During phase 0, the resting cardiac cell membrane suddenly becomes highly permeable to sodium ions, which rush from the outside of the cell membrane to the inside (influx) through what are known as *fast channels* or *sodium channels.* This disruption of the earlier polarized state of the membrane is known as **depolarization.** Depolarization can be thought of as a temporary equalization of positive and negative charges across the cell membrane. This releases electrochemical energy that drives the resulting electrical impulses through adjacent cells. Phase 1 of the action potential begins a rapid process of repolarization that continues through phases 2 and 3 to phase 4, which is the RMP. In phase 1, the sodium channels close and the concentrations of each ion begin to move back toward their ion-specific RMP levels. During phase 2, calcium influx occurs through the slow channels or calcium channels. They are called *slow channels* because the calcium influx occurs relatively more slowly than the earlier sodium influx. Potassium ions then flow from inside of the cell to outside (efflux) through specific potassium channels. This is done to offset the elevated positive charge caused by the influx of sodium and calcium ions. In the case of the Purkinje fibers, this causes a partial plateau (flattening on the graph) during which the overall membrane potential changes only slightly, as seen in Figure 25-2, *B.* In phase 3, the ionic flow patterns of phases 0 to 2 are changed by the sodium-potassium ATPase pump (or, more simply, the *sodium pump*). This reestablishes the baseline polarized state by restoring

both intracellular and extracellular concentrations of sodium, potassium, and calcium (see Figure 25-1). As a result, the cell membrane is ultimately repolarized to its baseline level or RMP (phase 4). Note that this entire process occurs over roughly 400 milliseconds—that is, four hundred thousandths (less than one half) of one second.

There is some variation in this time period between different parts of the conduction system. As an example, Figure 25-3 illustrates the pattern of movement of sodium, potassium, and calcium ions into and out of a Purkinje cell during the four phases of the action potential. Note that there are several differences in the action potentials of SA nodal cells and Purkinje cells. The level of the RMP for a given type of cell is an important determinant of the rate of its impulse conduction to other cells. The less negative (i.e., the closer to zero) the RMP at the onset of phase 0 of the action potential, the slower the upstroke velocity of phase 0. The slope of phase 0 is directly related to the impulse velocity. An upstroke with a steeper slope indicates faster conduction velocity. Thus, in Purkinje cells, electrical conduction is relatively fast, and therefore electrical impulses are conducted quickly. These cells are referred to as *fast-response cells,* or *fast-channel cells.* Purkinje fibers can therefore be thought of as fast-channel tissue. Many antidysrhythmic drugs affect the RMP and sodium channels, which in turn influences the rate of impulse conduction.

In contrast to Purkinje fibers, the cells of the SA node have a slower upstroke velocity, or a slower phase 0. This is illustrated in Figure 25-2, *A,* as an upstroke curve that is less steep, which indicates a relatively slower rate of electrical conduction in these cells.

AV nodal cells are comparable to SA nodal cells in this regard. This slower upstroke in the SA and AV nodes is primarily dependent on the entry of calcium ions through the slow channels or calcium channels. This means that nodal action potentials are affected by calcium influx as early as phase 0. The nodes are therefore called *slow-channel tissue,* and conduction is slower than that in other parts of the conduction system. Drugs that affect calcium ion movement into or out of these cells (e.g., calcium channel blockers) tend to have significant effects on the SA and AV nodal conduction rates.

The interval between phase 0 and phase 4 is called the **action potential duration** (Figure 25-4). The period between phase 0 and midway through phase 3 is called the absolute or **effective refractory period.** During the effective refractory period, the cardiac cell cannot be restimulated to depolarize and generate another action potential. During the remainder of phase 3 and until the return to the RMP (phase 4), the cardiac cell *can* be depolarized again if it receives a powerful enough impulse (such as one induced by drug therapy or supplied by an electrical pacemaker). This period is referred to as the **relative refractory**

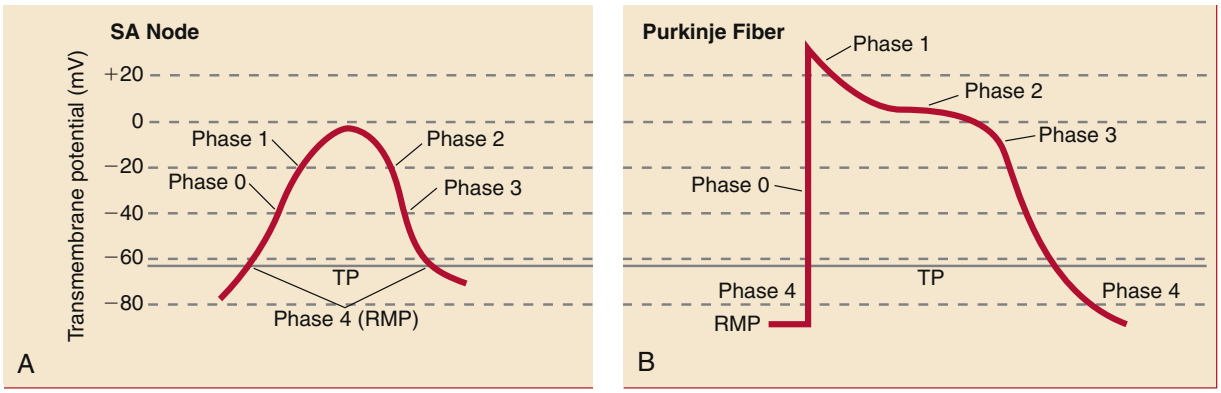

FIGURE 25-2 Action potentials. *RMP,* Resting membrane potential; *SA,* sinoatrial; *TP,* threshold potential.

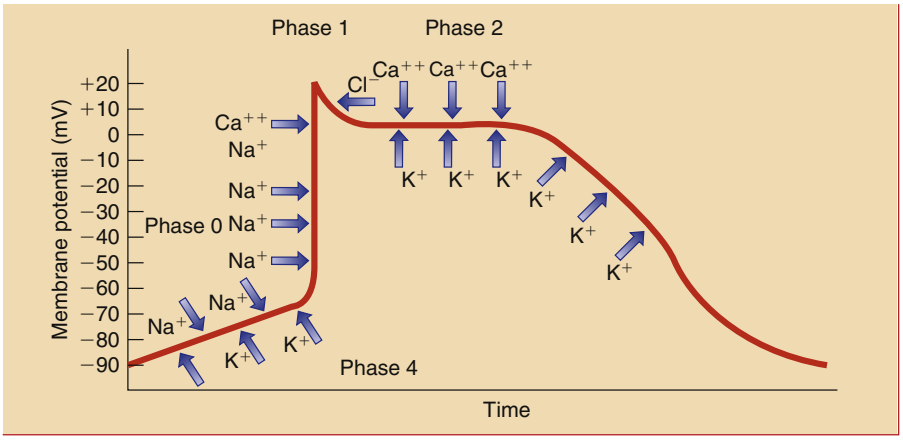

FIGURE 25-3 Purkinje fiber action potential.

period. Figure 25-4 illustrates these various aspects of an action potential. Again, the actual shape of the action potential curve varies in different parts of the conduction system.

The RMP of certain cardiac cells gradually decreases (becomes less negative) over time in ongoing cycles. This is due to small changes in the flux of sodium and potassium ions. Depolarization eventually occurs when a certain critical voltage is reached **(threshold potential).** This process of spontaneous depolarization is referred to as *automaticity*, or *pacemaker activity*. It is normal when it occurs in the SA node (see Figure 24-1 on p. 384). When spontaneous depolarizations occur elsewhere, however, dysrhythmias often result.

The SA node, the AV node, and His-Purkinje cells all possess the property of automaticity. The SA node is the natural pacemaker of the heart because it spontaneously depolarizes the most frequently. The SA node has an intrinsic rate of 60 to 100 depolarizations or beats per minute; that of the AV node is 40 to 60 beats per minute; and that of the ventricular Purkinje fibers is 40 or fewer beats per minute. The action potentials and other properties in different areas of the heart are compared in Table 25-1.

As the pacemaker of the heart, the SA node, which is located near the top of the right atrium, generates the electrical impulse that ultimately produces the heartbeat. First, however, this impulse travels through the atria via specialized pathways called the **internodal pathways (Bachmann bundle).** This causes the atrial myocardial fibers to contract, which creates the first heart sound. Next, the impulse reaches the AV node, which is located near the bottom of the right atrium. The AV node slows this very fast moving electrical impulse just long enough to allow the ventricles to fill with blood. If the AV node did not slow the impulse in this way, ventricular contraction would overlap that of the atria, which would result in a smaller volume of ejected ventricular blood and reduced cardiac output.

Next, the AV nodal cells generate an electrical impulse that passes into the bundle of His (or His bundle). The bundle of His is a band of cardiac muscle fibers located between the right and left ventricles in what is called the *ventricular septum* (wall between the ventricles). The bundle of His distributes the impulse into both ventricles via the right and left bundle branches. Each branch terminates in the Purkinje fibers that are located in the myocardium of the ventricles. Stimulation of the Purkinje fibers causes ventricular contraction and ejection of blood from the ventricles. Blood from the right ventricle is pumped into the pulmonary circulation, whereas blood from the left ventricle is pumped into the systemic circulation to supply the rest of the body. The bundle of His and Purkinje fibers are so named for the medical scientists who first identified them. Together, they are often referred to in the literature as the *His-Purkinje system.* Any abnormality in cardiac automaticity or impulse conduction often results in some type of dysrhythmia.

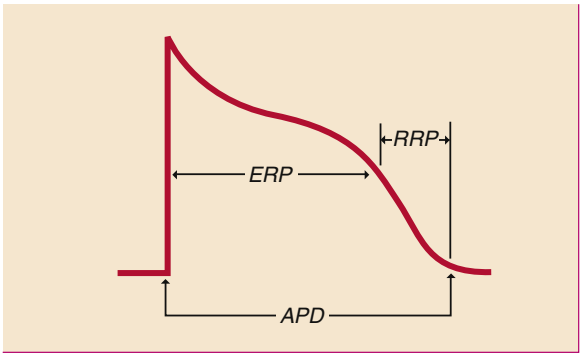

FIGURE 25-4 Aspects of an action potential. *APD,* Action potential duration; *ERP,* effective refractory period; *RRP,* relative refractory period.

Electrocardiography

The electrophysiologic cardiac events described thus far in this chapter correspond more simply to the tracings of an electrocardiogram, abbreviated as ECG or EKG (Figure 25-5). The P wave corresponds to spontaneous impulse generation in the SA node followed immediately by depolarization of atrial myocardial fibers and their muscular contraction. This normally determines the heart rate. It is affected by the balance between sympathetic and parasympathetic nervous system tone, the intrinsic automaticity of the SA nodal tissue, the mechanical stretch of atrial fibers due to incoming blood volume, and cardiac drugs. The QRS complex (or QRS interval) corresponds to depolarization and contraction of ventricular fibers. The J point marks the start of the ST segment, which corresponds to the beginning of ventricular repolarization. The T wave corresponds to completion of the repolarization of these ventricular fibers. As an analogy, depolarization can be thought of as discharge or contraction of cardiac muscle fibers, whereas repolarization can be thought of as a relaxation of muscle fibers to prepare for the next contraction (heartbeat). Note that the repolarization of the atrial fibers is obscured on the ECG tracing by the QRS complex and thus has no corresponding deflection in the tracing. The U wave is

TABLE 25-1 COMPARISON OF ACTION POTENTIALS IN DIFFERENT CARDIAC TISSUE

TISSUE	ACTION POTENTIAL	SPEED OF RESPONSE	THRESHOLD POTENTIAL (mV)	CONDUCTION VELOCITY (m/sec)
SA node		Slow	260	Less than 0.05
Atrium		Fast	290	1
AV node		Slow	260	Less than 0.05
His-Purkinje system		Fast	295	3
Ventricle		Fast	290	1

AV, Atrioventricular; *SA,* sinoatrial.

not always present, and its physiologic basis is uncertain. When the U wave occurs, it is generally correlated with electrophysiologic events such as repolarization of Purkinje fibers. These events may be a source of dysrhythmias caused by a triggered automaticity. Prominent U waves are often associated with sinus bradycardia, hypokalemia, use of quinidine and other class Ia antidysrhythmics, and hyperthyroidism. Abnormal U waves (inverted) are associated with serious conditions such as MI, acute angina, coronary artery spasms, and ischemic heart disease. The PR and QT intervals and the ST segment are parts of the ECG tracing that are often altered by disease or by the adverse effects of certain types of drug therapy or drug interactions, as discussed in later sections of this chapter.

Common Dysrhythmias

A variety of cardiac dysrhythmias are recognized. Some are easier to treat than others using drug therapy and/or interventional cardiology procedures such as pacemaker implantation, catheter ablation, cardioversion, and implantation of cardioverters-defibrillators. Dysrhythmias are subdivided into several broad categories depending on their anatomic site of origin in the heart. Supraventricular dysrhythmias originate above the ventricles in the SA or AV node or atrial myocardium. Ventricular dysrhythmias originate below the AV node in the His-Purkinje system or ventricular myocardium. Dysrhythmias that originate outside the conduction system (i.e., in atrial or ventricular cells) are known as *ectopic,* and their specific points of origin are called *ectopic foci* (*foci* is the plural of the Latin-derived word *focus*). Conduction blocks are dysrhythmias that involve disruption of impulse conduction between the atria and ventricles through the AV node, directly affecting ventricular function. They may also originate in the His-Purkinje system. Less commonly, impulse conduction between the SA and AV node is affected. Several of the most common dysrhythmias are described in Table 25-2, and corresponding ECG tracings are provided. They are also described further in the following text.

Among the supraventricular dysrhythmias, atrial fibrillation is a very common condition. It is characterized by rapid atrial contractions that incompletely pump blood into the

TABLE 25-2 COMMON DYSRHYTHMIAS

DYSRHYTHMIA	DESCRIPTION AND ECG TRACING
Atrial flutter (AF)	Often progresses to atrial fibrillation (F = flutter waves) Atrial fibrillation (AF)	Rapid, ineffective atrial contractions (f = fibrillation waves) Paroxysmal supraventricular tachycardia (PSVT)	Heart rate of 180-200 beats/min or higher 

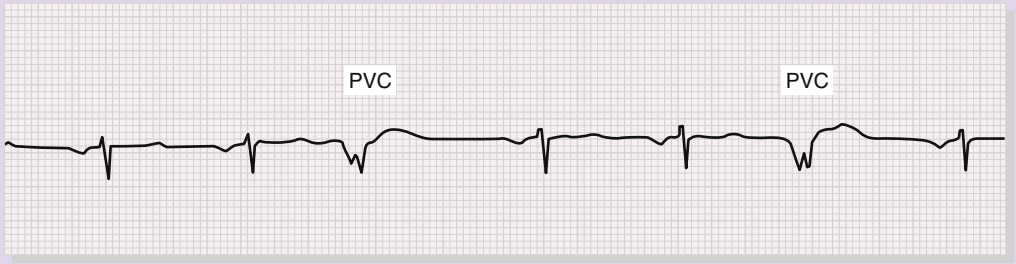
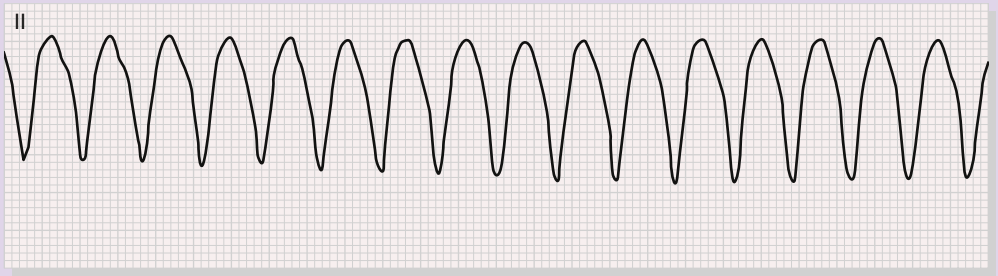
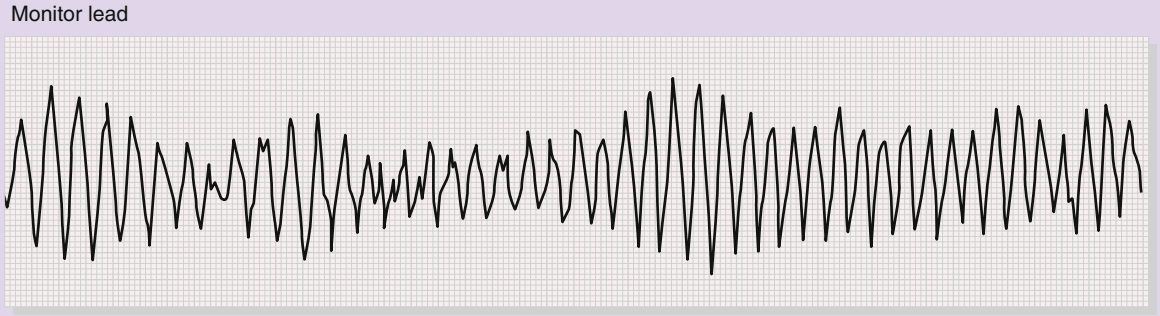
Continued

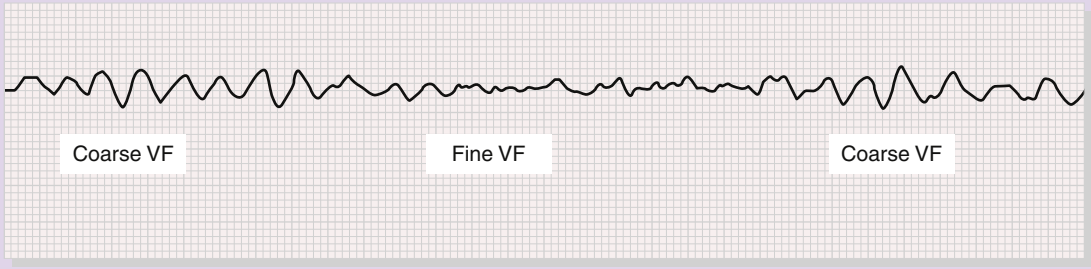
TABLE 25-2 COMMON DYSRHYTHMIAS—cont'd

DYSRHYTHMIA	DESCRIPTION AND ECG TRACING
Premature ventricular contractions (PVCs)	Contractions generated by impulses arising from ectopic foci within ventricular myocardium
Nonsustained ventricular tachycardia (NSVT)	Relatively brief period (20 sec or less) in which ventricles contract rapidly on their own as well as in response to AV impulses
Sustained ventricular tachycardia (SVT)	Same as above but more prolonged
Torsades de pointes (TdP)	Rapid ventricular tachycardia preceded by QT interval prolongation (often progresses to ventricular fibrillation)
Ventricular fibrillation (VF)	Rapid, ineffective ventricular contractions (fatal if not reversed)









ECG, Electrocardiogram.

ventricles. Atrial fibrillation is notable in that it predisposes the patient to stroke. This is due to the fact that the blood tends to stagnate in the incompletely emptied atria and is therefore more likely to clot. If such blood clots manage to make their way into the left ventricle, they may be embolized to the brain and cause a stroke. Although there is a theoretically similar risk for pulmonary embolism, this seems to be of less clinical concern with atrial fibrillation than the risk for stroke. Patients with ongoing atrial fibrillation are often given anticoagulant therapy with warfarin (see Chapter 26) to reduce the likelihood of stroke.

AV nodal reentrant tachycardia (AVNRT) is a conduction disorder that often gives rise to a dysrhythmia known as *paroxysmal supraventricular tachycardia (PSVT)*. (The word *paroxysmal* means "sudden.") AVNRT occurs when electrical impulse transmission from the AV node into the His-Purkinje system of the ventricles is disrupted. As a result, some of the impulses circle backward (retrograde impulses) and reenter the atrial tissues to produce a tachycardic response. In Wolff-Parkinson-White syndrome, ectopic impulses that begin near the AV node actually bypass the AV node and reach the His-Purkinje system before the normal AV-generated impulses. This is one cause of ventricular tachycardia, although it is technically supraventricular in origin.

Varying degrees of AV block (often called *heart block*) involve different levels of disrupted conduction of impulses from the AV node and His-Purkinje system to the ventricles. Although first-degree AV block is often asymptomatic, third-degree block, or complete heart block, often requires use of a cardiac pacemaker to ensure adequate ventricular function. There can also be blocks within the His-Purkinje system of the ventricles, known as *bundle branch blocks*.

Premature ventricular contractions (PVCs) occur when impulses originate from ectopic foci within the ventricles (His-Purkinje system). PVCs probably occur periodically in many people; they become problematic when they occur frequently enough to compromise systolic blood volume. *Ventricular tachycardia* refers to a rapid heartbeat from impulses originating in the ventricles. It can be nonsustained (brief) or sustained, requiring definitive treatment. Worsening ventricular tachycardia can deteriorate into **torsades de pointes,** an intermediate dysrhythmia that often deteriorates into ventricular fibrillation. Ventricular fibrillation is fatal if not reversed, which most often requires electrical defibrillation. Interestingly, torsades de pointes often responds preferentially to intravenous magnesium sulfate.

PHARMACOLOGY OVERVIEW

ANTIDYSRHYTHMIC DRUGS

Numerous drugs are available to treat dysrhythmias. These drugs are categorized according to where and how they affect cardiac cells. Although other classifications are described in the literature, the most commonly used system for this purpose is still the **Vaughan Williams classification.** This system is based on the electrophysiologic effect of particular drugs on the action potential. This approach identifies four major classes of drugs: I (including Ia, Ib, and Ic), II, III, and IV. The various drugs in these four classes are listed in Table 25-3.

There is currently a gradual trend away from the use of class Ia drugs. The formerly available class Ic drug encainide was removed from the market after research indicated that the risk of fatal cardiac dysrhythmias associated with this drug overshadowed its dysrhythmia suppression effects. Class III drugs have emerged as among the most widely used antidysrhythmics at this time. The class IV drugs (calcium channel blockers) have limited usefulness in treating tachydysrhythmias (dysrhythmias involving tachycardia), unlike most of the other classes. The role of class II drugs (beta blockers) continues to grow in the field of cardiology, including in dysrhythmia management. Digoxin, the cardiac glycoside discussed in Chapter 24, still has a place in dysrhythmia management, especially in the prevention of dangerous ventricular tachydysrhythmias secondary to atrial fibrillation.

Mechanism of Action and Drug Effects

Antidysrhythmic drugs work by correcting abnormal cardiac electrophysiologic function. They do this to varying degrees and by various mechanisms. Class I drugs are membrane-stabilizing drugs and exert their actions on the sodium (fast) channels. There are some slight differences in the actions of the drugs in this class, so they are divided into three subclasses. These subclasses are class Ia, Ib, and Ic drugs. The subclasses are based on the magnitude of the effects each drug has on phase 0, the action potential duration, and the effective refractory period. Class Ia drugs (quinidine, procainamide, and disopyramide) block the sodium channels; more specifically, they delay repolarization and increase the action potential duration. Class Ib drugs (phenytoin, lidocaine) also block the sodium

TABLE 25-3 VAUGHAN WILLIAMS CLASSIFICATION OF ANTIDYSRHYTHMIC DRUGS

FUNCTIONAL CLASS	DRUGS
Class I: membrane-stabilizing drugs; fast sodium channel blockers	
Ia: ↑ blockade of sodium channel, delay repolarization, ↑ action potential duration	Quinidine, disopyramide, procainamide
Ib: ↑ blockade of sodium channel, accelerate repolarization, ± action potential duration	Lidocaine, phenytoin
Ic: ↑↑↑ blockade of sodium channel, ± repolarization; also suppress reentry	Flecainide, propafenone
Class II: beta-blocking drugs	All beta blockers
Class III: drugs whose principal effect on cardiac tissue is to ↑ action potential duration	Amiodarone, dronedarone, sotalol,* ibutilide, dofetilide
Class IV: calcium channel blockers	Verapamil, diltiazem
Other: antidysrhythmic drugs that have the properties of several classes and therefore cannot be placed in one particular class	Digoxin, adenosine

↑, Increase; ±, increase or decrease.
*Sotalol also has class II properties.

channels, but unlike class Ia drugs, they accelerate repolarization and decrease the action potential duration. Phenytoin is more commonly used as an anticonvulsant (see Chapter 14) than as an antidysrhythmic drug. Class Ic drugs (flecainide, propafenone) have a more pronounced effect on the blockade of sodium channels but have little effect on repolarization or the action potential duration.

Class II drugs are the beta-adrenergic blockers (beta blockers; see Chapter 19), and they are commonly used as antihypertensives (see Chapter 22) and antianginal drugs (see Chapter 23). They work by blocking sympathetic nervous system stimulation to the heart and, as a result, the transmission of impulses in the heart's conduction system. This results in depression of phase 4 depolarization. These drugs mostly affect slower-conducting cardiac tissues.

Class III drugs (amiodarone, dronedarone, sotalol, ibutilide, and dofetilide) increase the action potential duration by prolonging repolarization in phase 3. They affect fast tissue and are most commonly used to manage dysrhythmias that are difficult to treat. They are usually reserved for patients for whom other therapies have failed. Sotalol actually has properties of both class II and class III drugs, and it may be listed as a member of either one or the other class, depending on the specific reference used.

Class IV drugs are the calcium channel blockers, which, like beta blockers, are also used as both antihypertensives (see Chapter 22) and antianginal drugs (see Chapter 23). As their name implies, they work specifically by inhibiting the calcium channels, which reduces the influx of calcium ions during action potentials. This results in depression of phase 4 depolarization. Diltiazem and verapamil are the calcium channel blockers most commonly used to treat cardiac dysrhythmias.

The mechanisms of action of the major classes of antidysrhythmics are summarized in Table 25-4. The effects of the various classes of antidysrhythmic drugs are presented in Box 25-1.

Indications

Antidysrhythmic drugs are effective in treating a variety of cardiac dysrhythmias. The antidysrhythmic drugs and the most common indications for their use are listed in Table 25-5.

TABLE 25-4 ANTIDYSRHYTHMIC DRUGS: MECHANISMS OF ACTION

	VAUGHAN WILLIAMS CLASS			
	I	II	III	IV
Action	Blocks sodium channels, affects phase 0	Decreases spontaneous depolarization, affects phase 4	Prolongs action potential duration	Blocks slow calcium channels
Tissue	Fast	Slow	Fast	Slow
Effect on action potential				

Contraindications

As with all drugs, contraindications to the use of antidysrhythmic drugs include known drug allergy to a specific product. Other contraindications may include second- or third-degree AV block, bundle branch block, cardiogenic shock, sick sinus syndrome, and any other ECG changes depending on the clinical judgment of a cardiologist. The concurrent use of certain drugs that interact with antidysrhythmics is also considered. The reason for these concerns is that antidysrhythmic drugs can potentially worsen existing dysrhythmias (also termed *dysrhythmogenic*). The risk is greater in patients with structural heart damage (e.g., after MI). In patients with AV block and bundle branch block, there is a danger of drug-induced ventricular failure if a drug further compromises the

BOX 25-1 EFFECTS OF ANTIDYSRHYTHMIC DRUGS

Class Ia (Disopyramide, Procainamide, Quinidine)
- Depress myocardial excitability
- Prolong the effective refractory period
- Eliminate or reduce ectopic foci stimulation
- Decrease inotropic effect
- Have anticholinergic (vagolytic) activity

Class Ib (Lidocaine, Phenytoin)
- Decrease myocardial excitability in the ventricles
- Eliminate or reduce ectopic foci stimulation in the ventricles
- Have minimal effect on the SA node and automaticity
- Have minimal effect on the AV node and conduction
- Have minimal anticholinergic (vagolytic) activity

Class Ic (Flecainide, Propafenone)
- Produce dose-related depression of cardiac conduction, especially in the bundle of His–Purkinje system
- Have minimal effect on atrial conduction
- Eliminate or reduce ectopic foci stimulation in the ventricles
- Have minimal anticholinergic (vagolytic) activity
- Flecainide use now reserved for the most serious dysrhythmias

Class II (Beta Blockers [e.g., Atenolol, Esmolol, Metoprolol])
- Block beta-adrenergic cardiac stimulation
- Reduce SA nodal activity
- Eliminate or reduce atrial ectopic foci stimulation
- Reduce ventricular contraction rate
- Reduce cardiac output and blood pressure

Class III (Amiodarone, Dronedarone, Sotalol,* Ibutilide, Dofetilide)
- Prolong the effective refractory period
- Prolong the myocardial action potential
- Block both alpha- and beta-adrenergic cardiac stimulation

Class IV (Diltiazem, Verapamil)
- Prolong AV nodal effective refractory period
- Reduce AV nodal conduction
- Reduce rapid ventricular conduction caused by atrial flutter

AV, Atrioventricular; *SA,* sinoatrial.
*Sotalol also has class II properties.

TABLE 25-5 ANTIDYSRHYTHMIC DRUGS: INDICATIONS

DRUG CLASS	INDICATIONS
Class Ia	
disopyramide procainamide quinidine	Atrial fibrillation, premature atrial contractions, premature ventricular contractions, ventricular tachycardia, Wolff-Parkinson-White syndrome
Class Ib	
lidocaine	Ventricular dysrhythmias only (premature ventricular contractions, ventricular tachycardia, ventricular fibrillation)
phenytoin	Atrial and ventricular tachydysrhythmias caused by digitalis toxicity; long QT syndrome
Class Ic	
flecainide propafenone	Ventricular tachycardia and supraventricular tachycardia dysrhythmias, atrial fibrillation and flutter, Wolff-Parkinson-White syndrome
Class II	
Beta Blockers	Both supraventricular and ventricular dysrhythmias (act as general myocardial depressants)
atenolol esmolol metoprolol	
Class III	
amiodarone dronedarone dofetilide ibutilide sotalol*	Life-threatening ventricular tachycardia or fibrillation Atrial fibrillation or flutter resistant to other drug therapy
Class IV	
Calcium Channel Blockers	Paroxysmal supraventricular tachycardia; rate control for atrial fibrillation and flutter
diltiazem verapamil	

*Sotalol also has class II properties.

TABLE 25-6 ANTIDYSRHYTHMIC DRUGS: COMMON ADVERSE EFFECTS

CLASS	DRUG	ADVERSE EFFECTS
Ia	procainamide	Hypotension, rash, diarrhea, nausea, vomiting, agranulocytosis, SLE-like syndrome
	quinidine	Hypotension, QT prolongation, lightheadedness, diarrhea, bitter taste, anorexia, blurred vision, tinnitus, angina
Ib	lidocaine	Bradycardia, dysrhythmia, hypotension, anxiety, metallic taste
	phenytoin	Hypotension, bradycardia, thrombophlebitis, hypertrichosis, gingival hyperplasia
Ic	flecainide	Dizziness, visual disturbances, dyspnea, palpitations, nausea, vomiting, diarrhea, weakness
	propafenone	Prodysrhythmic effect, angina, tachycardia, syncope, AV block, dizziness, fatigue, dyspnea
II	Beta blockers	Bradycardia, hypotension, dizziness, fatigue, AV block, heart failure, hyperglycemia, hypoglycemia, bronchospasm, wheezing, dry mouth, impotence
III	amiodarone	Pulmonary toxicity, thyroid disorders, bradycardia, hypotension, SA node dysfunction, AV block, ataxia, QT prolongation, torsades de pointes, vomiting, constipation, photosensitivity, abnormal liver function test results, jaundice, visual disturbances, hyperglycemia or hypoglycemia, dermatologic reactions including rash, toxic epidermal necrolysis, vasculitis, blue-gray coloring of the skin (face, arms, neck)
	dofetilide	Headache, insomnia, ventricular tachycardia, chest pain, torsades de pointes, rash, back pain, nausea, diarrhea
	ibutilide	Nonsustained ventricular tachycardia, ventricular extrasystoles, tachycardia, hypotension, AV block, headache, nausea
	sotalol*	Bradycardia, chest pain, palpitations, fatigue, dizziness, lightheadedness, weakness, dyspnea
IV	Calcium channel blockers	Constipation, bradycardia, heart block, hypotension, dizziness, dyspnea

AV, Atrioventricular; *SA,* sinoatrial; *SLE,* systemic lupus erythematosus.
*Sotalol also has class II properties.

already existing AV conduction delays. The safe prescribing of antidysrhythmic drugs is an area that requires especially strong clinical expertise and careful judgment on a case-by-case basis.

Adverse Effects

Adverse effects common to most antidysrhythmics include hypersensitivity reactions, nausea, vomiting, and diarrhea. Other common effects include dizziness, headache, and blurred vision. In addition, many antidysrhythmics are themselves capable of producing new dysrhythmias (prodysrhythmic effect). Prolongation of the QT interval is a potentially severe adverse effect shared by many antidysrhythmics. The concern with QT prolongation is the potential for induction of torsades de pointes. As with any drug class, there are also cases of unpredictable or idiosyncratic (see Chapter 2) adverse effects that are not related to drug concentration in the body. Idiosyncratic reactions are unpredictable; however, it is thought that such effects will eventually be explained by genetic variations. Table 25-6 summarizes the most commonly reported adverse effects by specific drug.

Toxicity and Management of Overdose

The main toxic effects of the antidysrhythmics involve the heart, circulation, and central nervous system (CNS). Specific antidotes are not available, and the management of an overdose involves maintaining adequate circulation and respiration

TABLE 25-7 SELECTED ANTIDYSRHYTHMIC DRUGS: MANAGEMENT OF OVERDOSE

DRUG	TOXIC EFFECT	MANAGEMENT
acebutolol	Bradycardia	Atropine 1-3 mg IV divided
	Bronchospasm	$Beta_2$-adrenergic or theophylline
	Cardiac failure	Digitalization
	Hypotension	Vasopressor
adenosine	Usually self-limiting due to a very short half-life	Competitive antagonists caffeine or theophylline
amiodarone	Bradycardia	Beta-adrenergic drug
	Hypotension	Positive inotropic drug or vasopressor
digoxin	Bradycardia	See Chapter 24 for more information
disopyramide	Loss of consciousness; cardiac and respiratory arrest	Neostigmine for anticholinergic effects, emesis induction, activated charcoal, and hemodialysis
esmolol	Same as for acebutolol	Same as for acebutolol
flecainide	Reduced heart rate	Dopamine or dobutamine; acidification of very alkaline urine
lidocaine	Convulsions	Diazepam or thiopental
moricizine	Hypotension, heart failure, myocardial infarction	Gastric evacuation and advanced life support measures
phenytoin	Circulatory and respiratory arrest, convulsions	Life support measures when required
procainamide	Cardiac depression	IV pressor drugs and supportive measures
	Convulsions	Diazepam and mechanically assisted respiration
propafenone	Same as for acebutolol	Same as for acebutolol
quinidine	Same as for acebutolol	Same as for acebutolol
sotalol*	Convulsions	Diazepam or short-acting barbiturate
verapamil	Cardiac failure	Dopamine or dobutamine
	Conduction problems	Cardiac pacing
	Hypotension	Vasopressors, 10% calcium chloride solution

IV, Intravenous.
*Sotalol also has class II properties.

using general support measures and providing any required symptomatic treatment (Table 25-7).

Interactions

Antidysrhythmics can interact with many different categories of drugs. The most serious drug interactions are those that can result in dysrhythmias, hypotension or hypertension, respiratory distress, or excessive therapeutic or toxic drug effects. Drug interactions occur when the presence of one drug strengthens or weakens the pharmacologic effects of another. This is most commonly seen when the first drug affects the activity of the enzymes that metabolize the second drug, either speeding or slowing its elimination. One particular interaction common to many antidysrhythmics is the potentiation of anticoagulant activity with warfarin (Coumadin) (see Chapter 26). Because many patients receiving antidysrhythmic therapy also need warfarin, the international normalized ratio (INR) must be closely monitored and necessary adjustments made to the warfarin dosage. This is especially true with amiodarone. The INR will increase by 50% in almost 100% of patients receiving amiodarone and warfarin. Grapefruit juice can also inhibit the metabolism of several antidysrhythmics such as amiodarone, disopyramide, and quinidine. Other common interactions are summarized in Table 25-8. To explain the mechanism for each interaction is beyond the scope of this text. Readers needing more detailed information are encouraged to consult other appropriate references.

Dosages

For dosage information on selected antidysrhythmic drugs, see the table on p. 407.

DRUG PROFILES

The four classes of antidysrhythmics produce a variety of effects on the action potential of the cardiac cell and exert a major influence on cardiac electrophysiologic function. The diversity of therapeutic effects and adverse effects pose a special challenge to ensuring the safe and efficacious use of these drugs. Because the aspects of the nursing process that relate to the administration of these drugs differ for each of the four classes of drug, each group is discussed separately.

CLASS Ia DRUGS

Class Ia drugs are considered membrane-stabilizing drugs because they possess local anesthetic properties. They stabilize the membrane and have depressant effects on phase 0 of the action potential. These drugs include procainamide, quinidine, and disopyramide.

procainamide

The electrophysiologic effect of procainamide (Pronestyl) is similar to that of quinidine. Procainamide is useful in the management of atrial and ventricular tachydysrhythmias, although it is not used frequently. Procainamide is chemically related to the local anesthetic procaine. Significant adverse effects include ventricular dysrhythmias and blood disorders. It can cause a

TABLE 25-8 SELECTED ANTIDYSRHYTHMIC DRUGS: COMMON DRUG INTERACTIONS

DRUG (CLASS)	INTERACTING DRUGS	EFFECTS*
quinidine (Ia)	Amiodarone, dronedarone, amitriptyline, erythromycin, haloperidol, sotalol, moxifloxacin	Additive QT prolongation
	Digoxin	Increase in digoxin levels by 50%
	HMG-CoA reductase inhibitors (statins)	Increased statin levels and toxicity
lidocaine (Ib)	Amiodarone, azole antifungals, beta blockers, erythromycin, verapamil, cimetidine, tolvaptan	Increased serum levels of lidocaine
propafenone (Ic)	Cimetidine, quinidine, conivaptan, pimozide	Increased propafenone levels; use is contraindicated
	Digoxin, warfarin, beta blockers	Increase in level of interacting drugs
	Class Ia and III antidysrhythmics, erythromycin	Prolonged QT interval
amiodarone (III)	Azole antifungals, clarithromycin, erythromycin, haloperidol, moxifloxacin, quinidine, procainamide	Prolonged QT interval
	Digoxin, diltiazem, verapamil, beta blockers	AV block
	Warfarin, digoxin	Increase in INR by 50% in almost 100% of patients, increase in digoxin levels by 50%
	Cyclosporine	Increased cyclosporine levels and toxicity
	HMG-CoA reductase inhibitors (statins)	Increased statin levels and toxicity
dofetilide (III)	Cimetidine, verapamil, hydrochlorothiazide (HCTZ), ketoconazole, trimethoprim	Increased dofetilide concentrations—use is contraindicated
	Bepridil, clarithromycin, erythromycin, tricyclic antidepressants, phenothiazines, moxifloxacin	Prolonged QT interval
sotalol (III)†	Calcium channel blockers	Additive effects on AV conduction, bradycardia
	Class I antidysrhythmics, erythromycin, bepridil, moxifloxacin, amiodarone	Prolonged QT interval, bradycardia
verapamil, diltiazem (IV)	Amiodarone, beta blockers, flecainide, digoxin	Bradycardia, decreased cardiac output, hypotension
	Azole antifungals, clarithromycin, erythromycin, isoniazid, HIV drugs	Increased verapamil effects
	HMG-CoA reductase inhibitors (statins)	Increased statin levels and toxicity

AV, Atrioventricular; *HIV,* human immunodeficiency virus; *HMG-CoA,* hydroxymethylglutaryl–coenzyme A; *INR,* international normalized ratio.
*Note that enhanced activity of any antidysrhythmic drug may reach the level of drug toxicity, including potentially fatal cardiac dysrhythmias.
†Sotalol also has class II properties.

DOSAGES

Selected Antidysrhythmic Drugs

DRUG NAME (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE
Class I		
quinidine (Quinidex [sulfate], Quinaglute, Dura-Tab [gluconate]) (C)	Class Ia antidysrhythmic	**Adult** Gluconate PO: 324-648 mg q8-12h IM: 600 mg followed by 400 mg q2-6h or more if needed IV: 200-750 mg infused at up to 10 mg/min Sulfate PO: 200-mg load; 100-600 mg q4-6h
♦ lidocaine (Xylocaine) (B)	Class Ib antidysrhythmic	**Pediatric** IV: bolus dose, 1 mg/kg; usual maintenance infusion rate, 20-50 mcg/kg/min **Adult** IV: Bolus dose 50-100 mg; may be repeated in 5 min; do not exceed 200-300 mg over 1 hr; usual maintenance infusion rate 1-4 mg/min
propafenone (Rythmol) (C)	Class Ic antidysrhythmic	**Adult** PO: Start with 150 mg q8h and increase q3-4d; usual range, 450-900 mg/day divided
Class II		
metoprolol (Lopressor) (D)	Beta$_1$ blocker (class II antidysrhythmic)	**Adult** IV/PO: 3 bolus injections of 5 mg at 2-min intervals followed by 50 mg PO q6h for 48 hr, thereafter 50-100 mg bid PO: 50-100 mg bid

Continued

DOSAGES—cont'd

Selected Antidysrhythmic Drugs

DRUG NAME (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE
Class III		
♦ amiodarone (Cordarone) (D)	Class III antidysrhythmic	**Adult** IV: 150 mg over 10 min, then 60 mg/hr for 6 hr, then 30 mg/hr as maintenance dose PO: 800-1600 mg/day for 1-3 wk, reduced to 400-800 mg/day for 5 wk; usual maintenance dose 200-400 mg/day
♦ dofetilide (Tikosyn) (C)	Class III antidysrhythmic	**Adult** PO: 125-500 mg bid (note dose is individualized)
ibutilide (Corvert) (C)	Class III antidysrhythmic	**Adult** IV: 1-mg infusion over 10 min (if less than 60 kg, then 0.1 mL/kg)
♦ sotalol* (Betapace) (B)	Class III antidysrhythmic	**Adult** PO: 160-320 mg/day divided into 2-3 doses
Class IV		
♦ diltiazem (Cardizem)	Calcium channel blocker (class IV antidysrhythmic)	**Adult** IV: Bolus dose 0.25 mg/kg over 2 min, second dose 0.35 mg/kg over 2 min after 15 min as needed, then 5-10 mg/hr by continuous infusion Oral: 120-360 mg daily
♦ verapamil (Calan, Isoptin, Verelan) (C)	Calcium channel blocker (class IV antidysrhythmic)	**Pediatric** IV: 1-15 yr: 0.1-0.3 mg/kg bolus over 2 min; do not exceed 5-mg dose; repeat dose not exceeding 10 mg may be given after 30 min **Adult** PO: Start with 80 mg tid-qid; daily range 240-480 mg IV: 2.5-5 mg bolus over 2 min; repeat dose of 5-10 mg may be given after 30 min
Unclassified		
adenosine (Adenocard) (C)	Unclassified antidysrhythmic	**Adult** IV: 6-mg bolus over 1-2 sec; second rapid bolus of 12 mg as needed, which may be repeated a second time as needed

IM, Intramuscular; *IV,* intravenous; *PO,* oral.
*Sotalol also has Class II properties.

systemic lupus erythematosus–like syndrome, which occurs in about 30% of patients on long-term therapy. It can also cause gastrointestinal effects such as nausea, vomiting, and diarrhea. Other adverse effects include fever, leukopenia, maculopapular rash, flushing, and torsades de pointes resulting from prolongation of the QT interval. Box 25-2 lists selected drugs known to prolong the QT interval. Use of procainamide is contraindicated in patients with a known hypersensitivity to it and in those with heart block and systemic lupus erythematosus. It is available in both oral and injectable forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV/IM	10-30 min	10-60 min	3 hr	3 hr
PO	0.5-1 hr	1-2 hr	3 hr	3-8 hr

quinidine

Quinidine (Quinidex) has both a direct action on the electrical activity of the heart and an indirect (anticholinergic) effect. Significant adverse effects of the drug include cardiac asystole and ventricular ectopic beats. Quinidine can cause cinchonism. Symptoms of mild cinchonism include tinnitus, loss of hearing, slight blurring of vision, and gastrointestinal upset. Contraindications to the use of the drug include hypersensitivity, thrombocytopenic purpura resulting from previous therapy, AV block, intraventricular conduction defects, and torsades de pointes. Quinidine is available in both oral and parenteral (injectable) forms and in three different salt forms. The oral preparations include sulfate and gluconate salts.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-3 hr	0.5-6 hr	6-7 hr	6-12 hr

CLASS Ib DRUGS

Class Ib drugs share many characteristics with class Ia drugs but act preferentially on ischemic myocardial tissue. They have little

BOX 25-2 SELECTED DRUGS THAT PROLONG THE QT INTERVAL*

Antidysrhythmics: amiodarone, procainamide, quinidine, dofetilide, bepridil, sotalol, flecainide
Antibiotics: azithromycin, clarithromycin, erythromycin, levofloxacin, moxifloxacin, telithromycin
Anticancer: tamoxifen, sunitinib
Antifungals: fluconazole, itraconazole, ketoconazole, voriconazole
Antidepressants: amitriptyline, imipramine, fluvoxamine, nefazodone, doxepin, imipramine, sertraline, venlafaxine, citalopram, amoxapine, nortriptyline, trimipramine
Antinausea: dolasetron, droperidol, ondansetron, granisetron
Antipsychotics: haldoperidol, pimozide, thioridazine, chlorpromazine, risperidone, clozapine, quetiapine
Bronchodilators: albuterol, levalbuterol, salmeterol, ephedrine, metaproterenol, terbutaline
Calcium channel blockers: diltiazem, verapamil
Miscellaneous: cocaine, foscarnet, galantamine, indapamide, lithium, midodrine, tacrolimus, tolterodine, amantadine, felbmate, fosphenytoin, methadone, octreotide, solifenacin, vardenafil, tizanidine
Protease Inhibitors: indinavir, saquinavir, nelfinavir, ritonavir

*NOTE: This list is not all-inclusive; rather only selected agents are listed. Further information can be found at www.qtdrugs.org.

effect on conduction velocity in normal tissue. Class Ib drugs have a weak depressive effect on phase 0 depolarization, the action potential duration, and the effective refractory period. They include lidocaine and phenytoin.

♦ lidocaine

Lidocaine (Xylocaine) is the prototypical Ib drug. It is one of the most effective drugs for the treatment of ventricular dysrhythmias, but it can only be administered intravenously because it has an extensive first-pass effect (i.e., when it is taken orally, the liver metabolizes most of it to inactive metabolites). Because of its extensive hepatic metabolism, dosage reduction by 50% is recommended for patients with liver failure or cirrhosis. Dosage reductions may also be necessary in patients with renal impairment because of extensive excretion of the drug and its metabolites by the kidney.

Lidocaine exerts its effects on the conduction system of the heart by making it difficult for the ventricles to develop a dysrhythmia. This action is known as *raising the ventricular fibrillation threshold.* It occurs by decreasing the sensitivity of the cardiac cell membrane to impulses and decreasing the cell's ability to depolarize on its own (decreasing automaticity). Many of these effects are accomplished by blocking the fast sodium channels.

Significant adverse effects include CNS toxic effects such as twitching, convulsions, and confusion; respiratory depression or arrest; and the cardiovascular effects of hypotension, bradycardia, and dysrhythmias. Use of the drug is contraindicated in patients who are hypersensitive to it, who have severe SA or AV intraventricular block, or who have Stokes-Adams or Wolff-Parkinson-White syndrome. Lidocaine is available only in parenteral form for intramuscular or intravenous administration. Lidocaine is commonly used as a local anesthetic (see Chapter 11); a transdermal form is also available for analgesia (see Chapter 10).

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	2-15 min	5-10 min	8 min	20 min–1.5 hr

CLASS Ic DRUGS

Class Ic drugs (flecainide, propafenone) produce a more pronounced blockade of the sodium channel than class Ia and Ib drugs but have little effect on repolarization or the action potential duration. These drugs significantly slow conduction in the atria, AV node, and ventricles. Because of their marked effect on conduction, class Ic drugs strongly suppress PVCs, reducing or eliminating them in a large number of patients.

flecainide

Flecainide (Tambocor) is a chemical analogue of procainamide. Historically, clinicians have been hesitant to prescribe flecainide because of the findings of a large multicenter study called the **Cardiac Arrhythmia Suppression Trial (CAST).** This study showed that mortality and nonfatal cardiac arrest rates in patients treated with flecainide were actually comparable to or higher than those seen in patients who received the placebo. Because of these findings, the U.S. Food and Drug Administration (FDA) required that the labeling of flecainide be revised to indicate that its use is to be limited to the treatment of documented life-threatening ventricular dysrhythmias. However, since the findings of the CAST were initially published in 1992, there have been numerous studies showing that flecainide is safe and effective for the treatment of atrial fibrillation. In fact, according to the most current practice guidelines, flecainide is considered a first-line drug in the treatment of atrial fibrillation.

Flecainide is better tolerated than quinidine or procainamide. It has a negative inotropic effect and depresses left ventricular function. Less serious but more common noncardiac adverse effects include dizziness, visual disturbances, and dyspnea. Contraindications to its use include hypersensitivity, cardiogenic shock, second- or third-degree AV block, and non–life-threatening dysrhythmias. Flecainide is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	3 hr	1.5-3 hr	11-12 hr	12-27 hr

propafenone

Propafenone (Rythmol) is similar in action to flecainide. It reduces the fast inward sodium current in Purkinje fibers and to a lesser extent in myocardial fibers. Unlike other class I drugs, propafenone has mild beta-blocking effects. This may contribute to its overall effects on the conduction system. It is also

believed to have calcium channel–blocking effects, which may contribute to its mild negative inotropic effects.

Until recently, propafenone's use was limited to the treatment of documented life-threatening ventricular dysrhythmias, as was flecainide. Recent findings suggest that it has benefit in the treatment of atrial fibrillation as well. Treatment is started while the patient is in the hospital. Unlike flecainide, however, propafenone can be given to patients with depressed left ventricular function and may be a better drug than disopyramide, procainamide, and quinidine in these patients. Propafenone must be used with caution in patients with heart failure, because it has some beta-blocking properties and dose-dependent negative inotropic effects.

Propafenone is generally well tolerated. The most commonly reported adverse reaction is dizziness. Patients may also complain of a metallic taste, constipation, and headache, along with nausea and vomiting. These gastrointestinal adverse effects may be reduced by taking propafenone with food. Propafenone use is contraindicated in patients with a known hypersensitivity to it and in those with bradycardia, bronchial asthma, significant hypotension, uncontrolled heart failure, cardiogenic shock, and various conduction disorders. It is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2 hr	3-5 hr	2-10 hr	Unknown

CLASS II DRUGS

Class II antidysrhythmics are also known as *beta blockers* (see Chapter 19). They work by blocking sympathetic nervous system stimulation to the heart and the heart's conduction system. By doing this, beta blockers prevent catecholamine-mediated actions on the heart. This is known as a *cardioprotective* quality of beta blockers. The resulting cardiovascular effects include a reduced heart rate, delayed AV node conduction, reduced myocardial contractility, and decreased myocardial automaticity. The pharmacologic effects of the beta blockers are especially beneficial after an MI. Following an MI, many catecholamines are released that make the heart hyperirritable and predisposed to many types of dysrhythmias. Beta blockers offer protection from these potentially very dangerous complications. Several studies have demonstrated a significant reduction (on the average of 25%) in the incidence of **sudden cardiac death** after MI in patients treated with beta blockers on an ongoing basis.

Although there are several beta blockers, only a few are commonly used as antidysrhythmics. Those currently approved by the FDA for this purpose are acebutolol, esmolol, propranolol, and sotalol (which has both class II and class III properties). Selected drugs are described here. The class II drugs are classified as pregnancy category C drugs, excepting acebutolol, pindolol, and sotalol, which are all category B drugs.

♦ atenolol

Atenolol (Tenormin) is a cardioselective beta blocker, which means that it preferentially blocks the $beta_1$-adrenergic receptors that are located primarily in the heart. Noncardioselective beta blockers block not only the $beta_1$-adrenergic receptors in the heart but also the $beta_2$-adrenergic receptors in the lungs and therefore can exacerbate preexisting asthma or chronic obstructive pulmonary disease. In addition to having class II antidysrhythmic properties, atenolol is useful in the treatment of hypertension and angina. Its use is contraindicated in patients with severe bradycardia, second- or third-degree heart block, heart failure, cardiogenic shock, or a known hypersensitivity to it. This drug is available in oral form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	2-4 hr	6-7 hr	24 hr

esmolol

Esmolol (Brevibloc) is an ultra-short-acting beta blocker with pharmacologic and electrophysiologic effects on the heart's conduction system similar to those of atenolol. Esmolol is also a cardioselective beta blocker that preferentially blocks the $beta_1$-adrenergic receptors in the heart. It is used in the acute treatment of supraventricular tachydysrhythmias or dysrhythmias that originate above the ventricles. It is also used to control hypertension and tachydysrhythmias that develop after an acute MI. Use of esmolol is contraindicated in patients with a known hypersensitivity to it or those with severe bradycardia, second- or third-degree heart block, heart failure, cardiogenic shock, or severe asthma. It is available only in injectable form and is most commonly used in anesthesia.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Immediate	6 min	9 min	15-20 min

♦ metoprolol

Metoprolol (Lopressor) is another cardioselective beta blocker commonly given after an MI to reduce the risk of sudden cardiac death. It is also used in the treatment of hypertension and angina. The contraindications to metoprolol use are the same as those for the use of atenolol and esmolol. It is available in both oral and injectable forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	1 min	20 min	3-8 hr	5-8 hr
PO	1 hr	2-4 hr	3-8 hr	10-20 hr

CLASS III DRUGS

Class III drugs consist of amiodarone, dronedarone, sotalol (which also has class II properties), ibutilide, and dofetilide. Amiodarone controls dysrhythmias by inhibiting repolarization

and markedly prolonging refractoriness and the action potential duration. Ibutilide and dofetilide are both indicated for conversion of atrial fibrillation or flutter to a normal sinus rhythm. Amiodarone is indicated for the management of life-threatening ventricular tachycardia or ventricular fibrillation that is resistant to other drug therapy. This drug has also been very effective in the treatment of sustained ventricular tachycardias. Amiodarone has recently been used more frequently to treat atrial dysrhythmias as well.

Dronedarone (Multaq) is the newest antidysrhythmic drug. It is very similar to amiodarone and is thought to have less potential for causing the classic amiodarone adverse effects and less potential for drug interactions. However, as with any newly marketed drug, the true incidence of toxicity is not known until it is used in numerous patients. In 2011, the FDA issued an advisory regarding the potential for hepatotoxicity related to dronedarone. Later that year, they also issued a safety communication regarding an increased risk of death and serious cardiovascular events associated with its use.

♦ amiodarone

Amiodarone (Cordarone, Pacerone) markedly prolongs the action potential duration and the effective refractory period in all cardiac tissues. Besides exerting these dramatic effects, it is also known to block both the alpha- and beta-adrenergic receptors of the sympathetic nervous system. Clinically it is one of the most effective antidysrhythmic drugs for controlling supraventricular and ventricular dysrhythmias. It is indicated for the management of sustained ventricular tachycardia, ventricular fibrillation, and nonsustained ventricular tachycardia. It is reported to be effective in 40% to 60% of all patients with ventricular tachycardia. It is the drug of choice for ventricular dysrhythmias according to the Advanced Cardiac Life Support guidelines. Recently it has shown promise in the management of atrial dysrhythmias that are difficult to treat with other less toxic drugs.

Amiodarone has many unwanted adverse effects, and these can be attributed to its chemical properties. Amiodarone is very *lipophilic,* or fat loving. Therefore, it can penetrate and concentrate in the adipose tissue of any organ in the body. It also has iodine in its chemical structure. One organ that sequesters iodine from the diet is the thyroid gland. As a result, amiodarone can cause either hypothyroidism or hyperthyroidism. The package insert for amiodarone lists iodine allergy as a contraindication. However, evidence for avoiding amiodarone in patients with iodine hypersensitivity is extremely limited and does not appear to support its contraindication in patients with severe dysrhythmias.

Adverse reactions occur in approximately 75% of patients treated with this drug, but the incidence is higher and the severity greater with higher dosages (those exceeding 400 mg/day) and prolonged therapy. One of the most common adverse effects is corneal microdeposits, which may cause visual halos, photophobia, and dry eyes. This occurs in virtually all adults who take the drug for longer than 6 months. Photosensitivity is also very common, reported in 10% to 75% of patients taking amiodarone.

The most serious adverse effect is pulmonary toxicity, which is fatal in about 10% of patients and involves a clinical syndrome of progressive dyspnea and cough accompanied by damage to the alveoli. The result can be pulmonary fibrosis. Another serious complication of amiodarone therapy is that it not only may treat the dysrhythmias but also may provoke them.

Amiodarone has an exceptionally long half-life, approaching many days. As a result, the therapeutic as well as any adverse effects of amiodarone may linger long after the drug has been discontinued. In fact, it may take as long as 2 to 3 months after the drug has been stopped for some adverse effects to subside. Therapy is usually started in the hospital and is closely monitored until the patient's serum levels are within a therapeutic range.

Amiodarone has two very significant drug interactions, namely with digoxin and warfarin. It is reported that digoxin levels will increase by 50% and that the INR will increase by 50% in 100% of patients taking these drugs in combination with amiodarone. When amiodarone is started in patients who are already taking one of these drugs, the dose of digoxin or warfarin is recommended to be reduced by 50% at the start of amiodarone therapy.

Use of amiodarone is contraindicated in patients who have a known hypersensitivity to it and in those with severe sinus bradycardia or second- or third-degree heart block. For cases in which the patient is maintained on long-term oral amiodarone therapy after intravenous amiodarone administration is discontinued, recommended conversions are available (Table 25-9). This drug is marketed in both oral and injectable forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-3 wk	2-10 hr	15-100 days	10-150 days

ibutilide

Ibutilide (Corvert) is a class III antidysrhythmic drug. Unlike the other two class III antidysrhythmics, ibutilide is indicated for atrial dysrhythmias. Atrial fibrillation and atrial flutter cause irregular contractions of the heart and can lead to serious conditions such as decreased cardiac output, heart failure, low blood pressure, and stroke. Although other pharmacologic

TABLE 25-9 RECOMMENDATIONS FOR ORAL DOSAGE AFTER INTRAVENOUS INFUSION OF AMIODARONE

DURATION OF AMIODARONE IV INFUSION	INITIAL DAILY DOSE OF ORAL AMIODARONE
Less than 1 wk	800-1600 mg
1-3 wk	600-800 mg
More than 3 wk	400 mg

IV, Intravenous.

therapies are used to treat atrial fibrillation and flutter, ibutilide and dofetilide are the only drugs available for rapid conversion of these two conditions to normal sinus rhythm. The only other treatment that can produce rapid conversion is electrical cardioversion. Although it is effective, electrical cardioversion carries the risk, expense, and inconvenience of both the procedure itself and the anesthesia it requires.

Ibutilide is dosed based on patient weight. Use of ibutilide is contraindicated in patients who have previously demonstrated hypersensitivity to it. As with other antidysrhythmic drugs, ibutilide is to be used with caution, because it can itself produce dysrhythmias, most significantly ventricular tachycardia and torsades de pointes. Class Ia antidysrhythmic drugs (e.g., disopyramide, quinidine, and procainamide) and other class III drugs (e.g., amiodarone and sotalol) should not be administered with ibutilide, nor should they be given within 4 hours after infusion of ibutilide because of their potential to prolong refractoriness. Ibutilide is available only in injectable form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	10 min	30 min	6 hr	4 hr

♦ dofetilide

Dofetilide (Tikosyn) is one of the newer antidysrhythmic drugs. Because dofetilide can cause serious toxicity, specifically torsades de pointes, only physicians who have received special training are allowed to prescribe it. Dofetilide therapy must be initiated in the hospital, and the patient must have continuous ECG monitoring for the first 3 days. Any dosage adjustment or re-initiation of therapy also requires hospitalization.

Dofetilide is contraindicated in patients with hypersensitivity to it, as well as patients with congenital or acquired long QT intervals or in whom the QT interval is longer than 440 msec. It is also contraindicated in patients with severe renal impairment and in those taking the following drugs: verapamil, cimetidine, hydrochlorothiazide, trimethoprim, itraconazole, ketoconazole, prochlorperazine, and megestrol. Other drugs that can prolong the QT interval must be used with great caution during dofetilide therapy. Dofetilide is also contraindicated in patients with hypokalemia and/or hypomagnesemia, because these two states predispose patients to toxicity.

The most common adverse effects are torsades de pointes, supraventricular dysrhythmias, headache, dizziness, and chest pain.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	2-3 hr	10 hr	12 hr

♦ sotalol

Sotalol (Betapace) is a selective beta blocker that is used to treat dysrhythmias. It is unique in that it possesses antidysrhythmic properties similar to those of the class III drugs (such as amiodarone) while simultaneously exerting beta blocker or class II effects on the conduction system of the heart. In addition, sotalol has prodysrhythmic properties similar to those of the class Ic drugs. This means that while patients are taking sotalol, it can cause serious dysrhythmias such as torsades de pointes or a new ventricular tachycardia or fibrillation. Like flecainide and propafenone, sotalol was historically reserved for the treatment of documented life-threatening ventricular dysrhythmias such as sustained ventricular tachycardia. However, recent data indicates it to be safe.

Contraindications to sotalol use include hypersensitivity to it, bronchial asthma, cardiogenic shock, and sinus bradycardia. Sotalol is available only in oral form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-2 hr	2.5-4 hr	12 hr	8-16 hr

CLASS IV DRUGS

Class IV antidysrhythmic drugs are calcium channel blockers. Although more than nine such drugs are currently available, only a few are commonly used as antidysrhythmics. Besides being effective antidysrhythmics, calcium channel blockers are useful in the treatment of hypertension (see Chapter 22) and angina (see Chapter 23). Verapamil and diltiazem are the two calcium channel blockers most commonly used for the following:

- Treating dysrhythmias, specifically those that arise above the ventricles (PSVT)
- Controlling the ventricular response to atrial fibrillation and flutter by slowing conduction and prolonging refractoriness of the AV node (i.e., preventing the ventricles from beating as fast as the atria)

These drugs block the slow inward flow of calcium ions into the slow (calcium) channels in cardiac conduction tissue. The conduction effects of these drugs are limited to the atria and the AV node, where conduction is prolonged and the tissues are made more refractory to stimulation. These drugs have little effect on the ventricular tissues.

♦ diltiazem

Diltiazem (Cardizem, others) is primarily indicated for the temporary control of a rapid ventricular response in patients with atrial fibrillation or flutter and PSVT. Its use is contraindicated in patients with hypersensitivity, acute MI, pulmonary congestion, Wolff-Parkinson-White syndrome, severe hypotension, cardiogenic shock, sick sinus syndrome, or second- or third-degree AV block. Diltiazem is available in both oral and parenteral forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	0.5-1 hr	2-3 hr	3.5-9 hr	4-12 hr

♦ verapamil

Verapamil (Calan, others) has actions similar to those of diltiazem in that it also inhibits calcium ion influx across the slow calcium channels in cardiac conduction tissue. This results in dramatic effects on the AV node. Verapamil is used to prevent and convert recurrent PSVT and to control ventricular response in atrial flutter or fibrillation. It can also temporarily control a rapid ventricular response to these frequent atrial stimulations, usually decreasing the heart rate by at least 20%. Verapamil is not only used for the management of various dysrhythmias but is also used to treat angina, hypertension, and hypertrophic cardiomyopathy. The contraindications that apply to diltiazem apply to verapamil as well. It is also available in both oral and parenteral forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-2 hr	3 hr	4.5-12 hr	6-8 hr

UNCLASSIFIED ANTIDYSRHYTHMIC

adenosine

Adenosine (Adenocard) is an unclassified antidysrhythmic drug. It slows the electrical conduction time through the AV node and is indicated for the conversion of PSVT to sinus rhythm. It is particularly useful when the PSVT has failed to respond to verapamil or when the patient has coexisting conditions such as heart failure, hypotension, or left ventricular dysfunction that limit the use of verapamil. Its use is contraindicated in patients with second- or third-degree heart block, sick sinus syndrome, atrial flutter or fibrillation, or ventricular tachycardia, as well as in those with a known hypersensitivity to it. It has an extremely short half-life of less than 10 seconds. For this reason, it is administered only intravenously and only as a fast intravenous push. It commonly causes asystole for a period of seconds. All other adverse effects are minimal because of its very short duration of action. Adenosine is available only in parenteral form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Immediate	Immediate	Less than 10 sec	Very brief

NURSING PROCESS

ASSESSMENT

Before administering any *antidysrhythmic* to a patient, conduct a thorough nursing assessment and head-to-toe physical assessment, and complete a medical history and medication profile. Assess for contraindications, cautions, and drug interactions. Review any baseline ECGs and interpret the results, and measure the patient's vital signs with attention to blood pressure, postural blood pressure, heart sounds, and heart rate, rhythm, and quality. Other signs and symptoms to assess for related to decreased cardiac functioning (as a result of a dysrhythmia and decrease in cardiac output) include apical-radial pulse deficits, jugular vein distension, edema, prolonged capillary refill (longer than 5 seconds), decreased urinary output, activity intolerance, chest pain or pressure, dyspnea, and fatigue. Document any changes in level of alertness, increase in anxiety levels, syncope, or dizziness.

