) for motion sickness for use during a vacation cruise. The nurse will include which instructions? (Select all that apply.)
- **a** "Apply the patch as soon as you board the ship."
- **b** "Apply the patch 3 to 4 hours before boarding the ship."
- **c** "The patch needs to be placed on a nonhairy area on your upper chest or upper arm."
- **d** "The patch needs to be placed on a nonhairy area just behind your ear."
- **e** "Change the patch every 3 days."
- **f** "Rotate the application sites."

7 The preoperative order for an adult patient reads: "Give scopolamine, 0.7 mg IM on call for surgery." The medication is available in vials of 0.4 mg/mL. How many milliliters will the nurse administer for this dose? (Round to tenths.)

1. a, 2. d, 3. b, 4. a, 5. c, 6. b, d, e, f, 7. 1.8 mL

PART 4

Drugs Affecting the Cardiovascular and Renal Systems

STUDY SKILLS TIPS

Linking Learning • Text Notation

LINKING LEARNING

The Part 3 Study Skills Tips stressed the importance of planning for the part as a whole. With that in mind, what is the focus of Part 4? The part title is Drugs Affecting the Cardiovascular and Renal Systems. What is the first question you think you should ask about this part? I would begin by asking, "What are the cardiovascular and renal systems?" This is a very obvious question and might seem to be so basic that it need not be asked, but the next eight chapters will all develop around this part title. Asking the obvious question is sometimes exactly the thing that should be done to get started.

Chapter Structure

Just as there is a structure to each part in the text, which is constant from one part to the next, there is also a structure in the chapters. This structure is a repeating model that was created by the authors in an attempt to organize the material and present it in the clearest way possible. The chapter structure is a valuable learning asset for those who make use of it .

Chapter Objectives

Each chapter begins with a set of objectives. These are established by the authors and serve to tell you what they expect you will know and be able to do when you have completed the chapter. It is sometimes tempting to ignore the objectives and get right on with the task of reading the chapter. Do not give in to that temptation. Read the objectives and spend some time thinking about what they reveal about the content of the chapter.

Example Based on Chapter 24 Objectives

Objective 1: Differentiate between the terms *inotropic, chronotropic,* and *dromotropic.*

What can you learn from this objective? First, there is the vocabulary. This objective makes it clear that you have some terms to learn. This means that you may want to have some blank note cards available to start setting up vocabulary cards for this chapter. In fact, you should write each of the terms in Objective 1 on a separate card and be ready to complete the card as the terms are introduced and explained in the chapter.

The next thing that stands out in this first objective is that the three terms contain a common element: *-tropic.* This should bring active questioning into play. What does the suffix *-tropic* mean? Asking this question now is a way of noting that these three terms do have some common meaning. Also it serves to provide an immediate focus for personal learning when you begin to read the chapter.

Objective 2: Briefly discuss the pathophysiology of heart failure.

From this comes the potential for a new question relating to the first objective. What do *inotropic, chronotropic,* and *dromotropic* have to do with the heart? Just as it is essential to see the relationship between parts and chapters, it is also essential to see relationships within the chapters. These first two objectives should cause you to consider those relationships and make your own learning much more active.

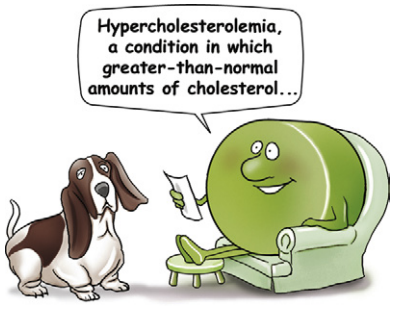
Chapter Headings

The next chapter structure to consider in this process is the chapter headings. Chapter 24 has the major sections Anatomy, Physiology, and Pathophysiology Overview; Pharmacology Overview; and Nursing Process. What is the importance of this heading structure? It tells you that the authors will focus on the pharmacologic aspects first and then explain how this relates to nursing. This does not tell the learner a great deal about what to anticipate in terms of chapter content, but it does make clear a structure that is consistent in most of the chapters in this text.

Heart failure drugs are broken down into subsections in this chapter. Spend several minutes considering the organization of these subsections. The first subtopic to consider is Mechanism of Action and Drug Effects. What is meant by mechanism of action? How do heart failure drugs act? On what do they act? It does not matter that you cannot answer these questions at this point. What is important is that you ask them as a means of fostering an active and participatory learning attitude when you begin to read the chapter. Think, question, anticipate, and then read. This sequence will enhance your learning.

Continue this process of looking at the subtopics and thinking ahead to what will be explained in the chapter. These subsections are the same in every chapter, and this thinking process should become automatic very quickly.

Key Terms



The next chapter structure is one that has already been stressed in previous Study Skills Tips, and it is one that is essential to learning. The list of key terms is a mini-dictionary for each chapter. Words that have not been introduced earlier in the text and that are central to the content of this chapter are presented here. The listing is in alphabetical order, which means that the key terms will not necessarily occur in the same order in the body of the chapter.

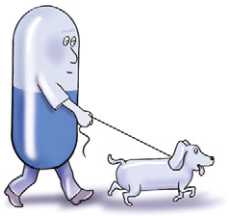
As you read the key terms, be aware of the nature of the definition. A key term definition is specific and brief. It is a very useful place to begin to learn the new terms in the chapter, but the definition presented may not be enough for full understanding. You will find that full understanding will come after reading the chapter and encountering the term within the fuller context of sentences and paragraphs of text that explain not only the term but how it applies in the particular situation.

Key Terms and Text Relationship

The term *inotropic drugs* is defined in the Chapter 24 key terms list. As I read it, I understand that inotropic has to do with force or energy of muscle contractions. Some of this information is clear, and some of it is still somewhat hazy. It should become clearer when connected with the chapter text. The first paragraph of the *Pharmacology Overview* section introduces inotropic drugs: "Drugs that increase the force of myocardial contraction are called positive **inotropic drugs,** and they have a role in the treatment of failing heart muscle."

With this sentence, I find I have a much clearer understanding of what is meant by *inotropic drugs,* and I have the added benefit of knowing that there are positive inotropic drugs. This is what must happen to fully master the content-specific vocabulary. You must see the core definition as presented in the list of key terms, but you must also read to determine how that core definition is expanded and exemplified in the body of the text.

When preparing vocabulary cards, it is not a good idea simply to copy the definition from the key terms list and assume that this definition will serve your purpose. Wait to fill out the card until after you encounter the same term in the body of the chapter, and then pick and choose the information from the key terms list and the chapter body that will provide you with the clearest understanding of the term. Also, when placing information on vocabulary cards, it is always useful to include a chapter number and page numbers so that you can locate the source of your definition quickly should you find it necessary later.



These chapter structures can provide you with a clear picture of what you are expected to learn and the organizational pattern in which the material will be presented. Being aware of the structures and making use of them in this way will improve your concentration when you begin to read the chapter for understanding and memory. The time spent working with chapter structure is not wasted and does not significantly increase the study time for the chapter. In fact, the time you spend working with the objectives, headings, and key terms will generally save time when you are doing intensive reading and study.

TEXT NOTATION

Highlighting or underlining text material is a tool that can be very helpful when rehearsing and reviewing materials after the study reading. The problem, as discussed in the *Study Guide,* is that it is often difficult to limit the quantity of material that

is marked. Although a good general guideline is to try to limit yourself to marking no more than 20% to 25% of the total material, this guideline applies to large blocks of material. Some paragraphs contain essential information and must be marked extensively, whereas in other paragraphs only one or two sentences may need to be marked. In this Study Skills Tips section, the object is to look at how the author's structure and language can help you to select what should be marked.

Text Notation Application

Reproduced here are two paragraphs from Chapter 29 with my model underlining completed, followed by a discussion of the reasons for which I made the choices. You should not view the model underlining as a "perfect" example. The decision as to what to mark is very much an individual choice based on a number of factors, including prior experience with the subject matter and awareness of personal learning objectives and needs. These model paragraphs with accompanying discussion are intended to provide you with a basic model to adapt to your own learning style and needs.

Chapter 29, Paragraphs 1 and 2

Fluid and electrolyte management is one of the cornerstones of patient care. Most disease processes, tissue injuries, and surgical procedures greatly influence the physiologic status of fluids and electrolytes in the body. Understanding fluid and electrolyte management requires knowledge of the extent and composition of the various body fluid compartments.

Approximately 60% of the adult human body is water. This is referred to as the total body water (TBW), and it is distributed in the three main compartments in the following proportions: intracellular fluid (ICF), 67%; interstitial fluid (ISF), 25%; and plasma volume, 8%. This distribution is illustrated in Figure 29-1. The actual volume of fluid that would normally be in each compartment in an average 70-kg man with a TBW content of 60% is shown in Table 29-1.

Discussion

The first thing you should notice is that the underlining I have done exceeds the 20% to 25% guideline. These are the first paragraphs in the chapter. First paragraphs are usually introductions to the topic and may vary a great deal in the quantity of important information. This chapter, in my view, contains a number of key points that must be considered. Because the content seems important, I have chosen to underline more text.

The first sentence was chosen because of the word *cornerstones.* This word suggests that fluid management is extremely important in patient care and that I must be sure to keep that focus throughout the chapter. Paying careful attention to the author's word choices plays a major role in selecting materials for text notation.

Paying attention to language led me to the third sentence, which begins, "Understanding fluid and electrolyte management requires…" That phrase should immediately capture your attention. The phrase says that there is something that is required before anything else that follows will make complete sense. The phrase should also serve as an instant cue to generate a question for reading. "What is required for the understanding fluid and electrolyte management?" This question is answered directly by the sentence containing the phrase. The question helps you select what you may possibly want to underline or highlight. Everything you do at this point serves as a guide to help you establish clear learning objectives and makes the process of selecting the best information for marking easier to accomplish.

The next segment was chosen because it stands out from the body of the paragraph. *Total body water* is italicized in Chapter 29. This is a print convention used as a means of putting emphasis on something that the author believes to be of special importance. The decision to underline words and phrases that are already emphasized is a personal one. You may feel that, since the author has already marked it, you have no need to add your own marks. I find that my own marking, even of italicized or bold print material, serves as a double reminder of the importance of the information. This is an excellent example of what I mean when I say that text notation is highly personal. Whether you choose to add your own marking or not, there is one aspect of this phrase that is essential. *Total body water* is part of the vocabulary of fluids and electrolytes. That means it is time to add to your vocabulary cards.

This term served as a lead-in to the next key point that I have marked. The next part of the sentence is, "…it is distributed in the three main compartments…" Whenever you see a phrase with a number and a word such as *main,* you should be aware that this is potentially important material. This phrase should generate a new question that will aid in your selection of material to mark: "What are the three main compartments?" You can see immediately that the rest of this sentence answers that question and therefore identifies what needs to be marked. This marking also identifies three additional vocabulary items to be added to your cards for this chapter. As you set up your cards, be careful. One fluid is *intra-* and the second is *inter-*. It would be easy to confuse the two, but they have very different meanings.

Chapter 29, Paragraph 3

The terms used to identify the various spaces within which the TBW is distributed can be quite confusing, and there are two basic approaches to distinguishing among the locations of the fluid. The TBW can be described as being in or out of the blood vessels (vasculature). If this point of reference is used, then the term intravascular fluid (IVF) is used to describe the fluid inside the blood vessels and the term extravascular fluid (EVF) is used to refer to the fluid outside the blood vessels. Examples of EVF include lymph and cerebrospinal fluid. As these concepts are learned, it is important to remember the difference between the prefixes intra- (inside), inter- (between), and extra- (outside). The term plasma is used to describe the fluid that flows through the blood vessels (intravascular fluid). Serum is a closely related term (see Key Terms). The interstitial fluid (ISF) is the fluid that is in the space between cells, tissues,

and organs. When discussing blood vessels, the term extravascular volume is used; extravascular volume is made up of plasma and ISF. When discussing cells, the term extracellular volume is used; extracellular volume is composed of ISF and intracellular fluid (ICF). These terms are often confused and misused. Table 29-1 lists these definitions for further clarity and understanding.

Discussion

The language conventions and the print conventions are the same that were used to help in the previous paragraph. This paragraph also makes a point about the possibility of confusing and/or misusing the terms introduced. Being told that there is confusing material suggests that it is crucial that you be able to identify, define, and explain each of the terms used, and that it will take some careful thought to do so. There is one additional point in this paragraph that is important. The last sentence points you to a table, Table 29-1. There are many tables in this text. Always remember that tables are often used in an effort to simplify complex material and to clarify the relationships between the items presented in the table. In these opening paragraphs, with the repeated reference to the confusing nature of the descriptions, Table 29-1 will almost certainly be important to your learning.

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Briefly discuss the normal anatomy and physiology of the autonomic nervous system, including the events that take place within the sympathetic and parasympathetic divisions as related to long-term and short-term control of blood pressure.
2 Define *hypertension.*
3 Compare primary and secondary hypertension and their related manifestations.
4 Describe the protocol for treating hypertension as detailed in the *Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7),* including the rationale for its use.
5 List the criterion pressure values (in millimeters of mercury) for the hypertension categories of normal blood pressure, prehypertension, hypertension stage 1, and hypertension stage 2 as defined in *JNC 7.*
6 Using the most recent guidelines, compare the various drugs used in the pharmacologic management of hypertension with regard to mechanism of action, specific indications, adverse effects, toxic effects, cautions, drug interactions, contraindications, dosages, and routes of administration.
7 Discuss the rationale for the nonpharmacologic management of hypertension.
8 Develop a nursing care plan that includes all phases of the nursing process for patients receiving antihypertensive drugs.

DRUG PROFILES

bosentan, p. 359
♦ **captopril, p. 356**
carvedilol, p. 353
♦ **clonidine, p. 353**
doxazosin, p. 353
enalapril, p. 356
eplerenone, p. 359
♦ **hydralazine, p. 359**
♦ **losartan, p. 357**
nebivolol, p. 353
sodium nitroprusside, p. 359
treprostinil, p. 360

♦ *Key drug*

KEY TERMS

Alpha$_1$ blockers Drugs that primarily cause arterial and venous dilation through their action on peripheral sympathetic neurons. (p. 351)

Antihypertensive drugs Medications used to treat hypertension. (p. 349)

Cardiac output The amount of blood ejected from the left ventricle, measured in liters per minute. (p. 348)

Centrally acting adrenergic drugs Drugs that modify the function of the sympathetic nervous system in the brain by stimulating alpha$_2$ receptors. Alpha$_2$ receptors are inhibitory in nature and thus have a reverse sympathetic effect and cause decreased blood pressure. (p. 351)

Essential hypertension Elevated systemic arterial pressure for which no cause can be found; also called *primary* or *idiopathic hypertension*. (p. 349)

Hypertension A common, often asymptomatic disorder in which systolic blood pressure persistently exceeds 140 mm Hg and/or diastolic pressure exceeds 90 mm Hg. (p. 348)

Orthostatic hypotension A common adverse effect of adrenergic blocking drugs involving a sudden drop in blood pressure when a person changes position, especially when rising from a seated or horizontal position. (p. 352)

Prodrug A drug that is inactive in its given form, and which must be metabolized to its active form in the body, generally by the liver, to be effective. (p. 354)

Secondary hypertension High blood pressure caused by another disease such as renal, pulmonary, endocrine, or vascular disease. (p. 349)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Hypertension, defined as a persistent systolic pressure of greater than 140 mm Hg and/or a diastolic pressure greater than 90 mm Hg, affects approximately 50 million people in the United States and approximately 1 billion people worldwide, designating it as the most common disease state. As the population ages, the incidence of hypertension will continue to increase.

Hypertension is a major risk factor for coronary artery disease, cardiovascular disease (CVD), and death resulting from cardiovascular causes. It is the most important risk factor for stroke and heart failure, and it is also a major risk factor for renal failure and peripheral vascular disease. There is indisputable evidence regarding the relationship between blood pressure and risk of CVD; the higher the blood pressure, the greater the chance of developing CVD. For people 40 to 70 years of age, the risk of developing CVD doubles with each 20 mm Hg increase in systolic blood pressure or 10 mm Hg increase in diastolic pressure.

To gain insight into the treatment of hypertension, it is necessary to have a basic understanding of blood pressure. Blood pressure is determined by the product of **cardiac output** (4 to 8 L/min) and systemic vascular resistance (SVR). Cardiac output is the amount of blood that is ejected from the left ventricle and is measured in liters per minute. SVR is the resistance to blood flow that is determined by the diameter of the blood vessel and the vascular musculature. It is calculated by the blood pressure divided by the cardiac output. Numerous factors interact to regulate these two major variables and keep the blood pressure within normal limits. These are illustrated in Figure 22-1. These are the same factors that can cause high blood pressure, or hypertension, and are the targets of action of many of the antihypertensive drugs.

The diagnosis and treatment of hypertension have varied considerably over the years. The *Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7)* was released in May 2003. This report provides treatment guidelines for hypertension assembled by two large expert panels based on a review of the latest clinical research publications on the disease. As with previous such reports, the development of *JNC 7* was sponsored by the National Heart, Lung, and Blood Institute of the National Institutes of Health, the major governmental health research entity of the United States. The efforts of the Joint National Committee are intended to educate both health care professionals and the general public about the dangers of the disease and the importance of its treatment. The *Eighth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 8)* is scheduled to be published in 2012, and more information is available at www.nhlbi.nih.gov/guidelines/hypertension/jnc8/index.htm.

A new classification system for blood pressure was identified in the *Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 6)* in 1997. The previously applied term *mild hypertension* did not adequately reflect the serious nature of the condition. This became evident when it was found that most of the morbidity and mortality actually occur in this group. In addition, whereas pre-*JNC 6* reports had recommended a stepped-care pharmacologic approach to treating the illness, many practitioners believed that this approach no longer adequately reflected the current range of pharmacologic alternatives. In the *JNC 6,* individualized therapy was proposed as a more appropriate treatment strategy. This individualized approach continues to be emphasized in the *JNC 7* and will most likely be continued in the *JNC-8*. Many patients will require two or more medications, even as initial therapy, depending on their individual cardiovascular risk factors such as obesity, diabetes, and family history.

The classification scheme used to categorize individual cases of hypertension has been simplified to the following four stages based on blood pressure measurements: normal, prehypertension, stage 1 hypertension, and stage 2 hypertension. (Refer to the *JNC 7* at www.nhlbi.nih.gov/guidelines/hypertension.)

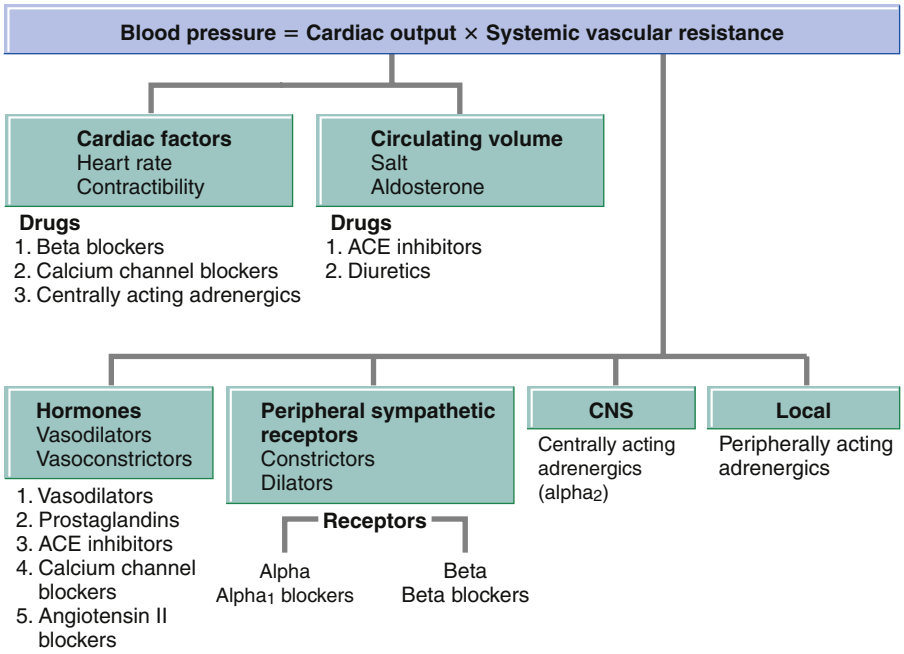

FIGURE 22-1 Normal regulation of blood pressure and corresponding medications. *ACE,* Angiotensin-converting enzyme; *CNS,* central nervous system.

Hypertension can also be defined by its cause. When the specific cause of hypertension is unknown, it may be called **essential hypertension** (or idiopathic or primary hypertension). About 90% of cases of hypertension are of this type. **Secondary hypertension** accounts for the other 10%. Secondary hypertension is most commonly the result of another disease such as pheochromocytoma (adrenal tumor), preeclampsia of pregnancy (a pregnancy complication involving acute hypertension, among other symptoms), renal artery disease, sleep apnea, thyroid disease, or parathyroid disease. It may also result from the use of certain medications. If the cause of secondary hypertension can be eliminated, blood pressure usually returns to normal. If untreated, hypertension can cause damage to end organs such as the heart, brain, kidneys, and eyes.

The goal of antihypertensive therapy is the reduction of cardiovascular and renal morbidity and mortality. According to the *JNC 7,* the goal is to achieve a pressure of less than 140/90, which is associated with a decrease in CVD complications. In patients with hypertension and diabetes or renal disease, the goal is less than 130/80 mm Hg.

Fortunately, many significant advances have been made in both the ways to treat hypertension and in the understanding of the disease process. Large numbers of clinical trials have shown that adequately treating hypertension can prevent or delay CVD. Over the past 40 years, the development of new antihypertensive medications has had an enormous impact on the quality of life of people with hypertension. Drug therapy for hypertension first became available in the early 1950s with the introduction of ganglionic blocking drugs. However, unpleasant adverse effects and inconsistent therapeutic effects were common problems with these **antihypertensive drugs.** In 1953, the vasodilator hydralazine was introduced, and in 1958 the thiazide diuretics became available.

Since that time, several additional drug categories have been developed, including loop diuretics (also called *potassium-wasting diuretics*), potassium-sparing diuretics, beta blockers (beta receptor antagonists), angiotensin-converting enzyme (ACE) inhibitors, alpha$_1$ antagonists, alpha$_2$ agonists, angiotensin II receptor blockers (ARBs), calcium channel blockers (CCBs), vasodilators, and the newest class, the direct renin inhibitors. Although some of the medications mentioned in this chapter represent older classes of drugs, all are current therapeutic options listed in the treatment guidelines for hypertension published by the National Heart, Lung, and Blood Institute.

PHARMACOLOGY OVERVIEW

Drug therapy for hypertension needs to be individualized. Important considerations in planning drug therapy are whether the patient has multiple medical problems and what impact drug therapy will have on the patient's quality of life. For example, sexual dysfunction in males is a common adverse effect of almost any antihypertensive drug and is the most common reason for nonadherence to drug therapy. Demographic factors, cultural implications, the ease of medication administration (e.g., a once-a-day dosing schedule or transdermal administration), and cost are other important considerations.

There are essentially seven main categories of pharmacologic drugs used to treat hypertension: diuretics, adrenergic drugs, vasodilators, angiotensin converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), calcium channel blockers (CCBs), and direct renin inhibitors. All of these antihypertensive drugs (with the exception of diuretics) have some vasodilatory action. Those drugs in the vasodilator category are also called *direct vasodilators.* Drugs in any of these classes may be used either alone or in combination. The various categories and subcategories of antihypertensive drugs are listed in Box 22-1. The diuretics are discussed in detail in Chapter 28 and therefore are not covered in this chapter.

REVIEW OF AUTONOMIC NEUROTRANSMISSION

There are two divisions of the autonomic nervous system (ANS): the parasympathetic nervous system (PSNS) and sympathetic nervous system (SNS). Stimulation of the ANS is controlled by the neurotransmitters acetylcholine and norepinephrine. Receptors for both divisions of the ANS are located throughout the body in a variety of tissues. ANS physiology is reviewed in greater detail in the introductory sections of Chapters 18 to 21. Receptors located between the postganglionic fiber and the effector cells (i.e., the postganglionic receptor) are called the *muscarinic* or *cholinergic* receptors in the PSNS. Receptors in the SNS are called *adrenergic* or *noradrenergic* receptors (i.e., alpha or beta receptors). Physiologic activity at muscarinic receptors is stimulated by acetylcholine and cholinergic agonist drugs (see Chapter 20) and is inhibited by cholinergic antagonists (anticholinergic drugs; see Chapter 21). Similarly, physiologic activity at adrenergic receptors is stimulated by norepinephrine and epinephrine and adrenergic agonists (see Chapter 18) and inhibited by antiadrenergics (adrenergic blockers; i.e., alpha or beta receptor blockers) (see Chapter 19). Figure 22-2 shows how these various receptors are arranged in both the PSNS and SNS and indicates their corresponding neurotransmitters.

BOX 22-1 CATEGORIES AND SUBCATEGORIES OF ANTIHYPERTENSIVE DRUGS

Adrenergic Drugs
- Centrally and peripherally acting adrenergic neuron blockers
- Centrally acting alpha$_2$ receptor agonists
- Peripherally acting alpha$_1$ receptor blockers
- Peripherally acting beta receptor blockers (beta blockers)
  - Cardioselective (beta$_1$ receptor blockers)
  - Nonselective (beta$_1$ and beta$_2$ receptor blockers)
- Peripherally acting dual alpha$_1$ and beta receptor blockers

Angiotensin-Converting Enzyme Inhibitors

Angiotensin II Receptor Blockers

Calcium Channel Blockers
- Benzothiazepines
- Dihydropyridines
- Phenylalkylamines

Diuretics
- Loop diuretics
- Potassium-sparing diuretics
- Thiazides and thiazide-like diuretics

Vasodilators

Act directly on vascular smooth muscle cells, *not* through alpha or beta receptors.

Direct Renin Inhibitors

ADRENERGIC DRUGS

Adrenergic drugs are a large group of antihypertensive drugs, as shown in Box 22-1. The alpha blockers and combined alpha/beta blockers were described in detail in Chapter 19. The adrenergic drugs discussed here exert their antihypertensive action at different sites.

Mechanism of Action and Drug Effects

Five specific drug subcategories are included in the adrenergic antihypertensive drugs as indicated in Box 22-1. Each of these subcategories of drugs can be described as having central action (in the brain) or peripheral action (at the heart and blood vessels). These drugs include the adrenergic neuron blockers (central and peripheral), the alpha$_2$ receptor agonists (central), the alpha$_1$ receptor

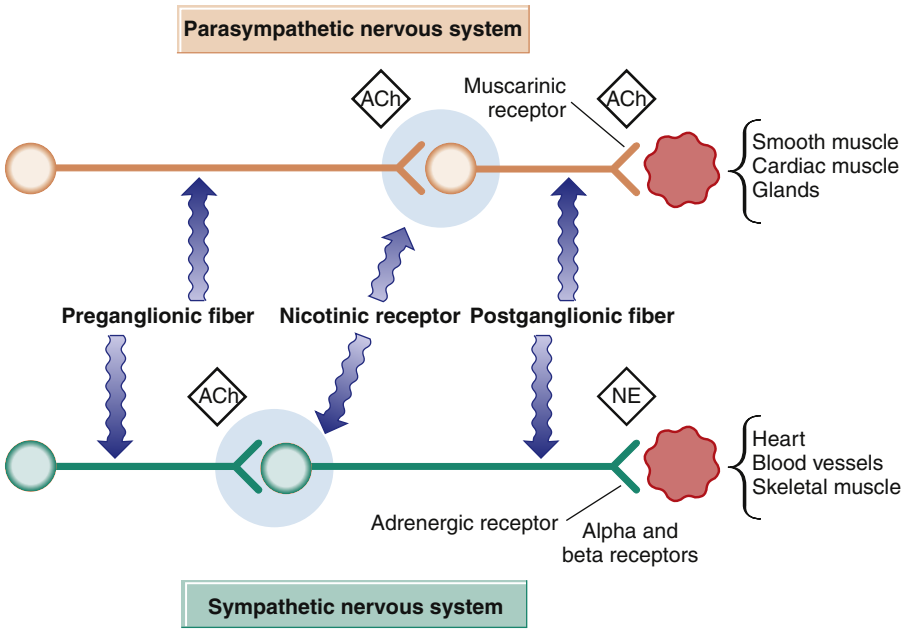

FIGURE 22-2 Location of the nicotinic receptors in the parasympathetic and sympathetic nervous systems. *ACh,* Acetylcholine; *NE,* norepinephrine.

blockers (peripheral), the beta receptor blockers (peripheral), and the combination alpha$_1$ and beta receptor blockers (peripheral).

The centrally acting alpha$_2$-adrenergic receptor agonists clonidine and methyldopa act by modifying the function of the SNS. Stimulation of the SNS leads to an increase in heart rate and force of contraction, the constriction of blood vessels, and the release of renin from the kidney, resulting in hypertension. The **centrally acting adrenergic drugs** work by stimulating the alpha$_2$-adrenergic receptors in the brain. The alpha$_2$-adrenergic receptors are unique in that receptor stimulation actually reduces sympathetic outflow, in this case from the central nervous system (CNS). This results in a lack of norepinephrine production, which reduces blood pressure. Stimulation of the alpha$_2$-adrenergic receptors also affects the kidneys, reducing the activity of renin. Renin is the hormone and enzyme that converts the protein precursor angiotensinogen to the protein angiotensin I, the precursor of angiotensin II (AII), a potent vasoconstrictor that raises blood pressure.

In the periphery, the **alpha$_1$ blockers** doxazosin, prazosin, and terazosin also modify the function of the SNS. They do so by blocking the alpha$_1$-adrenergic receptors. When alpha$_1$-adrenergic receptors are stimulated by circulating norepinephrine, they produce increased blood pressure. Thus, when these receptors are blocked, blood pressure is decreased. The drug effects of the alpha$_1$ blockers are primarily related to their ability to dilate arteries and veins, which reduces peripheral vascular resistance and subsequently decreases blood pressure. This produces a marked decrease in the systemic and pulmonary venous pressures and an increase in cardiac output. The alpha$_1$ blockers also increase urinary flow rates and decrease outflow obstruction by preventing smooth muscle contractions in the bladder neck and urethra. This can be beneficial in cases of benign prostatic hyperplasia (BPH).

The beta blockers also act in the periphery and include propranolol, metoprolol, and atenolol as well as several other drugs. These drugs are discussed in more detail in Chapters 23 and 25 because they are also used for angina and conduction problems. Their antihypertensive effects are related to their reduction of the heart rate through beta$_1$ receptor blockade. Furthermore, beta blockers also cause a reduction in the secretion of the hormone renin (see section on ACE inhibitors), which in turn reduces both AII-mediated vasoconstriction and aldosterone-mediated volume expansion. Long-term use of beta blockers also reduces peripheral vascular resistance.

Two dual-action alpha$_1$ and beta receptor blockers, labetalol and carvedilol, also act in the periphery at the heart and blood vessels. They have the dual antihypertensive effects of reduction in heart rate (beta$_1$ receptor blockade) and vasodilation (alpha$_1$

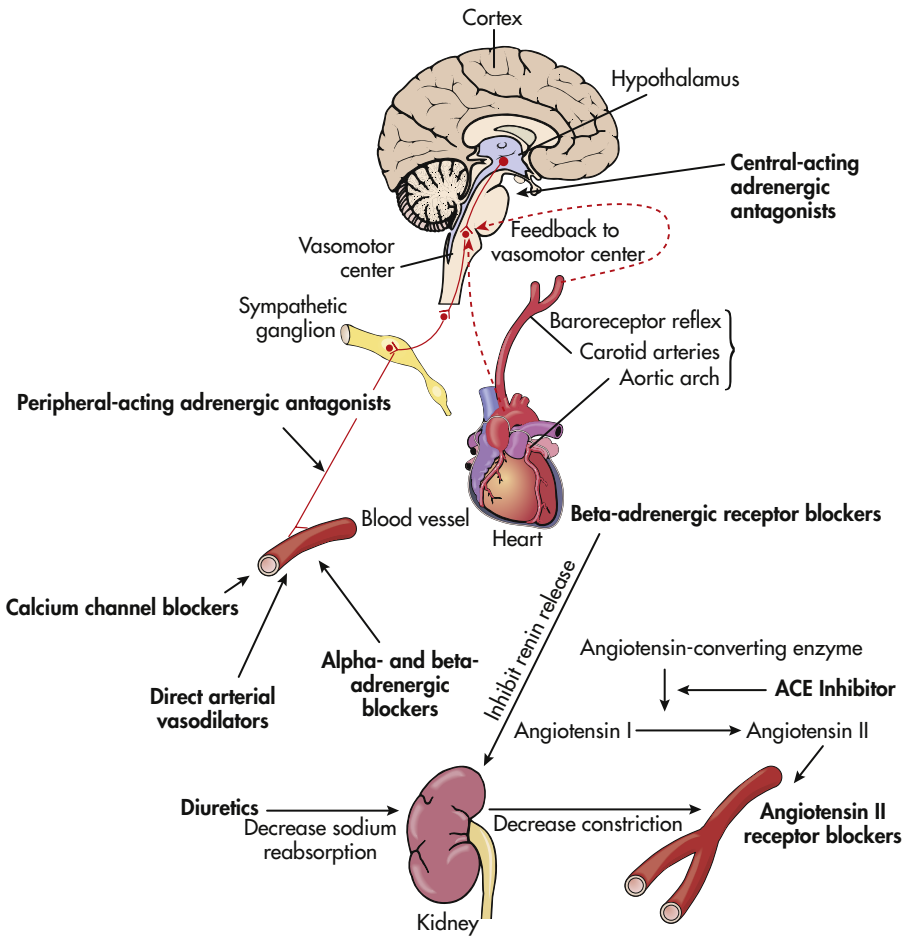

FIGURE 22-3 Site and mechanism of action of the various antihypertensive drugs. (Modified from Lewis SM et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 8, St Louis, 2011, Mosby.)

TABLE 22-1 ADRENERGIC DRUGS: DRUG INTERACTIONS

DRUG	INTERACTS WITH	MECHANISM	RESULT
clonidine	TCAs, MAOIs, appetite suppressants, amphetamines	Opposing actions	Decreased hypotensive effects
	Diuretics, nitrates, other antihypertensive drugs	Additive	Increased hypotensive effects
	Beta blockers	Additive	May potentiate bradycardia and increase the rebound hypertension in clonidine withdrawal
doxazosin	CNS depressants, alcohol	Additive	Increased CNS depression
	Beta blockers and other hypotensive drugs	Additive	Increased hypotension
	verapamil	Increased serum prazosin levels	Increased hypotension

CNS, Central nervous system; *MAOIs,* monoamine oxidase inhibitors; *TCAs,* tricyclic antidepressants.

receptor blockade). Figure 22-3 illustrates the site and mechanism of action of the various antihypertensive drugs.

Indications

All of the drugs mentioned in this section are used primarily for the treatment of hypertension, either alone or in combination with other antihypertensive drugs. Various forms of glaucoma may also respond to treatment with some of these drugs. Clonidine also has several off-label uses (not approved by the U.S. Food and Drug Administration but still common in practice), including prophylaxis against migraine headaches and treatment of severe dysmenorrhea or menopausal flushing. It is also useful in the management of withdrawal symptoms in persons with opioid, nicotine, or alcohol dependency (see Chapter 17). The alpha$_1$ blockers doxazosin, prazosin, and terazosin have been used to relieve the symptoms associated with BPH (see Chapter 19). They have also proved effective in the management of severe heart failure when used with cardiac glycosides (see Chapter 24) and diuretics (see Chapter 28).

Contraindications

Contraindications to the use of the adrenergic antihypertensive drugs include known drug allergy and may also include acute heart failure, concurrent use of monoamine oxidase inhibitors (see Chapter 16), severe mental depression, peptic ulcer, and severe liver or kidney disease. Asthma may also be a contraindication to the use of any noncardioselective beta blocker (e.g., carvedilol). The use of vasodilating drugs may also be contraindicated in cases of heart failure that is secondary to diastolic dysfunction.

Adverse Effects

The most common adverse effects of adrenergic drugs are bradycardia with reflex tachycardia, postural and postexercise hypotension, dry mouth, drowsiness, dizziness, depression, edema, constipation, and sexual dysfunction (e.g., impotence). Other effects include headaches, sleep disturbances, nausea, rash, and palpitations. There is a high incidence of **orthostatic hypotension** (a sudden drop in blood pressure during changes in position) in patients taking alpha blockers. Orthostatic hypotension is commonly referred to as *postural hypotension*. When the patient changes positions, a situation known as *first-dose syncope,* in which the hypotensive effect is severe enough to cause the patient to lose consciousness with even the first dose of medication, can occur. Educate the patient to change positions slowly.

In addition, the abrupt discontinuation of the centrally acting alpha$_2$ receptor agonists can result in rebound hypertension, characterized by a sudden and very high elevation of blood pressure. This may also be true for other antihypertensive drug classes, especially beta blockers. Nonselective blocking drugs are also commonly associated with bronchoconstriction (due to unrestrained parasympathetic tone) as well as metabolic inhibition of glycogenolysis in the liver, which can lead to hypoglycemia. However, hyperglycemic episodes are also among the adverse effects reported for this drug class.

Any change in the dosing regimen for cardiovascular medications should be undertaken gradually and with appropriate patient monitoring and follow-up. Although the same is also true for most other classes of medications, abrupt dosage changes of cardiovascular medications, either up or down, can be especially hazardous for the patient. Some of these drugs can also cause disruptions in blood count as well as in serum electrolyte levels and renal function. Periodic monitoring of white blood cell count, serum potassium and sodium levels, and urinary protein levels is recommended.

Interactions

Adrenergic drugs can cause additive CNS depression when taken with alcohol, benzodiazepines, and opioids. Other drug interactions that can occur with selected adrenergic drugs are summarized in Table 22-1. This list is merely representative and is not exhaustive. Always keep a drug information handbook available to check in cases in which a specific drug interaction is suspected. Hospital pharmacists are also excellent resources.

Dosages

For dosage information on selected adrenergic antihypertensive drugs, see the table on p. 353.

DRUG PROFILES

ALPHA$_2$-ADRENERGIC RECEPTOR STIMULATORS (AGONISTS)

Of the two alpha$_2$ receptor agonists—clonidine and methyldopa—clonidine is by far the most commonly used and is the prototypical drug for this class. Methyldopa is commonly used to treat hypertension in pregnancy. However, these drugs are not typically prescribed as first-line antihypertensive drugs, because their use is associated with a high incidence of unwanted adverse effects such as orthostatic hypotension, fatigue, and dizziness. They may be used as adjunct drugs in the treatment of hypertension after other drugs have failed or may be used in conjunction with other antihypertensives such as diuretics.

DOSAGES

Selected Antihypertensive Drugs: Adrenergic Agonists and Antagonists

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
carvedilol (Coreg) (C)	Peripherally acting alpha$_1$, beta$_1$, and beta$_2$ receptor antagonist (blocker)	PO: 3.125-25 mg bid	Hypertension (also used in heart failure)
♦ clonidine (Catapres, Catapres-TTS) (C)	Centrally acting alpha$_2$ receptor agonist	PO: 0.2-0.6 mg/day Transdermal patch: 0.1, 0.2, or 0.3 mg/24 hr, applied weekly	Hypertension (may have other unlabeled uses including treatment of psychiatric, cardiovascular, and gastrointestinal problems)
doxazosin (Cardura) (C)	Peripherally acting alpha$_1$ receptor antagonist	PO: Initial dose 1 mg/day; may titrate up to maximum of 16 mg/day	Hypertension

PO, Oral.

♦ clonidine

Clonidine (Catapres) is used primarily for its ability to decrease blood pressure. It is also useful in the management of opioid withdrawal. It has a better safety profile than the other centrally acting adrenergics and has the advantage of being available in several dosage formulations, including both topical and oral preparations. When the patch dosage form is used, it is important to remove the old patch before applying a new one. Clonidine must not be discontinued abruptly, as this will lead to severe rebound hypertension. Its use is contraindicated in patients who have shown hypersensitivity reactions to it. Recommended dosages are given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-60 min	3-5 hr	6-20 hr	8 hr

ALPHA$_1$ BLOCKERS

The alpha$_1$ blockers are doxazosin (Cardura), prazosin (Minipress), tamsulosin (Flomax), and terazosin (Hytrin). Their use is contraindicated in patients who have shown a hypersensitivity to them. They are classified as pregnancy category C drugs. They are available only as oral preparations. Tamsulosin is not used to control blood pressure but is indicated solely for symptomatic control of benign prostatic hyperplasia (BPH). This use is described further in Chapters 19 and 35.

doxazosin

Doxazosin (Cardura) is a commonly used alpha$_1$ blocker. It reduces peripheral vascular resistance and blood pressure by dilating both arterial and venous blood vessels. It has been shown to be beneficial in the treatment of hypertension and the relief of the symptoms of obstructive BPH. It is available in immediate- and extended-release formulations. When the drug is released from the extended-release form, the matrix of the capsule is expelled in the stool. Educate patients that this will happen, and reassure that the active drug has been absorbed. Confusion over the presence of the capsule matrix could cause patients to take more than the prescribed dosage. Recommended dosages are given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-2 hr	2-3 hr	15-22 hr	Less than 24 hr

DUAL-ACTION ALPHA$_1$ AND BETA RECEPTOR BLOCKERS

carvedilol

Carvedilol (Coreg) is a widely used drug and is well tolerated by most patients. In addition to treatment of hypertension, it is also indicated for treatment of mild to moderate heart failure in conjunction with digoxin, diuretics, and ACE inhibitors. Its contraindications include known drug allergy, cardiogenic shock, severe bradycardia or heart failure, bronchospastic conditions such as asthma, and various cardiac problems involving the conduction system. For dosage information, see the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	20-120 min	1-4 hr	6-8 hr	8-24 hr

BETA RECEPTOR BLOCKER

nebivolol

Nebivolol (Bystolic) is the newest beta blocker, released in 2008. It is a beta$_1$-selective beta blocker approved for use in hypertension. It is also used for the treatment of heart failure. Nebivolol is similar to other beta$_1$-selective blockers; however, in addition to blocking beta$_1$ receptors, it also produces an endothelium-derived nitric oxide–dependent vasodilatation, which results in a decrease in SVR. It is promoted as causing less sexual dysfunction. Like other beta blockers, it should not be stopped abruptly but must be tapered over 1 to 2 weeks. Dosing starts at 5 mg/day and may be increased at 2-week intervals to a maximum of 40 mg/day.

ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS

The ACE inhibitors are a large group of antihypertensive drugs. Currently, there are ten ACE inhibitors available for clinical use. In addition, various combination drug products

TABLE 22-2 ACE INHIBITORS

DRUG (TRADE NAME)	COMBINATION WITH HYDROCHLOROTHIAZIDE	DOSING SCHEDULE
benazepril (Lotensin)	Lotensin HCT	Once a day
captopril (Capoten)	Capozide	Multiple
enalapril (Vasotec)	Vaseretic	Multiple
fosinopril (Monopril)	None	Once a day
lisinopril (Prinivil)	Prinzide	Once a day
lisinopril (Zestril)	Zestoretic	Once a day
moexipril (Univasc)	None	Once a day
perindopril (Aceon)	None	Once to twice daily
quinapril (Accupril)	None	Once a day
ramipril (Altace)	None	Once a day
trandolapril (Mavik)	None	Once a day

ACE, Angiotensin-converting enzyme.

are available in which a thiazide diuretic or a calcium channel blocker (CCB) is combined with an ACE inhibitor. Combination products tend to increase adherence since the patient is taking fewer drugs. The available ACE inhibitors are captopril (Capoten), benazepril (Lotensin), enalapril (Vasotec), fosinopril (Monopril), lisinopril (Prinivil), moexipril (Univasc), perindopril (Aceon), quinapril (Accupril), ramipril (Altace), and trandolapril (Mavik). These drugs are very safe and efficacious and are often used as first-line drugs in the treatment of both heart failure and hypertension. Some of the available drug combinations and dosing schedules for the various drugs that make up this large class of antihypertensives are summarized in Table 22-2. The ACE inhibitors as a class are very similar to one another and differ in only a few of their chemical properties; however, there are some differences among them in their clinical properties.

Captopril has the shortest half-life and therefore must be dosed more frequently than any of the other ACE inhibitors. This may be an important drawback for patients with a history of nonadherence to their medication regimen. On the other hand, it may be best to start with a drug that has a short half-life in a patient who is critically ill, so that if problems arise they will be short-lived. Both captopril and enalapril can be dosed multiple times a day.

Captopril and lisinopril are the only two ACE inhibitors that are not prodrugs. A **prodrug** is a drug that is inactive in its administered form and must be metabolized to its active form in the body, generally by the liver, to be effective. This characteristic of captopril and lisinopril is an important advantage in treating a patient with liver dysfunction; all of the other ACE inhibitors are prodrugs, and their transformation to active form is dependent upon liver function to reveal the active drug.

Enalapril is the only ACE inhibitor that is available in a parenteral preparation. All of the newer ACE inhibitors, such as benazepril, fosinopril, lisinopril, quinapril, and ramipril, have long half-lives and long durations of action, which allows them to be given orally only once a day. A once-a-day medication regimen promotes better patient adherence.

All ACE inhibitors have detrimental effects on the unborn fetus and neonate. They are classified as pregnancy category C drugs for women in their first trimester and as pregnancy category D drugs for women in their second or third trimester. ACE inhibitors are to be used by pregnant women only if there are no safer alternatives. Fetal and neonatal morbidity and mortality have been reported to have occurred in at least 50 cases in which women received ACE inhibitors during their pregnancies.

Mechanism of Action and Drug Effects

The development of the ACE inhibitors was spurred by the discovery of an animal substance found to have beneficial effects in humans. This particular substance was the venom of a South American viper, which was found to inhibit kininase activity. Kininase is an enzyme that normally breaks down bradykinin, a potent vasodilator in the human body.

As their name implies, these drugs inhibit angiotensin-converting enzyme, which is responsible for converting AI (formed through the action of renin) to AII. AII is a potent vasoconstrictor and induces aldosterone secretion by the adrenal glands. Aldosterone stimulates sodium and water resorption, which can raise blood pressure. Together, these processes are referred to as the renin-angiotensin-aldosterone system. By inhibiting this process, blood pressure is lowered.

The primary effects of the ACE inhibitors are cardiovascular and renal. Their cardiovascular effects are due to their ability to reduce blood pressure by decreasing systemic vascular resistance (SVR). They do this by preventing the breakdown of the vasodilating substance bradykinin and also of substance P (another potent vasodilator), and preventing the formation of AII. These combined effects decrease afterload, or the resistance against which the left ventricle must pump to eject its volume of blood during contraction. The ACE inhibitors are beneficial in the treatment of heart failure because they prevent sodium and water resorption by inhibiting aldosterone secretion. This causes diuresis, which decreases blood volume and return to the heart. This in turn decreases preload, or the left ventricular end-diastolic volume, and the work required of the heart.

Indications

The therapeutic effects of the ACE inhibitors are related to their potent cardiovascular effects. They are excellent antihypertensives and adjunctive drugs for the treatment of heart failure. They may be used alone or in combination with other drugs such as diuretics in the treatment of hypertension or heart failure.

The beneficial hemodynamic effects of the ACE inhibitors have been studied extensively. Because of their ability to decrease SVR (a measure of afterload) and preload, ACE inhibitors can stop the progression of left ventricular hypertrophy, which is sometimes seen after a myocardial infarction (MI). This pathologic process is known as *ventricular remodeling.* The ability of ACE inhibitors to prevent this is termed a *cardioprotective effect.* ACE inhibitors have been shown to decrease morbidity and mortality in patients with heart failure. They are considered the drugs of choice for hypertensive patients with heart failure. ACE inhibitors also have been shown to have a protective effect on the kidneys, because they

TABLE 22-3 ACE INHIBITORS: THERAPEUTIC EFFECTS

BODY SUBSTANCE	EFFECT IN BODY	ACE INHIBITOR ACTION	RESULTING HEMODYNAMIC EFFECT
aldosterone	Causes sodium and water retention	Prevents its secretion	Diuresis = ↓ plasma volume = ↓ filling pressures or ↓ preload
angiotensin II	Potent vasoconstrictor	Prevents its formation	↓SVR = ↓ afterload
bradykinin	Potent vasodilator	Prevents its breakdown	↓ SVR = ↓ afterload

↓, Decreased; *ACE,* angiotensin-converting enzyme; *SVR,* systemic vascular resistance.

reduce glomerular filtration pressure. This is one reason that they are among the cardiovascular drugs of choice for diabetic patients. Numerous studies have shown that the ACE inhibitors reduce proteinuria, and they are considered by many to be standard therapy for diabetic patients to prevent the progression of diabetic nephropathy. The various therapeutic effects of the ACE inhibitors are listed in Table 22-3, which lists the biochemicals on which ACE inhibitors act and the resulting beneficial hemodynamic effects.

Contraindications

Contraindications to the use of ACE inhibitors include known drug allergy, especially a previous reaction of angioedema (e.g., laryngeal swelling) to an ACE inhibitor. Patients with a baseline potassium level of 5 mEq/L or higher may not be suitable candidates for ACE inhibitor therapy, because these drugs can promote hyperkalemia (see later discussion). All ACE inhibitors are contraindicated in lactating women, children, and in patients with bilateral renal artery stenosis.

Adverse Effects

Major CNS effects of the ACE inhibitors include fatigue, dizziness, mood changes, and headaches. A characteristic dry, nonproductive cough may occur that is reversible with discontinuation of the therapy. A first-dose hypotensive effect can cause a significant decline in blood pressure. Other adverse effects include loss of taste, hyperkalemia, rash, anemia, neutropenia, thrombocytosis, and agranulocytosis. In patients with severe heart failure whose renal function may depend on the activity of the renin-angiotensin-aldosterone system, treatment with ACE inhibitors may cause acute renal failure. ACE inhibitors promote potassium resorption in the kidney, although they promote sodium excretion due to their reduction of aldosterone secretion. For this reason, serum potassium levels must be monitored regularly. This is especially true when there is concurrent therapy with potassium-sparing diuretics, although many patients tolerate both types of drug therapy with no major problems. One rare, but potentially fatal, adverse effect is angioedema. Angioedema is a strong vascular reaction involving inflammation of submucosal tissues, which can progress to anaphylaxis.

Toxicity and Management of Overdose

The most pronounced symptom of an overdose of an ACE inhibitor is hypotension. Treatment is symptomatic and supportive and includes the administration of intravenous fluids to expand the blood volume. Hemodialysis is effective for the removal of captopril and lisinopril.

Interactions

Nonsteroidal antiinflammatory drugs (NSAIDs), such as ibuprofen, can reduce the antihypertensive effect of ACE inhibitors (see Chapter 44). The use of NSAIDs and ACE inhibitors may also predispose patients to the development of acute renal failure. Concurrent use of ACE inhibitors and other antihypertensives or diuretics can have hypotensive effects. Giving lithium and ACE inhibitors together can result in lithium toxicity. Potassium supplements and potassium-sparing diuretics, when administered with ACE inhibitors, may result in hyperkalemia. The monitoring of serum potassium levels becomes important in these cases. False-positive results on tests for acetone in the urine may occur in patients taking captopril.

Dosages

For dosage information on selected ACE inhibitors, see the table on this page.

DOSAGES

Selected Antihypertensive Drugs: ACE Inhibitors and Angiotensin II Receptor Blockers

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ captopril (Capoten) (C, first trimester; D, second and third trimesters)	ACE inhibitor	**Adult** PO: 25-150 mg bid-tid	Hypertension, heart failure
enalapril (Vasotec) (C, first trimester; D, second and third trimesters)	ACE inhibitor	**Adult** PO: 10-40 mg/day as a single dose or in 2 equal doses PO: 2.5-20 mg bid IV: 1.25-5 mg q6h over a 5-min period	Hypertension Heart failure Hypertension
♦ losartan (Cozaar) (C, first trimester; D, second and third trimesters)	Angiotensin II receptor blocker	**Adult** PO: 25-100 mg as a single dose or divided bid	Hypertension, heart failure

ACE, Angiotensin-converting enzyme; *IV,* intravenous; *PO,* oral.

DRUG PROFILES

♦ captopril

Captopril (Capoten) was the first available ACE inhibitor and is considered the prototypical drug for the class. Several large multicenter studies have shown its clinical efficacy in minimizing or preventing the left ventricular dilatation and dysfunction (also called *ventricular remodeling*) that can arise in the acute period after an MI and thereby improving the patient's chances of survival. It can also reduce the risk of heart failure in these patients. It has the shortest half-life of all of the currently available ACE inhibitors, and it must be given three or four times a day. Recommended dosages are given in the table on p. 355.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	15 min	1-2 hr	2 hr	2-6 hr

enalapril

Enalapril (Vasotec) is the only ACE inhibitor currently marketed that is available in both oral and parenteral preparations. The parenteral formulation (enalaprilat) is an active drug. It offers the hemodynamic benefit of inhibiting ACE activity in an acutely ill patient who cannot tolerate oral medications. The other benefit to intravenous enalapril is that it does not require cardiac monitoring as do the intravenous beta blockers and calcium channel blockers. Although its half-life is slightly longer than that of captopril, it may still have to be given twice a day. The oral form of enalapril differs from captopril in that it is a prodrug, and the patient must have a functioning liver for the drug to be converted into its active form. As with captopril, it has been shown in many large studies to improve a patient's chances of survival after an MI and to reduce the incidence of heart failure. Recommended dosages are given in the table on p. 355.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	4-6 hr	2 hr	12-24 hr
IV	15 min	1-4 hr	2 hr	4-6 hr

ANGIOTENSIN II RECEPTOR BLOCKERS

Angiotensin II receptor blockers (ARBs) are similar to the ACE inhibitors. The class includes losartan (Cozaar), eprosartan (Teveten), valsartan (Diovan), irbesartan (Avapro), candesartan (Atacand), olmesartan (Benicar), telmisartan (Micardis), and azilsartan (Edarbi).

Mechanism of Action and Drug Effects

The ARBs block the binding of AII to type 1 AII receptors. The ACE inhibitors such as enalapril block conversion of AI to AII, but AII also may be formed by other enzymes that are not blocked by ACE inhibitors. For comparison, recall that ACE inhibitors block the breakdown of bradykinins and substance P, which accumulate and may cause adverse effects such as cough but might also contribute to the drugs' antihypertensive and cardiac and nephroprotective effects. Bradykinins are potent vasodilators and help to reduce blood pressure by dilating arteries and decreasing SVR.

In contrast to ACE inhibitors, the ARBs affect primarily vascular smooth muscle and the adrenal gland. By selectively blocking the binding of AII to the type 1 AII receptors in these tissues, ARBs block vasoconstriction and the secretion of aldosterone. AII receptors have been found in other tissues throughout the body, but the effects of ARB blocking of these receptors is unknown.

Clinically, ACE inhibitors and ARBs appear to be equally effective for the treatment of hypertension. Both are well tolerated, but ARBs do not cause cough. There is evidence that ARBs are better tolerated and are associated with lower mortality after MI than ACE inhibitors. It is not yet clear whether ARBs are as effective as ACE inhibitors in treating heart failure (cardioprotective effects) or in protecting the kidneys, as in diabetes. Both types of drugs are contraindicated for use in the second or third trimester of pregnancy. Whether one or more of these drugs could prove to have unique adverse effects with long-term use is unknown at this time.

Indications

The therapeutic effects of ARBs are related to their potent vasodilating properties. They are excellent antihypertensives and adjunctive drugs for the treatment of heart failure. They may be used alone or in combination with other drugs such as diuretics in the treatment of hypertension or heart failure. The beneficial hemodynamic effect of ARBs is their ability to decrease SVR (a measure of afterload). Their use is rapidly growing, and multiple studies have verified their beneficial effects.

Contraindications

Contraindications to the use of ARBs are known drug allergy, pregnancy, and lactation. They need to be used cautiously in elderly patients and in patients with renal dysfunction because of increased sensitivity to its effects and risk for adverse effects in these patients. As with other antihypertensives, blood pressure and apical pulse rate need to be assessed before and during drug therapy.

Adverse Effects

The most common adverse effects of ARBs are upper respiratory infections and headache. Occasionally dizziness, inability to sleep, diarrhea, dyspnea, heartburn, nasal congestion, back pain, and fatigue can occur. Hyperkalemia is much less likely to occur than with the ACE inhibitors.

Toxicity and Management of Overdose

Overdose may manifest as hypotension and tachycardia; bradycardia occurs less often. Treatment is symptomatic and supportive, and includes the administration of intravenous fluids to expand the blood volume.

TABLE 22-4 ANGIOTENSIN II RECEPTOR BLOCKERS: DRUG INTERACTIONS

DRUG	MECHANISM	RESULT
NSAIDs	Decreased antihypertensive	Decreased effect of ARB and potential to renal failure
lithium	Inhibits lithium elimination	Increased lithium concentrations
rifampin	Increased metabolism	Decreased ARB effectiveness
Potassium supplements and potassium-sparing diuretics	Additive potassium-increasing effects	Possible hyperkalemia

ARB, Angiotensin II receptor blocker.

Interactions

The drugs that interact with ARBs, the mechanism responsible, and the result of the interaction are summarized in Table 22-4. In addition, as is the case with ACE inhibitors, ARBs can promote hyperkalemia, especially when taken concurrently with potassium supplements (although this occurs much less frequently than with ACE inhibitors). Patients' individual chemistries vary widely, however, so monitoring of the serum potassium level is necessary for all patients. Potassium supplements may still be indicated for patients with a tendency toward hypokalemia (whether acute or chronic).

Dosages

For dosage information on selected ARBs, see the table on p. 355.

DRUG PROFILE

♦ **losartan**

Losartan (Cozaar) has been shown to be beneficial in patients with hypertension and heart failure. Studies indicate that ARBs are better tolerated and produce a marginally lower mortality rate after MI than treatment with ACE inhibitors.

The use of losartan is contraindicated in patients who are hypersensitive to any component of this product. It is to be used with caution in patients with renal or hepatic dysfunction and in patients with renal artery stenosis. Breastfeeding women must not take losartan, because it can cause serious adverse effects on the nursing infant. Recommended dosages are given in the table on p. 355.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	6 hr	6-9 hr	24 hr

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers (CCBs) are also discussed in detail in the chapters on antidysrhythmic drugs (see Chapter 25) and antianginal drugs (see Chapter 23). As a class, they are used for several indications and have many beneficial effects and relatively few adverse effects. Their primary use is for the treatment of hypertension and angina. Their effectiveness in treating hypertension is related to their ability to cause smooth muscle relaxation by blocking the binding of calcium to its receptors, which thereby prevents contraction. Because of their effectiveness and safety, they have been added to the list of first-line drugs for the treatment of hypertension. Amlodipine (Norvasc) is the CCB most commonly used for hypertension. Calcium channel blockers are also effective antidysrhythmics (see Chapter 25). One specific CCB, nimodipine, can prevent the cerebral artery spasms that can occur after a subarachnoid hemorrhage. CCBs are also sometimes used in the treatment of Raynaud's disease and migraine headache. They are also used in combination with other drugs. Some examples are amlodipine/atorvastatin (Caduet), which is both an antihypertensive and a cholesterol-lowering drug (see Chapter 27); amlodipine/benazepril (Lotrel); amlodipine/olmesartan (Azar); and amlodipine/valsartan (Exforge).