Laboratory studies generally include renal and hepatic function tests because abnormal functioning may call for a decrease in the drug dosage by the prescriber to prevent toxicity. Be sure to emphasize to the patient the interaction with grapefruit juice, which inhibits metabolism by cytochrome P-450 3A4 hepatic enzymes (see Chapter 2 for a more in-depth discussion of this topic). The interaction of grapefruit juice with *amiodarone, disopyramide,* and *quinidine* leads to an increased risk of toxicity and cinchonism (see Table 25-8). Other drug interactions with antidysrhythmics are presented in Table 25-8.

With the use of *lidocaine,* assess the cardiovascular system, with attention to heart rate and blood pressure. With amiodarone, assess respiratory, thyroid, hepatic, dermatologic, and/or hypertensive conditions due to possible drug related pulmonary toxicity, exacerbation of thyroid disorders, abnormal liver function tests, and rash. Further assessment for drug interactions (see Table 25-8) as well as contraindications and cautions is also needed.

TEAMWORK AND COLLABORATION: PHARMACOKINETIC BRIDGE TO NURSING PRACTICE

A study of long-term oral amiodarone therapy for the treatment of dysrhythmias provides a different perspective on pharmacokinetics. To aid in evaluating the complex pharmacokinetic properties of amiodarone and developing an optimal dosing schedule for the drug in long-term oral drug therapy, serum concentrations of the drug and its metabolite, desethylamiodarone, were monitored in 345 Japanese patients receiving amiodarone. Serum concentrations of the drug and its metabolite were determined by an analysis called *chromatography.* In 245 participants who took fixed maintenance dosages of the drug for 6 months, there were small variations in the ratio of the serum level of the actual drug to the serum level of its metabolite. (The concept of metabolism as it relates to pharmacokinetics is discussed in Chapter 2.) Other pharmacokinetic properties of amiodarone included a slightly higher average clearance in women than in men, even though there were no differences between men and women with regard to age, dosage, or duration of action of the dose. Japanese patients showed little variation in the pharmacokinetics of the drug. From this study, one can see how important it is to understand basic pharmacokinetic parameters (e.g., dosing, clearance, drug metabolism, serum concentrations) and to recognize that they are very critical components of drug therapy and the nursing process. It is also important to note that culture, gender, age, and racial or ethnic group have an impact on how each person responds to a drug and how each drug may vary in its action.

CASE STUDY

Antidysrhythmic Medications

A 46-year-old patient, V.T., is admitted to the intensive care unit after going to the hospital with complaints of chest pain. He is diagnosed with coronary artery disease with a partial block of one of his coronary arteries and is awaiting an angioplasty procedure. He has a history of alcoholism but states that he has not had a drink for 2 years, thanks to Alcoholics Anonymous. In the intensive care unit, V.T.'s heart monitor indicates increased episodes of premature ventricular contractions. When a 20-second run of ventricular tachycardia is noted, the nurse decides to implement the standing orders for a lidocaine infusion. The standing order reads: "For episodes of ventricular tachycardia, give a loading dose of 75 mg of lidocaine intravenous (IV) push; repeat this dose in 5 minutes, and then begin a continuous infusion of 2 mg/min IV."

1. What factors will the nurse consider before beginning the lidocaine infusion?
2. What will the nurse monitor while V.T. is receiving this infusion?

Three days later, V.T. is ready for discharge. He has had the angioplasty procedure, which was deemed a success, and the lidocaine infusion was discontinued yesterday. He has been started on oral quinidine, 324 mg, every 6 hours. One month later, he calls the office and tells the nurse that he is hearing a "ringing sound" in his ears, even when the television and radio are turned off.

3. Is this ringing sound significant?

The physician decides to change V.T.'s medication to procainamide. V.T. asks the nurse, "What are the possible side effects of this drug? It seems that they all have bad side effects."

4. What is the nurse's best answer to this question?

For answers, see http://evolve.elsevier.com/Lilley.

NURSING DIAGNOSES

1. Decreased cardiac output related to the pathology of the dysrhythmia
2. Ineffective peripheral tissue perfusion related to the physiologic impact of the dysrhythmia
3. Deficient knowledge related to lack of experience with medication therapy

PLANNING

GOALS

1. Patient experiences improved cardiac output.
2. Patient experiences improved peripheral perfusion/circulation.
3. Patient demonstrates adequate knowledge about the medication therapy.

OUTCOME CRITERIA

1. Patient's symptoms of dysrhythmia and subsequent decreased cardiac output are decreased and/or alleviated.
2. Patient's peripheral pulses are equal, strong and regular bilaterally with warm, pink extremities.
3 Patient states rationale for taking medication as prescribed as well as its therapeutic effects and adverse effects.

- Patient experiences increase in energy and stamina and improved ability to carry out activities of daily living due to positive therapeutic outcomes from drug therapy.

IMPLEMENTATION

When *antidysrhythmics* are administered, monitor vital signs, especially pulse rate and blood pressure; if pulse rate is lower than 60 beats/min, notify the prescriber. During the initiation of therapy, closely monitor the electrocardiogram and vital signs because of possible prolongation of the patient's QT interval by more than 50%. The end result may be the occurrence of a variety of conduction disturbances. Advise patients that oral dosage forms are generally better tolerated if taken with food and fluids to help minimize gastrointestinal upset, unless otherwise ordered. *Quinidine* comes in different salt forms, and these are not interchangeable. During treatment with quinidine (or with any of the antidysrhythmics), immediately report any patient complaint of angina, hypotension, lightheadedness, loss of appetite, tinnitus, or diarrhea to the prescriber. It is recommended that an infusion pump be used for intravenous dosing of any of the classes of antidysrhythmics, with proper solution and dilution.

With *lidocaine,* vials of clear solution are labeled as either for cardiac or *not* for cardiac use. This is important to remember when reading the vial's label so that the wrong drug is not given. It is also important to remember that lidocaine solutions need to be used with extreme caution and that it is the plain solution that is used to treat various cardiac conditions. Parenteral solutions of these drugs are usually stable only for 24 hours. Lidocaine is also used as an anesthetic, and so the different concentrations of the drug need to double-checked—if not triple-checked. In addition, lidocaine comes in a solution with epinephrine, a potent vasoconstrictor. This combined solution is indicated when the surgeon or physician is suturing or repairing wounds, with the lidocaine acting as an anesthetic and the epinephrine causing vasoconstriction of the local blood vessels and helping to control bleeding of the area, or in dental or oral situations. The solution with epinephrine must *never* be used intravenously, but only as a topical anesthetic! With lidocaine, document vital signs prior to initiation of and during therapy, and closely monitor the ECG. Often patients are in a cardiac step-down unit, telemetry unit, or intensive care setting when receiving this drug.

Amiodarone may lead to gastrointestinal upset, which may be prevented or decreased by taking the drug with food or a snack. Photosensitivity (sunburn and other exaggerated skin reactions to the sunlight) and photophobia (light sensitivity) are other concerns with this drug. With photosensitivity, protective clothing/hat and sunscreen are needed. Emphasize protection of the eyes, with wearing of sunglasses and/or tinted contact lenses, to patients taking this medication. Recommend consumption of a high-fiber diet and forcing of fluids to minimize the constipation that is a common adverse effect of antidysrhythmic drugs. When beta blockers are used with an antidysrhythmic, any shortness of breath, weight gain, changes in baseline blood glucose levels, or excess fatigue

(see Chapters 19 and 25) must be reported to the prescriber immediately.

Beta blockers, diltiazem, and *verapamil* may all be used to manage abnormal rhythms and are to be given only after checking and documenting pulse rates and blood pressures. Contact the prescriber and withhold the drug—if supported by facility policy and the prescriber's guidelines—if the pulse rate is 60 beats/min or lower or 100 beats/min or higher and/or the systolic blood pressure is 90 mm Hg or lower.

With the use of *dofetilide,* continually monitor the patient for any changes in the ECG, especially over the first few days of treatment. This drug requires specialized monitoring once ordered by the prescriber, who must have received special prescription training. Encourage the patient to report any difficulty such as chest pain, nausea, or diarrhea to the prescriber immediately. If a dosage amount requires adjustment, hospitalization may be necessary.

EVALUATION

The monitoring of patients receiving all classes of antidysrhythmics is important to confirm the therapeutic effects as well as identify the adverse and toxic effects. Class I through class IV antidysrhythmics drugs have many overlapping therapeutic effects, adverse effects, and toxicities. Therapeutic effects, in general, include improved cardiac output; decreased chest discomfort; decreased fatigue; improved vital signs, skin color, and urinary output; and conversion of irregularities to normal rhythm. Adverse effects for the *class I antidysrhythmics* include hypotension, rash, diarrhea, SLE-like syndrome

EVIDENCE-BASED PRACTICE

A Short-Term, Randomized, Double-Blind, Parallel-Group Study to Evaluate the Efficacy and Safety of Dronedarone Versus Amiodarone in Patients with Persistent Atrial Fibrillation: The DIONYSOS Study

Review

Atrial fibrillation (AF) is a major cause of morbidity, increasing the risk of stroke and death and other health concerns. Amiodarone is widely used for the maintenance of sinus rhythm in patients with atrial fibrillation but is associated with adverse effects such as pulmonary toxicity, thyroid disorders, and hepatic toxicity. These adverse effects may lead to discontinuation of this drug and/or cause serious complications in its long-term use. Dronedarone is pharmacologically related to amiodarone but has improved pharmacokinetics resulting in a shorter half-life, less accumulation in tissues, and absence of amiodarone-like organ toxicity. These two drugs were part of a study that compared their efficacy and safety in patients with persistent atrial fibrillation.

Type of Evidence

DIONYSOS, or a comparative, randomized, double-blind, parallel-group research study, was conducted in some 112 centers in 23 countries after approval from local independent ethics committees, institutional review boards, and the protocol developed with the Helsinki principles. All patients provided written informed consent before the study was initiated. Outcomes of the study included the following: (1) a measurement of efficacy, recurrence of AF or the premature study drug discontinuation for lack of efficacy; and (2) a safety/tolerability measurement. Once the study was initiated in patients with AF, treatment failure was defined as unsuccessful electrical cardioversion as well as no spontaneous cardioversion and no electrical cardioversion. The primary composite endpoint was the recurrence of AF or premature study discontinuation. The main safety endpoint (MSE) was the occurrence of thyroid, hepatic, pulmonary, neurologic, skin, eye, or gastrointestinal-specific events or prematurely withdrawing from the study after experiencing an adverse event. After exclusion criteria were applied, the final sample size was 504 patients. After a period of up to 30 days of screening, patients were then randomized in a 1:1 ratio to dronedarone or amiodarone for at least 6 months with electrical cardioversion performed between 10 and 28 days if the patient had not converted spontaneously to sinus rhythm. Follow-up occurred at the 6-month endpoint with scheduled assessments within this time frame. Heart rhythms were documented by scheduled or unscheduled 12-lead ECGs, and other parameters being evaluated included vital signs and systolic and diastolic blood pressure readings after resting for 3 minutes and then in the supine position. Laboratory studies assessed included hematology, serum biochemistry, thyroid function levels, digoxin serum levels, and international normalized ratio (INR) in patients receiving oral anticoagulants.

Results of Study

All patients were randomized in this study to receive dronedarone 400 mg twice daily (sample size of 249) or amiodarone 600 mg every day for a period of 28 days then 200 mg every day (sample size of 255) over a total period of 6 months. Mean age was 64 ± 10.7 years, and about 20% of the patients were 75 years of age or older. The majority of patients were Caucasian (83.9%), and 15.3% were Asian. One-third of patients were female. Cardiovascular history included 66.9% with hypertension, 18% with coronary heart disease, and 16.5% with AF. Congestive heart failure was found distributed similarly in about one-third of the patients. The median treatment duration was 7 months and a maximum of 13.8 months in both treatment groups. The primary composite endpoint was 75.1% and 58.8% with dronedarone and amiodarone, respectively, at 12 months treatment. The main safety endpoint was 39.3% and 44.5% in the dronedarone and amiodarone groups, respectively, at 12 months treatment, and mainly driven by fewer thyroid, neurologic, and skin and eye events in the dronedarone group. AF recurrence after successful cardioversion was 36.5% and 24.3% with dronedarone and amiodarone, respectively. Premature drug discontinuation was less frequent with dronedarone.

Link of Evidence to Nursing Practice

This study is another example of how research may impact professional nursing practice by showing comparative evidence of efficacy of certain drugs for specific disorders such as AF. It is also studies like this one that look at different medical diagnoses with associated medical care, including pharmacologic advances. Mortality and morbidity issues are also brought forward for discussion within the health care arena, and specifically how certain therapeutic regimens may be helpful or not. Nurses not only gain knowledge about certain pharmacologic or nonpharmacologic measures but can always learn and gain from research findings to enhance nursing care delivery as well as facilitate further nursing research.

Reference: Le Heuzey AL, De Ferrari GM, Radzik D, et al. A short-term, randomized, double-blind, parallel-group study to evaluate the efficacy and safety of dronedarone versus amiodarone in patients with persistent atrial fibrillation: the DIONYSOS study, *J Cardiovasc Electrophysiol* 21(6):597-605, 2010.

(procainamide); ECG changes, bitter taste, anorexia, blurred vision, and tinnitus (quinidine); and gingival hyperplasia and decrease in blood pressure and pulse rate (phenytoin). *Class II beta blockers* may cause bradycardia, AV block, heart failure, bronchospasm, and changes in blood glucose levels. *Amiodarone,* a class III drug, may lead to pulmonary toxicity, thyroid disorders, decrease in blood pressure and pulse rate, photosensitivity, and abnormal liver function. Calcium channel blockers or class IV drugs are associated with heart block, hypotension, constipation, dizziness, and dyspnea (see Table 25-6).

PATIENT TEACHING TIPS

- Instruct patients not to crush or chew any oral dosage form that is identified as sustained-release, and not to alter the original dosage form of the drug in any way.
- Some dosage forms are delivered in a sustained-released tablet or capsule that may be composed of a wax matrix, and this matrix may be visible in the patient's stool. This extended-release dosage form provides for a slow release of the medicine, and the wax substance may then be passed out of the body through the stool. Advise patients that the passing of the matrix through the stool occurs after the drug has been absorbed, and although the matrix is often visible to the naked eye, it is of no major concern.
- If the use of an oral preparation is associated with continual and moderate or severe gastrointestinal upset, tell the patient to take the drug with food and to contact the prescriber if nausea and vomiting worsen.
- If an antacid is needed, it must be taken either 2 hours before or 2 hours after the drug to avoid interference with drug absorption.
- Recommend a well-balanced diet without an excess of alkaline ash foods (e.g., citrus fruits, vegetables, and milk). Encourage an increase in fluid intake of up to 8 glasses of water a day, unless contraindicated.
- Educate the patient to limit or avoid caffeine intake. Caffeine-containing foods and beverages include coffee (decaffeinated contains 2 to 4 mg caffeine per 8 oz versus caffeinated 65 to 120 mg per 8 oz.), tea, some soft drinks, chocolate, and high-energy drinks.
- Instruct the patient to take medications exactly as prescribed without doubling up or omitting doses. If the patient forgets a dose or is ill and cannot take a dose, contact the prescriber for further instructions.
- Provide written and verbal instructions and demonstrations on measuring pulse and blood pressure. The local fire department and/or rescue station will usually take blood pressure and pulse rates, if needed.
- Journaling is important to document how the patient feels each day. Advise the patient to record in the journal any worsening or improvement of symptoms, adverse effects, daily weights, activity tolerance, blood pressure readings, and pulse rate.
- Daily weights need to be measured at the same time every day and with the same amount of clothing.
- Contact the prescriber immediately if there is a weight gain of 2 pounds or more in 24 hours or 5 pounds or more in 1 week.
- Inform the patient that changing positions purposefully and with caution is important because of the common adverse effect of postural hypotension. Moving too quickly may lead to dizziness, syncope, and subsequent injury or falls.
- At the beginning of therapy and after any dosage increase, encourage the patient to avoid driving and other hazardous activities until sedating adverse effects have resolved.
- Dry mouth may be helped by frequent mouth care, drinking fluids, sucking on sugarless gum or candy, and/or eating ice chips. Artificial saliva and special toothpaste made specifically for dry mouth and its management is available over the counter. Encourage frequent dental visits.
- Counsel the patient to avoid exertion, hot temperatures, saunas, and hot tubs because of heat-induced vasodilation, leading to postural hypotension with dizziness and/or syncope and a subsequent risk for falls or injury. Alcohol intake may also lead to vasodilation and subsequent dizziness and syncope.
- Instruct the patient to carry a medical alert identification card on his or her person at all times. Medical alert jewelry is also available to provide information on medical diagnoses, allergies, and medications.
- Instruct the patient to report immediately to the prescriber any dizziness, shortness of breath, chest pain, and/or worsening of symptoms or occurrence of new symptoms.
- The patient must *never* stop taking these medications without specific instructions to do so; an abrupt discontinuation of these drugs may lead to severe or life-threatening complications.
- With amiodarone, photosensitivity is an adverse effect; advise the patient to avoid sun exposure and to wear sun-protective clothing and dark glasses when outside. Sunscreens are ineffective because they do not block ultraviolet B light, to which the patient may react while taking this medication. Instead, barrier sunblocks, such as zinc or titanium chloride, are recommended.
- With amiodarone, instruct the patient to immediately report any blue-gray discoloration of the skin (often after 1 year, and especially on the face, neck, and arms) as well as any jaundice, unusual rash or skin reactions, nausea, vomiting, or dizziness.

KEY POINTS

- The SA node, AV node, and His-Purkinje system are all areas in which there is automaticity (cells can depolarize spontaneously). The SA node is the pacemaker because it can spontaneously depolarize easier and faster than the other areas.
- Any disturbance or abnormality in the normal pattern of the heartbeat and pulse rate is termed a *dysrhythmia.*
- Antidysrhythmic drugs are used to correct dysrhythmias; however, they may also cause dysrhythmias, and for this reason are said to be *prodysrhythmic.* The Vaughan Williams classification is the system most commonly used to categorize antidysrhythmic drugs. It classifies drugs into the following groups according to where and how they affect cardiac cells and what their mechanisms of action is:
  - *Class I:* membrane-stabilizing drugs (e.g., class Ia, quinidine; class Ib, lidocaine; class Ic, flecainide)
  - *Class II:* beta-adrenergic blockers that depress phase 4 depolarization (e.g., atenolol)
  - *Class III:* drugs that prolong repolarization in phase 3 (e.g., amiodarone and dofetilide)
  - *Class IV:* calcium channel blockers that depress phase 4 depolarization (e.g., verapamil)
- Nursing actions for the various antidysrhythmics include skillful nursing assessment and close monitoring of heart rate, blood pressure, heart rhythms, general well-being, skin color, temperature, and heart and breath sounds.
- The therapeutic responses to antidysrhythmics include a decrease in blood pressure in hypertensive patients, a decrease in edema, and restoration of a regular pulse rate or a pulse rate without major irregularities or with improved regularity compared with the irregularity that existed before therapy.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A patient with a rapid, irregular heart rhythm is being treated in the emergency department with adenosine. During administration of this drug, the nurse will be prepared to monitor the patient for which effect?
- **a** Nausea and vomiting
- **b** Transitory asystole
- **c** Muscle tetany
- **d** Hypertension

2 When assessing a patient who has been taking amiodarone for 6 months, the nurse monitors for which potential adverse effect?
- **a** Hyperglycemia
- **b** Dysphagia
- **c** Photophobia
- **d** Urticaria

3 The nurse is assessing a patient who has been taking quinidine and asks about adverse effects. An adverse effect associated with the use of this drug includes:
- **a** muscle pain.
- **b** tinnitus.
- **c** chest pain.
- **d** excessive thirst.

4 A patient calls the family practice office to report that he has seen his pills in his stools when he has a bowel movement. How will the nurse respond?
- **a** "The pills are not being digested properly. You need to take them on an empty stomach."
- **b** "The pills are not being digested properly. You need to take them with food."
- **c** "What you are seeing is the waxy matrix that contained the medication, but the drug has been absorbed."
- **d** "This indicates that you are not tolerating this medication and will need to switch to a different form."

5 The nurse is administering lidocaine and considers which condition, if present in the patient, a caution for the use of this drug?
- **a** Tachycardia
- **b** Hypertension
- **c** Ventricular dysrhythmias
- **d** Renal dysfunction

6 When the nurse is teaching a patient about taking an antidysrhythmic drug, which statements by the nurse are correct? (Select all that apply.)
- **a** "Take the medication with an antacid if stomach upset occurs."
- **b** "Do not chew sustained-release capsules."
- **c** "If weight gain of 5 pounds within 1 week occurs, notify your physician at the next office visit."
- **d** "If you experience severe adverse effects, stop the drug and notify your physician."
- **e** "You may take the medication with food if stomach upset occurs."

7 A patient is in the emergency department with new-onset rapid rate atrial fibrillation. The nurse is about to add a continuous infusion of diltiazem (Cardizem) at 5 mg/hr, but must first give a bolus of 0.25 mg/kg over 2 minutes. The patient weighs 220 pounds. The medication comes in a vial of 5 mg/mL. How many milligrams will the patient receive, and how many milliliters will the nurse draw up for this dose?

1. b, 2. c, 3. b, 4. c, 5. d, 6. b, e, 7. 25 mg; 5 mL

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Briefly review the coagulation process and the impact of coagulation modifiers, including anticoagulants, antiplatelets, thrombolytics, and antifibrinolytics.
2 Compare the mechanisms of action, indications, cautions, contraindications, drug interactions, adverse effects, routes of administration, and dosages of the various anticoagulants, antiplatelets, thrombolytics, and antifibrinolytics.
3 Discuss the administration procedures and techniques as well as related standards of care for the various coagulation modifiers.
4 Identify any available antidotes for the coagulation modifiers.
5 Compare the laboratory tests used in conjunction with treatment with the various coagulation modifiers and their implications for therapeutic use of these drugs and monitoring for adverse reactions.
6 Develop a nursing care plan that includes all phases of the nursing process for patients receiving anticoagulants, antiplatelets, thrombolytics, and antifibrinolytics.

DRUG PROFILES

♦ *Key drug*

KEY TERMS

Anticoagulants Substances that prevent or delay coagulation of the blood. (p. 421)

Antifibrinolytic drugs Drugs that prevent the lysis of fibrin and in doing so promote clot formation. (p. 421)

Antiplatelet drugs Substances that prevent platelet plugs from forming. (p. 421)

Antithrombin III A substance that inactivates ("turns off") three major activating factors of the clotting cascade: activated factor II (thrombin), activated factor X, and activated factor IX. (p. 422)

Clot Insoluble solid elements of blood (e.g., cells, fibrin threads) that have chemically separated from the liquid (plasma) component of the blood. (p. 419)

Coagulation The process of blood clotting. More specifically, the sequential process by which the multiple coagulation factors of the blood interact in the *coagulation* cascade, ultimately forming an insoluble fibrin clot. (p. 419)

Coagulation cascade The series of steps beginning with the *intrinsic* or *extrinsic* pathways of coagulation and proceeding through the formation of a *fibrin clot.* (p. 420)

Deep vein thrombosis (DVT) The formation of a thrombus in one of the deep veins of the body. The deep veins most commonly affected are the iliac and femoral veins. (p. 422)

Embolus A blood clot *(thrombus)* that has been dislodged from the wall of a blood vessel and is traveling throughout the bloodstream. Emboli that lodge in critical blood vessels can result in ischemic injury to a vital organ (e.g., heart, lung, brain) and result in disability or death. (p. 419)

Enzyme A protein molecule that catalyzes chemical reactions of other substances without being altered or destroyed in the process. (p. 424)

Fibrin A stringy, insoluble protein produced by the action of thrombin on fibrinogen during the clotting process; a major component of blood *clots* or *thrombi* (see *thrombus*). (p. 420)

Fibrin specificity The property of some thrombolytic drugs of activating the conversion of plasminogen to plasmin only in the presence of established clots having fibrin threads rather than inducing systemic plasminogen activation throughout the body. (p. 431)

Fibrinogen A plasma protein that is converted into fibrin by thrombin in the presence of calcium ions. (p. 428)

Fibrinolysis The continual process of fibrin decomposition produced by the actions of the enzymatic protein fibrinolysin. It is the normal mechanism for removing small fibrin clots and is stimulated by anoxia, inflammatory reactions, and other kinds of stress. (p. 421)

Fibrinolytic system An area of the circulatory system undergoing fibrinolysis. (p. 421)

Hemophilia A rare, inherited blood disorder in which the blood does not clot normally. (p. 421)

Hemorheologic drugs Drugs that alter the function of platelets without compromising their blood-clotting properties. (p. 421)

Hemostasis The arrest of bleeding, either by the physiologic properties of vasoconstriction and coagulation or by mechanical, surgical, or pharmacologic means. (p. 419)

Hemostatic Referring to any procedure, device, or substance that arrests the flow of blood. (p. 421)

Plasmin The enzymatic protein that breaks down fibrin into fibrin degradation products; it is derived from plasminogen. (p. 421)

Plasminogen A plasma protein that is converted to plasmin. (p. 421)

Pulmonary embolism The blockage of a pulmonary artery by foreign matter such as fat, air, a tumor, or a thrombus (which usually arises from a peripheral vein). (p. 422)

Stroke Occlusion of the blood vessels of the brain by an embolus, thrombus, or cerebrovascular hemorrhage, resulting in ischemia of the brain tissue. (p. 422)

Thromboembolic events Events in which a blood vessel is blocked by an embolus carried in the bloodstream from the site of its formation. The tissue supplied by an obstructed artery may tingle and become cold, numb, cyanotic, and eventually necrotic (dead). (p. 422)

Thrombolytic drugs Drugs that dissolve thrombi by functioning similarly to *tissue plasminogen activator.* (p. 421)

Thrombus The technical term for a blood clot (plural: *thrombi*); an aggregation of platelets, fibrin, clotting factors, and the cellular elements of the blood that is attached to the interior wall of a vein or artery, sometimes occluding the vessel lumen. (p. 419)

Tissue plasminogen activator A naturally occurring plasminogen activator secreted by vascular endothelial cells in the walls of blood vessels. Thrombolytic drugs are based on this blood component. (p. 420)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Hemostasis is a general term for any process that stops bleeding. This can be accomplished by mechanical means (e.g., compression to the bleeding site) or surgical means (e.g., surgical clamping or cauterization of a blood vessel). When hemostasis occurs due to physiologic clotting of blood, it is called **coagulation,** which is the process of blood clot formation. The technical term for a blood clot is a **thrombus.** A thrombus that is not stationary but moves through blood vessels is called an **embolus.** Normal hemostasis involves the complex interaction of substances that promote **clot** formation and substances that either inhibit coagulation or dissolve the formed clot. Substances that promote

coagulation include platelets, von Willebrand factor, activated clotting factors, and tissue thromboplastin. Substances that inhibit coagulation include prostacyclin, antithrombin III, and proteins C and S. In addition, **tissue plasminogen activator** is a natural substance that dissolves clots that are already formed.

The coagulation system is illustrated in Figures 26-1 and 26-2. It is called a *cascade* (or **coagulation cascade**) because each activated clotting factor serves as a catalyst that amplifies the next reaction. The result is a large concentration of a clot-forming substance called **fibrin.** The coagulation cascade is

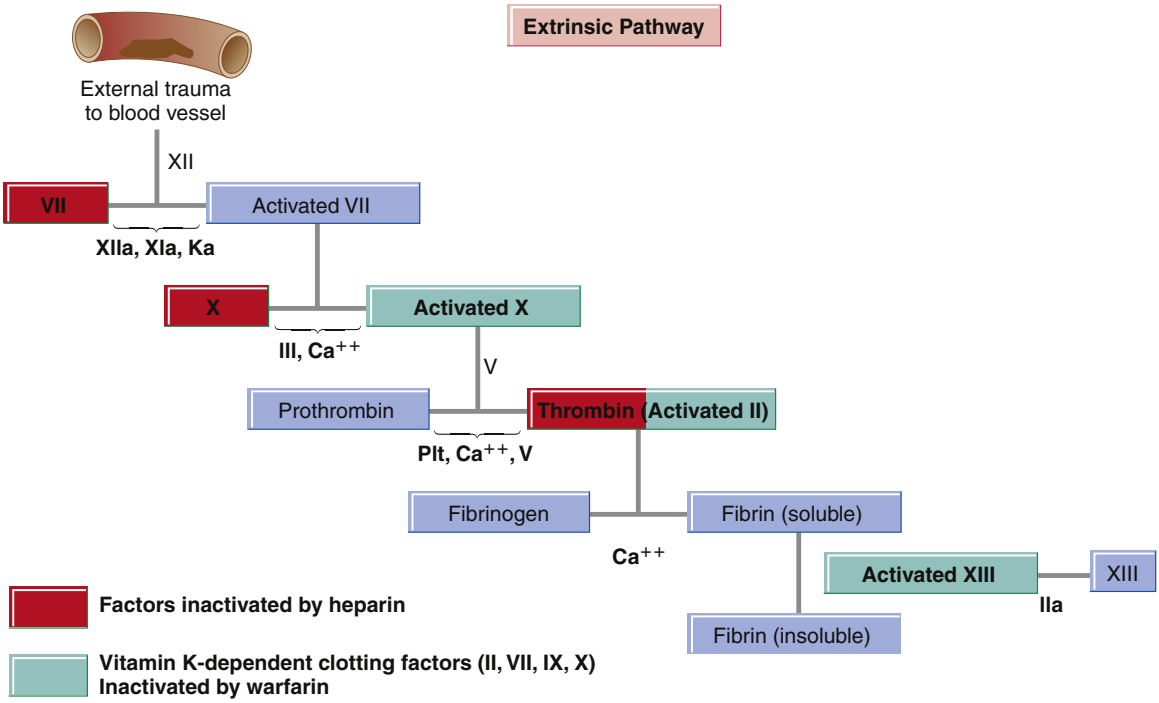

FIGURE 26-1 Coagulation pathway and factors: extrinsic pathway. *Plt,* Platelets.

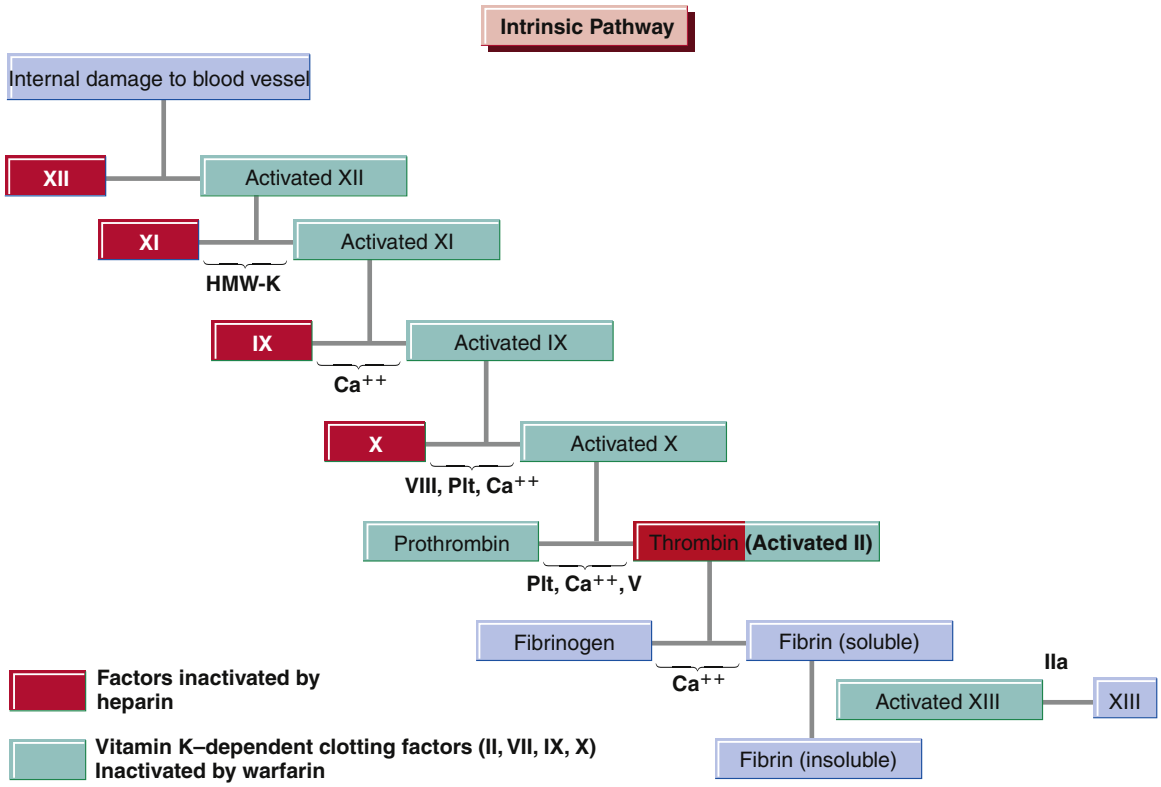

FIGURE 26-2 Coagulation pathway and factors: intrinsic pathway. *HMW-K,* High molecular weight kininogen; *Plt,* platelets.

typically divided into the intrinsic and extrinsic pathways, and these pathways are activated by different types of injury. When blood vessels are damaged by penetration from the outside (e.g., knife or bullet wound), thromboplastin, a substance contained in the walls of blood vessels, is released. This initiates the extrinsic pathway by activating factors VII and X (see Figure 26-1). The components of the intrinsic pathway are present in the blood in their inactive forms (see Figure 26-2). This pathway is activated when factor XII comes in contact with exposed collagen on the inside of damaged blood vessels. Figures 26-1 and 26-2 illustrate the steps that occur in the extrinsic and intrinsic pathways, respectively, and the coagulation factors involved. They also illustrate the site of action of two commonly used anticoagulant drugs: warfarin and heparin.

Once a clot is formed and fibrin is present, the **fibrinolytic system** is activated. This system initiates the breakdown of clots and serves to balance the clotting process. **Fibrinolysis** is the reverse of the clotting process. It is the mechanism by which formed thrombi are lysed (broken down) to prevent excessive clot formation and blood vessel blockage. Fibrin in the clot binds to a circulating protein known as **plasminogen.** This binding converts plasminogen to plasmin. **Plasmin** is the enzymatic protein that eventually breaks down the fibrin thrombus into fibrin degradation products. This keeps the thrombus localized to prevent it from becoming an embolus that can travel to obstruct a major blood vessel in the lung, heart, or brain. Figure 26-3 illustrates the fibrinolytic system.

Hemophilia is a rare genetic disorder in which the previously mentioned natural coagulation and hemostasis factors are limited or absent. Hemophilia is categorized into two main types depending on which of the coagulation factors is absent (factor VII, factor VIII, and/or factor IX). Patients with hemophilia can bleed to death if coagulation factors are not given.

PHARMACOLOGY OVERVIEW

Drugs that affect coagulation are some of the most dangerous drugs used today, and numerous factors can affect their action. These drugs are among the most commonly associated with adverse drug reactions. The Joint Commission, a hospital accreditation agency, has made safe use of these drugs a national patient safety goal. This goal requires hospitals to take steps to prevent adverse events associated with these drugs. Further information on this national patient safety goal may be found at www.jointcommission.org/standards_information/npsgs.aspx.

The drugs discussed in this chapter aid the body in reversing or achieving hemostasis, and they can be broken down into several main categories based on their actions. **Anticoagulants** inhibit the action or formation of clotting factors and therefore prevent clots from forming. **Antiplatelet drugs** prevent platelet plugs from forming by inhibiting platelet aggregation, which can be beneficial in preventing heart attacks and strokes. **Hemorheologic drugs** alter platelet function without preventing the platelets from working. Sometimes clots form and totally block a blood vessel. When this happens in one of the coronary arteries, a heart attack occurs, and the clot must be lysed to prevent or minimize damage to the myocardial muscle. **Thrombolytic drugs** lyse (break down) clots, or thrombi, that have already formed. This is a unique difference between thrombolytics and anticoagulants, which can only prevent the formation of a clot. **Antifibrinolytic drugs,** also known as **hemostatic** drugs, have the opposite effect of these other classes of drugs; they actually promote blood coagulation and are helpful in the management of conditions in which excessive bleeding would be harmful. The various drugs in each category of coagulation modifiers are listed in Table 26-1. Understanding the individual coagulation modifiers and their mechanisms of action requires a basic working knowledge of the coagulation pathway and coagulation factors, which is provided in the next section.

ANTICOAGULANTS

Drugs that prevent the formation of a clot by inhibiting certain clotting factors are called *anticoagulants.* These drugs have no direct effect on a blood clot that has already formed. They

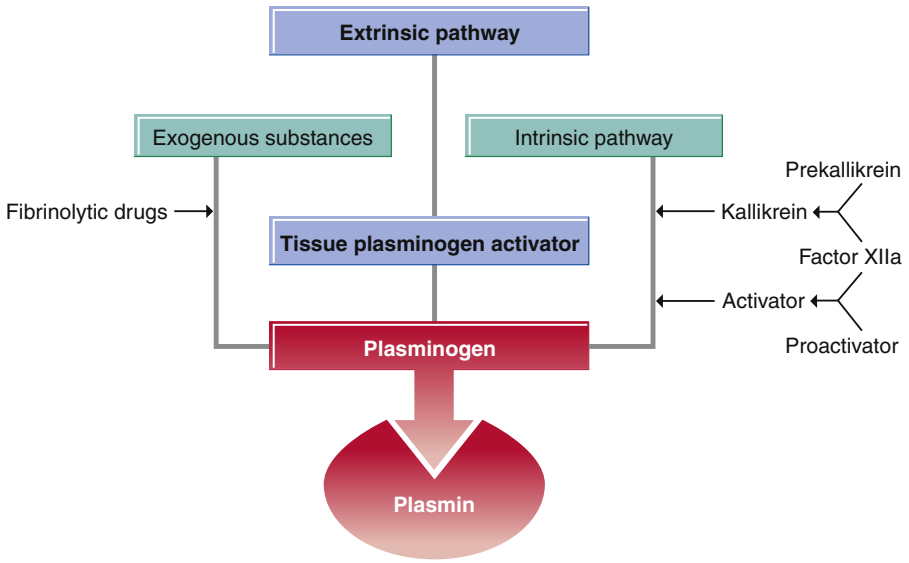

FIGURE 26-3 The fibrinolytic system.

TABLE 26-1 COAGULATION MODIFIERS: COMPARISON OF DRUG SUBCLASSES

TYPE OF COAGULATION MODIFIER AND MECHANISM OF ACTION	DRUG CLASS	INDIVIDUAL DRUGS
Prevent Clot Formation		
Anticoagulant		
Inhibit clotting factors IIa (thrombin) and Xa	Heparins	Unfractionated heparin ("heparin") and low molecular weight heparins (enoxaparin [Lovenox], dalteparin [Fragmin])
Inhibit vitamin K–dependent clotting factors II, VII, IX, and X	Coumarins	Warfarin (Coumadin)
Inhibit thrombin (factor IIa)	Direct thrombin inhibitors	Human antithrombin III (Thrombate), lepirudin (Refludan), argatroban (Argatroban), bivalirudin (Angiomax), dabigatran (Pradaxa)
Inhibit factor Xa	Selective factor Xa inhibitor	Fondaparinux (Arixtra), rivaroxaban (Xarelto)
Antiplatelet Drugs		
Interfere with platelet function	Aggregation inhibitors	Cilostazol (Pletal), clopidogrel (Plavix), prasugrel (Effient)
	Aggregation inhibitors/vasodilators	Treprostinil (Remodulin)
	Glycoprotein IIb/IIIa inhibitors	Abciximab (ReoPro), eptifibatide (Integrilin), tirofiban (Aggrastat)
	Miscellaneous	Anagrelide (Agrylin), dipyridamole (Persantine)
Lyse a Preformed Clot		
Thrombolytics		
Dissolve thrombi	Tissue plasminogen activators	Alteplase (Activase, Cathflo Activase), reteplase (Retavase), tenecteplase (TNKase)
Promote Clot Formation		
Antifibrinolytics		
Prevent lysis of fibrin	Systemic hemostatics	Aminocaproic acid (Amicar), tranexamic acid (Cyklokapron)
Reduce Blood Viscosity		
Reversal Drugs	Hemorheologic	Pentoxifylline (Trental)
	Heparin antagonist	Protamine sulfate
	Warfarin antagonist	Vitamin K

prevent intravascular thrombosis by decreasing blood coagulability. Their uses vary from preventing clot formation to preventing the extension of an established clot, or a thrombus.

Once a clot forms on the wall of a blood vessel, it may dislodge and travel through the bloodstream. This is referred to as an *embolus.* If it lodges in a coronary artery, it causes a myocardial infarction (MI); if it obstructs a brain vessel, it causes a **stroke;** if it goes to the lungs, it is a **pulmonary embolism;** and if it goes to a vein in the leg, it is a **deep vein thrombosis (DVT).** Collectively, these complications are called **thromboembolic events,** because they involve a thrombus that becomes an embolus and causes an adverse cardiovascular "event." Anticoagulants can prevent these from occurring if used in the correct manner. Both orally and parenterally administered anticoagulants are available, and each drug has a slightly different mechanism of action and indications. All of them have their own risks, mainly the risk for causing bleeding. The mechanisms of action of the anticoagulants vary depending on the drug. Drug classes of anticoagulants include older drugs such as unfractionated heparin and warfarin. There are also several newer drug classes, including low molecular weight heparins (LMWHs), direct thrombin inhibitors, and selective factor Xa inhibitors. For dosage information on anticoagulants, see the table on p. 426.

Mechanism of Action and Drug Effects

Anticoagulants are also called *antithrombotic drugs* because they work to prevent the formation of a clot or thrombus, a condition known as *thrombosis.* All anticoagulants work in the clotting cascade but do so at different points. As shown in Figures 26-1 and 26-2, heparin works by binding to a substance called **antithrombin III,** which turns off three main activating factors: activated factor II (also called *thrombin*), activated factor X, and activated factor IX. (Factors XI and XII are also inactivated but do not play as important a role as the other three factors.) Of these, thrombin is the most sensitive to the actions of heparin. Antithrombin III is the major natural inhibitor of thrombin in the blood. The overall effect of heparin is that it turns off the coagulation pathway and prevents clots from forming. However, it cannot lyse a clot. The drug name *heparin* usually refers to unfractionated heparin, which is a relatively large molecule and is derived from various animal sources. In contrast, low molecular weight heparins are synthetic and have a smaller molecular structure. These include enoxaparin (Lovenox) and dalteparin (Fragmin). Both drugs work similarly to heparin. Heparin primarily binds to activated factors II, X, and IX, whereas the LMWHs differ from heparin in that they are much more specific for activated factor X (Xa) than for activated factor II (IIa, or thrombin). This property gives LMWHs a much more predictable anticoagulant

response. As a result, frequent laboratory monitoring of bleeding times using tests such as activated partial thromboplastin time (aPTT), which is imperative with unfractionated heparin, is not required with LMWHs. When heparin is used for flushing catheters (10-100 units/mL), no monitoring is needed.

Warfarin (Coumadin) works by inhibiting vitamin K synthesis by bacteria in the gastrointestinal tract. This, in turn, inhibits production of clotting factors II, VII, IX, and X. These four factors are normally synthesized in the liver and are known as *vitamin K–dependent clotting factors.* As with heparin, the final effect is the prevention of clot formation. Figures 26-1 and 26-2 show where in the clotting cascade this occurs.

Fondaparinux (Arixtra) inhibits thrombosis by its specific action against factor Xa alone. Rivaroxaban (Xarelto) is a new oral acting factor Xa inhibitor that was approved in 2011. It is approved for DVT prophylaxis and atrial fibrillation. There are many new anticoagulants similar to rivaroxaban in the last stages of development, such as apixaban (Eliquis), which is anticipated to be approved in 2012. There are also currently five antithrombin drugs that inhibit the thrombin molecules directly, one natural and four synthetic. The natural drug is human antithrombin III (Thrombate), which is isolated from the plasma of human donors. The synthetic drugs are lepirudin (Refludan), argatroban (Argatroban), bivalirudin (Angiomax), and dabigatran (Pradaxa). Dabigatran is a new oral direct thrombin inhibitor that was approved in 2010. All of these drugs work similarly to inhibit thrombus formation by inhibiting thrombin.

Indications

The ability of anticoagulants to prevent clot formation is of benefit in certain settings in which there is a high likelihood of clot formation. These include MI, unstable angina, atrial fibrillation, use of indwelling devices such as mechanical heart valves, and conditions in which blood flow may be slowed and blood may pool, such as major orthopedic surgery or prolonged periods of immobilization like hospitalization or even long plane rides. The ultimate consequence of a clot can be a stroke or a heart attack, DVT, or PE; therefore, the prevention of these serious events is the ultimate benefit of these drugs. Warfarin is indicated for prevention of any of these events, whereas unfractionated heparins, LMWHs, direct thrombin inhibitors, and factor Xa inhibitors are used for both prevention and treatment. Patients at risk for clots are given DVT prophylaxis while in the hospital and after major surgery. LMWHs, especially enoxaparin, are also routinely used as anticoagulant bridge therapy in situations in which a patient must stop warfarin for surgery or other invasive medical procedures. The term *bridge therapy* refers to the fact that enoxaparin acts as a bridge to provide anticoagulation while the patient must be off of his or her warfarin therapy. The remainder of the antithrombotic drugs have similar but more restricted indications, which are listed in the Dosages table for anticoagulants.

Contraindications

Contraindications to the use of anticoagulants are similar for all of the different drugs. They include known drug allergy to a specific product and usually include any acute bleeding process or high risk for such an occurrence, as well as thrombocytopenia. Warfarin is strongly contraindicated in pregnancy, whereas the other anticoagulants are rated in lower pregnancy categories (B or C). LMWHs are contraindicated in patients with an indwelling epidural catheter; they can be given 2 hours after the epidural is removed. This is very important to remember, because giving an LMWH with an epidural has been associated with epidural hematoma.

TABLE 26-2 ANTICOAGULANTS: COMMON ADVERSE EFFECTS

DRUG SUBCLASS	ADVERSE EFFECTS
Heparins (unfractionated heparin, low molecular weight heparin)	Bleeding, hematoma, anemia, thrombocytopenia
Direct thrombin inhibitors (lepirudin, argatroban, bivalirudin, dabigatran)	Bleeding, dizziness, shortness of breath, fever, urticaria
Selective factor Xa inhibitor (fondaparinux, rivaroxaban)	Bleeding, hematoma, dizziness, rash, gastrointestinal distress, anemia
warfarin (Coumadin)	Bleeding, lethargy, muscle pain, purple toes

Adverse Effects

Bleeding is the main complication of anticoagulation therapy, and the risk increases with increasing dosages. Such bleeding may be localized (e.g., hematoma at the site of injection) or systemic. It also depends on the nature of the patient's underlying clinical disorder and is increased in patients taking high doses of aspirin or other drugs that impair platelet function. One particularly notable adverse effect of heparin is *heparin-induced thrombocytopenia (HIT),* which is also called *heparin-associated thrombocytopenia.* There are two types of HIT. Type I is characterized by a more gradual reduction in platelets. In this type, heparin therapy can generally be continued. In contrast, in type II HIT there is an acute fall in the number of platelets (more than 50% reduction from baseline). Heparin therapy must be discontinued in patients with type II HIT. The greatest risk to the patient with HIT is the paradoxical occurrence of thrombosis, something that heparin normally prevents or alleviates. Thrombosis that occurs in the presence of HIT can be fatal. The incidence of this disorder ranges from 5% to 15% of patients and is higher with *bovine* (cow-derived) than with *porcine* (pig-derived) heparins. The direct thrombin inhibitors lepirudin and argatroban are both specifically indicated for treatment of HIT. Warfarin can cause skin necrosis and "purple toes" syndrome. Other adverse effects are listed in Table 26-2.

Toxicity and Management of Overdose

Treatment of the toxic effects of anticoagulants is aimed at reversing the underlying cause. Although the toxic effects of heparin, LMWH, and warfarin are hemorrhagic in nature, the management is different for each drug. Symptoms that may be attributed to toxicity or an overdose of anticoagulants are hematuria, melena (blood in the stool), petechiae, ecchymoses, and gum or mucous membrane bleeding. In the event of heparin or warfarin toxicity, the drug is to be stopped immediately.

In the case of heparin, stopping the drug alone may be enough to reverse the toxic effects because of the drug's short half-life (1 to 2 hours). In severe cases or when large doses have been given intentionally (i.e., during cardiopulmonary bypass for heart surgery), IV injection of protamine sulfate is indicated. This drug is a specific heparin antidote and forms a complex with heparin, completely reversing its anticoagulant properties. This occurs in as few as 5 minutes. In general, 1 mg of protamine can reverse the effects of 100 units of heparin. Protamine may also be used to reverse the effects of LMWHs. A 1-mg dose of protamine is administered for each milligram of LMWH given, (e.g., 1 mg protamine for 1 mg enoxaparin). If the heparin overdose has resulted in a large blood loss, replacement with packed red blood cells may be necessary.

In the event of warfarin toxicity or overdose, the first step is to discontinue the warfarin. As with heparin, the toxicity associated with warfarin is an extension of its therapeutic effects on the clotting cascade. However, because warfarin inactivates the vitamin K–dependent clotting factors and because these clotting factors are synthesized in the liver, it may take 36 to 42 hours before the liver can resynthesize enough clotting factors to reverse the warfarin effects. Giving vitamin K_1 (phytonadione) can hasten the return to normal coagulation. The dose and route of administration of the vitamin K depend on the clinical situation and its acuity (i.e., how quickly the warfarin-induced effects must be reversed and whether the patient is having significant bleeding). High doses of vitamin K (10 mg) given IV will reverse the anticoagulation within 6 hours. Current recommendations are to use the lowest amount of vitamin K possible, based on the clinical situation. This is because once vitamin K is given, warfarin resistance will occur for up to 7 days; thus the patient cannot be anticoagulated by warfarin during this period. In such cases, either heparin or an LMWH may need to be added to provide adequate anticoagulation. In acute situations in which bleeding is severe and the time it would take for the vitamin K to take effect is too long, it may be necessary to administer transfusions of human plasma or clotting factor concentrates. Depending on the clinical situation, oral vitamin K is usually the preferred route. However, when the international normalized ratio (INR) is very elevated and/or the patient is bleeding, vitamin K is given IV. There is a risk of anaphylaxis when it is given by the IV route. The risk is diminished by diluting it and giving it over 30 minutes. Some institutions allow it to be given via IV push. Vitamin K is available in 5-mg tablets and in 10-mg and 1-mg injections. It is common to give the injectable form orally.

Transfusions may be indicated for overdoses of direct thrombin inhibitors and the selective factor Xa inhibitor fondaparinux, which both lack specific antidotes. These drugs may also be removed with hemodialysis.

Interactions

Drug interactions involving the oral anticoagulants are profound and complicated. The main interaction mechanisms responsible for increasing anticoagulant activity include the following:

- **Enzyme** inhibition of metabolism
- Displacement of the drug from inactive protein-binding sites
- Decrease in vitamin K absorption or synthesis by the bacterial flora of the large intestines
- Alteration in the platelet count or activity

The drugs that interact with warfarin and heparin are listed in Table 26-3. More specifics on significant drug interactions are discussed under the drug profiles. Although both aspirin and warfarin increase the risk of bleeding when given with heparin, they are commonly given together in clinical practice. In fact, when a patient is placed on IV heparin, it is recommended that warfarin be started at the same time. Heparin is continued until the warfarin effect is therapeutic for at least 2 days.

Dosages

For dosage information on selected anticoagulants, see the table on p. 426.

DRUG PROFILES

Of the anticoagulants, warfarin, dabigatran, and rivaroxaban are used orally. The rest are given by IV and/or subcutaneous injection only. Intramuscular (IM) injection of these drugs is contraindicated due to their propensity to cause large hematomas at the site of injection.

♦ warfarin

Warfarin sodium (Coumadin) is a pharmaceutical derivative of the natural plant anticoagulant known as *coumarin.* Warfarin is the most commonly prescribed oral anticoagulant and is available oral and IV; however, it is used almost exclusively in the oral form. Use of this drug requires careful monitoring of the prothrombin time/international normalized ratio (PT/INR), which is a standardized measure of the degree to which a patient's blood coagulability has been reduced by the drug. A normal INR (without warfarin) is 1.0, whereas a therapeutic INR (with warfarin) ranges from 2 to 3.5, depending on the indication for use of the drug (e.g., atrial fibrillation, thromboprevention, prosthetic heart valve). Patients older than 65 years of age may have a lower INR threshold for bleeding complications and may need to be monitored accordingly. Elderly patients should be started on lower dosages initially. Recently, it has been shown that about one third of patients receiving warfarin metabolize it differently than expected, based on variations in certain genes, *CYP2CP* and *VKORC1.* Genetic testing for these genes is helpful in determining the appropriate initial dosage of warfarin. The maintenance dosage is still determined by the INR.

Warfarin has significant interactions with many drugs, including amiodarone, fluconazole, erythromycin, metronidazole, sulfonamide antibiotics, and cimetidine. Although many more drugs can interact with warfarin, the aforementioned are by far the most common. Combining warfarin and amiodarone will lead to a 50% increase in the INR. When amiodarone is added to warfarin therapy, it is recommended that the warfarin dose be cut in half.

Because warfarin inhibits vitamin K–dependent clotting factors, foods that are high in vitamin K may reduce warfarin's ability to prevent clots. Common foods rich in vitamin K include leafy green vegetables (kale, spinach, collard greens).

TABLE 26-3 DRUG INTERACTIONS

DRUG	MECHANISM	RESULT
Warfarin		
acetaminophen (high doses), amiodarone, bumetanide, furosemide	Displacement from inactive protein-binding sites	Increased anticoagulant effect
aspirin, other NSAIDs, Broad-spectrum antibiotics	Decreased platelet activity	Increased anticoagulant effect
Barbiturates, carbamazepine, rifampin, phenytoin	Enzyme induction	Decreased anticoagulant effect
amiodarone, cimetidine, ciprofloxacin, erythromycin, ketoconazole, metronidazole, omeprazole, Sulfonamides, Macrolides, HMG-CoA reductase inhibitors (statins)	Enzyme inhibition	Increased anticoagulant effect
cholestyramine, sucralfate	Impaired warfarin absorption	Decreased anticoagulant effect
Herbal therapies: Dong quai, Garlic, Ginkgo, St. John's wort	Unknown; case reports of increased INR	Increased bleeding risk from warfarin
Heparin		
aspirin, other NSAIDs	Decreased platelet activity	Increased bleeding risk
Oral anticoagulants, Thrombolytics	Additive	Increased anticoagulant effect
Any other anticoagulant, antiplatelet, or thrombolytic drug	Additive	Increased bleeding risk
Antiplatelets		
aspirin, NSAIDs	Decreased platelet activity	Increased bleeding risk
warfarin, heparin, thrombolytics	Additive	Increased bleeding risk
rifampin	Increased effects	Increased bleeding risk
Herbal therapies: Garlic, Ginkgo, Kava	Platelet antagonism	Increased bleeding risk

HMG-CoA, Hydroxymethylglutaryl–coenzyme A; *INR,* international normalized ratio; *NSAIDs,* nonsteroidal antiinflammatory drugs.

The most important aspect of these food-drug interactions is consistency in diet. Educate patients to maintain consistency in their intake of leafy green vegetables. Many patients are under the misconception that they must avoid all leafy green vegetables. However, this is not true. Once their maintenance warfarin dose is established, patients may still eat greens, but they need to be consistent in their intake of green vegetables, because increasing or decreasing their intake can affect the INR. Herbal products that interact with warfarin and result in increased risk of bleeding include dong quai, garlic, ginkgo, and St. John's wort.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	24-72 hr	4 hr	0.5-3 days	2-5 days

♦ enoxaparin

Enoxaparin (Lovenox) is the prototypical LMWH and is obtained by enzymatically cleaving large unfractionated heparin molecules into small fragments. These smaller fragments of heparin have a greater affinity for factor Xa than for factor IIa and have a higher degree of bioavailability and a longer elimination half-life than unfractionated heparin. Laboratory monitoring, as done with heparin therapy, is not necessary when enoxaparin is given because of its greater affinity for factor Xa. It is available only in injectable form. Other anticoagulants with comparable pharmacology and indications include danaparoid and dalteparin. Enoxaparin is the most frequently used LMWH and is commonly given for both prophylaxis and treatment. All LMWHs have a distinct advantage over heparin in that it does not require any laboratory monitoring and can be given at home for the treatment of DVT or pulmonary embolism. This allows patients to be discharged from the hospital sooner. It is also used at home after major orthopedic surgery.

A potentially deadly medication error is to give heparin in combination with enoxaparin (or any LMWH, dabigatran, or rivaroxaban). Always double-check that enoxaparin and heparin are never given to the same patient.

DOSAGES

Selected Anticoagulant Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
argatroban (Argatroban) (B)	Synthetic direct thrombin inhibitor	**Adult** IV: 2 mcg/kg/min until aPTT in desired range	Thromboprevention and treatment of HIT and with PCI in patients at risk for HIT
♦ enoxaparin (Lovenox) (B)	LMWH	**Adult** Subcut: 30-40 mg every 12 hr for prophylaxis or 1 mg/kg every 12 hr for treatment	Prevention and treatment of thromboembolic and ischemic processes in unstable angina and postoperative and post-MI situations
♦ heparin (generic only) (C)	Natural anticoagulant	**Pediatric** IV: Initial 50 units/kg, then 12-25 units/kg/hr, increased by 2-4 units/kg/hr q6-8h prn **Adult** Subcut: 5000 units q8-12hr for prophylaxis IV infusion: 20,000-40,000 units/day usually given as 80 unit/kg bolus then 18 units/kg/hr (depending on indication) aPTT determines maintenance dosage	Thrombosis/embolism, coagulopathies (e.g., DIC), DVT and PE prophylaxis, clotting prevention (e.g., open heart surgery, dialysis)
dabigatran (Pradaxa) (C)	Synthetic direct thrombin inhibitor	**Adult** Oral: 75-150 mg bid (depending on renal function)	Prevention of strokes and thrombosis in patients with nonvalvular atrial fibrillation
fondaparinux (Arixtra) (B)	Factor Xa inhibitor	Prophylaxis: 2.5 mg subcut daily Treatment: less than 50 kg: 5 mg daily 50-100 kg: 7.5 mg daily Over 100 kg: 10 mg daily	Prevention and treatment of DVT and PE
♦ warfarin (X)	Coumarin anticoagulant	INR determines maintenance dose, usually 1-10 mg/day orally	Thromboprevention and treatment of DVT, PE, atrial fibrillation, post-MI status

aPTT, Activated partial thromboplastin time; *DIC,* disseminated intravascular coagulation; *DVT,* deep vein thrombosis; *HIT,* heparin-induced thrombocytopenia; *INR,* international normalized ratio; *IV,* intravenous; *LMWH,* low molecular weight heparin; *MI,* myocardial infarction; *PCI,* percutaneous coronary intervention; *PE,* pulmonary embolism; *subcut,* subcutaneous.

Pharmacokinetics (enoxaparin)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Subcut	3-5 hr	4-5 hr	4-5 hr	12 hr

♦ heparin

Heparin is a natural mucopolysaccharide anticoagulant obtained from the lungs, intestinal mucosa, or other suitable tissues primarily of pigs. One brand name for some of the commonly used heparin products is Hep-Lock. This brand name refers only to small vials of heparin IV flush solutions used to maintain the patency of heparin-lock IV insertion sites. Because of the risk for the development of HIT, however, most institutions routinely use normal saline (0.9% sodium chloride) as a flush for heparin-lock IV ports and have moved away from using heparin flush solutions for this purpose. Heparin flushes are still used for central catheters. When used for flushing purposes, there is no need for monitoring.

Heparin is commonly used for DVT prophylaxis in a dose of 5000 units two or three times a day given subcutaneously, and it does not need to be monitored when used for prophylaxis. When heparin is used therapeutically (for treatment), it is given by continuous IV infusion or, rarely, by subcutaneous injection. Most hospitals have weight-based protocols for heparin administration. Because the dosage is based on the patient's weight in kilograms, ensure that the appropriate weight is recorded and that only kilograms are used, not pounds. A potential double-dose medication error can occur if pounds and kilograms are mixed. This is also true for enoxaparin, because it is dosed on body weight when used therapeutically. When heparin is given by IV infusion, monitoring by frequent measurement of aPTT (usually every 6 hours until therapeutic effects are seen) is necessary. Because the required monitoring is very time-consuming, many institutions now use enoxaparin in place of heparin.

Other drugs that affect the coagulation cascade can have additive effects with heparin, which may lead to bleeding. Even though warfarin can cause additive effects, it is combined with IV heparin therapy. In fact, it is usually started within the first day or two of heparin infusion.

Heparin is available only in injectable form in multiple strengths ranging from 10 to 40,000 units/mL. The vials of different strengths of heparin are very similar and look very much alike. In fact, several newborns have died when a vial of more concentrated heparin was mistaken for a more dilute solution. Take great care in checking and double-checking the concentration of heparin before administering it.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Immediate	Immediate	1-2 hr	Dependent on infusion duration
Subcut	20-30 min	2-4 hr	1-2 hr	8-12 hr

dabigatran

Dabigatran (Pradaxa) is the first oral direct thrombin inhibitor that is approved for prevention of strokes and thrombosis in patients with nonvalvular atrial fibrillation. Dabigatran is a prodrug that becomes activated in the liver. It specifically and reversibly binds to both free and clot-bound thrombin. Dabigatran is excreted extensively in the kidneys, and the dose is dependent upon renal function. The normal dose is 150 mg twice daily, but it must be reduced to 75 mg twice daily if creatinine clearance is less than 30 mL/min. There is no antidote to dabigatran, and the most common and serious side effect is bleeding. No coagulation monitoring is required for dabigatran. Drug interactions include phenytoin (decreased effect) and amiodarone (increased effect). Information about storage and handling is discussed in the Nursing Process section later in the chapter.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2-3 hr	2 hr	12-17 hr	12 hr

fondaparinux

Fondaparinux (Arixtra) is a selective inhibitor of factor Xa, which is indicated for prophylaxis or treatment of DVT or PE. In 2009, the FDA required changes in the prescribing information to highlight potential adverse reactions and contraindications. It is contraindicated with known allergy or in patients with a creatinine clearance less than 30 mL/min or a body weight of less than 50 kg. Bleeding is the most common and serious adverse reaction. Thrombocytopenia has also been reported, and therapy should be stopped if platelet count falls below 100,000 platelets per microliter. It should not be given for at least 6 to 8 hours after surgery and should be used with caution in conjunction with warfarin or other anticoagulants. Other side effects include anemia, increased wound drainage, postoperative hemorrhage, hematoma, confusion, urinary tract infection, hypotension, dizziness, and hypokalemia. There is no antidote for fondaparinux, and its effect cannot be measured by standard anticoagulant tests. Fondaparinux is given only by subcutaneous injection. The dose for prophylaxis is 2.5 mg daily. The dose for acute DVT/PE treatment is 5 to 10 mg daily, depending on body weight.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Subcut	2 hr	2-3 hr	17-21 hr	24 hr

argatroban

Argatroban, which has the same trade name, is a synthetic direct thrombin inhibitor that is derived from the amino acid L-arginine. It is indicated both for treatment of active HIT and for *percutaneous coronary intervention* procedures in patients at risk for HIT (i.e., those with a history of the disorder). It is given only by the IV route. A lower dosage must be used in patients with severe hepatic dysfunction.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Immediate	1-3 hr	30-50 min	Dependent on infusion duration

ANTIPLATELET DRUGS

Another class of coagulation modifiers that prevent clot formation is the antiplatelet drugs. The anticoagulants work in the clotting cascade. In contrast, antiplatelet drugs work to prevent platelet adhesion at the site of blood vessel injury, which actually occurs before the clotting cascade.

Platelets normally flow through blood vessels without adhering to their surfaces. Blood vessels can be injured by a disruption of blood flow, trauma, or the rupture of plaque from a vessel wall. When such events occur, substances such as collagen and fibronectin, which are present in the walls of blood vessels, become exposed. Collagen is a potent stimulator of platelet adhesion, as is a prevalent component of the platelet membranes called *glycoprotein IIb/IIIa (GP IIb/IIIa).* Once platelet adhesion occurs, stimulators (compounds such as adenosine diphosphate [ADP], thrombin, thromboxane A_2 [TXA_2], and prostaglandin H_2) are released from the activated platelets. These cause the platelets to *aggregate* (accumulate) at the site of injury. Once at the site of vessel injury, the platelets change shape and release their contents, which include ADP, serotonin, and platelet factor IV. The hemostatic function of these substances is twofold. First, they act as platelet recruiters, attracting additional platelets to the site of injury; second, they are potent vasoconstrictors. Vasoconstriction limits blood flow to the damaged blood vessel to reduce blood loss.

A platelet plug that has formed at a site of vessel injury is not stable and can be dislodged. The clotting cascade is then stimulated to form a more permanent *fibrin* plug (blood clot). The role of platelets and their relationship to the clotting cascade are illustrated in Figure 26-4.

Mechanism of Action and Drug Effects

Many of the antiplatelet drugs affect the *cyclooxygenase* pathway, which is one of the common final enzymatic pathways in the complex *arachidonic acid* pathway that operates within platelets and on blood vessel walls. This pathway as it functions in both platelets and blood vessel walls is illustrated in Figure 26-5.