DIURETICS

The diuretics are a highly effective class of antihypertensive drugs. They are listed as the current first-line antihypertensives in the *JNC 7* guidelines for the treatment of hypertension. They may be used as monotherapy (single-drug therapy) or in combination with drugs of other antihypertensive classes. Their primary therapeutic effect is decreasing the plasma and extracellular fluid volumes, which results in decreased preload. This leads to a decrease in cardiac output and total peripheral resistance, all of which decrease the workload of the heart. This large group of antihypertensives is discussed in detail in Chapter 28. The thiazide diuretics (e.g., hydrochlorothiazide) are the most commonly used diuretics for treatment of hypertension.

VASODILATORS

Vasodilators act directly on arteriolar and/or venous smooth muscle to cause relaxation. They do not work through adrenergic receptors. Vasodilator drugs include minoxidil, hydralazine (Apresoline), diazoxide (Hyperstat), and nitroprusside (Nitropress).

Mechanism of Action and Drug Effects

Direct-acting vasodilators are useful as antihypertensive drugs because of their ability to directly cause peripheral vasodilation. This results in a reduction in systemic vascular resistance (SVR). In general, the most notable effect of the vasodilators is their hypotensive effect. However, minoxidil (Rogaine) (in its topical form) has also received attention because of its effectiveness in restoring hair growth. This application is described further in Chapter 56. Diazoxide, hydralazine, and minoxidil work primarily through arteriolar vasodilation, whereas nitroprusside has both arteriolar and venous effects.

Indications

All of the vasodilators can be used to treat hypertension, either alone or in combination with other antihypertensives. Sodium

nitroprusside and intravenous diazoxide are reserved for the management of hypertensive emergencies, in which blood pressure is severely elevated.

Contraindications

Contraindications include known drug allergy and may also include hypotension, cerebral edema, head injury, acute MI, and coronary artery disease. They may also be contraindicated in cases of heart failure that is secondary to diastolic dysfunction.

Adverse Effects

Diazoxide has many undesirable adverse effects including dizziness, headache, orthostatic hypotension, dysrhythmias, sodium and water retention, nausea, vomiting, and hyperglycemia in diabetic patients. These adverse effects have dramatically reduced the use of diazoxide. Adverse effects of hydralazine include dizziness, headache, anxiety, tachycardia, edema, dyspnea, nausea, vomiting, diarrhea, hepatitis, systemic lupus erythematosus (SLE), vitamin B_6 deficiency, and rash. Minoxidil adverse effects include T-wave electrocardiographic changes, pericardial effusion or tamponade, angina, breast tenderness, rash, and thrombocytopenia. Adverse effects of sodium nitroprusside include bradycardia, decreased platelet aggregation, rash, hypothyroidism, hypotension, methemoglobinemia, and, rarely, cyanide toxicity. Cyanide ions are a by-product of nitroprusside metabolism. Cyanide and thiocyanate toxicity are seen clinically when nitroprusside is used at high dosages for long periods of time and/or in patients with renal insufficiency. When nitroprusside is combined with sodium thiosulfate, the potential for cyanide toxicity is greatly reduced.

Toxicity and Management of Overdose

Hydralazine toxicity or overdose produces hypotension, tachycardia, headache, and generalized skin flushing. Treatment is supportive and symptomatic and includes the administration of intravenous fluids, digitalization if needed, and the administration of beta blockers for the control of tachycardia.

Minoxidil overdose or toxicity can precipitate excessive hypotension. Treatment is supportive and symptomatic and includes the administration of intravenous fluids. Norepinephrine and epinephrine should not be used to reverse the hypotension because of the possibility of causing excessive cardiac stimulation.

The main symptom of sodium nitroprusside overdose or toxicity is severe hypotension. This drug is normally administered only to patients receiving intensive care. Under these conditions, the infusion rate is usually carefully titrated, yielding immediately visible results on a cardiovascular monitor that provides constant measurements of blood pressure from centrally placed venous or arterial catheters. For this reason, excessive hypotension is usually avoidable. When it does occur, discontinuation of the infusion has an immediate effect because the drug is metabolized very rapidly (half-life of 10 minutes). Treatment for the hypotension is supportive and symptomatic; if necessary, pressor drugs can be infused to quickly raise blood pressure. The chemical structure of nitroprusside does contain cyanide groups, which are released upon its metabolism in the body and can result in cyanide or thiocyanate toxicity. This usually occurs clinically when the drug is used at high dosages for prolonged periods and/or in patients with renal failure. If cyanide or thiocyanate toxicity occurs, treatment can be administered using a standard cyanide antidote kit that includes sodium nitrite and sodium thiosulfate for injection and amyl nitrite for inhalation.

Interactions

The incidence of drug interactions is low for the direct-acting vasodilators as a class. Hydralazine can produce additive hypotensive effects when given with adrenergic or other antihypertensive drugs.

Dosages

For dosage information for selected vasodilator drugs, see the table on this page.

DOSAGES

Selected Antihypertensive Drugs: Vasodilators

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ hydralazine (Apresoline) (C)	Direct-acting peripheral vasodilators	**Pediatric** PO: 0.75-7.5 mg/kg/day to a max of 200 mg/day **Adult** PO: 10-25 mg 2-4 times/day × 7 days, then increase to 50 mg bid-qid. Titrate to effect to max dose of 300 mg/day IV: 20-40 mg prn	Hypertension
sodium nitroprusside (Nipride, Nitropress) (C)		**Pediatric and adult** IV: 0.3-0.5 mcg/kg/min, titrate to desired effect. Max of 10 mcg/kg/min	

IV, Intravenous; *PO,* oral.

DOSAGES

Miscellaneous Antihypertensive Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
bosentan (Tracleer) (X)	Endothelin receptor antagonist	**Adult only** PO: 62.5 mg bid	Pulmonary artery hypertension in patients with moderate to severe heart failure
eplerenone (Inspra) (B)	Aldosterone receptor antagonist	**Adult only** PO: Initial dose of 50 mg once/day ×4 wk, then increase as tolerated to max dose of 50 mg bid	Hypertension and post-MI status (to improve post-MI survival in patients with stable heart failure)
treprostinol (Remodulin) (B)	Vasodilator and platelet aggregation inhibitor	**Adult only** Continuous subcutaneous infusion: 1.25-2.5 ng/kg/min	Pulmonary artery hypertension in patients with severe heart failure

MI, Myocardial infarction; *PO,* oral.

DRUG PROFILES

♦ hydralazine

Hydralazine (Apresoline) is less commonly used now than when it first became available, but it is still effective for selected patients. It can be taken orally to treat routine cases of essential hypertension. It is also available in injectable form for hypertensive emergencies and is useful for patients who cannot tolerate oral therapy in the hospital. Hydralazine may be given intravenously. Some hospitals do not require cardiac monitoring when it is given intravenously. Contraindications include drug allergy, coronary artery disease, and mitral valve dysfunction, such as that related to childhood rheumatic fever. A new combination drug product is a tablet that contains both 37.5 mg of hydralazine and 20 mg of the antianginal drug isosorbide dinitrate (see Chapter 23). This drug combination is known as BiDil, and it is specifically indicated as an adjunct for treatment of heart failure in African-American patients. This drug combination has been shown to improve patient survival and prolong time to hospitalization for heart failure in African-American patient populations.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	5-20 min	30-45 min	2-8 hr	1-4 hr
PO	20-30 min	1-2 hr	2-8 hr	8 hr

sodium nitroprusside

Sodium nitroprusside (Nitropress), like diazoxide, is normally used in the intensive care setting for severe hypertensive emergencies and is titrated to effect by intravenous infusion. Its use is contraindicated in patients with a known hypersensitivity to the drug, severe heart failure, and known inadequate cerebral perfusion (especially during neurosurgical procedures). Recommended dosages are given in the table on p. 358.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Less than 2 min	2-5 min	2 min	1-10 min

MISCELLANEOUS ANTIHYPERTENSIVE DRUGS

Four newer medications exemplify some of the antihypertensive drugs most recently made available in the United States. These include eplerenone, bosentan, and treprostinil. All of these drugs are currently indicated for adult use only.

DRUG PROFILES

eplerenone

Eplerenone (Inspra) is currently the only drug in a new class of antihypertensive drugs called *selective aldosterone blockers.* It reduces blood pressure by blocking the actions of the hormone aldosterone at its corresponding receptors in the kidney, heart, blood vessels, and brain. Eplerenone is indicated for both routine treatment of hypertension and for post-MI heart failure. Its use is contraindicated in patients with known drug allergy, elevated serum potassium levels (higher than 5.5 mEq/L), or severe renal impairment and in those using a medication that inhibits the action of cytochrome P-450 enzyme 3A4. Many commonly used medications inhibit the action of this enzyme, including several antibiotic, antifungal, and antiviral drugs. Recommended dosages are given in the table on this page.

bosentan

Bosentan (Tracleer) works by blocking the receptors of the hormone endothelin. Normally this hormone acts to stimulate the narrowing of blood vessels by binding to endothelin receptors (ET_A and ET_B) in the endothelial (innermost) lining of blood vessels and in vascular smooth muscle. Bosentan reduces blood pressure by blocking this action. However, currently it is specifically indicated only for the treatment of pulmonary artery hypertension in patients with moderate to severe heart failure. It is available only through a limited distribution program directly from the manufacturer. Its use is contraindicated in patients with known drug allergy, pregnancy, or significant liver impairment, and in patients receiving concurrent drug therapy with cyclosporine or glyburide. Recommended dosages are given in the table on this page.

Ambrisentan (Letairis) is a new drug similar to bosentan. Other drugs used to treat pulmonary hypertension include epoprostenol, treprostinil, and iloprost. The erectile dysfunction drugs sildenafil and tadalafil are also used (see Chapter 35). Both of these drugs go by different trade names when used for

pulmonary hypertension. Sildenafil, which is commonly known as Viagra, also has the trade name Revatio; and tadalafil, which is commonly known as Cialis, is called Adcirca when used for pulmonary hypertension.

treprostinil

Treprostinil (Remodulin) lowers blood pressure through a combined mechanism of action by dilating both pulmonary and systemic blood vessels and by inhibiting platelet aggregation. Like bosentan, it is indicated specifically for treatment of pulmonary artery hypertension in patients with moderate to severe heart failure. Its only current contraindication is known drug allergy. It is also unique to date in being the only drug diluted to the nanogram level for administration. Recommended dosages are given in the table on p. 359.

NURSING PROCESS

Over the last several decades, the diagnosis and treatment of hypertension has changed greatly from a stepped approach to a medical regimen that is now based on guidelines from the National Institutes of Health (issued in May 2003). These guidelines apply to adults 18 years of age and older and describe evaluation, classification, diagnosis, risk factors, identifiable causes, and blood pressure measurement techniques. One of the major differences in these guidelines, contained in *JNC 7,* is the creation of a "prehypertension" category, defined as a systolic blood pressure of 120 to 139 mm Hg and/or a diastolic blood pressure of 80 to 89 mm Hg. This is a change from previous guidelines and provides a more aggressive approach to the identification and subsequent management of the disease process, instead of a later diagnosis and treatment when multiple organ damage may be present. The nursing process discussion that follows provides both general and specific information related to the pharmacologic and nonpharmacologic treatment of all stages of hypertension.

ASSESSMENT

Before any antihypertensive drug is given to a patient, obtain a thorough health history and perform a head-to-toe physical assessment. Measure and document blood pressure, pulse rate, respirations, and pulse oximetry readings. Monitor laboratory tests, including: (1) serum sodium, potassium, chloride, magnesium, and calcium levels; (2) serum level of troponin, which is usually elevated within 4 to 6 hours after a heart attack begins and may be a reliable indicator up to 14 days after a heart attack; (3) renal function studies, including BUN, serum, and urinary creatinine levels; and (4) hepatic function studies, including serum levels of ALT and AST.

Laboratory tests will most likely be complemented by more sophisticated scans and imaging studies. Noninvasive ophthalmoscopic examination of the eye structures (e.g., optic nerve, optic disk, vessels) by a professionally trained health care practitioner (e.g., nurse practitioner, physician assistant, physician, ophthalmologist, optometrist) allows easy visualization of the structures impacted by hypertension. If hypertensive retinopathy is present, the examination will reveal narrowing of blood vessels in the eye, oozing of fluid from these blood vessels, spots on the retina, swelling of the macula and optic nerve, and/or bleeding in the back of the eye. These problems may be prevented by controlling the blood pressure or treating hypertension with appropriate follow-up once it is diagnosed.

Assess also for conditions, factors, or variables that may be underlying causes of a patient's hypertension, such as:

- Addison's disease
- Coarctation of the aorta
- Coronary heart disease
- Culture and race or ethnicity
- Cushing's disease
- Family history of hypertension
- Nicotine use
- Obesity
- Peripheral vascular disease
- Pheochromocytoma
- Preeclampsia of pregnancy
- Renal artery stenosis
- Renal or liver insufficiency
- Stressful lifestyle

Many of these factors demand very cautious use of antihypertensive drugs. Other cautions and contraindications include the use of these drugs in the elderly and those with chronic illnesses because of further compromise of the physical condition these patients due to uncontrolled or untreated hypertension or the adverse effects of antihypertensives (e.g., fluid loss, dehydration, electrolyte imbalances, hypotension). For a complete listing of adverse effects as well as drug interactions associated with antihypertensives, see the pharmacology section of this chapter.

Use of *alpha-adrenergic agonists* demands close assessment of the patient's blood pressure, pulse rate, and weight before and during treatment because of their strong vasodilating properties and subsequent hypotensive adverse effects. These drugs may also be associated with fluid retention and edema, so assess heart and breath sounds and intake and output, as well as dependent edema. The *alpha-adrenergic antagonists* need to be used cautiously because of the potential for hypotension-induced dizziness and syncope. The use of either of these groups of drugs requires close assessment of all parameters, especially in the elderly or other patients with preexisting dizziness or syncope, or a debilitated state. With doxazosin, first-dose orthostatic hypotension may occur within 2 to 6 hours; therefore, carefully assess blood pressures (supine and standing) and measure corresponding pulse rates before the first dose and 2 to 6 hours afterward, as well as with any subsequent increase in the dosage. When any antihypertensive drug is used, measure blood pressures and pulse rates (supine and standing), and assess for cautions, contraindications, and drug interactions. With *centrally acting alpha blockers,* also assess white blood cell counts, serum potassium and sodium levels and level of protein in the urine (to identify proteinuria). Note the route of administration specified in the drug order because of concerns associated with different routes. For example, with clonidine transdermal patches, assess the skin for rash, redness, drainage, or broken integrity prior to application.

Review the *beta blockers* and their mechanisms of action before administering these drugs to a patient because of the risk for complications in certain patient populations. If the drug is a nonselective beta blocker, it blocks both $beta_1$ and $beta_2$ receptors and will have both cardiac and respiratory effects, whereas if a drug is only a $beta_1$-blocking drug, the cardiac system will be affected (pulse rate and blood pressure will decrease) but there will be no $beta_2$ effects. This limits any concern regarding respiratory problems (e.g., bronchoconstriction). Therefore, if a patient needs a beta blocker but has restrictive airway problems, a $beta_1$ blocker is recommended (to avoid bronchoconstriction). If there is no history of respiratory illness or concerns, however, the nonselective beta blockers may be very effective as antihypertensives. In addition, for patients with heart failure, understand that beta blockers also have a negative inotropic effect on the heart (decreased contractility); their use would lead to worsening of heart failure, which calls for a completely different class of antihypertensive.

With the use of beta blockers, assess blood pressure and apical pulse rate immediately before each dose. If the systolic blood pressure is less than 90 mm Hg or the pulse rate is less than 60 beats/min, notify the prescriber because of the risk of adverse effects (e.g., hypotension, bradycardia). In such cases, the drug would usually be withheld, as ordered or per protocol. These blood pressure and pulse rate parameters are also applicable with use of other antihypertensives. Also assess breath sounds and heart sounds before and during drug therapy.

With the use of *ACE inhibitors,* assess blood pressure, apical pulse rate, and respiratory status (because of the adverse effect of a dry, hacking, chronic cough). Take blood pressure readings immediately before initial and subsequent doses of the drug so that extreme fluctuations may be identified early. Also assess serum potassium, sodium, and chloride levels as ordered. Tests of baseline cardiac functioning will most likely be ordered prior to initiation of therapy. Because of the potential adverse effects of neutropenia and other blood disorders, assess complete blood count before and during therapy, as ordered. *Angiotensin receptor blockers (ARBs)* are to be used very cautiously in elderly patients and in patients with renal dysfunction because of their increased sensitivity to the drug's effects and increased risk for adverse effects.

Perform a baseline neurologic assessment with the use of *vasodilators,* with attention to level of consciousness and cognitive ability. Use these drugs with extreme caution with the elderly, because they are more sensitive to the drugs' blood pressure–lowering effects and may experience more problems with hypotension, dizziness, and syncope.

In summary, many assessment parameters are similar for the various groups of antihypertensives. The difference in the level of assessment depends on the drug's impact on blood pressure as well as the individual's response to the medication and any preexisting illnesses or conditions. Other factors to be assessed in any patient receiving these drugs, as well as most other drugs, include the patient's cultural background, racial or ethnic group, reading level, learning needs, developmental and cognitive status, financial status, mental health status, available support systems, and overall physical health. Encourage patients to learn how to assess and monitor themselves and their individual responses to drug therapy.

PATIENT-CENTERED CARE: CULTURAL IMPLICATIONS

Antihypertensive Drug Therapy

The following are some important generalizations about demographics and the drugs used to treat hypertension:

- Beta blockers and angiotensin-converting enzyme (ACE) inhibitors have been found to be more effective in lowering blood pressure in whites than in African Americans.
- Calcium channel blockers and diuretics have been shown to be more effective in African-American patients than in white patients.
- Captopril, used as monotherapy to treat hypertension, has been found to elicit a lesser response in African-American patients, who are considered to be low-renin hypertensives, than in the general treatment population.
- Losartan, used as monotherapy for hypertension, has been found to be less effective in African-American patients than in other racial groups because African-American patients are low-renin hypertensives.

These findings are important to remember in the care of patients, whether they are in an inpatient setting; are being seen by a physician, physician's assistant, or nurse practitioner; or are being screened by a nurse in the community. The significance of these cultural-ethnic factors is that they allow a better understanding of the dynamics of pharmacologic treatment in hypertensive patients of different ethnic groups and also underscore the importance of a thorough nursing assessment that includes attention to cultural influences. These factors also allow an appreciation of individual responses to drug therapy and aid in achieving more successful treatment of the disease. These responses are often considered by health care providers in selecting first-line therapy.

Modified from Kelerman RD, Rakel RE: *Conn's current therapy 2010,* Philadelphia, 2010, St Louis: Elsevier.

NURSING DIAGNOSES

1. Ineffective peripheral tissue perfusion related to the impact of the hypertensive disease process and/or possible severe hypotensive adverse effects associated with antihypertensive drug therapy
2. Sexual dysfunction related to adverse effects of some antihypertensive drugs
3. Constipation related to the adverse effects of antihypertensive drugs
4. Noncompliance with drug therapy related to lack of familiarity with or acceptance of the disease process
5. Risk for injury (e.g., possible falls) related to possible antihypertensive drug–induced orthostatic hypotension with dizziness and syncope

PLANNING

Focus nursing goals for antihypertensive therapy on educating the patient, family, and/or caregiver about the critical importance of adequate management to prevent end-organ damage. Goals must include making sure the patient understands the nature of the disease, its symptoms and treatment, and the importance of adhering to the treatment regimen. The patient must also come to terms with the diagnosis as well as with the fact that there is no cure for the disease and treatment will be lifelong. Emphasize the influence of chronic illness and the

importance of nonpharmacologic therapy, stress reduction, and follow-up care. Plan for ongoing assessment of blood pressure, weight, diet, exercise, smoking habits, alcohol intake, compliance with therapy, and sexual function in the patient receiving therapy for hypertension.

GOALS

1. Patient regains control of hypertension with return of adequate tissue perfusion.
2. Patient experiences minimal changes in sexual functioning while managing adverse drug effects.
3. Patient experiences minimal changes in bowel elimination patterns.
4. Patient remains compliant with antihypertensive drug therapy.
5. Patient remains free from injury during drug therapy.

OUTCOME CRITERIA

1. Patient states the importance of taking antihypertensive drug therapy as prescribed to maintain normal to near-normal blood pressure control.
   - Patient regains control of hypertension with a return of blood pressure to below the ranges set by the Joint National Committee, such as a systolic blood pressure of 120 to 139 mm Hg and/or a diastolic blood pressure of 80 to 89 mm Hg.
   - Patient states the importance of keeping follow-up appointments with prescriber as well as monitoring blood pressure.
2. Patient openly discusses any difficulty in sexual functioning during antihypertensive therapy.
   - Patient implements suggestions/interventions as shared by the prescriber to assist in decreasing any problems with sexual function.
   - Patient states the importance of avoiding abrupt discontinuation of drug therapy with antihypertensives while experiencing changes in sexual functioning to avoid rebound hypertension and risk for complications.
3. Patient manages constipation with healthy lifestyle/dietary changes.
   - Patient implements forcing fluids (unless contraindicated), increasing dietary fiber with increase in fruits and vegetables, and/or taking prescriber-suggested psyllium-based product for improving constipation.
4. Patient demonstrates an understanding of the importance of taking antihypertensive medication(s) exactly as prescribed.
   - Patient reports to prescriber any adverse effects such as dizziness, syncope, excessive fatigue, constipation, and/or changes in sexual functioning while continuing medication regimen unless prescribed by health care provider.
   - Patient's blood pressure begins to return to a range as defined by the prescriber and the Joint National Committee.
5. Patient follows instructions to maintain safety and minimize dizziness and syncope while on medication regimen.
   - Patient changes position slowly, carefully, and purposely.
   - Patient keeps daily journal with entries about diet, exercise, adverse effects, blood pressure readings, and daily weights.

IMPLEMENTATION

Nursing interventions may help patients achieve stable blood pressure while minimizing adverse effects during treatment with antihypertensives. Many patients have problems complying with treatment because the disease itself is silent or without symptoms. Because of this, some patients are unaware of their increased blood pressure or think that if they do not feel bad there is nothing wrong with them, which poses many problems for treatment. Also, the antihypertensives are often associated with multiple adverse effects that may impact patients' self-concept and/or sexual integrity. These adverse effects may lead patients to abruptly stop taking the medication. Inform patients that any abrupt withdrawal is a serious concern because of the risk of developing rebound hypertension, which is a sudden and very high elevation of blood pressure. This places the patient at risk for a cerebrovascular accident or other cerebral or cardiac adverse events. It is important to understand that with *all* antihypertensives there is a risk of rebound hypertension (with abrupt withdrawal), and prevention of this through patient education is critical to patient safety. Other interventions related to each major group of drugs are discussed in the following paragraphs. See the Patient Teaching Tips for more information.

Because of the potential for drug-related orthostatic hypotensive effects, patients taking *alpha-adrenergic agonists* will need to monitor their blood pressure and pulse rate at home or have these parameters measured by a family member who has received instructions or by local fire department, rescue, or emergency medical personnel or health care provider. The blood pressure machines found in grocery stores do not provide as accurate readings as measurement in the aforementioned ways. *Alpha-adrenergic antagonist drugs* are associated with first-dose syncope, so, to avoid injury, advise patients to remain supine for the first dose of the drug. More than likely, these drugs will be prescribed to be given at bedtime to allow the patient to sleep through the drug's first-dose syncope. It may take 4 to 6 weeks for the drug to achieve its full therapeutic effects. Educate the patient about this delayed onset of action and bedtime dosing to avoid injury. The patient needs continued monitoring for dizziness, syncope, edema, and other adverse effects (e.g., shortness of breath, exacerbation of preexisting cardiac disorders). Diuretics may be ordered as adjunctive therapy to minimize the adverse effects of edema, but they may lead to more dizziness and electrolyte problems. *Centrally acting alpha blockers* require the same type of nursing interventions as other alpha blockers; however, as their name indicates, the mechanism of action of these drugs is central, so adverse effects are often more pronounced (e.g., hypotension, sedation, bradycardia, edema). See the Patient Teaching Tips for more information.

The *beta blockers* are either nonselective (block both $beta_1$ and $beta_2$ receptors; e.g., propranolol) or cardioselective (block mainly $beta_1$ receptors; e.g., atenolol). With any beta blocker, careful adherence to the drug regimen is critical to patient safety. Patients taking beta blockers may experience an exacerbation of respiratory diseases such as asthma, bronchospasm, and chronic obstructive pulmonary disease (because of increased bronchoconstriction due to $beta_2$ blocking) or an exacerbation of heart failure (because of the drug's negative inotropic effects, i.e., decreased contractility

due to $beta_1$ blocking). Provide clear and concise instructions about reporting adverse effects and instructions for taking blood pressure and pulse rates. If a $beta_1$ blocker causes shortness of breath, it is most likely due to edema and/or exacerbation of heart failure. Any dizziness, postural hypotension, edema, constipation, or sexual dysfunction needs to be reported to the prescriber immediately. See Patient Teaching Tips for more information.

ACE inhibitors must also be taken exactly as prescribed. If angioedema occurs, contact the prescriber immediately. If the drug must be discontinued, weaning is recommended (as with all antihypertensives) to avoid rebound hypertension. Monitor serum sodium and potassium levels during therapy. Serum potassium levels increase as an adverse effect of these drugs, resulting in hyperkalemia and possible complications. Impaired taste may occur as an adverse effect and last up to 2 to 3 months after the drug has been discontinued. It is also important to educate the patient that it takes several weeks to see the full therapeutic effects and that potassium supplements are not needed with the ACE inhibitors because of the adverse effect of hyperkalemia.

Angiotensin receptor blockers (ARBs) must also be taken exactly as prescribed. They are often tolerated best with meals, as with many antihypertensives. The dosage must not be changed nor the medication discontinued except on the order of the prescriber. With ARBs, if the patient has hypovolemia or hepatic dysfunction, the dosage may need to be reduced. A diuretic such as hydrochlorothiazide may be ordered in combination with an ARB for patients who have hypertension with left ventricular hypertrophy. Losartan is also an option for patients at risk for stroke and for those who are hypertensive and have left ventricular hypertrophy. Most importantly, with ARBs, report any unusual dyspnea, dizziness, or excessive fatigue to the prescriber immediately.

Nursing considerations for *vasodilators* are similar to those for other antihypertensives; however, the impact of the vasodilators on blood pressure may be more drastic, depending on the specific drug and dosage. Hydralazine given by injection may result in reduced blood pressure within 10 to 80 minutes after administration and requires that you closely monitor the patient. With hydralazine, systemic lupus erythematosus (SLE) may be an adverse effect if the patient is taking more than 200 mg/day orally. If signs and symptoms of SLE occur, such as photosensitivity, characteristic skin rashes, CNS changes, or various blood dyscrasias (hemolytic anemia, leukopenia, thrombocytopenia), discontinue the drug, contact the prescriber immediately, and continue to closely monitor the patient. Electrocardiographic changes, cardiovascular inadequacies, and hypotension may have pronounced effects on the patient's cardiac status, so *never* give the drug without adequate monitoring and frequent assessment. Always dilute sodium nitroprusside per manufacturer's guidelines. Because this drug is a potent vasodilator, it may lead to extreme decreases in the patient's blood pressure. Severe drops in blood pressure may lead to irreversible ischemic injury and even death, so close monitoring is needed during drug administration. Remember that sodium nitroprusside should never be infused at the maximum dose rate for more than 10 minutes. If this drug does not control a patient's blood pressure after 10 minutes, it will most likely be discontinued by the prescriber.

Cyanide ions are a by-product of nitroprusside metabolism. Cyanide and thiocyanate toxicity are seen clinically when nitroprusside is used at high dosages for long periods of time and/or in patients with renal insufficiency. When nitroprusside is combined with sodium thiosulfate, the potential for cyanide toxicity is greatly reduced. To help prevent complications of cyanide and thiocyanate toxicity, (1) dilute the medication properly and avoid use of any solution that has turned blue, green, or red; (2) infuse only with use of a volumetric infusion pump, not through ordinary intravenous sets; (3) continuously monitor blood pressure during the infusion (often by invasive measures); and (4) when more than 500 mcg/kg of sodium nitroprusside is administered at a rate faster than 2 mcg/kg/min, be aware that this may result in production of cyanide at a faster rate than it can be eliminated by the patient unaided (see the Safety: Laboratory Values Related to Drug Therapy box below).

SAFETY: LABORATORY VALUES RELATED TO DRUG THERAPY

Sodium Nitroprusside

LABORATORY TEST	NORMAL RANGES	RATIONALE FOR ASSESSMENT
Serum methemoglobin and serum cyanide levels	Normally there are no detectable amounts with appropriate drug levels of sodium nitroprusside.	Use of sodium nitroprusside may be associated with sequestration of hemoglobin as methemoglobin. The appearance of this clinically significant adverse effect of methemoglobinemia is rare (less than 10% of cases). Serum laboratory testing is used to measure the amount of methemoglobin. One significant clinical sign of this adverse effect is impaired oxygen delivery despite adequate cardiac output. When the sequestration is diagnosed, the treatment of choice is 1 to 2 mg/kg of methylene blue given intravenously over several minutes to allow binding of the metabolic by-product of cyanide to methemoglobin as cyanmethemoglobin, but this must be given only as ordered and with extreme caution. In addition, sodium nitroprusside may lead to toxic reactions, even at dosages that are within the recommended ranges. Toxic reactions are manifested by extreme hypotension, cyanide toxicity, or thiocyanate toxicity. Cyanide toxicity is manifested by severe hypotension. Cyanide assays are performed to detect cyanide in body fluids, but the results of this test are difficult to interpret and so it is not the most reliable method of monitoring. Other laboratory tests that may be helpful in diagnosing cyanide toxicity are alterations of acid-base balance and venous oxygen concentrations. Actual cyanide levels in the blood may lag behind peak cyanide levels by 1 hour or longer.

Calcium channel blockers (CCBs) and related nursing interventions are discussed only briefly here, because these drugs are covered in other chapters. Drugs like enalapril are to be taken exactly as prescribed with a warning to the patient not to puncture, open, or crush the extended-release or sustained-release tablets and capsules. Be aware that CCBs are negative inotropic drugs (decrease cardiac contractility), because this action may induce more signs of heart failure if these drugs are given with drugs that are used to increase cardiac contractility, such as digitalis glycosides. Monitoring of blood pressure and pulse rate before and during therapy will aid in prevention or early detection of any problems related to the negative inotropic effects, negative chronotropic effects (decreased heart rate), and negative dromotropic effects (decreased conduction).

Remember always to base nursing interventions on a thorough assessment and plan of care that also includes consideration of the patient's cultural and ethnic group. This is particularly important with antihypertensives, because research studies have documented differences in responses to antihypertensives among different racial and ethnic groups. Some ethnic groups respond less favorably to certain drugs than to others. As for patients with any disease, patients with hypertension must be treated with respect and with an appreciation for a holistic approach to health care in which all physical, psychosocial, and spiritual needs are taken into consideration (see the Patient-Centered Care: Cultural Implications box on p. 361). Remember also that patient education is of critical importance and plays an important role in ensuring adherence to the drug regimen and in decreasing the incidence of problems related to these medications.

EVALUATION

Because patients with hypertension are at high risk for cardiovascular injury, it is critical for them to adhere to both their pharmacologic and nonpharmacologic treatment regimens. Monitoring patients for the adverse effects (e.g., orthostatic hypotension, dizziness, fatigue) and toxic effects of the various types of antihypertensive drugs helps to identify potentially life-threatening complications. The most important aspect of the evaluation process is collecting data and monitoring patients for evidence of controlled blood pressure. Blood pressure must be maintained at values lower than the parameters established by the Joint National Committee or below the levels set by the Joint National Committee for "prehypertension," namely, a systolic blood pressure of 120 to 139 mm Hg and/or a diastolic blood pressure of 80 to 89 mm Hg. If compelling indications are present, such as diabetes mellitus or kidney disease, the blood pressure goal is often lower. Blood pressure needs to be monitored at periodic intervals. Patient education about self-monitoring is very important to the safe use of these drugs. Updated information on hypertension and its diagnosis, treatment, and evaluation is available at the National Heart, Lung, and Blood Institute website at www.nhlbi.nih.gov/guidelines/hypertension.

In addition to measuring blood pressure, the prescriber will examine the fundus of the patient's eye. Changes in the fundus have been found to be a more reliable indicator of the long-term effectiveness of treatment than blood pressure readings because of the changes in the vasculature of the eye caused by high blood pressure. Continually monitor the patient for the development of end-organ damage and for the presence of the specific problems that the medication can cause. Counsel and constantly

EVIDENCE-BASED PRACTICE

Storytelling to Improve Blood Pressure

Review

Is it possible that patient-to-patient storytelling, such as the use of narrative communication, has the benefit of lowering blood pressure? In this study of hypertensive black patients in Alabama, researchers identified a focus group of patients who were able to clearly and persuasively describe their experiences with hypertension. There were patients who were selected to serve as storytellers on DVDs and offer lessons about how to interact with physicians as well as discuss ways to better achieve medication adherence, diet, and exercise. The benefits of this intervention will be compared to that of the use of some antihypertensive medications.

Type of Evidence

There were 231 participants in the study. Participants were randomly selected to receive either the storytellers' DVDs or DVDs about general health issues that were totally unrelated to hypertension. The intervention patients spent an average of about 88 minutes watching the storytellers' DVDs.

Results of Study

Patients in both groups who had controlled hypertension at baseline were found to exhibit no significant changes in blood pressure 6 to 9 months after the intervention. However, in comparison, patients with uncontrolled hypertension at baseline were found to have significant reductions in mean blood pressure, a 15 mm Hg drop in systolic pressure (versus 3 mm Hg in the control group), and a 3 mm Hg drop in diastolic pressure (versus no change in the control group). In this randomized study, storytelling by black patients for use in black hypertensive patients achieved dramatic reductions in blood pressure (as stated above) as compared to the control groups.

Link of Evidence to Nursing Practice

For black patients with hypertension, it is important to note that the authors state "listeners may be influenced if they actively engage in a story, identify themselves with the storyteller and picture themselves taking part in the action." The authors go on to discuss the fact that the magnitude of the effect in this study with these participants was similar to the use of antihypertensive mediations for lowering blood pressure. The important connection to nursing practice is that this study can be replicated in a larger sample size of black patients, and, if the benefits are sustained over time, the intervention of storytelling would be a substantial achievement.

CASE STUDY

Drugs for Hypertension

Hypertension was diagnosed in G.S., who is 30 years old. Both her mother and sister have hypertension, and both were also in their thirties when it was diagnosed. G.'s most current blood pressure reading is 150/96 mm Hg, and for this reason the nurse practitioner has recommended therapy with captopril (Capoten), light exercise in the form of walking, and relaxation therapy. After 1 month of therapy, G.'s blood pressure is 145/86 mm Hg. Stress reduction has been the biggest obstacle in her treatment, because she is a lawyer with a prominent law firm and has found that her blood pressure is consistently elevated (160/100 mm Hg) whenever she measures it at work. At this follow-up visit, she is also given a prescription for a diuretic to help with her blood pressure control.

1. What type of diuretic was probably prescribed for G.S. at this time? Explain your answer.
2. What possible adverse effects does G. need to be aware of while taking captopril?
3. G. tells you that she uses an over-the-counter pain reliever for occasional headaches. What potential interaction is of concern?
4. G.S. states that she and her husband are planning to start a family in 1 year. What will you, as her nurse, tell her about pregnancy and therapy with these drugs?
5. What lifestyle changes would you, as her nurse, recommend that she make, and, even more important, what information would you give her to help her change her lifestyle and more effectively reduce the stress in her life?

For answers, see http://evolve.elsevier.com/Lilley.

monitor male patients receiving antihypertensives for complaints of sexual dysfunction. This is important because the patient may experience sexual dysfunction and, if the patient is not expecting it, may not report the problem and decide to stop taking the medication abruptly. Once an antihypertensive drug is stopped abruptly, the patient is then placed at high risk for rebound hypertension and possible stroke or other complications. Communication is critical in these situations. Follow-up visits to the prescriber are important for monitoring these and other adverse effects and checking patient adherence to the drug regimen.

Therapeutic effects of antihypertensives in general include an improvement in blood pressure and in the disease process. Other therapeutic effects include a return to a normal baseline level of blood pressure with improved energy levels and decreased signs and symptoms of hypertension, such as less edema, improved breath sounds, no abnormal heart sounds, capillary refill in less than 5 seconds, and less shortness of breath. Monitor for the adverse effects discussed in the pharmacology section of the chapter as well as those described for each group of drugs earlier in the Nursing Process section.

PATIENT TEACHING TIPS

Antihypertensives in General

- Medications are to be taken exactly as ordered with avoidance of doubling up or omitting doses.
- Successful therapy requires adherence to the medication regimen as well as to any dietary restrictions (e.g., decreasing consumption of fatty or high-cholesterol foods).
- The patient needs to monitor stress levels and use biofeedback, imagery, and/or relaxation techniques or massage, as needed. Exercise, if approved by the prescriber, may also help in the management of hypertension and serves to relieve stress; supervised, prescribed exercise is usually ordered.
- Emphasize the importance of safety and the need to avoid smoking and excessive alcohol intake as well as excessive exercise, hot climates, saunas, hot tubs, and hot environments. Heat may precipitate vasodilation and lead to worsening of hypotension with the risk of fainting and injury to self.
- Frequent laboratory tests may be needed for the duration of therapy; emphasize the importance of keeping follow-up appointments to the patient.
- All medications must be kept out of the reach of children because of the potential for extreme toxicity. If a transdermal patch is used, instruct the patient on how to periodically check on its placement. There have been cases in which a patch that was placed on an adult later fell off and was accidentally picked up on the skin of a crawling infant, with severe consequences.
- Encourage the patient to wear a medical alert bracelet or necklace and to carry a medical identification card specifying his or her diagnosis, noting allergies, and listing all medications taken (e.g., prescribed drugs, over-the-counter medications, herbals, vitamins, and supplements). The same information must be kept in a visible location in the patient's car as well as in the patient's home (i.e., on the refrigerator) for emergency medical personnel.
- Emphasize the importance of recording blood pressure readings (and orthostatic blood pressure readings) and daily weights in a journal. Daily weights are to be done each morning, before breakfast, at the same time, and with the same amount of clothing. The patient must report to the prescriber an increase in weight by 2 pounds or more over a 24-hour period or 5 pounds or more in 1 week.
- Assess the patient's ability and comfort level in taking his or her own blood pressure and pulse rate. Monitor the patient's progress in the proper technique.
- Encourage patient to inform all health care providers (e.g., dentist, surgeon) about his or her antihypertensive medication regimen.
- Careful, purposeful, and cautious changing of positions is encouraged because of the possible adverse effect of postural hypotension and associated risk for dizziness, lightheadedness, and possible fainting and falls.

PATIENT TEACHING TIPS—cont'd

- Instruct the patient to always keep an adequate supply of antihypertensive medications on hand, especially while traveling.
- Scheduling of periodic eye examinations is recommended every 6 months due to the need to evaluate treatment effectiveness because of the impact of hypertension on the vasculature of the eyes.
- With successful therapy, the patient's condition will improve; however, the patient must understand to never abruptly stop taking the medication just because he or she is feeling better. Lifelong therapy is usually required.
- Saliva substitutes, use of sugar-free hard candy/gum, and forcing fluids (unless contraindicated) may help with dry mouth. Forcing fluids and increasing dietary fiber may help with preventing constipation. Instruct the patient to contact the prescriber if constipation remains a problem.
- Sexual dysfunction may occur with antihypertensives, and so encourage the patient to be open in reporting and discussing any problems or concerns. Inform the patient that, if this adverse effect occurs, options are available to help alleviate the problem, such as combination therapy that allows lower dosages of drugs to be used, as well as a change to other types of antihypertensives. Always reinforce the fact that these medications are to never be abruptly stopped because of the risk of severe hypertensive rebound.
- Inform the patient that antihypertensives may lead to depression and to report any change in emotional status to the prescriber.

Alpha-Adrenergic Agonists

- First-dose syncope is associated with alpha adrenergic agonists, so patients need to avoid conditions/situations/drugs that would exacerbate this.
- Caution the patient to be careful at first with driving and other activities requiring alertness. The patient may have to postpone driving and other activities until the drug-related drowsiness subsides.
- Instruct the patient to report any dizziness, palpitations, and orthostatic hypotension to the prescriber immediately.
- Because centrally acting alpha blockers may also affect the patient's sexual functioning (e.g., causing impotence or decreased libido), inform the patient of these possible adverse effects and advise the patient to contact the prescriber if these effects are problematic. Other treatment options may be indicated.
- Transdermal patches of clonidine are to be applied to nonhairy areas of the skin as ordered, and application sites rotated. All residual drug on the skin must be cleansed with a washcloth soaked in lukewarm water and the area thoroughly dried (avoid excess rubbing of site) before applying a new patch.

Beta Blockers

- Encourage the patient to move and change positions slowly to avoid possible dizziness, fainting, and falls. Instruct the patient to report a pulse rate lower than 60 beats/min, dizziness, or a systolic blood pressure of 90 mm Hg or lower to the prescriber.
- Prolonged sitting or standing and excessive physical exercise may also lead to exacerbation of hypotensive effects, so counsel the patient to avoid these activities or counteract them with healthy practices such as pumping the feet up and down while sitting.
- Heat may also exacerbate hypotensive effects of the beta blocker. Educate patient to avoid saunas, hot tubs and excessive heat or syncope (fainting) may result.

KEY POINTS

- All antihypertensives in some way affect cardiac output. Cardiac output is the amount of blood ejected from the left ventricle and is measured in liters per minute.
- The major groups of antihypertensives are diuretics (see Chapter 28), alpha blockers, centrally acting alpha blockers, beta blockers, ACE inhibitors, vasodilators, CCBs, and ARBs.
- ACE inhibitors work by blocking a critical enzyme system responsible for the production of AII (angiotensin II; a potent vasoconstrictor). They (1) prevent vasoconstriction caused by AII, (2) prevent aldosterone secretion and therefore sodium and water resorption, and (3) prevent the breakdown of bradykinin (a potent vasodilator) by AII.
- ARBs work by blocking the binding of angiotensin at the receptors; the end result is a decrease in blood pressure.
- Calcium channel blockers may be used to treat angina, dysrhythmias, and hypertension and help to reduce blood pressure by causing smooth muscle relaxation and dilatation of blood vessels. If calcium is not present, then the smooth muscle of the blood vessels cannot contract.
- A thorough nursing assessment includes determining whether the patient has any underlying causes of hypertension, such as renal or liver dysfunction, a stressful lifestyle, Cushing's disease, Addison's disease, renal artery stenosis, peripheral vascular disease, or pheochromocytoma.
- Always assess for the presence of contraindications, cautions, and potential drug interactions before administering any of the antihypertensive drugs. Contraindications include a history of MI or chronic renal disease. Cautious use is recommended in patients with renal insufficiency or glaucoma. Drugs that interact with antihypertensive drugs include other antihypertensive drugs, anesthetics, and diuretics.
- Hypertension is managed by both pharmacologic and nonpharmacologic measures. Patients need to consume a diet low in fat, make any other necessary modifications in their diet (such as possibly decrease the intake of sodium and increase fiber intake), engage in regular supervised exercise, and reduce the amount of stress in their lives.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is administering antihypertensive drugs to older adult patients. The nurse knows that which adverse effect is of most concern for these patients?
   a Dry mouth
   b Hypotension
   c Restlessness
   d Constipation

2 When giving antihypertensive drugs, the nurse will consider giving the first dose at bedtime for which class of drugs?
   a Alpha blockers such as doxazosin (Cardura)
   b Diuretics such as furosemide (Lasix)
   c ACE inhibitors such as captopril (Capoten)
   d Vasodilators such as hydralazine (Apresoline)

3 A 56-year-old man started antihypertensive drug therapy 3 months earlier and is in the office for a follow-up visit. While the nurse is taking his blood pressure, he informs the nurse that he has had some problems with sexual intercourse. Which would be the most appropriate response by the nurse?
   a "Not to worry. Eventually, tolerance will develop."
   b "The physician can work with you on changing the dose and/or drugs."
   c "Sexual dysfunction happens with this therapy, and you will learn to accept it."
   d "This is an unusual occurrence, but it is important to stay on your medications."

4 When a patient is being taught about the potential adverse effects of an ACE inhibitor, which of these effects should the nurse mention as possibly occurring when this drug is taken to treat hypertension?
   a Diarrhea
   b Nausea
   c Dry, nonproductive cough
   d Sedation

5 A patient has a new prescription for an ACE inhibitor. During a review of the patient's list of current medications, which would cause concern for a possible interaction with this new prescription? (Select all that apply.)
   a A benzodiazepine taken as needed for allergies
   b A potassium supplement taken daily
   c An oral anticoagulant taken daily
   d An opioid used for occasional severe pain
   e An NSAID taken as needed for headaches

6 The order reads: Give hydralazine (Apresoline) 0.75 mg/kg/day. The child weighs 16 pounds. How much hydralazine will be given? Round to hundredths.

1. b, 2. a, 3. b, 4. c, 5. b, e, 6. 5.45 mg/kg/day

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Briefly describe the pathophysiology of myocardial ischemia and the subsequent occurrence of angina.
2 Describe the various factors that may precipitate angina as well as measures that decrease its occurrence.
3 Contrast the major classes of antianginal drugs (nitrates, calcium channel blockers, and beta blockers) with regard to their mechanisms of action, dosage forms, routes of administration, cautions, contraindications, drug interactions, adverse effects, patient tolerance, and toxicity.
4 Develop a nursing care plan incorporating all phases of the nursing process related to the administration of antianginal drugs.

DRUG PROFILES

amlodipine, p. 376
♦ **atenolol, p. 374**
♦ **diltiazem, p. 376**
♦ **isosorbide dinitrate, p. 371**
♦ **isosorbide mononitrate, p. 371**
♦ **metoprolol, p. 374**
♦ **nitroglycerin, p. 372**
ranolazine, p. 376

♦ *Key drug*

KEY TERMS

Angina pectoris Chest pain that occurs when the heart's supply of blood carrying oxygen is insufficient to meet the demands of the heart. (p. 369)

Atherosclerosis A common form of arteriosclerosis involving deposits of fatty, cholesterol-containing material (plaques) within arterial walls. (p. 369)

Chronic stable angina Chest pain that is primarily caused by atherosclerosis, which results in a long-term but relatively stable level of obstruction in one or more coronary arteries. (p. 369)

Coronary arteries Arteries that deliver oxygen to the heart muscle. (p. 369)

Coronary artery disease (CAD) Any one of the abnormal conditions that can affect the arteries of the heart and produce various pathologic effects, especially a reduced supply of oxygen and nutrients to the myocardium. (p. 369)

Ischemia Poor blood supply to an organ. (p. 369)

Ischemic heart disease Poor blood supply to the heart via the coronary arteries. (p. 369)

Myocardial infarction (MI) Necrosis of the myocardium following interruption of blood supply; it is almost always caused by atherosclerosis of the coronary arteries and is commonly called a *heart attack.* (p. 369)

KEY TERMS—cont'd

Reflex tachycardia A rapid heartbeat caused by a variety of autonomic nervous system effects, such as blood pressure changes, fever, or emotional stress. (p. 371)

Unstable angina Early stage of progressive coronary artery disease. (p. 369)

Vasospastic angina Ischemia-induced myocardial chest pain caused by spasms of the coronary arteries; also referred to as *Prinzmetal* or *variant angina.* (p. 369)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

The heart is a very efficient organ that pumps blood to all the tissues and organs of the body. It is very demanding in an aerobic sense because it requires a large supply of oxygen to meet the incredible demands placed on it. The heart's much-needed oxygen supply is delivered to the heart muscle by means of the **coronary arteries.** When the heart's supply of blood carrying oxygen and energy-rich nutrients is insufficient to meet the demands of the heart, the heart muscle (or myocardium) aches. This is called **angina pectoris,** or chest pain. Poor blood supply to an organ is referred to as **ischemia.** When the heart is involved, the condition is called **ischemic heart disease.**

Ischemic heart disease is the number-one killer in the United States today. The primary cause is a disease of the coronary arteries known as **atherosclerosis** (fatty plaque deposits in the arterial walls). When atherosclerotic plaques project from the walls into the lumens of these vessels, the vessels become narrow. The supply of oxygen and energy-rich nutrients needed for the heart to meet its demand is then decreased. This disorder is called **coronary artery disease (CAD).** An acute result of CAD and of ischemic heart disease is **myocardial infarction (MI),** or heart attack. An MI occurs when blood flow through the coronary arteries to the myocardium is completely blocked so that part of the heart muscle cannot receive any of the blood-borne nutrients (especially oxygen). If this process is not reversed immediately, that area of the heart will die and become necrotic (dead or nonfunctioning). Damage to a large enough area of the myocardium can be disabling or fatal.

The rate at which the heart pumps and the strength of each heartbeat (contractility) influence oxygen demands on the heart. There are many substances and situations that can increase heart rate and contractility and thus increase oxygen demand. These include caffeine, exercise, and stress, among others, and result in stimulation of the sympathetic nervous system, which leads to increased heart rate and contractility. In a patient with CAD who has an already overburdened heart, this stimulation can worsen the balance between myocardial oxygen supply and demand and result in angina. Some of the drugs used to treat angina are aimed at correcting the imbalance between myocardial oxygen supply and demand by decreasing heart rate and contractility.

The pain of angina is a result of the following process: Under ischemic conditions when the myocardium is deprived of oxygen, the heart shifts to anaerobic metabolism to meet its energy needs. One of the byproducts of anaerobic metabolism is lactic acid. Accumulation of lactic acid and other metabolic byproducts causes the pain receptors surrounding the heart to be stimulated, which produces the heart pain known as *angina.* This is the same pathophysiologic mechanism responsible for causing the soreness in skeletal muscles after vigorous exercise.

There are three classic types of chest pain, or angina pectoris. **Chronic stable angina** has atherosclerosis as its primary cause. *Classic angina* and *effort angina* are other names for it. Chronic stable angina can be triggered by exertion or other stress (e.g., cold, emotions). The nicotine in tobacco as well as alcohol, coffee, and other drugs that stimulate the sympathetic nervous system can also exacerbate it. The pain of chronic stable angina is commonly intense but subsides within 15 minutes of either rest or appropriate antianginal drug therapy. **Unstable angina** is usually the early stage of progressive coronary artery disease (CAD). It often ends in an MI in subsequent years. For this reason, unstable angina is also called *preinfarction angina.* Another term for this type of angina is *crescendo angina,* because the pain increases in severity, as does the frequency of attacks. In later stages, pain may even occur while the patient is at rest. **Vasospastic angina** results from spasms in the layer of smooth muscle that surrounds atherosclerotic coronary arteries. In contrast to chronic stable angina, this type of pain often occurs at rest and without any precipitating cause. It does seem to follow a regular pattern, however, usually occurring at the same time of day. This type of angina is also called *Prinzmetal angina* or *variant angina.* Dysrhythmias and electrocardiogram (ECG) changes often accompany these different types of anginal attacks.

PHARMACOLOGY OVERVIEW

The three main classes of drugs used to treat angina pectoris are the nitrates and nitrites, the beta blockers, and the calcium channel blockers (CCBs). Their various therapeutic effects are summarized and compared in Table 23-1. There are three main therapeutic objectives of antianginal drug therapy: (1) minimize the frequency of attacks and decrease the duration and intensity of the anginal pain; (2) improve the patient's functional capacity with as few adverse effects as possible; and (3) prevent or delay the worst possible outcome, myocardial infarction. The overall goal of antianginal drug therapy is to increase blood flow to ischemic myocardium, decrease myocardial oxygen demand, or both. Figure 23-1 illustrates how drug therapy works to alleviate angina. Evidence exists to suggest that drug therapy may be at least as effective as angioplasty in treating angina.

TABLE 23-1 ANTIANGINAL DRUGS: THERAPEUTIC EFFECTS

THERAPEUTIC EFFECT	NITRATES	BETA BLOCKERS*	AMLODIPINE	VERAPAMIL	DILTIAZEM
Supply					
Blood flow	↑↑	↑	↑↑↑	↑↑↑	↑↑↑
Duration of diastole	0	↑↑↑	0/↑	↑↑↑	↑↑
Demand					
Preload†	↓↓	↑	↓/0	0	0/↓
Afterload	↓	0/↓	↓↓↓	↓↓	↓↓
Contractility	0	↓↓↓	↓	↓↓↓	↓↓
Heart rate	0/↑	↓↓↓	0/↓	↓↓	↓↓

↑, Increase; ↓, decrease; 0, little or no effect.
*In particular, those that are cardioselective and do not have intrinsic sympathomimetic activity.
†Preload is pressure in the heart caused by blood volume. The nitrates effectively move part of this blood out of the heart and into blood vessels, thereby decreasing preload or filling pressure.

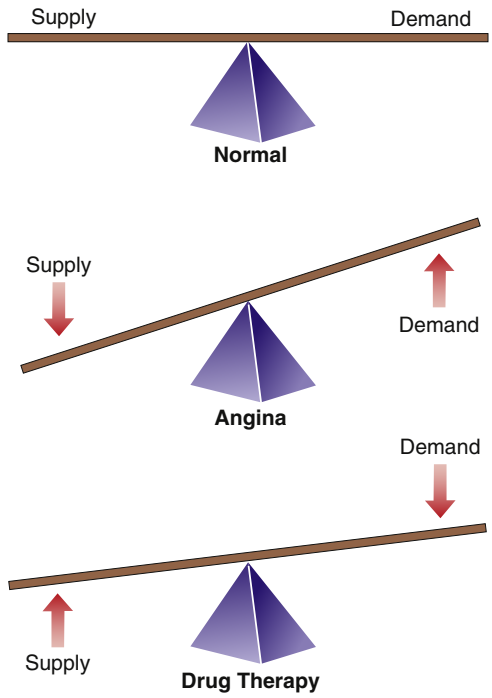

FIGURE 23-1 Benefit of drug therapy for angina through increasing oxygen supply and decreasing oxygen demands.

NITRATES AND NITRITES

Nitrates have long been the mainstay for both the prophylaxis and treatment for angina and other cardiac problems. Today there are several chemical derivatives of the early precursors, all of which are organic nitrate esters. They are available in a wide variety of preparations, including sublingual and oral tablets; capsules; ointments; patches; a translingual spray; and intravenous solutions. The following are the rapid- and long-acting nitrates available for clinical use:

- Amyl nitrite (rapid acting)
- Nitroglycerin (both rapid and long acting)
- Isosorbide dinitrate (both rapid and long acting)
- Isosorbide mononitrate (primarily long acting)

Mechanism of Action and Drug Effects

Medicinal nitrates and nitrites, more commonly referred to simply as *nitrates*, dilate all blood vessels. They predominantly affect venous vascular beds; however, they also have a dose-dependent arterial vasodilator effect. These vasodilatory effects are the result of relaxation of the smooth muscle cells that are part of the wall structure of veins and arteries. The nitrates have a potent dilating effect on the large and small coronary arteries. This causes redistribution of blood and oxygen to previously ischemic myocardial tissue and reduction of anginal symptoms. By causing venous dilation, the nitrates reduce venous return and, in turn, reduce the left ventricular end-diastolic volume (or preload), which results in a lower left ventricular pressure. Left ventricular systolic wall tension is thus reduced, as is myocardial oxygen demand. These and other drug effects are summarized in Table 23-1.

Coronary arteries that have been narrowed by atherosclerosis can still be dilated as long as smooth muscle surrounding the coronary artery and the atherosclerotic plaque does not completely obstruct the arterial lumen. Exercise-induced spasms in atherosclerotic coronary arteries can also be reversed or prevented by administration of nitrates, which encourages healthy physical activity in patients.

Indications

The nitrates are used to treat stable, unstable, and vasospastic (Prinzmetal) angina. Long-acting dosage forms are used more for prevention of anginal episodes. Rapid-acting dosage forms, most often sublingual nitroglycerin tablets, or an intravenous drip in the hospital setting, are used to treat acute anginal attacks.

Contraindications

Contraindications to the use of nitrates include known drug allergy, as well as severe anemia, closed-angle glaucoma, hypotension, and severe head injury. This is because the vasodilatory effects of nitrates can worsen these latter conditions. In anemia, a drug-induced hypotensive episode can further

compromise already reduced tissue oxygenation. Nitrates are also contraindicated with the use of the erectile dysfunction drugs sildenafil (Viagra), tadalafil (Cialis), and vardenafil (Levitra) (see Chapter 35).

Adverse Effects

Nitrates are well tolerated, and most adverse effects are usually transient and involve the cardiovascular system. The most common undesirable effect is headache, which generally diminishes soon after the start of therapy. Other cardiovascular effects include tachycardia and postural hypotension. If nitrate-induced vasodilation occurs too rapidly, the cardiovascular system overcompensates and increases the heart rate, a condition referred to as **reflex tachycardia.** This may occur with significant vasodilation that involves the systemic veins. There is a large shift in blood volume toward the systemic venous circulation and away from the heart. Baroreceptors (blood pressure receptors) in the heart then falsely sense that there has been a dramatic loss of blood volume. At this point, the heart begins beating more rapidly to move the apparently smaller volume of blood more quickly throughout the body, especially toward the vital organs (including the heart itself). However, the same baroreceptors soon sense that there has not been a loss of blood volume but that the volume of blood missing in the heart is now in the periphery (e.g., venous system), and the heart rate slows back to normal.

Topical nitrate dosage forms can produce various types of contact dermatitis (skin inflammation), but these are actually reactions to the dosage delivery system and not to the nitroglycerin itself; thus, it is not a true drug allergy. It is important for the nurse to document the type of allergic reaction, so that clinicians do not avoid this important drug class if the reaction is only a contact dermatitis.