Aspirin is widely used for its analgesic, antiinflammatory, and antipyretic (antifever) properties (see Chapter 44). Aspirin also has antiplatelet effects. Aspirin (acetylsalicylic acid) acetylates and inhibits cyclooxygenase in the platelet irreversibly so that the platelet cannot regenerate this enzyme. Therefore, the effects of aspirin last the lifespan of a platelet, or 7 days. This irreversible inhibition of cyclooxygenase in the platelet prevents the formation of TXA_2, a substance that causes blood vessels to constrict

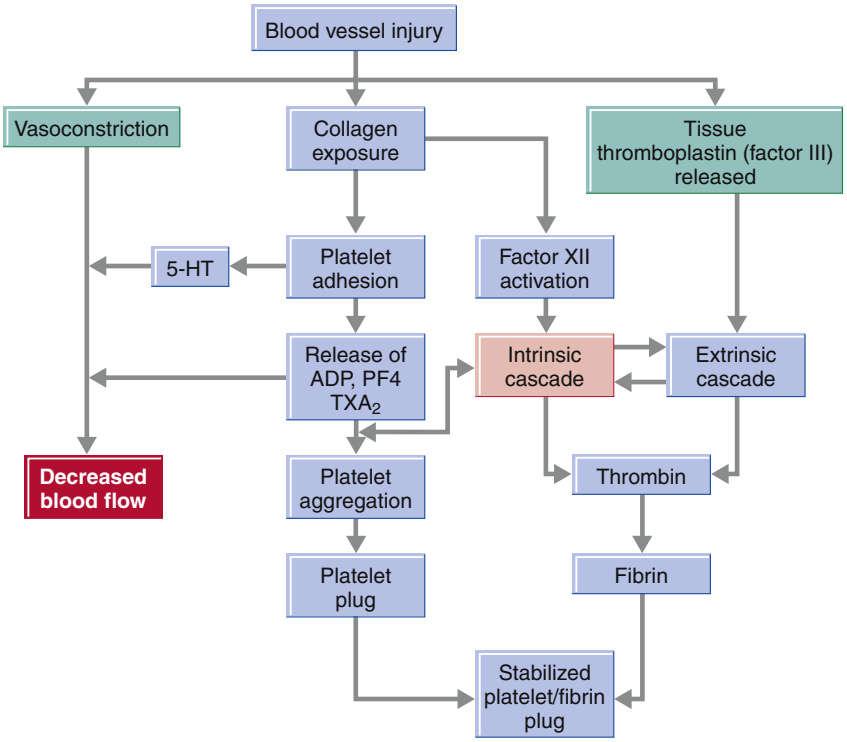

FIGURE 26-4 Relationship between platelets and the clotting cascade. *ADP,* Adenosine diphosphate; *5-HT,* serotonin; *PF4,* platelet factor IV; *TXA_2,* thromboxane A_2.

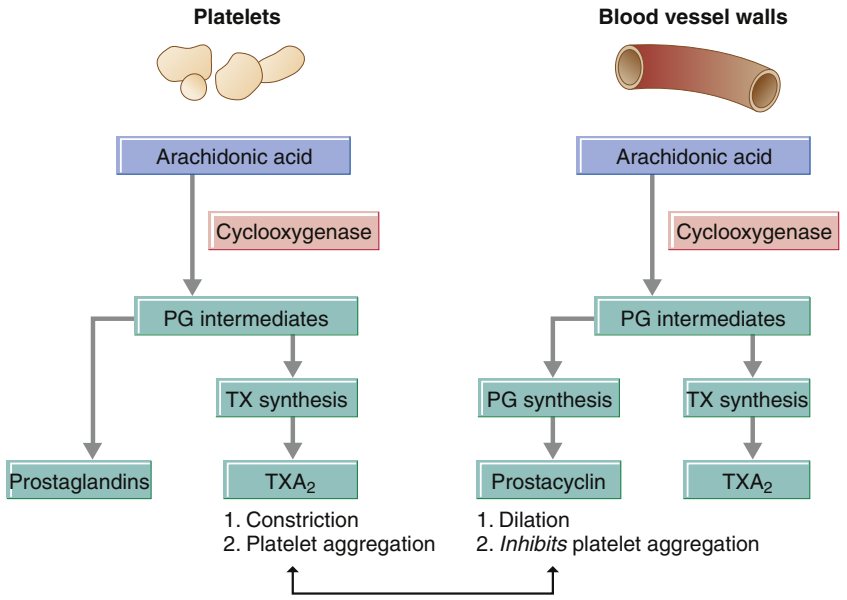

FIGURE 26-5 Cyclooxygenase pathway. *PG,* Prostaglandin; *TX,* thromboxane; *TXA_2,* thromboxane A_2.

and platelets to aggregate. Thus, by preventing TXA_2 formation, aspirin prevents these actions, which results in dilation of the blood vessels and prevention of platelets from aggregating or forming a clot.

Dipyridamole, another antiplatelet drug, also works to inhibit platelet aggregation by preventing the release of ADP, platelet factor IV, and TXA_2, all substances that stimulate platelets to aggregate or form a clot. Figure 26-4 shows how these substances accomplish this. Dipyridamole may also directly stimulate the release of prostacyclin and inhibit the formation of TXA_2 (see Figure 26-5).

Clopidogrel is a drug that belongs to the class of antiplatelet drugs called the ADP inhibitors. Its use has largely superseded that of the original ADP inhibitor ticlopidine. Its mechanism of action is entirely different from that of aspirin in that it inhibits platelet aggregation by altering the platelet membrane so that it can no longer receive the signal to aggregate and form a clot. This signal is in the form of **fibrinogen** molecules, which

attach to glycoprotein receptors (GP IIb/IIIa) on the surface of the platelet. Clopidogrel inhibits the activation of this receptor. Clopidogrel has been shown to be somewhat better than aspirin at reducing the number of heart attacks, strokes, and vascular deaths in patients at risk. The combination of aspirin and clopidogrel has been shown to be effective in patients with known cardiovascular disease, but not in patients who only have risk factors. Prasugrel (Effient) is a newer antiplatelet drug, similar to clopidogrel, that is used primarily after interventional cardiac procedures and for patients who do not respond to clopidogrel. The newest antiplatelet drug is ticagrelor (BRILINTA), which was approved in 2011. It is indicated for patients with acute coronary syndrome. It must be avoided in patients taking more than 100 mg of aspirin daily.

Pentoxifylline, another antiplatelet drug, is a methylxanthine derivative with properties similar to those of other methylxanthines, such as caffeine and theophylline (see Chapter 37). It was one of the earliest antiplatelet drugs but is now much less commonly used. It reduces the viscosity of blood by increasing the flexibility of red blood cells and reducing the aggregation of platelets. It is sometimes referred to as a *hemorheologic* drug, or a drug that alters the fluid dynamics of the blood. The antiplatelet effects of pentoxifylline are attributed to its inhibition of ADP, serotonin, and platelet factor IV (see Figure 26-4). Pentoxifylline also stimulates the synthesis and release of prostacyclin from blood vessels (see Figure 26-5). In addition, it may have effects on the fibrinolytic system by raising the plasma concentrations of tissue plasminogen activator (see Figure 26-3).

Cilostazol is another antiplatelet drug, which works through inhibition of type 3 phosphodiesterase in the platelets and primarily lower-extremity blood vessels. Its effects are to reduce platelet aggregation and promote vasodilation.

Another class of antiplatelet drugs is the GP IIb/IIIa inhibitors. They work by blocking the receptor protein by the same name that occurs in the platelet wall membranes. This protein plays a role in promoting the aggregation of platelets in preparation for fibrin clot formation. There are currently three available drugs in this class: tirofiban (Aggrastat), eptifibatide (Integrilin), and abciximab (ReoPro). The GP IIb/IIIa inhibitors are available only for IV infusion.

Indications

The therapeutic effects of the antiplatelet drugs depend on the particular drug. Aspirin has multiple therapeutic effects, but many of them vary depending on the dosage. Aspirin is officially recommended for stroke prevention by the American Stroke Society in daily doses of 50 to 325 mg. (However, in clinical practice, dosages may vary.) Clopidogrel is given to reduce the risk for fatal and nonfatal thrombotic stroke, and is used for prophylaxis against transient ischemic attacks as well for post-MI prevention of thrombosis. Dipyridamole is used as an adjunct to warfarin in the prevention of postoperative thromboembolic complications. It is also used to decrease platelet aggregation in various other thromboembolic disorders. The GP IIb/IIIa inhibitors are used to treat acute unstable angina and MI, and are given during percutaneous coronary intervention procedures, such as angioplasty. Their purpose is to prevent the formation of thrombi. This is known as *thromboprevention.* This treatment approach is based on the fact that *prevention* of thrombus formation is easier and less risky overall from a pharmacologic standpoint than is lysing a formed thrombus. Pentoxifylline is indicated for peripheral vascular disease, whereas cilostazol is indicated specifically for *intermittent claudication* (pain and cramping in the calf muscles associated with walking). Cilostazol has been shown to be superior to pentoxifylline in improving exercise tolerance in elderly patients.

TABLE 26-4 SELECTED ANTIPLATELET DRUGS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Aspirin	
Central nervous	Drowsiness, dizziness, confusion, flushing
Gastrointestinal	Nausea, vomiting, gastrointestinal bleeding, diarrhea
Hematologic	Thrombocytopenia, agranulocytosis, leukopenia, neutropenia, hemolytic anemia, bleeding
Clopidogrel	
Cardiovascular	Chest pain, edema
Central nervous	Flulike symptoms, headache, dizziness, fatigue
Gastrointestinal	Abdominal pain, diarrhea, nausea
Miscellaneous	Epistaxis, rash, and pruritus (itching)
Glycoprotein IIb/IIIa Inhibitors	
Cardiovascular	Bradycardia, hypotension, edema
Central nervous	Dizziness
Hematologic	Bleeding, thrombocytopenia

Contraindications

Contraindications to the use of antiplatelet drugs include known drug allergy to a specific product, thrombocytopenia, active bleeding, leukemia, traumatic injury, gastrointestinal ulcer, vitamin K deficiency, and recent stroke.

Adverse Effects

The potential adverse effects of the various antiplatelet drugs can be serious, and they all pose a risk for inducing a serious bleeding episode. The most common adverse effects are listed in Table 26-4.

Interactions

Some potentially dangerous drug interactions can occur with antiplatelet drugs. The use of dipyridamole with clopidogrel, aspirin, and/or other nonsteroidal antiinflammatory drugs (NSAIDs) produces additive antiplatelet activity and increased bleeding potential. The combined use of steroids or nonaspirin NSAIDs with aspirin can increase the ulcerogenic effects of aspirin. The combined use of aspirin and heparin with GP IIb/IIIa inhibitors also further enhances antiplatelet activity and increases the likelihood of a serious bleeding episode. In spite of all of these interactions, it is not uncommon to see patients

DOSAGES

Selected Antiplatelet Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
♦ aspirin (C/D)	Salicylate antiplatelet	**Adult**	
		PO: 81-325 mg once daily	MI prophylaxis
		PO: 40-325 mg once daily	TIA prophylaxis
♦ clopidogrel (Plavix) (B)	ADP inhibitor	**Adult**	
		PO: 75 mg once daily; 300 mg may be given as a one-time loading dose after coronary stent implantation	Reduction of atherosclerotic events; acute coronary syndrome without ST segment elevation
♦ eptifibatide (Integrilin) (B)	GP IIb/IIIa inhibitor	IV: Single bolus followed by continuous infusion; specific doses are based on patient weight from 37 to more than 121 kg*	Unstable angina, MI, percutaneous coronary procedures

ADP, Adenosine diphosphate; *GP,* glycoprotein; *IV,* intravenous; *MI,* myocardial infarction; *PO,* oral; *TIA,* transient ischemic attack.
*See table in package insert for specific dose.

taking daily maintenance doses of aspirin for thrombopreventive purposes, sometimes in combination with other antiplatelet drugs. The most commonly used dose is the "baby aspirin" dose of 81 mg (the standard adult dose is 325 mg). Even though GP IIb/IIIa and heparin have additive therapeutic effects when given concurrently and are listed as interacting drugs, it is very common to see both used together. However, the therapeutic goal of heparin treatment, and thus the dose, is lower when used with a GP IIb/IIIa inhibitor.

Dosages

For dosage information on selected antiplatelet drugs, see the table on this page.

DRUG PROFILES

Antiplatelet drugs are extremely useful in the management of thromboembolic disorders. Each has unique pharmacologic properties, and therefore they all are somewhat different from one another.

♦ aspirin

Aspirin is available in many combinations with other prescription and nonprescription drugs and goes by many product names. One unique contraindication for aspirin is flulike symptoms in children and teenagers. The use of aspirin in this situation is associated with the occurrence of Reye's syndrome, a rare, acute, and sometimes fatal condition involving hepatic and central nervous system damage (see Chapter 44). There is also allergic cross-reactivity between aspirin and other NSAIDs. Patients with documented aspirin allergy must not receive NSAIDs. Aspirin is available in both oral and rectal forms. A combination form of aspirin and dipyridamole (Aggrenox) is used for antiplatelet purposes.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	15-30 min	0.25-2 hr	2-3 hr	4-6 hr

♦ clopidogrel

Clopidogrel (Plavix) is currently the most widely used ADP inhibitor on the market. It has superseded ticlopidine (Ticlid) due to the associated serious adverse reactions to the latter drug, including life-threatening neutropenia and agranulocytosis. It was initially believed that clopidogrel might be free from such adverse effects. However, some case reports are emerging of clopidogrel-associated hematologic adverse effects. It is available only for oral use. Prasugrel (Effient) and ticagrelor (BRILINTA) are similar to clopidogrel.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-2 hr	1 hr	8 hr	7-10 days

♦ eptifibatide

Eptifibatide (Integrilin) is a GP IIb/IIIa inhibitor, along with tirofiban (Aggrastat) and abciximab (ReoPro). These drugs are usually administered in intensive care or cardiac catheterization laboratory settings where continuous cardiovascular monitoring is the norm. All are available only for IV use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	1 hr	Unknown	2-2.5 hr	4 hr

THROMBOLYTIC DRUGS

Thrombolytics are coagulation modifiers that lyse thrombi in the blood vessels that supply the heart with blood, the coronary arteries. This reestablishes blood flow to the blood-starved heart muscle. If the blood flow is reestablished early, the heart muscle and left ventricular function can be saved. If blood flow is not reestablished early, the affected area of the heart muscle becomes ischemic, and eventually necrotic and nonfunctional.

Thrombolytic therapy made its debut in 1933 when a substance that broke down fibrin clots was isolated from a patient's blood. This substance was determined to be produced by certain bacteria growing in the patient's blood. The bacteria were found to be *beta-hemolytic streptococci (group A),* and the substance was eventually called *streptokinase.*

Streptokinase was first used in a patient in 1947 to dissolve a clotted hemothorax, but it was not until 1958 that it was given to a patient with an acute MI. In 1960, a naturally occurring human plasminogen activator called urokinase, which was found to exert fibrinolytic effects on pulmonary emboli (clots in the lungs), became available. However, the results of the early thrombolytic trials conducted during the 1960s and 1970s that enrolled patients who had had an acute MI were not taken seriously by the medical community. In the 1980s, the underlying cause of acute MI was determined to be due to coronary artery occlusion. This marked the start of rapid growth in the use of thrombolytic drugs for the early treatment of acute MI. Since that time, several new thrombolytics have become available for this and other clinical uses. *Tissue plasminogen activator (t-PA)* and *anisoylated plasminogen streptokinase activator complex (APSAC)* are two of these drugs. Following the advent of these new thrombolytics came the results of several large landmark thrombolytic research studies. These studies showed that early thrombolytic therapy could bring about a 50% reduction in mortality, a reduction in the infarct size, an improvement in left ventricular function, and a reduction in the incidence and severity of congestive heart failure. These findings and developments, along with a better understanding of the pathogenesis of acute MI, have led the way to the advancements made in the treatment of acute MI. However, the use of thrombolytics has almost completely been replaced by interventional cardiologic procedures, such as percutaneous coronary intervention. Thrombolytics are still a viable option in hospitals that do not offer percutaneous coronary intervention. Currently available thrombolytic drugs include t-PAs (anistreplase [Eminase], alteplase [Activase], reteplase [Retavase], and tenecteplase [TNKase]). For dosage information on thrombolytics, see the table on p. 432.

Mechanism of Action and Drug Effects

There is a fine balance between the formation and dissolution of a clot. The coagulation system is responsible for forming clots, whereas the fibrinolytic system is responsible for dissolving clots. The natural fibrinolytic system within the blood takes several days to break down a clot (thrombus). This is of little value in the case of a clotted blood vessel that supplies blood to the heart muscle. Necrosis of the myocardium would not be prevented by these natural means, but thrombolytic drug therapy activates the fibrinolytic system to break down the thrombus in the blood vessel quickly so that the delivery of blood to the heart muscle via the coronary arteries is quickly reestablished. This prevents myocardial tissue (heart muscle) and heart function from being destroyed. Thrombolytics accomplish this by activating the conversion of plasminogen to plasmin, which breaks down, or lyses, the thrombus (see Figure 26-3). Plasmin is a proteolytic enzyme, which means that it breaks down proteins. It is a relatively nonspecific serine protease that is capable of degrading proteins such as fibrin, fibrinogen, and other procoagulant proteins like factors V, VIII, and XII. In other words, the substances that form clots are destroyed by plasmin. Essentially, thrombolytic drugs work by mimicking the body's own process of clot destruction. Although the individual thrombolytic drugs are somewhat diverse in their actions, they all have this common result.

Streptokinase, the original thrombolytic enzyme, and the naturally occurring urokinase have been removed from the U.S. market, primarily due to their adverse effects—namely, they were not fibrin specific. The newer thrombolytics have chemical specificity for fibrin threads **(fibrin specificity)** and work primarily at the site of a clot. They still carry some bleeding risk, but much less than that of the thrombolytic enzymes.

Tissue plasminogen activator is a naturally occurring plasminogen activator secreted by vascular endothelial cells (the walls of blood vessels). However, the amount secreted naturally is not sufficient to dissolve a coronary thrombus quickly enough to restore circulation to the heart and save the heart muscle. Recombinant DNA techniques are now used to produce t-PA, and thus it can be administered in quantities sufficient to dissolve a coronary thrombus quickly. It is fibrin specific (clot specific); that is, only the fibrin clot stimulates t-PA to convert plasminogen to plasmin. Therefore, it has a lower propensity to induce a systemic thrombolytic state, compared to the thrombolytic enzymes.

Indications

The purpose of all the thrombolytic drugs is to activate the conversion of plasminogen to plasmin, the enzyme that breaks down a thrombus. The presence of a thrombus that interferes significantly with normal blood flow on either the venous or the arterial side of the circulation is an indication for the use of thrombolytic therapy. An exception may be a thrombus that has formed in blood vessels that connect directly with the central nervous system. The indications for thrombolytic therapy include acute MI, arterial thrombosis, DVT, occlusion of shunts or catheters, pulmonary embolism, and acute ischemic stroke.

Contraindications

Contraindications to the use of thrombolytic drugs include known drug allergy to the specific product and any preservatives, and concurrent use of other drugs that alter clotting.

Adverse Effects

The most common undesirable effect of thrombolytic therapy is internal, intracranial, and superficial bleeding. Other problems include hypersensitivity, anaphylactoid reactions, nausea, vomiting, and hypotension. These drugs can also induce cardiac dysrhythmias.

Toxicity and Management of Overdose

Acute toxicity primarily causes an extension of the adverse effects of the thrombolytic drug. Treatment is symptomatic and

DOSAGES

Selected Thrombolytic Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ alteplase (Activase) (C)	Tissue plasminogen activator	**Adult**	
		IV: 100 mg over 90 min given as a 15-mg IV bolus, then 50 mg over 30 min, then 35 mg over 60 min	Acute myocardial infarction
		IV: 100 mg over 2 hr or 30-50 mg over 1.5-2 hr via pulmonary artery	Pulmonary embolism
		IV: 0.9 mg/kg (total dose not to exceed 90 mg); 10% given as an IV bolus over 1 min, remainder over 60 min; must be given within 3 hr of onset of symptoms	Acute ischemic stroke

IV, Intravenous.

supportive, because thrombolytic drugs have a relatively short half-life and no specific antidotes.

Interactions

The most common effect of drug interactions is an increased bleeding tendency resulting from the concurrent use of anticoagulants, antiplatelets, or other drugs that affect platelet function.

A laboratory test interaction that can occur with thrombolytic drugs is a reduction in the plasminogen and fibrinogen levels.

Dosages

For dosage information on alteplase, see the table on this page.

DRUG PROFILE

All thrombolytic drugs exert their effects by activating plasminogen and converting it to plasmin, which is capable of digesting fibrin, a major component of clots.

♦ alteplase

Alteplase (Activase) is a pharmaceutically available t-PA made through recombinant DNA techniques. It is fibrin specific and therefore does not produce a systemic lytic state. In addition, because it is present in the human body in a natural state, its administration for therapeutic use does not induce an antigen-antibody reaction. Therefore, it can be readministered immediately in the event of reinfarction. The drug t-PA has a very short half-life of 5 minutes. It is believed to open the clogged artery rapidly, but its action is short-lived. Therefore, it is given with heparin to prevent reocclusion of the affected blood vessel. Alteplase is available only in parenteral form. There is also a smaller dosage form known as Cathflo Activase that is used to flush clogged IV or arterial lines. Tenecteplase (TNKase) is a newer form of alteplase that is given by IV push after MI. Alteplase is also used in ischemic stroke.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	30 min	60 min	26-50 min	Dependent on infusion duration

ANTIFIBRINOLYTIC DRUGS

The individual antifibrinolytic drugs have varying mechanisms of action, but all prevent the lysis of fibrin. Fibrin is the substance that helps make a platelet plug insoluble and anchors the clot to the damaged blood vessel (see Figures 26-1 and 26-2). The term *antifibrinolytic* refers to what these drugs do, which is to prevent the lysis of fibrin; in doing so, they actually *promote* clot formation. For this reason, they are also called *hemostatic* drugs. Their effects are opposite to those of anticoagulant and antiplatelet drugs, which *prevent* clot formation. Three synthetic antifibrinolytics are available—aminocaproic acid, tranexamic acid, and desmopressin. Dosages, indications, and other information appear in the associated Dosages table. There are also hemostatic drugs that are used *topically* (on the skin or tissue surface) in surgical settings to stop excessive bleeding. These include topical thrombin, microfibrillar collagen, absorbable gelatin, and oxidized cellulose.

Although not technically antifibrinolytic drugs, there are three drugs used for the treatment of hemophilia. These are produced by recombinant DNA technology, which eliminates the risk associated with obtaining them from human blood. Products currently available include rVII, rVIII, and rIX. As mentioned earlier, factors VII, VIII, and IX are important in the coagulation pathway. Warfarin also inhibits these factors. These products are used in patients with hemophilia and are also used in patients with severe bleeding due to warfarin therapy.

Mechanism of Action and Drug Effects

The antifibrinolytic drugs vary in several ways. The various antifibrinolytic drugs and their proposed mechanisms of action are described in Table 26-5.

TABLE 26-5 ANTIFIBRINOLYTICS: MECHANISMS OF ACTION

ANTIFIBRINOLYTIC DRUG	MECHANISM OF ACTION
aminocaproic acid (Amicar) and tranexamic acid (Cyklokapron)	Form a reversible complex with plasminogen and plasmin. By binding to the lysine-binding site of plasminogen, these drugs displace plasminogen from the surface of fibrin. This prevents plasmin from lysing the fibrin clot. Therefore, these drugs can work only if a clot has formed.
desmopressin (DDAVP)	Works by increasing the level of factor VII (von Willebrand factor), which anchors platelets to damaged vessels via the glycoprotein Ib platelet receptor. It appears that desmopressin acts as a general endothelial stimulant, promoting the release of factor VIII, prostaglandin I2, and plasminogen activator.

The drug effects of the antifibrinolytics are very specific and limited. They do not have many effects outside of their hematologic ones. Aminocaproic acid and tranexamic acid inhibit the breakdown of fibrin, which prevents the destruction of the formed platelet clot. Desmopressin causes a dose-dependent increase in the concentration of plasma factor VIII (von Willebrand factor), along with an increase in the plasma concentration of tissue plasminogen activator. The overall effect of this is increased platelet aggregation and clot formation. This drug is also an analogue of antidiuretic hormone and is discussed further in Chapter 30.

Indications

Antifibrinolytics are useful in both the prevention and treatment of excessive bleeding resulting from systemic hyperfibrinolysis or surgical complications. They have also proved successful in arresting excessive oozing from surgical sites such as chest tubes as well as in reducing the total blood loss and the duration of bleeding in the postoperative period.

Desmopressin may also be used in patients who have hemophilia A or type I von Willebrand disease. As stated earlier, recombinant factors VII, VIII, and IX are used to treat hemophilia or to stop the bleeding from excessive warfarin therapy.

TABLE 26-6 ANTIFIBRINOLYTICS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Dysrhythmias, orthostatic hypotension, bradycardia
Central nervous	Headache, dizziness, fatigue, hallucinations, convulsions
Gastrointestinal	Nausea, vomiting, abdominal cramps, diarrhea

Contraindications

Contraindications to the use of antifibrinolytic drugs include known drug allergy to a specific product and disseminated intravascular coagulation, which could be worsened by these drugs.

Adverse Effects

The adverse effects of antifibrinolytic drugs occur uncommonly and are mild. However, there have been rare reports of these drugs causing thrombotic events, such as acute cerebrovascular thrombosis and acute MI. The common adverse effects of antifibrinolytics are listed in Table 26-6.

Interactions

When drugs such as estrogens or oral contraceptives are used concurrently with aminocaproic acid or tranexamic acid, additive effects may occur, resulting in increased coagulation. Few specific interactions have been reported for desmopressin, although use caution when giving to patients receiving lithium, large doses of epinephrine, heparin, or alcohol. Drugs such as chlorpropamide and fludrocortisone may potentiate the antidiuretic response, which may lead to edema.

Dosages

For dosage information on aminocaproic acid and desmopressin, see the table on this page.

DRUG PROFILES

aminocaproic acid

Aminocaproic acid (Amicar) is a synthetic antifibrinolytic drug used to prevent and control the excessive bleeding that can result from surgery or overactivity of the fibrinolytic system. It is available in both oral and parenteral preparations.

DOSAGES

Selected Antifibrinolytic Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
aminocaproic acid (Amicar) (C)	Hemostatic	**Adult** IV infusion: 4-5 g during first hour, then 1 g at 1-hr intervals up to a daily max of 30 g	Excessive bleeding caused by systemic hyperfibrinolysis or urinary fibrinolysis
desmopressin (DDAVP) (B)	Synthetic posterior pituitary hormone	**Adult** IV: 0.3 mcg/kg infused over 15-30 min; preoperative use: drug is administered 30 min before surgery	Surgical and postoperative hemostasis and management of bleeding in patients with hemophilia A or type I von Willebrand disease

IV, Intravenous.

Pharmacokinetics (aminocaproic acid)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Unknown	1.2 hr	2 hr	3 hr

desmopressin

Desmopressin (DDAVP) is a synthetic polypeptide. It is structurally very similar to vasopressin, which is antidiuretic hormone, the natural human posterior pituitary hormone (see Chapter 30). Because of these physical characteristics, it is most often used to increase the resorption of water by the collecting ducts in the kidneys to prevent or control polydipsia, polyuria, and dehydration in patients with diabetes insipidus due to a deficiency of endogenous posterior pituitary vasopressin or in patients with polyuria and polydipsia resulting from trauma or surgery in the pituitary region.

Desmopressin also causes a dose-dependent increase in plasma factor VIII (von Willebrand factor), along with an increase in tissue plasminogen activator, which results in increased platelet aggregation and clot formation; thus it is often used to stop bleeding. Desmopressin is contraindicated in patients with a known hypersensitivity to it and in those with nephrogenic diabetes insipidus. It is available in both injectable and intranasal dosage forms. Desmopressin nasal spray is used for primary nocturnal enuresis.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	15-30 min	1-2 hr	2 hr	Unknown

NURSING PROCESS

Coagulation modifiers have a variety of uses, including the following: (1) prevention or elimination of clotting in a peripherally inserted catheter (PIC, or PICC—a peripherally inserted central catheter), (2) maintenance of patency (without clotting) of central venous catheters, (3) clot prevention in coronary artery bypass grafting, (4) prevention of clotting after major vessel injury, (5) treatment of thrombophlebitis to prevent venous and/or arterial thromboembolism, and (6) prevention of clotting with use of prosthetics (e.g., heart valve replacements) and in atrial fibrillation. The drugs that are used for these different indications are varied in their mechanisms of action, and the related general and specific nursing process issues will be discussed.

ASSESSMENT

Begin the nursing assessment associated with the use of all *coagulation-modifying* drugs by taking a thorough patient health history. This includes the following: any drug or food allergies, current medical problems, underlying systemic disease processes, past and present medical history, family health history, dietary habits, changes in body weight over time, ability to perform activities of daily living, level of exercise and/or degree of sedentary lifestyle, employment activities, success of previous treatment regimens, blood pressure, pulse rate, respirations, body weight, height, dietary intake, and fluid intake. A medication history is also needed and should include a listing of all drugs the patient takes on a daily basis such as prescription drugs, over-the-counter medications, herbal products, and dietary supplements, as well as nicotine, alcohol, and intake of other substances. Perform a thorough patient assessment to identify the presence of the following risk factors: immobility; history of limited activity or prolonged bed rest (e.g., generally for longer than 3 to 5 days); dehydration; obesity; smoking; congestive heart failure; mitral or aortic stenosis; coronary heart disease with documented atherosclerosis or arteriosclerosis; peripheral vascular disease; pelvic, gynecologic-genitourinary, abdominal, orthopedic, or vascular major surgery; history of thrombophlebitis, DVT, thromboembolism including pulmonary embolism, myocardial infarct, atrial fibrillation; edema of the periphery; trauma to the lower extremities; use of oral contraceptives; and/or recent extended airline travel time. If the patient has a history of clotting disorders and/or thromboembolism, assess and document the following: presenting signs and symptoms of thrombophlebitis of the leg such as calf edema; pain, warmth, or redness directly over the vessel (more indicative of a superficial clot); increased diameter of the calf of the affected leg; pain in the calf with dorsiflexion (often called the Homans sign; however, this is a very controversial method of assessment) or pain upon gentle compression of the calf muscle against the tibial bone; and presenting signs and symptoms of pulmonary embolism such as chest pain, cough, dyspnea, tachypnea, drop in oxygen saturation (by oximetry or blood gas measurement), hemoptysis, tachycardia, drop in blood pressure, and possible shock. All contraindications, cautions, and drug interactions also need to be assessed (see pharmacology discussion) and documented.

Because of the effects of *anticoagulants,* it is also important to assess the skin, oral mucous membranes, gums, urine, and stool for any evidence of bleeding. Assess patients for any blood in the urine or stool, easy bruising, excessive bleeding from tooth brushing or shaving, or unexplained nosebleeds while receiving these medications, and report any such findings. Laboratory tests performed before and during therapy with these drugs usually include, but are not limited to, baseline complete blood counts, hemoglobin level, hematocrit, lipoprotein fractionation, triglyceride and cholesterol levels, various clotting studies, and liver function tests. The serum laboratory tests that are usually ordered with anticoagulant therapy are presented in the Safety: Laboratory Values Related to Drug Therapy box.

With *heparin* and *LMWHs,* it is critical to patient safety to continually assess the skin to identify potential subcutaneous injection sites. For these injection sites, *avoid* any area within 2 inches of the umbilicus, open wounds, scars, open or abraded areas, incisions, drainage tubes, stomas, or areas of bruising or oozing. These sites would be at higher risk for further tissue damage with injection of the anticoagulant. Appropriate sites

for injection of subcutaneous heparin and LMWHs include the upper, outer area of the arms, the thigh, and the subcutaneous fatty area across the lower abdomen and between the iliac crests (see Chapter 9 for more information).

With use of the *parenteral anticoagulant heparin*, to ensure patient safety and prevent injury, assess for allergies, contraindications, cautions, and drug interactions (see pharmacology discussion). Severe hypertension, ulcer disease, ulcerative colitis, aneurysms, malignant hypertension, alcoholism, and head injuries are all conditions in which a bleed is potential and possibly precipitated by parenteral anticoagulation. An important caution for heparin use is pregnancy or lactation; however, if there is a need for an anticoagulant during pregnancy, heparin is the drug of choice, not warfarin. Other information is presented in Table 26-1.

It is crucial to patient safety to remember that heparin is *not* interchangeable unit for unit with drugs in another class of anticoagulants, the LMWHs. It is important to know that heparin sodium contains benzyl alcohol; therefore, assess for allergy to this additional component. Although the use of *LMWHs* leads to fewer adverse reactions in some patients, these drugs are still associated with specific contraindications, cautions, and drug interactions (see previous discussion). When assessing the medication profile, remember that a potentially deadly medication error is to give heparin in combination with enoxaparin (or any LMWH). Always double-check that enoxaparin and heparin are never given to the same patient! The same assessment parameters discussed earlier for heparin are also appropriate for LMWHs. In addition, LMWHs contain sulfites and benzyl alcohol, and so assess the patient for allergies to these substances. It is important to note again that the LMWHs differ from standard heparin and also from each other and, for this reason, they are not interchangeable. LMWHs may be used for outpatient anticoagulant therapy because these drugs usually require less close monitoring than standard heparin. Assess the results of clotting studies prior to therapy.

The *oral anticoagulant* warfarin and its related contraindications, cautions, and drug interactions have been discussed earlier in this chapter. All of the previously mentioned assessment parameters are applicable to warfarin. Because of the drug's action, withdraw warfarin (as with all drugs altering bleeding/clotting)—as ordered—before the patient undergoes any dental procedures or if there is any evidence of tissue necrosis, gangrene, diarrhea, intestinal flora imbalances, or steatorrhea. Important to emphasize with this drug is the fact that warfarin is indicated for prophylaxis and long-term treatment of a variety of thromboembolic disorders (see previous pharmacology discussion), and constant and skillful assessment of the patient and clotting results is required. Most prescribers use standard protocols for warfarin to assist in dosing the drug based on PT/INR (the standardized measures of blood coagulability). The most common starting dosage for warfarin is 5 mg daily. However, the dose can range from 1 to 10 mg, and occasionally even higher (e.g., 12 mg) depending on individual patient response. In most situations, the dosage for adults is between 1 and 5 mg orally every day. In addition, it is important to understand the pharmacokinetics of warfarin, because it takes about 3 days for the drug to reach a steady state. Patients taking heparin may receive warfarin before discontinuation of heparin for anticoagulation.

Dabigatran (Pradaxa), although an anticoagulant, is the first oral *direct thrombin inhibitor*. Additional assessment parameters include renal function studies. No coagulation monitoring is needed for this drug. Assess for drug interactions with phenytoin and amiodarone. With fondaparinux (Arixtra), carefully assess renal function. As with dabigatran, its effect cannot be measured by standard anticoagulant tests. Liver function tests need to be assessed prior to the use of argatroban.

With *antiplatelet* drugs, obtain a thorough nursing history and medication history as well as a physical assessment before beginning drug therapy. Possible drug interactions, cautions, and contraindications have been discussed, but close assessment of any bleeding is most important to patient safety. Because aspirin, other NSAIDs, and other antiplatelet drugs alter bleeding times, withhold these drugs as ordered for 5 to 7 days before the patient undergoes surgical procedures. Specific guidelines are generally given by the prescriber to avoid the concurrent use of other anticoagulants, antiplatelets, and fibrinolytics. See Chapter 44 for more information on aspirin. Perform a baseline cardiovascular assessment with clopidogrel and document any preexisting chest pain, edema, headache, dizziness, epistaxis, or flulike symptoms. Laboratory values usually include complete blood count, hemoglobin level and hematocrit, platelet counts, and PT and INR values. These laboratory values provide baseline levels with which therapy values can be compared. If platelet counts are at or fall below 80,000 cells/mm^3, notify the prescriber; antiplatelet therapy most likely will not be initiated (or will be discontinued).

In addition, it is important to patient safety to reemphasize the fact that aspirin is not to be used in children and teenagers, in patients with any bleeding disorder, in pregnant or lactating women, or in patients with vitamin K deficiency or peptic ulcer disease. These are situations in which major consequences could occur if aspirin were used; for example, Reye's syndrome in children and teenagers, teratogenic effects in pregnant women, and ulcers or bleeding tendencies in patients with vitamin K deficiency or peptic ulcer disease. Know how each of the drugs works in the body so that a sound knowledge base exists for critical thinking and decision making: for example, the decision to call the prescriber and not to administer two antiplatelets at the same time or not to give a thrombolytic with heparin, warfarin, or aspirin or other NSAIDs. This type of critical drug information is very important to make sure the patient receives the safest and most appropriate care during all phases of the nursing process.

The *GP IIb/IIIa inhibitors* (e.g., eptifibatide, tirofiban, and abciximab) require the same baseline assessment information (e.g., vital signs, medical history, history of chest pain or cardiac disease, complete blood counts, hemoglobin level, hematocrit, renal function tests, platelet counts) as well as assessment for any edema, bradycardia, and/or leg pain. Before or during therapy, if the platelet count is below 90,000/mm^3, contact the prescriber for further orders.

Thrombolytics require similar assessments, including attention to baseline complete blood counts and results of clotting studies. Additional concerns include a history of hypotension and cardiac dysrhythmias. The use of alteplase and other thrombolytics always carries major concerns/cautions, contraindications, and drug interactions (see previous pharmacology discussion). Constantly assess any arterial punctures, venous cut-down sites, peripherally inserted central catheter sites, and central infusion ports or sites for bleeding. Do not use IM injections in any situation, as they pose problems with bleeding. As with any drugs that alter clotting and platelet activity, the thrombolytics are associated with the risk of bleeding from wounds or from the gastrointestinal, genitourinary, or respiratory tract, so assess any drainage, urine, stool, emesis, sputum, and secretions for the presence of blood.

Antifibrinolytics require the same skillful assessment of baseline parameters and laboratory testing; however, there are additional concerns for patients with dysrhythmias, hypotension, bradycardia, convulsive disorders, nausea, vomiting, and abdominal pain or diarrhea. These are possible adverse effects and situations in which the prescriber may need to decrease the dosage of medication.

NURSING DIAGNOSES

1. Deficient knowledge related to the new medication regimen and the need for altered lifestyle
2. Risk for ineffective cerebral tissue perfusion related to the clotting disorder, such as thrombus and subsequent embolus formation
3. Risk for injury related to possible adverse reactions to drugs altering blood clotting

PLANNING

GOALS

1. Patient demonstrates adequate knowledge regarding medication therapy and its potential adverse effects as well as the need for lifestyle changes.
2. Patient exhibits improved blood flow/tissue perfusion as a result of the therapeutic effects of the anticoagulant.
3. Patient remains free from injury resulting from either the disease or the medication being taken.

OUTCOME CRITERIA

1. Patient states the adverse effects of the drug therapy, ways to monitor for complications of the anticoagulants, the importance of scheduling follow-up appointments with the prescriber and of frequent laboratory studies, and the circumstances under which to contact the prescriber to prevent complications such as hemorrhage.
   - Patient states the nature of and rationale for the lifestyle changes needed, such as improved diet, exercise, and avoidance of smoking.
2. Patient shows evidence of improved cerebral circulation with maintaining alertness, orientation and stable neurological status.
   - Patient's remains free of evidence of peripheral clotting with maintaining of pink, warm extremities with strong pedal pulses and/or experiences a return to his or her predisease state of maximal tissue perfusion.
3. Patient is free from bruising, bleeding problems, and any other injury to self because of safe medication use.

IMPLEMENTATION

Routinely monitor vital signs, heart sounds, peripheral pulses, and neurologic status in all patients during and immediately after anticoagulant therapy. The various laboratory values to be monitored are presented in the Safety: Laboratory Values Related to Drug Therapy box on p. 440. If there is any change in pulse rate or rhythm, blood pressure, or level of consciousness, and/or unexplained restlessness occurs, contact the prescriber immediately. These changes may indicate bleeding or hemorrhage.

Knowledge of the proper techniques of administration is crucial for the safe and effective use of *heparin* and the *LMWHs* (see Box 26-1 for other dosing and route information). Heparin

CASE STUDY

Heparin Therapy

In the past 2 years, Mr. L., a 56-year-old architect, has experienced three episodes of deep vein thrombosis. All occurred without complications, and all were treated successfully with anticoagulant therapy and bed rest. He now arrives at the urgent care center because of increased pain and swelling in his left calf that has lasted for the past 3 days. Initially he is given 5000 units of heparin IV. On admission to the hospital for anticoagulant therapy, he is started on a continuous infusion of 25,000 units of heparin in 1000 mL of 0.9% sodium chloride.

1. What nursing actions should be implemented to ensure the accuracy and safety of the continuous heparin infusion?
2. What patient findings would indicate a therapeutic response to the heparin therapy?

During Mr. L.'s hospital stay, the physician orders an extra bolus of 10,000 units of heparin, IV push, because the results of Mr. L.'s laboratory tests indicated that his activated partial thromboplastin time (aPTT) was not at a therapeutic level. After giving the dose, the nurse notices that a dose of 50,000 units was given instead of 10,000 units.

3. What will the nurse do first, and what subsequent orders will the nurse prepare to carry out?
4. How could this error have been prevented?

For answers, see http://evolve.elsevier.com/Lilley.

BOX 26-1 ANTICOAGULATION THERAPY AND RELATED NURSING CONSIDERATIONS

Subcutaneous Heparin and Low Molecular Weight Heparin Injections

- After thoroughly checking the prescriber's order, assess the patient for any allergies, contraindications, cautions, or drug interactions.
- Always begin by performing hand hygiene and maintain Standard Precautions. Gloves must be worn. Prefilled syringes are available. When the medication is not available in a prefilled or premeasured syringe use a ½ to ⅝ inch, 25 to 28 gauge needle. Check the site for bleeding or bruising, and do *not* massage/rub the site before or after the injection. *Do not aspirate* before injecting to prevent hematoma formation. See Chapter 9 for more information on the technique associated with heparin and LMWH injections.
- Make sure the patient is comfortable, and then remove gloves and wash hands. Document the medication given on the medication record, and monitor the patient for a therapeutic response as well as for adverse reactions.

Intravenous Heparin Administration

- Always double-check the specific prescriber's order for dosage and rate of infusion before beginning therapy. Always follow the "Six Rights" of medication administration to prevent overdosing or erroneous dosing. Make sure the proper diluent is used. Check the compatibility of solutions or other drugs before beginning the infusion.
- For continuous intravenous (IV) administration of heparin, an IV pump must be used to ensure a precise rate of infusion.
- Continuous dosing is preferred over intermittent dosing because continuous dosing helps maintain blood levels of the drug and because intermittent IV dosing is associated with a higher risk for bleeding abnormalities.
- Treatment by continuous IV infusion generally begins with a loading dose and is followed by a maintenance dose. Be aware that dosage adjustments are made exactly as ordered. The patient's activated partial thromboplastin time (aPTT) and/or results of other related clotting studies are used as parameters for dosing of standard heparin.
- For intermittent infusions, a heparin lock was used in the past. Heparin locks are now referred to as *intermittent infusion locks* or *saline locks* (because the locks are flushed with isotonic saline and not with heparin). The exception is with PICC lines and central lines in which heparin is still used as a flush.
- Intermittent infusions of heparin are usually ordered to be given every 4 to 6 hours because of heparin's short half-life. Needleless systems are used for intermittent infusions and all other types of IV infusions.
- Regardless of the type of IV infusion (e.g., intermittent or continuous IV infusion), it is crucial to check the site to determine whether infiltration has occurred so that hematoma formation may be prevented. If infiltration is suspected, remove the lock and replace at a new site before the next scheduled infusion. Document appropriately.
- The therapeutic dosage of heparin is guided by aPTT with a targeted level of 1.5 to 2.5 times the control (normal) value. The aPTT is measured within 24 hours of beginning therapy, 24 to 48 hours after therapy starts, and 1 to 2 times weekly for about 3 to 4 weeks on average. With long-term therapy, aPTT is monitored 1 to 2 times per month.

Oral Anticoagulant Administration

- It is important to recheck the prescriber's orders and the patient's medication and medical history before administering any coagulation modifying drug. Always check to make sure the patient has no known hypersensitivity to the drug.
- Scored tablets may be crushed and may be given with or without food.
- Many more drugs can interact with oral anticoagulants than with heparin, especially those that are highly protein bound (see Table 26-3). Always check the patient's medication list before initiating therapy with warfarin.
- Dosages of warfarin are calculated based on international normalized ratio (INR) blood values. INRs are also used to monitor the effectiveness of therapy. Remember, however, that dosing is highly individualized!
- Oral anticoagulants are to be administered at the same time every day to maintain steady blood levels.
- Document the dose, time of administration, and any other pertinent facts with these and all other medications.

may be given by the subcutaneous or IV routes but *not* IM. You can easily avoid inadvertent IM injection if you use only subcutaneous syringes, which are usually made available in prefilled syringes that include a ½-inch (1.5-cm) 25- to 28-gauge needle. No major harm would result if a subcutaneous dose were inadvertently administered IV. If rapid anticoagulation is needed, IV heparin by continuous or intermittent infusion may be prescribed. Whether the drug is given by IV infusion or subcutaneous injection, monitor daily clotting study results, and perform these studies as ordered for therapeutic doses (monitoring is not done for prophylactic treatment).

The drug effects of heparin can be reversed with the IV administration of protamine sulfate. With subcutaneous heparin, several doses of protamine sulfate may be needed to reverse the anticoagulant effect because of the variable rates of absorption of this dosage form. See Box 26-1 for the procedure for the intermittent or continuous IV administration of heparin.

Administer *LMWHs* by subcutaneous injection deep into the injection site (see previous discussion) using the same techniques as for heparin. Rotate sites frequently. Avoid aspiration with subcutaneous injections to prevent hematoma formation and tissue injury. To avoid bruising, do not massage the site after the injection. Prefilled syringes of LMWHs are available for inpatient use and for at-home treatment. Solutions may be clear to pale yellow. The usual length of therapy is approximately 5 to 10 days, and it is important to constantly be aware of any bleeding problems while the patient is taking this or other clotting-altering drugs. Complete blood counts, platelet counts, and stool tests for occult blood are tests that will probably be performed during therapy for monitoring purposes. Tests for occult blood in the stool can be done simply if occult blood test paper and developer are available. Blood in the stool may occur as an adverse effect of LMWHs or any clotting-altering drug.

When the *oral anticoagulant warfarin* is prescribed, therapy is often initiated while the patient is still receiving heparin. This overlapping is done purposefully to allow time for the blood levels of warfarin to rise, so that when the heparin is eventually discontinued, therapeutic anticoagulation levels of warfarin will have been achieved. The full therapeutic effect of warfarin does not occur until 4 to 5 days after the first dose. This overlap of activity is required in patients who have been receiving heparin for anticoagulation and are to be switched to warfarin so that prevention of clotting is continuous. Monitoring results of the various clotting studies is still of utmost priority, as is watching

for any clotting or bleeding problems. The administration procedures for warfarin are outlined in Box 26-1.

For conversion from heparin to an oral anticoagulant such as warfarin, the dose of the oral drug is the usual initial dosage amount, with the prescriber using the PT/INR levels to determine the next appropriate dosage of warfarin. Once there is continuous therapeutic anticoagulation coverage and warfarin has reached therapeutic levels, the heparin or LMWH may be discontinued without tapering. If uncontrolled bleeding occurs with any of these medications, take action to control bleeding, institute emergency measures to stabilize the patient's condition, and contact the prescriber immediately.

The anticoagulant *dabigatran* (Pradaxa) is given orally. Important safety information about dabigatran (Pradaxa) from the U.S. Food and Drug Administration (FDA) includes that it is to be stored in and dispensed from its original bottle. This is important because if not stored properly and with the desiccant-drying agent (which absorbs moisture) in the packaging cap, the substance in the drug is easily broken down and a loss of potency occurs. This would result in less therapeutic effectiveness. This storage information is not widely disseminated and so it is important to be aware of these precautions. Additionally, the FDA is also alerting consumers that even though the label says to discard the drug after 30 days of opening the original container, recent data suggests that it can maintain its potency for up to 60 days if the cap is closed tightly after each use and the bottle is kept away from excessive moisture, heat, and/or cold. More information is to be released from the FDA once they complete further review of this product. The FDA suggests that Pradaxa be kept in the original bottle or blister package; not stored or placed in any other type of container; opened one bottle at a time; closed tightly after the capsule is removed; not used after 60 days; and have the blister package opened at time of use and not have the blister punctured prior to the use/administration of the drug. For more information, see www.consumermedsafety.org/alerts. *Fondaparinux* (Arixtra) is given subcutaneously and, as with dabigatran, has no standard anticoagulant tests for monitoring.

Of benefit to counter the toxic effects of *anticoagulants* is the use of antidotes. The antidote to hemorrhage or uncontrolled bleeding resulting from heparin or LMWH therapy is protamine sulfate. For heparin, 1 mg of protamine sulfate given intravenously neutralizes 100 units of heparin. For the LMWHs, 1 mg of protamine sulfate neutralizes 1 mg of each LMWH given. It is important to note that too-rapid an infusion may lead to acute hypotensive episodes, bradycardia, dyspnea, and transient feelings of warmth and flushing. If the heparin overdose has resulted in a large blood loss, replacement with packed red blood cells may be necessary.

The aPTT ranges and hematocrit levels are generally used as ordered to monitor bleeding, clotting, and risk for bleeding. Always monitor the patient, especially for any changes in blood pressure and pulse rate. The antidote to oral anticoagulant (warfarin sodium) therapy is vitamin K. See the pharmacology section for more discussion on dosing and reversibility of vitamin K on the effects of warfarin. When given IV, vitamin K may lead to anaphylaxis with resultant dyspnea, dizziness, rapid or weak pulse, chest pain, and hypotension, which may progress to shock and cardiac arrest. Always check facility policy and the prescriber's order on the specific dosage and route of administration. Continual monitoring of the patient's vital signs, cardiac parameters, and bleeding times and other clotting study results are very important.

Constantly monitor the patient being treated with *antiplatelet* drugs (or any clotting-altering drug) for signs and symptoms of bleeding during and after their use, including epistaxis, hematuria, hematemesis, easy or excessive bruising, blood in the stools, and bleeding of the gums. If invasive procedures must be performed or injections given, apply appropriate pressure to bleeding sites, and closely watch all areas of venous or arterial catheter insertion for bleeding. Advise patients to take extended-release dosage forms in their entirety and without chewing or crushing. Enteric-coated aspirin is best taken with 6 to 8 oz of water and with food to help decrease gastrointestinal upset. To avoid irritation to the esophagus, instruct the patient to remain upright and not lie down for up to 30 minutes after the dose of aspirin. If the aspirin has a strong, vinegar-like odor, discard the drug. Interventions with clopidogrel therapy are similar to those for aspirin. Advise the patient to report the following if they occur: aches in the joints, back pain, dizziness, severe headache, dyspepsia, flulike signs and symptoms, and epigastric pain. These drugs are often discontinued for 7 days prior to surgery, as ordered. However, some surgical procedures (e.g., cardiovascular surgery) may warrant that the patient remain in an anticoagulated state intraoperatively. Oral forms of dipyridamole are recommended to be taken on an empty stomach; however, if this is not tolerated, the patient can take the drug with food. If nausea occurs, cola, unsalted crackers, or dry toast may help to alleviate this adverse effect. In addition, it may take up to 2 to 3 months of continuous therapy for the drug to reach therapeutic levels. Encourage patients to change positions slowly and to take their time in going from lying to sitting to standing because of the adverse effects of dizziness and postural hypotension with antiplatelets.

Nursing considerations associated with the *GP IIb/IIIa inhibitors,* such as abciximab, eptifibatide, and tirofiban, include some similar, yet different, nursing actions. Close monitoring of all vital signs, electrocardiogram readings, peripheral pulses, heart sounds, skin color, and temperature are an important part of nursing care during and after the use of these drugs. Because these drugs are used in combination with heparin to treat individuals suspected of having acute coronary syndrome or those undergoing percutaneous transluminal coronary angioplasty (PTCA), there is always concern for the stability of the patient as well as a high risk for serious bleeding and/or extension of an acute MI. The patient in this situation is at risk for other medical complications, and this risk may be intensified by the drug. Avoid further invasive procedures while the patient is taking these drugs to help prevent bleeding. If invasive procedures are required, constantly monitor for bleeding and measure all vital parameters before, during, and after the procedure. Protect IV tirofiban from light. Discard any unused solutions 24 hours after an infusion has been started. Do NOT give any other

drugs with this drug except for heparin, which may be administered through the same IV line. For PCTA, abciximab can be given by bolus or by continuous infusion; closely monitor infusion rates. Manufacturer guidelines call for the use of a sterile, nonpyrogenic, low protein-binding 0.2- or 0.22-micron filter, and while the vascular shield is in position, keep the patient on complete bed rest with the head of the bed elevated 30 degrees. Maintain the affected extremity in a straight position, and constantly monitor peripheral pulses and the color and temperature of the distal extremities. Once the sheath is removed, apply pressure to the femoral artery for at least 30 minutes, either by manual or mechanical pressure. Apply a pressure dressing once bleeding has stopped. Closely monitor the site for any oozing or bleeding.

If serious bleeding occurs, discontinue the GP IIb/IIIa inhibitor and heparin (the usual protocol for PTCA) immediately, monitor the patient closely, and notify the prescriber immediately for initiation of emergency treatment. Always move and handle these patients with caution and avoid unnecessary trauma because of the risk for hematoma formation or bleeding. Do *not* take blood pressures in the lower extremities, but keep a close and constant watch on the patient's blood pressure (for hypotension) and pulse rate (for tachycardia). Also closely monitor the patient for any complaints of abdominal or back pain, severe headache, and any other signs or symptoms of hemorrhage. When adhesive or sticky tape is removed, take care to avoid tearing or ripping the skin, which would lead to tissue trauma and further risk for bleeding. Monitor aPTT levels after the procedure, and observe for bleeding, with attention to IM injection sites, arterial or venous puncture sites, and bleeding from nasogastric tubes and/or urinary catheters. Avoid such invasive procedures, if at all possible, during and immediately after the angioplasty.

Nursing considerations related to *thrombolytics* are very similar to those for the other drugs already discussed. Specifically, carry out the preparation for their IV administration per manufacturer guidelines and per protocol. Avoid invasive procedures during the use of these drugs. Avoid simultaneous use of anticoagulants or antiplatelets. Frequently monitor IV infusion sites for bleeding, redness, and pain. IM injections of other drugs are contraindicated to prevent tissue damage and bleeding. Report any bleeding from gums or mucous membranes or the occurrence of epistaxis or increased pulse (higher than 100 beats/min) to the prescriber immediately, and frequently monitor all vital signs. Other nursing considerations include monitoring for hypotension, restlessness, and a decrease in hemoglobin level or hematocrit, which are to be reported to the prescriber immediately (indicating possible shock). Advise patients to report pink, red, or cloudy urine; black, tarry stools or frank red blood in the stools; abdominal or chest pain; dizziness; or severe headache. The drug requires reconstitution for IV dosing with sodium chloride or 5% dextrose in water. Gently roll, not shake, the solutions to mix to maintain a stable solution. Continually monitor the INR, aPTT, platelet counts, and fibrinogen levels, beginning no later than 2 to 3 hours after the administration of thrombolytics. Measure the patient's fibrinogen level to check for the occurrence of fibrinolysis. With the breakdown of fibrin (or fibrinolysis), INR will increase and aPTT will be prolonged. If bleeding occurs, the prescriber will most likely discontinue the drug and replace fibrinogen through infusions of whole blood plasma or cryoprecipitate. The antifibrinolytics, aminocaproic acid and tranexamic acid, may also be given. See the Patient Teaching Tips.

With *antifibrinolytics,* it is important to understand the reasons for the use of these drugs, such as to stop bleeding from overdosages of thrombolytic drugs or to control bleeding during cardiac surgery. Aminocaproic acid and tranexamic acid are usually given IV until bleeding is controlled. Because of the possibility of drug-induced internal, intracranial, and superficial bleeding, closely monitor the patient, and if there is any change in motor strength or level of consciousness, notify the prescriber immediately. You must apply your knowledge of certain adverse effects of drugs like these to prevent complications, maintain safety, and return the patient to a healthier state. It is also important to monitor heart rate and blood pressure with attention to the quality and strength of peripheral pulses. For the patient with hemophilia, tranexamic acid may be used to help decrease bleeding from dental extractions.

EVALUATION

Monitoring for the therapeutic and adverse effects of coagulation modifier drugs is crucial for safe administration. Because these drugs are used for a variety of purposes, therapeutic responses vary. Some of the therapeutic effects include decreased chest pain and a decrease in dizziness, as well as in other neurologic symptoms. Adverse effects of *anticoagulants* include bleeding and hematoma formation (heparin); thrombocytopenia (heparin and LWMHs); bleeding, dizziness, shortness of breath, and fever (direct thrombin inhibitors); bleeding, hematoma, dizziness, and gastrointestinal distress (selective factor Xa inhibitors); and bleeding, lethargy, and muscle pain (warfarin). Early signs of drug overdose for any of the clotting-altering drugs (i.e., anticoagulants) include bleeding of the gums while brushing the teeth, unexplained nosebleeds or bruising, and heavier-than-usual menstrual bleeding. Abdominal pain, back pain, bloody or tarry stools, bloody urine, constipation, blood in the sputum, severe or continuous headaches, and the vomiting of frank red blood or a coffee ground–like substance (old blood) are all possible indications of internal bleeding.

Therapeutic effects of clopidogrel and other *antiplatelet drugs* include a decrease in the occurrence of clotting events such as transient ischemic attacks and strokes. The adverse effects of aspirin, as an antiplatelet drug, include dizziness, confusion, nausea, vomiting, gastrointestinal bleeding, diarrhea, thrombocytopenia, agranulocytosis, leukopenia, and neutropenia. Adverse effects of clopidogrel include chest pain, edema, flulike symptoms, headache, dizziness, fatigue, abdominal pain, diarrhea, and epistaxis. Therapeutic levels of anticoagulants and other clotting-altering drugs or coagulation modifier drugs are also monitored by laboratory studies such as aPTT, PT, and INR, which are described in the Safety: Laboratory Values Related to Drug Therapy box on p. 440. Remember, however, that aPTT

levels are measured with heparin, whereas PT and INR are measured with warfarin. Once the level of the particular drug stabilizes and maintenance therapy is ongoing, the clotting studies may be performed at 1- to 4-week intervals, depending on the specific drug, the patient's response, and the patient's overall physical condition. If a heparin or LMWH overdose occurs, the antidote is protamine sulfate, whereas vitamin K, or phytonadione, is the antidote to oral anticoagulant overdose.

Continuous monitoring of the patient for the signs and symptoms of internal or external bleeding is critical during both the initiation and maintenance of therapy. Therapeutic effects of *thrombolytics* include improvement in cardiac status during an acute MI, improved blood flow from resolution of DVT, and improved neurologic status. Adverse effects include bleeding, hypotension, and cardiac dysrhythmias. Therapeutic effects of *antifibrinolytics* include the arrest of oozing of blood from a surgical site or a decrease in blood loss. Adverse effects to monitor for with the antifibrinolytics include orthostatic hypotension, dysrhythmias, headache, dizziness, fatigue, convulsions, nausea, vomiting, abdominal cramps, and diarrhea. Because of the complexity and life-threatening nature of the conditions for which these drugs are used, continually monitor and reevaluate the patient's response to the treatment, document this response accordingly, and always keep goals and outcome criteria within the plan of care to serve as a benchmark. From the evaluation phase, the patient will hopefully emerge experiencing full therapeutic effects and minimal adverse and/or toxic effects related to drug therapy.

SAFETY: LABORATORY VALUES RELATED TO DRUG THERAPY

Anticoagulants

LABORATORY TEST	NORMAL RANGES	RATIONALE FOR ASSESSMENT
Activated partial thromboplastin time (aPTT), partial thromboplastin time (PTT)*	With heparin therapy, aPTT values need to fall between 1.5 and 2.5 times the control or baseline value. Normal control values are 25 to 35 seconds (sec). Target therapeutic level of anticoagulation is between 45 and 70 sec.	Therapeutic levels of aPTT indicate decreased levels of clotting factors and subsequent clotting activity and is the more sensitive part of PTT (and often replaces it). It is used to determine whether there are deficiencies in the patient's intrinsic coagulation pathway and to monitor heparin therapy. aPTT is sensitive to changes in blood clotting factors, except for factor VII. Therefore, it is used to assess for normal blood coagulation. With continuous IV infusions of heparin, blood samples for aPTT testing can be drawn at any time, but with intermittent infusions the blood sample is to be drawn approximately 1 hr before a dose of heparin is scheduled to be given. Monitoring of aPTT is not done for prophylactic doses (i.e., 5000 units every 12 hours subcut).
Prothrombin time (PT)	The normal control PT value ranges from 11 to 13 sec; target therapeutic level of anticoagulation is 1.5 times the control value, or about 18 sec.	Prothrombin is a vitamin K–dependent protein and a major component of the clotting process. It reflects clotting activity and is used to monitor the effectiveness of warfarin therapy. PT values vary for each laboratory center and are based on the specifics of the testing procedure.
International normalized ratio (INR)	Target levels of INR range from 2 to 3 or an average of 2.5. For individuals taking warfarin for treatment of recurring systemic clots or emboli and those with mechanical heart valves, the target INR may be 2.5 to 3.5, with a middle value of 3.	INR determination is a routine test to evaluate coagulation while patients are taking warfarin. When the therapy is initiated, the INR and PT are measured daily until a stable daily dose is reached (the dose maintains the PT and INR within therapeutic ranges and does not cause bleeding). INR values actually reflect the dose of warfarin given 36 to 72 hr prior to the testing. Advantages of INR testing include the fact that there is more consistency among laboratories and a more consistent warfarin dosage is achieved. Some laboratories report INR and PT together.

IV, Intravenous.
*These terms are used interchangeably.

PATIENT TEACHING TIPS

- The use of coagulation-modifying drugs to prevent serious complications related to clotting, such as strokes, heart attacks, clot formation (deep vein thrombosis of the legs) with heart valve replacements, and mini-strokes/TIAs (transient ischemic attacks), requires frequent and close monitoring. Educate the patient that a healthy lifestyle is an important part of therapy and will most likely include eating the right foods, weight reduction if needed, smoking cessation, control of blood pressure, and stress reduction. Advise the patient to provide a listing of all medications to all possible prescribers (e.g., dentists).
- Direct the patient to take all of the clotting-altering drugs exactly as prescribed because too little of the drug may lead to clot formation and too much of the drug may lead to bleeding. Regular follow-up appointments are an important part of patient care, with frequent blood tests to monitor for therapeutic effects and adverse effects of the medication. The results of the blood tests will help the prescriber determine the proper dosage.
- The patient must carry an identification card or wear a medical alert bracelet or necklace at all times stating allergies, medical diagnosis, list of drugs, prescriber's name and phone number, as well as an emergency contact name and number.

PATIENT TEACHING TIPS—cont'd

- Home heparin therapy may require injections for a period of time, and LMWHs are generally used. If there is a switch from heparin to warfarin (Coumadin), there may be an overlap period of approximately 3 to 5 days during which both drugs are taken to allow therapeutic levels of the oral warfarin to be reached before the heparin is discontinued. This process may occur in the hospital or at home. Provide complete and thorough instructions to the patient, and use return demonstrations to evaluate learning (see Chapter 9).
- Advise the patient to report to the prescriber any unusual bleeding from anywhere on the body or the occurrence of a severe headache, blurred vision, vomiting of blood, dizziness, fainting, fever, muscular or limb weakness, rash, nosebleeds, or excessive vaginal or menstrual bleeding.
- With dabigatran (Pradaxa), educate the patient to protect the original bottle from moisture. Once a bottle is opened, it must be used within 60 days; this needs to be written on the bottle/label with the date of expiration. Instruct the patient to remove only 1 capsule from the opened bottle at the time of use and that the bottle needs to be immediately and tightly closed. Encourage the patient to take the medication with food if dyspepsia occurs. These capsules are *not* to be repackaged or placed in other pillboxes/organizers. For more information, visit www.pradaxapro.com.
- Journal keeping by the patient with daily notation of how the patient is feeling as well as how the patient is tolerating the medication and any adverse effects is beneficial to ensure safe, effective treatment.
- To reduce risk factors for cardiovascular disease, the prescriber may recommend consumption of a low-fat, low-cholesterol diet; cholesterol-lowering drug therapy; weight reduction; control of blood pressure if hypertension is present; avoidance of smoking; management of stress; and regular exercise.
- Teach the patient about clot-preventive measures, including situations to minimize sluggish circulation (e.g., avoid tight-fitting clothing, minimize sitting for prolonged periods of time, avoid crossing the legs at the knees and wearing of tight-fitting socks/stockings, avoid prolonged bed rest, make stops during long trips to walk around every 1 to 2 hours, keep well hydrated).
- When taking any of the anticoagulants (oral drugs and/or heparin or LMWHs) or clotting-altering drugs, encourage the patient to avoid brushing the teeth with a hard-bristled toothbrush, shaving with a straight razor, and/or engaging in any activity that would increase the risk for tissue injury. Always caution the patient when shaving, nail trimming, gardening, and/or participating in rough or contact sports.
- Instruct the patient to avoid ingesting large amounts of foods high in vitamin K (e.g., broccoli, Brussels sprouts, collard greens, kale, lettuce, mustard greens, tomatoes) while taking an anticoagulant to minimize food/drug interactions.
- Capsicum (red pepper), feverfew, garlic, ginger, ginkgo, and St. John's wort are some herbals that have potential interactions, especially with warfarin. Educate the patient about these and other interactions.
- Report any decrease in urine output; constant ringing in the ears; swelling of the feet, ankles, or legs; dark urine; clay-colored stools; abdominal pain; rash (use needs to be discontinued as ordered if rash occurs); and/or blurred vision to the prescriber immediately.
- If doses of medications are omitted, advise the patient to contact the prescriber for further instructions.
- Oral dosage forms of any of these medications are to be taken with at least 8 oz of water and/or with food to help minimize stomach upset.
- Keep all medication containers out of the reach of children, and use childproof tops. All syringes, needles, and other equipment must be kept out of the reach of children and other individuals as well.