Tolerance to the antianginal effects of nitrates can occur surprisingly quickly in some patients, especially those taking long-acting formulations or taking nitrates around the clock. In addition, cross-tolerance can arise when a patient receives more than one nitrate dosage form. To prevent this, a regular nitrate-free period is arranged to allow certain enzymatic pathways to replenish themselves. A common regimen with transdermal patches is to remove them at night for 8 hours and apply a new patch in the morning. This has been shown to prevent tolerance to the beneficial effects of nitrates. However, some studies have questioned the advisability of this practice.

Interactions

Nitrate antianginal drugs can produce additive hypotensive effects when taken in combination with alcohol, beta blockers, calcium channel blockers, phenothiazines, and erectile-dysfunction drugs such as sildenafil, tadalafil, and vardenafil. In fact, numerous deaths have been reported due to interactions with erectile-dysfunction drugs.

Dosages

The organic nitrates are available in an array of forms and doses. For dosage information, see the table on this page.

DOSAGES

Selected Antianginal Nitrate Coronary Vasodilators

DRUG (PREGNANCY CATEGORY)	USUAL DOSAGE RANGE	INDICATIONS
♦ isosorbide dinitrate (Isordil, Dilatrate-SR) (C)	**Adult** PO: 5-20 mg bid-tid and 40-80 mg at 8 AM and 2 PM for SR formulations	Angina
♦ isosorbide mononitrate (Imdur, Monoket) (C)	**Adult** PO: 20 mg bid given 7 hr apart and 30-120 mg/day for SR formulations (Imdur)	
♦ nitroglycerin (Nitro-Bid, Nitrostat, Nitrol, others) (C)	**Adult** IV (continuous infusion): 5-20 mcg/min Ointment, 2%: 1-2 inch ribbon q8h Spray: 1-2 sprays onto or under the tongue at onset of attack; repeat as needed to max of 3 sprays in 15 min Sublingual: 1 tab under the tongue at first sign of chest pain; if pain not relieved after 1 dose, call 911; may repeat up to 3 tablets Patch: 0.1 to 0.8 mg/hr applied once daily	

IV, Intravenous; *PO,* oral; *SL,* sublingual; *SR,* sustained release.

DRUG PROFILES

♦ isosorbide dinitrate

Isosorbide dinitrate (Isordil) is an organic nitrate. It exerts the same effects as the other nitrates. When isosorbide dinitrate is metabolized in the liver, it is broken down into two active metabolites, both of which have the same therapeutic actions as isosorbide dinitrate itself. This drug is available in rapid-acting sublingual tablets, immediate-release tablets, and long-acting oral dosage forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	Unknown	3-5 hr	4-6 hr

♦ isosorbide mononitrate

Isosorbide mononitrate (Imdur) is one of the two active metabolites of isosorbide dinitrate, but it has no active metabolites itself. Because of these qualities, it produces a more consistent, steady therapeutic response, with less variation in response within the same patient and between patients. It is available in both immediate- and sustained-release oral dosage forms but is most commonly used in the sustained-release form.

Pharmacokinetics (isosorbide mononitrate)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	15-30 min	0.5-1 hr	5 hr	5-12 hr

♦ nitroglycerin

Nitroglycerin is the prototypical nitrate and is manufactured by many pharmaceutical companies; therefore, it goes by many different trade names (e.g., Nitro-Bid, Nitrostat). It is often abbreviated as NTG or TNG. It has traditionally been the most important drug used in the symptomatic treatment of ischemic heart conditions such as angina. When given orally, nitroglycerin goes to the liver to be metabolized before it can become active in the body. During this process, a very large amount of the nitroglycerin is removed from the circulation. This is called a *large first-pass effect* (see Chapter 2). For this reason, nitroglycerin is administered by other routes to avoid the first-pass effect. Tablets administered by the sublingual route are used for the treatment of chest pain or angina of acute onset. They are also used for the prevention of angina when patients find themselves in situations likely to provoke an attack. Use of these routes is advantageous for relieving these acute conditions because the area under the tongue and inside the cheek is highly vascular. This means that the nitroglycerin is absorbed quickly and directly into the bloodstream, and hence its therapeutic effects occur rapidly. Sublingual nitroglycerin tablets must be stored in their original container, because exposure to air and moisture can inactivate the drug. Nitroglycerin also comes as a metered-dose aerosol that is sprayed under the tongue. Nitroglycerin is available in an intravenous form that is used for blood pressure control in hypertensive patients perioperatively; for the treatment of ischemic pain, heart failure, and pulmonary edema associated with acute MI; and in hypertensive emergency situations. Oral and topical dosage formulations are used for the long-term prophylactic management of angina pectoris. The topical formulation offers the same advantages as the sublingual formulation in that it also bypasses the liver and the first-pass effect. This formulation allows for the continuous slow delivery of nitroglycerin, so that a steady dose of nitroglycerin is supplied to the patient. See the Safety: Preventing Medication Errors box on p. 372.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Sublingual	2-3 min	Unknown	1-4 min	0.5-1 hr

BETA BLOCKERS

The beta-adrenergic blockers, more commonly referred to as *beta blockers,* have become the mainstay in the treatment of several cardiovascular diseases. These include angina, MI, hypertension (see Chapter 22), and dysrhythmias (see Chapter 25). Most available beta blockers demonstrate antianginal efficacy, although not all have been approved for this use. Those beta blockers approved as antianginal drugs are atenolol, metoprolol, nadolol, and propranolol.

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Understanding Rate Versus Dose

The Institute for Safe Medication Practices (ISMP) reported an incident in which a nitroglycerin intravenous drip was set to infuse at 60 mL/hr rather than 60 mcg/min. With the medication concentration used (50 mg/250 mL) the patient actually received 200 mcg/min instead of the ordered 60 mcg/min. Investigation of this incident revealed that the nurses were using a handwritten, nonstandard dosing table rather than one that corresponded to the available concentrations of premixed solutions in the hospital. According to the report, the patient became hypotensive but recovered.

It is crucial to understand the difference between "mL/hr" and "mcg/min" when programming infusion pumps; rates are not interchangeable with ordered doses! In addition, using standardized dosing charts that correspond to available concentrations of solutions is important. Some facilities also require double-checking of infusion pump settings before medication therapy is begun.

For more information, see Improvised dosing charts can cause errors, *Nurse Advise-ERR* 3(6):3, 2005, available at http://www.ismp.org/Newsletters/nursing/Issues/NurseAdviseERR200506.pdf.

Mechanism of Action and Drug Effects

The primary effects of the beta blockers are related to the cardiovascular system. As discussed in Chapters 19 and 22, the predominant beta-adrenergic receptors in the heart are the $beta_1$ receptors. $Beta_1$ receptors are located in the heart's conduction system and throughout the myocardium. The beta receptors are normally stimulated by the binding of the neurotransmitters epinephrine and norepinephrine. These catecholamines are released in greater quantities during times of exercise or other stress to stimulate the heart muscle to contract more strongly. At the normal heart rate of 60 to 80 beats/min, the heart spends 60% to 70% of its time in diastole. As the heart rate increases during stress or exercise, the heart spends more time in systole and less time in diastole. The physiologic consequence is that the coronary arteries receive increasingly less blood, and eventually the myocardium becomes ischemic.

In an ischemic heart, the increased oxygen demand from increasing contractility (systole) also leads to increasing degrees of ischemia and chest pain. The physiologic act of systole requires energy in the form of adenosine triphosphate (ATP) and oxygen. Therefore, any decrease in the energy demands on the heart is beneficial for alleviating conditions such as angina. When beta receptors are blocked by beta blockers, the rate at which the pacemaker (sinoatrial [SA] node) fires decreases, and the time it takes for the node to recover increases. The beta blockers also slow conduction through the atrioventricular (AV) node and reduce myocardial contractility (negative inotropic effect). Both of these effects serve to slow the heart rate (negative chronotropic effect). These effects reduce myocardial oxygen demand, which aids in the treatment of angina by reducing the workload of the heart. Slowing the heart rate is also beneficial in patients with ischemic heart disease, because the coronary arteries have more diastolic time to fill with

oxygen- and nutrient-rich blood and deliver these substances to the myocardial tissues.

The beta blockers also have many therapeutic effects after an MI. Following an MI, there is a high level of circulating catecholamines (norepinephrine and epinephrine). These catecholamines will produce harmful consequences if their actions go unopposed. They cause the heart rate to increase, which leads to a further imbalance in the supply-and-demand ratio, and they irritate the conduction system of the heart, which can result in potentially fatal dysrhythmias. The beta blockers block all of these harmful effects, and their use has been shown to improve the chances for survival in patients after MI. Unless strongly contraindicated, beta blockers are given to all patients in the acute stages after an MI.

The beta blockers also suppress the activity of the hormone renin, which is the first step in the renin-aldosterone-angiotensin system. Renin is a potent vasoconstrictor released by the kidneys when they sense that they are not being adequately perfused. When beta blockers inhibit the release of renin, blood vessels to and in the kidney dilate, causing reduced blood pressure (see Chapter 22).

Indications

The beta blockers are most effective in the treatment of exertional angina (i.e., that caused by exercise). This is because the usual physiologic effects of an increase in the heart rate and systolic blood pressure that occurs during exercise or stress are blunted by the beta blockers, thereby decreasing the myocardial oxygen demand. For an individual (often elderly) with significant angina, "exercise" may simply be carrying out the activities of daily living, such as bathing, dressing, cooking, or housekeeping. Performing such activities with significant angina can become a major stressor for these patients. The beta blockers are also approved for the treatment of MI, hypertension (see Chapter 22), cardiac dysrhythmias (see Chapter 25), and essential tremor. Some uses that are common but are not U.S. Food and Drug Administration (FDA) approved are treatment of migraine headache and, in low dosages, even treatment of the tachycardia associated with stage fright.

Contraindications

There are a number of contraindications to the use of beta blockers, including systolic heart failure and serious conduction disturbances, because of the effects of beta blockade on heart rate and myocardial contractility. These drugs should be used with caution in patients with bronchial asthma, because any level of blockade of $beta_2$ receptors can promote bronchoconstriction. These contraindications are relative rather than absolute and depend on patient-specific risks and expected benefits of this drug therapy. Other relative contraindications include diabetes mellitus (due to masking of hypoglycemia-induced tachycardia) and peripheral vascular disease (the drug may further compromise cerebral or peripheral blood flow).

Adverse Effects

The adverse effects of the beta blockers result from their ability to block beta-adrenergic receptors ($beta_1$ and $beta_2$ receptors) in various areas of the body. Blocking of $beta_1$ receptors may lead to a decrease in heart rate, cardiac output, and cardiac contractility. Blocking of $beta_2$ receptors may result in bronchoconstriction and increased airway resistance in patients with asthma or chronic obstructive pulmonary disease. Beta blockers may lead to cardiac rhythm problems, decreased SA and AV nodal conduction, a decrease in systolic and diastolic blood pressures, and possible peripheral receptor blockade and/or decreased renin release from the kidneys. Beta blockers can mask the tachycardia associated with hypoglycemia, and diabetic patients may not be able to tell when their blood sugar falls too low. Fatigue, insomnia, and weakness may occur because of the negative effects on the cardiac and central nervous systems. The beta blockers can also cause both hypoglycemia and hyperglycemia, which is of particular concern in diabetic patients. Other common beta blocker–related adverse effects are listed in Table 23-2.

TABLE 23-2 BETA BLOCKERS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Bradycardia, hypotension, atrioventricular block
Central nervous	Dizziness, fatigue, depression, lethargy
Metabolic	Hyperglycemia and/or hypoglycemia, hyperlipidemia
Other	Wheezing, dyspnea, impotence

TABLE 23-3 BETA BLOCKERS: COMMON DRUG INTERACTIONS

INTERACTING DRUG	MECHANISM	RESULT
Diuretics and antihypertensives	Additive effects	Hypotension
Calcium channel blockers (diltiazem, verapamil)	Additive atrioventricular node suppression	Hypotension, bradycardia, heart block
Insulin and oral antidiabetic drugs	Masking of hypoglycemic effects	Unrecognized hypoglycemia

Interactions

There are many important drug interactions that involve the beta blockers. The more common and important of these are listed in Table 23-3.

Dosages

For dosage information on selected beta blockers, see the table on p. 374.

DRUG PROFILES

Beta blockers are the mainstay in the treatment of a wide range of cardiovascular diseases, mainly hypertension, angina, and the acute stages of MI. The three most commonly used beta blockers are carvedilol, metoprolol, and atenolol. Carvedilol (Coreg) is not indicated for angina per se, but it is instead indicated for

DOSAGES

Selected Beta$_1$-Adrenergic–Blocking Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ atenolol (Tenormin) (C) ♦ metoprolol (Lopressor, Toprol-XL) (C)	Beta$_1$ blocker	**Adult** PO: 50-200 mg/day as a single dose **Adult** PO: 100-400 mg/day in 2 divided doses IV: 5 mg every 2 min × 3 doses, then PO therapy as indicated	Angina

IV, Intravenous; *PO,* oral.

heart failure, essential hypertension, and left ventricular dysfunction. The newest beta blocker, nebivolol (Bystolic), is used to treat hypertension. Atenolol, metoprolol, nadolol, and propranolol all are indicated for angina. The drug profile for carvedilol appears in Chapter 19 on p. 318.

♦ atenolol

Atenolol (Tenormin) is a cardioselective beta$_1$-adrenergic receptor blocker and is indicated for the prophylactic treatment of angina pectoris. Use of atenolol after MI has been shown to decrease mortality. It was formerly available in an injectable form, but it is now only available in oral form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	2-4 hr	6-7 hr	24 hr

♦ metoprolol

Metoprolol (Lopressor, Toprol-XL) is also a cardioselective beta$_1$-adrenergic receptor blocker that is used for the prophylactic treatment of angina and has many of the same characteristics as atenolol. It has shown similar efficacy in reducing mortality in patients after MI and in treating angina. It is available in both oral (immediate-release and long-acting) and parenteral (injectable) forms. Intravenous metoprolol is commonly administered to hospitalized patients after an MI and is used for treatment of hypertension in patients unable to take oral medicine.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	1 min	20 min	3-8 hr	5-8 hr
PO	1 hr	2-4 hr	3-8 hr	10-20 hr

CALCIUM CHANNEL BLOCKERS

There are three chemical classes of calcium channel blockers (CCBs): phenylalkylamines, benzothiazepines, and dihydropyridines, commonly represented by verapamil, diltiazem, and amlodipine, respectively (Table 23-4). Although they all block calcium channels, their chemical structures and therefore their mechanisms of action differ slightly. More than nine CCBs are available today. Those that are used for the treatment of chronic stable angina are amlodipine, diltiazem, nicardipine, nifedipine, and verapamil.

TABLE 23-4 CLASSIFICATION OF CALCIUM CHANNEL BLOCKERS

GENERIC NAME	TRADE NAME	AVAILABLE ROUTES
Benzothiazepines		
diltiazem	Cardizem, Dilacor, Tiazac, Dilacor XR, Cartia XT, Matzim LA, Taztia XT, Diltia XT	PO/IV
Dihydropyridines		
amlodipine	Norvasc	PO
felodipine	Plendil	PO
isradipine	DynaCirc	PO
nicardipine	Cardene	PO/IV
nifedipine	Adalat, Procardia	PO
nimodipine	Nimotop	PO
Phenylalkylamines		
verapamil	Calan, Isoptin, Verelan	PO/IV

IV, Intravenous; *PO,* oral.

Mechanism of Action and Drug Effects

Calcium plays an important role in the excitation-contraction coupling process that occurs in the heart and vascular smooth muscle cells, as well as in skeletal muscle. Preventing calcium from entering into this process prevents muscle contraction and promotes muscle relaxation. Relaxation of the smooth muscles that surround the coronary arteries causes them to dilate. This dilation increases blood flow to the ischemic heart, which in turn increases the oxygen supply and helps shift the supply/demand ratio back to normal. Dilation also occurs in the arteries throughout the body, which results in a decrease in the force (systemic vascular resistance) against which the heart must exert itself when delivering blood to the body

TABLE 23-5 CALCIUM CHANNEL BLOCKERS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Hypotension, palpitations, tachycardia or bradycardia
Gastrointestinal	Constipation, nausea
Other	Dyspnea, rash, flushing, peripheral edema

(afterload). Decreasing the afterload reduces the workload of the heart and therefore reduces myocardial oxygen demand. This is the primary beneficial antianginal effect of the dihydropyridine CCBs such as amlodipine and nifedipine. These drugs have a less negative inotropic effect than do verapamil and diltiazem.

Another cardiovascular effect of the CCBs is depression of the automaticity of and conduction through the SA and AV nodes. For this reason, they are useful in treating cardiac dysrhythmias (see Chapter 25). Finally, the CCBs reduce myocardial contractility and peripheral and coronary artery tone. Verapamil and diltiazem also decrease heart rate. Their strongest antianginal properties are secondary to their effects on myocardial contractility and the smooth muscle tone of peripheral and coronary arteries.

Indications

The therapeutic benefits of the CCBs are numerous. Because of their very acceptable adverse effect and safety profiles, they are considered first-line drugs for the treatment of such conditions as angina, hypertension, and supraventricular tachycardia. They are often effective for the treatment of coronary artery spasms (vasospastic or Prinzmetal angina). However, they may not be as effective as the beta blockers in blunting exercise-induced elevations in heart rate and blood pressure. CCBs are also used for the short-term management of atrial fibrillation and flutter (see Chapter 25), migraine headaches (see Chapter 13), and Raynaud's disease (a type of peripheral vascular disease). The dihydropyridine CCB nimodipine is indicated solely for cerebral artery spasms associated with aneurysm rupture.

Contraindications

Contraindications include known drug allergy, acute MI, second- or third-degree AV block (unless the patient has a pacemaker), and hypotension.

Adverse Effects

The adverse effects of the CCBs are limited and primarily relate to overexpression of their therapeutic effects. The most common adverse effects are listed in Table 23-5. Historically, immediate-release nifedipine was used to lower blood pressure in acute hypertensive emergencies (the capsule was punctured and given sublingually). However, negative outcomes were reported with the rapid, dramatic reduction in blood pressure. For this reason, only the extended-release form of nifedipine is used today. (The exception is the use of immediate-release nifedipine for the treatment of premature labor.) Medication errors have occurred when a nurse drew up the contents of the capsule to be given sublingually, but inadvertently gave it intravenously. For this reason, the Institute for Safe Medication Practice recommends that the contents be drawn up into an oral syringe by the pharmacy.

TABLE 23-6 CALCIUM CHANNEL BLOCKERS: COMMON DRUG INTERACTIONS

INTERACTING DRUG	MECHANISM	RESULT
Beta blockers	Additive effects	Bradycardia and atrioventricular block
digoxin	Interference with drug elimination	Possible increased digoxin levels
amiodarone	Decreased metabolism	Bradycardia and decreased cardiac output
Azole antifungals, clarithromycin, erythromycin, HIV drugs	Decreased metabolism	Elevated levels and effects of calcium channel blockers
Statins	Inhibited statin metabolism	Increased risk of statin toxicity
cyclosporine	Decreased metabolism of either drug	Possible toxicity of either drug

Interactions

Important drug interactions are listed in Table 23-6. A particular food interaction of note is the interaction with grapefruit juice, which can reduce the metabolism of the CCBs, especially nifedipine.

Dosages

For dosage information on selected CCBs, see the table below.

DOSAGES

Selected Calcium Channel–Blocking Drugs

DRUG (PREGNANCY CATEGORY)	USUAL DOSAGE RANGE	INDICATIONS
amlodipine (Norvasc) (C)	**Adult** PO: 5-10 mg/day	Angina
♦ diltiazem (Cardizem, Dilacor XR, Tiazac, Cartia XT, Diltia XT, Matzim LA, Taztia XT) (C)	**Adult** PO: Initial dose 30 mg qid before meals and at bedtime; range of 180-360 mg divided in 3-4 doses, or 1 daily for extended-release capsule; dosages of 480 mg/day may be needed	

PO, Oral.

DRUG PROFILES

♦ diltiazem

Diltiazem (Cardizem, Dilacor, Tiazac) is the only benzothiazepine CCB. It has a particular affinity for the cardiac conduction system and is very effective for the treatment of angina pectoris resulting from coronary insufficiency and hypertension. It is one of the few CCBs that are also available in parenteral form, for which it is used in the treatment of atrial fibrillation and flutter along with paroxysmal supraventricular tachycardia (see Chapter 25). Verapamil is another CCB with similar indications. Several sustained-delivery formulations of diltiazem are available, which can be confused with each other. For example, there is Cardizem SR, which is taken twice a day, and Cardizem CD, which is taken once a day. In addition to other brands of these two dosage forms, the drug is also available in several strengths of immediate-release capsule as well as in intravenous form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	0.5-1 hr	2-3 hr	3.5-9 hr	4-12 hr

amlodipine

Amlodipine (Norvasc) is currently the most popular CCB of the dihydropyridine subclass. It is indicated for both angina and hypertension and is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-50 min	6-12 hr	30-50 hr	24 hr

MISCELLANEOUS ANTIANGINAL DRUG

DRUG PROFILE

ranolazine

Ranolazine (Ranexa) is the newest antianginal drug, approved by the FDA in 2006 for chronic angina. Its mechanism of action is unknown. Unlike other antianginal drugs, its antianginal and antiischemic effects do not involve reductions in heart rate or blood pressure. Ranolazine is known to prolong the QT interval on the ECG. For this reason, this drug is reserved for patients who have failed to benefit from other antianginal drug therapy. In fact, ranolazine is contraindicated in patients with preexisting QT prolongation or hepatic impairment, in those taking other QT-prolonging drugs (see Chapter 25), and in patients taking moderately potent cytochrome P-450 enzyme 3A4 inhibitors such as diltiazem. Other significant drug interactions include interactions with ketoconazole and verapamil, both of which can raise ranolazine levels. Ranolazine can also raise digoxin levels. The usual dose of ranolazine is 500 mg orally twice daily, which may be advanced to 1000 mg orally twice daily based on clinical symptoms. The drug is available only for oral use.

SUMMARY OF ANTIANGINAL PHARMACOLOGY

In patients with coronary artery disease, clinical symptoms result from a lack of or inadequate delivery of blood carrying oxygen and nutrients to the heart, which results in ischemic heart disease. Antianginal drugs such as nitrates, nitrites, beta blockers, and calcium channel blockers are used to reduce ischemia by increasing the delivery of oxygen-rich blood to cardiac tissues or by reducing oxygen consumption by the coronary vessels. Either of these mechanisms can reduce ischemia and lead to a decrease in anginal pain. Nitrates and nitrites work mainly by decreasing venous return to the heart (preload) and decreasing systemic vascular resistance (afterload). Calcium channel blockers decrease calcium influx into the smooth muscle, causing vascular relaxation. This either reverses or prevents the spasms of coronary vessels that cause the anginal pain associated with Prinzmetal or chronic angina. Beta blockers help by slowing the heart rate and decreasing contractility, thereby decreasing oxygen demands. Although these groups of drugs have similar clinical effects, the nursing process required for each is somewhat specific because of the characteristics and effects of the drugs and the indications for and contraindications to their use.

TEAMWORK AND COLLABORATION: PHARMACOKINETIC BRIDGE TO NURSING PRACTICE

Not only are the pharmacokinetic properties of the nitrates very interesting, but knowledge of these specific properties is critical to safe and accurate nursing care. Moreover, the patient's understanding of nitrate pharmacokinetics is important because the level of the patient's knowledge may strongly influence adherence to the drug regimen and the effectiveness of treatment for angina. The pharmacokinetics differ for the various dosage forms of nitroglycerin and include the following:

Intravenous infusion: Onset of action 1 to 2 minutes (fastest of all dosage forms), peak action not applicable, duration of action 3 to 5 minutes

Sublingual tablet: Onset of action 2 to 3 minutes, peak action unknown, duration of action 0.5 to 1 hour

Immediate-release tablet: Onset of action 1 hour, peak action unknown, duration of action 4 to 6 hours

Transdermal patch: Onset 30 to 60 minutes, peak action 1 to 3 hours, duration of action 8 to 12 hours

If the goal of treatment is to abort or treat a sudden attack of angina, then *rapid* onset of action is needed, so the clinical decision (by the prescriber) would be to order either intravenous infusion, sublingual tablet, and/or translingual spray, which has a similar onset time. These dosage forms have pharmacokinetics that allow quick entry of the drug into the bloodstream and lead to more rapid vasodilation. This provides more oxygenated blood to the myocardium and aborts acute attacks. If symptoms persist, more drastic medical management would be indicated. The quick-onset nitroglycerin dosage forms may also be used by the patient before engaging in activities known to provoke angina, such as increased physical activity, sexual intercourse, or other forms of physical exertion. If the purpose of treatment is maintenance therapy, the nitrate form must have other pharmacokinetic properties, such as a longer duration of action to provide protection against angina; a longer onset of action is acceptable because stopping an attack is not needed in this situation. Use of ointments, transdermal patches, or extended-release preparations would be appropriate in such cases. If an acute episode of angina occurs while the patient is taking maintenance therapy, a dosage form with a rapid onset of action is indicated (as ordered). It is easy to see that thorough knowledge of a drug and its pharmacokinetics allows for safe and sound decisions about drug therapy for patients with angina.

NURSING PROCESS

ASSESSMENT

Before *antianginal* drugs are administered, obtain a thorough past and present medical-health history and medication history (e.g., listing of all prescription drugs, over-the-counter products, herbals, vitamins, and supplements being taken) and document the findings. Also measure weight, height, and vital signs, with attention to supine, sitting, and standing blood pressures. Report a systolic blood pressure reading of less than 90 mm Hg to the prescriber before administering a dose of any of these drugs. With use of any drugs affecting blood pressure or pulse rate, such as antianginals, take the apical pulse rate for 1 full minute. If the pulse rate is 60 beats/min or less or 100 beats/min or greater (reflex tachycardia is an adverse effect), contact the prescriber for further instructions. In addition to rate, assess the quality and rhythm of the heartbeat and document prior to the administration of antianginal drugs. If the patient is experiencing any chest pain, include in your assessment description of onset, character (e.g., sharp, dull, piercing, squeezing, radiating), intensity, location, duration, precipitating factors (e.g., physical exertion, exercise, eating, stress, sexual intercourse), alleviating factors, and presence of nausea or vomiting. The prescriber may order an ECG, and you must review these results as well. Thoroughly assess for any contraindications, cautions, and drug interactions prior to giving these drugs. Significant interactions include alcohol, beta blockers, calcium channel blockers, phenothiazines, and erectile-dysfunction drugs such as sildenafil, tadalafil, and vardenafil. Taking these drugs with nitrates will result in worsening of hypotensive responses, paradoxical bradycardia, and a resultant increase in angina with subsequent significant risk of cardiac or cerebrovascular complications due to the decreased perfusion. Elderly patients often have difficulty with blood pressure control because of the occurrence of normal age-related periods of hypotension, and the use of antianginals may lead to worsening of hypotensive responses. If patients are taking nitrates on a long-term basis, it is important to assess continued therapeutic responses because of the development of tolerance to the drug's effects. During assessment and initiation of drug therapy, it is critical to patient safety to notify the prescriber of any increased angina, because another antianginal or vasodilating drug may be needed.

Concerns arise with the use of *nonselective beta blockers* and *beta$_2$ blockers* (as vasodilators) in patients with bronchospastic disease because of the drug-related effects of bronchoconstriction and increased airway resistance, which results in wheezing and dyspnea as adverse effects. Therefore, if asthma or other respiratory problems are present, beta blockers would not be indicated because bronchoconstriction could be exacerbated. In addition, there are also concerns about the use of beta blockers in patients with peripheral vascular disease, hypotension, hyperglycemia or hypoglycemia (see pharmacology discussion), and bradycardia. Nonselective beta blockers may also exacerbate preexisting heart failure. Assessment for edema is important in patients with cardiac risk factors and a weight gain of 2 pounds or more in 24 hours or 5 pounds or more in 1 week. This weight gain is to be reported to the prescriber immediately. Assess for significant drug interactions, including the concurrent use of other antihypertensives, calcium channel blockers, and oral antidiabetic drugs (see Table 23-3 for more information).

In patients taking *calcium channel blockers* (CCBs), assess for possible drug-food interactions, including grapefruit. Grapefruit juice reduces the metabolism of nifedipine, leading to possible toxicity; grapefruit must be avoided. Another area to be thoroughly assessed is that of the dosage form of nifedipine, which is available in extended and immediate-release forms. Therefore, follow the orders for administration of nifedipine carefully, and closely monitor the patient (e.g., vital signs). Diltiazem (Cardizem) is available in several sustained-delivery forms; closely assess the order to avoid medication error. Cautious use is important in patients with a history of hypotension, palpitations, tachycardia/bradycardia, constipation, dyspnea, and edema. Significant drug interactions are included in Table 23-6.

Assess patients taking *ranolazine (Ranexa),* one of the newest antianginal drugs, for liver dysfunction through specific liver function testing prior to taking the medication. Additionally, assess for other medications the patient is taking, with an emphasis on medications that prolong the QT interval for which an EKG may also be ordered. Other medications to be concerned about include those that inhibit cytochrome P450, such as diltiazem.

NURSING DIAGNOSES

1. Decreased cardiac output related to the pathology of coronary artery disease
2. Deficient knowledge related to first-time use of antianginal drugs and a new diagnosis of coronary artery disease
3. Risk for injury to self related to possible adverse drug effect of hypotension with subsequent dizziness and/or syncope/falls

PLANNING

GOALS

1. Patient exhibits therapeutic effects of antianginal drug therapy, such as improved cardiac output, with fewer episodes of chest pain.
2. Patient demonstrates increased knowledge about disease process and drug therapy.
3. Patient remains free from injury while receiving antianginal drug therapy.

OUTCOME CRITERIA

1. Patient states that there are more frequent periods of comfort while carrying out activities of daily living, engaging in supervised exercise, and performing moderate activity, without recurring angina and without major adverse effects on follow-up with the prescriber.
   - Patient experiences fewer episodes to no episodes of chest pain (angina).

CASE STUDY

Nitroglycerin for Angina

M.S., a 68-year-old accountant, has been diagnosed with coronary artery disease (CAD) after experiencing chest pain at times when he jogs. After undergoing a thorough physical examination, including cardiac catheterization, he is given a prescription for extended-release nitroglycerin capsules, 6.5 mg, three times a day. He also has a prescription for 0.4-mg sublingual nitroglycerin tablets to take as needed for chest pain.

1. What type of angina is M.S. experiencing, and what are the therapeutic goals of the drug therapy he has received?

M.S. asks you, "Why do I have two prescriptions for the same drug? It doesn't make sense to me!"

2. What is the best answer to his question?
3. Two days after he begins the nitroglycerin, M.S. calls the office and says, "I'm having awful headaches. What is wrong?" What is the best explanation, and what can he do about the headaches?

After 1 month, M.S. is switched from the extended-release capsules to a transdermal nitroglycerin patch. He says that he is glad he does not have to remember to "take those pills" three times a day. However, 2 months later, he calls and says, "I don't think this patch is working. I'm having more episodes of chest pain now when I jog."

4. What could be the explanation for this, and what can be done?

For answers, see http://evolve.elsevier.com/Lilley

2. Patient states rationale for antianginal drug therapy and importance of taking medication exactly as prescribed.
   - Patient states adverse effects of antianginal drug therapy, such as postural hypotension, dizziness, and severe headache, as well as measures to decrease their occurrence.
   - Patient states appropriate time frame of when to seek out emergency care (i.e., no relief after 1 dose of sublingual nitrates) and call 911.
3. Patient states measures to decrease risk for injury, such as changing positions slowly, keeping legs moving when in a still position, increasing fluid intake with medication regimen, and removing rugs or carpets that can cause tripping or slipping.

IMPLEMENTATION

Always review and/or record the patient's vital signs and description of chest pain for the duration of therapy. Take into account the following considerations associated with the use of the various dosage forms and routes of administration: (1) *For any dosage form:* Administer the drug while the patient is seated to avoid falls or injury from drug-induced hypotension. This hypotension may last for up to 30 minutes after dosing of the drug. When administering nitrates, monitor the patient's chest pain, and have the patient rate the pain on a scale of 1 to 10 before, during, and after therapy. Monitor the patient's response to drug therapy by measuring the patient's blood pressure and pulse rate and assessing for the presence of headache, dizziness, and/or lightheadedness. When the patient is in a supine position, an appropriate dose of a nitrate will produce a clinical response of a fall in blood pressure of about 10 mm Hg and/or a rise in heart rate of 10 beats/min. However, the following parameters are alerts that there may be a problem with the patient and to contact the prescriber: a systolic blood pressure of 90 mm Hg or less and/or a pulse rate of 60 beats/min or less or a pulse rate greater than 100 beats/min. (2) *For oral dosage forms:* Counsel the patient that these forms are to be taken as ordered before meals and with 6 oz of water. Extended-release preparations must not be crushed, chewed, or altered in any way. Acetaminophen may be given if there is a drug-related headache and if not contraindicated. (3) *For sublingual forms:* Advise the patient to place the tablet under the tongue as directed and *not* to swallow until the drug is completely dissolved. Metered-dose aerosol sprays are applied onto or under the tongue (see Dosages table). Instruct the patient to keep nitrates in their original packaging or container (e.g., sublingual tablets come in a small amber-colored glass container with a metal lid). Exposure to light, plastic, cotton filler, and moisture must be avoided. (4) *For ointment:* Use the proper dosing paper supplied by the drug company to apply a thin layer on clean, dry, hairless skin of the upper arms or body. Avoid areas below the knees and elbows. Do not apply the ointment with the fingers unless a glove is worn to avoid contact with the skin and subsequent absorption. A tongue depressor may also be used, but in most situations the ointment may be squeezed directly from the tube onto the proper dosing paper. Once the ointment is in place, do *not* rub it into the skin; cover the area with an occlusive dressing if not provided (e.g., plastic wrap). Rotate application sites, and remove all residual from the previous dose of ointment gently with soap and water and pat the area dry. (5) *For transdermal forms:* Apply patches to a clean, residue-free, hairless area, and rotate sites. If cardioversion or use of an automated electrical defibrillator is required, remove the transdermal patch to avoid burning of the skin and damage to the defibrillator paddles. Before a new patch is applied, locate and remove the old patch and clean the skin of any residual drug. Carefully dispose of used, unneeded, or defective transdermal patches of any medication as indicated by hospital policy or per discharge instructions. It is important to follow any packaging insert instructions and/or facility policy because transdermal patches delivering potent medications need to be flushed down the toilet to avoid possible contact of residual drug by babies, children, pets and even adults (see Chapter 2). For more information visit www.fda.gov/downloads/Drugs/ResourcesForYou/Consumers/BuyingUsingMedicineSafely/UnderstandingOver-the-CounterMedicines/ucm107163 or www.ismp.org. (6) *For intravenous forms:* Intravenous dosing is for use in

emergency situations only and in settings that provide close automatic monitoring of the blood pressure and pulse as well as constant ECG monitoring. Intravenous administration of nitrates may lead to sudden and severe hypotension, cardiovascular collapse, and shock. Always check for incompatibilities and the proper diluent. Only give intravenous solutions through an infusion pump and as ordered. Intravenous dosage forms are available as ready-to-use injectable doses and are administered using *specific nonpolyvinylchloride* (non-PVC) plastic intravenous bags and tubing. The non-PVC infusion kits are used to avoid absorption or uptake of the nitrate by the intravenous tubing and bag. This prevents decomposition of the nitrate with breakdown into cyanide when the drug is exposed to light. Intravenous forms of nitroglycerin are stable for about 96 hours after preparation. If parenteral solutions are not clear and are discolored, discard the solution.

With *isosorbide,* tablets are best taken on an empty stomach; however, if the patient complains of headache or gastrointestinal upset, the medicine needs to be taken with meals. Oral tablets of isosorbide can be crushed; however, the sublingual and extended-release forms are *not* to be crushed or chewed. As with sublingual nitroglycerin, instruct the patient not to swallow the medication until it is completely dissolved. If dizziness or lightheadedness occurs, assist the patient and encourage him or her to change positions slowly. Closely monitor the patient's blood pressure, including orthostatic blood pressures. Document the occurrence of anginal episodes, their character, precipitating factors, severity, and frequency noted.

Beta blockers need to be given as ordered and may be taken with or without food. Abrupt withdrawal must be avoided. Daily weights need to be measured every day at the same time and with the patient wearing the same amount of clothing. If there is a weight gain of 2 pounds or more in 24 hours or 5 pounds or more in 1 week, contact the prescriber immediately. When these drugs are used, take measures to reduce the incidence of orthostatic hypotension, such as advising the patient to dangle the legs on the side of the bed before standing and to move slowly and purposefully. Instruct the patient to contact the prescriber immediately if any excessive or intolerable dizziness, fatigue/lethargy, wheezing, or dyspnea occurs (see Chapter 19 for further discussion).

Calcium channel blockers (CCBs) are to be taken as ordered and without sudden withdrawal. Abrupt withdrawal can precipitate rebound hypertension and worsening of tissue ischemia. Weight needs to be measured daily (see later discussion). Constantly monitor the patient for edema and shortness of breath. Instruct the patient to move and change positions slowly and cautiously to prevent syncope. Constipation may be prevented by increasing fluids and fiber in the diet. If the patient experiences palpitations, pronounced dizziness, nausea, or dyspnea, contact the prescriber immediately. Intravenous administration of any CCB requires the use of an infusion pump and careful monitoring (see Chapter 25).

Patients taking any of the vasodilators must avoid alcohol, saunas, hot tubs, hot showers, and hot weather or a hot environment. These conditions will exacerbate vasodilation and increase the occurrence of orthostatic hypotension, increasing the risk for dizziness, syncope, and falls. Caution the patient that with certain sustained-release forms of medication, the wax matrix may appear in the stool. Advise patients that the passing of the wax matrix occurs after the drug has been absorbed and that, even though the matrix is visible, it is of no concern. Instruct the patient on how to self-monitor blood pressure and pulse rate, as well as how to document the findings in a journal so that the information can be shared with health care providers. The journal can also list daily weights, response to the medication regimen, and any adverse effects. See the Patient Teaching Tips for more information.

EVALUATION

Carefully monitor patients taking antianginals for the occurrence of an allergic reaction, which may be manifested by dyspnea, swelling of the face, or hives. Include in your evaluation a review for accomplishment of goals and outcomes, such as appropriate decrease in blood pressure, increase in cardiac output and tissue perfusion with decrease in angina, and a gradual increase in activity and performance of activities of daily living without exacerbation of anginal episodes. In addition, monitor the patient for adverse reactions such as headache, lightheadedness, dizziness, and decreased blood pressure, which may indicate the need to decrease the dosage. If the patient is receiving intravenous nitroglycerin, evaluate for excessive drops in blood pressure, worsening of angina, and significant changes in pulse rate (less than 60 beats/min or greater than100 beats/min), and contact the prescriber immediately.

PATIENT TEACHING TIPS

Nitroglycerin

- Emphasize to the patient the importance of keeping a daily journal with documentation of how he or she feels and number of anginal episodes, noting their intensity, frequency, duration, and character, as well as precipitating and/or relieving factors. Any evidence of possible tolerance to the medication is important to note and report to the prescriber.
- *Capsules* or *extended-release* dosage forms are never to be chewed, crushed, or altered in any way.
- Instruct the patient taking *aerosol* (spray) dosage forms not to shake the canister before lingual spraying and to avoid inhaling or swallowing the lingual aerosol until the drug is dispersed. With *sublingual* forms, the medication must be taken at the first sign of chest pain and not delayed until the pain is severe. The patient needs to sit or lie down and take one sublingual tablet. According to current guidelines, if the chest pain or discomfort is not relieved in 5 minutes, after *one* dose, the patient (or family member) must call 911 immediately. The patient can take one more tablet while awaiting

PATIENT TEACHING TIPS—cont'd

emergency care and a third tablet 5 minutes later, but no more than three tablets total. These guidelines reflect the fact that angina pain that does not respond to nitroglycerin may indicate a myocardial infarction. The sublingual dose is to be placed under the tongue and the patient must avoid swallowing until the tablet is dissolved. Instruct the patient not to eat or drink until the drug has completely dissolved.

- Educate the patient about the best place to store the medication, such as keeping medicine away from moisture, light, heat, and cotton filler material. The *sublingual* dosage form of nitroglycerin needs to be kept in its original amber-colored glass container with metal lid to avoid loss of potency from exposure to heat, light, moisture, and cotton filler.
- Potency of the sublingual nitroglycerin is noted if there is burning or stinging once the medication is placed under the tongue; if the medication does not burn, then the drug has lost its potency, and a new prescription must be obtained.
- It is important to emphasize that the medication is potent only for 3 to 6 months. Remind the patient to always have a fresh supply of the drug on hand, to plan ahead if traveling, and (no matter the dosage form) to sit or lie down when taking the medication to avoid falls secondary to a drop in blood pressure.
- With *all forms of nitrates,* educate the patient about adverse effects such as flushing of the face, dizziness, fainting, brief throbbing headache, increase in heart rate, and lightheadedness. Headaches associated with nitrates last approximately 20 minutes (with sublingual forms) and may be managed with acetaminophen. If headaches are bothersome when an oral dosage form is used, the drug may be taken with meals, and the patient must contact the prescriber if adverse effects continue. Blurred vision, dry mouth, or severe headaches may indicate drug overdose and require immediate medical attention. While taking an antianginal, the patient must avoid alcohol, hot environmental temperatures, saunas, hot tubs, and excessive exertion. These increase vasodilation with subsequent worsening of hypotension, which possibly can lead to syncope (fainting) and/or other cardiac events.
- In many situations, the prescriber specifies that nitroglycerin be taken *before* stressful activities or events such as emotional situations, consumption of large meals, smoking, or sudden increase in activity (e.g., sexual intercourse). The patient needs to follow the prescriber's directions regarding prophylactic dosing very closely.
- With *ointment* forms, remind the patient to use the appropriate dosage paper for application of the ointment and not to use the fingers to apply the medicine. The medication can be pressed evenly and directly from the tube onto the printed dosing line on the paper. Instruct the patient to squeeze a thin line of ointment onto the paper and follow instructions regarding its application, such as measuring and applying ½ inch of ointment. An occlusive covering must be used, such as applying a piece of plastic wrap taped around the edges to adhere the dose to the skin. Only clean, nonirritated, and nonhairy areas free of residual medication are to be used for these ointments.
- With *transdermal nitrate* use, the patient must apply the patch at the same time each day and be sure to have only one patch in place at a time, cleansing all residue off the skin before applying a new patch. Advise the patient to avoid skinfolds, hairy areas, and any area distal to the knees or elbows as application sites. A transdermal patch must never be applied to irritated or open skin, and if the patch becomes loose, the patient needs to remove it and gently wash off the residue with lukewarm soap and water, *pat* the area dry, and place another patch in another area. Encourage rotation of sites to prevent irritation (with ointments, too). The prescriber may order the removal of the patch for an 8-hour period on specific days to help decrease or prevent drug tolerance, which may develop over time. Emphasize all instructions with both written and verbal instructions.

Isosorbide Dinitrate or Isosorbide Mononitrate

- Educate the patient about the basic differences in oral nitrates (e.g., the mononitrate form is well absorbed after oral dosing; the dinitrate form is poorly absorbed, but its metabolite, isosorbide mononitrate, is active and well absorbed). It is important that the patient know that these drugs are *not interchangeable.*
- Inform the patient to take the medication exactly as ordered with emphasis on the need to lie down when doses are taken to avoid injury from the sudden drop in blood pressure. The sudden drop in blood pressure may lead to dizziness, lightheadedness, and fainting.
- Isosorbide dinitrate is generally given three times a day with a 12-hour drug-free interval, such as dosing at 0700, 1300, and 1900. The 12-hour drug-free interval helps prevent the development of tolerance.
- Oral dosage forms are not to be altered in any way and must be taken with 6 to 8 oz of water.
- The patient must be cautious while taking these drugs and encouraged to rise slowly and move the legs about before standing up from a lying or sitting position to help prevent dizziness, possible fainting, and falls. The avoidance of alcohol, heat, and saunas must be emphasized because these factors exacerbate the hypotensive effects of the drug and may result in bodily harm/injury.
- Advise the patient that these and other antianginals are not to be stopped abruptly.

KEY POINTS

- Angina pectoris (chest pain) occurs because of a mismatch between the oxygen supply and oxygen demand, with either too high a demand for oxygen or too little oxygen delivery.
- The heart is a very aerobic (oxygen-requiring) muscle, and when it does not receive enough oxygen, pain (angina) occurs. When the coronary arteries that deliver oxygen to the heart muscle become blocked, a heart attack or MI occurs.
- Coronary artery disease is an abnormal condition of the arteries (blood vessels) that deliver oxygen to the heart muscle. These arteries may become narrowed, which results in reduced flow of oxygen and nutrients to the myocardium.
- Nitrates, CCBs, and beta blockers may be used to treat the symptoms of angina.
- Nitroglycerin is the prototypical nitrate. Nitrates dilate constricted coronary arteries, helping to increase the supply of oxygen and nutrients to the heart muscle. Nitrates also dilate all other blood vessels. The venous dilation results in a decrease in blood return to the heart (decreased preload), whereas the arterial dilation results in a decrease of peripheral resistance (decreased afterload—that is, the pressure or force against which the left ventricle must pump). Isosorbide dinitrates were the first group of oral drugs used to treat angina; isosorbide mononitrates are new and improved nitrates used for angina therapy. Beta blockers are also used to relieve angina and do so by decreasing the heart rate, reducing workload on the heart, and decreasing oxygen demands.
- Dosage forms for nitrates include conventional tablets, translingual spray, controlled-release and sustained-release capsules, transdermal patch, topical ointment, and intravenous injection.
- Quick-onset nitrates are used to treat acute anginal attacks, while longer-onset nitrates are used for prophylaxis.
- Instruct patients to always keep a fresh supply of sublingual nitroglycerin on their person and in their home, because the drug is only stable for 3 to 6 months.
- CCBs and beta blockers may be associated with the adverse effects of postural hypotension, dizziness, headache, and edema. The nonselective beta blockers may exacerbate congestive heart failure, problems related to respiratory bronchospasm, and hypoglycemia. Check the patient's pulse rate before drug administration, and if it is 60 beats/min or lower, contact the prescriber for further instructions.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A patient has a new prescription for transdermal nitroglycerin patches. The nurse teaches the patient that these patches are most appropriately used for which reason?
- **a** To relieve exertional angina
- **b** To prevent palpitations
- **c** To prevent the occurrence of angina
- **d** To stop an episode of angina

2 A nurse with adequate knowledge about the administration of intravenous nitroglycerin will recognize that which statement is correct?
- **a** The intravenous form is given by IV push injection.
- **b** Because the intravenous forms are short-lived, the dosing must be every 2 hours.
- **c** Intravenous nitroglycerin must be protected from exposure to light through use of special tubing.
- **d** Intravenous nitroglycerin can be given via gravity drip infusions.

3 Which statement by the patient reflects the need for additional patient education about the calcium channel blocker diltiazem (Cardizem)?
- **a** "I can take this drug to stop an attack of angina."
- **b** "I understand that food and antacids alter the absorption of this oral drug."
- **c** "When the long-acting forms are taken, the drug cannot be crushed."
- **d** "This drug may cause my blood pressure to drop, so I need to be careful when getting up."

4 While assessing a patient with angina who is to start beta blocker therapy, the nurse is aware that the presence of which condition may be a problem if these drugs are used?
- **a** Hypertension
- **b** Essential tremors
- **c** Exertional angina
- **d** Asthma

5 A 68-year-old man has been taking the nitrate isosorbide dinitrate (Isordil) for 2 years for angina. He recently has been experiencing erectile dysfunction and wants a prescription for sildenafil (Viagra). Which response would the nurse most likely hear from the prescriber?
- **a** "He will have to be switched to isosorbide mononitrate if he wants to take sildenafil."
- **b** "Taking sildenafil with the nitrate may result in severe hypotension, so a contraindication exists."
- **c** "I'll write a prescription, but if he uses it, he needs to stop taking the isosorbide for one dose."
- **d** "These drugs are compatible with each other, and so I'll write a prescription."

6 The nurse is reviewing drug interactions with a male patient who has a prescription for isosorbide dinitrate (Isordil) as treatment for angina symptoms. Which substances listed below could potentially result in a drug interaction? (Select all that apply.)
- **a** A glass of wine
- **b** Thyroid replacement hormone
- **c** tadalafil (Cialis), an erectile dysfunction drug
- **d** metformin (Glucophage), an antidiabetic drug
- **e** carvedilol (Coreg), a beta blocker

7. The order reads, "Give metoprolol (Lopressor) 300 mg/day PO in 2 divided doses." The tablets are available in 50-mg strength. How many tablets will the patient receive per dose?

1. c, 2. c, 3. a, 4. d, 5. b, 6. a, c, e, 7. 3 tablets per dose (150 mg per dose)

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Differentiate between the terms *inotropic, chronotropic,* and *dromotropic.*
2 Briefly discuss the pathophysiology of heart failure.
3 Identify the approach to treatment of heart failure as outlined by the American Heart Association and American College of Cardiology Guidelines for the Diagnosis and Management of Heart Failure in Adults (last updated in 2009).
4 Compare the mechanisms of action, pharmacokinetics, indications, dosages, dosage forms, routes of administration, cautions, contraindications, adverse effects, and toxicity of the following drugs used in treatment of heart failure: lisinopril, valsartan, carvedilol, metoprolol, dobutamine, nesiritide, hydralazine/isosorbide dinitrate, milrinone, and digoxin.
5 Briefly discuss the process of rapid versus slow digitalization as well as the use of the antidote digoxin immune Fab.
6 Identify significant drug-drug, drug–laboratory test, and drug-food interactions associated with digoxin and other heart failure drugs.
7 Develop a nursing care plan that includes all phases of the nursing process for patients undergoing treatment for heart failure and that reflects the American Heart Association and American College of Cardiology Guidelines for the Diagnosis and Management of Heart Failure in Adults.

DRUG PROFILES

- **digoxin, p. 389**
  digoxin immune Fab, p. 390
- **dobutamine, p. 385**
  hydralazine/isosorbide dinitrate, p. 385
- **lisinopril, p. 385**
- **milrinone, p. 387**
- **nesiritide, p. 386**
- **valsartan, p. 385**

♦ *Key drug*

KEY TERMS

Atrial fibrillation A common cardiac dysrhythmia with atrial contractions that are so rapid that they prevent full repolarization of myocardial fibers between heartbeats. (p. 387)

Automaticity A property of specialized excitable tissue in the heart that allows self-activation through the spontaneous development of an action potential, such as in the pacemaker cells of the heart. (p. 385)

KEY TERMS—cont'd

Chronotropic drugs Drugs that influence the rate of the heartbeat. (p. 384)

Dromotropic drugs Drugs that influence the conduction of electrical impulses within tissues. (p. 384)

Ejection fraction The proportion of blood that is ejected during each ventricular contraction compared with the total ventricular filling volume. (p. 383)

Heart failure An abnormal condition in which the heart cannot pump enough blood to keep up with the body's demand. It is often the result of myocardial infarction, ischemic heart disease, or cardiomyopathy. (p. 383)

Inotropic drugs Drugs that influence the force of muscular contractions, particularly contraction of the heart muscle. (p. 384)

Left ventricular end-diastolic volume The total amount of blood in the ventricle immediately before it contracts, or the preload. (p. 383)

Refractory period The period during which a *pulse generator* (e.g., the *sinoatrial node* of the heart) is unresponsive to an electrical input signal, and during which it is impossible for the myocardium to respond. This is the period during which the cardiac cell is readjusting its sodium and potassium levels and cannot be depolarized again. (p. 388)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Heart failure is a not a specific disease per se but rather a clinical syndrome caused by numerous different cardiac disorders. More than 5.7 million people in the United States have heart failure. It is one of the most common causes for hospitalization in the United States, estimated to result in more than 3.5 million hospitalizations annually. This is especially true for elderly patients. Heart failure also causes more than 300,000 deaths annually. The findings of one of the largest and most frequently cited studies involving patients with heart failure, the Framingham study, show that the 5-year survival rate in patients with heart failure is approximately 50%. The best way to prevent heart failure is to control risk factors associated with heart failure including hypertension, coronary artery disease, obesity, and diabetes.

Heart failure is a pathologic state in which the heart is unable to pump blood in sufficient amounts from the ventricles (i.e., cardiac output is insufficient) to meet the body's metabolic needs, or can do so only at elevated filling pressures. The signs and symptoms typically associated with this insufficiency make up the syndrome of heart failure. Initially, the patient is asymptomatic. As the disease progresses, so do the symptoms. Failure of the ventricle(s) to eject blood efficiently results in fluid volume overload, chamber dilation, and elevated intracardiac pressure. This syndrome can affect the left ventricle, the right ventricle, or both ventricles simultaneously. Left ventricular or "left-sided" heart failure often leads to pulmonary edema, coughing, shortness of breath, and dyspnea. Right ventricular heart failure typically involves systemic venous congestion, pedal edema, jugular venous distension, ascites, and hepatic congestion. Both syndromes occur due to increased hydrostatic pressure from the ventricles into the pulmonary and/or systemic circulation.

More specifically, heart failure occurs due to a reduced ratio of **ejection fraction** to **left ventricular end-diastolic volume.** The ejection fraction is the amount of blood ejected with each contraction, whereas the left ventricular end-diastolic volume is the total amount of blood in the ventricle just before contraction. The ejection fraction is an index of left ventricular function, and the normal value is approximately 65% (0.65) of the total volume in the ventricle.

When a person has heart failure, the heart cannot then meet the increased demands, and the blood supply to certain organs is reduced. The organs that are most dependent on blood supply, the brain and heart, are the last to be deprived of blood. The kidney is relatively less dependent on blood supply and has its blood supply shunted away from it. Therefore, the filtration of fluids and removal of waste products is impaired. This can lead to acute or chronic renal failure. It also contributes to conditions such as pulmonary edema, shortness of breath, and peripheral edema.

The physical defects causing heart failure are of two types: (1) a myocardial defect such as myocardial infarction or valve insufficiency, which leads to inadequate cardiac contractility and ventricular filling; and (2) a defect outside the myocardium (e.g., coronary artery disease, pulmonary hypertension, or diabetes), which results in an overload on an otherwise normal heart. Either or both of these defects may be present in a given patient. These and other common causes of myocardial deficiency and systemic defects are listed in Box 24-1.

The emphasis of this chapter is on systolic dysfunction or inadequate ventricular contractions (systole) during the pumping of the heart. Less common, but still important, is diastolic dysfunction or inadequate ventricular filling during ventricular relaxation (diastole). This condition is most commonly associated with left ventricular hypertrophy secondary to chronic hypertension. However, it may also result from cardiomyopathy (e.g., virus induced), pericardial disease, and diabetes.

Heart failure is stratified into classes using The New York Heart Association's functional classification. Class I describes a patient who is not limited with normal physical activity by symptoms. Class II occurs when ordinary physical activity results in fatigue, dyspnea, or other symptoms. Class III is characterized by a marked limitation in normal physical activity.

BOX 24-1 MYOCARDIAL DEFICIENCY AND INCREASED VENTRICULAR WORKLOAD: COMMON CAUSES

Myocardial Deficiency

Inadequate Contractility
Myocardial infarction
Coronary artery disease
Cardiomyopathy
Valvular insufficiency

Inadequate Filling
Atrial fibrillation
Infection
Tamponade
Ischemia

Increased Workload

Pressure Overload
Pulmonary hypertension
Systemic hypertension
Outflow obstruction

Volume Overload
Hypervolemia
Congenital abnormalities
Anemia
Thyroid disease
Infection
Diabetes

Class IV is defined by symptoms at rest or with any physical activity. Drug therapy is individualized based on the patient's class of heart failure.

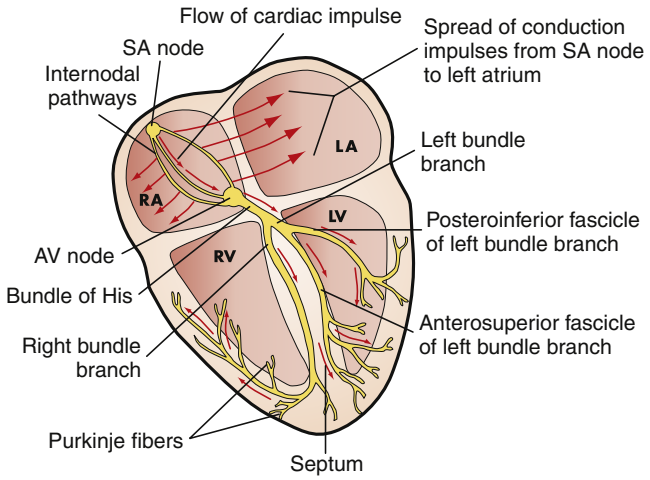

FIGURE 24-1 Conduction system of the heart. *AV,* Atrioventricular; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle; *SA,* sinoatrial. (Modified from Kinney MR, Packa DR: Andreoli's Comprehensive cardiac care, ed 8, St Louis, 1996, Mosby; Lewis SM, Dirksen SR, Heitkemper MM, et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 7, St Louis, 2007, Mosby.)

PHARMACOLOGY OVERVIEW

Drugs that increase the force of myocardial contraction are called positive **inotropic drugs,** and they have a role in the treatment of failing heart muscle. Negative inotropic drugs reduce the force of contraction. Drugs that increase the rate at which the heart beats are called positive **chronotropic drugs.** Negative chronotropic drugs do the opposite. Drugs may also affect how quickly electrical impulses travel through the conduction system of the heart (the sinoatrial [SA] node, atrioventricular [AV] node, bundle of His, and Purkinje fibers) (Figure 24-1). Drugs that accelerate conduction are referred to as positive **dromotropic drugs.** Negative dromotropic drugs do the opposite. This chapter focuses on the positive inotropic drugs, phosphodiesterase inhibitors and cardiac glycosides, as well as the newest class of medications for heart failure, B-type natriuretic peptides. Although several other drugs are used in the treatment of heart failure, they are discussed in detail in other chapters; for example, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) are covered in Chapter 22; beta blockers are discussed in Chapters 19, 22 and 23; and diuretics are discussed in Chapter 28. These drugs are mentioned in this chapter as well, but for specifics, refer to the indicated chapters.