KEY POINTS

- Coagulation modifiers work by preventing/promoting clot formation, lysing a preformed clot, and/or reversing the action of anticoagulants. Coagulation modifiers include anticoagulants, antiplatelets, thrombolytics, antifibrinolytics, and reversal drugs.
- Warfarin prevents clot formation by inhibiting vitamin K–dependent clotting factors (factors II, VII, IX, and X) and is used prophylactically to prevent clots from forming; it cannot lyse preformed clots.
- The degree of anticoagulation (for any of these medications) is monitored by the PT.
- Heparin, given IV or subcutaneously, prevents clot formation by binding to antithrombin III, which turns off certain activating factors. The overall effect is to inactivate the coagulation pathway and prevent clots from forming. Heparin does not lyse (break down) a clot. Antiplatelet drugs prevent clot formation by preventing platelet involvement in clot formation.
- Thrombolytics are able to break down or lyse preformed clots in blood vessels such as those that supply the heart with blood. Therapeutic effects for which to monitor include improved tissue perfusion, decreased chest pain, and prevention of further myocardial damage. The therapeutic effects of most coagulation modifier drugs include improved circulation, improved tissue perfusion, decreased pain, and prevention of further tissue damage. Before giving these drugs, a thorough physical assessment should be performed as well as checking of pertinent laboratory values (e.g., INR, aPTT, PT).
- Antifibrinolytics prevent the lysis of fibrin, thus promoting clot formation, and have an effect opposite to that of the anticoagulants. Nursing care is very individualized and is based on the characteristics of the patient, thorough assessment data, existing medical conditions, and the specific drug.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is monitoring a patient who is receiving antithrombolytic therapy in the emergency department because of a possible MI. Which adverse effect would be of the greatest concern at this time?
- **a** Dizziness
- **b** Blood pressure of 130/98 mm Hg
- **c** Slight bloody oozing from the IV insertion site
- **d** Irregular heart rhythm

2 A patient is receiving instructions regarding warfarin therapy and asks the nurse about what medications she can take for headaches. The nurse will tell her to avoid which type of medication?
- **a** Opioids
- **b** acetaminophen (Tylenol)
- **c** NSAIDs
- **d** There are no restrictions while taking warfarin.

3 The nurse is teaching a patient about self-administration of enoxaparin (Lovenox). Which statement should be included in this teaching session?
- **a** "We will need to teach a family member how to give this drug in your arm."
- **b** "This drug is given in the folds of your abdomen, but at least 2 inches away from your navel."
- **c** "This drug needs to be taken at the same time every day with a full glass of water."
- **d** "Be sure to massage the injection site thoroughly after giving the drug."

4 A patient is receiving dabigatran (Pradaxa), 150 mg twice daily, as part of treatment for atrial fibrillation. Which condition, if present, would be a concern if the patient were to receive this dose?
- **a** Asthma
- **b** Renal impairment
- **c** History of myocardial infarction
- **d** Elevated liver enzymes

5 A patient has received a double dose of heparin during surgery and is bleeding through the incision site. While the surgeons are working to stop the bleeding at the incision site, the nurse will prepare to take what action at this time?
- **a** Give IV vitamin K as an antidote
- **b** Give IV protamine sulfate as an antidote
- **c** Call the blood bank for an immediate platelet transfusion
- **d** Obtain an order for packed red blood cells

6 A patient is starting warfarin (Coumadin) therapy as part of treatment for atrial fibrillation. The nurse will follow which principles of warfarin therapy? (Select all that apply.)
- **a** Teach proper subcutaneous administration
- **b** Administer the oral dose at the same time every day
- **c** Assess carefully for excessive bruising or unusual bleeding
- **d** Monitor laboratory results for a target INR of 2 to 3
- **e** Monitor laboratory results for a therapeutic aPTT value of 1.5 to 2.5 times the control value

7 The order for enoxaparin (Lovenox) reads: Give 1 mg/kg subcut every 12 hours. The patient weighs 242 lb, and the medication is available in an injection form of 120 mg/0.8 mL. How many milligrams will this patient receive? How many milliliters will the nurse draw up for the injection? (Round to hundredths.)

1. d, 2. c, 3. b, 4. b, 5. b, 6. b, c, d, 7. 110 mg; 0.73 mL

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Explain the pathology of primary and secondary hyperlipidemia, including causes and risk factors.
2 Discuss the different types of lipoproteins and their role in cardiovascular diseases and in hyperlipidemia.
3 List the overall drug classes and specific drugs that are used to treat hyperlipidemia.
4 Compare the various drugs used to treat hyperlipidemia with regard to the rationale for treatment, indications, mechanisms of action, dosages, routes of administration, adverse effects, toxicity, cautions, contraindications, and associated drug interactions.
5 Develop a nursing care plan that includes all phases of the nursing process for patients receiving antilipemic drugs.

DRUG PROFILES

- **atorvastatin, p. 450**
- **cholestyramine, p. 451**
- **ezetimibe, p. 453**
- **gemfibrozil, p. 453**
- **niacin, p. 452**
- **simvastatin p. 450**

♦ *Key drug*

KEY TERMS

Antilipemic drugs Drugs that reduce lipid levels. (p. 444)

Apolipoproteins The protein components of lipoproteins. (p. 444)

Cholesterol A fat-soluble steroid found in animal fats, oils, and egg yolk and widely distributed in the body, especially in the bile, blood, brain tissue, liver, kidneys, adrenal glands, and myelin sheaths of nerve fibers. (p. 444)

Chylomicrons Microscopic droplets made up of fat and protein that are produced by cells in the small intestine and released into the bloodstream. Their main purpose is to carry fats to the tissues throughout the body, primarily the liver. Chylomicrons consist of about 90% triglycerides and small amounts of cholesterol, phospholipids, and proteins. (p. 445)

Exogenous lipids Lipids originating outside the body or an organ (e.g., dietary fats). (p. 445)

Foam cells The characteristic initial lesion of atherosclerosis, also known as a *fatty streak.* (p. 446)

Hydroxymethylglutaryl–coenzyme A (HMG–CoA) reductase inhibitors A class of cholesterol-lowering drugs that work by inhibiting the rate-limiting step in cholesterol synthesis; also commonly referred to as *statins.* (p. 448)

KEY TERMS — cont'd

Hypercholesterolemia A condition in which higher than normal amounts of cholesterol are present in the blood. High levels of cholesterol and other lipids may lead to the development of atherosclerosis and serious illnesses such as coronary heart disease. (p. 445)

Lipoprotein A conjugated protein synthesized in the liver that contains varying amounts of triglycerides, cholesterol, phospholipids, and protein; classified according to its composition and density. (p. 444)

Statins A class of cholesterol-lowering drugs that are more formally known as *HMG–CoA reductase inhibitors.* (p. 447)

Triglycerides Compounds that consist of fatty acids and a type of alcohol known as *glycerol.* Triglycerides make up most animal and vegetable fats and are the principal lipids in the blood, where they circulate bound to a protein, forming high-density and low-density lipoproteins (HDLs and LDLs). (p. 444)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Key to understanding the use of **antilipemic drugs** is a working knowledge of the pathology of lipid abnormalities and their contribution to coronary heart disease (CHD). It is also important to understand, at the cellular level, the transporting and use of **cholesterol** and **triglycerides** in the human body. Lipoproteins, apolipoproteins, receptors, and enzyme systems are all integral parts of these processes. Armed with this knowledge, you can develop and implement a rational approach to treatment using both nonpharmacologic and pharmacologic interventions. See to the Safety: Herbal Therapies and Dietary Supplements boxes below and on p. 446 for information on some common dietary supplements patients may use to control hyperlipidemia.

LIPIDS AND LIPID ABNORMALITIES

Primary Forms of Lipids

Triglycerides and cholesterol are the two primary forms of lipids in the blood. Triglycerides function as an energy source and are stored in adipose (fat) tissue. Cholesterol is primarily used to make steroid hormones, cell membranes, and bile acids. Triglycerides and cholesterol are both water-insoluble fats that must be bound to specialized lipid-carrying proteins called **apolipoproteins.** The combination of triglycerides and cholesterol with an apolipoprotein is referred to as a **lipoprotein.**

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

***Garlic* (Allium sativum)**

Overview
Garlic obtains its pharmacologic effects from the active ingredient allicin.

Common Uses
Antispasmodic, antiseptic, antibacterial and antiviral, antihypertensive, antiplatelet, lipid reducer

Adverse Effects
Dermatitis, vomiting, diarrhea, anorexia, flatulence, antiplatelet activity

Potential Drug Interactions
May inhibit iodine uptake. May interact with warfarin, diazepam, protease inhibitors. Use with nonsteroidal antiinflammatory drugs may enhance bleeding.

Contraindications
Contraindicated in patients who will undergo surgery within 2 weeks and in patients with human immunodeficiency virus infection or diabetes.

Follow manufacturer directions on the bottle or box for use of specific preparations.

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

Flax

Overview
Flax is a flowering annual found in Europe, Canada, and the United States. Both the seed and the oil of the plant are used medicinally.

Common Uses
Atherosclerosis, hypercholesterolemia, hypertriglyceridemia, gastrointestinal distress (especially constipation), menopausal symptoms, and bladder inflammation, among other uses

Adverse Effects
Diarrhea, allergic reactions

Potential Drug Interactions
Antidiabetic drugs: Theoretically can potentiate hypoglycemic effects
Anticoagulant drugs: Theoretically can potentiate anticoagulant effects by reducing platelet aggregation and prolonging bleeding time

Contraindications
Pregnancy (more information needed), bowel obstruction; use with caution in diabetes and cardiovascular disease

Follow manufacturer directions on the bottle or box for use of specific preparations.

Lipoproteins transport lipids via the blood. The various types of lipoproteins are classified according to their density and the type of apolipoproteins they contain. The lipoproteins and their classifications are presented in Table 27-1.

Cholesterol Homeostasis

Cholesterol homeostasis involves a complex array of biochemical factors. Figure 27-1 summarizes the major concepts. Fats are taken into the body through the diet and are broken down in the small intestine to form triglycerides. Triglycerides are then incorporated into **chylomicrons** in the cells of the intestinal wall and are absorbed into the lymphatic system. The primary purpose of chylomicrons is to transport lipids obtained from dietary sources **(exogenous lipids)** from the intestines to the liver to be used to make steroid hormones, lipid structural components for peripheral body cells, and bile acids.

TABLE 27-1 LIPOPROTEIN CLASSIFICATION

LIPID CONTENT	LIPOPROTEIN CLASSIFICATION	PROTEIN CONTENT
Most ↓	Chylomicron	Least ↑
	VLDL	
	LDL	
	IDL	
Least	HDL	Most

HDL, High-density lipoprotein; *IDL,* intermediate-density lipoprotein; *LDL,* low-density lipoprotein; *VLDL,* very-low-density lipoprotein.

The liver is the major organ where lipid metabolism occurs. The liver produces very-low-density lipoprotein (VLDL) from both endogenous and exogenous sources. The major role of VLDL is the transport of endogenous lipids to peripheral cells. Once VLDL is circulating, it is enzymatically cleaved by lipoprotein lipase and then loses triglycerides. This creates intermediate-density lipoprotein (IDL), which is soon also cleaved by lipoprotein lipase to create low-density lipoprotein (LDL). Cholesterol is almost all that remains in LDL after this process. Any tissues that require LDL, such as endocrine cells, have LDL receptors. LDL and about half of IDL are reabsorbed from the circulation into the liver by means of LDL receptors on the liver.

High-density lipoprotein (HDL) is produced in the liver and intestines and is also formed when chylomicrons are broken down. Lipids that are not used by peripheral cells are transferred as cholesterol esters to HDL. HDL then transfers the cholesterol esters to IDL to be returned to the liver. HDL is responsible for the "recycling" of cholesterol. HDL is sometimes referred to as the *good lipid* (or good cholesterol) because it is believed to be cardioprotective.

If the liver has an excess amount of cholesterol, the number of LDL receptors on the liver decreases, which results in an accumulation of LDL in the blood. One explanation for **hypercholesterolemia** (cholesterol in the blood), therefore, is downregulation (reduced production) of hepatic LDL receptors. A major function of the liver is to manufacture cholesterol,

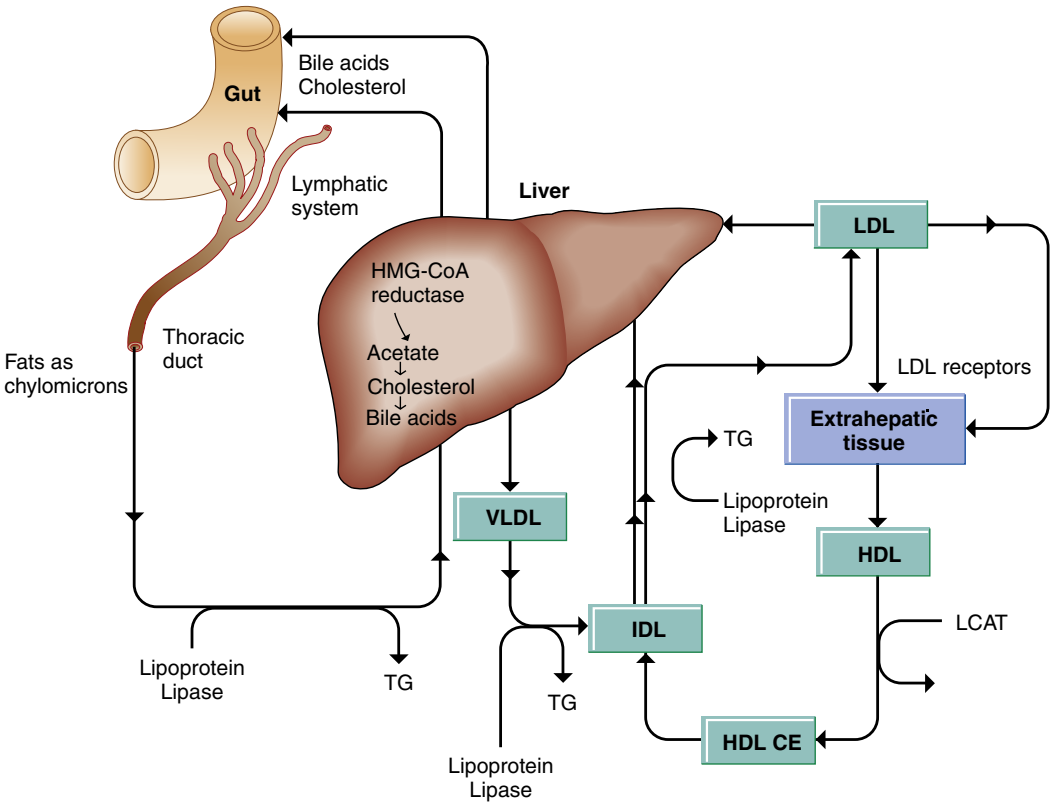

FIGURE 27-1 Cholesterol homeostasis. *CE,* Cholesterol ester; *HDL,* high-density lipoprotein; *HMG-CoA,* hydroxymethylglutaryl-coenzyme A; *IDL,* intermediate-density lipoprotein; *LCAT,* lecithin cholesterol acetyltransferase; *LDL,* low-density lipoprotein; *TG,* triglyceride; *VLDL,* very-low-density lipoprotein.

a process that requires acetyl coenzyme A (CoA) reductase. Inhibition of this enzyme thus results in decreased cholesterol production by the liver.

ATHEROSCLEROTIC PLAQUE FORMATION

Lipids and lipoproteins participate in the formation of atherosclerotic plaque, which subsequently leads to the development of CHD. When serum cholesterol levels are elevated, circulating monocytes adhere to the smooth endothelial surfaces of the coronary vasculature. These monocytes burrow into the next layer of the blood vessel (subendothelial tissue) and change into macrophage cells, which then take up cholesterol from circulating lipoproteins until they become filled with fat. Soon they become what are known as **foam cells,** the characteristic precursor lesion of atherosclerosis, also known as a *fatty streak.* Once this process is established, it is usually present throughout the coronary and systemic circulation.

CHOLESTEROL AND CORONARY HEART DISEASE

Numerous epidemiologic trials have shown that as blood cholesterol levels increase, the incidence of death and disability related to CHD also increases. The risk for CHD in patients with cholesterol levels of 300 mg/dL is three to four times greater than that in patients with levels of less than 200 mg/dL. The incidence of CHD is lower in premenopausal women. This is thought to be secondary to the effects of estrogen, because the risk for CHD climbs considerably in postmenopausal women. However, there is controversy regarding this longstanding belief, because two major trials of estrogen replacement therapy (ERT) did not demonstrate prevention of cardiovascular events in women receiving ERT. Other experimental studies that looked for any benefits of low-dose estrogen therapy in male patients also failed to demonstrate significant cardioprotective efficacy.

Statistics show that half of all Americans, both male and female, will die of a heart attack. Thus, the goals of treatment are two-pronged: primary prevention of cardiac events in patients with risk factors and secondary prevention of subsequent cardiac events in individuals who have previously experienced a cardiac event (e.g., myocardial infarction). The benefits of cholesterol reduction for primary prevention have been illustrated in a number of trials. Results of some of the larger investigations support the view that, in patients with known risk factors for CHD, therapy with an antilipemic drug can reduce the occurrence of CHD. Drug therapy can also reduce first-time heart attack and death caused by heart disease. Benefits of cholesterol reduction for secondary prevention have been illustrated in a variety of trials as well. In patients with documented CHD, treatment with a cholesterol-lowering drug has many positive outcomes; decreased coronary events, regression of coronary atherosclerotic lesions, and prolonged survival.

Measures taken early in life to reduce and maintain cholesterol levels in a desirable range can have a dramatic effect in terms of preventing CHD. These include lifestyle modifications related to diet, weight, and activity level. Diets lower in saturated fat and higher in fiber and plant chemicals known as *sterols* and *stanols,* and possibly the substitution of soy-based proteins for animal proteins, appear to promote healthier lipid profiles. These are among the dietary recommendations made by the National Cholesterol Education Program (NCEP) Adult Treatment Panel III (ATP III) of the National Institutes of Health. The consumption of fatty fish or dietary supplements containing omega-3 fatty acids appears to have beneficial effects on triglyceride and HDL levels and is currently recommended by the American Heart Association (AHA). The AHA also strongly emphasizes the substantial therapeutic benefits of even modest weight reduction and exercise in both improvement of lipid profiles and reduction of the likelihood of heart disease.

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

Omega-3 Fatty Acids

Overview
Omega-3 fatty acids are essential fatty acids, most commonly supplied as fish oil products. Several over-the-counter products are available, as well as one prescription product, known as Lovaza. Lovaza was originally named Omacor, but because of look-alike sound-alike errors that occurred with Amicar (aminocaproic acid, described in Chapter 26), the manufacturer agreed to change the name to Lovaza.

Common Uses
Cholesterol reduction

Adverse Effects
Rash, burping, allergic reactions, possible increase in total cholesterol or LDL levels in those patients with a combined hyperlipidemia, weight gain

Potential Drug Interactions
Anticoagulant drugs: May prolong bleeding time. There is a theoretical risk of increased bleeding with anticoagulant drugs, but the studies to date are inconclusive.

Contraindications
Pregnancy (more information is needed), allergy to fish oil
Follow manufacturer directions on the bottle or box for use of specific preparations.

HYPERLIPIDEMIAS AND TREATMENT GUIDELINES

The decision to prescribe antilipemic drugs as an adjunct to dietary therapy in patients with an elevated cholesterol level is based on the patient's clinical profile. This includes the patient's age, sex, menopausal status for women, family history, and response to dietary treatment, as well as the presence of risk factors (other than hyperlipidemia) for premature CHD and the cause, duration, and phenotypic pattern of the patient's hyperlipidemia.

A major source of guidance for antilipemic treatment in the United States has been the NCEP, which is developed in close cooperation with major professional organizations such

as the AHA. This program has two main focuses, both aimed at reducing the total risk for CHD. One is focused on the entire population and consists of general guidelines for the prevention of CHD. It emphasizes the appropriate dietary intake of total cholesterol and saturated fat, weight control, physical activity, and the control of other lifestyle risk factors. The other focus is on the management of individual patients who are at increased risk for CHD. The original guidelines for the detection, evaluation, and treatment of high serum cholesterol levels in adults were published in 1988 and 2001. They were updated again in July 2004 and will be updated in 2012.

The selection of dietary and drug therapy options is determined by the presence of certain risk factors. The latest guidelines are the first to include CHD risk equivalents. CHD risk equivalents have been statistically calculated to equate a person's 10-year risk for a major coronary event (e.g., myocardial infarction) for those patients who do not currently have CHD, but may have other diseases such as diabetes. These risk factors and risk equivalents are listed in Box 27-1.

When the decision to institute drug therapy has been made, the choice of drug is determined by the specific lipid profile of the patient. Five patterns or phenotypes of hyperlipidemia have been identified, and these are defined by the plasma (serum) concentrations of total cholesterol, triglycerides, and lipoprotein fractions (i.e., HDL, LDL, IDL, VLDL). The various types of hyperlipidemia are listed in Table 27-2. The process of characterizing a patient's specific lipid profile in this way is referred to as *phenotyping*.

One of the basic tenets of the NCEP guidelines is that all reasonable nonpharmaceutical means of controlling the blood cholesterol level (e.g., diet, exercise) are to be tried for at least 6 months and found to fail before drug therapy is considered. This is because the drug treatment for hyperlipidemias entails a long-term commitment to the therapy. Factors to be considered before the initiation of therapy are the type and magnitude of dyslipidemia, the age and lifestyle of the patient, the relative indications and contraindications of different drugs, potential drug interactions, adverse effects, and the overall cost of therapy. The 2004 NCEP guidelines recommend that all patients with LDL cholesterol levels exceeding 190 mg/dL and those with LDL cholesterol levels between 160 and 190 mg/dL who have CHD or two or more risk factors for heart disease be considered for drug therapy after an adequate trial of dietary and other nondrug therapies has proved ineffective. The treatment decisions made based on the LDL cholesterol levels are listed in Table 27-3. The updated guidelines also recommend optional use of drug therapy to reduce LDL to less than 70 mg/dL in patients at very high risk and to less than 100 mg/dL in patients at moderately high risk. "Very high risk" patients include those with active cardiovascular disease with other major risk factors such as diabetes, continued smoking, or *metabolic syndrome*. Metabolic syndrome is a set of risk factors associated with obesity, including hypertriglyceridemia and low HDL level. "Moderately high risk" patients include those without cardiovascular disease but with two or more risk factors. Box 27-2 lists the identifying features of metabolic syndrome.

There are currently four established classes of drugs used to treat dyslipidemia: hydroxymethylglutaryl–coenzyme A (HMG–CoA) reductase inhibitors **(statins)**, bile acid sequestrants, the B vitamin niacin (vitamin B_3, also known as *nicotinic acid*), and the fibric acid derivatives (fibrates). In addition, a cholesterol absorption inhibitor, ezetimibe (Zetia), is also available. Vytorin is an example of a combination tablet that contains both the statin drug simvastatin and ezetimibe.

BOX 27-1 CORONARY HEART DISEASE: RISK FACTORS

Positive Risk Factors

- Age: Males: 45 years or older
- Family history: History of premature CHD (e.g., MI or sudden death before 55 years of age in father or other male first-degree relative, or before 65 years of age in mother or other female first-degree relative)
- Current cigarette smoking
- Hypertension: blood pressure higher than 140/90 mm Hg or current antihypertensive drug therapy
- Low HDL cholesterol level: lower than 40 mg/dL
- Diabetes mellitus

Negative Risk Factor

- High HDL cholesterol: 60 mg/dL or higher—if the HDL cholesterol is 60 mg/dL or higher, subtract one risk factor

CHD, Coronary heart disease; *HDL,* high-density lipoprotein; *MI,* myocardial infarction.

TABLE 27-2 TYPES OF HYPERLIPIDEMIAS

		LIPID COMPOSITION	
PHENOTYPE	**LIPOPROTEIN ELEVATED**	**CHOLESTEROL (mg/dL)**	**TRIGLYCERIDE**
I	Chylomicrons	Greater than or equal to 300	Greater than 3000
IIa	LDL	Greater than 300	Normal ≃ 148
IIb	LDL, VLDL	Greater than 300	Normal ≃ 148
III	IDL	Greater than 400	Greater than 600 (1-3 times higher than cholesterol)
IV	VLDL	Normal or mildly elevated approximately equal to 250	Greater than 400
V	VLDL, chylomicrons	Greater than 300	Greater than 2000

≃, Approximately equal to; *IDL,* intermediate-density lipoprotein; *LDL,* low-density lipoprotein; *VLDL,* very-low-density lipoprotein.

TABLE 27-3 TREATMENT DECISIONS BASED ON LDL CHOLESTEROL LEVEL

PATIENT CATEGORY	INITIATION LEVEL	LDL GOAL
Dietary Therapy		
Without CHD and with less than 2 risk factors (low risk)	Greater than or equal to 160 mg/dL (4.1 mmol/L)	Less than 160 mg/dL (4.1 mmol/L)
Without CHD and with greater than or equal to 2 risk factors (moderately high risk)	Greater than or equal to 130 mg/dL (3.4 mmol/L)	Less than 130 mg/dL (3.4 mmol/L)
With CHD (high or very high risk)	Greater than or equal to 100 mg/dL (2.6 mmol/L)	Less than 100 mg/dL (2.6 mmol/L)
Drug Therapy		
Without CHD and with less than 2 risk factors (low risk)	Greater than or equal to 190 mg/dL (4.9 mmol/L)	Less than 160 mg/dL (4.1 mmol/L)
Without CHD and with greater than or equal to 2 risk factors (moderately high risk)	Greater than or equal to 160 mg/dL (4.1 mmol/L)	Less than 130 mg/dL (3.4 mmol/L)
With CHD (high or very high risk)	Greater than or equal to 130 mg/dL (3.4 mmol/L)	Less than 100 mg/dL (2.6 mmol/L)

CHD, Coronary heart disease; *LDL,* low-density lipoprotein.

BOX 27-2 METABOLIC SYNDROME: IDENTIFYING FEATURES

- Waist circumference greater than 40 inches in men or 30 inches in women
- Serum triglyceride level of 150 mg/dL or more
- High-density lipoprotein cholesterol level of less than 40 mg/dL in men or less than 50 mg/dL in women
- Blood pressure of 130/85 mm Hg or higher
- Fasting serum glucose level higher than 110 mg/dL

PHARMACOLOGY OVERVIEW

HYDROXYMETHYLGLUTARYL–COENZYME A REDUCTASE INHIBITORS

The rate-limiting enzyme in cholesterol synthesis is known as HMG–CoA reductase. The class of medications that competitively inhibit this enzyme, called the **hydroxymethylglutaryl–coenzyme A (HMG–CoA) reductase inhibitors,** are the most potent of the drugs available for reducing plasma concentrations of LDL cholesterol. Lovastatin was the first drug in this class to be approved for use, which occurred in 1987. Since that time, six other HMG–CoA reductase inhibitors have become available on the U.S. market: pravastatin, simvastatin, atorvastatin, fluvastatin, rosuvastatin, and pitavastatin. Because of the shared suffix of their generic names, these drugs are often collectively referred to as *statins.* Lipid levels may not be lowered to their maximum extent until 6 to 8 weeks after the start of therapy. Few direct comparisons of the statins have been reported in the literature. The following doses of drugs are considered to be "therapeutically equivalent," meaning they produce the same therapeutic effect: simvastatin 20 mg, pravastatin 40 mg, lovastatin 40 mg, atorvastatin 10 mg, fluvastatin 80 mg, rosuvastatin 5 mg, and pitavastatin 2 mg.

Mechanism of Action and Drug Effects

Statins lower the blood cholesterol level by decreasing the rate of cholesterol production. The liver requires HMG–CoA reductase to produce cholesterol. It is the rate-limiting enzyme in the reactions needed to make cholesterol. The statins inhibit this enzyme, thereby decreasing cholesterol production. When less cholesterol is produced, the liver increases the number of LDL receptors to recycle LDL from the circulation back into the liver, where it is needed for the synthesis of other required substances such as steroids, bile acids, and cell membranes. Lovastatin and simvastatin are administered as inactive drugs or prodrugs that must be biotransformed into their active metabolites in the liver. In contrast, pravastatin is administered in its active form.

Indications

The statins are recommended as first-line drug therapy for hypercholesterolemia (especially elevated levels of LDL cholesterol), the most common and dangerous form of dyslipidemia. More specifically, they are indicated for the treatment of type IIa and IIb hyperlipidemia and have been shown to reduce the plasma concentrations of LDL cholesterol by 30% to 40%. Their cholesterol-lowering properties are dose dependent; that is, the larger the dose, the greater the cholesterol-lowering effects. A 10% to 30% decrease in the concentrations of plasma triglycerides has also been observed in patients receiving these drugs. Another very important therapeutic effect of the statins is an overall tendency for the HDL cholesterol level to increase by 2% to 15%, a known beneficial factor that reduces risk (i.e., a negative risk factor) for cardiovascular disease.

These drugs appear to be equally effective in their ability to reduce LDL cholesterol concentrations. However, simvastatin, atorvastatin, and pitavastatin are more potent on a milligram basis. Atorvastatin appears to be more effective in lowering triglyceride levels than other HMG–CoA reductase inhibitors. Combined drug therapy with more than one class of antilipemic drug may be necessary for desired results. The statins are often combined with niacin or fibrates for this purpose, though this combination can increase the risk of adverse drug effects (see Adverse Effects).

Contraindications

Contraindications to the use of HMG–CoA reductase inhibitors (statins) include known drug allergy and pregnancy. Other contraindications may include liver disease or elevation of liver enzyme levels.

TABLE 27-4 HMG-COA REDUCTASE INHIBITORS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Central nervous	Headache, dizziness, blurred vision, fatigue, insomnia
Gastrointestinal	Constipation, diarrhea, nausea
Other	Myalgias, skin rashes

HMG-CoA, Hydroxymethylglutaryl–coenzyme A.

Adverse Effects

The HMG–CoA reductase inhibitors are generally well tolerated, and significant adverse effects are fairly uncommon. However, mild, transient gastrointestinal disturbances, rash, and headache are the most common problems and tend to be underreported in clinical trials. These and other less common adverse effects are listed in Table 27-4. Elevations in liver enzyme levels may also occur, and patients need to be monitored for excessive elevations, which may indicate the need for alternative drug therapy. Dose-dependent elevations in liver enzyme levels to values of more than three times the upper limit of normal have been noted in 0.4% to 1.9% of patients taking HMG–CoA reductase inhibitors. Serum creatine phosphokinase concentrations may be increased to more than 10 times the normal level in patients receiving these drugs. Most of these patients have remained asymptomatic, however.

A clinically important adverse effect is myopathy (muscle pain), which may progress to a serious condition known as *rhabdomyolysis.* The U.S. Food and Drug Administration (FDA) has issued public health advisories regarding reports of myopathy and rhabdomyolysis associated with the use of statins. Rhabdomyolysis is the breakdown of muscle protein accompanied by myoglobinuria, which is the urinary elimination of the muscle protein myoglobin. This abnormal urinary excretion of protein can place a severe strain on the kidneys, possibly leading to acute renal failure and even death. It appears to be dose dependent and is more common in patients receiving a statin in combination with cyclosporine, niacin, gemfibrozil (a fibrate), or erythromycin. Advise patients receiving statin therapy to immediately report to the prescriber any unexplained muscular pain or discomfort. When recognized reasonably early, rhabdomyolysis is usually reversible with discontinuation of the statin drug. Risk factors for myopathy include: age older than 65 years, hypothyroidism, renal insufficiency, and concurrent use of the immunosuppressant drug cyclosporine or the antihyperlipidemic drug gemfibrozil. Although these adverse effects are relatively uncommon, and although much benefit is often derived from the use of statin drugs, prescribers are advised to use minimal effective doses, with regular laboratory blood monitoring of liver and kidney function (every 3 to 6 months). Educate patients regarding these serious adverse drug effects, and instruct them to immediately report any signs of toxicity, including muscle soreness, changes in urine color, fever, malaise, nausea, or vomiting. In 2011, the FDA imposed new restrictions on simvastatin, which are discussed in detail in its Drug Profile. In 2012, the FDA required added warnings including memory loss, confusion, increase in blood glucose levels and glycosylated hemoglobin (HbA-1c) levels, dosage limitations to lovastatin, and drug interactions with HIV and hepatits C medications.

TABLE 27-5 HMG-COA REDUCTASE INHIBITORS: DRUG INTERACTIONS

DRUG	MECHANISM	EFFECT
warfarin	Inhibit warfarin metabolism	Increased risk of bleeding
erythromycin, azole antifungals, quinidine, verapamil, amiodarone, grapefruit juice, HIV and hepatitis C protease inhibitors, cyclosporine, clarithromycin, diltiazem, amlodipine	Inhibit statin metabolism	Increased risk of myopathy
gemfibrozil	Potentiation	Increased risk of myopathy

Toxicity and Management of Overdose

Very limited data are available on the nature of toxicity and overdose in patients taking HMG–CoA reductase inhibitors. Treatment, if needed, is supportive and based on presenting symptoms.

Interactions

Drug interactions with the HMG–CoA reductase inhibitors are listed in Table 27-5. They are to be used cautiously in patients taking oral anticoagulants. In addition, the coadministration of the statins with drugs that are metabolized by cytochrome P-450 enzyme 3A4 (CYP3A4) (see Chapter 2), such as erythromycin, azole antifungals, verapamil, diltiazem, HIV and hepatitis C protease inhibitors, amiodarone, and grapefruit juice, may lead to the development of rhabdomyolysis. Patients are advised to limit grapefruit juice to less than 1 quart daily, which is probably more than most people drink. The mechanism for most significant drug interactions involves inhibition of the metabolic protein CYP3A4. The following example involving grapefruit juice illustrates the interaction. Components in grapefruit juice inactivate CYP3A4 in both the liver and intestines. This enzyme plays a key role in statin metabolism. The presence of grapefruit juice in the body results in sustained levels of unmetabolized statin drug, which increases the risk for major drug toxicity (e.g., rhabdomyolysis). Pravastatin and fluvastatin inhibit CYP3A4 to a much smaller degree than the other statins, whereas lovastatin and simvastatin are the most potent inhibitors of this enzyme. The use of gemfibrozil and statins together is not generally recommended due to increased risk of rhabdomyolysis.

Laboratory Test Interactions

Laboratory interactions that can occur include increases in ALT levels and activated clotting time, thrombocytopenia, and transient eosinophilia.

Dosages

For dosage information on atorvastatin, see the table on p. 450.

DOSAGES

Selected Antilipemic Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ atorvastatin (Lipitor) (X)	HMG–CoA reductase inhibitor	**Adult** PO: 10-80 mg/day	Hyperlipidemia
♦ cholestyramine (Questran) (C)	Bile acid sequestrant	**Adult** PO: 4-16 g/day	
ezetimibe (Zetia) (C)	Cholesterol absorption inhibitor	**Adult** PO: 10 mg 1×/day	
gemfibrozil (Lopid) (C)	Fibric acid derivative	**Adult** PO: 600 mg bid 30 min ac in AM and PM	
♦ niacin (nicotinic acid, vitamin B_3) (A; C if dose exceeds RDA)	B vitamin	**Adult** PO: 1.5 to 6 g/day in 2-4 divided doses.	
simvastatin (Zocor) (X)	HMG–CoA reductase inhibitor	**Adult** PO: 5-40 mg daily	

HMG–CoA, Hydroxymethylglutaryl–coenzyme A; *PO,* oral; *RDA,* recommended daily allowance.

DRUG PROFILES

The HMG–CoA reductase inhibitors, or statins, are all potent inhibitors of the enzyme that catalyzes the rate-limiting step in the synthesis of cholesterol. Seven statins are currently on the market in the United States: atorvastatin (Lipitor), fluvastatin (Lescol), lovastatin (Mevacor), pravastatin (Pravachol), simvastatin (Zocor), rosuvastatin (Crestor), and pitavastatin (Livalo). There are some minor differences between drugs in this class of antilipemics; the most dramatic difference is that of potency. All statins are prescription-only drugs and are contraindicated in those with active liver dysfunction or elevated serum transaminase levels of unknown cause. They are classified as pregnancy category X drugs and are to be avoided during pregnancy and lactation. There is little evidence to recommend one drug over another.

♦ atorvastatin

Atorvastatin (Lipitor) has become one of the most commonly used drugs in this class of cholesterol-lowering drugs. It is used to lower total and LDL cholesterol levels as well as triglyceride levels. Atorvastatin has also been shown to raise levels of "good" cholesterol, the HDL component. All statins are dosed once daily, usually with the evening meal or at bedtime. One particular advantage of atorvastatin is that it can be dosed at any time of day. However, bedtime dosing provides peak drug levels in a time frame that correlates better with the natural *diurnal* (daytime) rhythm of cholesterol production in the body. The recommended dosage for atorvastatin is 10 to 80 mg daily. It is available only in tablet form in strengths of 10, 20, 40, and 80 mg. It is classified as a pregnancy category X drug.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	0.5 hr	1-2 hr	7-14 hr	Unknown

♦ simvastatin

Simvastatin (Zocor) was the one of the first statins to become generic and is one of the most commonly used drugs in this class. As with all statins, it is used primarily to lower total and LDL cholesterol levels as well as triglyceride levels. It can also modestly raise levels of HDL, the "good" cholesterol. The recommended dosage for simvastatin is 5 to 40 mg daily. It is available only in tablet form in strengths of 10, 20, 40, and 80 mg. It is classified as a pregnancy category X drug. In 2011, the FDA imposed new prescribing restrictions on simvastatin, stating "Physicians should limit using the 80-mg dose unless the patient has already been taking the drug for 12 months and there is no evidence of myopathy. Simvastatin 80 mg should not be started in new patients, including patients already taking lower doses of the drug." In addition, simvastatin is not to be used with certain other drugs including itraconazole, ketoconazole, posaconazole, erythromycin, clarithromycin, telithromycin, HIV protease inhibitors, nefazodone, femfibrozil, cyclosporine, and danazol. In patients taking verapamil and diltiazem, the dose of simvastatin is not to exceed 10 mg. In patients taking amiodarone, amlodipine, and ranolazine, the dose is not to exceed 20 mg.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	3 days	1.3-2.4 hr	Unknown	Unknown

BILE ACID SEQUESTRANTS

Bile acid sequestrants, also called *bile acid–binding resins* and *ion-exchange resins,* include cholestyramine, colestipol, and colesevelam. The first two of these drugs have been used widely for more than 20 years and have been evaluated extensively in well-controlled clinical trials. They have proven efficacy, but their powdered forms are somewhat inconvenient to use.

Colestipol is also available in tablet form. Colesevelam has a similar mechanism of action and is available only in tablet form. These drugs are considered second-line drugs after the more potent statins. They are suitable alternatives for patients intolerant of the statins. Generally these drugs lower the plasma concentrations of LDL cholesterol by 15% to 30%. They also increase the HDL cholesterol level by 3% to 8% and increase hepatic triglyceride and VLDL production, which may result in a 10% to 50% increase in the triglyceride level.

Mechanism of Action and Drug Effects

Bile acid sequestrants bind bile and prevent the resorption of the bile acids from the small intestine. An insoluble bile acid and resin (drug) complex is formed and then excreted in the bowel movement. Bile acids are necessary for the absorption of cholesterol from the small intestine and are also synthesized from cholesterol by the liver. This is one natural way that the liver excretes cholesterol from the body. The more that bile acids are excreted in the feces, the more the liver converts cholesterol to bile acids. This reduces the level of cholesterol in the liver and thus in the circulation as well. The liver then attempts to compensate for the loss of cholesterol by increasing the number of LDL receptors on its surface. Circulating LDL molecules bind to these receptors to be taken up into the liver, which has the benefit of reducing circulating LDL in the bloodstream.

Indications

Bile acid sequestrants may be used as primary or adjunct drug therapy in the management of type II hyperlipoproteinemia. A common strategy is to use them along with statins for an additive drug effect in reducing LDL cholesterol levels. In addition, cholestyramine is used to relieve the pruritus associated with partial biliary obstruction. Colesevelam may be better tolerated by higher-risk patients who are intolerant of other antilipemic therapy, including organ transplant recipients and those with serious liver or kidney disease.

Contraindications

Contraindications to the use of bile acid sequestrants include known drug allergy, biliary or bowel obstruction, and phenylketonuria (PKU).

Adverse Effects

The adverse effects of colestipol, cholestyramine, and colesevelam are similar; however, colesevelam is reported to have fewer gastrointestinal adverse effects and drug interactions. Constipation is a common problem and may be accompanied by heartburn, nausea, belching, and bloating. These adverse effects tend to disappear over time. Many patients require extra education and support to help them deal with the gastrointestinal effects and comply with the medication regimen. It is important that therapy be initiated with low dosages and that patients be instructed to take the drugs with meals to reduce the adverse effects. Increasing dietary fiber intake or taking a fiber supplement such as psyllium (Metamucil and others), as well as increasing fluid intake, may relieve constipation and bloating. These drugs may also cause mild increases in triglyceride levels.

TABLE 27-6 BILE ACID SEQUESTRANTS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Gastrointestinal	Constipation, nausea, belching, bloating
Other	Headache, tinnitus, burnt odor of urine

The most common adverse effects of the bile acid sequestrants are listed in Table 27-6.

Toxicity and Management of Overdose

Because the bile acid sequestrants are not absorbed, an overdose can cause obstruction of the gastrointestinal tract. Therefore, treatment of an overdose involves restoring gut motility.

Interactions

The significant drug interactions associated with the use of bile acid sequestrants are limited to effects on the absorption of concurrently administered drugs. All drugs must be taken at least 1 hour before or 4 to 6 hours after the administration of bile acid sequestrants. In addition, high doses of a bile acid sequestrant decrease the absorption of fat-soluble vitamins (A, D, E, and K).

Dosages

For dosage information on a selected bile acid sequestrant, see the table on p. 450.

DRUG PROFILE

The bile acid sequestrants cholestyramine, colestipol, and colesevelam are indicated for the treatment of type IIa and IIb hyperlipidemia. They lower the cholesterol level, in particular the LDL cholesterol level, by increasing the destruction of LDL. However, their use may result in increases in the VLDL cholesterol level. Because of the high incidence of gastrointestinal adverse effects, adherence to the prescribed dosage schedules is often poor. However, educating patients about the purpose and expected adverse effects of therapy can foster improved adherence. Warn patients not to take bile acid sequestrants at the same time as other drugs because of reduced absorption. Other drugs must be taken at least 1 hour before or 4 to 6 hours after the bile sequestrant. This requirement cannot be overemphasized.

♦ cholestyramine

Cholestyramine (Questran) is a prescription-only drug that is contraindicated in patients with a known hypersensitivity to it and in those who have complete biliary obstruction or PKU. It may interfere with the distribution of proper amounts of fat-soluble vitamins to the fetus or nursing infant of a pregnant or nursing woman taking the drug. Cholestyramine is now being used for its constipating effect, often given as needed for loose bowel movements.

NIACIN

Niacin, or nicotinic acid, is not only a very unique lipid-lowering drug, it is also a vitamin. Much larger doses of the drug are required for its lipid-lowering effects than are commonly

TABLE 27-7 NIACIN (NICOTINIC ACID): ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Gastrointestinal	Abdominal discomfort
Integumentary	Cutaneous flushing, pruritus
Other	Blurred vision, glucose intolerance, hepatotoxicity

given when it is used as a vitamin. Niacin is a B vitamin, specifically vitamin B_3. It is an effective and inexpensive medication that exerts favorable effects on the plasma concentrations of all lipoproteins. Niacin is often given in combination with other antilipemic drugs to enhance the lipid-lowering effects.

Mechanism of Action and Drug Effects

Although the exact mechanism of action of niacin is unknown, the beneficial effects are believed to be related to its ability to inhibit lipolysis in adipose tissue, decrease esterification of triglycerides in the liver, and increase the activity of lipoprotein lipase. The drug effects are primarily limited to reduction of the metabolism or catabolism of cholesterol and triglycerides. Niacin decreases the LDL levels moderately (10% to 20%), decreases the triglyceride levels (30% to 70%), and increases the HDL levels moderately (20% to 35%). Niacin is also a vitamin needed for many bodily processes. In large doses, it may produce vasodilatation that is limited to the cutaneous vessels. This effect seems to be induced by prostaglandins. Niacin also causes the release of histamine, which results in an increase in gastric motility and acid secretion. Niacin may also stimulate the fibrinolytic system to break down fibrin clots.

Indications

Niacin has been shown to be effective in lowering lipid levels, including triglyceride, total serum cholesterol, and LDL cholesterol levels. It also increases HDL cholesterol levels. Niacin may also lower the levels of lipoprotein (a), except in patients with severe hypertriglyceridemia. It has been shown to be effective in the treatment of type IIa, IIb, III, IV, and V hyperlipidemia. Niacin's effects on triglyceride levels begin to be noticed after 1 to 4 days of therapy, with the maximum effects seen after 3 to 5 weeks of continuous therapy.

Contraindications

Contraindications to the use of niacin include known drug allergy and may include liver disease, hypertension, peptic ulcer, and the presence of any active hemorrhagic process.

Adverse Effects

Niacin can cause flushing, pruritus, and gastrointestinal distress. Small doses of aspirin or nonsteroidal antiinflammatory drugs (NSAIDs) may be taken 30 minutes before the niacin dose to minimize the cutaneous flushing. These undesirable effects can also be minimized by starting patients on a low initial dosage and increasing it gradually, and by having patients take the drug with meals. The most common adverse effects associated with niacin therapy are listed in Table 27-7.

Interactions

Drug interactions associated with niacin are minimal. However, when niacin is taken with an HMG–CoA reductase inhibitor, the likelihood of myopathy development is greatly increased, although it is not uncommon to see these drugs used together.

Dosages

For dosage information on niacin, see the table on p. 450.

DRUG PROFILE

♦ **niacin**

Used alone or in combination with other lipid-lowering drugs, niacin (nicotinic acid, vitamin B_3) (Nicobid) is a very effective, inexpensive medication that has beneficial effects on LDL cholesterol, triglyceride, and HDL cholesterol levels. Drug therapy is usually initiated at a small daily dose taken with or after meals to minimize the adverse effects. Liver dysfunction has been observed in individuals taking sustained-release forms of niacin, but not immediate-release forms. Extended-release dosage forms, which dissolve more slowly than the immediate-release but faster than the sustained-release forms, appear to have better adverse effect profiles, including less hepatotoxicity and flushing of the skin. Niacin is contraindicated in patients who have shown a hypersensitivity to it; in those with peptic ulcer, hepatic disease, hemorrhage, or severe hypotension; and in lactating women. It is also not recommended for patients with gout. Niacin is available over the counter and by prescription.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Rapid	30-60 min	45 min	Unknown

FIBRIC ACID DERIVATIVES

Current fibric acid derivatives include gemfibrozil and fenofibrate. These drugs primarily affect the triglyceride levels but may also lower the total cholesterol and LDL cholesterol levels and raise the HDL cholesterol level. They are often collectively referred to as *fibrates.*

Mechanism of Action and Drug Effects

Fibric acid drugs are believed to work by activating lipoprotein lipase, an enzyme responsible for the breakdown of cholesterol. This enzyme usually cleaves off a triglyceride molecule from VLDL or LDL, leaving behind lipoproteins. Fibric acid derivatives also suppress the release of free fatty acid from adipose tissue, inhibit the synthesis of triglycerides in the liver, and increase the secretion of cholesterol into bile. They have been shown to reduce triglyceride levels and serum VLDL and LDL concentrations. Independent of their lipid-lowering actions, fibric acid derivatives can also induce changes in blood coagulation. This involves a tendency toward a decrease in platelet adhesiveness. They can also increase plasma fibrinolysis, the process that causes fibrin, and therefore clots, to be broken down.

TABLE 27-8 FIBRIC ACID DERIVATIVES: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Gastrointestinal	Nausea, vomiting, diarrhea, gallstones
Genitourinary	Impotence, decreased urine output, hematuria
Other	Drowsiness, dizziness, rash, pruritus, vertigo

Indications

The fibric acid derivatives gemfibrozil and fenofibrate decrease the triglyceride level and increase the HDL cholesterol level by as much as 25%. Both decrease the LDL concentrations in patients with type IIa and IIb hyperlipidemia but increase the LDL levels in patients with type IV and V hyperlipidemia. They are indicated for the treatment of type III, IV, and V hyperlipidemia, and in some cases the type IIb form, although other classes of antilipemics are usually tried first.

Contraindications

Contraindications to the use of fibrates include known drug allergy and may include severe liver or kidney disease, cirrhosis, and gallbladder disease.

Adverse Effects

The most common adverse effects of the fibric acid derivatives are abdominal discomfort, diarrhea, nausea, headache, blurred vision, increased risk for gallstones, and prolonged prothrombin time. Liver function tests may also show increased enzyme levels. The more common adverse effects are listed in Table 27-8.

Toxicity and Management of Overdose

The management of fibrate overdose, which is uncommon, is supportive care based on presenting symptoms.

Interactions

Gemfibrozil can enhance the action of oral anticoagulants, thus careful adjustment of the dosage of warfarin is required. The risk for myositis, myalgias, and rhabdomyolysis is increased when either gemfibrozil or fenofibrate is given with a statin. Combining gemfibrozil with a statin is generally not recommended due to an increased risk of rhabdomyolysis. Laboratory test interactions that can occur in patients taking gemfibrozil include a decrease in the hemoglobin level, hematocrit value, and white blood cell count. In addition, the aspartate aminotransferase level, activated clotting time, lactate dehydrogenase level, and bilirubin level can be increased.

Fenofibrate may raise the blood level of ezetimibe if the two are taken concurrently.

Dosages

For dosage information on gemfibrozil, see the table on p. 450.

DRUG PROFILES

FIBRIC ACID DERIVATIVES (FIBRATES)

The fibric acid derivatives gemfibrozil and fenofibrate are prescription-only drugs and are the only two drugs available in this class. They are both classified as pregnancy category C drugs and are contraindicated in patients with a known hypersensitivity, preexisting gallbladder disease, significant hepatic or renal dysfunction, and primary biliary cirrhosis. Both drugs decrease the triglyceride levels and increase the HDL levels by as much as 25%. They are good drugs for the treatment of mixed hyperlipidemias.

gemfibrozil

Gemfibrozil (Lopid) is a fibric acid derivative that decreases the synthesis of apolipoprotein B and lowers the VLDL level. It can also increase the HDL level. It is highly effective for lowering plasma triglyceride levels. In a landmark study reported in 1987 in the *New England Journal of Medicine,* known as the Helsinki study, the triglyceride levels of the group receiving gemfibrozil were reduced by as much as 43% compared with those in the control group. Total cholesterol and LDL cholesterol levels were reduced by 11% and 10%, respectively, and the HDL level was increased by 10%. Gemfibrozil is indicated for the treatment of type IV and V hyperlipidemia, and, in some cases, the type IIb form. Recommended dosages are given in the table on p. 450.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Several days	1-2 hr	1.3-1.5 hr	Unknown

CHOLESTEROL ABSORPTION INHIBITOR

ezetimibe

Ezetimibe (Zetia) is currently the only cholesterol absorption inhibitor available. Ezetimibe has a novel mechanism of action in that it selectively inhibits absorption of cholesterol and related sterols in the small intestine. The result is a reduction in several blood lipid parameters: total cholesterol level, LDL cholesterol level, apolipoprotein B level, and triglyceride level. Serum levels of HDL cholesterol, the so-called *good* cholesterol, have been shown to increase with the use of ezetimibe. Beneficial effects of ezetimibe appear to be further enhanced when given with a statin drug. Ezetimibe may also be used as monotherapy. Recent studies have shown that, although the combination of ezetimibe and a statin is effective in reducing LDL, the rate of atherosclerotic progression is no different than when a statin is given alone. A large multicenter trial is currently underway that will provide further information in defining the role of ezetimibe. Until the results are available, current recommendations are to reserve ezetimibe for patients who have not responded to or are intolerant of other therapy. In 2011, the FDA expanded the use of ezetimibe in patients with moderate to severe chronic kidney disease, as studies showed it was effective in reducing the risk of vascular events in such patients.

Ezetimibe levels are increased by the fibric acid derivatives (fibrates). It is not known whether this is harmful, but concurrent use of ezetimibe and fibrates is not recommended. The use of ezetimibe with bile acid sequestrants has been shown to reduce the serum level of ezetimibe by 55% to 80%. Ezetimibe is contraindicated in those with a known hypersensitivity to it and in those with active liver disease or unexplained elevations in serum liver enzyme levels. It may be taken with or without food, and for patient convenience it may be dosed at the same time as a statin drug, if prescribed.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action

NURSING PROCESS

ASSESSMENT

Before initiating therapy with any *antilipemic* drug, obtain a thorough health and medication history with a listing of allergies and any prescription drugs, over-the-counter drugs, herbals, or supplements the patient is taking. Assess the patient's dietary patterns, exercise program and frequency, weight, height, and vital signs, and document these parameters—especially food intake—over time, such as for several weeks. Also, document the patient's use of tobacco, alcohol, and/or social drugs, along with information about frequency, amount, and duration of use. Some lipid disorders are hereditary; therefore, perform a thorough assessment of family history. Positive risk factors for CHD for which the patient needs to be assessed include the following: (1) males 45 years of age or older; (2) family history: history of premature CHD (e.g., myocardial infarction or sudden death before 55 years of age in father or other male first-degree relative, or before 65 years of age in mother or other female first-degree relative); (3) current cigarette smoking; (4) hypertension with a blood pressure higher than 140/90 mm Hg or current antihypertensive drug therapy; (5) low HDL cholesterol level: lower than 40 mg/dL; and, (6) diabetes mellitus.

Perform an assessment to identify any cautions, contraindications, and potential drug interactions before initiating use of any of the antilipemics. Also assess serum lipid values and lipoprotein levels (see the Safety: Laboratory Values Related to Drug Therapy box on p. 457). With the use of cholestyramine, which contains aspartame, it is of particular interest to know if there is a history of PKU. Patients with PKU cannot properly process the amino acid phenylalanine, a component of protein. It is known that high levels of phenylalanine lead to behavioral, cognitive, and learning dysfunction as early as 3 weeks of age in such patients. Dietary restrictions must continue throughout life. Adult patients require monthly testing of phenylalanine levels. Because of the aspartame in cholestyramine, another class of antilipemics would be indicated, as ordered, to prevent further complications from this disorder.

HMG–CoA reductase inhibitors (the statins) are not to be used in patients with liver disease or who have increased liver enzymes. Other contraindications, cautions, and drug interactions have been previously discussed in the pharmacology section of this chapter. With the use of the statins and all antilipemics, assess the patient's intake of alcohol, including the amount consumed and the period of time that alcohol has been used, because of the potential for liver dysfunction associated with the majority of lipid-lowering drugs. The statins may have more adverse effects on an already damaged liver. Monitor levels of liver enzymes that are indicative of liver function, including AST, CPK, and/or ALT. Review lipid and lipoprotein levels before, during, and after drug therapy with the statins as well as with other antilipemic drugs. Assess the patient for any musculoskeletal problems or complaints due to the possible adverse effect of myopathy. If AST or ALT blood levels increase or signs and symptoms of myopathy or rhabdomyolysis occur (i.e., muscle soreness, changes in urine color, fever, malaise, nausea, or vomiting), the drug will most likely be discontinued by the prescriber. It is always important to assess for cultural practices because of the impact of one's beliefs on dietary restrictions. Cultural practices may also include herbal or homeopathic therapies that may pose as contraindications to use of statins and other antilipemics.

Use of *bile acid sequestrants* requires careful assessment of possible contraindications such as a patient history of biliary or bowel obstructions and PKU. Drug interactions are numerous (see previous discussion) because of the decreased absorption of drugs by the bile acid sequestrants. With *niacin,* patient assessment includes noting contraindications such as liver disease, peptic ulcer disease, gout, hypertension, and any active bleeding. Liver function studies are usually ordered for baseline and comparative levels with the majority of antilipemics. *Fibric acid derivatives* are not used in patients with liver, kidney, or gallbladder disease, and so assessment for these disorders is critical to patient safety. With *ezetimibe* (Zetia), assess for liver disease and liver enzyme elevation before initiation of therapy.

NURSING DIAGNOSES

1. Imbalanced nutrition, more than body requirements, related to poor dietary habits of high fat intake
2. Deficient knowledge related to a lack of information about the disease, related complications, and lack of information about drug therapy
3. Risk for impaired liver function related to potential adverse and toxic effects of drug therapy

PLANNING

GOALS

1. Patient maintains healthy nutritional intake with appropriate restrictions.
2. Patient demonstrates adequate knowledge of disease process and its associated drug therapeutic regimens.
3. Patient maintains baseline liver function during drug therapy.

CASE STUDY

Antilipemic Drug Therapy

S.P., a 49-year-old mayor, lives a busy life but manages to exercise regularly and tries to follow a healthy lifestyle, including watching her diet. She is a nonsmoker and is not overweight. Recently S.P. had a medical checkup and, to her surprise, was told that her lipid levels are elevated. She has no history of diabetes mellitus, and her blood pressure is within normal limits. Her nurse practitioner has recommended that she start the HMG–CoA reductase inhibitor (statin) drug atorvastatin (Lipitor) at a dosage of 20 mg every evening.

1. S.P. says, "Isn't there something else I can do instead of taking this medicine? I really don't like taking pills." What alternatives may be available to her?
2. After 4 months, S.P.'s lipid levels are not improved. The nurse practitioner discusses S.P.'s risk factors, including the fact that her father died at 54 years of age of a myocardial infarction. What other risk factors need to be considered?
3. S.P. agrees to take the medication and schedules a follow-up appointment for 3 months. Two months later, she wakes up with some pain in her legs and feels extremely tired. She thinks she is suffering the effects of a new workout program that she started the previous day. But when she goes to work, the pain gets worse, and she calls the office nurse to describe her symptoms. What could be happening?
4. S.P. asks whether she will just be switched to another "statin" drug. How will the nurse respond?

For answers, see http://evolve.elsevier.com/Lilley.

OUTCOME CRITERIA

1. Patient states the importance of dietary restrictions with emphasis on low-fat, low-cholesterol, high-fiber, and low-calorie (if appropriate) diet as prescribed.
   - Patient has nutritional/dietary consult for implementation of changes in lifestyle and dietary intake to help decrease cholesterol and triglyceride levels.
   - Patient follows guidelines as designated by the Adult Treatment Panel III of the National Cholesterol Education Program such as decrease in saturated and trans fat intake; boosting intake of polyunsaturated and monounsaturated fats; and low-carbohydrate and/or low-fat diet.
   - Patient implements regular aerobic exercise for 2 hours or more per week as prescribed.
2. Patient demonstrates adequate knowledge about disease process and the need for lifelong treatment with drug therapy.
   - Patient states the rationale for antilipemic drug therapy (decrease in lipid levels).
   - Patient states the importance of taking the medication exactly as prescribed.
   - Patient states the various adverse effects, such as gastrointestinal upset, changes in liver function tests, and belching, as related to the specific drug prescribed.
   - Patient returns for follow-up care for monitoring of lipid levels and for adverse effects.
3. Patient demonstrates knowledge of the risk for liver dysfunction associated with antilipemic therapy.
   - Patient states the conditions that may arise of which the prescriber must be notified, such as jaundice and abdominal pain.
   - Patient states the importance of follow-up care with the prescriber to monitor for changes in liver function and monitoring of liver function tests.

IMPLEMENTATION

Patients who are taking *antilipemics* for a long period may have altered levels of the fat-soluble vitamins and may then require supplementation of vitamins A, D, and K. Antilipemics may also cause problems with the liver and biliary systems and may cause gastrointestinal tract problems such as constipation. Appropriate actions need to be taken to avoid or minimize constipation, such as increasing intake of fiber and fluids. Monitoring the results of blood studies per the prescriber's instructions often includes reviewing levels of serum transaminases and results of other tests of liver function.

With the *HMG-CoA reductase inhibitors* or statin drugs, serum levels of the aforementioned components are often measured every 6 to 8 weeks for the first 6 months of statin therapy and then every 3 to 6 months, depending on the prescriber and the patient situation. If a lipid profile is ordered, instruct the patient to fast for 12 to 14 hours before the blood sample is drawn. Also, inform patients of the desired laboratory levels to achieve (see Table 27-3). Because severe cardiovascular diseases and cerebral vascular accidents (also known as *strokes*) are associated with very high cholesterol levels, it is critical to the maintenance of health and the prevention of complications that the patient continue with any prescribed nonpharmacologic and/or pharmacologic therapies, regardless of the specific antilipemic used. Another aspect to consider when administering these medications, specifically simvastatin (Zocor), is dosage amount. The FDA has imposed new prescribing restrictions on simvastatin 80-mg dosage forms (see pharmacology discussion). The FDA also recommends that the 80-mg dose of simvastatin "not be started in new patients, including patients already taking lower doses of the drug." There are additional concerns about simvastatin and other medications that have been discussed in the pharmacology section of this chapter.

Bile acid sequestrants often come in powder form and must be mixed thoroughly with food or fluids (at least 4 to 6 oz of fluid). The powder may not mix completely at first, but patients need to be sure to mix the dose as much as possible and then dilute any undissolved portion with additional fluid. The powder needs to be dissolved for at least 1 full minute. Powder and/or granule dosage forms are *never* to be taken in dry form. It is important that colestipol and any of these drugs be taken 1 hour before or 4 to 6 hours after any other oral medication or meals because of the high risk for drug-drug and drug-food interactions. Bile acid sequestrants do interfere

EVIDENCE-BASED PRACTICE

Post-Stroke Statins Improve Patient Outcomes

Review

A prospective population-based analysis of ischemic stroke patients participating in the North Dublin Populations Stroke Study was performed to examine the relationship between acute treatment with statins (after ischemic stroke) and an improvement in survival and functional outcome.

Type of Evidence

The main researcher and her colleagues of Mater University Hospital in Dublin compared a statin to a no-statin group in 418 patients who had ischemic strokes. A prospective population-based analysis of these patients was done mainly because of the time and expense that would have been involved in the conducting of a randomized clinical trial for the same research purpose. Additionally, researchers assessed patients using the modified Rankin scale (mRS). The mRS is a commonly used scale for measuring the degree of disability or dependence in activities of daily living of people who have had a stroke. This scale ranges from 0 (no symptoms) to 6 (death), with 3 representing moderate disability and requiring some help but able to walk unassisted.

Results of Study

Of the total sample size, 30% of the patients had been on a statin drug before experiencing a stroke, and 87.3% of them continued to take their statin drug after the stroke. Forty-four percent of the sample size began taking statins within 72 hours of their stroke. Seventy-one percent of the group in all took a statin drug acutely after the stroke. Atorvastin was the specific statin in 87% of the patients. Researchers assessed the patients using the mRS and fatality at 1 week, 28 days, 90 days, and 1 year poststroke. Those patients who were taking statins after having the stroke, regardless of the fact that the drug was being taken beforehand or not, were more likely to have good outcomes or have an mRS score of 0 to 2 as compared to those who were not taking statins. Fatality risk was also significantly reduced among the patients on statins poststroke at every time point. It was also found that patients taking atorvastatin who increased their dose poststroke were more likely to have good outcomes. There was, however, no relationship between poststroke statin therapy and risk of having a recurrent stroke. Recurrent strokes did occur in 1.8% of the patients.

Link of Evidence to Nursing Practice

The results of this population-based prospective study emphasize the importance of initiation of preventative drug therapy (in this study, statins) in patients with the onset of a stroke. Specifically, it was found that statin therapy at the onset of stroke and newly begun statins were associated with improved early and late outcomes. With study results such as these, there is support for more research in the area of improving early and late outcomes with stroke patients. Dr. Ni Chroinin and her colleagues stated that randomized trials of statin for therapy in acute stroke patients are needed. Although the benefits of statins are known, there are still many patients at risk that could benefit from them. Nurses play a major role in performing assessments and interventions for patients with cardiovascular disorders, including strokes, as well as in monitoring pharmacologic management of these same disorders. Nurses also continue to play an important part in research clinical trials and in the education of patients about risk factors, new therapies, and lifestyle management associated with stroke and other cardiovascular diseases.

Reference: Ni Chroinin D et al: Association between acute statin therapy, survival, and improved functional outcome after ischemic stroke: the North Dublin Population Stroke Study, *Stroke* 42(4):1021-1029, 2011. The Modified Rankin Scale can be found at www.strokecenter.org/trials/scales/rankin.html.

with the absorption of other medications. Colestipol is also available in tablet form. Cholestyramine is to be taken just before meals or with meals, and it must never be given to a patient with PKU because it contains aspartame (see previous discussion). Constipation may be prevented with high fiber and increase in fluid intake.

With *niacin,* flushing of the face may occur; educate the patient on this adverse effect. To minimize gastrointestinal upset, advise the patient to take this medication with meals. Of the different dosage forms available, the extended-release dosage forms, which dissolve more slowly than the immediate-release forms but faster than the sustained-release forms, appear to be associated with less flushing of the skin. Other actions that may help to minimize flushing of the skin include titrating the drug dosage or taking a small dose of aspirin or NSAIDs 30 minutes before the niacin is taken, but only as ordered or recommended by the prescriber. Educate patients that *fibric acid derivatives* are to be taken as prescribed. Frequently monitor liver/kidney function tests and prothrombin times with these drugs. The *cholesterol absorption inhibitor* ezetimibe (Zetia) may be taken with or without food and may be taken with statin drugs.

EVALUATION

Evaluation of goals and outcome criteria is the best place to begin when trying to evaluate for the therapeutic versus adverse effects of these medications. In addition, cholesterol and triglyceride levels are used to monitor the patient's response to the medication regimen, and specific target levels are listed in Table 27-3. While taking *antilipemics,* patients remain on a low-fat, low-cholesterol diet as an integrated part of a change in lifestyle. Monitor patients receiving antilipemic drugs for therapeutic and adverse effects during their therapy. The therapeutic effects of both nonpharmacologic and pharmacologic measures are evidenced by a decrease in cholesterol and triglyceride levels to within normal ranges (see previous serum laboratory values). Nonpharmacologic measures include a low-fat, low-cholesterol diet; supervised, moderate exercise; weight loss; cessation of smoking and drinking; and relaxation therapy. Adverse effects for which to monitor include gastrointestinal upset, increased liver enzyme levels, hepatomegaly, myalgias, and other effects mentioned earlier in the chapter. Closely monitor patients' renal and liver function before and throughout treatment to detect the development of liver or renal dysfunction.

SAFETY: LABORATORY VALUES RELATED TO DRUG THERAPY

Coronary Heart Disease

LABORATORY TEST	NORMAL RANGES*	RATIONALE FOR ASSESSMENT
Serum lipid panel with cholesterol, triglycerides, and various lipids	Serum cholesterol level: less than or equal to 200 mg/dL (less than 5.17 mmol/L) Triglyceride level: less than 150 mg/dL Low-density lipoprotein (LDL) cholesterol level: less than 100 mg/dL (less than 2.6 mmol/L) High-density lipoprotein (HDL) cholesterol level: greater than or equal to 60 mg/dL (1.56 mmol/L[CB8]) Very-low-density lipoprotein (VLDL) level: less than 130 mg/dL (less than 3.4 mmol/L)	A lipid panel is a serum test that measures the levels of lipids, fats, and fatty substances used as a source of energy in the body. Lipids include cholesterol, triglycerides, HDL, and LDL. When a lipid panel is ordered, the levels of all of the following are reported: total cholesterol, triglycerides, HDL, LDL, VLDL, ratio of total cholesterol to HDL, and ratio of LDL to HDL. Lipid levels are important to health status and are indicators of health; if there are abnormalities (e.g., high cholesterol, triglyceride, VLDL, and LDL levels and low HDL level), the individual is at increased risk for heart disease and stroke. Dietary and other lifestyle changes may be implemented to help decrease the levels of "bad" cholesterols (LDL and VLDL) and elevate the levels of "good" cholesterol (HDL). Medical treatment protocols may also be implemented to help prevent heart attack and strokes.

*The values in this table are from the National Cholesterol Education Program of the National Institutes of Health.

PATIENT TEACHING TIPS

- Notify the prescriber if there are any new or troublesome symptoms or if there is persistent gastrointestinal upset, constipation, gas, bloating, heartburn, nausea, vomiting, abnormal or unusual bleeding, or yellow discoloration of the skin. Another symptom to report is muscle pain.
- Advise the patient to keep these and all medications out of the reach of children and protected with childproof lids.
- Encourage a diet that is plentiful in raw vegetables, fruit, and bran. Forcing fluids (up to 3000 mL/day unless contraindicated) may also help prevent the constipation associated with these medications.
- Advise the patient to inform health care providers about all medications he or she is taking, including antilipemics. These drugs are highly protein bound and are therefore associated with many drug interactions, including drugs that a dentist may prescribe. In addition, these drugs may alter clotting if taken on a long-term basis. This information is also important for the patient to share with the dentist.
- Educate patients that exercise is to be done in moderation and often with supervision as indicated.
- Alert the patient to concerns regarding the use of 80-mg doses of simvastatin.
- When taking an HMG–CoA reductase inhibitor or statin drug, it is best taken with at least 6 oz of water or with meals to help minimize gastric upset. It takes several weeks before therapeutic results are seen. Monitor liver and renal function laboratory studies every 3 to 6 months.
- Drug and food interactions associated with the statin drugs that must be avoided include oral anticoagulants, erythromycin, verapamil, some antifungal drugs, and grapefruit juice.
- With the HMG-CoA reductase inhibitors or statin drugs, any muscle soreness, change in color of the urine, fever, nausea, vomiting, and/or malaise must be reported to the prescriber immediately.
- If taking a bile acid sequestrant, advise the patient to take the medication with meals to decrease gastrointestinal upset. Other drugs must be taken 1 hour before or 4 to 6 hours after taking a bile acid sequestrant.
- Niacin is contraindicated in those with liver disease, peptic ulcer disease, gout, hypertension, or active bleeding. Instruct patients to take niacin with meals to decrease gastrointestinal upset.

KEY POINTS

- There are two primary forms of lipids: triglycerides and cholesterol. Triglycerides function as an energy source and are stored in adipose (fat) tissue. Cholesterol is primarily used to make steroid hormones, cell membranes, and bile acids.
- Lipids and lipoproteins participate in the formation of atherosclerotic plaque, which leads to CHD, and it is important to understand the pathology of this disease process so that appropriate patient education may be delivered.
- When plaque forms in the blood vessels that supply the heart with needed oxygen and nutrients, the lumens of these blood vessels will eventually decrease in size and the amount of oxygen and nutrients that can reach the heart (and major organs) will be reduced.
- Antilipemic drugs are used to lower the high levels of lipids in the blood (triglycerides and cholesterol).
- The major classes of antilipemics include HMG–CoA reductase inhibitors, bile acid sequestrants, niacin, fibric acid derivatives, and cholesterol absorption inhibitors, with each having their own mechanism of action.
- While taking a history, it is important to assess the patient for any possible cautions, contraindications, and drug interactions.

KEY POINTS — cont'd

- Fat-soluble vitamins may need to be prescribed for patients taking these medications for long periods because the antilipemics have long-term effects on the liver's production of these vitamins.
- Monitoring for adverse effects of the antilipemics includes periodic liver and renal function studies.
- The statins have gained much attention for their adverse effects of muscle aches and pain due to breakdown of muscle tissue. Some patients experience irreversible renal damage and severe pain and may have to alter dosages or change drugs as ordered by the prescriber.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A nurse administering niacin would implement which action to help to reduce adverse effects?
- **a** Give the medication with grapefruit juice.
- **b** Administer a small dose of aspirin or an NSAID 30 minutes before the niacin dose.
- **c** Administer the medication on an empty stomach.
- **d** Have the patient increase dietary fiber intake.

2 When administering niacin, the nurse needs to monitor for which adverse effect?
- **a** Cutaneous flushing
- **b** Muscle pain
- **c** Headache
- **d** Constipation

3 Which point will the nurse emphasize to a patient who is taking an antilipemic medication in the "statin" class?
- **a** The drug needs to be taken on an empty stomach before meals.
- **b** A low-fat diet is not necessary while taking these medications.
- **c** It is important to report muscle pain immediately.
- **d** Improved cholesterol levels will be evident within 2 weeks.

4 A patient is being assessed before a newly ordered antilipemic medication is given. Which condition would be a potential contraindication?
- **a** Diabetes insipidus
- **b** Pulmonary fibrosis
- **c** Liver cirrhosis
- **d** Myocardial infarction

5 A patient is currently taking a statin. The nurse considers that the patient may have a higher risk of developing rhabdomyolysis when also taking which product?
- **a** NSAIDs
- **b** A fibric acid derivative
- **c** Orange juice
- **d** Fat soluble vitamins

6 The nurse is administering cholestyramine (Questran), a bile acid sequestrant. Which nursing intervention(s) is appropriate? (Select all that apply.)
- **a** Administering the drug on an empty stomach
- **b** Administering the drug with meals
- **c** Instructing the patient to follow a low-fiber diet while taking this drug
- **d** Instructing the patient to take a fiber supplement while taking this drug
- **e** Increasing fluid intake
- **f** Not administering this drug at the same time as other drugs

7 The medication order reads: niacin, 500 mg PO, every evening. The medication is available in 250-mg tablets. How many tablets will the patient receive per dose?

1. b, 2. a, 3. c, 4. c, 5. b, 6. b, d, e, f, 7. 2 tablets

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Describe the normal anatomy and physiology of the renal system.
2 Briefly discuss the impact of the renal system on blood pressure regulation.
3 Describe how diuretics work in the kidneys and how they lower blood pressure.
4 Distinguish among the different classes of diuretics with regard to mechanisms of action, indications, dosages, routes of administration, adverse effects, toxicity, cautions, contraindications, and drug interactions.
5 Develop a nursing care plan that includes all phases of the nursing process for patients receiving diuretics.

DRUG PROFILES

acetazolamide, p. 462
amiloride, p. 466
♦ **furosemide, p. 484**
♦ **hydrochlorothiazide, p. 467**
♦ **mannitol, p. 465**
metolazone, p. 468
♦ **spironolactone, p. 466**
triamterene, p. 466

♦ *Key drug*

KEY TERMS

Afferent arterioles The small blood vessels approaching the glomerulus (proximal part of the nephron). (p. 460)

Aldosterone A mineralocorticoid steroid hormone produced by the adrenal cortex that regulates sodium and water balance. (p. 461)

Ascites Intraperitoneal accumulation of fluid (defined as a volume of 500 mL or more) containing large amounts of protein and electrolytes. (p. 464)

Collecting duct The most distal part of the nephron between the distal convoluted tubule and the ureters, which lead to the urinary bladder. (p. 461)

Distal convoluted tubule The part of the nephron immediately distal to the ascending loop of Henle and proximal to the collecting duct. (p. 460)

Diuretics Drugs or other substances that tend to promote the formation and excretion of urine. (p. 460)

Efferent arterioles The small blood vessels exiting the glomerulus. At this point blood has completed its filtration in the glomerulus. (p. 460)

Filtrate The material that passes through a filter. In the case of the kidney, the filter is the glomerulus and the filtrate is the material extracted from the blood (normally liquid) that becomes urine. (p. 461)

KEY TERMS—cont'd

Glomerular capsule The open, rounded, and most proximal part of the proximal convoluted tubule that surrounds the glomerulus and receives the filtrate from the blood. (p. 460)

Glomerular filtration rate (GFR) An estimate of the volume of blood that passes through the glomeruli of the kidney per minute. (p. 460)

Glomerulus The cluster of kidney capillaries that marks the beginning of the nephron and is immediately proximal to the proximal convoluted tubule. (p. 460)

Loop of Henle The part of the nephron between the proximal and distal convoluted tubules. (p. 460)

Nephron The functional filtration unit of the kidney, consisting of (in anatomic order from proximal to distal) the glomerulus, proximal convoluted tubule, loop of Henle, distal convoluted tubule, and collecting duct, which empties urine into the ureters. There are approximately 1 million nephrons in each kidney. (p. 460)

Open-angle glaucoma A condition in which pressure is elevated in the eye because of obstruction of the outflow of aqueous humor. (p. 461)

Proximal convoluted (twisted) tubule The part of the nephron that is immediately distal to the glomerulus and proximal to the loop of Henle. (p. 460)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Diuretics are drugs that accelerate the rate of urine formation via a variety of mechanisms. The result is the removal of sodium and water from the body. Diuretics were discovered by accident when it was noticed that a mercury-based antibiotic had a very potent diuretic effect. All the major classes of diuretic drugs in use today were developed between 1950 and 1970, and they remain among the most commonly prescribed drugs in the world.

The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure reaffirmed the role of diuretics, especially the thiazides, as first-line drugs in the treatment of hypertension. The hypotensive activity of diuretics is due to many different mechanisms. They cause direct arteriolar dilation, which decreases peripheral vascular resistance. They also reduce extracellular fluid volume, plasma volume, and cardiac output, which may account for the decrease in blood pressure. They have long been the mainstay of therapy not only for hypertension but also for heart failure. Two of their advantages are their relatively low cost and their favorable safety profile. The main problem with their use is the metabolic adverse effects that can result from excessive fluid and electrolyte loss. These effects are usually dose related and are controllable with dosage *titration* (careful adjustment).

This chapter reviews the essential properties and actions of the following important classes of diuretic drugs: carbonic anhydrase inhibitors, loop diuretics, osmotic diuretics, potassium-sparing diuretics, and thiazide and thiazide-like diuretics. All diuretics work primarily in the kidney.

The kidney plays a very important role in the day-to-day functioning of the body. It filters out toxic waste products from the blood while simultaneously conserving essential substances. This delicate balance between elimination of toxins and retention of essential chemicals is maintained by the **nephron.** The nephron is the main structural unit of the kidney, and each kidney contains approximately 1 million nephrons. Diuretics exert their effect in the nephron. The initial filtering of the blood takes place in the **glomerulus,** a cluster of capillaries surrounded by the **glomerular capsule.** The rate at which this filtering occurs is referred to as the **glomerular filtration rate (GFR),** and it is used as a gauge of how well the kidneys are functioning as filters. The GFR can be estimated mathematically by calculating creatinine clearance. This is typically calculated by hospital pharmacists and is used to adjust drugs based on the patient's renal function. Normally about 180 L of blood are filtered through the nephrons every day.

The GFR, which can also be thought of as the rate at which blood flows into and out of the glomerulus, is regulated by the small blood vessels approaching the glomerulus **(afferent arterioles)** and the small blood vessels exiting the glomerulus **(efferent arterioles).** A mnemonic (memory aid) for remembering which arteriole is which is "*A* for *approach* and *afferent*" and "*E* for *exit* and *efferent.*" Alterations in blood flow such as those that occur in a patient in shock can therefore have a dramatic effect on kidney (renal) function. Diuretics may have diminished effects in situations of low blood flow, because the kidney receives less blood, and therefore less diuretic reaches the site of action.

The **proximal convoluted (twisted) tubule** or, more simply, the *proximal tubule,* follows the glomerulus anatomically and returns 60% to 70% of the sodium and water from the filtered fluid back into the bloodstream. Blood vessels surround the nephrons and allow substances to be directly resorbed from or secreted into the bloodstream. This process is one of active transport that requires energy in the form of adenosine triphosphate (ATP) molecules. The active transport of sodium and potassium ions back into the blood causes the passive resorption of chloride and water. The chloride ions (Cl^-) and water passively follow the sodium ions (Na^+) and, to a lesser extent, potassium ions (K^+) by osmosis. Another 20% to 25% of sodium is resorbed back into the bloodstream in the ascending **loop of Henle.** Chloride is actively resorbed in the loop of Henle, and sodium passively follows it.

The remaining 5% to 10% of sodium resorption takes place in the **distal convoluted tubule,** often called the *distal tubule,* which anatomically follows the ascending loop of Henle. In the distal tubule, sodium is actively filtered in exchange for potassium or hydrogen ions, a process regulated by the

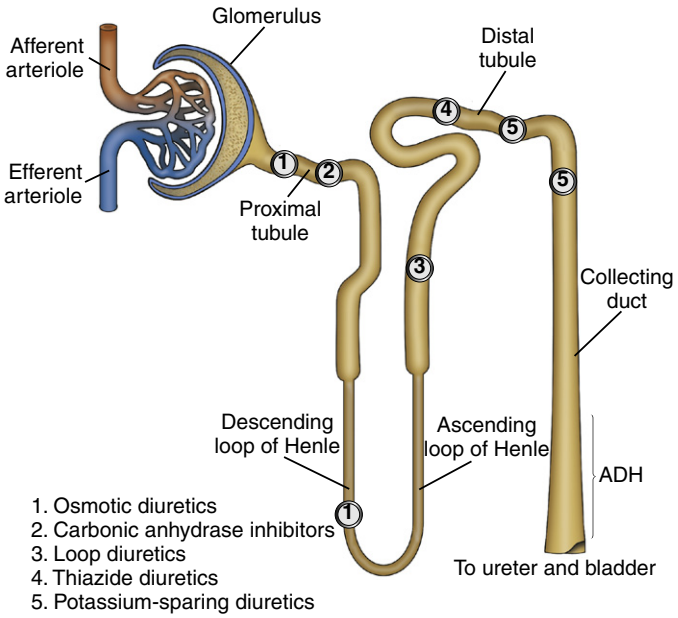

FIGURE 28-1 The nephron and diuretic sites of action. *ADH,* Antidiuretic hormone.

hormone **aldosterone.** The **collecting duct** is the final common pathway for the **filtrate** that started in the glomerulus. It is here that antidiuretic hormone acts to increase the absorption of water back into the bloodstream, thereby preventing it from being lost in the urine. The entire nephron, along with the sites of action of the different classes of diuretics, is shown in Figure 28-1.

PHARMACOLOGY OVERVIEW

The various diuretics are classified according to their sites of action within the nephron, their chemical structure, and their diuretic potency. The sites of action of the various diuretics are determined by the way in which they affect the various solute (electrolyte) and water transport systems located along the nephron (see Figure 28-1). The commonly used classes of drugs and the individual drugs in these classes are listed in Table 28-1. The most potent diuretics are the loop diuretics, followed by mannitol, metolazone (a thiazide-like diuretic), the thiazides, and the potassium-sparing diuretics. The potency of these diuretics is a function of where they work in the nephron to inhibit sodium and water resorption. The more sodium and water they inhibit from resorption, the greater the amount of diuresis and therefore the greater the potency.

CARBONIC ANHYDRASE INHIBITORS

Carbonic anhydrase inhibitors (CAIs) are chemical derivatives of sulfonamide antibiotics. As their name implies, CAIs inhibit the activity of the enzyme carbonic anhydrase, which is found in the kidneys, eyes, and other parts of the body. The CAIs work at the location of the carbonic anhydrase enzyme system along the nephron, primarily in the proximal tubule. Acetazolamide is the CAI most commonly used today.

TABLE 28-1 CLASSIFICATION OF DIURETICS

CLASS	DRUGS
Carbonic anhydrase inhibitors	Acetazolamide
Loop diuretics	Bumetanide, ethacrynic acid, furosemide, torsemide
Osmotic diuretics	Mannitol
Potassium-sparing diuretics	Amiloride, spironolactone, triamterene
thiazide and thiazide-like diuretics	Chlorthalidone, chlorothiazide, hydrochlorothiazide, indapamide, metolazone

Mechanism of Action and Drug Effects

The carbonic anhydrase system in the kidney is located just distal to the glomerulus in the proximal tubules, where roughly two thirds of all sodium and water is resorbed into the blood. In the proximal tubules, there is an active transport system that exchanges sodium for hydrogen ions. For sodium and water to be resorbed back into the blood, hydrogen must be exchanged for it. Without hydrogen, this cannot occur, and the sodium and water will be eliminated with the urine. Carbonic anhydrase makes hydrogen ions available for this exchange. When its actions are inhibited by a CAI such as acetazolamide, little sodium and water can be resorbed into the blood and they are eliminated with the urine. The CAIs reduce the formation of hydrogen (H^+) and bicarbonate (HCO_3^-) ions from carbon dioxide and water through the noncompetitive, reversible inhibition of carbonic anhydrase activity. This results in a reduction in the availability of the ions, mainly hydrogen, for use by active transport systems.

The reduction in the formation of bicarbonate and hydrogen ions can have effects on other parts of the body. CAIs can induce respiratory and metabolic acidosis. Both respiratory and metabolic acidosis can increase oxygenation during hypoxia by increasing ventilation, cerebral blood flow, and the dissociation of oxygen from oxyhemoglobin. These actions are usually beneficial to the patient. An undesirable effect of CAIs is elevation of the blood glucose level and glycosuria in diabetic patients. This may be due in part to CAI-enhanced potassium loss through the urine.

Indications

Therapeutic applications of CAIs include the treatment of glaucoma, edema, and high-altitude sickness.

CAIs are used as adjunct drugs in the long-term management of **open-angle glaucoma** that cannot be controlled by topical miotic drugs or epinephrine derivatives alone (see Chapter 57). Glaucoma is caused by the obstruction of the outflow of aqueous humor. When CAIs are given, an increase in the outflow of aqueous humor results. They are also used short term in conjunction with miotics to lower intraocular pressure in preparation for ocular surgery and as an adjunct in the treatment of secondary glaucoma.

Acetazolamide is also used to manage edema secondary to heart failure that has become resistant to other diuretics.

However, as a class, CAIs are much less potent diuretics than loop diuretics or thiazides, and the metabolic acidosis they induce diminishes their diuretic effect in 2 to 4 days.

Acetazolamide is also effective in both the prevention and treatment of the symptoms of high-altitude sickness. These symptoms include headache, nausea, shortness of breath, dizziness, drowsiness, and fatigue.

Contraindications

Contraindications to the use of CAIs include known drug allergy, hyponatremia, hypokalemia, severe renal or hepatic dysfunction, adrenal gland insufficiency, and cirrhosis.

Adverse Effects

Common undesirable effects of CAIs are metabolic abnormalities such as acidosis and hypokalemia. Drowsiness, anorexia, paresthesias, hematuria, urticaria, photosensitivity, and melena (blood in the stool) can also occur.

Interactions

Because CAIs can cause hypokalemia, an increase in digoxin toxicity may occur when they are combined with digoxin. Use with corticosteroids may also cause hypokalemia. The effects of amphetamines, carbamazepine, cyclosporine, phenytoin, and quinidine may be increased when these drugs are taken concurrently with CAIs.

Dosages

The usual dose of acetazolamide is 250 to 500 mg per day, which may be given orally or IV.

DRUG PROFILE

acetazolamide

Use of acetazolamide (Diamox) is contraindicated in patients who have shown a hypersensitivity to it as well as in those with significant liver or kidney dysfunction, low serum potassium or sodium levels, acidosis, or adrenal gland failure. Acetazolamide is available in both oral and parenteral forms. It is classified as a pregnancy category C drug.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	2-4 hr	10-15 hr	8-12 hr

LOOP DIURETICS

Loop diuretics (bumetanide, ethacrynic acid, furosemide, and torsemide) are very potent diuretics. Bumetanide, furosemide, and torsemide are chemically related to the sulfonamide antibiotics. Because they are structurally related to the sulfonamides, they are often listed as contraindicated in sulfa-allergic patients. However, analysis of the literature indicates that cross-reaction is unlikely to occur. Loop diuretics are commonly given to patients with sulfa allergy with no problems; however, always be aware of the potential of allergy.

Mechanism of Action and Drug Effects

Loop diuretics have renal, cardiovascular, and metabolic effects. These drugs act primarily along the thick ascending limb of the loop of Henle, blocking chloride and, secondarily, sodium resorption. They are also thought to activate renal prostaglandins, which results in dilatation of the blood vessels of the kidneys, the lungs, and the rest of the body (i.e., reduction in renal, pulmonary, and systemic vascular resistance). The hemodynamic effects of loop diuretics are a reduction in both the preload and central venous pressures (which are the filling pressures of the ventricles). These actions make them useful in the treatment of the edema associated with heart failure, hepatic cirrhosis, and renal disease.

Loop diuretics are particularly useful when rapid diuresis is needed, because of their rapid onset of action. The diuretic effect lasts at least 2 hours. Loop diuretics have a distinct advantage over thiazide diuretics in that their diuretic action continues even when creatinine clearance decreases below 25 mL/min. This means that even when kidney function diminishes, loop diuretics can still work. Because of their potent diuretic effect and the duration of action, loop diuretics are usually effective when given in a single daily dose. This allows the renal tubule time to partially compensate for the potassium depletion and other electrolyte derangements that often accompany around-the-clock diuretic therapy. Despite this, the major adverse effect of loop diuretics is electrolyte disturbances. Prolonged administration of high dosages can also result in hearing loss stemming from ototoxicity, although this is rare.

Summary of Major Drug Effects of Loop Diuretics

Loop diuretics produce a potent diuresis and subsequent loss of fluid. The resulting decreased fluid volume leads to a decreased return of blood to the heart, or decreased filling pressures. This has the following cardiovascular effects:

- Reduces blood pressure
- Reduces pulmonary vascular resistance
- Reduces systemic vascular resistance
- Reduces central venous pressure
- Reduces left ventricular end-diastolic pressure

The metabolic effects of the loop diuretics are secondary to the electrolyte losses resulting from the potent diuresis. Major electrolyte losses include loss of sodium and potassium and, to a lesser extent, calcium. Changes in the plasma levels of insulin, glucagon, and growth hormone have also been observed in association with loop diuretic therapy.

Indications

Loop diuretics are used to manage the edema associated with heart failure and hepatic or renal disease, to control hypertension, and to increase the renal excretion of calcium in patients with hypercalcemia. As with certain other classes of diuretics, they may also be indicated in cases of heart failure resulting from diastolic dysfunction.

Contraindications

Contraindications to the use of loop diuretics include known drug allergy, hepatic coma, and severe electrolyte loss. Although

allergy to sulfonamide antibiotics is listed as a contraindication, analysis of the literature indicates that cross-reaction with the loop diuretics is unlikely to occur. Loop diuretics are commonly given to such patients in clinical practice.

Adverse Effects

Common undesirable effects of the loop diuretics are listed in Table 28-2. Hypokalemia is of serious clinical importance. To prevent hypokalemia, patients often receive potassium supplements along with furosemide. Furosemide can produce erythema multiforme, exfoliative dermatitis, photosensitivity, and in rare cases aplastic anemia. Torsemide may rarely cause blood disorders, including thrombocytopenia, agranulocytosis, leukopenia, and neutropenia. It may also cause a severe skin disorder called Stevens-Johnson syndrome.

Toxicity and Management of Overdose

Electrolyte loss and dehydration, which can result in circulatory failure, are the main toxic effects of loop diuretics that require attention. Treatment involves electrolyte and fluid replacement.

Interactions

Loop diuretics exhibit both neurotoxic and nephrotoxic properties, and they produce additive effects when given in combination with drugs that have similar toxicities. The drug interactions are summarized in Table 28-3.

Loop diuretics also affect certain laboratory results. They cause increases in the serum levels of uric acid, glucose, alanine aminotransferase, and aspartate aminotransferase. Their combined use with a thiazide (especially metolazone) results in the blockade of sodium and water resorption at multiple sites in the nephron, a property referred to as *sequential nephron blockade,* which increases their effects. Nonsteroidal antiinflammatory drugs (NSAIDs) may diminish the reduction in vascular resistance induced by loop diuretics because these two drug classes have opposite effects on prostaglandin activity.

Dosages

For dosage information on loop diuretics, see the table on this page.

DRUG PROFILE

The currently available loop diuretics are bumetanide, ethacrynic acid, furosemide, and torsemide. Ethacrynic acid is rarely used clinically. As a class they are very potent diuretics, but

TABLE 28-2 LOOP DIURETICS: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Central nervous	Dizziness, headache, tinnitus, blurred vision
Gastrointestinal	Nausea, vomiting, diarrhea
Hematologic	Agranulocytosis, thrombocytopenia, neutropenia
Metabolic	Hypokalemia, hyperglycemia, hyperuricemia

TABLE 28-3 LOOP DIURETICS: COMMON DRUG INTERACTIONS

INTERACTING DRUG	MECHANISM	RESULTS
Aminoglycosides vancomycin	Additive effect	Increased neurotoxicity, especially ototoxicity
Corticosteroids digoxin	Hypokalemia	Additive hypokalemia Increased digoxin toxicity
lithium	Decrease in renal excretion	Increased lithium toxicity
NSAIDs	Inhibition of renal prostaglandins	Decreased diuretic activity

NSAIDs, Nonsteroidal antiinflammatory drugs.

DOSAGES

Selected Loop Diuretics and Osmotic Diuretics

DRUG	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ furosemide (Lasix)	Loop diuretic	**Pediatric** IM/IV/PO: 1-2 mg/kg/dose; do not exceed 6 mg/kg/day **Adult** IM/IV: 20-40 mg/dose; max 600 mg/day; administer high-dose IV therapy as a controlled infusion at a rate of 4 mg/mL or less PO: 20-120 mg/day as a single dose	Heart failure, hypertension, renal failure, pulmonary edema, cirrhosis
♦ mannitol (Osmitrol)	Osmotic diuretic	**Adult** IV infusion: 20-200 g/day, over a 24-hr period 1-2 g/kg over 30-60 min followed by 0.25-1 g/kg infusion 50-200 g IV given at a rate to induce urine output of 100-500 mL/hr	Renal failure High intraocular or intracranial pressure Drug intoxication (to induce diuresis)

IM, Intramuscular; *IV,* intravenous; *PO,* oral.

potency varies for the different drugs. The equipotent doses of the drugs are as follows:

bumetanide	ethacrynic acid	furosemide	torsemide
1 mg	50 mg	40 mg	10-20 mg

♦ furosemide

Furosemide (Lasix) is by far the most commonly used loop diuretic in clinical practice and the prototypical drug in this class. It has all the therapeutic and adverse effects of the loop diuretics mentioned earlier. It is used in the management of pulmonary edema and the edema associated with heart failure, liver disease, nephrotic syndrome, and **ascites.** It has also been used in the treatment of hypertension, usually that caused by heart failure.

Furosemide use is contraindicated in patients who have shown a hypersensitivity to it or to the sulfonamides (see previous discussion regarding sulfonamide allergy) and in patients with anuria, hypovolemia, or electrolyte depletion. It is available in oral form as a solution, tablets, and an injectable form. It is classified as a pregnancy category C drug. Recommended dosages are given in the table on p. 463.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	5 min	15 min	1-2 hr	2 hr
PO	30-60 min	1-2 hr	1-2 hr	6-8 hr

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

Diuretics

- Calculate pediatric dosages of diuretic medications carefully, regardless of whether the patient is in the hospital or in the home setting. Measure weight daily at the same time every day and record so that therapeutic and/or adverse effects of diuretics can be assessed. Because pediatric patients are at greater risk for adverse effects and toxicity, they need closer and more cautious daily assessment to avoid excess fluid volume and electrolyte loss, hypotension, and shock.
- The half-life of furosemide is increased in neonates, so the interval between doses may need to be lengthened, as ordered by the prescriber.
- The oral forms of diuretics may be taken with food or milk and are to be taken early in the day and at the same time every day.
- Lengthy exposure to either heat or sun must be avoided because it may precipitate heat stroke, exhaustion, and fluid volume loss in pediatric patients taking diuretics.
- Thiazide diuretics cross the placenta and pass through to the fetus. Small amounts are distributed in breast milk; thus, breastfeeding is not advised for mothers who are taking these drugs.
- Alterations in laboratory test results that may be caused by diuretics include an increase in serum levels of calcium, glucose, and uric acid. Loop diuretics may interfere with BUN, chloride, magnesium, potassium, and sodium levels; therefore, perform frequent monitoring.

OSMOTIC DIURETICS

The osmotic diuretics include mannitol, urea, organic acids, and glucose. Mannitol, a nonabsorbable solute, is the most commonly used of these drugs.

Mechanism of Action and Drug Effects

Mannitol works along the entire nephron. Its major site of action, however, is the proximal tubule and descending limb of the loop of Henle. Because it is nonabsorbable, it increases osmotic pressure in the glomerular filtrate, which in turn pulls fluid, primarily water, into the renal tubules from the surrounding tissues. This process also inhibits the tubular resorption of water and solutes, which produces a rapid diuresis. Ultimately, this reduces cellular edema and increases urine production, causing diuresis. However, it produces only a slight loss of electrolytes, especially sodium. Therefore, mannitol is not indicated for patients with peripheral edema because it does not promote sufficient sodium excretion.

Mannitol may induce vasodilation and in doing so increase both glomerular filtration and renal plasma flow. This makes it an excellent drug for preventing kidney damage during acute renal failure. It is also often used to reduce intracranial pressure and cerebral edema resulting from head trauma. In addition, mannitol treatment may be tried when elevated intraocular pressure is unresponsive to other drug therapies.

Indications

Mannitol is the osmotic diuretic of choice. It is commonly used in the treatment of patients in the early, oliguric phase of acute renal failure. For it to be effective in this setting, however, enough renal blood flow and glomerular filtration must still remain to enable the drug to reach the renal tubules. Increased renal blood flow resulting from the dilatation of blood vessels supplying blood to the kidneys is another therapeutic benefit of mannitol. It can also be used to promote the excretion of toxic substances, reduce intracranial pressure, and treat cerebral edema. In addition, it can be used as a genitourinary irrigant in the preparation of patients for transurethral surgical procedures and as supportive treatment in patients with edema induced by other conditions.

Contraindications

Contraindications to the use of mannitol normally include known drug allergy, severe renal disease, pulmonary edema (loop diuretics are used instead), and active intracranial bleeding.

Adverse Effects

Significant undesirable effects of mannitol include convulsions, thrombophlebitis, and pulmonary congestion. Other less significant effects are headaches, chest pains, tachycardia, blurred vision, chills, and fever.

Interactions

There are no drugs that interact significantly with mannitol.

Dosages

For dosage information on mannitol, see the table on p. 463.

DRUG PROFILE

♦ **mannitol**

Mannitol (Osmitrol) is the prototypical osmotic diuretic. Its use is contraindicated in patients with a hypersensitivity to it as well as in those with anuria, severe dehydration, pulmonary congestion, or cerebral hemorrhage. Treatment is terminated if severe cardiac or renal impairment develops after the initiation of therapy. It is available only in parenteral form as 5%, 10%, 15%, 20%, and 25% solutions for intravenous injection. The volume infused differs based on the concentration of mannitol provided. Calculations may need to performed to determine the volume to be used. Mannitol may crystallize when exposed to low temperatures. This is more likely to occur when concentrations exceed 15%. Because of this, mannitol is always administered intravenously through a filter, and vials of the drug are often stored in a warmer. Before administering mannitol, visually inspect the mannitol container for precipitants. Mannitol is classified as a pregnancy category C drug. Recommended dosages are given in the table on p. 463.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	0.5-1 hr	0.25-2 hr	1.5 hr	6-8 hr

POTASSIUM-SPARING DIURETICS

The currently available potassium-sparing diuretics are amiloride, spironolactone, and triamterene. These diuretics are also referred to as *aldosterone-inhibiting diuretics* because they block the aldosterone receptors. Spironolactone is a competitive antagonist of aldosterone, and for this reason it causes sodium and water to be excreted while potassium is retained. It is the most commonly used of the three drugs.

Mechanism of Action and Drug Effects

Potassium-sparing diuretics work in the collecting ducts and distal convoluted tubules, where they interfere with sodium-potassium exchange. Spironolactone competitively binds to aldosterone receptors and therefore blocks the resorption of sodium and water that is induced by aldosterone secretion. These receptors are found primarily in the distal tubule. Amiloride and triamterene do not bind to aldosterone receptors. However, they inhibit both aldosterone-induced and basal sodium reabsorption, working in both the distal tubule and collecting ducts. They are often prescribed for children with heart failure, because pediatric cardiac problems are frequently accompanied by an excess secretion of aldosterone.

The potassium-sparing diuretics are relatively weak compared with the thiazide and loop diuretics. When diuresis is needed, they are generally used as adjuncts to thiazide treatment. This combination is beneficial in two respects. First, the drugs have synergistic diuretic effects; second, the two drugs counteract the adverse metabolic effects of one another. The thiazide diuretics cause potassium, magnesium, and chloride to be lost in the urine, and the potassium-sparing diuretics counteract this by elevating the potassium and chloride levels.

TABLE 28-4 POTASSIUM-SPARING DIURETICS: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Central nervous	Dizziness, headache
Gastrointestinal	Cramps, nausea, vomiting, diarrhea
Other	Urinary frequency, weakness, hyperkalemia

Indications

Therapeutic applications of the potassium-sparing diuretics vary depending on the particular drug. Spironolactone and triamterene are used to treat hyperaldosteronism and hypertension and to reverse the potassium loss caused by the potassium-wasting (e.g., loop, thiazide) diuretics. One common feature of heart failure is a hyperactive renin-angiotensin-aldosterone system. Research has identified this hyperactivity as a causative factor in permanent ventricular myocardial wall damage, known as *remodeling*, following myocardial infarction. Various clinical trials have demonstrated a cardioprotective benefit of spironolactone in preventing this remodeling process, due to its aldosterone-inhibiting activity. The uses for amiloride are similar to those for spironolactone and triamterene, but amiloride is less effective in the long term. It may be more effective than spironolactone or triamterene in the treatment of metabolic alkalosis, however. It is primarily used in the management of heart failure. As with certain other classes of diuretics, potassium-sparing diuretics may also be indicated in cases of heart failure due to diastolic dysfunction.

Contraindications

Contraindications to the use of potassium-sparing diuretics include known drug allergy, hyperkalemia (i.e., serum potassium level exceeding 5.5 mEq/L), and severe renal failure or anuria. Triamterene use may also be contraindicated in cases of severe hepatic failure.

Adverse Effects

Potassium-sparing diuretics have several common undesirable effects, which are listed in Table 28-4. There are also some significant adverse effects that are specific to individual drugs. Spironolactone can cause gynecomastia, amenorrhea, irregular menses, and postmenopausal bleeding. Triamterene may reduce folic acid levels and cause the formation of kidney stones and urinary casts. It may also precipitate megaloblastic anemia. However, adverse effects from triamterene are rare. Hyperkalemia may occur when potassium-sparing diuretics are used in combination with each other and/or with other potassium-sparing

drugs such as angiotensin-converting enzyme (ACE) inhibitors (see Chapter 22, as well as the Interactions section to follow).

Interactions

Concurrent use of potassium-sparing diuretics and lithium, ACE inhibitors, or potassium supplements can result in significant drug interactions. The administration of ACE inhibitors or potassium supplements in combination with potassium-sparing diuretics can result in hyperkalemia. When lithium and potassium-sparing diuretics are given together, lithium toxicity can result. NSAIDs can inhibit renal prostaglandins, which decreases blood flow to the kidneys and therefore decreases the delivery of diuretic drugs to this site of action. This in turn can lead to a diminished diuretic response.

Dosages

For dosage information on potassium-sparing diuretics, see the table below.

DOSAGES

Selected Potassium-Sparing Diuretic Drugs

DRUG	USUAL DOSAGE RANGE	INDICATIONS
amiloride (Midamor)	**Adult** PO: 5-20 mg/day	Edema, heart failure (as an adjunct to loop diuretics)
♦ spironolactone (Aldactone)	**Pediatric** PO: 3.3 mg/kg/day in single or divided doses **Adult** PO: 25-200 mg/day; given once or divided twice daily	Edema, hypertension, heart failure, ascites
triamterene (Dyrenium)	**Adult** PO: 50-100 mg bid; do not exceed 300 mg/day	Edema, hypertension, heart failure, ascites

PO, Oral.

DRUG PROFILES

amiloride

Amiloride (Midamor) is generally used in combination with a thiazide or loop diuretic in the treatment of heart failure. Hyperkalemia may occur in as many as 10% of the patients who take amiloride alone. It should be used with caution in patients who have renal impairment or diabetes mellitus and in elderly patients. It has only weak antihypertensive properties. Amiloride is available only in oral form. It is also available in combination with hydrochlorothiazide. Amiloride is classified as a pregnancy category B drug. Recommended dosages are given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2 hr	6-10 hr	6-9 hr	24 hr

♦ spironolactone

Spironolactone (Aldactone) is a synthetic steroid that blocks aldosterone receptors. It is used in high dosages for the treatment of ascites, a condition commonly associated with cirrhosis of the liver. Monitor serum potassium levels frequently in patients who have impaired renal function or who are currently taking potassium supplements, because hyperkalemia is a common complication of spironolactone therapy. It is the potassium-sparing diuretic most commonly prescribed for children who have heart failure. Recently spironolactone has been shown to reduce morbidity and mortality in patients with severe heart failure when added to standard therapy. Of the three commonly used potassium-sparing diuretics, spironolactone has the greatest antihypertensive activity. It is available only in oral form. It also is available in combination with hydrochlorothiazide. Spironolactone is classified as a pregnancy category D drug. Recommended dosages are given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-3 days	2-3 days	13-24 hr	2-3 days

triamterene

The pharmacologic properties of triamterene (Dyrenium) are similar to those of amiloride. Like amiloride, triamterene acts directly on the distal renal tubule of the nephron to depress the resorption of sodium and the excretion of potassium and hydrogen. It has little or no antihypertensive effect. Triamterene is available only in oral form and is also available in combination with hydrochlorothiazide. It is classified as a pregnancy category D drug. Recommended dosages are given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2-3 hr	6-8 hr	2-3 hr	12-16 hr

THIAZIDES AND THIAZIDE-LIKE DIURETICS

Thiazide and thiazide-like diuretics are considered equivalent in their effects. Thiazide diuretics, like several of the loop diuretics, are benzothiadiazines, chemical derivatives of sulfonamide antibiotics. The thiazide diuretics include chlorothiazide and hydrochlorothiazide. Hydrochlorothiazide is the most commonly prescribed and the least expensive of the thiazide diuretics. Hydrochlorothiazide is included in numerous combination products with antihypertensive drugs. The thiazide-like diuretics are very similar to the thiazides and include chlorthalidone, indapamide, and metolazone. Metolazone may be more effective than other drugs in this class in the treatment of patients with renal dysfunction.

Mechanism of Action and Drug Effects

The primary site of action of thiazides and thiazide-like diuretics is the distal convoluted tubule, where they inhibit

the resorption of sodium, potassium, and chloride. This results in osmotic water loss. Thiazides also cause direct relaxation of the arterioles (small blood vessels), which reduces peripheral vascular resistance (afterload). Decreased preload (filling pressures) and decreased afterload (the force the ventricles must overcome to eject the volume of blood they contain) are beneficial hemodynamic effects. This makes them very effective for the treatment of both heart failure and hypertension.

As renal function decreases, the efficacy of thiazides diminishes, because delivery of the drug to the site of activity is impaired. Thiazides are not to be used if creatinine clearance is less than 30 to 50 mL/min. Normal creatinine clearance is 125 mL/min, depending on age of the patient. However, metolazone remains effective to a creatinine clearance of 10 mL/min, and thus is used in cases of renal failure. The major adverse effects of the drugs stem from the electrolyte disturbances they produce. They are noted for precipitating hypokalemia and hypercalcemia, as well as metabolic disturbances such as hyperlipidemia, hyperglycemia, and hyperuricemia.

Indications

The thiazide and thiazide-like diuretics are used in the treatment of edema of various origins, idiopathic hypercalciuria, and diabetes insipidus, in addition to hypertension. They are also used as adjunct drugs in the management of heart failure and hepatic cirrhosis. Any of these drugs can be used either as monotherapy or in combination with other drugs. As with certain other classes of diuretics, they may also be indicated in cases of heart failure due to diastolic dysfunction.

Contraindications

Contraindications to the use of thiazides and thiazide-like diuretics include known drug allergy, hepatic coma (metolazone), anuria, and severe renal failure.

Adverse Effects

Major adverse effects of the thiazide and thiazide-like diuretics relate to the electrolyte and metabolic disturbances they cause—mainly reduced potassium levels and elevated levels of calcium, lipids, glucose, and uric acid. Other effects, such as gastrointestinal disturbances, skin rashes, photosensitivity, thrombocytopenia, pancreatitis, and cholecystitis, are less common. Dizziness and vertigo are common adverse effects of metolazone therapy and are attributed to sudden shifts in the plasma volume brought about by the drug. Headache, impotence, and decreased libido are other important adverse effects of these drugs. Many of these adverse effects are dose related and are seen at higher doses, especially those above 25 mg. The more common adverse effects of the thiazide and thiazide-like diuretics are listed in Table 28-5.

Toxicity and Management of Overdose

An overdose of these drugs can lead to an electrolyte imbalance resulting from hypokalemia. Symptoms include anorexia, nausea, lethargy, muscle weakness, mental confusion, and hypotension. Treatment involves electrolyte replacement.

TABLE 28-5 THIAZIDE AND THIAZIDE-LIKE DIURETICS: POTENTIAL ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Central nervous	Dizziness, headache, blurred vision
Gastrointestinal	Anorexia, nausea, vomiting, diarrhea
Genitourinary	Impotence
Hematologic	Jaundice, leukopenia, agranulocytosis
Integumentary	Urticaria, photosensitivity
Metabolic	Hypokalemia, hyperglycemia, hyperuricemia, hypochloremic alkalosis

TABLE 28-6 THIAZIDE AND THIAZIDE-LIKE DIURETICS: COMMON DRUG INTERACTIONS

INTERACTING DRUG	MECHANISM	RESULTS
Antidiabetic drugs	Antagonism	Reduced therapeutic hypoglycemic effect (i.e., increased blood glucose levels)
Corticosteroids	Additive effect	Hypokalemia
digoxin	Hypokalemia	Increased digoxin toxicity
lithium	Decreased clearance	Increased lithium toxicity
NSAIDs	Inhibition of renal prostaglandins	Decreased diuretic activity

NSAIDs, Nonsteroidal antiinflammatory drugs.

Interactions

Thiazides and related drugs interact with corticosteroids, diazoxide, digitalis, and oral hypoglycemics. The mechanisms and results of these interactions are summarized in Table 28-6. Excessive consumption of licorice can lead to an additive hypokalemia in patients taking these drugs.

Dosages

For dosage information on thiazides and thiazide-like diuretics, see the table on p. 468.

DRUG PROFILES

♦ hydrochlorothiazide

Hydrochlorothiazide (HydroDIURIL), which is considered the prototypical thiazide diuretic, is a very commonly prescribed and inexpensive thiazide diuretic. It is also a very safe and effective diuretic. Hydrochlorothiazide is used in combination with many other drugs, including methyldopa, propranolol, spironolactone, triamterene, hydralazine, ACE inhibitors, beta blockers, and labetalol. Dosages exceeding 50 mg/day rarely produce additional clinical results and may only increase drug toxicity. This property is known as a *ceiling effect.* However, doses up to 100 mg/day are not uncommon.

Hydrochlorothiazide is available only in oral form. It is classified as a pregnancy category B drug. Recommended dosages are given in the table on p. 468.

DOSAGES

Selected Thiazide and Thiazide-Like Diuretic Drugs

DRUG	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ hydrochlorothiazide (HydroDIURIL)	Thiazide diuretic	**Pediatric** Younger than 6 mo: 2-4 mg/kg/day Older than 6 mo: 2-3 mg/kg/day **Adult** 25-100 mg/day, usually divided **Elderly** 12.5-25 mg/day	Edema, heart failure (as an adjunct to loop diuretics)
metolazone (Zaroxolyn)	Thiazide-like diuretic	**Adult** PO: 2.5-20 mg/day	

PO, Oral.

Pharmacokinetics (hydrochlorothiazide)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2 hr	4-6 hr	5-15 hr	6-12 hr

metolazone

Metolazone (Zaroxolyn) is a thiazide-like diuretic that appears to be more potent than the thiazide diuretics. This greater potency becomes important in patients with renal dysfunction. It remains effective to a creatinine clearance as low as 10 mL/min. It may also be given in combination with loop diuretics to produce diuresis in patients with moderate to severe symptoms of heart failure. Metolazone is more efficacious when given 30 minutes before loop diuretics. It is available only in oral form. Metolazone is classified as a pregnancy category B drug. Recommended dosages are given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	1-2 hr	6-20 hr	24 hr

NURSING PROCESS

ASSESSMENT

Before giving a patient any type of diuretic, obtain a complete patient history and thorough medication history. Perform a physical assessment and document all findings, with emphasis on the body systems affected by the disease process or indication for the diuretic as well as by potential drug-related adverse effects. This would most likely include assessing baseline breath sounds, heart sounds, neurologic status, as well as checking skin turgor (for edema), moisture levels of mucus membranes, and capillary refill. Because fluid volume levels and electrolyte concentrations are affected by diuretics, assess and document the patient's baseline fluid volume status (as indicated by vital signs, weight, and intake-output measurements). Assess postural blood pressures (e.g., lying, sitting, standing) before and during drug therapy because of diuretic-induced fluid volume loss, which may lead to postural or orthostatic hypotension. Postural or orthostatic hypotension is a drop in blood pressure of 20 mm Hg or more upon standing.

In addition, assess specific laboratory values associated with renal and hepatic functioning; for example, BUN level (normal range, 8 to 25 mg/100 mL) and creatinine level (normal range, 0.6 to 1.5 mg/100 mL) for renal function, and ALP (normal range, 13 to 39 units/L), AST (normal range, 8 to 46 units/L in males, 7 to 34 units/L in females), and LDH (normal range, 45 to 90 units/L) for hepatic function. It is important to note, however, that normal ranges of these laboratory values may vary somewhat from facility to facility. Serum electrolyte levels are also critical to assess before and during diuretic therapy because of the subsequent loss of electrolytes through the urine and their relationship to fluid volume status. Specifically, obtain and document serum potassium, sodium, chloride, magnesium, calcium, uric acid, and creatinine levels, as ordered. Arterial blood gas levels may also be ordered.

Carbonic anhydrase inhibitors require close assessment of sodium and potassium levels. These drugs are not to be used in patients with a history of renal or liver dysfunction. As with any diuretic that results in loss of potassium (excluding potassium-sparing diuretics), if these drugs are given concurrently with digoxin, there is increased risk for digoxin toxicity (because of the hypokalemia).

Loop diuretics are more potent than thiazide diuretics, combination products, and potassium-sparing diuretics. These drugs may pose more problems for the elderly or those with severe electrolyte loss and liver failure. An additional and significant concern for patients taking loop diuretics is their interaction with other medications that are neurotoxic or ototoxic (see Table 28-3). Cross-sensitivity has been documented in patients who are allergic to sulfonamide antibiotics (see pharmacology discussion). Loop diuretics may also cause severe skin reactions (i.e., exfoliative dermatitis with furosemide, Steven Johnsons syndrome with torsemide), so a thorough assessment of the patient's skin prior to administration is important. With torsemide, assess baseline complete blood counts and clotting studies, if ordered, because of the adverse effects of leukopenia, neutropenia, and thrombocytopenia. Additionally, with loop diuretics, potential

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

Diuretic Therapy

- Before and during diuretic drug therapy, measure the patient's height, weight, intake and output, blood pressure, pulse rate, respiratory rate, and temperature. Assess breath and heart sounds and edematous areas. Monitor serum sodium, potassium, and chloride levels.
- Emphasize to the elderly patient that diuretics need to be taken at the same time every day. These drugs are generally ordered to be taken in the morning to help prevent nocturia (voiding at night), which can result in lack of sleep. More importantly, nocturia can lead to injury if the individual needs to get out of bed to void, becomes dizzy and/or confused, and falls. A bedside commode may be used to decrease the risk of injury.
- If the elderly patient is living alone and has minimal or no assistance with the medication regimen, visits from a home health aide or other health care professional may help ensure safety, efficacy, and compliance not only in taking the medication but also in following all aspects of the therapeutic regimen.
- Exercise caution in administering diuretics to the elderly, because they are more sensitive to the therapeutic effects of these drugs (often reacting to smaller dosages of medication than are required by other patients) and are also more likely to experience the adverse effects of diuretics such as dehydration, electrolyte loss, dizziness, and syncope.
- Encourage the patient to change positions slowly because of the risk of orthostatic hypotension and subsequent falls and injury. Emphasize the importance of daily recording of weight, blood pressure, and overall well-being.
- Advise patients to carry a card containing a brief medical history, blood pressure readings, names and telephone numbers of contact persons, and a list of medications to ensure safety and minimize complications. The card can be formatted so that it may fit in a wallet. A copy may also be placed in the kitchen on the refrigerator door or in another visible location so that it will be easily available to emergency personnel. Copies of the card may be given to the caregiver(s), family members, significant others, prescribers, dentist, and relevant health care personnel. The card then needs to be updated at regular intervals by the patient or another adult, caregiver, or prescriber involved in the patient's care. Such a card can be made easily using standard card stock or an index card. It can be placed in a wallet sleeve and information entered using an erasable pen or pencil. The following sample shows suggested headings and content for such a card:

Name:_____ **Age:**_____ **Allergies (drug/food):**_____ **Medical history (place X to the right of all that apply; write in any not listed):** Anemia__ Asthma__ Bleeding problems__ Blood clots __ Breathing problems __ Cancer __ Depression__ Diabetes__ Difficulty swallowing__ Heart problems__ High blood pressure__ Low blood pressure__ Nerve problems__ Pacemaker or defibrillator device__ Recent weight gain__ Recent weight loss__ Stroke__ Thyroid problems__ Others:_____
Surgery (list all with date, type of surgery, purpose, any complications):_____
_____
Prosthetics used:_____ **Dentures/ dental problems:**_____ **Assistive devices:** Glasses __ Hearing aids_____ Mobility assistance_____

Current medications (prescription drugs; over-the-counter drugs; herbals, vitamins, others)
Name(s) _____
Dosage (s) _____
Frequency of doses _____
Why taking the drug _____

drug-laboratory value interactions include increased serum uric acid and glucose levels.

With *potassium-sparing diuretics,* hyperkalemia may be an adverse effect; therefore, assess the patient's serum levels of potassium. Additionally, because of the potassium-sparing effect, contraindications include drugs or conditions that may result in hyperkalemia. Thus, potassium supplements, ACE inhibitors, and severe renal failure are contraindications. Lithium toxicity may occur if given with these diuretics because of the hyperkalemia. See the pharmacology section of this chapter for further discussion of additional cautions, contraindications, and drug interactions associated with diuretic use.

NURSING DIAGNOSES

1. Decreased cardiac output related to drug effects and adverse effects of diuretics (e.g., fluid and electrolyte loss)
2. Deficient fluid volume related to drug effects and adverse effects of diuretics
3. Risk for injury related to postural hypotension and dizziness

PLANNING

GOALS

1. Patient regains and maintains balanced cardiac output.
2. Patient regains and maintains balanced fluid volume status.
3. Patient remains free from injury.

OUTCOME CRITERIA

1. Patient continues to show normal cardiac output while receiving diuretic therapy, as evidenced by vital signs, adequate intake, and output within normal limits (pulse between 60 and 100 beats/min; blood pressure 120/80 mm Hg or within normal parameters; urine output 30 mL/hr or higher).

- Patient has strong pedal pulses and warm, pink extremities with rapid capillary refill.

2. Patient regains balanced fluid volume status without dehydration or overhydration.
   - Patient's skin is pliable and with firm turgor.
   - Patient's laboratory values return within normal limits for urine specific gravity, serum sodium, chloride, and potassium.
3. Patient takes diuretic therapy as directed and with adequate fluid intake while avoiding hypotensive episodes.
   - Patient changes positions slowly and with purpose while on diuretic therapy.
   - Patient reports excessive dizziness, lightheadedness, palpitations, tingling of fingers and toes, confusion, disorientation, and/or any fainting episodes.

IMPLEMENTATION

Measure and record blood pressure, pulse rate, intake and output, and daily weights during diuretic therapy. Changes from the initial baseline assessment data that alert you to possible problems with the drug therapy include the presence of dizziness, fainting, lightheadedness on standing or changing positions, weakness, fatigue, tremor, muscle cramping, changes in mental status, or cold clammy skin. Diuretic therapy may also precipitate cardiac irregularities or palpitations; therefore, continue to monitor heart rate and rhythm. Fluid loss from the action of the diuretic may lead to the adverse effect of constipation, so preventative measures are needed, such as increased intake of fluids and fiber (unless contraindicated) and/or the use of natural bulk-forming products. If constipation continues, the prescriber may need to provide alternatives to psyllium-based bulk-forming laxatives. Always give diuretics exactly as directed but with consideration of the patient's age and related needs. Dosing and timing of the drugs are often very important to enhance therapeutic effects and minimize adverse effects. Because diuretics taken late in the afternoon or evening may lead to nocturia (urination at night) and subsequent loss in sleep, these medications are usually scheduled for morning dosing. Safety concerns exist with nocturia, especially in the elderly, because possible confusion and dizziness associated with getting up in the middle of the night may create the potential for falls and injury.

Loop diuretics (if taken at high dosages as ordered) may put patients at greater risk for fluid volume and electrolyte depletion (e.g., hypokalemia, hyponatremia, dehydration). Monitoring of therapy includes frequent assessment of blood pressure and pulse rate, including orthostatic blood pressures and pulse rates (supine and standing), hydration status, and capillary refill, as well as daily measurement of weight. Acute hypotensive episodes may occur with higher dosages of loop diuretics and precipitate syncope and falls; therefore, educate the patient about safety measures to prevent falls. Hypokalemia is the most commonly encountered electrolyte imbalance and may be very dangerous. Symptoms include anorexia, nausea, lethargy, muscle weakness, mental confusion, and hypotension. If intravenous dosage forms are given, it is crucial to check for proper diluents, drug incompatibilities, and intactness of the intravenous site. Double-check rates of infusion and use an infusion pump as deemed necessary.

With *potassium-sparing diuretics,* potassium is reabsorbed and not excreted (as previously discussed), so hyperkalemia, rather than hypokalemia, may become problematic. Signs and symptoms of hyperkalemia include nausea, vomiting, and diarrhea (see Chapter 29), with toxic levels manifested by cardiac rhythm abnormalities. Any of the signs and symptoms of hyperkalemia need to be reported immediately. See the Patient Teaching Tips for more information.

EVALUATION

The therapeutic effects of *diuretics* include the resolution of or reduction in edema, fluid volume overload, heart failure, or hypertension, or a return to normal intraocular pressures (if used for that purpose, as with the CAIs). Monitor the patient for the occurrence of adverse reactions to the diuretics, such as hypotension (from volume loss), electrolyte imbalances,

CASE STUDY

Hydrochlorothiazide Therapy

Dr. G., a 62-year-old university professor, has been diagnosed with primary hypertension and will be taking 50 mg of hydrochlorothiazide (HCTZ) daily. There is no evidence of renal insufficiency or cardiac damage at this time, nor is there evidence of retinopathy or other signs and symptoms of end-organ disease. She is anxious because the fall semester is starting and she has a heavy teaching load but is willing to take the steps needed for better health.

At her 1-month follow-up appointment, Dr. G. complains of "feeling so tired" and asks whether the medication causes sleepiness. When questioned, she says that she takes the HCTZ at dinnertime because she is afraid it will "interfere with her classes."

1. What do you suspect is happening with Dr. G., and what would you recommend?
2. During this follow-up appointment, you ask Dr. G. if she is eating foods high in potassium. She looks embarrassed and answers, "I lost that pamphlet about the foods with potassium, but I try to drink orange juice every day." What foods should she eat for the potassium content?
3. The report on Dr. G.'s potassium levels comes back from the laboratory, and the results are 3.4 mEq/L. She asks, "Am I going to be put on a potassium pill too?" What is your answer?
4. Six months later, Dr. G. is diagnosed with type 2 diabetes mellitus and is started on oral hypoglycemic therapy. What will you teach her about managing her diabetes while taking the HCTZ?

For answers, see http://evolve.elsevier.com/Lilley.

metabolic acidosis (arterial blood gas values may need to be measured), drowsiness (with *CAIs*), hypokalemia, tachycardia (less significant with *mannitol*), and hyperkalemia *(potassium-sparing diuretics)*. Hypokalemia may be manifested by anorexia, nausea, lethargy, muscle weakness, mental confusion, and hypotension. With potassium-sparing diuretics, hyperkalemia may be the adverse effect for which to monitor and is manifested by nausea, vomiting, and diarrhea (see Chapter 29), and cardiac rhythm abnormalities with severe hyperkalemia. Review all goals and outcome criteria in the evaluation process.

PATIENT TEACHING TIPS

- Patients taking diuretics need to maintain proper nutritional intake and fluid volume and eat potassium-rich foods, except when contraindicated or when potassium-sparing diuretics are used. Foods high in potassium include bananas, oranges, apricots, dates, raisins, broccoli, green beans, potatoes, tomatoes, meats, fish, wheat bread, and legumes.
- Potassium supplementation may be recommended by a prescriber, depending on the symptoms the patient presents and the serum levels. Normal serum potassium levels are 3.5-5 mEq/L (see Chapter 29).
- Frequent laboratory tests may be indicated at the beginning of and during therapy with diuretics. These tests may include measurement of electrolytes, uric acid, and blood gases.
- Encourage patients to change positions slowly and to rise slowly after sitting or lying to prevent dizziness and possible fainting (syncope).
- Forcing of fluids may be needed (if not contraindicated) to prevent dehydration and minimize constipation. Increased consumption of fiber may also help with constipation.
- Any unusual adverse effects or problems, such as excessive dizziness, syncope, weakness, or muscle aches, need to be reported immediately to the prescriber.
- Advise the patient to keep a daily journal; entries should include weight, how the patient feels each day, dosage of diuretic, and any other important information related to the diagnosis and medical treatment.
- Educate the patient about the signs and symptoms of hypokalemia, such as anorexia, nausea, lethargy, muscle weakness, mental confusion, and hypotension. In addition, emphasize the importance of being cautious with hot climates, excessive sweating, fever, and the use of saunas or hot tubs. Heat raises core body temperature and causes further loss of potassium, sodium, and water through sweat, which may increase the risk of more problems with hypotension and fluid-electrolyte imbalances. Fluid volume and electrolyte loss may also occur with vomiting and diarrhea.
- If the patient is taking a diuretic along with digoxin, educate the patient, family members, and anyone involved in the patient's care about how to monitor pulse rate. The warning signs and symptoms of digoxin toxicity include headache, dizziness, confusion, nausea, visual disturbances, and bradycardia. A pulse rate of 60 beats/min or lower is often used as a guideline, but always check facility policy or guidelines.
- Educate patients with diabetes who are also taking thiazide and/or loop diuretics about the need for close monitoring of blood glucose levels.

KEY POINTS

- The five main types of diuretics are CAIs, loop, osmotic, potassium-sparing, and thiazide and thiazide-like diuretics.
- The loop, potassium-sparing, and thiazide diuretics are the most commonly used. Remember that the loop diuretics are more potent than the thiazides, combination diuretics, and potassium-sparing diuretics.
- It is important to have a thorough knowledge of renal anatomy and physiology and how it relates to the action of the various diuretics; for example, if a loop diuretic is given, its site of action is the loop of Henle and it causes the excretion of sodium, potassium, and chloride into the urine.
- Methods for monitoring excess and deficit fluid volume states include assessment of skin and mucous membranes, blood pressure, pulse rate, intake and output, and daily weights.
- With diuretics, always be concerned about the more vulnerable patient populations, such as the elderly, those with chronic illnesses, and patients with altered renal or liver function.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is reviewing the medications that have been ordered for a patient for whom a loop diuretic has just been prescribed. The loop diuretic may have a possible interaction with which of the following?
- **a** Vitamin D
- **b** warfarin
- **c** Penicillins
- **d** NSAIDs

2 When monitoring laboratory test results for patients receiving loop and thiazide diuretics, the nurse knows to look for
- **a** decreased serum levels of potassium.
- **b** increased serum levels of calcium.
- **c** decreased serum levels of glucose.
- **d** increased serum levels of sodium.

3 When the nurse is checking the laboratory data for a patient taking spironolactone (Aldactone), which result would be a potential concern?
- **a** Serum sodium level of 140 mEq/L
- **b** Serum calcium level of 10.2 mg/dL
- **c** Serum potassium level of 5.8 mEq/L
- **d** Serum magnesium level of 2.0 mg/dL

4 Which statement needs to be included when the nurse provides patient education for a patient with heart failure who is taking daily doses of spironolactone (Aldactone)?
- **a** "Be sure to eat foods that are high in potassium."
- **b** "Avoid foods that are high in potassium."
- **c** "Avoid grapefruit juice while taking this medication."
- **d** "A low-fiber diet will help prevent adverse effects of this medication."

5 A patient with diabetes has a new prescription for a thiazide diuretic. Which statement will the nurse include when teaching the patient about the thiazide drug?
- **a** "There is nothing for you to be concerned about when you are taking the thiazide diuretic."
- **b** "Be sure to avoid foods that are high in potassium."
- **c** "You need to take the thiazide at night to avoid interactions with the diabetes medicine."
- **d** "Monitor your blood glucose level closely, because the thiazide diuretic may cause the levels to increase."

6 An elderly patient has been discharged following treatment for a mild case of heart failure. He will be taking a loop diuretic. Which instruction(s) from the nurse are appropriate? (Select all that apply.)
- **a** "Take the diuretic at the same time each morning."
- **b** "Take the diuretic only if you notice swelling in your feet."
- **c** "Be sure to stand up slowly because the medicine may make you feel dizzy if you stand up quickly."
- **d** "Drink at least 8 glasses of water each day."
- **e** "Here is a list of foods that are high in potassium—you need to avoid these."
- **f** "Please call your doctor immediately if you notice muscle weakness or increased dizziness."

7 The order reads: Give mannitol 0.5 g/kg IV now, over 2 hours. The patient weighs 165 lb, and you have a 100-mL vial of 20% mannitol. How many grams will the patient receive? How many milliliters of mannitol will you prepare for this infusion?