The treatment of heart failure has changed dramatically over the past decade. Digoxin used to be the mainstay in heart failure treatment, but because of adverse effects and drug interactions, it has been replaced by other drugs. According to the latest American Heart Association and American College of Cardiology Guidelines for the Diagnosis and Management of Heart Failure in Adults (2005, updated in 2009), the approach to the treatment of chronic heart failure revolves around reducing the effects of the renin-angiotensin-aldosterone system and the sympathetic nervous system. Therefore, the drugs of choice at the start of therapy are the ACE inhibitors (lisinopril, enalapril, captopril, and others) or the angiotensin II receptor blockers (valsartan, candesartan, losartan, and others) and certain beta blockers (metoprolol, a cardioselective beta blocker; carvedilol, a nonspecific beta blocker). Loop diuretics (furosemide) are used to reduce the symptoms of heart failure secondary to fluid overload, and the aldosterone inhibitors (spironolactone, eplerenone) are added as the heart failure progresses. Only after these drugs are used is digoxin added. Dobutamine, a positive inotropic drug, has also been used to treat heart failure. In 2005, a combination drug containing hydralazine and isosorbide dinitrate became the first drug approved for a specific ethnic group. Hydralazine/isosorbide dinitrate (BiDil) was approved specifically for use in the African-American population.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

The angiotensin-converting enzyme (ACE) inhibitors are a class of drugs that, as their name implies, inhibit angiotensin-converting enzyme, which is responsible for converting angiotensin I (formed through the action of renin) to angiotensin II. Angiotensin II is a potent vasoconstrictor and induces aldosterone secretion by the adrenal glands. Aldosterone stimulates sodium and water resorption, which can raise blood pressure. Together, these processes are referred to as the renin-angiotensin-aldosterone system. The ACE inhibitors are beneficial in the treatment of heart failure because they prevent sodium and water resorption by inhibiting aldosterone secretion. This causes diuresis, which decreases blood volume and blood return to the heart. This in turn decreases preload, or the left ventricular end-diastolic volume, and the work required of the heart.

Numerous ACE inhibitors are available, including lisinopril, enalapril, fosinopril, quinapril, captopril, ramipril, trandolapril, and perindopril. These drugs are all very similar, and lisinopril will be used as the class representative.

DRUG PROFILE

♦ **lisinopril**

Lisinopril (Prinivil, Zestril) is a commonly used ACE inhibitor and is available in a generic form. It is used for hypertension, heart failure, and acute myocardial infarction. Like all ACE inhibitors, it is classified as a category C drug for women in the first trimester of pregnancy and a category D drug for women in the second and third trimesters; it can cause fetal death when used in the last two trimesters. Hyperkalemia may occur with any ACE inhibitor, and potassium supplementation or potassium-sparing diuretics need to be used with caution. Like all ACE inhibitors, lisinopril can cause a dry cough, which will not harm the patient but is annoying. Lisinopril (and all ACE inhibitors) may be associated with a decrease in renal function and hyperkalemia. For drug interactions, see Chapter 22.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	6 hr	11-12 hr	24 hr

ANGIOTENSIN II RECEPTOR BLOCKERS

The therapeutic effects of angiotensin II receptor blockers (ARBs) in heart failure are related to their potent vasodilating properties. They may be used alone or in combination with other drugs such as diuretics in the treatment of hypertension or heart failure. The beneficial hemodynamic effect of ARBs is their ability to decrease systemic vascular resistance (a measure of afterload). Seven ARBs are currently available: valsartan (Diovan), candesartan (Atacand), eprosartan (Teveten), irbesartan (Avapro), telmisartan (Micardis), olmesartan (Benicar), and losartan (Cozaar). All of the ARBs are similar in action. Valsartan will be used as the class representative.

DRUG PROFILE

♦ **valsartan**

Valsartan (Diovan) is a commonly used ARB. Like all ARBs, it is a pregnancy category D drug. Valsartan shares many of the same adverse effects as lisinopril, profiled earlier. The ARBs are not as likely to cause the cough associated with the ACE inhibitors, nor are they as likely to cause hyperkalemia. For drug interactions, see Chapter 22.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2 hr	Unknown	6 hr	12 hr

BETA BLOCKERS

Beta blockers (also discussed in Chapters 19, 22, and 23) work by reducing or blocking sympathetic nervous system stimulation to the heart and the heart's conduction system. By doing this, beta blockers prevent catecholamine-mediated actions on the heart. This is known as a cardioprotective quality of beta blockers. The resulting cardiovascular effects include reduced heart rate, delayed AV node conduction, reduced myocardial contractility, and decreased myocardial **automaticity.** Metoprolol is the beta blocker most commonly used to treat heart failure. Metoprolol is available as an immediate-release and a sustained-release product, as well as an intravenous formulation.

Carvedilol (Coreg) has many effects, including acting as a nonselective beta blocker, an alpha$_1$ blocker, and possibly a calcium channel blocker and antioxidant. It is used primarily in the treatment of heart failure but is also beneficial for hypertension and angina. It has been shown to slow the progression of heart failure and to decrease the frequency of hospitalization in patients with mild to moderate (class II or III) heart failure. Carvedilol is most commonly added to digoxin, furosemide, and ACE inhibitors when used to treat heart failure. Carvedilol is available only for oral use. A controlled-release formulation, called Coreg CR, was recently approved. The dosages are different from those for immediate-release Coreg, and the two dosage forms cannot be interchanged.

ALDOSTERONE ANTAGONISTS

Aldosterone antagonists spironolactone and eplerenone are useful in severe stages of heart failure. Activation of the renin-angiotensin-aldosterone system causes increased levels of aldosterone, which causes retention of sodium and water, leading to edema that can worsen heart failure. Spironolactone (Aldactone) is a potassium-sparing diuretic and is discussed in detail in Chapter 28. It also acts as an aldosterone antagonist, which has been shown to reduce the symptoms of heart failure. Eplerenone (Inspra) is a *selective aldosterone blocker,* blocking aldosterone at its receptors in the kidney, heart, blood vessels, and brain. It is discussed in detail in Chapter 22.

MISCELLANEOUS HEART FAILURE DRUGS

DRUG PROFILES

hydralazine/isosorbide dinitrate

Hydralazine/isosorbide dinitrate (BiDil) was the first drug approved for a specific ethnic group, namely African Americans. This combination of two older drugs contains 37.5 mg of hydralazine and 20 mg of isosorbide dinitrate. The individual drugs are discussed in detail in Chapter 22 (hydralazine) and Chapter 23 (isosorbide). Peak plasma levels of hydralazine/isosorbide dinitrate are achieved in 1 hour. The dose is 1 tablet three times a day, titrated up to a maximum of 2 tablets three times a day.

♦ **dobutamine**

Dobutamine (generic, formerly Dobutrex) is a beta$_1$-selective vasoactive adrenergic drug that is structurally similar to the naturally occurring catecholamine dopamine. Through

stimulation of the beta$_1$ receptors on heart muscle (myocardium), it increases cardiac output by increasing contractility (positive inotropy), which increases the stroke volume, especially in patients with heart failure. Dobutamine is available only as an intravenous drug and is given by continuous infusion. See Chapter 18 for further discussion on this drug.

B-TYPE NATRIURETIC PEPTIDE

The newest class of medications for heart failure, the B-type natriuretic peptides, currently includes only one drug, nesiritide.

DRUG PROFILE

♦ **nesiritide**

Nesiritide (Natrecor) is classified as a synthetic version of *human B-type natriuretic peptide.* B-type natriuretic peptide (BNP) is a substance secreted from the ventricles of the heart in response to changes in pressure that occur when heart failure develops. The level of BNP in the blood increases when heart failure symptoms worsen. A related hormone that occurs naturally in the body is *atrial natriuretic peptide,* which affects vascular permeability. *Vascular permeability* refers to the ability of plasma to flow between blood vessels and their surrounding tissues, and it serves as one way for the body to regulate blood pressure.

Nesiritide is a synthetic b-type natriuretic hormone that has vasodilating effects on both arteries and veins. This vasodilation takes place in the heart itself and throughout the body. The effects of nesiritide have been shown to include diuresis (urinary fluid loss), *natriuresis* (urinary sodium loss), and vasodilation. These properties lead to an indirect increase in cardiac output and suppression of neurohormonal systems such as the renin-angiotensin system.

Nesiritide is used in the intensive care setting as a final effort to treat severe, life-threatening heart failure, often in combination with several other cardiostimulatory medications. It is no longer recommended to be used as a first-line drug for heart failure. In 2005, an expert panel reviewed nesiritide at the request of the U.S. Food and Drug Administration in response to reports of worsened renal function and mortality. The expert panel stated that the use of nesiritide be strictly limited to treatment of patients with acutely decompensated heart failure who have dyspnea at rest. It is not to be used to replace diuretics and is not to be used repetitively or to improve renal function. Its only current contraindication is drug allergy, although it is not recommended for use in patients with low cardiac filling pressures, as typically measured in the intensive care unit. Adverse effects include hypotension, cardiac dysrhythmias, insomnia, headache, and abdominal pain. Currently identified drug interactions include additive hypotensive effects with coadministration of ACE inhibitors and diuretics. This drug is available only in injectable form. Recommended dosages are given in the table below.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	15 min	1 hr	18 min	1 to several hr

DOSAGES

Selected Drugs for Heart Failure

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ digoxin (Lanoxin) (C)	Digitalis cardiac glycoside	**Pediatric** Digitalizing dose: IV: 8-35 mcg/kg, divided into 3 doses, depending on age from premature infant to child older than 10 yr PO: 20-40 mcg/kg, divided into 3 doses, depending on age from premature infant to child older than 10 yr Usual maintenance dose: 20%-35% of digitalizing dose **Adult** PO/IV: Usual digitalizing dose: 1-1.5 mg divided into 3 doses; usual oral maintenance dose: 0.125-0.25 mg/day	Heart failure, supraventricular dysrhythmias
♦ milrinone (Primacor) (C)	Phosphodiesterase inhibitor	**Adult** IV loading dose: 50 mcg/kg IV continuous infusion dose: 0.375-0.75 mcg/kg/min	Heart failure
♦ nesiritide (Natrecor) (C)	Recombinant human B-type natriuretic peptide	**Adult only (pediatric use not yet established)** IV: Initial bolus of 2 mcg/kg, followed by continuous infusion of 0.01 mcg/kg/min	Acutely decompensated heart failure in patients with dyspnea at rest or with minimal activity

IV, Intravenous; *PO,* oral.

PHOSPHODIESTERASE INHIBITORS

As the name implies, phosphodiesterase inhibitors (PDIs) are a group of inotropic drugs that work by inhibiting the action of an enzyme called phosphodiesterase. These drugs were discovered in the search for positive inotropic drugs with a wider therapeutic window than digoxin. Presently only one drug in this category is available in the United States: milrinone (Primacor).

Mechanism of Action and Drug Effects

The mechanism of action of PDIs differs from other inotropic drugs such as digoxin and the catecholamines. PDIs share a similar pharmacologic action with methylxanthines such as theophylline (see Chapter 37). Both types of drug inhibit the action of phosphodiesterase, which results in an increase in intracellular cyclic adenosine monophosphate (cAMP). However, milrinone is more specific for phosphodiesterase type III, which is common in the heart and vascular smooth muscles.

The beneficial effects of milrinone come from the intracellular increase in cAMP, which results in two beneficial effects in a patient with heart failure: a positive inotropic response and vasodilation. For this reason, this class of drugs may also be referred to as *inodilators* (inotropics and dilators). Milrinone has a 10 to 100 times greater affinity for smooth muscle fibers surrounding pulmonary and systemic blood vessels than they do for cardiac muscle. This suggests that the primary beneficial effects of inodilators come from their vasodilating effects, which cause a reduction in the force against which the heart must pump to eject its volume of blood.

Finally, inhibition of phosphodiesterase results in the availability of more calcium for myocardial muscle contraction. This leads to an increase in the force of contraction (i.e., positive inotropic action). The increased calcium present in heart muscle is taken back up into its storage sites in the sarcoplasmic reticulum at a much faster rate than normal. As a result, the heart muscle relaxes more than normal and is also more compliant. In summary, PDIs have positive inotropic and vasodilatory effects. They may also increase heart rate in some instances and therefore may also have positive chronotropic effects as well.

Indications

Phosphodiesterase inhibitors (PDIs) are primarily used in the intensive care unit setting for the short-term management of acute heart failure. The American Heart Association and American College of Cardiology guidelines, last updated in 2009, do not recommend long-term infusion of the PDIs.

Contraindications

Contraindications to the use of PDIs include known drug allergy and may include the presence of severe aortic or pulmonary valvular disease and heart failure resulting from diastolic dysfunction.

Adverse Effects

The primary adverse effect seen with milrinone therapy is dysrhythmia. Milrinone-induced dysrhythmias are mainly ventricular. Ventricular dysrhythmias occur in approximately 12% of patients treated with this drug. Some other adverse effects associated with milrinone therapy are hypotension, angina (chest pain), hypokalemia, tremor, and thrombocytopenia.

Toxicity and Management of Overdose

No specific antidote exists for an overdose of milrinone. Hypotension secondary to vasodilation is the primary effect seen with excessive dosages. The recommendation is to reduce the dosage or temporarily discontinue the drug if excessive hypotension occurs. This is to be done until the patient's condition has stabilized. Initiation of general measures for circulatory support is also recommended.

Interactions

Concurrent administration of diuretics may cause significant hypovolemia and reduced cardiac filling pressure. Appropriately monitor the patient in an intensive care setting to detect and respond to these problems. Additive inotropic effects may be seen with coadministration of digoxin. Furosemide must not be injected into intravenous lines with milrinone because it will precipitate immediately.

Dosages

For dosage information, see the table on p. 386.

DRUG PROFILE

♦ **milrinone**

Milrinone (Primacor) is the only presently available PDI after the discontinuation of inamrinone (Inocor) in May 2011. Milrinone is also referred to as an *inodilator* because it exerts both a positive inotropic effect and a vasodilatory effect. Milrinone is contraindicated in cases of known drug allergy. Adverse effects include cardiac dysrhythmias, headache, hypokalemia, tremor, thrombocytopenia, and elevated liver enzyme levels. Interacting drugs include diuretics (additive hypotensive effects) and digoxin (additive inotropic effects). Milrinone is available only in injectable form. Recommended dosages are given in the table on p. 386.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	5-15 min	Immediate	2-3 hr	8-10 hr

CARDIAC GLYCOSIDES

Cardiac glycosides are one of the oldest groups of cardiac drugs. Not only do they have beneficial effects on the failing heart, but they also help control the ventricular response to **atrial fibrillation.** They were originally obtained from either the *Digitalis purpurea* or *Digitalis lanata* plant, both commonly known as foxglove. For this reason, cardiac glycosides are sometimes referred to as *digitalis glycosides.* Cardiac glycosides were the mainstay of therapy for heart failure for more than 200 years; however, they are no longer used as first-line drugs. Digoxin

is the only cardiac glycoside currently available in the United States. Although digoxin is a powerful positive inotropic drug, it has not been shown to reduce mortality.

Mechanism of Action and Drug Effects

The beneficial effect of digoxin is thought to be an increase in myocardial contractility—known as a *positive inotropic effect*. This occurs secondarily to the inhibition of the sodium-potassium adenosine triphosphatase pump. When the action of this enzyme-complex is inhibited, the cellular sodium and calcium concentrations increase. The overall result is enhanced myocardial contractility. Digoxin also augments cholinergic (or parasympathetic) stimulation via the vagus nerve of the parasympathetic nervous system. This is more commonly referred to as *vagal tone* and results in increased diastolic filling between heartbeats secondary to reduced heart rate. Vagal tone is also believed to sensitize cardiac baroreceptors, which reduces sympathetic stimulation from the central nervous system. All of these processes further enhance cardiac efficiency and output.

Digoxin changes the electrical conduction properties of the heart, and this markedly affects the conduction system and cardiac automaticity. Digoxin decreases the velocity (rate) of electrical conduction and prolongs the **refractory period** in the conduction system. The particular site in the conduction system where this occurs is the area between the atria and the ventricles (SA node to AV node). The cardiac cells remain in a state of depolarization longer and are unable to start another electrical impulse, which also reduces heart rate and improves cardiac efficiency.

The following is a summary of the inotropic, chronotropic, dromotropic, and other effects produced by digoxin:

- A positive inotropic effect—an increase in the force and velocity of myocardial contraction without a corresponding increase in oxygen consumption
- A negative chronotropic effect—reduced heart rate
- A negative dromotropic effect—decreased automaticity at the SA node, decreased AV nodal conduction, reduced conductivity at the bundle of His, and prolongation of the atrial and ventricular refractory periods
- An increase in stroke volume
- A reduction in heart size during diastole
- A decrease in venous blood pressure and vein engorgement
- An increase in coronary circulation
- Promotion of tissue perfusion and diuresis as a result of improved blood circulation
- Decrease in exertional and paroxysmal nocturnal dyspnea, cough, and cyanosis
- Improved symptom control, quality of life, and exercise tolerance, but no apparent reduction in mortality

Indications

Digoxin is primarily used in the treatment of systolic heart failure and atrial fibrillation. However, the latest heart failure treatment guidelines recommend that it be used as an adjunct to drugs of other classes, including beta blockers, diuretics, ACE inhibitors, and ARBs.

TABLE 24-1 DIGOXIN: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Bradycardia or tachycardia; hypotension
Central nervous	Headache, fatigue, confusion, convulsions
Eye	Colored vision (i.e., green, yellow, or purple), halo vision
Gastrointestinal	Anorexia, nausea, vomiting, diarrhea

Normal therapeutic level = 0.5 to 2 ng/mL.

Contraindications

Contraindications to the use of digoxin include known drug allergy and may include second- or third-degree heart block, atrial fibrillation, ventricular tachycardia or fibrillation, heart failure resulting from diastolic dysfunction, and subaortic stenosis (obstruction in the left ventricle below the aortic valve). However, digoxin may be used to treat some of these conditions, if recommended by a competent cardiologist, depending on the given clinical situation.

Adverse Effects

The common undesirable effects associated with digoxin use are cardiovascular, central nervous system, ocular, and gastrointestinal effects. These are outlined in Table 24-1.

Toxicity and Management of Overdose

Digoxin has a low therapeutic index (see Chapter 2). Digoxin levels are monitored when the patient first starts taking the drug. However, monitoring of digoxin levels after the drug reaches steady state is usually necessary only if there is suspicion of toxicity, noncompliance, or deteriorating renal function. Normal therapeutic levels for digoxin are 0.5 to 2 ng/mL. Low potassium or magnesium levels may increase the potential for digoxin toxicity. Therefore, frequent monitoring of serum electrolytes is also important. Estimates are that as many as 20% of patients taking digoxin exhibit symptoms of toxicity. A decrease in renal function is also a common cause of digoxin toxicity, because digoxin is excreted almost exclusively via the kidneys. Signs and symptoms of digoxin toxicity include bradycardia, headache, dizziness, confusion, nausea, and visual disturbances (blurred vision or yellow vision). With toxicity, ECG findings may include heart block, atrial tachycardia with block, or ventricular dysrhythmias. Predisposing factors to digoxin toxicity are listed in Table 24-2.

The treatment strategies for digoxin toxicity depend on the severity of the symptoms. These strategies can range from simply withholding the next dose to instituting more aggressive therapies. The steps usually taken in the management of digoxin toxicity are listed in Table 24-3.

When significant toxicity develops as a result of digoxin therapy, the administration of digoxin immune Fab may be indicated. Digoxin immune Fab is an antibody that recognizes digoxin as an antigen and forms an antigen-antibody complex with the drug, thus inactivating the free digoxin. Digoxin immune Fab therapy is not indicated for every patient who is

TABLE 24-2 CONDITIONS PREDISPOSING TO DIGITALIS TOXICITY

CONDITION/DISEASE	SIGNIFICANCE
Use of cardiac pacemaker	A patient with this device may exhibit digitalis toxicity at lower dosages than usual.
Hypokalemia	The patient's risk of serious dysrhythmias is increased, and the patient is more susceptible to digitalis toxicity.
Hypercalcemia	The patient is at higher risk of experiencing sinus bradycardia, dysrhythmias, and heart block.
Atrioventricular block	Heart block may worsen with increasing levels or digitalis.
Dysrhythmias	Dysrhythmias may occur that did not exist before digitalis use and thus could be related to digitalis toxicity.
Hypothyroidism, respiratory or renal disease	Patients with these disorders require lower dosages because they cause delayed renal drug excretion.
Advanced age	Because of decreased renal function and the resultant diminished drug excretion along with decreased body mass in this patient population, a lower dosage than usual is needed to prevent toxicity. The practice of polypharmacy may also lead to toxicity.
Ventricular fibrillation	Ventricular rate may actually increase with digitalis use.

TABLE 24-3 DIGOXIN TOXICITY: STEP-BY-STEP MANAGEMENT

STEP	ACTIONS
1	Discontinue administration of drug.
2	Begin continuous electrocardiographic monitoring for cardiac dysrhythmias; administer any appropriate antidysrhythmic drugs as ordered.
3	Determine serum digoxin and electrolyte levels.
4	Administer potassium supplements for hypokalemia if indicated, as ordered.
5	Institute supportive therapy for gastrointestinal symptoms (nausea, vomiting, or diarrhea).
6	Administer digoxin antidote (i.e., digoxin immune Fab) if indicated, as ordered.

showing signs of digoxin toxicity. The following are the clinical settings in which its use may be indicated:

- Hyperkalemia (serum potassium level higher than 5 mEq/L) in a patient with digoxin toxicity
- Life-threatening cardiac dysrhythmias, sustained ventricular tachycardia or fibrillation, and severe sinus bradycardia or heart block unresponsive to atropine treatment or cardiac pacing
- Life-threatening digoxin overdose: more than 10 mg digoxin in adults; more than 4 mg digoxin in children

Interactions

A wide variety of significant drug interactions are possible with digoxin. Common examples are given in Table 24-4. The most important drug-drug interactions occurring with digoxin are interactions with amiodarone, quinidine, and verapamil. These three drugs can increase digoxin levels by 50%. When large amounts of bran are ingested, the absorption of oral digoxin may be decreased. Certain herbal supplements may interact with digoxin; for example, ginseng may increase digoxin levels, hawthorn may potentiate the effects of digoxin, licorice may increase the risk of cardiac toxicity due to potassium loss, and St. John's wort may reduce digoxin levels. Drugs that lower serum potassium or magnesium levels can predispose patients to digoxin toxicity.

TABLE 24-4 DIGOXIN: DRUG INTERACTIONS

INTERACTING DRUG	MECHANISM	RESULT
Antidysrhythmics calcium (parenteral)	Increase cardiac irritability	Increased digoxin toxicity
cholestyramine colestipol sucralfate	Decrease oral absorption	Reduced therapeutic effect
Beta blockers	Block beta$_1$ receptors in the heart	Enhanced bradycardic effect of digoxin
Calcium channel blockers	Block beta$_1$ receptors in the heart	Enhanced bradycardic effect of digoxin
quinidine	Block calcium channels in the myocardium	Enhanced bradycardic and negative inotropic effects of digoxin
verapamil amiodarone dronedarone cyclosporine Azole antifungals	Decrease clearance	Digoxin levels increased by 50%; digoxin dose should be reduced by 50%

Dosages

For dosage information, see the table on p. 386. Also see the Safety and Quality Improvement: Preventing Medication Errors box on p. 390.

DRUG PROFILES

♦ digoxin

Digoxin (Lanoxin) is indicated for the treatment of heart failure and atrial fibrillation and flutter. Digoxin use is contraindicated in patients who have shown a hypersensitivity to it and in those with ventricular tachycardia and fibrillation. Normal therapeutic drug levels of digoxin are between 0.5 and 2 ng/mL. However, levels higher than 2 ng/mL are used for the treatment of atrial fibrillation. Digoxin is available in oral and injectable forms. Because of digoxin's fairly long duration of action and half-life, a loading, or "digitalizing," dose is often given to bring serum levels of the drug up to a desirable therapeutic level more quickly. Recommended digitalizing doses and the daily oral

and intravenous adult and pediatric dosages are given in the table on p. 386.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-2 hr	2-8 hr	35-48 hr	3-4 days
IV	5-30 min	1-4 hr	35-48 hr	3-4 days

digoxin immune Fab

Digoxin immune Fab (Digifab) is the antidote for severe digoxin overdose and is indicated for the reversal of such life-threatening cardiotoxic effects as severe bradycardia, advanced heart block, ventricular tachycardia or fibrillation, and severe hyperkalemia. Use of digoxin immune Fab is contraindicated in patients who have shown a hypersensitivity to it. It is available only in parenteral form as a 40-mg vial. It is dosed based on the patient's serum digoxin level in conjunction with his or her weight. The recommended dosages vary according to the amount of cardiac glycoside ingested. One vial binds 0.5 mg of digoxin. It is important to bear in mind that after digoxin immune Fab is given, all subsequent measurements of serum digoxin level will be elevated for days to weeks. Therefore, after its administration, the clinical signs and symptoms of digoxin toxicity, rather than the digoxin serum levels, are the primary focus in monitoring for the effectiveness of reversal therapy.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Immediate	Immediate	14-20 hr	Days to weeks

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

The Importance of Decimal Points

Incorrect decimal placement can be lethal when calculating digoxin dosages! According to the Institute for Safe Medication Practices (ISMP), trailing zeros are *not* to be used after decimal points. In the case of digoxin, if a "1 mg" dose is ordered and is written as "1.0 mg," the order could be misread as "10 mg," and the patient would receive 10 times the ordered dose.

The ISMP also recommends that leading zeroes be used if a dose is less than a whole number. For example, ".25 mg" can look like "25 mg," which is a dose that is 100 times the ordered dose. Instead, the order must be written as "0.25 mg" to avoid any errors.

Of course, such an error hopefully would be caught when the nurse realizes how many 250-mcg digoxin tablets it would take to give a "25 mg" dose, or how many milliliters would be needed for an intravenous dose. However, such errors have occurred. Consider what would happen if a digoxin overdose leads to digoxin toxicity and the serious effects this would have on the patient!

Data from Institute for Safe Medication Practices: ISMP's list of error-prone abbreviations, symbols, and dose designations, Huntington Valley, PA, 2007, available at www.ismp.org/Tools/errorproneabbreviations.pdf. Accessed February 1, 2012.

NURSING PROCESS

ASSESSMENT

Before a drug used to treat heart failure is given, perform a thorough assessment, including assessment of the patient's past and present medical history, drug allergies, and family medical history with emphasis on any history of cardiac, hypertensive, or renal diseases. Your review may yield findings that either dictate very cautious use of the drug or even represent contraindications to its use. Assess the following clinical parameters and other data:

- Blood pressure
- Pulse rate—both apical and radial, measured for 1 full minute
- Peripheral pulse location and grading of strength
- Capillary refill
- Presence or absence of edema
- Heart sounds
- Breath sounds
- Weight
- Intake and output amounts
- Serum laboratory values such as potassium, sodium, magnesium, and calcium levels
- Electrocardiogram
- Results of renal function tests, including BUN and creatinine levels
- Results of liver function tests such as levels of AST, ALT, CPK, LDH, and ALP
- Medication history and profile, including all prescription drugs, over-the-counter drugs, herbals, and nutritional supplements taken; for example, herbal products (e.g., Siberian ginseng) may increase digitalis drug levels; consumption of large amounts of bran with digoxin will decrease the drug's absorption
- Dietary habits and all meals and snacks consumed over the previous 24 hours
- Smoking history
- Alcohol intake

ACE inhibitors, such as lisinopril, require thorough assessment of cautions, contraindications, and drug interactions (see Chapter 22). Hyperkalemia is an adverse effect; therefore, perform an assessment of serum potassium before giving these drugs and administer potassium supplementation and/or potassium-sparing diuretics with caution. Assess respiratory history, specifically any previous problems of cough. ACE inhibitors may cause a dry cough, which is not harmful but may be annoying. Patients may be switched to an *ARB,* such as valsartan (see Chapter 22), if the cough becomes problematic for the patient.

As mentioned earlier, metoprolol is the *beta blocker* most commonly used to treat heart failure. Carvedilol also has many therapeutic effects (see Chapters 19, 22, and 23 for a detailed discussion) and is commonly added to existing regimens of digoxin, furosemide (loop diuretic), and ACE inhibitors in the management of heart failure. Related assessment information for alpha- and beta-blocking drugs may be found in Chapter 19.

Dobutamine, a beta$_1$-selective adrenergic, is also used to treat heart failure and is discussed further in Chapter 18. The status of the patient's veins is important to assess when this drug is indicated because it is only given intravenously.

Aldosterone antagonists, such as spironolactone and eplerenone, require close assessment of heart and breath sounds as well as for the occurrence of edema, which is a known adverse effect (see Chapter 22 for more information). *Hydralazine/isosorbide dinitrate* is used mainly in African-American patients and is discussed further in Chapter 22.

The newest class of medications for heart failure, the *B-type natriuretic peptides,* includes the drug nesiritide. Carefully assess all body functions, especially cardiac function, with attention to heart sounds, blood pressure, pulse rate, and the presence of any cardiac dysrhythmias, hypotension, insomnia, and headache. These may be exacerbated with the use of this drug. See previous discussion for other cautions, contraindications, and drug interactions.

With any medication regimen, it is always important to assess support systems at home, because safe and effective therapy depends on close observation, monitoring of appropriate parameters (e.g., daily weight), attention to patient complaints, and evaluation of how the patient is feeling and functioning. With milrinone, a *phosphodiesterase inhibitor,* closely monitor cardiac status, which is critical to patient safety. These patients are usually in an ICU setting and require frequent assessment of heart sounds, vital signs, and any evidence of ventricular dysrhythmias on ECG readings. Assess also for any history of angina, hypotension, and hypokalemia, which may all be exacerbated with this drug. Significant drug interactions to assess for include parenteral furosemide that will precipitate immediately if milrinone is present in the IV lines.