1. d, 2. a, 3. c, 4. b, 5. d, 6. a, c, f, 7. 37.5 g, 187.5 mL

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Review the function of fluid volume and compartments within the body as well as the role of each of the major electrolytes in maintaining homeostasis.
2 Identify the various electrolytes, and give normal serum values for each.
3 Briefly discuss the various fluid and electrolyte disorders that commonly occur in the body with attention to fluid volume and/or electrolyte deficits and excesses.
4 Identify the fluid and electrolyte solutions commonly used to correct states of deficiency or excess.
5 Discuss the mechanisms of action, indications, dosages, routes of administration, contraindications, cautions, adverse effects, toxicity, and drug interactions of the various fluid and electrolyte solutions.
6 Compare the various solutions used to expand and/or decrease a patient's fluid volume and electrolytes with regard to how they work, why they are used, and specific antidotes available to counter any toxic effects.
7 Develop a nursing care plan that includes all phases of the nursing process for patients receiving fluid and electrolyte solutions.

DRUG PROFILES

albumin, p. 478
conivaptan, p. 483
dextran, p. 479
fresh frozen plasma, p. 480
packed red blood cells, p. 480
potassium, p. 482
sodium chloride, pp. 477, 483
sodium polystyrene sulfonate (potassium exchange resin), p. 482

KEY TERMS

Blood The fluid that circulates through the heart, arteries, capillaries, and veins, carrying nutriment and oxygen to the body cells. It consists of plasma, its liquid component, plus three major solid components: erythrocytes (red blood cells or RBCs), leukocytes (white blood cells or WBCs), and platelets. (p. 474)

Colloids Protein substances that increase the colloid oncotic pressure (p. 478)

Colloid oncotic pressure Another name for oncotic pressure. It is a form of osmotic pressure exerted by protein in blood plasma that tends to pull water into the circulatory system. (p. 475)

Crystalloids Substances in a solution that diffuse through a semipermeable membrane. (p. 476)

KEY TERMS—cont'd

Dehydration Excessive loss of water from the body tissues. It is accompanied by an imbalance in the concentrations of essential electrolytes, particularly sodium, potassium, and chloride. (p. 475)

Edema The abnormal accumulation of fluid in interstitial spaces. (p. 475)

Extracellular fluid (ECF) That portion of the body fluid comprising the interstitial fluid and blood plasma. (p. 475)

Extravascular fluid (EVF) Fluid in the body that is outside the blood vessels. (p. 474)

Gradient A difference in the concentration of a substance on two sides of a permeable barrier. (p. 476)

Hydrostatic pressure (HP) The pressure exerted by a liquid. (p. 475)

Hyperkalemia An abnormally high potassium concentration in the blood, most often due to defective renal excretion but also caused by excessive dietary potassium or certain drugs, such as potassium-sparing diuretics or ACE inhibitors. (p. 480)

Hypernatremia An abnormally high sodium concentration in the blood; may be due to defective renal excretion but is more commonly caused by excessive dietary sodium or replacement therapy. (p. 482)

Hypokalemia A condition in which there is an inadequate amount of potassium, the major intracellular cation, in the bloodstream. (p. 480)

Hyponatremia A condition in which there is an inadequate amount of sodium, the major extracellular cation, in the bloodstream, caused either by inadequate excretion of water or by excessive water intake. (p. 482)

Interstitial fluid (ISF) The extracellular fluid that fills in the spaces between most of the cells of the body. (p. 474)

Intracellular fluid (ICF) The fluid located within cell membranes throughout most of the body. It contains dissolved solutes that are essential to maintaining electrolyte balance and healthy metabolism. (p. 474)

Intravascular fluid (IVF) The fluid inside blood vessels. (p. 474)

Isotonic Having the same concentration of a solute as another solution and hence exerting the same osmotic pressure as that solution, such as an isotonic saline solution that contains an amount of salt equal to that found in the intracellular and extracellular fluid. (p. 475)

Osmotic pressure The pressure produced by a solution necessary to prevent the osmotic passage of solvent into it when the solution and solvent are separated by a semipermeable membrane. (p. 475)

Plasma The watery, straw-colored fluid component of lymph and blood in which the leukocytes, erythrocytes, and platelets are suspended. (p. 474)

Serum The clear, cell-free portion of the blood from which fibrinogen has also been separated during the clotting process, as typically carried out with a laboratory sample. (p. 474)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Fluid and electrolyte management is one of the cornerstones of patient care. Most disease processes, tissue injuries, and surgical procedures greatly influence the physiologic status of fluids and electrolytes in the body. Understanding fluid and electrolyte management requires knowledge of the extent and composition of the various body fluid compartments.

Approximately 60% of the adult human body is water. This is referred to as the *total body water (TBW),* and it is distributed in the three main compartments in the following proportions: **intracellular fluid (ICF),** 67%; **interstitial fluid (ISF),** 25%; and plasma volume, 8%. This distribution is illustrated in Figure 29-1. The actual volume of fluid that would normally be in each compartment in an average 70-kg man with a TBW content of 60% is shown in Table 29-1.

The terms used to identify the various spaces within which the TBW is distributed can be quite confusing, and there are two basic approaches to distinguishing among the locations of the fluid. The TBW can be described as being in or out of the **blood** vessels (vasculature). If this point of reference is used, then the term **intravascular fluid (IVF)** is used to describe the fluid inside the blood vessels and the term **extravascular fluid (EVF)** is used to refer to the fluid outside the blood vessels. Examples of EVF include lymph and cerebrospinal fluid. As these concepts are learned, it is important to remember the difference between the prefixes *intra-* (inside), *inter-* (between), and *extra-* (outside). The term **plasma** is used to describe the fluid that flows through the blood vessels (intravascular fluid). **Serum** is a closely related term (see Key Terms). The interstitial fluid (ISF) is the fluid that is in the space between cells, tissues, and organs. When discussing blood *vessels,* the term extra*vascular* volume is used; extravascular volume is made up of plasma and interstitial fluid (ISF). When discussing *cells,* the term

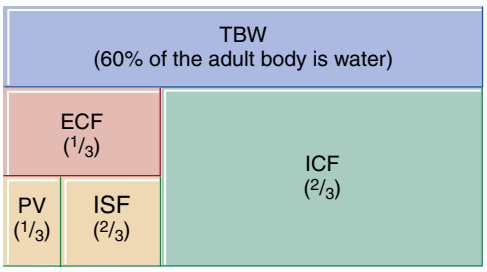

FIGURE 29-1 Distribution of total body water (TBW). *ECF,* Extracellular fluid; *ICF,* intracellular fluid; *ISF,* interstitial fluid; *PV,* plasma volume.

extra*cellular* volume is used; extracellular volume is composed of ISF and intracellular fluid (ICF). These terms are often confused and misused. Table 29-1 lists these definitions for further clarity and understanding.

Extracellular fluid (ECF) consists of both plasma and ISF. There is one big difference between the plasma and the ISF. Plasma has a protein concentration four times greater than that of the ISF, composed primarily of albumin. The reason for this higher intravascular concentration of protein is that these solutes (proteins) have a very large molecular weight, which makes them too large to pass through the walls of the blood vessels. Because of the difference in the concentration, fluid flows from the area of low concentration in the interstitial compartment to the area of high concentration inside the blood vessel, trying to create an **isotonic** environment on either side of the blood vessel wall. (*Isotonic* means an equal concentration of solutes across a membrane.) The protein in the blood vessels exerts a constant **osmotic pressure** that prevents the leakage of too much plasma through the capillaries into the tissues. Because proteins suspended in plasma are in a *colloidal* state, this particular pressure is called **colloid oncotic pressure,** and normally it is 24 mm Hg. The opposing pressure, that exerted by the interstitial fluid (ISF), is called **hydrostatic pressure (HP),** and normally it is 17 mm Hg—which is less than the colloid oncotic pressure. The phenomenon of colloid oncotic pressure is illustrated in Figure 29-2.

TABLE 29-1 FLUID LOCATION: DESCRIPTIVE TERMS AND ACTUAL VOLUMES

TERM	LOCATION	ACTUAL VOLUMES (IN A 70-kg MAN WITH A TBW CONTENT OF 60% OF TOTAL BODY WEIGHT)
If the Point of Reference Is the Cells, These Terms Are Used		
Intracellular fluid (ICF)	Inside of cells	28,000 mL
Extracellular fluid (ECF)	Outside of cells	14,000 mL (composed of both intravascular plasma and interstitial fluid)
If the Point of Reference Is the Blood Vessels, These Terms Are Used		
Intravascular fluid or plasma volume (PV)	In blood vessels	3500 mL
Extravascular fluid (EVF)	Out of blood vessels	38,500 mL
If the Point of Reference Is the Tissues, These Terms Are Used		
Interstitial fluid (ISF)	In the spaces between cells, tissues, and organs but not in the plasma or the cells	10,500 mL

TBW, Total body water.

This regulation of the volume and composition of body water is essential for life, because body water is the medium in which all metabolic reactions occur. The body maintains the volume and composition remarkably constant by preserving the balance between intake and excretion. The amount of water gained each day is kept roughly equal to the amount of water lost. When the body cannot maintain this equilibrium, therapy with various agents is necessary. If the amount of water gained exceeds the amount of water lost, a water excess or overhydration occurs. Such fluid excesses often accumulate in interstitial spaces, such as in the pericardial sac, intrapleural space, peritoneal cavity, joint capsules, and lower extremities. This is referred to as **edema.** In contrast, if the quantity of water lost exceeds that gained, a water deficit, or **dehydration,** occurs. Death often occurs when 20% to 25% of TBW is lost.

Dehydration leads to a disturbance in the balance between the amount of fluid in the extracellular compartment and that in the intracellular compartment. Sodium is the principle extracellular electrolyte and plays a primary role in maintaining water concentration due to its highly osmotic chemistry. In the initial stages of dehydration, water is lost first from the extracellular compartments. The amount of further fluid losses, colloid oncotic pressure changes, or both determines the type of clinical dehydration that develops (Table 29-2). Clinical conditions that can result in dehydration and fluid loss, as well as the symptoms of dehydration and fluid loss, are presented in Table 29-3. When fluid that has been lost must be replaced, there are three categories of agents that can be used to accomplish this: crystalloids, colloids, and blood products. The clinical situation dictates which category of agents is most appropriate.

Acid-base balance is also important to normal bodily functions and is regulated by the respiratory system and the kidney. An *acid* is a substance that can donate or release hydrogen ions, such as carbonic acid or hydrochloric acid. A *base* is a substance that can accept hydrogen ions, such as bicarbonate. The *pH* is a measure of the degree of acidosis and alkalinity and is inversely related to hydrogen ion concentration. For example, when hydrogen ion concentration

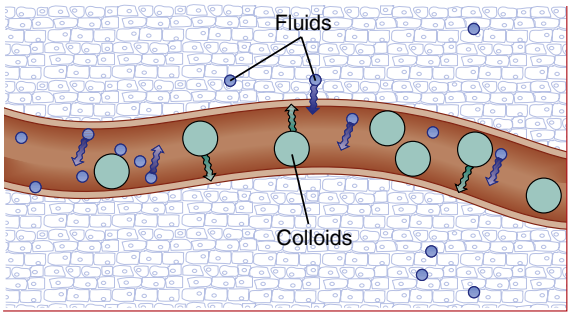

FIGURE 29-2 Colloid osmotic pressure (oncotic pressure). As shown, the colloids inside the blood vessel are too large to pass through the vessel wall. The resulting oncotic pressure exerted by the colloids draws fluid from the surrounding tissues and other extravascular spaces into the blood vessels and also keeps fluid inside the blood vessel.

increases, the pH decreases and leads to acidity. As hydrogen ion concentration decreases, the pH increases, leading to more alkalinity. With the normal pH ranging from 7.35 to 7.45, acidosis occurs when there is an excess of hydrogen or carbon dioxide (CO_2) and the pH falls below 7.35. Conversely, alkalosis occurs when there is a hydrogen or CO_2 deficit and the pH rises above 7.45.

Regulation of the acid-base balance requires healthy functioning of the respiratory and renal systems. The respiratory system compensates for metabolic problems and pH imbalances by regulation of CO_2. In acidosis, CO_2 can be exhaled to try to normalize the lower pH; however, in alkalosis, carbon dioxide will be retained by the respiratory system to try and elevate the pH. The kidney also compensates by reabsorbing and generating bicarbonate and excreting hydrogen ions in acidosis to normalize the low pH. Conversely, the kidney can excrete bicarbonate and retain hydrogen ions to normalize the high pH seen with alkalosis. Certain drugs, such as the diuretic acetazolamide (see Chapter 28) and sodium bicarbonate (tablets or injection), can also be used to correct metabolic acid-base disturbances.

TABLE 29-2 TYPES OF DEHYDRATION

TYPE OF DEHYDRATION	CHARACTERISTICS
Hypertonic	Occurs when water loss is greater than sodium loss, which results in a concentration of solutes outside the cells and causes the fluid inside the cells to move to the extracellular space, thus dehydrating the cells. Example: Elevated temperature resulting in perspiration.
Hypotonic	Occurs when sodium loss is greater than water loss, which results in higher concentrations of solute inside the cells and causes fluid to be pulled from outside the cells (plasma and interstitial spaces) into the cells. Examples: Renal insufficiency and inadequate aldosterone secretion.
Isotonic	Caused by a loss of both sodium and water from the body, which results in a decrease in the volume of extracellular fluid. Examples: Diarrhea and vomiting.

TABLE 29-3 CONDITIONS LEADING TO FLUID LOSS OR DEHYDRATION AND ASSOCIATED CORRESPONDING SYMPTOMS*

CONDITION	ASSOCIATED SYMPTOMS
Bleeding	Tachycardia and hypotension
Bowel obstruction	Reduced perspiration and mucous secretions
Diarrhea	Reduced urine output (oliguria)
Fever	Dry skin and mucous membranes
Vomiting	Reduced lacrimal (tears) and salivary secretions

*There may be overlap involving more than one of the symptoms depending on the patient's specific condition.

PHARMACOLOGY OVERVIEW

CRYSTALLOIDS

Crystalloids are fluids given by intravenous (IV) injection that supply water and sodium to maintain the osmotic **gradient** between the extravascular and intravascular compartments. Their plasma volume–expanding capacity is related to their sodium concentration. The different crystalloids are listed in Table 29-4.

Mechanism of Action and Drug Effects

Crystalloid solutions contain fluids and electrolytes that are normally found in the body. They do not contain proteins (colloids), which are necessary to maintain the colloid oncotic pressure and prevent water from leaving the plasma compartment. In fact, the administration of large quantities of crystalloid solutions for fluid resuscitation decreases the colloid oncotic pressure, due to a dilutional effect. Crystalloids are distributed faster into the interstitial and intracellular compartments than colloids. This makes crystalloids better for treating dehydration than for expanding the plasma volume alone, such as in hypovolemic shock.

Indications

Crystalloid solutions are most commonly used as maintenance fluids. They are used to compensate for insensible fluid losses, to replace fluids, and to manage specific fluid and electrolyte disturbances. Crystalloids also promote urinary flow. They are much less expensive than colloids and blood products. In addition, there is no risk for viral transmission or anaphylaxis and no alteration in the coagulation profile associated with their

TABLE 29-4 CRYSTALLOIDS

	COMPOSITION (mEq/L)							
PRODUCT	Na	Cl	K	Ca	Mg	LACTATE	VOLUME (mL)	COST*
NS	154	154	0	0	0	0	1000	1
Hypertonic saline	513	513	0	0	0	0	500	1

Ca, Calcium; *Cl,* chloride; *D_5W,* 5% dextrose in water; *K,* potassium; *Mg,* magnesium; *Na,* sodium; *NS,* normal saline.
*Relative cost compared with the cost of normal saline; for example, D_5W is two times the cost of normal saline.

use, unlike with blood products. The choice of whether to use a crystalloid or a colloid depends on the severity of the condition. The following are the common indications for either crystalloid or colloid replacement therapy:

- Acute liver failure
- Acute nephrosis
- Adult respiratory distress syndrome
- Burns
- Cardiopulmonary bypass
- Hypoproteinemia
- Reduction of the risk for deep vein thrombosis
- Renal dialysis
- Shock

Contraindications

Contraindications to the use of crystalloids include known drug allergy to a specific product and hypervolemia, and may include severe electrolyte disturbance, depending on the type of crystalloid used.

Adverse Effects

Crystalloids are a very safe and effective means of replacing needed fluid. They do, however, have some unwanted effects. Because they contain no large particles, such as proteins, they do not stay within the blood vessels and can leak out of the plasma into the tissues and cells. This may result in edema anywhere in the body. Peripheral edema and pulmonary edema are two common examples. Crystalloids also dilute the proteins that are in the plasma, which further reduces the colloid oncotic pressure. To be effective, large volumes (liters of fluid) are usually required. As a result, prolonged infusions may worsen acidosis or alkalosis, or adversely affect central nervous system function, due to fluid overload. Another disadvantage of crystalloids is that their effects are relatively short-lived.

Interactions

Interactions with crystalloid solutions are rare because they are very similar if not identical to normal physiologic substances. Certain electrolytes contained in lactated Ringer's solution may be incompatible with other electrolytes, forming a chemical precipitate. Phenytoin precipitates if mixed with dextrose.

Dosages

For the dosage information on crystalloids, see Table 29-5.

DRUG PROFILE

The most commonly used crystalloid solutions are normal saline (NS or 0.9% sodium chloride) and lactated Ringer's solution. The available crystalloid solutions and their compositions are summarized in Table 29-4. Sodium chloride is also discussed briefly in the section on electrolytes and in the Nursing Process section under electrolytes.

sodium chloride

Sodium chloride (NaCl) is available in several concentrations, the most common being 0.9%. This is the physiologically normal concentration of sodium chloride, and it is referred to as *normal saline* (NS). Other concentrations are 0.45% ("half-normal"), 0.25% ("quarter-normal"), 3% (hypertonic saline), and 5% (hypertonic saline). These solutions have different indications and are used in different situations, depending on how urgently fluid volume restoration is needed and/or the extent of the sodium loss.

Sodium chloride is a physiologic electrolyte that is present throughout the body's water. Thus, there are no hypersensitivity reactions to it. It is safe to administer it during any stage of pregnancy, but it is contraindicated in patients with hypernatremia and/or hyperchloremia. Hypertonic saline injections (3% and 5%) are contraindicated in the presence of increased, normal, or only slightly decreased serum electrolyte concentrations. Hypertonic saline is considered a high-risk drug because deaths have occurred when it is infused inappropriately. Correcting sodium too rapidly with hypertonic saline can lead to *osmotic demyelination syndrome,* which is potentially fatal. Conversely, infusing hypotonic saline (0.25% NaCl) is not recommended because it can cause hemolysis of the red blood cells. Adding potassium to hypotonic solutions makes them isotonic and safe to give. Sodium chloride is also available as a 650-mg tablet.

The dose of sodium chloride administered depends on the clinical situation. The volume of crystalloid or colloid needed to expand the plasma volume by 1 L (1000 mL) is given in Table 29-5, and this can be used as a general guide to dosing.

Pharmacokinetics

Plasma Volume Expansion*	Colloid Oncotic Pressure	Duration of Expansion
60-70 mL	30 mm Hg	A few hours

*500 mL of normal saline will expand the plasma volume by 60 to 70 mL.

TABLE 29-5 CRYSTALLOIDS AND COLLOIDS: DOSING GUIDELINES

	CRYSTALLOIDS AND COLLOIDS			
	0.9% SALINE	3% SALINE*	5% COLLOID†	25% COLLOID‡
To Raise Plasma Volume by 1 L, Administer:	5-6 L	1.5-2 L	1 L	0.5 L
Compartment to Which Fluid Is Distributed:				
Plasma	25%	25%	100%	200%-300%
Interstitial space	75%	75%	0	Decreased fluid levels
Intracellular space	0	0	0	Decreased fluid levels

*Hypertonic saline is a high-risk drug and should not be given faster than 100 mL/hr for short periods. Frequent monitoring of serum levels is required.
†Iso-oncotic solutions such as 5% albumin, dextran 70, and hetastarch.
‡Hyperoncotic solutions such as 25% albumin.

COLLOIDS

Colloids are protein substances that increase the colloid oncotic pressure and move fluid from the interstitial compartment to the plasma compartment by pulling the fluid into the blood vessels. Normally, this task is performed by the three blood proteins: albumin, globulin, and fibrinogen. The total protein level must be in the range of 7.4 g/dL. If this level falls below 5.3 g/dL, fluid shifts out of blood vessels into the tissues. When this happens, colloid replacement therapy is required to reverse this process by increasing the colloid oncotic pressure. Colloid oncotic pressure decreases with age and also with hypotension and malnutrition. The commonly used colloids are listed in Table 29-6.

Mechanism of Action and Drug Effects

The mechanism of action of colloids is related to their ability to increase the colloid oncotic pressure. Because the colloids cannot pass into the extravascular space, there is a higher concentration of colloid solutes (solid particles) inside the blood vessels (intravascular space) than outside the blood vessels. Fluid thus moves from the extravascular space into the blood vessels in an attempt to make it isotonic. As such, colloids increase the blood volume, and they are sometimes called *plasma expanders*. They also make up part of the total plasma volume.

Colloids increase the colloid oncotic pressure and move fluid from outside the blood vessels to inside the blood vessels. They can maintain the colloid oncotic pressure for several hours. They are naturally occurring products and consist of proteins (albumin), carbohydrates (dextrans or starches), fats (lipid emulsion), and animal collagen (gelatin). Usually they contain a combination of both small and large particles. The small particles are eliminated quickly and promote diuresis and perfusion of the kidneys; the larger particles maintain the plasma volume. Albumin is the one exception in that it contains particles that are all the same size.

Indications

Colloids are used to treat a wide variety of conditions (see the list on p. 477). Clinically, colloids are superior to crystalloids because of their ability to maintain the plasma volume for a longer time. However, crystalloids are less expensive and are less likely to promote bleeding. Crystalloids are more likely to cause edema because of the larger volumes needed to achieve the desired clinical effect. Crystalloids are better than colloids for emergency short-term plasma volume expansion.

TABLE 29-6 COMMONLY USED COLLOIDS

	COMPOSITION (mEq/L)			
PRODUCT	Na	Cl	VOLUME (mL)	COST*
Dextran 70†	154	154	500	1
Dextran 40†	154	154	500	2
Hetastarch	154	154	500	5
5% Albumin	145	145	500	10
25% Albumin	145	145	100	10

Cl, Chloride; *Na,* sodium.
*Relative cost compared with the cost of dextran 70.
†Dextran is available in NaCl, which has 154 mEq/L of both Na and Cl. It is also available in 5% dextrose in water, which contains no Na or Cl.

Contraindications

Contraindications to the use of colloids include known drug allergy to a specific product and hypervolemia, and may include severe electrolyte disturbance.

Adverse Effects

Colloids are relatively safe agents, although there are some disadvantages to their use. They have no oxygen-carrying ability and contain no clotting factors, unlike blood products. Because of this, they can alter the coagulation system through a dilutional effect, which results in impaired coagulation and possibly bleeding. They may also dilute the plasma protein concentration, which in turn may impair platelet function. Rarely, dextran therapy causes anaphylaxis or renal failure.

Interactions

No drug interactions occur with colloids.

Dosages

For dosage information on colloids, see Table 29-5.

DRUG PROFILES

The specific colloid used for replacement therapy varies from institution to institution. The three most commonly used are 5% albumin, dextran 40, and hetastarch. They all have a very rapid onset of action as well as a long duration of action. They are metabolized in the liver and excreted by the kidneys. Albumin is the one exception; it is metabolized by the reticuloendothelial system and excreted by the kidneys and the intestines. Hetastarch is a synthetic colloid with properties similar to those of albumin and dextran.

albumin

Albumin is a natural protein that is normally produced by the liver. It is responsible for generating approximately 70% of the colloid oncotic pressure. Human albumin is a sterile solution of serum albumin that is prepared from pooled blood, plasma, serum, or placentas obtained from healthy human donors. It is pasteurized (heated at 140° F [60° C] for 10 hours) to destroy any contaminants. Unfortunately, because it is derived from human donors, the supply is limited. Many institutions have specific indications for the use of albumin.

Albumin is contraindicated in patients with a known hypersensitivity to it and in those with heart failure, severe anemia, or renal insufficiency. Albumin is available only in parenteral form in concentrations of 5% and 25%. It is classified as a pregnancy category C drug. See Table 29-5 for dosing guidelines.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Less than 1 min	Unknown	16 hr	Less than 24 hr

dextran

Dextran is a solution of glucose. It is available in three concentrations, dextran 40 and the more concentrated dextran 70 and dextran 75, and it has a molecular weight similar to that of albumin. Dextran 40 is the more commonly used of the two. It is a derivative of sugar that has actions similar to those of human albumin in that it expands the plasma volume by drawing fluid from the interstitial space to the intravascular space.

Dextran is contraindicated in patients with a known hypersensitivity to it and in those with heart failure, renal insufficiency, and extreme dehydration. It is available only in parenteral form in either a 5% dextrose solution or a 0.9% sodium chloride solution. It is classified as a pregnancy category C drug. See Table 29-5 for dosing guidelines.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	5 min	Unknown	2-6 hr	4-6 hr

BLOOD PRODUCTS

Blood products can be thought of as biologic drugs. All of them can augment the plasma volume. Red blood cell (RBC)–containing products can also improve tissue oxygenation, as well as augment plasma volume. Blood products are more expensive than crystalloids and colloids and are less available because they are natural products and require human donors. The available blood products are listed in Table 29-7. They are most often indicated when a patient has lost 25% or more blood volume.

Mechanism of Action and Drug Effects

The mechanism of action of blood products is related to their ability to increase the colloid oncotic pressure, and hence the plasma volume. They do so in the same manner as colloids and crystalloids, by pulling fluid from the extravascular space to the intravascular space. Because of this they are also considered plasma expanders. RBC products also have the ability to carry oxygen. They can maintain the colloid oncotic pressure for several hours to days. Because they come from human donors, they have all the benefits (and hazards) that human blood products have. They are administered when a person's body is deficient in these products.

TABLE 29-7 BLOOD PRODUCTS

PRODUCT	DOSAGE	COST*
Cryoprecipitate	1 unit	1
FFP	1 unit	1.7
PRBCs	1 unit	2.2
PPF	1 unit	1
Whole blood	1 unit	3.33

FFP, Fresh frozen plasma; *PPF,* plasma protein fraction; *PRBCs,* packed red blood cells.
*Relative cost compared with the cost of cryoprecipitate.

Indications

Blood products are used to treat a wide variety of clinical conditions, and the blood product used depends on the specific indication. The available blood products and the specific conditions they are used to treat are listed in Table 29-8.

Contraindications

There are no absolute contraindications to the use of blood products. However, because there is a risk for transfer of infectious disease, although remote, their use needs to be based on careful clinical evaluation of the patient's condition.

Adverse Effects

Blood products can produce undesirable effects, some potentially serious. Because these products come from other humans, they can be incompatible with the recipient's immune system. These incompatibilities are tested for before their administration by determining the respective blood types of the donor and recipient and by performing cross-matching tests to screen for incompatibility between selected blood proteins. This helps reduce the likelihood that the recipient will reject the blood product, which would precipitate transfusion reactions and anaphylaxis. These products can also transmit pathogens from the donor to the recipient. Examples of such pathogens are hepatitis virus and human immunodeficiency virus. Various preparation techniques are now used to reduce the risk for pathogen transmission, and these have resulted in a drastic reduction in the incidence of such problems.

Interactions

As with crystalloids and colloids, blood products are very similar if not identical to normal physiologic substances; therefore, they are involved in very few interactions. Calcium and aspirin, which normally affect coagulation, may interact with these

TABLE 29-8 BLOOD PRODUCTS: INDICATIONS

BLOOD PRODUCT	INDICATION
Cryoprecipitate and PPF	To manage acute bleeding (over 50% blood loss slowly or 20% rapidly)
FFP	To increase clotting factor levels in patients with a demonstrated deficiency
PRBCs	To increase oxygen-carrying capacity in patients with anemia, in patients with substantial hemoglobin deficits, and in patients who have lost up to 25% of their total blood volume
Whole blood	Same as for PRBCs, except that whole blood is more beneficial in cases of extreme (over 25%) loss of blood volume because whole blood also contains plasma, the chief fluid volume of the blood; it also contains plasma proteins, the chief osmotic component, which help draw fluid back into blood vessels from surrounding tissues

FFP, Fresh frozen plasma; *PPF,* plasma protein fraction; *PRBCs,* packed red blood cells.

TABLE 29-9 SUGGESTED GUIDELINES FOR BLOOD PRODUCTS: MANAGEMENT OF BLEEDING

AMOUNT OF BLOOD LOSS	FLUID OF CHOICE
20% or less (slow loss)	Crystalloids
20%-50% (slow loss)	Nonprotein plasma expanders (dextran and hetastarch)
Over 50% (slow loss) or 20% (acutely)	Whole blood or PRBCs, and/or PPF and FFP
80% or more	As above, but for every 5 units of blood given, administer 1 to 2 units of FFP and 1 to 2 units of platelets to prevent the hemodilution of clotting factors and bleeding

FFP, Fresh frozen plasma; *PPF,* plasma protein fraction; *PRBCs,* packed red blood cells.

substances when infused in the body in much the same way that they interact with the body's own blood components. Blood must not be administered with any solution other than normal saline.

Dosages

For dosage information on blood products, see Table 29-9.

DRUG PROFILES

Packed red blood cells (PRBCs) and fresh frozen plasma (FFP) are among the most commonly used blood products. All of the blood products are derived from pooled blood from human donors. Other less commonly used, but still important, blood products are whole blood, plasma protein fraction, cryoprecipitate, and platelets.

packed red blood cells

Packed red blood cells (PRBCs) are obtained by the centrifugation of whole blood and the separation of RBCs from plasma and the other cellular elements. The advantage of PRBCs is that their oxygen-carrying capacity is better than that of the other blood products, and they are less likely to cause cardiac fluid overload. Their disadvantages include high cost, limited shelf life, and fluctuating availability, as well as their ability to transmit viruses, trigger allergic reactions, and cause bleeding abnormalities. The suggested guidelines for their use are given in Table 29-9.

fresh frozen plasma

Fresh frozen plasma (FFP) is obtained by centrifuging whole blood and thereby removing the cellular elements. The resulting plasma is then frozen at –0.4° F (–18° C). FFP is not recommended for routine fluid resuscitation, but it may be used as an adjunct to massive blood transfusion in the treatment of patients with underlying coagulation disorders. The plasma-expanding capability of FFP is similar to that of dextran but slightly less than that of hetastarch. The disadvantage of FFP use is that it can transmit pathogens. The suggested guidelines for use are given in Table 29-9.

PHYSIOLOGY OF ELECTOLYTE BALANCE

The chemical composition of the fluid compartments varies. The principal electrolytes in the extracellular fluid are sodium cations (Na^+) and chloride anions (Cl^-). The major electrolyte in the intracellular fluid (ICF) is the potassium cation (K^+). Other important electrolytes are calcium, magnesium, and phosphorus. These different chemical components are vital to the normal function of all body systems. They are controlled by the renin-angiotensin-aldosterone system, antidiuretic hormone system, and sympathetic nervous system. When these neuroendocrine systems are out of balance, adverse electrolyte imbalances commonly result. Patients who receive diuretics (see Chapter 28) are at risk of electrolyte abnormalities.

POTASSIUM

Potassium is the most abundant cationic (positively charged) electrolyte inside cells (the intracellular space), where the normal concentration is approximately 150 mEq/L. Approximately 95% of the potassium in the body is intracellular. In contrast, the amount of potassium outside the cells in the plasma ranges from 3.5 to 5 mEq/L. These plasma levels are critical to normal body function.

Potassium is obtained from a variety of foods, the most common being fruit and juices, vegetables, fish, and meats. It has been estimated that for normal body functions to be maintained, a person must consume 5 to 10 mEq of potassium per day. Fortunately, the average daily diet usually provides 35 to 100 mEq of potassium, which is well above the required daily amount. Excess dietary potassium is usually excreted by the kidneys in the urine. However, if the kidneys lose their ability to filter and secrete waste products, potassium can accumulate. Excessive potassium can precipitate ventricular fibrillation and cardiac arrest. Hyperaldosteronism and use of potassium-sparing diuretics can alter normal potassium balance as well. **Hyperkalemia** is the term for an excessive serum potassium level and is defined as a serum potassium level exceeding 5.5 mEq/L. There are several causes of hyperkalemia, including the following:

- Angiotensin-converting enzyme (ACE) inhibitor use
- Burns
- Excessive loss from cells
- Infections
- Metabolic acidosis
- Potassium supplementation
- Potassium-sparing diuretic use
- Renal failure
- Trauma

The opposite of hyperkalemia is **hypokalemia,** or a deficiency of potassium. Hypokalemia is defined as a serum potassium level of less than 3.5 mEq/L. This condition is more often the result of excessive potassium loss than of poor dietary intake, however. As with hyperkalemia, there are many clinical conditions and other situations that can cause it. These include the following:

- Alkalosis
- Increased secretion of mineralocorticoids (hormones of the adrenal cortex)

BOX 29-1 SYMPTOMS OF HYPOKALEMIA

Early	Late
Anorexia	Cardiac dysrhythmias
Hypotension	Neuropathy
Lethargy	Paralytic ileus
Mental confusion	Secondary alkalosis
Muscle weakness	
Nausea	

- Burns*
- Corticosteroid use
- Crash diets
- Diarrhea
- Hyperaldosteronism
- Ketoacidosis
- Consumption of large amounts of licorice
- Loop diuretic use
- Malabsorption
- Prolonged laxative misuse
- Thiazide or thiazide-like diuretic use
- Vomiting

A low serum potassium level can increase the toxicity associated with digoxin, and this can precipitate serious ventricular dysrhythmias.

The early detection of hypokalemia is important to prevent the serious, life-threatening consequences of this metabolic disturbance if it goes untreated. The key to early detection is recognizing its early symptoms, which are generally mild and can easily go unnoticed. Both the early (mild) symptoms and late (severe) symptoms of hypokalemia are listed in Box 29-1. Treatment involves both identifying and treating the cause and restoring the serum potassium levels to normal (higher than 3.5 mEq/L). The consumption of potassium-rich foods can usually correct mild hypokalemia, but clinically significant hypokalemia requires the oral or parenteral administration of a potassium supplement, which usually contains potassium chloride.

Mechanism of Action and Drug Effects

The importance of potassium as the primary intracellular electrolyte is highlighted by the number of life-sustaining physiologic functions that require it. Muscle contraction, the transmission of nerve impulses, and the regulation of heartbeats (the pacemaker function of the heart) are just a few of these functions.

Potassium is also essential for the maintenance of acid-base balance, isotonicity, and the electrodynamic characteristics of the cell. It plays a role in many enzymatic reactions, and it is an essential component in gastric secretion, renal function, tissue synthesis, and carbohydrate metabolism.

Indications

Potassium replacement therapy is indicated in the treatment or prevention of potassium depletion in patients whenever dietary measures prove inadequate. Potassium salts commonly used for this purpose include potassium chloride, potassium phosphate, and potassium acetate. The chloride is required to correct the hypochloremia (low level of chloride in the blood) that commonly accompanies potassium deficiency, and the phosphate is used to correct hypophosphatemia. The acetate salt may be used to raise the blood pH in acidotic conditions.

Other therapeutic effects of potassium are related to its role in the contraction of muscles and the maintenance of the electrical characteristics of cells. Potassium salts may be used to stop irregular heartbeats (dysrhythmias) and to manage the tachydysrhythmias that can occur after cardiac surgery.

Contraindications

Contraindications to potassium replacement products include known allergy to a specific drug product, hyperkalemia from any cause, severe renal disease, acute dehydration, untreated Addison's disease, severe hemolytic disease, and conditions involving extensive tissue breakdown (e.g., multiple trauma, severe burns).

Adverse Effects

The adverse effects of oral potassium are primarily limited to the gastrointestinal (GI) tract, including diarrhea, nausea, and vomiting. More significant effects include GI bleeding and ulceration. The parenteral administration of potassium usually produces pain at the injection site. Cases of phlebitis have been associated with IV administration. The generally accepted maximum concentration for peripheral infusion is 20 to 40 mEq/L and up to 60 mEq/L for a central line. Excessive administration of potassium salts can lead to hyperkalemia and toxic effects. If IV potassium is administered too rapidly, cardiac arrest may occur. IV potassium must not be given faster than 10 mEq/hr to patients who are not on cardiac monitors. For critically ill patients on cardiac monitors, rates of 20 mEq/hr or more may be used.

Toxicity and Management of Overdose

The toxic effects of potassium are the result of hyperkalemia. Symptoms include muscle weakness, paresthesia, paralysis, cardiac rhythm irregularities that can result in ventricular fibrillation, and cardiac arrest. The treatment instituted depends on the degree of the hyperkalemia and ranges from reversal of life-threatening problems to simple dietary restrictions. In the event of severe hyperkalemia, the IV administration of sodium bicarbonate, calcium gluconate or chloride, or dextrose solution with insulin is often required. These drugs correct severe hyperkalemia by causing a rapid intracellular shift of potassium ions, which reduces the serum potassium concentration. Such interventions are often followed with orally or rectally administered sodium polystyrene sulfonate (Kayexalate) or hemodialysis to eliminate the extra potassium from the body. Less critical levels can be reduced with dietary restrictions.

Interactions

Concurrent use of potassium-sparing diuretics and ACE inhibitors can produce a hyperkalemic state. Concurrent use of

*Burn patients can exhibit either hyperkalemia or hypokalemia.

non–potassium-sparing diuretics, amphotericin B, and mineralocorticoids can produce a hypokalemic state.

Dosages

Fluid and electrolyte therapy involves replacing any deficits or losses and/or providing maintenance levels for specific patient requirements. Accordingly, specific dosage amounts of fluids or electrolytes depend on several clinical factors, including the following:

- Specific patient losses
- Efficacy of patient physiologic systems involved in fluid and electrolyte metabolism, especially adrenal, cardiovascular, and kidney functions
- Current drug therapy for pathologic conditions that complicate the amount and duration of replacement
- Selection of oral or parenteral replacement formulations

Suggested dosage guidelines for potassium with subsequent adjustments are 10 to 20 mEq administered orally several times a day or parenteral administration of 30 to 60 mEq every 24 hours.

DRUG PROFILES

potassium

Potassium supplements are administered either to prevent or to treat potassium depletion. The acetate, bicarbonate, chloride, citrate, and gluconate salts of potassium are available for oral administration, including tablets, solutions, elixirs, and powders for solution. The parenteral salt forms of potassium for IV administration are acetate, chloride, and phosphate. The dosage of potassium supplements is usually expressed in milliequivalents of potassium and depends on the requirements of the individual patient. Different salt forms of potassium deliver varying milliequivalent amounts of potassium.

Potassium is contraindicated in patients with severe renal disease, severe hemolytic disease, or Addison's disease and in those with hyperkalemia, acute dehydration, or extensive tissue breakdown stemming from multiple traumas. It is classified as a pregnancy category A drug.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Immediate	Rapid	Variable	Variable

sodium polystyrene sulfonate (potassium exchange resin)

Sodium polystyrene sulfonate (Kayexalate) is known as a *cation exchange resin* and is used to treat hyperkalemia. It is usually administered orally via nasogastric tube or as an enema. It works in the intestine, where potassium ions from the body are exchanged for sodium ions in the resin. Although the drug effects in each case are unpredictable, approximately 1 mEq of potassium is lost from the body per gram of resin administered. It can cause disturbances in electrolytes other than potassium, such as calcium and magnesium. For this reason, patients' electrolytes are closely monitored during treatment with sodium polystyrene sulfonate. In 2011, the FDA required safety labeling changes to state that cases of intestinal or colonic necrosis and other serious GI adverse events (bleeding, ischemic colitis, perforation) had been reported. Kayexelate should not be used in patients who do not have normal bowel function and should be discontinued in patients who develop constipation. It should not be used concurrently with sorbitol. Concurrent use of sorbitol with kayexelate has been implicated in cases of intestinal colonic necrosis. This condition may be fatal. Other adverse effects include hypernatremia, hypokalemia, hypocalcemia, hypomagnesemia, nausea, and vomiting. Drug interactions include antacids and laxatives, which should be avoided. It is typically dosed in multiples of 15 to 30 grams until the desired effect on serum potassium occurs. Onset of action varies from 2 to 12 hours and is generally faster with the oral route than with rectal administration. It is available in 15 g/60 mL suspensions and in a powder for reconstitution. It is classified as a pregnancy category C drug.

SODIUM

Although sodium was discussed under colloids, it is also presented in the electrolyte section because it is most commonly given for replenishing purposes. Sodium is the counterpart of potassium, in that potassium is the principal cation inside cells, whereas sodium is the principal cation outside cells. The normal concentration of sodium outside cells is 135 to 145 mEq/L, and it is maintained through the dietary intake of sodium in the form of sodium chloride, which is obtained from salt, fish, meats, and other foods flavored, seasoned, or preserved with salt.

Hyponatremia is a condition of sodium loss or deficiency and occurs when the serum levels decrease less than 135 mEq/L. It is manifested by lethargy, hypotension, stomach cramps, vomiting, diarrhea, and seizures. Some of the same conditions that cause hypokalemia can also cause hyponatremia, and these are listed on pp. 480-481. Other causes of hyponatremia are excessive perspiration, occurring during hot weather or physical work; prolonged diarrhea or vomiting, especially in young children; renal disorders; and adrenocortical impairment.

Hypernatremia is the condition of sodium excess and occurs when the serum levels of sodium exceed 145 mEq/L. The most common cause is poor renal excretion stemming from kidney malfunction. Inadequate water consumption and dehydration are other causes. Symptoms of hypernatremia include red, flushed skin; dry, sticky mucous membranes; increased thirst; temperature elevation; water retention (edema); hypertension; and decreased or absent urination.

Mechanism of Action and Drug Effects

As one of the body's electrolytes, sodium performs many physiologic roles necessary for the normal function of the body. It is the major cation in extracellular fluid and is involved in the control of water distribution, fluid and electrolyte balance, and osmotic pressure of body fluids. Sodium also participates along with both chloride and bicarbonate in the regulation of acid-base balance. Chloride, the major extracellular anion (negatively charged substance), closely complements the physiologic action of sodium. Sodium is also capable of causing diuresis.

Indications

Sodium is primarily administered for the treatment or prevention of sodium depletion when dietary measures have proved inadequate. Sodium chloride is the primary salt used for this purpose. Mild hyponatremia is usually treated with the oral administration of sodium chloride tablets and/or fluid restriction. Pronounced sodium depletion is treated with IV normal saline or lactated Ringer's solution. These drugs were discussed earlier in this chapter.

Hypertonic saline (3% NaCl) is sometimes used to correct severe hyponatremia. It is considered a high-risk drug because giving it too rapidly or in too high of a dose can cause a syndrome known as *central pontine myelinolysis,* also known as *osmotic demyelination syndrome.* This can cause irreversible brainstem damage.

A new class of drugs for the treatment of euvolemic (normal fluid volume) hyponatremia is the dual arginine vasopressin (AVP) V1A and V2 receptor antagonists. These drugs are conivaptan (Vaprisol) and tolvaptan (Samsca). This class of drugs is often referred to as *vaptans.* Specific information on conivaptan is listed under its drug profile.

Contraindications

The only usual contraindications to the use of sodium replacement products are known drug allergy to a specific product and hypernatremia.

Adverse Effects

The oral administration of sodium chloride can cause gastric upset consisting of nausea, vomiting, and cramps. Venous phlebitis can be a consequence of its parenteral administration.

Toxicity and Management of Overdose

Hypernatremia leads to hypertension, edema, thirst, tachycardia, weakness, convulsions, and possibly coma. Treatment consists of increased fluid intake and dietary restrictions. In more serious cases, diuretics may be required to enhance urinary sodium excretion. IV administration of dextrose in water solution (e.g., 5% dextrose in water [D_5W] or 10% dextrose in water [$D_{10}W$]) may also be helpful by producing both intravascular sodium dilution and enhanced urine volume output.

Interactions

Sodium is not known to interact significantly with any drugs with the exception of the antibiotic Synercid (quinupristin and dalfopristin), with which it is incompatible.

Dosages

Fluid and electrolyte therapy involves replacing any deficit losses and/or providing maintenance levels for specific patient requirements. Accordingly, specific dosage amounts of fluids or electrolytes depend on several clinical factors, as follows:

- Specific patient losses
- Efficacy of patient physiologic systems involved in fluid and electrolyte metabolism, especially adrenal, cardiovascular, and kidney functions
- Current drug therapy for pathologic conditions that complicate the amount and duration of replacement
- Selection of oral or parenteral replacement formulations

Suggested dosage guidelines for sodium chloride with subsequent adjustments are 1 to 2 g administered orally several times a day or parenteral administration of 1 L of sodium chloride injection (NS).

DRUG PROFILES

sodium chloride

Sodium chloride is primarily used as a replacement electrolyte for either the prevention or treatment of sodium loss. It is also used as a diluent for the infusion of compatible drugs and in the assessment of kidney function after a fluid challenge. Sodium chloride is contraindicated in patients who are hypersensitive to it. It is available in many IV preparations and in oral form as 650-mg tablets. It is classified as a pregnancy category C drug.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Immediate	Rapid	Unknown	Variable

conivaptan

Conivaptan (Vaprisol) is a nonpeptide dual arginine vasopressin (AVP) V1A and V2 receptor antagonist. It inhibits the effects of arginine vasopressin, also known as *antidiuretic hormone,* on receptors in the kidneys. It is specifically indicated for the treatment of hospitalized patients with euvolemic hyponatremia, or low serum sodium levels at normal water volumes. Conivaptan is available for IV infusion. The recommended regimen is a loading dose of 20 mg delivered via a 30-minute infusion, followed by an additional infusion of 20 mg continuously over 24 hours. Subsequent infusions can be administered every 1 to 3 days at 20 mg/day via continuous infusion. Dose may be titrated up to 40 mg/day if response is not sufficiently rapid.

Adverse events associated with the use of Vaprisol may include infusion site reactions (e.g., phlebitis, pain), thirst, headache, hypokalemia, vomiting, diarrhea, and polyuria. Closely monitor serum sodium levels during treatment, as overly rapid increases in serum sodium levels have been associated with potentially permanent adverse events, including osmotic demyelination syndrome. Several potential drug-drug interactions have been identified. Conivaptan is metabolized by the hepatic enzyme CYP3A4; co-administration drugs that inhibit this enzyme (including but not limited to ketoconazole, itraconazole, clarithromycin, ritonavir, and indinavir) may increase serum levels. Tolvaptan (Samsca) is an oral version of conivaptan. It is available at 15-mg and 30-mg tablets.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Immediate	Rapid	6.7-8.6 hr	12 hr after infusion is stopped

NURSING PROCESS

ASSESSMENT

For fluid replacement, a patient's needs vary. Any medications or solutions ordered must be given exactly as prescribed and without substitution. However, never take the prescriber's order at face value without confirming any medication order against authoritative resources (e.g., current drug reference guides, *Physician's Desk Reference,* nursing pharmacology textbook, manufacturer's drug insert) or speaking with a pharmacist. Important to remember is that you are responsible for making sure that the drug therapy administration process—beginning with the assessment phase of the nursing process and through to evaluation—is accurate and safe, and meets professional standards of care.

To assist in the development of a thorough assessment, a brief review of the various solutions is needed. Parenterally administered hydrating and hypotonic solutions include 0.25% NaCl and 0.45% NaCl/D_5W. These are used mainly for the prevention and/or treatment of dehydration. D_5W alone in an IV bag is considered isotonic but acts as a hypotonic solution once in the bloodstream. Isotonic solutions (e.g., 0.9% NaCl [normal saline] and lactated Ringer's solution) are customarily used to augment extracellular volume in patients experiencing blood loss and/or severe vomiting. Isotonic NaCl is also used as diluting fluid for blood transfusions because D_5W results in hemolysis of red blood cells (in transfusions). Hypertonic solutions (e.g., 3% or 5% sodium chloride) are used for replacement of fluids and electrolytes in specific situations (see pharmacology discussion).

Because of the potential risks related to the use of these solutions, they are rarely administered outside of the hospital setting. After verifying all prescriber orders and checking for accuracy and completeness (as with all drugs), assess the solution or product, the patient, and the IV site (if applicable). Also assess the following for IV infusions of fluids and/or electrolytes: the solution to be infused, infusion equipment, infusion rate of the solution, concentration of the parenteral solution, related mathematical calculations, laboratory values (e.g., sodium, chloride, potassium), and parenteral compatibilities. More specific assessment of the patient who is to receive a parenteral replacement solution needs to focus on gathering information about the patient's medical history, including diseases of the GI, renal, cardiac, and/or hepatic systems. Obtain a medication history, including a list of prescription drugs, over-the-counter medications, supplements, and herbals. Also take a dietary history including specific dietary habits and recall of all foods consumed during the previous 24 hours. Assess fluid volume and electrolyte status (through laboratory testing and measurement of urinary specific gravity, vital signs, and intake and output). The skin and mucous membranes also reflect a patient's hydration status; assess skin turgor and/or rebound elasticity of skin over the top of the hand and other areas over the body. Document the findings as "immediate" rebound or "delayed" rebound. You count the number of seconds that the patient's skin stays in the pinched-up position, with normal return being immediately or within 3 to 5 seconds.

Potassium is presented first in the discussion of electrolytes, and one important place to begin assessment is knowledge of the normal range, usually 3.5 to 5 mEq/L. Serum potassium levels below 3.5 mEq/L, or hypokalemia, may result in a variety of problems, such as cardiac irregularities and muscle weakness. Early symptoms of hypokalemia include anorexia, hypotension, lethargy, mental confusion, muscle weakness, and nausea. Late symptoms of hypokalemia include cardiac irregularities, neuropathies, and paralytic ileus. Avoid potassium supplementation or use with extreme caution in patients taking ACE inhibitors or potassium-sparing diuretics (such as spironolactone). These drugs are associated with adverse effects of hyperkalemia and, if given with potassium supplementation, could worsen hyperkalemia and possibly result in severe cardiac dysrhythmias. Other concerns regarding contraindications with potassium include severe renal disease, untreated Addison's disease, severe tissue trauma, and acute dehydration. Oral potassium supplements are irritants and may be ulcerogenic; thus, perform a thorough GI tract assessment. If the patient has a history of ulcers or GI bleeding and oral supplementation is prescribed, contact the prescriber for further instructions.

The range of serum potassium levels defined as normal often varies depending on the institution and/or the prescriber. For identification and treatment of hyperkalemia, the normal range of potassium must be established. Realize that potassium levels of 5.3 mEq/L may be identified as abnormally high by some laboratories, whereas other laboratories may categorize 5.0 mEq/L as being abnormally high. Be sure to check hospital policy and laboratory guidelines for normal ranges and report any elevations (or decreases) in serum potassium. However, a serum level exceeding 5.5 mEq/L is considered by most sources to be toxic and dangerous to the patient; report this finding to the prescriber immediately. With close monitoring of patients, the dangerous effects of hyperkalemia (i.e., cardiac dysrhythmias) will hopefully be prevented or at least identified early and treated appropriately to prevent potentially life-threatening complications.

Venous access is an important issue with parenteral potassium supplementation because the vein can be irritated if infiltration occurs or if the solution has not been mixed thoroughly. The following are some important considerations regarding assessment and peripheral venous access (for potassium, sodium, fluid, and any other type of medication given by the IV route): (1) Assess the overall condition of the veins prior to selecting a site. (2) Try to use distal veins first as the IV site. (3) Know the purpose of administering potassium and other electrolytes. (4) Calculate and set the rate, as ordered, for the infusion. (5) Know the anticipated duration of therapy. (6) Know the restrictions imposed by the patient's history. For example, in post-mastectomy patients with lymph node dissection, the affected arm must not be used. The affected arm of a patient with a stroke must not be used. Limb circulation may be inadequate in these

SAFETY: LABORATORY VALUES RELATED TO DRUG THERAPY

Serum Potassium

LABORATORY TEST	NORMAL RANGES	RATIONALE FOR ASSESSMENT
Serum potassium	3.5-5 mEq/L	The main function of potassium is the regulation of water and electrolyte content in the cell. Potassium also assists in the cellular metabolism of carbohydrates and proteins. A decrease is generally considered to be a level less than 5.5 mEq/L. A serum level less than 3.5 mEq/L is known as hypokalemia and a small decrease in potassium levels may have profound effects with lethargy, muscle weakness, hypotension, and cardiac dysrhythmias. A serum potassium level greater than 5 mEq/L is known as hyperkalemia and is manifested by muscle weakness, paresthesia, paralysis, and cardiac rhythm abnormalities. Knowing the normal ranges allows quicker identification of abnormalities and thus more timely management.

situations and lead to edema and other complications if used as a venous access site.

Sodium is another electrolyte that is an ingredient in various IV replacement solutions. Hyponatremia, or serum sodium level below 135 mEq/L, if not resolved with dietary and/or oral intake, may need to be treated with parenteral infusions. Signs and symptoms of hyponatremia include lethargy, hypotension, stomach cramps, vomiting, and diarrhea. Carefully assess venous access sites because of possible irritation of the vein and subsequent phlebitis. If replacement to correct hyponatremic states is overzealous, the result may be hypernatremia with fluid overload, edema, and dyspnea. Assess baseline vital signs. Continually monitor vital signs, hydration status of the skin and mucous membranes, and level of consciousness for safe replacement and prevention of further complications. Contraindications to sodium replacement include elevated serum sodium levels, edema, and hypertension.

Hypernatremia also requires careful assessment. Manifestations of hypernatremia include red, flushed skin; dry, sticky mucous membranes; increased thirst; temperature elevation; water retention (edema), hypertension; and decreased or absent urination. Identifying any precipitating events, medical concerns, and risk-prone patient situations is important to finding early solutions for treatment. The populations at risk for hypernatremia include the elderly, those with renal and cardiovascular diseases, patients who are receiving sodium supplements or who have increased sodium intake, and those with decreased fluid intake. Perform an assessment of cautions, contraindications, and drug interactions.

Albumin and other colloids (e.g., dextran) have associated cautions, contraindications, and drug interactions that need to be assessed. Contraindications include patients with heart failure, severe anemia, and renal insufficiency. The rationale is that these products cause fluids to shift from interstitial to intravascular spaces. This places more strain on the patient's cardiac and respiratory systems. Assess the patient's hematocrit, hemoglobin levels, and serum protein levels. Assess the patient's blood pressure, pulse rate, respiratory status, and intake and output. Document and report any abnormal assessment findings (e.g., dyspnea, edema) immediately.

Fluid infusions may also include the giving of blood or blood components. Obtain a thorough history regarding any transfusions received previously and the patient's response. Report any history of adverse reactions to blood transfusions or problems with PRBCs and/or FFP to the prescriber, and document the nature of these reactions. Assess the status of venous access areas. Check the patient's laboratory values (e.g., hematocrit, hemoglobin, white blood cells [WBCs], RBCs, platelets, and clotting factors). Note baseline vital signs, blood pressure, pulse rate, respiratory rate, and temperature before infusing the blood or blood product. Even the general appearance of the patient, energy levels, ability to carry out activities of daily living, and color of extremities are important to note. Assess for any potential drug interactions, specifically aspirin and calcium, as these may potentially alter clotting. During the infusion of blood components, constantly assess for the occurrence of fever and blood in the urine. Both of these findings are indicative of a reaction requiring immediate medical attention.

In summary, safety and caution are top priorities when patients receive any drug, and fluid and electrolyte replacements are no exception. Deficient and/or excess fluid and electrolyte levels may pose tremendous risks to patients. A thorough assessment is critical to patient safety. In addition, because so many patients receive therapies in the home setting, there is even more accountability and responsibility for performing skillful and thorough assessment before, during, and after therapy.

NURSING DIAGNOSES

1. Risk for falls related to fluid and electrolyte losses
2. Risk for imbalanced fluid volume related to drug-induced fluid and electrolyte deficits and/or excesses.
3. Risk for injury related to complications of the transfusion or infusion of blood products, blood components, or related agents

PLANNING

GOALS

1. Patient remains free from falls and injury.
2. Patient regains balanced fluid volume status.
3. Patient remains free from injury related to complications of blood product infusion.

OUTCOME CRITERIA

1. Patient minimizes risk for falls through careful actions.
   - Patient changes positions slowly and ambulates with assistance until symptoms (e.g., dizziness, lightheadedness) have subsided.
2. Patient regains fluid volume status through replacement of at least 8 to 10 glasses/day or up to 3 L/day of water, unless contraindicated.
   - Patient receives adequate fluid volume infusions with improvement of fluid and electrolyte status.
   - Patient's urinary output is at least 30 mL/hr.
   - Patient reports any dizziness, lethargy, confusion, disorientation, muscle weakness, irregular heart rhythm, and/or abdominal cramping.
3. Patient remains free from injury during infusion of blood products/components.
   - Patient reports any shortness of breath, irregular heart rate or palpitations, or feeling of increased body temperature.
   - Patient's laboratory values (e.g., hemoglobin, hematocrit, RBCs) return to normal levels.

IMPLEMENTATION

Continued monitoring of the patient during fluid or electrolyte therapy is crucial to ensure safe and effective treatment. It is also important to continue monitoring to identify adverse effects early and to prevent complications of overzealous treatment and/or undertreatment. During replacement therapy, serum electrolyte levels need to remain within normal ranges. Educate patients at risk for volume deficits (especially the elderly) about this risk and about the effect of a hot, humid environment on physiologic functioning and the danger of exacerbation by excessive perspiration. Water is at the crux of every metabolic reaction that occurs within the body, and deficits will negatively impact physiologic reactions and alter the composition of fluids and electrolytes. For any age group, staying hydrated at all times is a preventive measure.

With parenteral dosing, you must monitor infusion rates as well as the appearance of the fluid or solution (i.e., potassium and saline solutions are clear, whereas albumin is brown, clear, and viscous). Frequently monitor the IV site, as per facility policy and nursing standards of care, for evidence of infiltration (e.g., swelling, coolness of skin to the touch around IV site, no or decreased flow rate, and no blood return from IV catheter) or thrombophlebitis (e.g., swelling, redness, heat, and pain at IV site). Volume overload, drug toxicity, fever, infection, and emboli are other complications of IV therapy. With the administration of any of these drugs per the IV route, maintain a steady and even flow rate to prevent complications. Ensure that infusion rates follow the prescriber's orders, and recheck all calculations for accuracy. Check the IV site, tubing, IV bag, and fluids or solutions as well as expiration dates. Always behave in a prudent, safe, and thorough manner when administering fluids and electrolyte solutions. Remember that elderly and/or pediatric patients have an increased sensitivity to fluids and electrolytes.

With the various IV solutions, knowing their osmolality and concentrations is important to their safe use. Administration of *isotonic solutions* (e.g., 0.9% sodium chloride, lactated Ringer's solution) requires constant monitoring during and after therapy with vital signs and observation for possible fluid overload, especially in those at risk, or those with heart failure. *Hypertonic solutions* are used rarely because of the risk of cellular dehydration and vascular volume overload. These solutions are also associated with phlebitis and spasm if IV infiltration and/or extravasation occur in the peripheral veins. Therefore, if ordered, administer these solutions through a larger bore vein (e.g., central line), but only with close monitoring of the patient's vital signs and cardiac status.

For the patient who is at risk for hypokalemia, provide educational materials and patient teaching to encourage consumption of certain foods high in potassium. The minimal daily requirement for potassium is between 40 and 50 mEq for adults and 2 to 3 mEq/kg of body weight for infants. Share a list of foods containing potassium with the patient. Two medium-sized bananas or an 8-oz glass of orange juice contains 45 mEq; 20 large dried apricots contain 40 mEq; and a level teaspoon of salt substitute (KCl) contains 60 mEq of potassium. Conversely, if the patient is already hyperkalemic, advise the patient to avoid these food items (see the Patient Teaching Tips for more information). If potassium levels do not increase with dietary changes, supplementation may be needed. Oral preparations of *potassium*, rather than parenteral dosage forms, are preferred whenever possible. Prepare the oral dosage forms per the manufacturer's insert or per policy and standard of care. Generally, oral forms of potassium should be taken with food to minimize gastric distress or irritation. Prepare powder or effervescent forms according to the package guidelines, and mix thoroughly with at least 4 to 6 oz of fluid before administering the medication. Enteric-coated and sustained-release forms may still result in gastric upset and lead to ulcer development (ulcerogenic). With oral supplementation, the safest and most effective intervention is frequent and close monitoring for complaints of nausea, vomiting, abdominal pain, or bleeding (such as the occurrence of melena or blood in the stool and/or hematemesis or blood in the vomitus). If abnormalities are noted, continue to monitor vital signs and other parameters, and report findings to the prescriber immediately. Monitor serum levels of potassium during therapy as well.

Hyperkalemia is treated with *sodium polystyrene sulfonate* (Kayexalate). It is used only under very specific situations

and under very close monitoring of the patient and his or her serum potassium, sodium, calcium, and magnesium levels (see Pharmacology discussion). If Kayexalate is given orally (or via nasogastric tube), elevate the head of the patient's bed to prevent aspiration. The FDA issued a warning in 2011 regarding cases of intestinal necrosis associated with the use of Kayexalate (see pharmacology discussion). Never give Kayexelate with sorbitol because of the connection of these two drugs with the potentially fatal condition of colonic intestinal necrosis. If oral Kayexelate is given, do not give it with antacids or laxatives. Administer each dose as a suspension in a small quantity of water for improved palatability. Follow directions regarding the amount of water to use; it generally ranges from 20 to 100 mL, depending on the dose. If given per the rectal route, a retention enema is used. Follow the medication orders carefully, and expect that more than one dose may be needed. The enema must be retained as long as possible and followed by a physician-prescribed cleansing enema. Usually an initial cleansing enema is prescribed, and then the resin solution is administered. If leakage occurs, elevating the patient's hips on a pillow or placing the patient in a knee-chest position may be helpful.

Potassium chloride is the salt customarily used for IV infusions. The concern and caution with potassium chloride use is to avoid overdosage, because it can lead to cardiac arrest. *IV dosage forms of potassium must always be given in a DILUTED form. There is no use or place for undiluted potassium because undiluted potassium is associated with cardiac arrest!* Therefore, parenteral forms of potassium need to be diluted properly. Nowadays, most pharmacies premix the infusion; however, it is still imperative to double-check the order, amount of diluent, and concentration of potassium to diluent. Never assume that what was premixed is 100% correct, because you are ultimately responsible for whatever you administer. Additionally, *only give diluted potassium when there is adequate urine output of at least 30 mL/hr* (to prevent toxicity). Toxicity or overdosage of potassium (hyperkalemia) is manifested by cardiac rhythm irregularities, muscle spasms, paresthesia, and possible cardiac arrest. Most policy protocols recommend that IV solutions be given at concentrations of less than 40 mEq/L of potassium and a rate not exceeding 20 mEq/hr. As previously discussed, IV potassium is to be given no faster than 10 mEq/hr to those patients not on cardiac monitoring. In patients who are critically ill and on cardiac monitors, a rate of 20 mEq/hr or more may be used. Avoid adding potassium chloride to an already existing IV solution because the exact concentration cannot be accurately calculated and overdosage or toxicity may result. Make sure that all IV fluids are labeled appropriately and documented, as with any medication. If the IV fluid rate must be monitored very closely, an infusion pump may be used. *There is no place for IV push or IV bolus potassium replacement!* Treatment of severe hyperkalemia caused by IV administration is through use of IV sodium bicarbonate, calcium gluconate or chloride, or dextrose solution with insulin. These drugs work by leading to a rapid shifting of potassium ions intracellularly, thereby reducing the serum potassium concentration.

Replacement of sodium carries the same concern regarding dosing and route of administration. When the patient is only mildly depleted, an increase in oral intake of sodium needs to be tried. Food items high in sodium include catsup, mustard, cured meats, cheeses, potato chips, peanut butter, popcorn, and table salt. In some situations, salt tablets may be necessary. If the patient is given salt tablets, advise him or her to take plenty of fluids, up to 3000 mL/24 hr, unless contraindicated. If the sodium deficit requires IV replacement, venous access issues and drip rate are as important as with volume and potassium infusions (see previous discussion regarding IV infusion and IV sites). *Hypertonic saline* (3% NaCl) is sometimes used for severe hyponatremia but is considered to be a high risk due to the possible occurrence of osmotic demyelination syndrome. This occurs if the 3% NaCl is given too fast or in too high amounts. It results in irreversible brainstem damage. Other treatment of hyponatremia includes the use of either IV *conivaptan* (Vaprisol) or orally administered *tolvaptan* (Samsca). These drugs are indicated for euvolemic hyponatremia (see pharmacology discussion). Administer these drugs as ordered while monitoring serum sodium levels. Hypernatremia is treated with increased fluid intake and dietary restrictions, so you must provide thorough and complete patient education. Intravenous dextrose in water (D_5W or $D_{10}W$) may be indicated and helps by creating intravascular sodium dilution and enhanced urine volume output with sodium excretion.

Always carry out IV infusion of *albumin* and other colloids slowly and cautiously. Carefully monitor the patient to prevent fluid overload and potential heart failure, especially in patients who are at particular risk. Fluid overload is evidenced by shortness of breath, crackles at the bases of the lungs, decreased pulse oximeter readings, edema of dependent areas, and increase in weight (see previous parameters). Determine serum hematocrit and hemoglobin values in advance of therapy—as well as during and after therapy—so that any dilutional effects can be determined. For example, if a patient has received albumin and other colloids too quickly, and hypervolemia results, the patient's hemoglobin and hematocrit may actually be decreased. This decrease would be from a caused by dilutional factor because of too much volume in relation to the concentration of solutes. Clinically, the patient would appear to be anemic but in fact the deficit would be attributable to the increase in volume. It is also important to remember that albumin is to be given at room temperature.

For infusion of blood, always check the expiration date of *blood* and/or *blood components* to make sure that the blood is not outdated. *Under NO circumstances is outdated blood to be used!* Policies at most hospitals and other health care agencies require that blood and blood products be double-checked by another registered nurse BEFORE the blood is hung and infused. This is important to prevent a mix-up in blood types. Blood types must always be a major concern because of the possible complications that can occur, some life-threatening, if the wrong blood type is given or if the blood is given to the wrong person. The "Six Rights" of drug administration remain critical in all that you do with medications, and administering blood is no exception.

When blood and blood products are infused, it is important to patient safety to document all vital signs and related parameters before, during, and after administration of the blood product, component (e.g., PRBCs, FFP), or solution. Monitor vital signs, and frequently record during and after administration. A transfusion reaction would most likely be manifested by the occurrence of the following: apprehension, restlessness, flushed skin, increased pulse and respirations, dyspnea, rash, joint or lower back pain, swelling, fever and chills (a febrile reaction beginning 1 hour after the start of administration and possibly lasting up to 10 hours), nausea, weakness, and jaundice. Report these signs and symptoms to the prescriber immediately, and (regardless of when the reaction occurs), stop the blood or product, and keep the IV line patent with isotonic NS solution infusing at a slow rate. Monitor patient and vital signs closely. Always follow the facility's protocol for transfusion reactions.

In summary, encourage patients receiving any type of fluid or electrolyte substance, colloid, or blood component to immediately report unusual adverse effects to their prescriber. Such complaints may include chest pain, dizziness, weakness, and shortness of breath.

EVALUATION

The therapeutic response to *fluid, electrolyte*, and *blood* or *blood component* therapy includes normalization of fluid volume and laboratory values, including RBC and WBC counts, hemoglobin level, hematocrit, and sodium and potassium levels. In addition to review of these laboratory values, evaluation of the patient's cardiac, respiratory, musculoskeletal, and GI functioning is also important. Therapeutic effects include improved energy levels and tolerance of activities of daily living. Skin color will improve, and there will be improved shortness of breath as well as minimal to no chest pain, weakness, or fatigue. Correct treatment of blood volume problems will be evidenced by a return of laboratory values to the normal range, improved vital signs, an increase in energy, and near-normal oxygen saturation levels. The therapeutic response to albumin therapy includes an elevation of blood pressure, decreased edema, and increased serum albumin levels. Frequently monitor for adverse effects of any of these drugs and/or solutions, and check for distended neck veins; shortness of breath; anxiety; insomnia; expiratory crackles; frothy, blood-tinged sputum; and cyanosis (indicative of fluid volume overload).

CASE STUDY

Fluid and Electrolyte Replacement

M.S., an 85-year-old retired engineer, seemed somewhat confused when his daughter came home from work. When she brings him to the emergency department, his blood pressure is 90/62 mm Hg, his heart rate is 114 beats/min, and his skin is dry but cool. His daughter says that he seems "much weaker" than usual, and he is unable to answer questions clearly. His daughter reports that he has "lost his appetite" lately and has not taken in much food or drink. The nurse starts an IV infusion of 0.9% sodium chloride (NS) at 100 mL/hr via a gravity drip infusion.

1. What do you think is M.S.'s main medical problem at this time?

The emergency department is very busy, and when the nurse returns, she is shocked to see that almost the entire 500-mL bag of NS has infused within an hour's time.

2. What will the nurse do first? What will the nurse watch for at this time?
3. When monitoring M.S.'s fluid status, which indicators will the nurse consider the most reliable?

Twenty-four hours after his admission, M.S. is much less confused and is able to move to a chair for lunch without much difficulty. He is receiving 5% dextrose/½ NS with 20 mEq of potassium chloride at a rate of 75 mL/hr via an infusion pump. His daughter notices that the area above the IV insertion site is red, and M.S. complains that the area is "very sore."

4. What is the possible problem with the IV line? What needs to be done at this time?

For answers, see http://evolve.elsevier.com/Lilley.

PATIENT TEACHING TIPS

- As needed, educate the patient about the difference in the signs and symptoms of hyponatremia and hypernatremia. Hyponatremia is manifested by lethargy, hypotension, stomach cramps, vomiting, diarrhea, and seizures. Some of the causes of hyponatremia include excessive perspiration, occurring during hot weather or physical work, and prolonged diarrhea or vomiting.
- Hypernatremia is associated with symptoms of water retention (edema); hypertension; red, flushed skin; dry, sticky mucous membranes; increased thirst; temperature elevation; and decreased or absent urination. The most common cause is poor renal excretion as a result of kidney malfunction. Inadequate water consumption and dehydration are other causes.
- Educate the patient about the early symptoms of hypokalemia, such as anorexia, hypotension, lethargy, mental confusion, nausea, and muscle weakness. Late symptoms include cardiac dysrhythmias (the patient may feel palpitations or shortness of breath), neuropathies, and paralytic ileus.
- Share the symptoms of hyperkalemia with the patient, including muscle weakness, paresthesia, paralysis, and cardiac rhythm abnormalities.
- Provide the patient with adequate and appropriate information about how to take oral potassium chloride. In the directions, include the fact that the powdered or liquid solutions require thorough mixing in at least 4 to 8 oz of cold water/juice before drinking the mixture slowly. Encourage the patient to take oral doses with food or a snack, and tell

PATIENT TEACHING TIPS—cont'd

patients taking potassium supplements to report to the prescriber immediately any GI upset or abdominal pain (indicative of gastric irritation from the oral potassium). Educate the patient about potential drug interactions such as potassium-sparing diuretics and ACE inhibitors because their concurrent use may produce hyperkalemia.

- Educate patients on foods high in potassium, including bananas, oranges, apricots, dates, raisins, broccoli, green beans, potatoes, tomatoes, meats, fish, wheat bread, and legumes.
- Advise patients that sustained-release potassium capsules and tablets must be swallowed whole and should not be crushed, chewed, or allowed to dissolve in the mouth.
- Encourage the patient to report any difficulty in swallowing, painful swallowing, or feeling that the capsule or tablet is getting stuck in the throat. Other serious adverse effects that need to be reported include vomiting of coffee ground–like material, stomach or abdominal pain or swelling, and black tarry stools.
- Educate the patient that extended-release dosage forms of potassium need to be taken in full. Each prescribed dose is to be taken with meals and full glass of water. If the patient has difficulty swallowing the whole tablet, and if approved by the prescriber, the patient can break the tablet in half and take each half separately, drinking half a glass of water (4 oz) with each half and taking the entire dose within a few minutes. The patient must take the full dose and not save partial dosages of potassium for later. Another option is to take the extended-release dosage form and place the whole tablet in 4 ounces of water. Instruct the patient to allow 2 minutes for the tablet to dissolve in the recommended 4 ounces of water, stir for 30 seconds, and then drink immediately. Adding 1 oz of water to the glass, swirling it, and then drinking the residual will allow adequate dosing. Water is recommended as the fluid for mixing the extended-release dosage form. A straw may be used.
- Instruct the patient to dissolve effervescent potassium tablets, as directed. At least 3 ounces of cold water needs to be used per tablet. The patient needs to take the dose as soon as it is fully dissolved, sipping the mixture over 5 to 10 minutes and taking the dose after food to minimize GI upset.
- Educate the patient that salt substitutes contain potassium. Another alternative must be recommended if the patient is hyperkalemic.
- If receiving IV potassium, tell the patient to report any feelings of irritation (e.g., burning) at the IV site.
- Educate the patient about the safe use of salt tablets, and instruct him or her to take them as prescribed. Salt tablets must be taken with adequate fluid intake.

KEY POINTS

- Total body water (TBW) is divided into intracellular (inside the cell) and extracellular (outside the cell) compartments. Fluid volume outside the cells is either in the plasma (intravascular volume) or between the tissues, cells, or organs.
- Colloids are large protein particles that cannot leak out of the blood vessels. Because of their greater concentration inside blood vessels, fluid is pulled into the blood vessels. Examples of colloids include albumin, hetastarch, and dextran. Administer albumin with caution because of the high risk for hypervolemia and possible heart failure. Monitor intake and output, weights, heart and breath sounds, and appropriate laboratory values.
- Blood products are the only fluids that are able to carry oxygen because they are the only fluids that contain hemoglobin. Patients will hopefully begin to show improved energy and increasing tolerance for activities of daily living as a result of the treatments with blood products. Pulse oximeter readings will also show improved readings.
- Dehydration may be hypotonic, resulting from the loss of salt; hypertonic, resulting from fever with perspiration; or isotonic, resulting from diarrhea or vomiting. Each form of dehydration is treated differently. Carefully assess intake and output as well as skin turgor, urine specific gravity, and blood levels of potassium, sodium, and chloride.
- Hypertonic solutions must be used very cautiously and given slowly because of the risk for hypervolemia from overzealous replacement.
- Early symptoms of hypokalemia include anorexia, hypotension, lethargy, mental confusion, nausea, and muscle weakness. Late symptoms include cardiac dysrhythmias (the patient may feel palpitations or shortness of breath), neuropathies, and paralytic ileus.
- Symptoms of hyperkalemia include muscle weakness, paresthesia, paralysis, and cardiac rhythm abnormalities.
- Hyponatremia is manifested by lethargy, hypotension, stomach cramps, vomiting, diarrhea, and seizures. Hypernatremia is associated with symptoms of water retention (edema), hypertension, red, flushed skin; dry, sticky mucous membranes; increased thirst; temperature elevation; and decreased or absent urination.
- With administration of blood products, measurement of vital signs and frequent monitoring of the patient before, during, and after infusions are critical to patient safety. Blood products must be given only with normal saline (0.9% sodium chloride), because the solution of D_5W results in hemolysis of red blood cells.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 Which action by the nurse is most appropriate for the patient receiving an infusion of packed red blood cells?
- **a** Flush the IV line with normal saline before the blood is added to the infusion.
- **b** Flush the IV line with dextrose before the blood is added to the infusion.
- **c** Check the patient's vital signs once the infusion is completed.
- **d** Anticipate that flushed skin and fever are expected reactions to a blood transfusion.

2 When preparing an IV solution that contains potassium, the nurse knows that a contraindication to the potassium infusion would be
- **a** diarrhea.
- **b** serum sodium level of 145 mEq/L.
- **c** serum potassium level of 5.6 mEq/L.
- **d** dehydration.

3 When assessing a patient who is about to receive an albumin infusion, the nurse knows that a contraindication for albumin would be
- **a** acute liver failure.
- **b** heart failure.
- **c** severe burns.
- **d** fluid-volume deficit.

4 The nurse is preparing an infusion for a patient who has a deficiency in clotting factors. Which type of infusion is most appropriate?
- **a** Albumin 5%
- **b** Packed RBCs
- **c** Whole blood
- **d** Fresh frozen plasma

5 While monitoring a patient who is receiving an infusion of a crystalloid solution, the nurse will monitor for which potential problem?
- **a** Bradycardia
- **b** Hypotension
- **c** Decreased skin turgor
- **d** Fluid overload

6 The nurse is administering an IV solution that contains potassium chloride to a patient in the critical care unit who has a severely decreased serum potassium level. Which action(s) by the nurse are appropriate? (Select all that apply.)
- **a** Administer the potassium by slow IV bolus.
- **b** Administer the potassium at a rate no faster than 20 mEq/hr.
- **c** Monitor the patient's cardiac rhythm with a heart monitor.
- **d** Use an infusion pump for the administration of IV potassium chloride.
- **e** Administer the potassium IV push.

7 The order reads: "Infuse 1000 mL of normal saline over the next 8 hours." The IV tubing has a drop factor of 15 gtt/mL. Calculate the mL/hour rate, and calculate the drops/minute setting for the IV tubing with this gravity infusion.

1. a, 2. c, 3. b, 4. d, 5. d, 6. b, c, d, 7. 125 mL/hr; 31 gtt/min

PART 5

Drugs Affecting the Endocrine System

STUDY SKILLS TIPS

Questioning Strategy

QUESTIONING STRATEGY

One of the most important activities for learning is to become actively involved with the text. The best way to achieve this involvement is to develop the habit of asking questions. These questions can be generated using a number of different cues and elements that are part of the part and chapter structure. Some of what you anticipate as related material will not be correct, so you will adjust your expectations as you read the material. For now, focus on asking a lot of questions and making use of everything you know, which can help start the process of answering your questions.

Part Title

As you begin each new part, ask a question to focus your attention, seeking to learn what all the chapters in this part have in common. In Part 5, this question is, "What is the endocrine system?" This same question could be asked of Parts 2 through 9 by simply replacing *endocrine* with the appropriate system for the specific part. Looking at the chapter titles in the part tells you that the endocrine system has to do with the pituitary drugs, thyroid and antithyroid drugs, antidiabetic drugs, adrenal drugs, women's health drugs, and men's health drugs. Although this answer is far too general to demonstrate any real understanding of the endocrine system, it is a beginning and helps keep you aware of what you need to learn from each chapter.

Chapter Titles

Chapter titles provide the first mechanism that can be used to generate questions. The first question to ask about each chapter is a very basic one, involving what the chapter is about. That question is also answered immediately. "What is Chapter 30 about?" It is about pituitary drugs.

The next question is equally obvious but also extremely important. The question to ask next is, "To what do pituitary (see Chapter 30), thyroid and antithyroid (see Chapter 31), antidiabetic (see Chapter 32), adrenal (see Chapter 33), women's health (see Chapter 34), and men's health (see Chapter 35) refer?" Take the chapter title and state it as a question. What do you know about these subjects?

Chapter Objectives

To enhance your study, turn each chapter objective into one or more questions. Here are some possible questions using the objectives from Chapter 32.

Objective 1: Discuss the normal functions of the pancreas.
- What are the normal functions of the pancreas?

Objective 2: Contrast age of onset, signs and symptoms, pharmacologic and nonpharmacologic treatment, incidence, and etiology of type 1 and type 2 diabetes mellitus.
- What is type 1 diabetes mellitus?
- What is type 2 diabetes mellitus?
- How do types 1 and 2 diabetes mellitus differ in age of onset, signs and symptoms, treatment, incidence, and etiology?

Because the objectives tell you what the authors expect you to know at the end of the chapter, starting out with questions based on the objectives will improve your learning and probably save you time.

Chapter Headings

The same principle can be applied to each of the topic headings set out in the chapter. Continuing to use Chapter 32 as a model, here are some samples of questions that might be useful as preparation for reading.

Type 1 Diabetes Mellitus

- What is type 1 diabetes?
- What is mellitus?

As you start to process the chapter headings, you should also notice that they begin to answer some of the questions from the chapter objectives. This is a good time to begin setting up vocabulary cards.

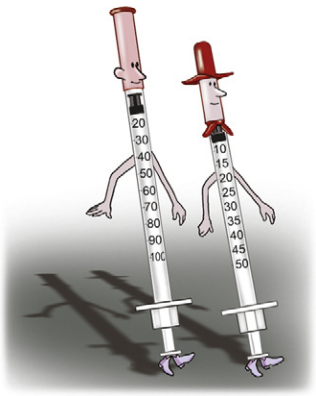
Mechanism of Action and Drug Effects

- What is the mechanism of action of insulin?
- Is there more than one mechanism?
- What are the most important drug effects of insulin?
- Where do these effects take place?
- What is the evidence of these effects?

The idea is to focus on the major content of the chapter and establish a guide for learning as you read.

Print Conventions within the Body of the Chapter

Print conventions are useful in this study skills strategy. The use of *italics,* **bold,** underlining, and **multiple colors of ink** are examples of print conventions. They are designed to catch your attention. Use them as a basis for questions.



In the first paragraph of Chapter 32, the first obvious print convention is the word **insulin.** It is printed in bold and in the color blue. If you let your eyes float down the page and do not read anything, this word stands out. It must be important.
- What is insulin?
- What is the relationship between insulin and type 1 diabetes mellitus?

There are more words on the first page of the chapter text that are in the same print style. Apply the same procedure to these terms. Also, notice that two of the terms, **glycogen** and **glycogenolysis,** must have some direct relationship, because the second term contains the first term. The basic question in each case is, "What does the term mean?" However, there should be more to your questions than just the basics. *Glycogenolysis* seems to mean that there is some operation or activity taking place. Ask yourself the following:
- What happens in glycogenolysis?
- Where does glycogenolysis occur?
- When does glycogenolysis occur?
- How does it relate to type 1 diabetes mellitus?

Chapter Tables

Tables serve as a summary of information discussed in the chapter. You can learn a great deal from tables if you take the time.

Look at Table 32-2. The table summarizes characteristics of type 1 and type 2 diabetes. There are two obvious questions for each type.
- What is type 1 (and type 2) diabetes?
- What are its characteristics?

Use these questions to study Table 32-2 and you will find that all the information you need for responding to these questions is found here. It may be useful to make a first pass through the chapter, focusing only on the tables before you begin to read. You will learn a great deal about some of the topics, and you will have established background information that will help you ask better questions and read with better understanding.

The time you spend asking questions makes the reading and learning go more quickly. Another benefit is that some of the questions you ask may appear on tests. These questions will be easy for you to answer. This promotes test-taking confidence, and better test scores result in better grades. If you have not been using questioning strategy up to this point in your text, begin now. After you use the strategy for two or three chapters, you will find that the benefits far outweigh the time it takes.

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Describe the normal function of the anterior and posterior lobes of the pituitary gland and the impact of the pituitary gland on the human body.
2 Compare the various pituitary drugs with regard to their indications, mechanisms of action, dosages, routes of administration, adverse effects, cautions, contraindications, and drug interactions.
3 Develop a nursing care plan that includes all phases of the nursing process for patients receiving pituitary drugs, such as desmopressin, vasopressin, octreotide, and somatropin.

DRUG PROFILES

- **octreotide, p. 496**
- **somatropin, p. 497**
- **vasopressin, p. 497**

- ***Key drug***

KEY TERMS

Hypothalamus The gland above and behind the pituitary gland and the optic chiasm. Both glands are suspended beneath the middle area of the bottom of the brain. The hypothalamus secretes the hormones vasopressin and oxytocin, which are stored in the posterior pituitary gland. The hypothalamus also secretes several hormone-releasing factors that stimulate the anterior pituitary gland to secrete a variety of hormones that control many body functions. (p. 494)

Negative feedback loop A system in which the production of one hormone is controlled by the levels of a second hormone in a way that reduces the output of the first hormone. A gland produces a hormone that stimulates a second gland to produce a second hormone. In response to the increased levels of the second hormone, the source gland of the first hormone reduces production of that hormone, until blood levels of the second hormone fall below a certain minimum level needed; then the cycle begins again. (p. 494)

Neuroendocrine system The system that regulates the reactions to both internal and external stimuli and involves the integrated activities of the endocrine glands and nervous system. (p. 494)

Pituitary gland An endocrine gland that is suspended beneath the brain and supplies numerous hormones that control many vital processes. (p. 494)

ANATOMY, PHYSIOLOGY AND PATHOPHYSIOLOGY OVERVIEW

ENDOCRINE SYSTEM

Maintenance of physiologic stability is the main goal of the endocrine system. The endocrine system must accomplish this task despite constant changes in the internal and external environments. Every cell and organ in the body comes under the influence of the endocrine system. It communicates with the nearly 50 million target cells in the body using a chemical "language" called *hormones.* Hormones are a large group of natural substances that cause highly specific physiologic effects in the cells of their target tissues. They are secreted into the bloodstream in response to the body's needs and travel through the blood to their site of action—the target cell.

For decades, the pituitary gland was believed to be the master gland that regulated and controlled the other endocrine glands. However, evidence now suggests that the central nervous system (CNS), specifically the **hypothalamus,** controls the pituitary gland. The hypothalamus and pituitary gland are now viewed as functioning together as an integrated unit, with the primary direction coming from the hypothalamus. For this reason, these structures are now commonly referred to as the **neuroendocrine system.** In fact, the endocrine system can be considered in much the same way as the CNS. Each is basically a system for signaling, and each operates in a stimulus-and-response manner. Together these two systems essentially govern all bodily functions.

The **pituitary gland** is made up of two distinct lobes—the anterior pituitary gland (adenohypophysis) and posterior pituitary gland (neurohypophysis). They are individually linked to and communicate with the hypothalamus, and each lobe secretes its own different set of hormones. These various hormones are listed in Box 30-1 and shown in Figure 30-1.

Hormones are either water- or lipid-soluble. The water-soluble hormones are protein-based substances such as the catecholamines norepinephrine and epinephrine. The lipid-soluble hormones consist of the steroid and thyroid hormones.

The activity of the endocrine system is regulated by a system of surveillance and signaling usually dictated by the body's ongoing needs. Hormone secretion is commonly regulated by a **negative feedback loop**. This is best explained using a fictional example: When gland X releases hormone X, this stimulates target cells to release hormone Y. When there is an excess of hormone Y, gland X senses this excess and decreases its release of hormone X.

BOX 30-1 HORMONES OF THE ANTERIOR AND POSTERIOR PITUITARY GLAND

Anterior Pituitary Gland (Adenohypophysis)
Adrenocorticotropic hormone (ACTH)
Follicle-stimulating hormone (FSH)
Growth hormone (GH)
Luteinizing hormone (LH)
Prolactin (PH)
Thyroid-stimulating hormone (TSH)

Posterior Pituitary Gland (Neurohypophysis)
Antidiuretic hormone (ADH)
Oxytocin

PHARMACOLOGY OVERVIEW

PITUITARY DRUGS

A variety of drugs affect the pituitary gland. They are generally used either as replacement drug therapy to make up for a hormone deficiency or as diagnostic aids to determine the status of the patient's hormonal functions. The currently identified anterior and posterior pituitary hormones and the drugs that mimic or antagonize their actions are listed in Table 30-1.

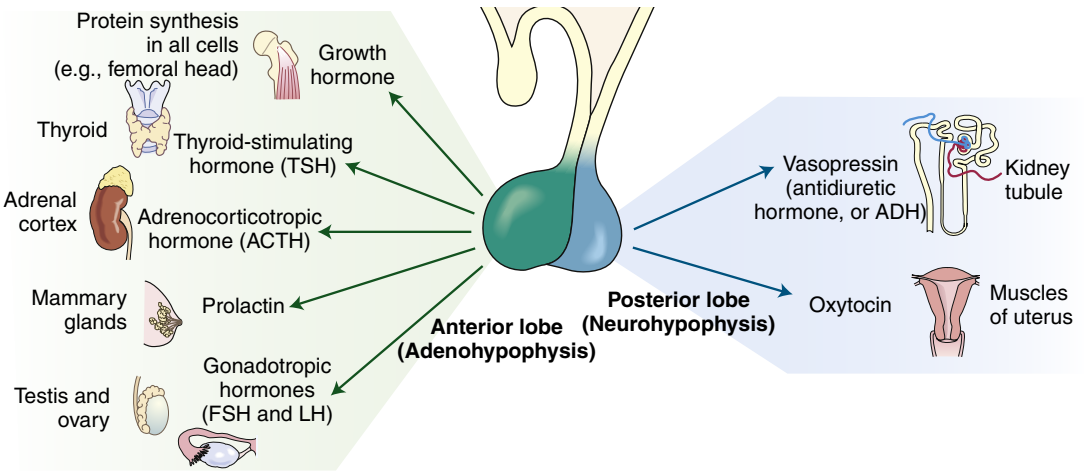

FIGURE 30-1 Pituitary hormones. *FSH,* Follicle-stimulating hormone; *LH,* luteinizing hormone. (Adapted from McKenry LM, Tessier E, Hogan MA: *Mosby's pharmacology in nursing,* ed 22, St Louis, 2006, Mosby.)

The anterior pituitary drugs discussed in this chapter are cosyntropin, somatropin, and octreotide; the posterior pituitary drugs discussed in this chapter are vasopressin and desmopressin.

Mechanism of Action and Drug Effects

The mechanisms of action of the various pituitary drugs differ depending on the drug, but overall they either augment or antagonize the natural effects of the pituitary hormones. Exogenously administered corticotropin elicits all of the same pharmacologic responses as those elicited by endogenous corticotropin (also known as adrenocorticotropic hormone, or ACTH). Intravenous exogenous corticotropin is no longer manufactured; however, an intramuscular/subcutaneous injection, known as H.P. Acthar Gel, is available. The intravenous corticotropin has been replaced by cosyntropin (Cortrosyn). Cosyntropin travels to the adrenal cortex, located just above the kidney, and stimulates the secretion of cortisol (the drug form of which is hydrocortisone [Solu-Cortef]). Cortisol has many antiinflammatory effects, including reduction of inflammatory leukocyte functions and scar tissue formation. Cortisol also promotes renal retention of sodium, which can result in edema and hypertension.

The drugs that mimic growth hormone (GH) are somatropin and somatrem. These drugs promote growth by stimulating various anabolic (tissue-building) processes, liver glycogenolysis (to raise blood sugar levels), lipid mobilization from body fat stores, and retention of sodium, potassium, and phosphorus. Both drugs promote linear growth in children who lack normal amounts of the endogenous hormone.

Octreotide is a drug that antagonizes the effects of natural GH. It does so by inhibiting GH release. Octreotide is a synthetic polypeptide that is structurally and pharmacologically similar to GH release–inhibiting factor, which is also called *somatostatin*. It also reduces plasma concentrations of vasoactive intestinal polypeptide (VIP), a protein secreted by a type of tumor known as a *VIPoma* that causes profuse watery diarrhea (see Chapter 46).

The drugs that affect the posterior pituitary gland, such as vasopressin and desmopressin, mimic the actions of the naturally occurring antidiuretic hormone (ADH). They increase water resorption in the distal tubules and collecting ducts of the nephrons, and they concentrate urine, reducing water excretion by up to 90%. Vasopressin is also a potent vasoconstrictor in larger doses and is therefore used in certain hypotensive emergencies, such as vasodilatory shock (septic shock). It is also used in the Advanced Cardiac Life Support (ACLS) guidelines for treatment of pulseless cardiac arrest. Vasopressin is also used to stop bleeding of esophageal varices. Desmopressin causes a dose-dependent increase in the plasma levels of factor VIII (antihemophilic factor), von Willebrand factor (acts closely with factor VIII), and tissue plasminogen activator. These properties make it useful in treating certain blood disorders. Desmopressin is also used for management of nocturnal enuresis. The drug form of oxytocin mimics the endogenous hormone, thus promoting uterine contractions (see Chapter 34).

Indications

Cosyntropin is used in the diagnosis of adrenocortical insufficiency. Upon diagnosis, the actual drug treatment generally

TABLE 30-1 ANTERIOR AND POSTERIOR PITUITARY HORMONES AND DRUGS

HORMONE	FUNCTION AND MIMICKING DRUG
Anterior Pituitary Gland	
Adrenocorticotropic hormone (ACTH)	Targets adrenal gland; mediates adaptation to physical and emotional stress and starvation; redistributes body nutrients; promotes synthesis of adrenocortical hormones (glucocorticoids, mineralocorticoids, androgens); involved in skin pigmentation
	Cosyntropin: Used for diagnosis of adrenocortical insufficiency
Follicle-stimulating hormone (FSH)	Stimulates oogenesis and follicular growth in females and spermatogenesis in males
	Menotropins: Same pharmacologic effects as FSH; many of the other gonadotropins also stimulate FSH (see Chapter 34)
Growth hormone (GH)	Regulates anabolic processes related to growth and adaptation to stressors; promotes skeletal and muscle growth; increases protein synthesis; increases liver glycogenolysis; increases fat mobilization
	Somatropin, somatrem: Human GH for treatment of hypopituitary dwarfism
	Octreotide: A synthetic polypeptide structurally and pharmacologically similar to GH release–inhibiting factor; inhibits GH
Luteinizing hormone (LH)	Stimulates ovulation and estrogen release by ovaries in females; stimulates interstitial cells in males to promote spermatogenesis and testosterone secretion
	Pergonal and clomiphene: Increase LH levels and the chance of pregnancy
Prolactin	Targets mammary glands; stimulates lactogenesis and breast growth in females; purpose in males in poorly understood
	Bromocriptine: Inhibits action of prolactin and therefore inhibits lactogenesis (see Chapter 15)
Thyroid-stimulating hormone (TSH)	Stimulates secretion of thyroid hormones T_3 and T_4 by the thyroid gland
	Thyrotropin: Increases the production and secretion of thyroid hormones (see Chapter 31)
Posterior Pituitary Gland	
Antidiuretic hormone (ADH)	Increases water resorption in distal tubules and collecting duct of nephron; concentrates urine; causes potent vasoconstriction
	Vasopressin: ADH; performs all the physiologic functions of ADH
	Desmopressin: A synthetic vasopressin
Oxytocin	Targets mammary glands; stimulates ejection of milk and contraction of uterine smooth muscle
	Pitocin: Has all the physiologic actions of oxytocin (see Chapter 34)

T_3, Triiodothyronine; T_4, thyroxine.

involves replacement hormonal therapy using drug forms of the deficient corticosteroid hormones. These drugs are discussed in more detail in Chapter 33. Somatropin and somatrem are human GH produced by recombinant technology. They are effective in stimulating skeletal growth in patients with an inadequate secretion of normal endogenous GH, such as those with hypopituitary dwarfism, and are also used for wasting associated with human immunodeficiency virus infection (HIV). Octreotide is useful in alleviating certain symptoms of carcinoid tumors stemming from the secretion of VIP, including severe diarrhea and flushing and potentially life-threatening hypotension associated with a carcinoid crisis. It is also used for the treatment of esophageal varices. Vasopressin and desmopressin are used to prevent or control polydipsia (excessive thirst), polyuria, and dehydration in patients with diabetes insipidus caused by a deficiency of endogenous ADH. Because of their vasoconstrictor properties, they are useful in the treatment of various types of bleeding, in particular gastrointestinal hemorrhage. Desmopressin is useful in the treatment of hemophilia A and type I von Willebrand's disease because of its effects on various blood-clotting factors.

Contraindications

Contraindications for the use of pituitary drugs vary with each individual drug and are listed in each of the drug profiles included in this chapter. Because even small amounts of these drugs can initiate major physiologic changes, all of them should be used with special caution in patients with acute or chronic illnesses such as migraine headaches, epilepsy, and asthma.

Adverse Effects

Most of the adverse effects of the pituitary drugs are specific to the individual drug. Those drugs possessing similar hormonal effects generally have similar adverse effects. The most common adverse effects of the pituitary drugs described here are listed in Tables 30-2 to 30-4.

Interactions

Selected interactions involving pituitary drugs are summarized in Table 30-5.

Dosages

For dosage information on pituitary drugs, see the table on p. 497.

TABLE 30-2 OCTREOTIDE: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Central nervous	Fatigue, malaise, headache
Endocrine	Increase or decrease in blood glucose levels
Gastrointestinal	Diarrhea, nausea, vomiting
Respiratory	Dyspnea
Musculoskeletal	Arthralgia
Cardiovascular	Conduction abnormalities

DRUG PROFILES

♦ octreotide

Octreotide (Sandostatin) is useful in alleviating certain symptoms of carcinoid tumors stemming from the secretion of VIP, including severe diarrhea and flushing and potentially life-threatening hypotension associated with a carcinoid crisis. It is also used for the treatment of esophageal varices. It is contraindicated in patients who have shown a hypersensitivity to it or any of its components. Octreotide may impair gallbladder function and needs to be used with caution in patients with renal impairment. It may affect glucose regulation, and severe hypoglycemia may occur in patients with type 1 diabetes. It may cause hyperglycemia in patients with type 2

TABLE 30-3 DESMOPRESSIN AND VASOPRESSIN: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Increased blood pressure
Central nervous	Fever, vertigo, headache
Gastrointestinal	Nausea, heartburn, cramps
Genitourinary	Uterine cramping
Other	Nasal irritation and congestion, tremor, sweating

TABLE 30-4 GROWTH HORMONE ANALOGUES: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Central nervous	Headache
Endocrine	Hyperglycemia, hypothyroidism
Genitourinary	Hypercalciuria
Other	Rash, urticaria, development of antibodies to growth hormone, inflammation at injection site, flulike syndrome

TABLE 30-5 PITUITARY DRUGS: SELECTED DRUG INTERACTIONS

PITUITARY DRUG	INTERACTING DRUG	POTENTIAL RESULT
desmopressin	carbamazepine	Enhanced desmopressin effects
	lithium, alcohol, demeclocycline	Reduced desmopressin effects
octreotide	cyclosporine	Case report of transplant rejection
	thioridazine, Ciprofloxacin	Prolongation of QT interval
somatropin	Glucocorticoids	Reduction of growth effects
vasopressin	carbamazepine, fludrocortisone	Enhanced antidiuretic effect
	demeclocycline, norepinephrine, lithium	Reduced antidiuretic effect

DOSAGES

Selected Pituitary Drugs

DRUG	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
♦ octreotide (Sandostatin, Sandostatin LAR Depot)	Somatostatin (GH inhibitor) analogue	**Adult***	Acromegaly
		IV/subcut: Initial dose of 50 mcg bid-tid; may titrate up to 500 mcg tid	Metastatic carcinoid tumor (to control flushing and diarrhea symptoms)
		IV/subcut: 100-750 mcg/day divided bid-qid	VIPoma
		Depot IM: 10-30 mg q4wk	Small bowel fistula
			Esophageal varices
♦ somatropin (Humatrope, others)	Anterior pituitary hormone	**Pediatric**	Growth hormone deficiency
		0.35mg/kg/week IM or subcut	
♦ vasopressin (Pitressin)	Natural or synthetic ADH	**Adult**	Diabetes insipidus
		IM/subcut: 5-10 units bid-qid	
		Pediatric	
		IV: 2.5-10 units bid-qid	
		Adult	Vasodilatory shock (septic shock)
		IV: 0.01-0.04 units/min	
		Pediatric	
		IV: 0.3-0.4 milliunits/kg/min	
		Adult	GI hemorrhage
		IV: 0.2-0.4 unit/min	Esophageal varices
		Pediatric	
		IV: 0.002-0.005 units/kg/min	

ADH, Antidiuretic hormone; *GH,* growth hormone; *GI,* gastrointestinal; *IM,* intramuscular; *IV,* intravenous; *subcut,* subcutaneous; *VIPoma,* vasoactive intestinal peptide–producing tumor.
*Normally used only in adults.

diabetes or in patients without diabetes. Octreotide may enhance the toxic effects of drugs that prolong the QT interval. Ciprofloxacin may enhance the QT-prolonging effects of octreotide. Octreotide can be given intravenously (IV), intramuscularly (IM), or subcutaneously. It is classified as a pregnancy category B drug. Recommended dosages are given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Rapid	0.4-1 hr	1.7-1.9 hr	6-12 hr

♦ somatropin

Somatropin (Humatrope, Nutropin, Serostim, others) is a growth hormone that is indicated in the treatment of growth failure due to inadequate endogenous growth hormone secretion. It is also used for patients with HIV infection with wasting or cachexia in conjunction with antiviral therapy. It is classified as a pregnancy category B or C drug, depending on the manufacturer. Somatropin is contraindicated in patients with hypersensitivity to any component of the product and in children with closed growth plates, patients with tumors, and patients with acute illnesses. Adverse effects include headache, injection site reactions, muscle pain, hypoglycemia, or hyperglycemia. It is important not to shake the product. It is generally given subcutaneously; however, some manufactured products can be given intramuscularly. Check the specific prescribing information before administering.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Subcut or IM	Not available	2-6 hr	2-4 hr (subcut)	18-20 hr

♦ vasopressin

Vasopressin (Pitressin) and desmopressin (DDAVP) are used to prevent or control polydipsia (excessive thirst), polyuria, and dehydration in patients with diabetes insipidus caused by a deficiency of endogenous ADH. Vasopressin is also used to control various types of bleeding (in particular gastrointestinal hemorrhage) and in pulseless arrest and vasodilatory shock. Desmopressin is also useful in the treatment of hemophilia A and type I von Willebrand's disease because of its effects on various blood-clotting factors. Vasopressin is contraindicated in patients with known hypersensitivity. It is classified as a pregnancy category C drug. It should be used with caution in patients with seizure disorders, asthma, cardiovascular disease, and renal disease. IV infiltration may lead to severe vasoconstriction and localized tissue necrosis. Watch the IV site closely for any signs of infiltration, and use a central venous access device when possible. Vasopressin is available as a nasal spray or injection for IM or IV use. When used to treat septic shock, it is given by continuous IV infusion. Both drugs can be given via the nasal route. Vasopressin nasal is used topically to nasal membranes and must not be inhaled. Desmopressin is given via nasal pump.

Pharmacokinetics (vasopressin)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Rapid	1 hr	0.5 hr	2-8 hr

NURSING PROCESS

ASSESSMENT

Before administering any of the pituitary drugs, perform a thorough assessment and document the findings. Assess the patient's height, weight, and vital signs. Take a complete medication history with notation of allergies, prescription drug use, and use of over-the-counter drugs and herbals. With octreotide, the prescriber may order an electrocardiogram prior to use because of the adverse effect of conduction abnormalities. Assess baseline glucose levels and note respiratory status with *octreotide acetate* use. Patients taking octreotide may require special dosing if they have decreased liver and kidney function; therefore, assess and record baseline liver and kidney function tests. It is also important to be sure that assessment includes steps to prevent medication errors and awareness of concerns regarding look-alike sound-alike drugs. Specifically, octreotide acetate, or Sandostatin and Sandostatin LAR are not to be confused with Sandimmune (cyclosporine) or Sandoglobulin (IV immune globulin).

With *desmopressin,* check vital signs and assess for a history of seizures, asthma, or cardiovascular disease. These conditions require cautious use with careful monitoring of vital signs, heart sounds, and breath sounds. If *vasopressin* is being administered for shock, close monitoring in an intensive care setting is needed with ECG, vital signs, and other possibly invasive monitoring methods (e.g., arterial lines, central venous pressure lines, arterial blood gases). Obtain baseline thyroid, glucose, and calcium levels in patients receiving *growth hormones* due to the potential side effects of hyperglycemia, hypothyroidism, and hypercalciuria. Specifically, use of *somatropin* requires attention to the growth, motor skills, height, and weight of the pediatric patient. Additionally, with all of the pituitary drugs, always perform a thorough assessment of cautions, contraindications, and drug interactions prior to their administration.

NURSING DIAGNOSES

1. Disturbed body image related to the specific disease process and/or drug adverse effects and their impact on the patient's physical characteristics
2. Acute pain related to gastrointestinal adverse effects associated with the use of various pituitary drugs
3. Deficient knowledge related to lack of information and experience with pituitary drug treatment

PLANNING

GOALS

1. Patient maintains positive body image while receiving drug therapy.
2. Patient experiences little to no pain related to medication-induced gastrointestinal upset or epigastric distress.
3. Patient gains increased knowledge about drug therapy.

OUTCOME CRITERIA

1. Patient openly verbalizes fears, anxieties, and concerns to health care professionals regarding changes in body image related to disease process and the adverse effects of drug therapy.
2. Patient experiences minimal gastrointestinal upset and gastric distress by taking medication with food or at mealtimes.
3. Patient states specific rationale for drug therapy as well as adverse effects.
   - Patient states the importance of keeping follow-up appointments with the prescriber.

CASE STUDY

Octreotide for VIPoma-Related Diarrhea

J.R., a 56-year-old beautician, has been diagnosed with a VIPoma (vasoactive intestinal peptide–producing tumor). She was scheduled for surgery but developed severe diarrhea. She has been hospitalized because she became dehydrated after 2 days of profuse, watery diarrhea. She has not eaten for several days. In addition to having diarrhea, she is nauseated, has facial flushing, and has lost 5 pounds in 2 days. Intravenous fluid replacement with normal saline has been started, and she will be receiving octreotide (Sandostatin). She had her gallbladder removed 8 years ago but has no history of other illnesses.

1. How does the octreotide work to control the VIPoma-related diarrhea?
2. As J.R. begins therapy with octreotide, the nurse should continue to assess what parameters?

After 2 days of treatment, the episodes of diarrhea have become less frequent. However, the nurse notes that J.R.'s blood glucose levels are elevated.

3. What is the best explanation for this elevation?

For answers, see http://evolve.elsevier.com/Lilley.

IMPLEMENTATION

Octreotide must be given as ordered with attention to the route of administration. To avoid giving the wrong medication, be careful not to confuse octreotide acetate injection with the injectable depot suspension dosage form. Use only clear solutions, and always check for incompatibilities. Make sure patients understand the importance of immediately reporting to the prescriber any abdominal distress such as diarrhea, nausea, or vomiting if not manageable. Stress the importance of follow-up appointments for laboratory testing during treatment with this drug. Monitor glucose levels during therapy, especially if patients are already diabetic. Octreotide may cause alterations in blood glucose levels; closely monitor blood glucose during drug therapy.

Administer *desmopressin* per the prescriber's orders because dosage and route may vary with the indication. Dosage forms include oral, IV, intranasal, and subcutaneous. For desmopressin and somatropin, rotate subcutaneous injection sites (also given IM, in ventral gluteal site) to avoid tissue damage. Mix

injectable solutions by gently swirling the liquid, using only clear solutions. Intranasal use may lead to changes in the nasal mucosa with unpredictable absorption. Instruct the patient to contact the prescriber immediately if the condition worsens. If used in patients diagnosed with diabetes insipidus, fluid intake may be adjusted according to the predicted risk of water intoxication and sodium deficit. See the Patient Teaching Tips for more information on dosage administration.

Vasopressin is available as a nasal spray or as an injection for IM or IV use. Always check the clarity of parenteral solutions before administering the medication, and discard the solution if there are visible particles or any fluid discoloration. Be alert to the adverse effects of elevated blood pressure, fever, nausea, abdominal cramping, or diarrhea. If these worsen or persist, notify the prescriber immediately.

EVALUATION

Once goals and outcome criteria have been reviewed, evaluate the therapeutic responses to these drugs. With *octreotide,* therapeutic effects include improved symptoms related to carcinoid tumors, VIPoma, or esophageal varices. With *vasopressin,* an improvement in diabetes insipidus, esophageal varices, or vasodilatory shock is expected. With *somatropin,* increased growth is expected for whom it is indicated. Adverse effects to evaluate for include fatigue, headache, altered blood glucose levels, diarrhea, nausea, vomiting, conduction disorders, and dyspnea. Adverse effects associated with desmopressin and vasopressin include increased blood pressure, fever, headache, abdominal cramps, and nausea. *Growth hormones* may lead to headache, hyperglycemia, hypothyroidism, hypercalciuria, and flulike syndrome.

PATIENT TEACHING TIPS

- Carefully discuss routes and techniques of administration with the patient and anyone else involved in the patient's care. With pediatric patients, demonstrate the technique of administration to the family or caregiver before discharge, and evaluate comprehension with return demonstrations. Provide written instructions to the patient, if age-appropriate, but also to the parents or caregiver. Keeping a journal about how the drug is being tolerated may prove to be beneficial. As for any medication or illness, the patient should keep a medical alert bracelet, necklace, or wallet card on his or her person at all times.
- Intranasal dosage forms of desmopressin are to be given only after the nasal passages have been cleared. The pump must be primed prior to use. Instruct the patient to prime the nasal pump by pressing down the pump four times. The spray pump delivers 10 mcg of drug each time it is pressed. To administer a 10-mcg dose as ordered, place the spray nozzle in the nostril (for a child, have a parent/adult/caregiver administer the dose) and press the spray pump once. If a higher dose has been prescribed, half the dose is to be administered in each nostril. The pump cannot deliver doses smaller than 10 mcg. Once completed, replace the cap on the bottle. The pump will stay primed for up to 1 week. After 1 week, the pump will require re-priming. Carefully monitor the level of drug left in the pump so that there is always enough medication on hand. The pump may not have enough medication left after 25 doses (at 150 mcg per spray) or 50 doses (at 10 mcg per spray).
- Vasopressin is given topically to the nasal membranes and is not to be inhaled.
- Educate parents about the fact that children with endocrine disorders may have an increased risk of bone problems. Instruct parents that if they notice their child limping, this needs to be evaluated by the prescriber. Closely monitor the diabetic patient for changes in serum glucose levels if he or she is taking ocreotide.
- Water intake amounts may need to be monitored closely in patients with diabetes insipidus. Exact amounts may be prescribed or determined for each patient.

KEY POINTS

- The pituitary gland is composed of two distinct lobes: anterior and posterior. Each lobe secretes its own set of hormones: *anterior:* thyroid-stimulating hormone (TSH), GH, ACTH, prolactin, follicle-stimulating hormone (FSH), luteinizing hormone; *posterior:* ADH, oxytocin.
- Pituitary drugs are used to either mimic or antagonize the action of endogenous pituitary hormones.
- Drugs that mimic the action of endogenous pituitary hormones include cosyntropin, somatropin, somatrem, vasopressin, and desmopressin. A drug that antagonizes the actions of endogenous pituitary hormones is octreotide.
- In the assessment of patients receiving pituitary hormones, measure baseline vital signs, review blood glucose levels, and measure weight.
- For patients receiving somatropin, constantly monitor levels of thyroid hormones and growth hormones. Include measurement of vital signs, intake/output, and weight in the assessment.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A patient is experiencing severe diarrhea, flushing, and life-threatening hypotension associated with carcinoid crisis. The nurse will prepare to administer which drug?
- **a** octreotide (Sandostatin)
- **b** vasopressin (Pitressin)
- **c** somatropin (Humatrope)
- **d** cosyntropin (Cortrosyn)

2 A patient is suspected of having adrenocortical insufficiency. The nurse expects to administer which drug to aid in the diagnosis of this condition?
- **a** octreotide (Sandostatin)
- **b** vasopressin (Pitressin)
- **c** somatropin (Humatrope)
- **d** cosyntropin (Cortrosyn)

3 The nurse is reviewing the medication list for a patient who will be starting therapy with somatropin. Which type of drug would raise a concern that needs to be addressed before the patient starts the somatropin?
- **a** Nonsteroidal antiinflammatory drug for arthritis
- **b** Antidepressant drug
- **c** Penicillin
- **d** Glucocorticoid

4 A patient who is about to be given octreotide is also taking a diuretic, IV heparin, ciprofloxacin (Cipro), and an opioid as needed for pain. The nurse will monitor for what possible interaction?
- **a** Hypokalemia due to an interaction with the diuretic
- **b** Decreased anticoagulation due to an interaction with the heparin
- **c** Prolongation of the QT interval due to an interaction with ciprofloxacin
- **d** Increased sedation if the opioid is given

5 When monitoring for the therapeutic effects of intranasal desmopressin (DDAVP) in a patient who has diabetes insipidus, which assessment finding will the nurse look for as an indication that the medication therapy is successful?
- **a** Increased insulin levels
- **b** Decreased diarrhea
- **c** Improved nasal patency
- **d** Decreased thirst

6 Which drugs have an action similar to that of the naturally occurring hormone ADH? (Select all that apply.)
- **a** cosyntropin (Cortrosyn)
- **b** desmopressin (DDAVP)
- **c** somatropin (Humatrope)
- **d** vasopressin (Pitressin)
- **e** octreotide (Sandostatin)

7 The order reads: "Give ocreotide (Sandostatin) 50 mcg subcut twice a day." The medication is available in an injectable form of 0.05 mg/mL. How many milliliters will the nurse draw up for the ordered dose?

1 mL. 7. d, 6. b, d, 5. d, 4. c, 3. d, 2. d, 1. a

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Briefly describe the normal anatomy and physiology of the thyroid gland.
2 Discuss the various functions of the thyroid gland and related hormones.
3 Describe the differences in the diseases resulting from the hyposecretion and hypersecretion of thyroid gland hormones.
4 Identify the various drugs used to treat the hyposecretion and hypersecretion states of the thyroid gland.
5 Discuss the mechanisms of action, indications, dosages, routes of administration, contraindications, cautions, drug interactions, and adverse effects of the various drugs used to treat hypothyroidism and hyperthyroidism.
6 Develop a nursing care plan that includes all phases of the nursing process for patients receiving thyroid replacement therapy as well as for patients receiving antithyroid drugs.

DRUG PROFILES

- **levothyroxine, p. 504**
- **propylthiouracil, p. 506**

♦ *Key drug*

KEY TERMS

Euthyroid Referring to normal thyroid function. (p. 503)

Hyperthyroidism A condition characterized by excessive production of the thyroid hormones. A severe form of this disorder is called *thyrotoxicosis*. (p. 502)

Hypothyroidism A condition characterized by diminished production of the thyroid hormones. (p. 502)

Thyroid-stimulating hormone (TSH) An endogenous substance secreted by the pituitary gland that controls the release of thyroid gland hormones and is necessary for the growth and function of the thyroid gland (also called *thyrotropin*). (p. 502)

Thyroxine (T_4) The principle thyroid hormone that influences the metabolic rate. (p. 502)

Triiodothyronine (T_3) A secondary thyroid hormone that also affects body metabolism. (p. 502)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

THYROID FUNCTION

The thyroid gland lies across the larynx in front of the thyroid cartilage ("Adam's apple"). Its lobes extend laterally on both sides of the front of the neck. It is responsible for the secretion of three hormones essential for the proper regulation of metabolism: **thyroxine (T_4), triiodothyronine (T_3),** and calcitonin (see Chapter 34). It is located close to and communicates with the parathyroid glands, which lie just above and behind it. The parathyroid glands are two pairs of bean-shaped glands. These glands are made up of encapsulated cells, which are responsible for maintaining adequate levels of calcium in the extracellular fluid, primarily by mobilizing calcium from bone.

Thyroxine (T_4) and triiodothyronine (T_3) are produced in the thyroid gland through the coupling of iodine and the amino acid tyrosine. The iodide (I^-, which is the ionized form of iodine) needed for this process is acquired from the diet. One mg of iodide is needed per week. This iodide is absorbed from the blood and then sequestered by the thyroid gland, where it is concentrated to 20 times its blood level. Here it is also converted to iodine (I_2), which is combined with tyrosine to make diiodotyrosine. The combination of two molecules of diiodotyrosine causes the formation of thyroxine, which therefore has four iodine molecules in its structure (T_4). Triiodothyronine is formed by the coupling of one molecule of diiodotyrosine with one molecule of monoiodotyrosine; thus it has three iodine molecules in its structure (T_3). The biologic potency of T_3 is about four times greater than that of T_4, but T_4 is present in much greater quantities. After the synthesis of these two thyroid hormones, they are stored in the follicles in the thyroid gland in a complex with thyroglobulin (a protein that contains tyrosine and an amino acid) called the *colloid*. When the thyroid gland is signaled to do so, the thyroglobulin–thyroid hormone complex is enzymatically broken down to release T_3 and T_4 into the circulation. This entire process is triggered by **thyroid-stimulating hormone (TSH),** also called *thyrotropin*. Its release from the anterior pituitary gland is stimulated when blood levels of T_3 and T_4 are low.

The thyroid hormones are involved in a wide variety of bodily processes. They regulate the basal metabolic rate and lipid and carbohydrate metabolism, are essential for normal growth and development, control the heat-regulating system (thermoregulatory center in the brain), and have various effects on the cardiovascular, endocrine, and neuromuscular systems. Therefore, hyperfunction or hypofunction of the thyroid gland can lead to a wide range of serious consequences.

PATHOPHYSIOLOGY OF HYPOTHYROIDISM

There are three types of **hypothyroidism.** Primary hypothyroidism stems from an abnormality in the thyroid gland itself. It occurs when the thyroid gland is not able to perform one of its many functions, such as releasing the thyroid hormones from their storage sites, coupling iodine with tyrosine, trapping iodide, converting iodide to iodine, or any combination of these defects. Primary hypothyroidism is the most common of the three types of hypothyroidism. Secondary hypothyroidism begins at the level of the pituitary gland and results from reduced secretion of thyroid stimulating hormone (TSH). TSH is needed to trigger the release of the T_3 and T_4 stored in the thyroid gland. Tertiary hypothyroidism is caused by a reduced level of the thyrotropin-releasing hormone from the hypothalamus. This reduced level, in turn, reduces TSH and thyroid hormone levels. Symptoms of hypothyroidism include cold intolerance, unintentional weight gain, depression, dry brittle hair and nails, and fatigue.

Hypothyroidism can also be classified by when it occurs in the lifespan. Hyposecretion of thyroid hormone during youth may lead to cretinism. Cretinism is characterized by low metabolic rate, retarded growth and sexual development, and possible mental retardation. Hyposecretion of thyroid hormone as an adult may lead to myxedema. Myxedema is a condition manifested by decreased metabolic rate, but it also involves loss of mental and physical stamina, weight gain, hair loss, firm edema, and yellow dullness of the skin.

Some forms of hypothyroidism may result in the formation of a goiter, which is an enlargement of the thyroid gland resulting from its overstimulation by elevated levels of TSH. The TSH level is elevated because there is little or no thyroid hormone in the circulation. Certain drugs can cause hypothyroidism, with amiodarone (see Chapter 25) being the most common. Interestingly, amiodarone can also cause hyperthyroidism.

PATHOPHYSIOLOGY OF HYPERTHYROIDISM

Excessive secretion of thyroid hormones, or **hyperthyroidism,** may be caused by several different diseases. Diseases known to cause hyperthyroidism include Graves' disease, which is the most common cause; Plummer's disease, also known as *toxic nodular disease,* which is the least common cause; multinodular disease; and thyroid storm, which is a severe and potentially life-threatening exacerbation of the symptoms of hyperthyroidism that is usually induced by stress or infection.

Hyperthyroidism can affect multiple body systems, resulting in an overall increase in metabolism. Commonly reported symptoms are diarrhea, flushing, increased appetite, muscle weakness, fatigue, palpitations, irritability, nervousness, sleep disorders, heat intolerance, and altered menstrual flow.

PHARMACOLOGY OVERVIEW

THYROID REPLACEMENT DRUGS

Hypothyroidism is treated with thyroid hormone replacement using various thyroid preparations. These drugs can be either natural or synthetic in origin. The natural thyroid preparations are derived from the thyroid glands of animals such as cattle and hogs. Currently only one natural preparation is available in the United States, and it is called simply *thyroid* or *thyroid, desiccated. Desiccation* is the term for the drying process used to prepare this drug form. All natural preparations are standardized for their iodine content. The synthetic thyroid preparations are

levothyroxine (T_4), liothyronine (T_3), and liotrix (which contains a combination of T_4 and T_3 in a 4:1 ratio). The approximate clinically equivalent doses of the drugs are given in Table 31-1. This information is useful for guiding dosage adjustments when a patient is switched from one thyroid hormone to another. Monitoring of serum TSH and free thyroid hormone levels are required to determine the appropriate dose of thyroid replacement drugs.

Mechanism of Action and Drug Effects

Thyroid drugs work in the same manner as the endogenous thyroid hormones, affecting many body systems. At the cellular level, they work to induce changes in the metabolic rate, including the rate of protein, carbohydrate, and lipid metabolism, and to increase oxygen consumption, body temperature, blood volume, and overall cellular growth and differentiation. They also stimulate the cardiovascular system by increasing the number of myocardial beta-adrenergic receptors. This, in turn, increases the sensitivity of the heart to catecholamines and ultimately increases cardiac output. In addition, thyroid hormones increase renal blood flow and the glomerular filtration rate, which results in a diuretic effect.

Indications

Thyroid preparations are given to replace what the thyroid gland itself cannot produce to achieve normal thyroid hormone levels (**euthyroid** condition). Levothyroxine is the preferred thyroid drug because its hormonal content is standardized and its effect is predictable. Thyroid drugs can also be used for the diagnosis of suspected hyperthyroidism (as in a TSH-suppression test) and in the prevention or treatment of various types of goiters. They are also used for replacement hormonal therapy in patients whose thyroid glands have been surgically removed or destroyed by radioactive iodine in the treatment of thyroid cancer or hyperthyroidism. Hypothyroidism during pregnancy is treated with dosage adjustments every 4 weeks to maintain the TSH level at the lower end of the normal range. Fetal growth may be retarded if maternal hypothyroidism remains untreated during pregnancy.

Contraindications

Contraindications to thyroid preparations include known drug allergy, recent myocardial infarction, adrenal insufficiency, and hyperthyroidism.

TABLE 31-1 THYROID DRUGS: CLINICALLY EQUIVALENT DOSES

THYROID DRUG	APPROXIMATE EQUIVALENT DOSE
Natural Thyroid Preparation	
thyroid	60-65 mg (1 grain)
Synthetic Thyroid Preparations	
levothyroxine	100 mcg or more
liothyronine	25 mcg
liotrix	50 mcg/12.5 mcg (T_4/T_3)

T_3, Triiodothyronine; *T_4,* thyroxine.

Adverse Effects

The adverse effects of thyroid medications are usually the result of overdose. The most significant adverse effect is cardiac dysrhythmia with the risk for life-threatening or fatal irregularities. Other more common undesirable effects are listed in Table 31-2.

Interactions

Thyroid drugs may enhance the activity of oral anticoagulants, the dosages of which may need to be reduced. Taking thyroid preparations concurrently with digitalis glycosides may decrease serum digitalis levels. Cholestyramine binds to thyroid hormone in the gastrointestinal tract, which possibly reduces the absorption of both drugs. Diabetic patients taking a thyroid drug may require increased dosages of their hypoglycemic drugs. In addition, the use of thyroid preparations with epinephrine in patients with coronary disease may induce coronary insufficiency. See Table 31-3 for more drug interactions.

Dosages

For dosage information on the thyroid drugs, see the table on p. 504.

DRUG PROFILE

The most commonly used thyroid replacement drugs are the synthetic drugs levothyroxine and liotrix. Some patients experience better results with the animal-derived products. Although the thyroid drugs differ chemically, their therapeutic actions are all the same. Factors to be considered before the initiation of drug therapy with a thyroid drug include the desired ratio of

TABLE 31-2 THYROID DRUGS: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Tachycardia, palpitations, angina, dysrhythmias, hypertension
Central nervous	Insomnia, tremors, headache, anxiety
Gastrointestinal	Nausea, diarrhea, cramps
Other	Menstrual irregularities, weight loss, sweating, heat intolerance, fever

TABLE 31-3 THYROID DRUGS: INTERACTIONS

DRUG	ACTION
insulin	Decreased efficacy of insulin (resulting in increased blood glucose levels)
Antidiabetic oral drugs	Decreased efficacy of antidiabetic drugs (resulting in increased blood glucose levels)
estrogen	Reduced thyroid drug activity
digoxin	Decreased digoxin effectiveness
phenytoin and fosphenytoin	Reduced levothyroxine effectiveness
phenobarbital	Reduced levothyroxine effectiveness

DOSAGES

Selected Thyroid Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ levothyroxine (Synthroid, Levoxyl, others) (A)	Synthetic thyroid hormone (T_4)	**Adult** PO: 25-200 mcg/day IM/IV: 50% of oral dose	Hypothyroidism
		IV: 300-500 mcg in a single dose; repeat next day 100-300 mcg if necessary	Myxedema coma
		Pediatric 0-12 yr PO: 25-150 mcg/day	Congenital hypothyroidism
liotrix (Thyrolar)	Synthetic thyroid hormone (T_4: T_3 in a 4:1 ratio)	**Adult** PO: 30-120 mg/day **Pediatric** Dose varies depending on age	Hypothyroidism
thyroid, dessicated (Armour Thyroid, Westhroid)	Desiccated thyroid	**Adult** PO: 60-120 mg/day **Pediatric** Dose varies depending on age	Hypothyroidism

IM, Intramuscular; *IV,* intravenous; *PO,* oral.

T_3 to T_4, the cost, and the desired duration of effect. Thyroid hormone replacement drugs are classified as pregnancy category A drugs. They are all contraindicated in patients who have had a hypersensitivity reaction to them in the past and in those with adrenal insufficiency, previous myocardial infarction, or hyperthyroidism.

♦ levothyroxine

Levothyroxine (Levoxyl, Levothroid, Synthroid, others), or T_4, is the most commonly prescribed synthetic thyroid hormone and is generally considered the drug of choice. One advantage it has over the natural thyroid preparations is that it is chemically pure, being 100% T_4 (thyroxine); this makes its effects more predictable than other thyroid preparations. Its half-life is long enough that it only needs to be administered once a day. It is available in oral form and in parenteral form. It is classified as a pregnancy category A drug.

Switching between different brands of levothyroxine during treatment can destabilize the course of treatment. Thyroid function test results need to be monitored more carefully when switching products. Recommended dosages are given in the table on this page. Levothyroxine is dosed in micrograms. A common medication error is to write the intended dose in milligrams instead of micrograms. If not caught, this error would result in a thousandfold overdose. Doses higher than 200 mcg need to be questioned in case this error has occurred. Levothyroxine is available in an intravenous form. The intravenous dose is generally 50% of the oral dose.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	3-5 days	24 hr	6-10 days	24 hr

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Giving IV Doses of Levothyroxine

Care must be taken when preparing IV doses of levothyroxine for infusions. The medication comes in vials for reconstitution, either in 200-mcg or 500-mcg vials. The vials must be reconstituted with 5 mL of 0.9% NaCl to provide a concentration of 40 mcg/mL (the 200-mcg vial) or 100 mcg/mL (the 500-mcg vial).

Problems occur when pharmacy computer systems profile the dose as "X amount of the *vial*" instead of calculating the dose based on the diluted strength. For example, for a dose of 120 mcg, the computer may list the dose as 120 mcg/0.755 vials, when actually the nurse needs to draw up 3 mL (40 mcg/mL) for the 120-mcg dose.

Other errors have occurred when the final volume was miscalculated using 10 mL (the size of the vial), which yields an incorrect concentration of 50 mcg/mL. As a result, the patient received too much medication.

It is essential to remember that the vial must be diluted FIRST, and then the dose is calculated upon the concentration of the reconstituted medication, not the size of the vial.

Data from Institute for Safe Medication Practices (ISMP): ISMP Medication Safety Alert, September 6, 2000, available at www.ismp.org/Newsletters/acutecare/articles/20000906_2.asp. Accessed Sept 2, 2011.

ANTITHYROID DRUGS

Treatment of hyperthyroidism is aimed at treating either the primary cause or the symptoms of the disease. Antithyroid drugs, iodides, ionic inhibitors, surgery, and radioactive isotopes of iodine are used to treat the underlying cause, and drugs such as beta blockers are used to treat the symptoms. The focus of the discussion here is on the antithyroid drugs called *thioamide derivatives,* namely methimazole and propylthiouracil. In addition to the thioamides, radioactive iodine (iodine 131) and potassium iodide may be used to treat hyperthyroidism. Radioactive iodine works by destroying the thyroid

gland, in a process known as *ablation*. It does this by emitting destructive beta rays once it is taken up into the follicles of the thyroid gland. It is a commonly used treatment for both hyperthyroidism and thyroid cancer. Potassium iodide is also used as prophylaxis for radiation exposure (see Chapter 49). Thyroid surgery involves removal of part or all of the thyroid gland. It is usually a very effective way to treat hyperthyroidism, but lifelong hormone replacement therapy is normally required after thyroid surgery.

Mechanism of Action and Drug Effects

Methimazole and propylthiouracil act by inhibiting the incorporation of iodine molecules into the amino acid tyrosine, a process required to make the precursors of T_3 and T_4. By doing so, these drugs impede the formation of thyroid hormone. Propylthiouracil has the added ability to inhibit the conversion of T_4 to T_3 in the peripheral circulation. Neither drug can inactivate already existing thyroid hormone, however.

The drug effects of methimazole and propylthiouracil are primarily limited to the thyroid gland, and their overall effect is a decrease in the thyroid hormone level. Administration of these medications to patients with hyperthyroidism lowers the high levels of thyroid hormone, thereby normalizing the overall metabolic rate.

Indications

Antithyroid drugs are used to treat hyperthyroidism and to prevent the surge in thyroid hormones that occurs after the surgical treatment of or during radioactive iodine therapy for hyperthyroidism or thyroid cancer. In some types of hyperthyroidism, such as that seen in Graves' disease, the long-term administration of these drugs (for several years) may induce a spontaneous remission. Surgical resection of the thyroid gland (thyroidectomy) is often used both in patients who are intolerant of antithyroid drug therapy and in pregnant women, in whom both antithyroid drugs and radioactive iodine therapy are usually contraindicated.

Contraindications

The only usual contraindications to the use of the two antithyroid drugs is known drug allergy. Their use in pregnancy, although necessary, is somewhat controversial. Per the U.S. Food and Drug Administration (FDA), propythiouracil is to be used during the first trimester only, and then methimazole is used for the remainder of the pregnancy. However, there are case reports of scalp abnormalities when methimazole is used. The choice of how to treat pregnant patients is physician specific. Both drugs are classified as pregnancy category D drugs.

Adverse Effects

The most damaging or serious adverse effects of the antithyroid medications are liver and bone marrow toxicity. These and the more common adverse effects of methimazole and propylthiouracil are listed in Table 31-4.

Interactions

Drug interactions that occur with antithyroid drugs include additive leukopenic effects when they are taken in conjunction with other bone marrow depressants and an increase in the activity of oral anticoagulants.

Dosages

For dosage information on propylthiouracil, see the table on this page.