Before giving *digoxin,* closely monitor serum electrolytes. Specifically, assess potassium levels because low levels or hypokalemia may precipitate digoxin toxicity. Hypokalemia is manifested by muscle weakness, confusion, lethargy, anorexia, nausea, and changes in the ECG. Low levels of magnesium or hypomagnesemia may also precipitate digoxin toxicity. Hypomagnesemia is manifested by agitation, twitching, hyperactive reflexes, nausea, vomiting, and ECG changes. You also need to closely assess digoxin levels once it has been administered because of the narrow range between the therapeutic and toxic levels of digoxin (also called a low therapeutic index; see Chapter 2). Measure and document baseline weight as well. Perform a careful assessment of the following systems: (1) Neurologic system: Note any history of headaches, fatigue, confusion, and/or convulsions; assess level of alertness and orientation; (2) Gastrointestinal system: Document any changes in appetite (decreased) and/or complaints of diarrhea, nausea, or vomiting; (3) Cardiac system: Note the history of any irregularities, pulse rate of lower than 60 beats/min or higher than 100 beats/min, hypotension, abnormal heart sounds, and abnormal ECG findings (if this test is ordered); and (4) Visual and sensory system: Document baseline vision as well as any changes in vision, such as green, yellow, or purple halo surrounding the peripheral field of vision. See Table 24-1 for more information on adverse effects of digoxin. Also assess for any cautions, contraindications, and drug interactions (see Table 24-2).

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

Heart Failure

The cause, symptoms, treatment, and prognosis of heart failure in children vary depending on age. In infants, the cause of heart failure is generally due to holes in the heart or other structural problems. In older children, the structure of the heart may be normal but the heart muscle may be weakened. Symptoms of heart failure differ depending on age and become worse with age because the heart must keep up with increased oxygen demands and energy demands (with increased growth).

- Symptoms may include poor growth, difficulty in feeding, and tachypnea; in older children, inability to tolerate exercise and other activities, the need to rest more often, and dyspnea with minimal exertion occur more frequently.
- Treatment is generally age- and cause-specific. For septal defects, surgery or medication may be indicated. For more complex problems, surgery may be needed within the first few weeks of life.
- Drug therapy may include furosemide (a loop diuretic), angiotensin-converting enzyme inhibitors, beta blockers, and sometimes digoxin to help improve heart pumping efficiency.
- Correct calculation of dosages for any of the medications used is very important to safe and cautious nursing care. A one-decimal-point placement error will result in a tenfold dosage error, which could be fatal.
- Digoxin toxicity is manifested in children by nausea, vomiting, bradycardia, anorexia, and dysrhythmias.
- The prescriber needs to be notified immediately if any of the following develop or worsen: fatigue, sudden weight gain (2 pounds or more in 24 hours), palpitations, tachycardia or bradycardia, and/or respiratory distress.

Modified from Cincinnati Children's Hospital Medical Center: Signs and symptoms: congestive heart failure, 2006, available at http://www.cincinnatichildrens.org/health/c/chf. Accessed February 1, 2012.

NURSING DIAGNOSES

1. Ineffective peripheral tissue perfusion related to the pathophysiologic influence of heart failure
2. Deficient knowledge related to lack of information and experience with heart failure as well as the first-time use of drugs indicated for heart failure
3. Noncompliance with therapy regimen related to lack of information about the disease process as well as the drug(s) and adverse effects

PLANNING

GOALS

1. Patient exhibits improved cardiac output with improved tissue perfusion once drug therapy is initiated.
2. Patient states use, action, adverse effects, and toxic effects of therapy.
3. Patient remains compliant with drug therapy regimen.

OUTCOME CRITERIA

1. Patient experiences improved to strong peripheral pulses; pink, warm extremities and improved ability to carry out activities of daily living (ADLs).

2. Patient demonstrates sufficient knowledge about disease process related to heart failure, stating the importance of the need for life-long therapy, constant monitoring by physicians/health care provider, conserving of energy, and other measures to minimize oxygen demands.
   - Patient demonstrates proper technique for measuring radial pulse for 1 full minute before taking medication.
   - Patient states the most common adverse effects to expect with digoxin therapy, such as bradycardia or tachycardia (pulse rate less than 60 beats/min or greater than 100 beats/min as indicated by prescriber), headache, fatigue, confusion, halo vision, anorexia, nausea, and vomiting.
   - Patient states the importance of reporting to the prescriber symptoms that are indicative of digoxin toxicity, specifically anorexia, nausea, vomiting, and loss of appetite.
3. Patient's compliance with therapy results in improved heart function with subsequent heart rate above 60 beats/min and below 100 beats/min with regular rhythm.
   - Patient reports improved ability to perform simple ADLs with minimal dyspnea and increased energy levels.
   - Patient reports the consistent taking of medication at the same time every day along with performing daily weights.
   - Patient remains free from exacerbations of heart failure and states no severe adverse effects while taking medication exactly as ordered.

IMPLEMENTATION

Nursing interventions associated with the use of *ACE inhibitors, ARBs, beta blockers,* and *adrenergic drugs* are discussed further in Chapters 18, 19, and 22. When administering the *b-type natriuretic peptide* nesiritide, give the drug as ordered and with extreme caution. Nesiritide is strictly used in an intensive care setting in very ill patients who are experiencing acute decompensated heart failure and receiving continuous cardiac monitoring. While the drug is being administered intravenously, monitor the patient for all of its severe adverse effects, such as hypotension, dysrhythmias, headache, and abdominal pain. Avoid co-administration of drugs that decrease the patient's blood pressure, such as ACE inhibitors and diuretics, if at all possible. Hydralazine/isosorbide dinitrate must also be used with extreme caution because of the associated syncope. If this occurs, the drug will most likely be discontinued. Monitor blood pressure and other vital signs, especially with the first few doses of hydralazine/isosorbide dinitrate (because of the syncope). Drug interactions, cautions, and contraindications have been previously discussed.

Always check for compatibility of solutions when giving the *phosphodiesterase inhibitor* milrinone. Record intake and output, heart rate, blood pressure, daily weight, and respiration rate as well as heart and breath sounds. Report any evidence of hypokalemia to the prescriber immediately, and monitor the patient closely (vital signs). When heart failure drugs such as digoxin, milrinone, and digoxin immune Fab are administered parenterally, use an infusion pump unless the order is to administer them as an intravenous push.

Before administering any dose of the *cardiac glycoside* digoxin, check the serum potassium and magnesium levels to be sure they are within normal limits and to prevent toxicity. *Always* measure the patient's apical pulse rate (auscultate the apical heart rate, found at the apical impulse located at the fifth left midclavicular intercostal space) for 1 full minute. If the pulse rate is 60 beats/min or lower, or if it is higher than 100 beats/min, you will generally withhold the dose and notify the prescriber of the problem immediately. Although withholding of the dose is usually indicated, health care facilities and prescribers often have their own protocols that apply to individual patients. In addition, contact the prescriber if the patient experiences any of the following signs and symptoms of digoxin toxicity: headache, dizziness, confusion, nausea, and visual disturbances (yellow-green halo or blurred vision). ECG findings in a patient with digoxin toxicity would show heart block, atrial tachycardia with block, or ventricular dysrhythmias. Remember that most institutions and/or nursing units follow protocol or policy with regard to digitalis and its administration.

Other nursing interventions include checking the dosage form and prescribed amounts and the prescriber's order carefully to make sure that the correct drug dosage has been dispensed (e.g., 0.125 or 0.25 mg). Oral digoxin may be administered with meals but not with foods high in fiber (bran), because the fiber will bind to the digitalis and lead to altered absorption/bioavailability of the drug. If the medication is to be given intravenously, the following interventions are critical to patient safety: infuse undiluted intravenous forms at around 0.25 mg/min or over longer than a 5-minute period, or as per hospital protocol. The administration of intramuscular forms of cardiac glycosides is extremely painful and is not indicated or recommended, because tissue necrosis and erratic absorption are often the outcome. Digoxin is incompatible with many other medications in solution or syringe; therefore, double-check compatibility before parenteral administration.

Consider the interventions for patients undergoing digitalization separately from other drugs. Again, although digitalization is not commonly used in contemporary practice, it may still be performed in some areas of practice for the management of heart failure. Rapid digitalization (to achieve faster onset of action) is generally reserved for patients who have heart failure and are in acute distress. Such patients are hospitalized because digitalis toxicities can appear quickly (in this setting) and are directly correlated with the high drug concentrations used. If the patient undergoing rapid digitalization exhibits any of the manifestations of toxicity, contact the prescriber immediately. Continuously observe these patients, with frequent measurement of vital signs and serum drug and potassium levels. Slow digitalization (rarely used) is generally performed on an outpatient basis in patients with heart failure who are not in acute distress. In this situation, it takes longer for toxic effects to appear (depending on the drug's half-life) than with rapid digitalization. The main advantages of slow digitalization are that it can be performed

on an outpatient basis, oral dosage forms can be used, and it is safer than rapid digitalization. The disadvantages are that it takes longer for the therapeutic effects to occur and the symptoms of toxicity are more gradual in onset and therefore more insidious.

If toxicity occurs and digoxin rises to a life-threatening level, administer the antidote, *digoxin immune Fab*, as ordered. It is given parenterally over 30 minutes, and in some scenarios it is given as an intravenous bolus (e.g., if cardiac arrest is imminent). All vials of the drug need to be refrigerated. The drug is stable for 4 hours after being mixed; use it immediately, and if not used within 4 hours, discard the drug. One vial of digoxin immune Fab binds 0.5 mg of digoxin. Check compatible solutions for dilution prior to infusion of the antidote. Closely monitor blood pressure, apical pulse rate and rhythm, electrocardiogram, and serum potassium levels, and record the findings. Document baseline data, and begin to observe closely for changes in assessment findings such as changes in muscle strength, occurrence of tremors and muscle cramping, changes in mental status, irregular cardiac rhythms (from hypokalemia), and confusion, thirst, and cold clammy skin (from hyponatremia). If the treatment does reduce the toxicity, these problems will improve considerably compared with the patient's baseline.

EVALUATION

Monitoring patients after the administration of drugs to improve heart contractility, or *positive inotropic drugs*, is critical for identifying therapeutic effects and adverse effects. Because *positive inotropic drugs* increase the force of myocardial contractility; alter electrophysiologic properties, leading to a decrease in heart rate (negative chronotropic effect); and decrease AV node conduction properties (negative dromotropic effect), the therapeutic effects of these drugs include the following:

- Increased urinary output
- Decreased edema
- Decreased dyspnea and crackles
- Decreased fatigue
- Resolution of paroxysmal nocturnal dyspnea
- Improved peripheral pulses, skin color, and temperature

For patients taking *lisinopril, valsartan, metoprolol, dobutamine, nesiritide,* and *hydralazine/isosorbide dinitrate,* therapeutic effects include improvement in symptoms of heart failure and improved cardiac function. During therapy, the evaluation must also monitor for the adverse effects of these medications, which have been discussed previously in the pharmacology section.

Therapeutic effects of *milrinone* include an improvement in cardiac function with a corresponding improvement in the patient's heart failure. Monitor for the adverse effects of hypotension, dysrhythmias, headache, ventricular fibrillation, chest pain, and hypokalemia. Evaluate patients taking milrinone for significant hypotension. If hypotension occurs, contact the prescriber, and discontinue the infusion or decrease the rate while waiting to hear from the prescriber.

While monitoring for the therapeutic effects of *digoxin*, assess the patient for the development of toxicity because of the drug's low therapeutic index. Toxic effects associated with digoxin may include nausea, vomiting, and anorexia. Monitoring laboratory values such as serum creatinine, potassium, calcium, sodium, and chloride levels—as well as watching the serum levels of digoxin (normal levels between 0.5 and 2 ng/mL)—is important to ensure safe and efficacious treatment.

CASE STUDY

Phosphodiesterase Inhibitor for Heart Failure

Jim, a 58-year-old retired bus driver, has been in the hospital for a week for treatment of heart failure. He had a myocardial infarction a year earlier and tells the nurse that he "hasn't felt well for weeks." He is currently receiving carvedilol, lisinopril, furosemide, and potassium supplements (all orally), but he has had little improvement.

Today during morning rounds, the nurse notes that Jim is having increased difficulty with breathing, and his heart rate is up to 120 beats/min. His weight has increased from 72 to 76 kg overnight, and his lower legs and ankles show edema rated as 3+. Crackles are heard over both lungs, and his pulse oximetry reading is 91% (down from 98% earlier). In addition, Jim is very restless. Oxygen is started, a Foley catheter is inserted, and Jim is transferred to the intensive care unit.

After examining Jim, Dr. Horne writes new medication orders as follows:

Change furosemide to 60 mg intravenously twice a day

Continue carvedilol and lisinopril

Start an infusion of milrinone as follows:

Loading dose: 50 mcg/kg over 10 minutes, followed by an infusion of 0.5 mcg/kg/min

1. Describe the drug effects of the medications Jim is receiving for the heart failure.
2. What laboratory values will you need to monitor while Jim is receiving the milrinone?

The charge nurse is in Jim's room when another nurse comes in to give Jim the intravenous dose of furosemide. As the nurse reaches for the tubing of the milrinone infusion to administer the diuretic, the charge nurse gently stops the nurse from giving the medication. Out in the hallway, the charge nurse speaks to the nurse.

3. What was the potential problem?

The next morning, Jim's breathing is better, his lungs are clearer, and his peripheral edema is now evaluated as trace edema. However, he complains of feeling his heart "skip" more than usual.

4. Is there a concern? What will the nurse need to do at this point?

After a week, Jim's condition has improved greatly. The milrinone was stopped, he was transferred to a regular room, and today he is ready to go home.

5. In addition to receiving education regarding his medications, what should Jim be taught to monitor while recovering at home?

For answers, see http://evolve.elsevier.com/Lilley.

PATIENT TEACHING TIPS

- Hydralazine/isosorbide dinitrate may cause syncope, and this needs to be explained to the patient, with instructions to change positions carefully.
- Instruct the patient on how to take the radial pulse before each dose of digoxin or as indicated. Daily weights are important and need to be done the same time every morning and with the exact amount of clothing. For elderly or physically or mentally challenged patients, it is important that home health care personnel or a heart failure/hospital-based clinic supervise the medication regimen. This is important because these individuals are at risk for adverse effects, toxicity, and drug interactions. If the pulse rate is below 60 beats/min or is erratic, if the pulse rate is 100 beats/min or higher, or if there is anorexia, nausea, or vomiting, the health care provider must be contacted. Emphasize the importance of the patient reporting any palpitations or a feeling that the heart is racing, change in heart rate and/or irregular heart rate, the occurrence of dizziness or fainting, any changes in vision, and weight gain (2 pounds or more in 24 hours or 5 pounds or more in 1 week).
- Advise the patient to keep a daily journal with notation of medications, daily weights, dietary intake and appetite, any adverse effects or changes in condition, and a rating of how the he or she is feeling day to day.
- Instruct the patient to wear a medical alert bracelet or necklace and to keep a current medication and medical history card on his or her person at all times that lists allergies, medical diagnosis, and medications. Medical information and lists of medications need to be updated frequently or with each visit to the prescriber.
- Digoxin is usually taken once a day. Encourage the patient to take it at the same time every day. If a dose is missed, the patient may take the omitted dose if no more than 12 hours have passed from the time the drug was to have been taken. Instruct the patient that if more than 12 hours have passed since the missed dose, the patient should *not* skip that dose, *not* double up on the next digoxin dose, and contact the prescriber immediately for further instructions.
- Instruct the patient to *never* abruptly stop any of the medications being taken for heart failure. If problems occur, advise the patient to always contact the prescriber.
- If potassium-depleting diuretics are being taken as part of the therapy, encourage the patient to consume foods high in potassium and to report any weakness, fatigue, or lethargy. In addition, any worsening of dizziness or dyspnea or the occurrence of any unusual problems should be reported immediately.
- With medication regimens for heart failure, most patients are encouraged to avoid using antacids or eating ice cream, milk products, yogurt, cheese (dairy products), or bran for 2 hours before or 2 hours after taking medication to avoid interference with the absorption of the oral dosage forms of these medications.

KEY POINTS

- Inotropic drugs affect the force of myocardial contraction; positive inotropics (e.g., digoxin) increase the force of contractions, and negative inotropics (e.g., beta blockers, calcium channel blockers) decrease myocardial contractility. Chronotropics affect heart rate per minute, with positive chronotropics increasing heart rate and negative chronotropics decreasing the heart rate. Dromotropic drugs affect the conduction of electrical impulses through the heart; positive dromotropic drugs increase the speed of electrical impulses through the heart, whereas negative drugs have the opposite effect.
- Know the protocol for heart failure management, because digoxin, once the cornerstone of treatment for heart failure, is now used only after all other recommended drugs have been tried. The American Heart Association and American College of Cardiology treatment guidelines (last updated in 2009) provide the protocol guidelines of treatment for heart failure, including the following: Drugs of choice to initiate treatment are the ACE inhibitors (lisinopril, enalapril, captopril, and others) or the ARBs (valsartan, candesartan, losartan) and beta blockers (metoprolol, a cardioselective beta blocker; carvedilol, a nonspecific beta blocker). The loop diuretics (furosemide) are used to reduce the symptoms of heart failure secondary to fluid overload, and the aldosterone inhibitors (spironolactone, eplerenone) are added as the heart failure progresses. Only after these drugs are used is digoxin added. Hydralazine/isosorbide dinitrate became the first drug approved for use in the African-American population. Nesiritide is used in special situations in intensive care.
- Be aware of the important physiologic concepts such as ejection fraction. A patient's ejection fraction reflects the contractility of the heart and is about 65% (0.65) in a normal heart. This value decreases as heart failure progresses; therefore, patients with heart failure have low ejection fractions because their hearts are failing to pump effectively.
- Recognize that hypotension, dysrhythmias, and thrombocytopenia are major adverse effects of milrinone.
- Keep informed of the contraindications to the use of digoxin, which include a history of allergy to the digitalis medications, ventricular tachycardia and fibrillations, and AV block.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 When teaching the patient about the signs and symptoms of cardiac glycoside toxicity, the nurse should alert the patient to watch for
   a visual changes such as photophobia.
   b flickering lights or halos around lights.
   c dizziness when standing up.
   d increased urine output.

2 During assessment of a patient who is receiving digoxin, the nurse monitors for findings that would indicate an increased possibility of toxicity, such as:
   a apical pulse rate of 62 beats/min.
   b digoxin level of 1.5 ng/mL.
   c serum potassium level of 2.0 mEq/L.
   d serum calcium level of 9.9 mEq/L.

3 When monitoring a patient who is receiving an intravenous infusion of nesiritide (Natrecor), the nurse will look for which adverse effect?
   a Dysrhythmia
   b Proteinuria
   c Hyperglycemia
   d Hypertension

4 A patient is taking a beta blocker as part of the treatment plan for heart failure. The nurse knows that the purpose of the beta blocker for this patient is to
   a increase urine output.
   b prevent stimulation of the heart by catecholamines.
   c increase the contractility of the heart muscle.
   d cause peripheral vasodilation.

5 The nurse is assessing a patient who is receiving a milrinone infusion and checks the patient's cardiac rhythm on the heart monitor. What adverse cardiac effect is most likely to occur in a patient who is receiving intravenous milrinone?
   a Tachycardia
   b Bradycardia
   c Atrial fibrillation
   d Ventricular dysrhythmia

6 The nurse is administering an intravenous infusion of a phosphodiesterase inhibitor to a patient who has heart failure. The nurse will evaluate the patient for which therapeutic effects? (Select all that apply.)
   a Positive inotropic effects
   b Vasodilation
   c Decreased heart rate
   d Increased blood pressure
   e Positive chronotropic effects

7 The medication order for a 5-year-old child reads: "Give digoxin elixir, 15 mcg/kg, PO now." The child weighs 20 kg. How many milligrams will this child receive?

1. b, 2. c, 3. a, 4. b, 5. d, 6. a, b, e, 7. 0.3 mg

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Describe the anatomy and physiology of the heart as well as cardiac electrophysiology, including normal conduction patterns, rate, and rhythm.
2 Briefly discuss the various disorders of cardiac electrophysiology and consequences to the patient.
3 Define the terms *dysrhythmia* and *arrhythmia.*
4 Identify the various causes of abnormal heart rhythms and their impact on the patient's health and activities of daily living.
5 Identify the most commonly encountered dysrhythmias.
6 Compare the various dysrhythmias with regard to their basic characteristics, impact on the structures of the heart, and related symptoms.
7 Contrast the various classes of antidysrhythmic drugs, citing prototypes in each class and describing their mechanisms of action, indications, routes of administration, dosing, any related drug protocols, adverse effects, cautions, contraindications, drug interactions, and any toxic reactions.
8 Develop a nursing care plan that includes all phases of the nursing process for patients receiving each class of antidysrhythmic drug.

DRUG PROFILES

adenosine, p. 413
♦ **amiodarone, p. 411**
♦ **atenolol, p. 410**
♦ **diltiazem, p. 412**
♦ **dofetilide, p. 412**
esmolol, p. 410
flecainide, p. 409
ibutilide, p. 411
♦ **lidocaine, p. 409**
♦ **metoprolol, p. 410**
procainamide, p. 406
propafenone, p. 409
♦ **quinidine, p. 408**
♦ **sotalol, p. 412**
♦ **verapamil, p. 413**

♦ *Key drug*

KEY TERMS

Action potential Electrical activity that consists of a series of polarizations and depolarizations that travel across the cell membrane of a nerve fiber during transmission of a nerve impulse and across the cell membranes of a muscle cell during contraction. (p. 398)

Action potential duration The interval beginning with baseline (resting) membrane potential followed by depolarization and ending with repolarization to baseline membrane potential. (p. 399)

Arrhythmia Technically "no rhythm," meaning absence of heart rhythm (i.e., no heartbeat at all). More commonly used in clinical practice to refer to any variation from the normal rhythm of the heart. A synonymous term is *dysrhythmia,* which is the primary term used in this chapter and book. (p. 397)

Cardiac Arrhythmia Suppression Trial (CAST) The name of the major research study conducted by the National Heart, Lung, and Blood Institute to investigate the possibility of eliminating sudden cardiac death in patients with asymptomatic ectopy after a myocardial infarction. (p. 409)

Depolarization The movement of positive and negative ions on either side of a cell membrane across the membrane in a direction that brings the net charge to zero. (p. 398)

Dysrhythmia Any disturbance or abnormality in heart rhythm. (p. 397)

Effective refractory period The period after the firing of an impulse during which a cell may respond to a stimulus but the response will not be passed along or continued as another impulse. (p. 399)

Internodal pathways (Bachmann bundle) Special pathways in the atria that carry electrical impulses generated by the sinoatrial node. These impulses cause the heart to beat. (p. 400)

Relative refractory period The time after generation of an action potential during which a nerve fiber will show a (reduced) response only to a strong stimulus. (p. 399)

Resting membrane potential (RMP) The voltage that exists when the cell membranes of heart muscle (or other muscle or nerve cells) are at rest. (p. 397)

Sodium-potassium adenosine triphosphatase (ATPase) pump A mechanism for transporting sodium and potassium ions across the cell membrane against an opposing concentration gradient. Energy for this transport is obtained from the hydrolysis of adenosine triphosphate (ATP) by means of the enzyme ATPase. (p. 397)

Sudden cardiac death Unexpected, fatal cardiac arrest. (p. 410)

Threshold potential The critical state of electrical tension required for spontaneous depolarization of a cell membrane. (p. 400)

Torsades de pointes A rare ventricular arrhythmia that is associated with long QT interval and can degenerate into ventricular fibrillation and sudden death without medical intervention; often simply referred to as *torsades*. (p. 403)

Vaughan Williams classification The system most commonly used to classify antidysrhythmic drugs. (p. 403)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

DYSRHYTHMIAS AND NORMAL CARDIAC ELECTROPHYSIOLOGY

A **dysrhythmia** is any deviation from the normal rhythm of the heart. The term **arrhythmia** (literally "no rhythm") implies asystole, or no heartbeat at all. Thus, the more accurate term for an irregular heart rhythm is *dysrhythmia.* However, *arrhythmia* is commonly used in clinical practice. Dysrhythmias can develop in association with many conditions, such as after a myocardial infarction (MI), cardiac surgery, or as the result of coronary artery disease. Dysrhythmias are usually serious and may require treatment with an antidysrhythmic drug or nonpharmacologic therapies; however, not all dysrhythmias require medical treatment. A cardiologist is usually consulted to make the judgment.

Disturbances in cardiac rhythm are the result of abnormally functioning cardiac cells. Thus, an understanding of the mechanism responsible for dysrhythmias first requires review of the electrical properties of these cells. Figure 24-1 on p. 384 shows the overall anatomy of the conduction system of the heart. Figure 25-1 illustrates some of the properties of this system from the standpoint of a single cardiac cell. Inside a resting cardiac cell, a net negative charge exists relative to the outside of the cell. This difference in the electronegative charge exists in all types of cardiac cells and is referred to as the **resting membrane potential (RMP).** The RMP results from an uneven distribution of ions (e.g., sodium, potassium, and calcium) across the cell membrane. This is known as *polarization.* Each ion moves through its own specific channel, which is a specialized protein molecule that sits across the cell membrane. These proteins work continuously to restore the specific intracellular and extracellular concentrations of each ion. At RMP, the ionic concentration gradient (distribution) is such that potassium ions are more highly concentrated intracellularly, whereas sodium and calcium ions are more highly concentrated extracellularly. For this reason, potassium is generally thought of as an intracellular ion, whereas sodium and calcium are generally thought of as extracellular ions. Negatively charged intracellular and extracellular ions such as chloride (Cl^-) and bicarbonate (HCO_3^-) also contribute to this uneven distribution of ions, which is known as a *polarized* state. This polarized distribution of ions is maintained by the **sodium-potassium adenosine triphosphatase (ATPase) pump,** an energy-requiring ionic pump. The energy that drives this pump comes from molecules of adenosine triphosphate (ATP), which are a major source of energy in cellular metabolism.

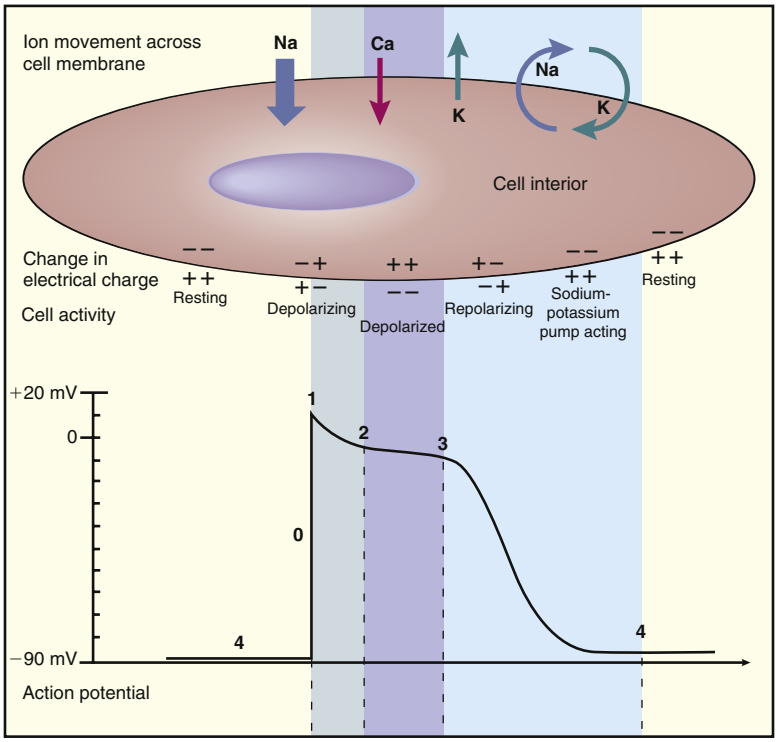

FIGURE 25-1 Phases of the action potential of a cardiac cell. In resting phase (4), the cell membrane is polarized. The cell's interior has a net negative charge, and the membrane is more permeable to potassium ions (K) than to sodium ions (Na). When the cell is stimulated and begins to depolarize (0), sodium ions enter the cell, potassium leaves the cell, calcium (Ca) channels open, and sodium channels close. In its depolarized phase (1), the cell's interior has a net positive charge. In the plateau phase (2), calcium and other positive ions enter the cell and potassium permeability declines, which lengthens the action potential. Then (3), calcium channels close and sodium is pulled from the cell by the sodium-potassium pump. The cell's interior then returns to its polarized, negatively charged state (4). (From Monahan FD: *Phipps' medical-surgical nursing: health and illness perspectives,* ed 8, St Louis, 2007, Mosby.)

Cardiac cells become excited when there is a change in the baseline distribution of ions across their membranes (RMP) that leads to the propagation of an electrical impulse. This change is known as an **action potential.** Action potentials occur in a continuous and regular manner in the cells of the cardiac conduction system, such as the sinoatrial node (SA), atrioventricular node (AV), and His-Purkinje system. All of these tissues have the property of spontaneous electrical excitability known as *automaticity.* This excited state creates action potentials, which in turn generate electrical impulses that travel through the myocardium ultimately to create the heartbeat via contraction of cardiac muscle fibers.

An action potential has five phases. Phase 0 is also called the *upstroke* because it appears as an upward line on the graph of an action potential, as shown in Figure 25-2, *A* and *B*. Both of these figures graphically illustrate the cycle of electrical changes that create an action potential. Note the variation in the shape of the curve depending on the relative conduction speed of the specific tissue involved (SA node versus Purkinje fiber). A faster rate of conduction corresponds to a steeper slope on the graph.