TABLE 31-4 ANTITHYROID DRUGS: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Central nervous	Drowsiness, headache, vertigo, paresthesia
Gastrointestinal	Nausea, vomiting, diarrhea, hepatitis, loss of taste
Genitourinary	Smoky urine, decreased urine output
Hematologic	Agranulocytosis, leukopenia, thrombocytopenia, hypothrombinemia, lymphadenopathy, bleeding
Integumentary	Rash, pruritus
Musculoskeletal	Myalgia, arthralgia
Renal	Increased blood urea nitrogen and serum creatinine levels
Other	Enlarged thyroid gland, nephritis

DOSAGES

Selected Antithyroid Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ propylthiouracil* (generic only) (D)	Antithyroid	**Adult** 300-900 mg/day **Pediatric 6-10 yr** PO: 50-150 mg/day **Pediatric older than 10 yr** PO: 150-300 mg/day	Hyperthyroidism
methimazole (Tapazole)	Antithyroid	**Adult** 15-60 mg/day **Pediatric** 0.2 mg/kg/day with a maximum of 30 mg/day	Hyperthyroidism

PO, Oral.
*Often abbreviated PTU.

DRUG PROFILE

♦ **propylthiouracil**

Propylthiouracil (PTU) is a thioamide antithyroid drug and is classified as a pregnancy category D drug. Approximately 2 weeks of therapy with propylthiouracil may be necessary before symptoms improve. It is available only in oral form as a 50-mg tablet. Methimazole is the only alternative drug in this class and is rarely used clinically. Recommended dosages are given in the table on p. 505.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	24-36 hr	1 hr	1.5-5 hr	2-3 hr

NURSING PROCESS

ASSESSMENT

In assessing the patient taking *thyroid replacement drugs* for hypothyroidism, include baseline vital signs for comparative purposes. Assess levels of T_3, T_4, and TSH before and during drug therapy, as ordered. It is also important to thoroughly assess and document any past and present medical problems or concerns with a thorough physical assessment. Take a medication history that includes drug allergies and a list of all prescription drugs, over-the-counter drugs, herbals, and supplements the patient is taking. Cautions, contraindications, and drug interactions associated with the use of thyroid hormone have been previously discussed; thoroughly assess the patient for these before giving the medication. Review baseline vital signs with increased attention to a history of cardiac dysrhythmias because of the possible adverse effects of cardiac irregularities. These may be life-threatening. For the female patient, perform a thorough assessment of the reproductive system due to the impact of thyroid hormones on this system.

It is also important to remember that certain thyroid hormones may work faster than others because of their dosage form and properties (see the Teamwork and Collaboration: Pharmacokinetic Bridge to Nursing Practice box). Drug interactions that deserve emphasis because of their importance for patient safety and because they involve commonly used medications include interactions with oral anticoagulants (increased activity of the oral anticoagulants), digitalis glycosides (decrease in digitalis levels), cholyestyramine, and oral hypoglycemic drugs. See Table 31-3 for a more detailed listing of drug interactions. If the patient is taking an oral anticoagulant, monitor blood levels of the anticoagulant closely. Lifespan considerations include increased sensitivity to the effects of thyroid medications in elderly patients. Individualization of drug therapy is important with thyroid replacement, because different patients may respond very differently to the same drug and/or dosage.

For *antithyroid drugs,* such as propylthiouracil and methimazole, first measure vital signs and assess for signs and symptoms of thyroid crisis, or what is often called *thyroid storm.* Thyroid storm is manifested by exacerbation of hyperthyroidism symptoms (see pharmacology discussion) and is potentially life-threatening.

TEAMWORK AND COLLABORATION: PHARMACOKINETIC BRIDGE TO NURSING PRACTICE

Thyroid replacement drugs possess very specific pharmacokinetic characteristics, as do many drugs. You must understand the pharmacokinetics to think your way critically through clinical situations involving patients who are taking thyroid replacement drugs. For levothyroxine (Synthroid, Levothroid, Levoxyl), the pharmacokinetic characteristics include an onset of action of 3 to 5 days, peak plasma concentrations within 24 hours, elimination half-life of 6 to 10 days, and a duration of action of 24 hours. Due to the prolonged half-life of this drug, there is an increased risk of toxicity. Toxicity is manifested by the following: weight loss, tachycardia, nervousness, tremors, hypertension, headache, insomnia, menstrual irregularities, and cardiac irregularities or palpitations. Another important pharmacokinetic property is that the drug is protein bound. A highly protein-bound drug acts like a biologic sustained-release drug and remains in the body longer, with increased risk of more interactions with other highly protein-bound drugs as well as greater potential for toxicity. This is yet another example of how important a current and thorough knowledge base about drugs—and specifically about their pharmacokinetics—is to their safe and efficient administration.

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

Thyroid Hormones

- Elderly patients are much more sensitive to thyroid hormone replacement drugs (as they are to most drugs). They are also more likely to experience adverse reactions to thyroid hormones than are patients in any other age group.
- Elderly patients experience more negative consequences related to drug therapy because their hepatic and renal functioning is decreased.
- Thyroid hormone replacement requirements are approximately 25% lower in patients 60 years of age and older than in younger patients. Dosage in elderly patients may therefore need to be adjusted or titrated downward.
- Elderly patients must contact the prescriber immediately if they experience palpitations, chest pain, stumbling, falling, depression, incontinence, sweating, shortness of breath and/or aggravated heart disease, cold intolerance, or weight gain.
- Drug therapy for elderly patients must be initiated with caution and with very individualized dosages. If higher dosages are necessary, increases must be made with the prescriber's guidance and done gradually.

Assessing for thyroid storm also means assessing for potential causes, such as stress or infection. Related cautions and contraindications have been discussed previously, but some important drug interactions to reemphasize include the interactions with oral anticoagulants (which can cause an increase in anticoagulation and thus risk for bleeding) and any medications that may lead to bone marrow suppression or cause leukopenia (antithyroid drugs may cause additive effects or worsening of bone marrow suppression).

NURSING DIAGNOSES

1. Noncompliance due to lack of experience/education regarding thyroid hormone replacement and the need for everyday self-administration.

2. Ineffective health management due to lack of experience/education about the use of thyroid medication
3. Risk for infection related to the bone marrow depression caused by antithyroid medication

PLANNING

GOALS

1. Patient remains compliant with daily administration of thyroid hormone replacement therapy.
2. Patient demonstrates improvement in health management behaviors through more experience/education about the rationale for use of the thyroid drug and related adverse effects.
3. Patient remains free from infection while receiving antithyroid medication.

OUTCOME CRITERIA

1. Patient states the importance of taking thyroid hormone replacement therapy daily as ordered.
   - Patient takes thyroid hormone replacement therapy upon awakening in the morning and on an empty stomach to maximize therapeutic effects.
   - Patient takes medication in a single daily dose before breakfast and does not stop the medication unless consulting with the prescriber.
   - Patient understands the fact that replacement therapy is lifelong in most situations.
2. Patient states the importance of taking the medication as prescribed as well as the rationale for its use (e.g., lifelong replacement therapy).
   - Patient states adverse effects associated with thyroid replacement therapy that need to be reported to the prescriber (i.e., cardiac dysrhythmias [felt as palpitations]).
   - Patient reports adverse effects that may indicate the need for re-regulation of dosage such as signs and symptoms of hyperthyroidism (i.e., irregular heartbeat, palpitations).
3. Patient states ways to decrease the risk for infection while receiving an antithyroid medication, such as avoiding persons with infections, eating a proper diet, getting adequate rest, and increasing fluid intake.

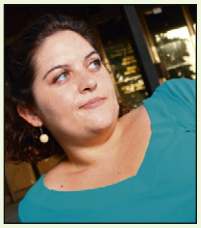
IMPLEMENTATION

When *thyroid drugs* are administered, it is important that the drug be given at the same time every day to help maintain consistent blood levels of the drug. Emphasize to the patient that it is best to administer thyroid drugs once daily in the morning, if possible, to decrease the likelihood of insomnia, which may result from evening dosing and the subsequent increase in energy level. Patients must also avoid interchanging brands because of problems with the bioequivalence of drugs from different manufacturers. If needed, patients may crush tablets. If the patient is scheduled to undergo radioactive iodine isotope studies, the thyroid medication is usually discontinued about 4 weeks before the test, but only as prescribed. Elderly patients may require alteration of the dosage amount, with a decrease of up to 25% for patients 60 years of age and older.

Educate the patient taking the *antithyroid drug* propylthiouracil about dosing the medication with meals to help decrease stomach upset. Any fever, sore throat, mouth ulcers or sores, or skin eruptions, as well as any unusual bleeding or bruising needs to be reported to the prescriber immediately. These symptoms may indicate problems of liver and bone marrow toxicity and possible leukopenia. Further educate patients to avoid the use of iodized salt or eating shellfish because of their potential for altering the drug's effectiveness. Advise patients to be aware of the signs and symptoms of hypothyroidism, including unexplained weight gain, loss of mental and physical stamina, hair loss, firm edema, and yellow dullness of the skin (indicative of myxedema or a decrease in metabolic rate). If these occur, patients must report them immediately to the prescriber. Frequently monitor complete blood counts to watch for potential problems with leukopenia. It is also important to monitor the results of liver function studies during follow-up visits with the prescriber.

CASE STUDY

Antithyroid Drug Therapy



R.C., a 28-year-old woman, has been diagnosed with hyperthyroidism due to Graves' disease. Her health care provider has explained the proposed therapy with propylthiouracil to her and her husband. She has no other known health problems at this time.

1. What laboratory studies will be performed before drug therapy with propylthiouracil is started? Explain your answer.
2. R.C. asks, "What do I need to know while I'm taking this drug?" List pertinent patient teaching points.
3. After 1 month of therapy, R.C. comes into the health care provider's office for a follow-up visit. She is upset because a friend told her about a relative who had antithyroid therapy for cancer and said he was "radioactive." She is wondering if her medication has made her "radioactive." How will the nurse answer her question?
4. Six months later, R.C. calls the office and says, "I think I might be pregnant. What do I do about taking this drug?" What does the nurse need to tell her?

For answers, see http://evolve.elsevier.com/Lilley.

EVALUATION

A therapeutic response to *thyroid drugs* is manifested by the disappearance of the symptoms of hypothyroidism; the patient would demonstrate improved energy levels as well as improved mental and physical stamina. Adverse effects to monitor for include cardiac dysrhythmia (see Table 31-2). Clues that a

patient is possibly receiving inadequate doses of the thyroid medication include a return of the symptoms of hypothyroidism (see previous discussion).

A therapeutic response to *antithyroid medications* includes a return to normal status with little to no evidence of hyperthyroid. Adverse effects include the possibility of leukopenia, which may be manifested by fever, sore throat, lesions, or other signs of infection. Clues that a patient is not receiving adequate doses include continued signs and symptoms of hyperthyroidism (see previous discussion).

PATIENT TEACHING TIPS

- Thyroid replacement drugs are best taken ½ to 1 hour before breakfast on an empty stomach to enhance their absorption orally, maintain constant hormone levels, and help prevent insomnia.
- These medications are not to be abruptly discontinued. Lifelong therapy is usually the norm.
- Emphasize to the patient the importance of keeping follow-up visits so the prescriber can monitor thyroid hormone levels, complete blood counts, and results of liver function studies.
- Brands of thyroid replacement drugs cannot be interchanged. Advise patients to always check that the pharmacy has provided the correct brand of thyroid replacement drug.
- Signs and symptoms associated with hypothyroidism include myxedema with decreased metabolic rate, loss of mental/physical stamina, weight gain, hair loss, firm edema, and yellow dullness of the skin. Share this information with the patient.
- Instruct the patient taking thyroid replacement drugs to immediately report any of the following to the prescriber: chest pain, weight loss, palpitations, tremors, sweating, nervousness, shortness of breath, or insomnia. These may indicate toxicity.
- Encourage the patient to keep a daily journal, with notations about how the patient is feeling, energy levels, appetite, and any adverse effects.
- Advise the patient that it may take up to 3 to 4 weeks to see the full therapeutic effects of thyroid drugs.
- All thyroid tablets must be protected from light.
- Signs and symptoms of hyperthyroidism include increased metabolic rate, diarrhea, flushing, increased appetite, muscle weakness, fatigue, palpitations, irritability, nervousness, sleep disorders, heat intolerance, and altered menstrual flow. Patients with this disorder and on drug therapy need to be aware of these signs and symptoms.
- Antithyroid medications are better tolerated when taken with meals or a snack. These drugs must also be given at the same time every day to maintain consistent blood levels of the drug. They must never be withdrawn abruptly.
- Instruct patients taking thyroid or antithyroid drugs not to take any over-the-counter medications without first consulting with the prescriber or pharmacist and to read all drug labels thoroughly.
- Patients taking antithyroid medications must avoid eating foods high in iodine, such as tofu and other soy products, turnips, seafood, iodized salt, and some breads. These foods may interfere with the effectiveness of the antithyroid drug.

KEY POINTS

- T_4 and T_3 are the two hormones produced by the thyroid gland; thyroid hormones are made by iodination and coupling with the amino acid tyrosine.
- Thyroid hormone replacement is generally carried out carefully by the prescriber with frequent monitoring of serum levels until stabilization appears to have occurred. Monitor and review laboratory values to be sure that serum levels are within normal limits to avoid possible toxicity.
- Hyperthyroidism is caused by excessive secretion of thyroid hormone by the thyroid gland and may be caused by different diseases (Graves' disease, Plummer's disease, and multinodular disease) or drugs. Always assess and document important information about the patient's medical history appropriately.
- Patients receiving levothyroxine need to report the occurrence of excitability, irritability, or palpitations to the prescriber because these symptoms may indicate toxicity.
- Adverse effects associated with thyroid drugs include tachycardia, palpitations, angina, dysrhythmias, hypertension, insomnia, tremors, headache, anxiety, nausea, diarrhea, cramps, menstrual irregularities, weight loss, sweating, fever, and heat intolerance.
- Adverse effects associated with antithyroid drugs include drowsiness, headache, vertigo, nausea, vomiting, diarrhea, loss of taste, bleeding, leukopenia, rash, myalgia, and arthralgia.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 When monitoring the laboratory values of a patient who is taking antithyroid drugs, the nurse knows to watch for
- **a** increased platelet counts.
- **b** decreased white blood cell counts.
- **c** decreased blood urea nitrogen level.
- **d** increased blood glucose levels.

2 The pharmacy has called a patient to notify her that the current brand of thyroid replacement hormone is on back order. The patient calls the clinic to ask what to do. Which is the best response by the nurse?
- **a** "Go ahead and take the other brand that the pharmacy has available for now."
- **b** "You can stop the medication until your current brand is available."
- **c** "You can split the thyroid pills that you have left so that they will last longer."
- **d** "Let me ask your physician what needs to be done; we will need to watch how you do if you switch brands."

3 When assessing the elderly patient, the nurse keeps in mind that certain nonspecific symptoms may represent hypothyroidism in these patients, such as:
- **a** leukopenia, anemia
- **b** loss of appetite, polyuria
- **c** weight loss, dry cough
- **d** cold intolerance, depression

4 To help with the insomnia associated with thyroid hormone replacement therapy, the nurse will teach the patient to
- **a** take half the dose at lunchtime and the other half 2 hours later.
- **b** use a sedative to assist with falling asleep.
- **c** take the dose upon awakening in the morning.
- **d** reduce the dosage as needed if sleep is impaired.

5 The nurse is teaching a patient who has a new prescription for the antithyroid drug propylthiouracil (PTU). Which statement by the nurse is correct?
- **a** "There are no food restrictions while on this drug."
- **b** "You need to avoid foods high in iodine, such as iodized salt, seafood, and soy products."
- **c** "This drug is given to raise the thyroid hormone levels in your blood."
- **d** "Take this drug in the morning on an empty stomach."

6 When teaching a patient who has a new prescription for thyroid hormone, the nurse will instruct the patient to notify the physician if which adverse effects are noted? (Select all that apply.)
- **a** Palpitations
- **b** Weight gain
- **c** Angina
- **d** Fatigue
- **e** Cold intolerance

7 The nurse is giving an intravenous dose of levothyroxine (Synthroid). The order reads: "Give 0.1 mg IV push now." What is the ordered dose in micrograms?

1. b, 2. d, 3. d, 4. c, 5. b, 6. a, c, 7. 100 mcg

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the normal functions of the pancreas.
2 Contrast age of onset, signs and symptoms, pharmacologic and nonpharmacologic treatment, incidence, and etiology of type 1 and type 2 diabetes mellitus.
3 Differentiate gestational diabetes from type 1 and type 2 diabetes mellitus.
4 Discuss the various factors influencing blood glucose level in nondiabetic individuals and in patients with diabetes mellitus.
5 Identify the various drugs used to manage type 1 and type 2 diabetes mellitus.
6 Discuss the mechanisms of action, indications, contraindications, cautions, drug interactions, and adverse effects of insulin, oral antidiabetic drugs, and injectable antidiabetic drugs.
7 Compare rapid-, short-, intermediate-, and long-acting insulins with regard to their onset of action, peak effects, and duration of action.
8 Compare the signs and symptoms of hypoglycemia and hyperglycemia and their related treatments.

KEY TERMS

Diabetes mellitus A complex disorder of carbohydrate, fat, and protein metabolism resulting from the lack of insulin secretion by the beta cells of the pancreas or from defects of the insulin receptors; it is commonly referred to simply as *diabetes.* There are two major types of diabetes: type 1 and type 2. (p. 512)

Diabetic ketoacidosis (DKA) A severe metabolic complication of uncontrolled diabetes that, if untreated, leads to diabetic coma and death. (p. 513)

Gestational diabetes Diabetes that develops during pregnancy. It may resolve after pregnancy but may also be a precursor of type 2 diabetes in later life. (p. 515)

KEY TERMS—cont'd

Glucagon A hormone produced by the alpha cells in the islets of Langerhans that stimulates the conversion of glycogen to glucose in the liver. (p. 511)

Glucose One of the simple sugars that serves as a major source of energy. It is found in foods (e.g., fruits, refined sweets) and also is the final breakdown product of complex carbohydrate metabolism in the body; it is commonly referred to as *dextrose*. (p. 511)

Glycogen A polysaccharide that is the major carbohydrate stored in animal cells. (p. 511)

Glycogenolysis The breakdown of glycogen to glucose. (p. 511)

Hemoglobin A1C (A1C) Hemoglobin molecules to which glucose molecules are bound; blood levels of hemoglobin A1C are used as a diagnostic measure of average daily blood glucose levels in the monitoring and diagnosing of diabetes; it is also called *glycosylated hemoglobin* and most commonly referred to as *A1C*. (p. 515)

Hyperglycemia A fasting blood glucose level of 126 mg/dL or higher or a nonfasting blood glucose level of 200 mg/dL or higher. (p. 512)

Hyperosmolar nonketotic syndrome (HNKS) A metabolic complication of uncontrolled type 2 diabetes, similar in severity to diabetic ketoacidosis but without ketosis and acidosis. (p. 514)

Hypoglycemia A blood glucose level of less than 50 mg/dL, or above 50 mg/dL with signs and symptoms of hypoglycemia. (p. 525)

Impaired fasting glucose level A fasting glucose level of at least 100 mg/dL but lower than 126 mg/dL; it defines a prediabetic state that is sometimes called *prediabetes*. (p. 515)

Insulin A naturally occurring hormone secreted by the beta cells of the islets of Langerhans in the pancreas in response to increased levels of glucose in the blood. (p. 511)

Ketones Organic chemical compounds produced through the oxidation of secondary alcohols (e.g., fat molecules), including dietary carbohydrates. (p. 512)

Polydipsia Chronic excessive intake of water; it is a common symptom of uncontrolled diabetes. (p. 512)

Polyphagia Excessive eating; it is a common symptom of uncontrolled diabetes. (p. 512)

Polyuria Increased frequency or volume of urinary output; it is a common symptom of diabetes. (p. 512)

Type 1 diabetes mellitus Diabetes mellitus that is a genetically determined autoimmune disorder characterized by a complete or nearly complete lack of insulin production; it most commonly arises in children or adolescents. (p. 513)

Type 2 diabetes mellitus A type of diabetes mellitus that most commonly presents in adults and is becoming more common in children and adolescents due to inactivity and weight gain. The disease may be controlled by lifestyle modifications, oral drug therapy, and/or insulin, but patients are not necessarily dependent on insulin therapy. (p. 514)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

PANCREAS

The pancreas is a large, elongated organ that is located behind the stomach. It is both an exocrine gland (secreting digestive enzymes through the pancreatic duct) and an endocrine gland (secreting hormones directly into the bloodstream and not through a duct). The endocrine functions of the pancreas are the focus of this chapter. Two main hormones that are produced by the pancreas are **insulin** and **glucagon.** Both hormones play an important role in the regulation of glucose homeostasis, specifically the use, mobilization, and storage of glucose by the body. **Glucose** is one of the primary sources of energy for the cells of the body. It is also the simplest form of carbohydrate (sugar) found in the body and is often referred to as *dextrose*. There is a normal amount of glucose that circulates in the blood to meet requirements for quick energy. When the quantity of glucose in the blood is sufficient, the excess is stored as **glycogen** in the liver and, to a lesser extent, in skeletal muscle tissue, where it remains until the body needs it. Glucose is also stored in adipose tissue as triglyceride body fat. When more circulating glucose is needed, glycogen—primarily that stored in the liver—is converted back to glucose through a process called **glycogenolysis.** The hormone responsible for initiating this process is glucagon. Glucagon has only minimal effects on muscle glycogen and adipose tissue triglyceride stores.

Glucagon is a protein hormone consisting of a single chain of amino acids (polypeptide chain). Its molecules are about half the size of those of insulin. Glucagon is released from the alpha cells of the islets of Langerhans in the pancreas. Insulin is secreted from the beta cells of these same islets. Insulin is a protein hormone composed of two amino acid chains (acidic A chain and basic B chain) joined by a disulfide linkage. There is a continuous homeostatic balance in the body between the actions of insulin and those of glucagon. This natural balance serves to maintain optimal blood glucose levels, which normally range between 70 and 100 mg/dL. Because of the critical role of the pancreas in producing and maintaining these two hormones, the drastic measures of pancreatic or islet cell transplant are sometimes undertaken to treat type 1 diabetes that has not been successfully controlled by other means. Another common treatment is continuous insulin administration via a mechanized insulin pump, which may be used to treat type 1 or type 2 diabetes.

Insulin serves several important metabolic functions in the body. It stimulates carbohydrate metabolism in skeletal and cardiac muscle and in adipose tissue by facilitating the transport

of glucose into these cells. In the liver, insulin facilitates the phosphorylation of glucose to glucose-6-phosphate, which is then converted to glycogen for storage. By causing glucose to be stored in the liver as glycogen, insulin keeps the kidney free of glucose. Without insulin, blood glucose levels rise; when the kidneys are unable to reabsorb this excess glucose, they excrete large amounts of glucose (a critical body nutrient and energy source), **ketones**, and other solutes into the urine. This loss of nutrient energy sources eventually leads to **polyphagia,** weight loss, and malnutrition. The presence of these solutes in the distal renal tubules and collecting ducts also draws large volumes of water into the urine through osmotic diuresis, which leads to **polyuria,** dehydration, and **polydipsia.**

Insulin also has a direct effect on fat metabolism. It stimulates lipogenesis and inhibits lipolysis and the release of fatty acids from adipose cells. In addition, insulin stimulates protein synthesis and promotes the intracellular shift of potassium and magnesium into the cells, thereby temporarily decreasing elevated blood concentrations of these electrolytes. Other substances such as cortisol, epinephrine, and growth hormone work synergistically with glucagon to counter the effects of insulin and cause increases in the blood glucose level.

PATHOPHYSIOLOGY OF DIABETES MELLITUS

Hyperglycemia is a state involving excessive concentrations of glucose in the blood and results when the normal counterbalancing actions of glucagon and insulin fail to maintain normal glucose homeostasis (i.e., serum levels of 70 to 100 mg/dL). Complications in protein and fat metabolism (*dyslipidemia*; see Chapter 27) are also involved. The current key diagnostic criterion for diabetes mellitus is hyperglycemia with a fasting plasma glucose level of higher than 126 mg/dL or a hemoglobin A1C (A1C) level greater than or equal to 6.5%. Diagnostic indicators are described in more detail in Box 32-1. It is important to note that the diagnostic definition of diabetes established by the American Diabetes Association (ADA) differs from that issued by the American College of Endocrinology. This text uses the ADA as a reference.

Diabetes mellitus, more commonly referred to simply as *diabetes,* is primarily a disorder of carbohydrate metabolism that involves either a deficiency of insulin, a resistance of tissue (e.g., muscle, liver) to insulin, or both. Whatever the cause of the diabetes, the result is hyperglycemia. Uncontrolled hyperglycemia correlates strongly with serious long-term macrovascular and microvascular complications. Macrovascular complications are usually secondary to large vessel damage caused by deposition of atherosclerotic plaque. This compromises both central and peripheral circulation. In contrast, microvascular complications are secondary to damage to the capillary vessels, which impairs peripheral circulation and damages eyes and kidneys. In addition, both autonomic and somatic nerve damage occur, caused primarily by the metabolic changes themselves and to a lesser degree by the compromised circulation. Table 32-1 lists the common long-term complications of diabetes.

Diabetes mellitus has been recognized since 1550 BC, when Egyptians wrote of a malady they called *honeyed urine.* The first step toward identifying the cause of diabetes mellitus occurred in 1788 when Thomas Cawley, an English physician, voiced his suspicion that the source of the illness lay in the pancreas. However, it took over a century to prove this conjecture correct, and it took even longer to discover the active substance, insulin, that is secreted from the pancreas. Not until the early 1920s was insulin finally isolated. Its discovery is now considered one of the greatest triumphs of twentieth-century medicine, and its

BOX 32-1 CRITERIA FOR DIAGNOSIS OF DIABETES

Fasting plasma glucose level of 126 mg/dL or higher, or A1C greater than 6.5%. "Fasting" is defined as no caloric intake for at least 8 hours.

OR

Symptoms of diabetes plus casual plasma glucose level of 200 mg/dL or higher. "Casual" means measured at any time of day without regard to time since last meal. The classic symptoms of hyperglycemia include polyuria, polydipsia, and unexplained weight loss.

OR

Two-hour plasma glucose level of 200 mg/dL or higher during an oral glucose tolerance test (OGTT). The glucose load should contain the equivalent of 75 gm of glucose dissolved in water. Note that the OGTT is not recommended for routine clinical use.

Any positive finding for the above assessments should be confirmed by repeat testing on a different day.

Data from American Diabetes Association: Diagnosis and classification of diabetes mellitus, *Diabetes Care* 35(Suppl 1): S64-S71, 2012.

TABLE 32-1 MAJOR LONG-TERM CONSEQUENCES OF TYPE 1 AND TYPE 2 DIABETES

PATHOLOGY	POSSIBLE CONSEQUENCES
Macrovascular (Atherosclerotic Plaque)	
Coronary arteries	Myocardial infarction
Cerebral arteries	Stroke
Peripheral vessels	Peripheral vascular disease (e.g., neuropathies [see below], foot ulcers, possible amputations)
Microvascular (Capillary Damage)	
Retinopathy (retinal damage)	Partial or complete blindness
Neuropathy (autonomic and somatic nerve damage, due to both metabolic alterations and compromised circulation)	Autonomic nerve damage: Example: diabetic gastroparesis, bladder dysfunction, unawareness of hypoglycemia, sexual dysfunction Somatic nerve damage: Example: diabetic foot ulcer and/or leg or foot amputation (resulting from undetected injuries due to loss of sensation and also from compromised circulation)
Nephropathy (kidney damage)	Proteinuria (microalbuminuria), chronic renal failure (may require dialysis or kidney transplantation)

Data from American Diabetes Association: Executive summary: standards of medical care in diabetes, *Diabetes Care* 35(Suppl 1): S4-S10, 2012.

use in the treatment of diabetes mellitus has proved to be life saving for millions of people affected by the disease.

Diabetes mellitus actually is not a single disease, but a group of progressive diseases. For this reason, it is often regarded as a syndrome rather than a disease. In some cases, diabetes is caused by a relative or absolute lack of insulin that is believed to result from the destruction of beta cells in the pancreas. As a result, insulin cannot be produced. However, hyperglycemia can also be caused by defects in insulin receptors that result in insulin resistance. The proteins that serve as insulin receptors are attached to the surface of cells in the liver, muscle, and adipose tissue. These receptor proteins are stimulated by insulin molecules to move glucose from blood to cells. When insulin receptors become defective, they no longer respond normally to insulin molecules. Although serum insulin and glucose levels are both elevated, they do not respond and transport glucose into the cell where it is needed. The result is that glucose molecules remain in the blood, rather than being used in the cell or stored in the tissues.

Two major types of diabetes mellitus are currently recognized and designated by the ADA: type 1 and type 2. Type 1 diabetes was previously called *insulin-dependent diabetes mellitus (IDDM)* or *juvenile-onset diabetes.* Type 2 diabetes was previously called *non–insulin-dependent diabetes mellitus (NIDDM)* or *adult-onset diabetes.* The numeric designations for both conditions were adopted by the ADA as the preferred terms in 1995. The previous designations were abandoned for several reasons. One reason is that many patients with type 2 diabetes do eventually become dependent on insulin therapy for control of their illness. A second reason is that the current epidemic of both child and adult obesity in the United States is increasing the incidence of type 2 diabetes in children, adolescents, and young adults. Obesity is one of the major risk factors for the development of type 2 diabetes. Nonwhite ethnic groups, including African Americans, Asian Americans, Hispanic Americans, and Native Americans, are all at higher risk for the disease than are whites.

The usual differences between type 1 and type 2 diabetes mellitus are listed in Table 32-2. Interestingly, approximately 10% of patients with type 2 diabetes have circulating antibodies that suggest an autoimmune origin for the disease. This condition is known as *latent autoimmune diabetes in adults (LADA)* and is basically a more slowly progressing form of type 1 diabetes.

The most common signs and symptoms of diabetes are elevated blood glucose level (fasting glucose level higher than 126 mg/dL) and polyuria, polydipsia, polyphagia, glucosuria, weight loss, blurred vision, and fatigue.

Type 1 Diabetes Mellitus

Type 1 diabetes mellitus is characterized by a lack of insulin production or by the production of defective insulin, which results in acute hyperglycemia. Affected patients require exogenous insulin to lower the blood glucose level and prevent diabetic complications. It is believed that a genetically determined autoimmune reaction gradually destroys the insulin-producing beta cells of the pancreatic islets of Langerhans (Figure 32-1). The preclinical phase of beta cell destruction may be prolonged, possibly lasting several years. At some critical point, a rapid transition from preclinical to clinical type 1 diabetes occurs. This transition is believed to be triggered by a specific event such as an acute illness or major emotional stress. An unidentified viral infection is also strongly suspected as an environmental trigger. Those stressors trigger the release of the counter-regulatory hormones cortisol and epinephrine. These hormones then mobilize glucagon to release glucose from the storage sites in the liver. This further increases the already rising levels of glucose in the blood secondary to islet cell damage. At some point during this critical cascade of events, an autoimmune reaction may be initiated that destroys the insulin-producing beta cells of the pancreatic islets of Langerhans. The result is essentially a complete lack of endogenous insulin production by the pancreas, which necessitates long-term insulin replacement therapy. Fortunately, type 1 diabetes accounts for fewer than 10% of all diabetes cases. Uncontrolled type 1 diabetes is often referred to as *brittle diabetes,* and these patients have large fluctuations in their blood glucose levels.

Acute Diabetic Complications: Diabetic Ketoacidosis and Hyperosmolar Nonketotic Syndrome

When blood glucose levels are high but no insulin is present to allow glucose to be used for energy production, the body may break down fatty acids for fuel, producing ketones as a metabolic by-product. If this occurs to a sufficient degree, **diabetic ketoacidosis (DKA)** may result. DKA is a complex multisystem

TABLE 32-2 CHARACTERISTICS OF TYPE 1 AND TYPE 2 DIABETES

CHARACTERISTIC	TYPE 1	TYPE 2
Etiology	Autoimmune destruction of beta cells in the pancreas	Multifactorial genetic defects; strong association with obesity and insulin resistance resulting from a reduction in the number or activity of insulin receptors
Incidence	10% of cases	90% of cases
Onset	Juvenile onset, usually younger than 20 yr	Previously maturity onset, age older than 40 yr; now increasingly seen in younger adults and even adolescents—attributed to obesity epidemic
Endogenous insulin	Little or none	Normal or high levels in early disease; reduced later in disease
Insulin receptors	Normal	Decreased or defective
Body weight	Usually nonobese	Obese (80% of cases)
Treatment	Insulin	Weight loss, diet and exercise, and oral hypoglycemics; only about one third of all patients need insulin. Earlier use of insulin is associated with improved outcomes.

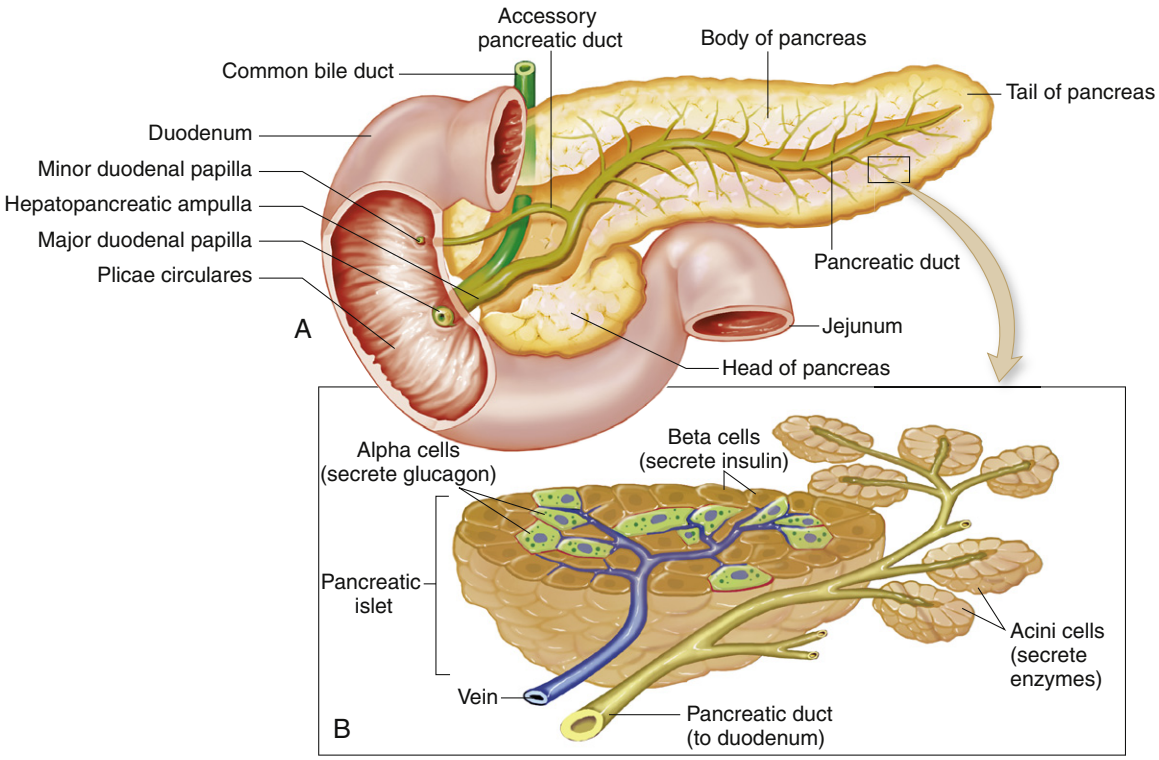

FIGURE 32-1 The pancreas. **A,** Pancreas dissected to show main and accessory ducts. **B,** Exocrine glandular cells (around small pancreatic ducts) and endocrine glandular cells of the pancreatic islets (adjacent to blood capillaries). Exocrine pancreatic cells secrete pancreatic enzymes, alpha endocrine cells secrete glucagon, and beta endocrine cells secrete insulin. (From Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 7, St Louis, 2010, Mosby.)

complication of uncontrolled diabetes. Without treatment, DKA will lead to coma and death. DKA is characterized by extreme hyperglycemia, the presence of ketones in the serum, acidosis, dehydration, and electrolyte imbalances. Approximately 25% to 30% of patients with newly diagnosed type 1 diabetes mellitus present with DKA. Another complication of comparable severity that is also triggered by extreme hyperglycemia is **hyperosmolar nonketotic syndrome (HNKS).** The most common precipitator of DKA and HNKS is some type of physical or emotional stress. It was formerly believed that DKA occurred only in type 1 diabetes and HNKS occurred only in type 2 diabetes. However, it is now recognized that both disorders can occur with diabetes of either type, and this overlap is increasingly common with the rapidly decreasing age of patients with type 2 diabetes.

Table 32-3 describes the subtle differences between DKA and HNKS. Treatment for either complication involves fluid and electrolyte replacement as well as intravenous insulin therapy (more common for DKA).

Type 2 Diabetes Mellitus

Type 2 diabetes mellitus is by far the most common form of diabetes, accounting for at least 90% of all cases of diabetes mellitus and affecting over 23 million people in the United States. Because this form of diabetes does not always require insulin therapy, there are many common and dangerous misconceptions regarding type 2 diabetes mellitus: that it is a mild diabetes;

TABLE 32-3 COMPARISON OF FEATURES OF DIABETIC KETOACIDOSIS AND HYPEROSMOLAR NONKETOTIC SYNDROME

	CONDITION	
FEATURE	DIABETIC KETOACIDOSIS	HYPEROSMOLAR NONKETOTIC SYNDROME
Age of patient	Younger than 40 yr	Older than 40 yr
Duration of symptoms	Less than 2 days	More than 5 days
Serum glucose level	Lower than 800 mg/dL	Higher than 800 mg/dL
Serum Na level	Normal or low	Normal or high
Serum HCO_3 level	Low	Normal
Ketone bodies	At least 4+	Less than 2+
pH	Low	Normal
Serum osmolality	Less than 350 mOsm/kg	Greater than 350 mOsm/kg
Prognosis	3% to 10% mortality	10% to 20% mortality or more
Subsequent course	Insulin therapy required in all cases	Insulin therapy not required in many cases after initial treatment

Adapted from Harmel AP, Mathur R: *Davidson's diabetes mellitus: diagnosis and treatment,* ed 5, Philadelphia, 2004, Saunders.

that it is easy to treat; and that tight metabolic control is unnecessary because these patients, who are mostly older adults, will die before diabetic complications develop. The clinical realities of this disease demonstrate otherwise.

Type 2 diabetes mellitus is caused by both insulin resistance and insulin deficiency, but there is no absolute lack of insulin as in type 1 diabetes. One of the normal roles of insulin is to facilitate the uptake of circulating glucose molecules into tissues to be used as energy. In type 2 diabetes, all of the main target tissues of insulin (i.e., muscle, liver, and adipose tissue) are hyporesponsive (resistant) to the effects of the hormone. Not only is the absolute number of insulin receptors in these tissues reduced, but their individual sensitivity and responsiveness to insulin is decreased as well. Therefore, it is possible for a patient with type 2 diabetes mellitus to have normal or even elevated levels of insulin yet still have high blood glucose levels. These processes also result in impaired postprandial (after a meal) glucose metabolism, which is another problematic feature of type 2 diabetes that contributes to the hazardous hyperglycemic state.

In addition to the reduction in the number and sensitivity of insulin receptors in type 2 diabetes, there is often reduced insulin secretion by the pancreas. This insulin deficiency results from a loss of the normal responsiveness of the beta cells in the pancreas to elevated blood glucose levels. When the beta cells do not recognize glucose, they do not secrete insulin, and the normal insulin-facilitated transport of glucose into cells of muscle, liver, and adipose tissue does not occur.

Type 2 diabetes is a multifaceted disorder. Although loss of blood glucose control is its primary hallmark, several other significant conditions are strongly associated with the disease. These include obesity, coronary heart disease, dyslipidemia, hypertension, microalbuminuria (spilling of protein into the urine), and an increased risk for thrombotic (blood clotting) events. For patients with type 2 diabetes, the ADA recommends the use of aspirin for prevention of coronary artery (heart) disease and antihyperlipidemic drug therapy (see Chapter 27), when indicated, in addition to any necessary antidiabetic drug therapy. These comorbidities are strongly associated with the development of type 2 diabetes and are collectively referred to as *metabolic syndrome* (also known as *insulin-resistance syndrome* and *syndrome X*). Roughly 80% of patients with diabetes are obese at the time of initial diagnosis. Obesity serves only to worsen the insulin resistance, because adipose tissue is often the site of a large proportion of the body's defective insulin receptors. The goal for patients with diabetes is a blood pressure less than 130/80 mm Hg and a low-density lipid (LDL) less than 100 mg/dL.

Gestational Diabetes

Gestational diabetes is a type of hyperglycemia that develops during pregnancy. Relatively uncommon, it occurs in about 2% to 10% of pregnancies. Many patients are well controlled with diet, but the use of insulin may be necessary to decrease the risk of birth defects, hypoglycemia in the newborn, and high birth weight. In most cases, gestational diabetes subsides after delivery. However, as many as 30% of patients who experience gestational diabetes are estimated to develop type 2 diabetes within 10 to 15 years.

All pregnant women need to have blood glucose screenings at regular prenatal visits. Women who develop gestational diabetes need to be screened for lingering diabetes 6 to 8 weeks postpartum and be advised of their increased risk for recurrent diabetes and of the importance of regular medical checkups and weight control. Women who are known to be diabetic before pregnancy should have detailed prepregnancy counseling and prenatal care from a prescriber who is experienced in managing pregnancies in diabetic women. Specific drug therapy issues pertaining to gestational diabetes are discussed further in the section on insulins.

Prevention and Screening

Both macrovascular and microvascular problems are now recognized to occur at fasting plasma glucose (FPG) levels as low as 126 mg/dL. *Fasting* is defined loosely as an 8-hour or an overnight fast (no food from midnight until after the blood sample is taken in the morning). **Impaired fasting glucose level** is defined as an FPG level higher than or equal to 100 mg/dL but less than 126 mg/dL. This condition often proves to be a precursor to diabetes and is therefore referred to as *prediabetes*. The 2012 ADA guidelines renamed *prediabetes* as "categories of increased risk for diabetes" and define it as impaired fasting glucose and hemoglobin A1C of 5.7% to 6.4%. Another recognized prediabetic condition is impaired glucose tolerance, which is identified using an oral glucose challenge test (see Box 32-1). The ADA, the National Institute of Diabetes and Digestive and Kidney Diseases, and the Centers for Disease Control and Prevention recommend that all adults 45 years of age and older be screened for elevated FPG levels every 3 years. Several preventive measures are also recommended. Reducing alcohol consumption is helpful, because alcohol is broken down in the body to simple carbohydrates, which leads to increases in blood glucose levels. Regular exercise, in addition to having beneficial effects on weight and high blood pressure, also lowers blood glucose levels by increasing insulin receptor sensitivity.

Nonpharmacologic Treatment Interventions

Patients diagnosed with type 1 diabetes always require insulin therapy. For patients with new-onset type 2 diabetes, lifestyle changes should be initiated as a first step in treatment. Weight loss not only lowers the blood glucose and lipid levels of these patients, but it also reduces another common comorbidity, hypertension. Other recommended lifestyle changes include improved dietary habits (e.g., consumption of a diet higher in protein and lower in fat and carbohydrates), smoking cessation, reduced alcohol consumption, and regular physical exercise. Cigarette smoking doubles the risk of cardiovascular disease in diabetic patients, largely because of its effects on peripheral vascular circulation and respiratory function. In fact, smoking cessation would probably save far more lives than antihypertensive, antilipemic, and antidiabetic drug treatment combined!

Glycemic Goal of Treatment

The glycemic goal recommended by the ADA for diabetic patients is a **hemoglobin A1C (A1C)** level of less than 7%. The A1C test measures the percentage of hemoglobin A that is

irreversibly glycosylated. A1C is an indicator of glycemic control in a patient over the preceding 2 to 3 months (the average lifespan of a red blood cell) and is not affected by recent fluctuations in blood glucose levels. The ADA recommended a fasting blood glucose goal for diabetic patients of 70 to 130 mg/dL.

PHARMACOLOGY OVERVIEW

The major classes of drugs used to treat diabetes mellitus are the insulins and the oral antidiabetic drugs. Several new classes of injectable drugs with unique mechanisms of action have been developed that may be used in addition to insulins or oral antidiabetic drugs to treat resistant diabetes. All of these drugs are referred to as *antidiabetic drugs*, and they are aimed at producing a normoglycemic or euglycemic (normal blood glucose) state.

INSULINS

Insulin is required in patients with type 1 diabetes. Patients with type 2 diabetes are not generally prescribed insulin until other measures (i.e., lifestyle changes and oral drug therapy) no longer provide adequate glycemic control. Currently insulin is synthesized in laboratories using recombinant deoxyribonucleic acid (DNA) technology and is referred to as *human insulin*. Insulin was originally isolated from cattle or pigs, but bovine (cow) and porcine (pig) insulins are associated with a higher incidence of allergic reactions and insulin resistance than human insulin and are no longer available in the U.S. market. Recombinant insulin is produced by bacteria or yeast that have been altered to contain the genetic information necessary for them to reproduce an insulin that is like human insulin. The pharmacokinetic properties of insulin (onset of action, peak effect, and duration of action) can be altered by making various minor modifications to either the insulin molecule itself or the drug formulation (final product). This practice has led to the development of many different insulin preparations, including several combination insulin products that contain more than one type of insulin in the same solution. Chemical manipulation of insulin activity in this way helps to meet the individual meal-related metabolic demands of patients with diabetes. Further modifications can be accomplished by mixing compatible insulin preparations in the syringe before administration. The latest syringe compatibility data for currently available insulin products are given in Table 32-4. Thoroughly educate patients regarding how, when, and whether they can (or cannot) mix different types of insulin. Some combinations are chemically incompatible and can result in an undesirable alteration of glycemic effects.

Mechanism of Action and Drug Effects

Exogenous insulin functions as a substitute for the endogenous hormone. It serves to replace the insulin that is either not made or is made defectively in a diabetic patient. The drug effects of exogenously administered insulin involve many body systems. They are the same as those of normal endogenous insulin. That is, exogenous insulin restores the patient's ability to metabolize carbohydrates, fats, and proteins; to store glucose in the liver; and to convert glycogen to fat stores. Unfortunately, exogenous insulin does not reverse defects in insulin receptor sensitivity. Insulin pumps are a very attractive way to administer insulin to patients. The insulin pump provides an alternative to multiple daily subcutaneous injections and allows patients to match their insulin intake to their lifestyle. When an insulin pump is used, insulin is administered constantly over a 24-hour period, and the patient is then allowed to give bolus injections based on the amount of food ingested. Insulin pumps are described further in the Nursing Process section.

TABLE 32-4 INSULIN MIXING COMPATIBILITIES

TYPE OF INSULIN	COMPATIBLE WITH
Regular insulin (Humulin R, Novolin R)	All insulins except glargine, and glulisine
Insulin glulisine (Apidra)	NPH only
Insulin lispro (Humalog), insulin aspart (NovoLog)	Regular, NPH insulins
Insulin detemir (Levemir)	Must be given alone
Insulin glargine (Lantus)	Must be given alone due to low pH of diluent
NPH 70% and regular insulin 30% (Humulin 70/30, Novolin 70/30)	Premixed; do not mix with other insulins
NPH 50% and regular insulin 50% (Humulin 50/50)	
Insulin aspart protamine suspension 75% and insulin aspart 25% (NovoLog Mix 75/25)	
Insulin lispro protamine suspension 75% and insulin lispro 25% (Humalog Mix 75/25)	

Indications

All insulin preparations can be used to treat both type 1 and type 2 diabetes, but each patient requires careful customization of the dosing regimen for optimal glycemic control. Additional therapeutic approaches such as lifestyle modifications (e.g., dietary and exercise habits) are also indicated and, for type 2 diabetes, oral drug therapy as well.

Contraindications

Contraindications to the use of all insulin products include known drug allergy to the specific product. Insulin is never to be administered to an already hypoglycemic patient. Blood glucose must always be tested prior to administration.

Adverse Effects

Hypoglycemia resulting from excessive insulin dosing can result in brain damage, shock, and possible death. This is the most immediate and serious adverse effect of insulin. Other adverse effects of insulin therapy include weight gain, lipodystrophy at the site of repeated injections, and in rare cases allergic reactions. Because weight gain is a common and often undesirable adverse effect, insulin therapy is usually delayed in type 2 patients until other agents and lifestyle changes have failed to bring the blood glucose to target levels.

Interactions

Drug interactions that can occur with the insulins are significant; they are listed in Table 32-5.

TABLE 32-5 SELECTED DRUG INTERACTIONS WITH ANTIDIABETIC DRUGS

DRUG	INTERACTING DRUG	MECHANISM	RESULT
insulin	Corticosteroids, niacin, diuretics, sympathomimetic drugs, thyroid drugs	Antagonizes insulin effect	Increased blood glucose levels
	Alcohol, anabolic steroids, sulfa antibiotics, clofibrate, MAOIs, salicylates	Increases the hypoglycemic effects of insulin	Decreased blood glucose levels
	Nonselective beta blockers	Masks the tachycardia from hypoglycemia	Risk of not noticing hypoglycemic symptoms
	Hypoglycemic drugs	Additive effects	Additive hypoglycemia
metformin	Cimetidine	Inhibits metabolism	Increased metformin effects
	Diuretics, steroids	Additive effects	Additive hypoglycemia
	Contrast media	Decreases excretion	Lactic acidosis
glipizide	Alcohol, antacids, cimetidine, clofibrate, fluconazole, NSAIDs, sulfonamide antibiotics, garlic, ginger, ginseng	Enhanced effects	Increased hypoglycemia
	Carbamazepine, phenobarbital, phenytoin, rifampin	Increases metabolism	Decreased effectiveness

MAOI, Monoamine oxidase inhibitor; *NSAID,* nonsteroidal antiinflammatory drug

DOSAGES

Selected Human-Based Insulin Products

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
Rapid Acting			
insulin lispro (Humalog) (B)	Human recombinant rapid-acting insulin analogue	Subcut: 0.5-1 unit/kg/day; doses are highly individualized to desired glycemic control; rapid-acting insulins are best given 15 min before a meal May be given per sliding scale or as basal/bolus; may also be given via continuous subcutaneous infusion pump	Diabetes mellitus type 1 and type 2
Short Acting			
♦ regular insulin (Humulin R, Novolin R) (B)	Human recombinant short-acting insulin	Subcut: Same dosage as insulin lispro; subcut doses of regular insulin are best given 30 min before a meal Regular insulin may also be given per sliding scale or basal/bolus and is the insulin usually given IV as a continuous infusion	
Long Acting			
insulin glargine (Lantus) (C)	Human recombinant long-acting insulin analogue	Subcut only: Same dosage as others but is approved only for once- or twice-daily dosage (basal dosing)	

IV, Intravenous; *Subcut,* subcutaneous.

Dosages

For dosage information on the various insulin products, see the table above. The concentration of insulin is expressed as the number of units of insulin per milliliter. For example, U-100 insulin has 100 units in 1 milliliter. Insulin is usually given by subcutaneous injection or via a subcutaneous infusion pump. In emergency situations requiring prompt insulin action, regular insulin can be given intravenously.

Insulin Use in Special Populations

Two special patient populations for whom careful attention is required during insulin therapy are pediatric patients and pregnant women. Insulin dosages for both are calculated by weight as they are for the general adult population. The usual dosage range is 0.5 to 1 units/kg/day as a total daily dose. Be aware that there are a few important differences regarding the use of some insulin products in pediatric populations. The rapid-acting insulin lispro is approved for use in children older than 3 years of age. However, the combination lispro product Humalog 75/25, which contains 75% insulin lispro protamine (an intermediate-acting insulin) and 25% insulin lispro (a rapid-acting insulin), is not currently approved for use in children younger than 18 years of age. Children need age-appropriate education and supervision by health care professionals and parents, which includes a safe and gradual transfer of responsibility for self-management of their illness, as appropriate.

Pregnant women also require special care with regard to diabetes management. Although most of these mothers will

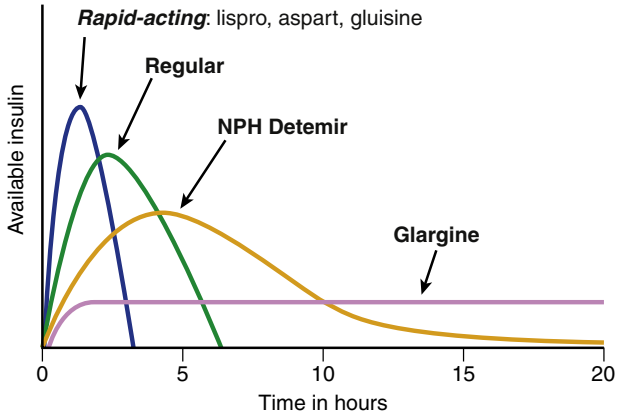

FIGURE 32-2 Comparison of the pharmacokinetics of various insulins. (From Messinger-Rapport BJ, Thomas DR, Gammack JK: Clinical update on nursing home medicine: 2008, *J Am Med Dir Assoc* 9(7):460-475, 2008.)

return to a normal glycemic state after pregnancy, they are at risk of developing diabetes again in later life. All currently available oral and injectable antidiabetic drugs are classified as pregnancy category B or C drugs. Oral medications are generally not recommended for pregnant patients because of a lack of firm safety data. For this reason, insulin therapy is the only currently recommended drug therapy for pregnant women with diabetes. Roughly 15% of women who develop gestational diabetes require insulin therapy during pregnancy. Insulin does not normally cross the placenta. Effective glycemic control during pregnancy is essential because infants born to women with gestational diabetes have a twofold to threefold greater risk of congenital anomalies. In addition, the incidence of stillbirth is directly related to the degree of maternal hyperglycemia. Weight reduction is generally not advised for these women, because it can jeopardize fetal nutritional status. Women with gestational diabetes tend to have babies that weigh more, and these children may have low blood sugar postnatally. Insulin is excreted into human milk. It is currently unknown whether insulin glargine is excreted in breast milk, and thus it is to be avoided in breast-feeding women. It is very important that insulin therapy and diet be well controlled for a nursing mother, because inadequate or excessive glycemic control may reduce milk production.

DRUG PROFILES

There are currently four major classes of insulin, as determined by their pharmacokinetic properties: rapid acting, short acting, intermediate acting, and long acting. The duration of action ranges from several hours to over 24 hours depending on the insulin class (Figure 32-2). The insulin dosage regimen for all diabetic patients is highly individualized and may consist of one or more classes of insulin administered at either fixed dosages or variable dosages in response to self-measurements of blood glucose level or the number of grams of carbohydrate consumed. With the use of insulins, clarity, color, and appearance are important to understand for patient safety and for the prevention of adverse effects and complications. Several insulins are clear, colorless solutions. These include regular insulin, insulin lispro (Humalog), and insulin glargine (Lantus). Other insulins, such as NPH insulin (insulin isophane), are white opaque (cloudy) solutions. This issue is discussed further in the Implementation section under Nursing Process.

RAPID-ACTING INSULINS

insulin lispro

There are currently three insulin products that are classified as rapid acting: insulin lispro (Humalog), insulin aspart (NovoLog), and the most recently developed, insulin glulisine (Apidra). These have the most rapid onset of action (roughly 15 minutes) as well as a shorter duration of action than other insulin categories. The effect of insulin lispro is most like that of the endogenous insulin produced by the pancreas in response to a meal. After, or during a meal, the glucose that is ingested stimulates the pancreas to secrete insulin. This insulin then facilitates the uptake of the excess glucose at hepatic insulin receptor sites for storage in the liver as glycogen. In people with diabetes, the insulin response to meals is often impaired; therefore, a rapid-acting insulin product is often used within 15 minutes of mealtime. This corresponds to the time required for the onset of action of these products. It is essential that patients with diabetes eat a meal after injection. Otherwise profound hypoglycemia may result. Insulin lispro was approved by the U.S. Food and Drug Administration (FDA) in 1996, becoming the first new insulin product to appear in the U.S. market in 14 years.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Subcut	15 min	1-2 hr	80 min	3-5 hr

SHORT-ACTING INSULIN

♦ regular insulin

Regular insulin (Humulin R) is currently the only insulin that is classified as a short-acting insulin. Regular insulin can be given via intravenous bolus, intravenous infusion, or even intramuscularly. These routes, especially the intravenous infusion route, are often used in cases of DKA or coma associated with uncontrolled type 1 diabetes.

Regular insulin solution was the first medicinal insulin product developed. It was originally isolated from bovine and porcine sources, but it is now made primarily from human insulin sources using recombinant DNA technology.

There are some differences between regular insulin and the newer rapid-acting drugs. Both insulin lispro and insulin aspart are human insulin analogues. This means that they are insulin molecules with synthetic alterations to their chemical structures that alter their onset or duration of action. Both insulins have a faster onset of action and a shorter time to peak plasma level, but they also have a shorter duration of action than does regular insulin.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Subcut	30-60 min	2.5 hr	Unknown	6-10 hr

INTERMEDIATE-ACTING INSULINS

insulin isophane suspension (NPH)

Insulin isophane suspension (also known as *NPH insulin*) is the only available intermediate-acting insulin product. NPH is an acronym for *neutral protamine Hagedorn insulin,* the original name of this type of insulin. NPH insulin is a sterile suspension of zinc insulin crystals and protamine sulfate in buffered water for injection. The suspension appears cloudy or opaque. NPH insulin has a slower onset and longer duration of action than regular insulin, but not as long as the long-acting insulins. NPH insulin is often combined with regular insulin to reduce the number of insulin injections per day.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Subcut	1-2 hr	4-8 hr	Unknown	10-18 hr

LONG-ACTING INSULINS

♦ insulin glargine and insulin detemir

Two long-acting insulin products are now available: insulin glargine (Lantus) and insulin detemir (Levemir). Insulin glargine is normally a clear, colorless solution with a pH of 4.0. Once it is injected into subcutaneous tissue at physiologic pH, it forms microprecipitates that are slowly absorbed over the next 24 hours. It is a recombinant DNA–produced insulin analogue and is unique in that it provides a constant level of insulin in the body. This enhances its safety because blood levels do not rise and fall as with other insulins. Insulin glargine is usually dosed once daily, but the drug may be dosed every 12 hours, depending on the patient's glycemic response. Because insulin glargine provides a more prolonged, consistent blood glucose level, it is sometimes referred to as a *basal insulin.*

Often for those being switched from twice-daily NPH to insulin glargine, the initial daily glargine dose is reduced to 80% of the previous total NPH dose. Insulin detemir has a different mechanism of action from insulin glargine, and the two insulins are not considered interchangeable. The duration of action of insulin detemir is dose dependent, so that lower doses require twice-daily dosing and higher doses may be given once daily.

FIXED-COMBINATION INSULINS

Currently available fixed-combination insulin products include Humulin 70/30, Humulin 50/50, Novolin 70/30, Humalog Mix 75/25, Humalog 50/50, and NovoLog 70/30. Each of these products contains two different insulins, one intermediate-acting type and either one rapid-acting type (Humalog, NovoLog) or one short-acting type (Humulin). The numeric designations indicate the percentages of each of the two components in the product. For example, Novolin 70/30 has 70% short-acting and 30% intermediate-acting insulin. Notice that the numbers add up to 100 (percent). These products were developed to more closely simulate the varying levels of endogenous insulin that occur normally in nondiabetic people. In most insulin regimens, patients take a combination of a rapid-acting insulin to deal with the surges in glucose that occur after meals and an intermediate- or long-acting insulin for the period between meals when glucose levels are lower. However, this requires the mixing and administration of different types of insulins. Fixed-combination products were developed in an attempt to simplify the dosing process. The insulin lispro protamine component of Humalog Mix 75/25 is a modified insulin lispro molecule with a longer duration of action. These combinations allow for twice daily dosing but often result in glycemic control that is not as tight as daily dosing with meals. Patients who cannot afford frequent glucose monitoring or who refuse more than two injections per day may insist on using a combination insulin with twice daily dosing.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Subcut	1-2 hr	None	Unknown	24 hr

BASAL-BOLUS AND SLIDING-SCALE INSULIN DOSING

Historically, sliding scale insulin was used to correct blood glucose levels. In this method, subcutaneous doses of rapid-acting (lispro or aspart) or short-acting (regular) insulin are adjusted according to blood glucose test results. This method was typically used in treating hospitalized diabetic patients, whose insulin requirements may vary drastically because of stress (e.g., infections, surgery, acute illness), inactivity, or variable caloric intake, including receipt of total parenteral nutrition (TPN), enteral nutrition, or time spent with a "nothing by mouth" (NPO) diet. Other hospital diets that result in high numbers of carbohydrates consumed are full liquid and clear liquid diets.

When an individual is on a sliding-scale insulin regimen, blood glucose concentrations are determined several times a day (e.g., before meals and at bedtime) for patients on normal meal schedules, or every 4 to 6 hours around the clock for patients receiving TPN or enteral tube feedings. Subcutaneously administered regular or rapid insulin is then given in an amount that increases with the rise in blood glucose level. The disadvantage of sliding-scale dosing is that, because it delays insulin administration until hyperglycemia occurs, it does not meet basal insulin requirements and results in large swings in glucose control. Current research does not support the use of sliding scales or insulin without basal insulin, and many institutions are moving away from sliding-scale coverage. Nonetheless, sliding-scale dosing is still commonly used.

Basal-bolus insulin therapy is now the preferred method of treatment for hospitalized diabetic patients. Basal-bolus therapy is the attempt to mimic a healthy pancreas by delivering basal insulin constantly as a basal and then as needed as a bolus. The basal insulin is a long-acting insulin (insulin glargine) administered constantly to keep the blood glucose from fluctuating due to the normal release of glucose from the liver. Bolus insulin (insulin lispro or insulin aspart) mimics the burst secretions of the pancreas in response to increases in

blood glucose levels. Bolus insulin is broken up into meal and correction boluses. Meal boluses are given to reduce blood glucose with the intake of carbohydrates. Correction boluses are any boluses taken to bring blood glucose back to normal. Blood glucose levels are monitored frequently when using basal-bolus insulin. This method of treatment is far superior to the traditional sliding scale. Still, patients who need to receive nothing by mouth for therapeutic or diagnostic reasons are not good candidates for basal insulin due to the risk of hypoglycemia and the unpredictability of insulin needed for glucose control while not eating.

ORAL ANTIDIABETIC DRUGS

Type 2 diabetes is a very complex illness. Effective treatment involves several elements, including lifestyle modifications (e.g., diet control, exercise, smoking cessation, nutrition therapy), careful monitoring of blood glucose levels, and therapy with one or more drugs. In addition, the treatment of associated comorbid conditions (such as high cholesterol and high blood pressure) is a necessity that serves to further complicate the entire process. The goal blood pressure for patients with diabetes is less than 130/80 mm Hg, and the goal LDL (low-density lipid) level is less than 100 mg/dL.

The consensus statement from the ADA in 2011 recommends that new-onset type 2 diabetes be treated with both lifestyle interventions and the oral biguanide drug metformin, if there are no contraindications to the drug. In some past statements, only lifestyle changes were recommended as initial treatment. The consensus recognizes the reality that lifestyle changes, although essential, usually are not effective enough alone to lower blood glucose to the desired levels. If lifestyle modifications and the maximum tolerated metformin dose do not achieve the recommended A1C goals after 2 to 3 months, additional treatment with basal insulin or either a sulfonylurea or a thiazolidinedione is recommended. Studies have shown that metformin and the sulfonylureas (available in generic form) were either similar to or superior to the more expensive thiazolidinediones, glinides, and alpha-glucosidase inhibitors. Although not a traditional oral antidiabetic agent, bromocriptine (Cycloset), a dopamine agonist (see Chapter 15), is now being marketed for the treatment of diabetes. The exact mechanism of action is not known, but it has been shown to lower A1C levels in patients with type 2 diabetes.

BIGUANIDE

Mechanism of Action and Drug Effects

Metformin is currently the only drug classified as a biguanide. It is considered a first-line drug, especially for patients with a body mass index over 25, and is the most commonly used oral drug for the treatment of type 2 diabetes. It is not used for type 1 diabetes. Metformin works by decreasing glucose production by the liver. It may also decrease intestinal absorption of glucose and improve insulin receptor sensitivity. This results in increased peripheral glucose uptake and use, and decreased hepatic production of triglycerides and cholesterol. Unlike sulfonylureas, metformin does not stimulate insulin secretion and therefore is not associated with weight gain and significant hypoglycemia when used alone.

Indications

The ADA guidelines recommend metformin as the initial oral antidiabetic drug for treatment of newly diagnosed type 2 diabetes if no contraindications exist. Because it may also cause moderate weight loss, it is particularly useful for the many patients with type 2 diabetes who are overweight or obese. Metformin may be used as monotherapy or in combination with other oral antidiabetic drugs if single-drug therapy is unsuccessful. For this reason, it is available in combination products containing either sulfonylureas, thiazolidinediones, or incretin mimetics. Metformin may also be combined with insulin. It is also used in prediabetic patients.

Contraindications

Metformin is contraindicated in patients with renal disease or renal dysfunction (serum creatinine level higher than 1.5 mg/dL in males or higher than 1.4 mg/dL in females). Because metformin is primarily excreted by the kidneys, it can accumulate in these individuals, increasing the risk of development of lactic acidosis. Other contraindications include alcoholism, metabolic acidosis, hepatic disease, heart failure, and other conditions that predispose to tissue hypoxia and increase the risk of lactic acidosis.

Adverse Effects

The most common adverse effects of metformin are gastrointestinal. Metformin can cause abdominal bloating, nausea, cramping, a feeling of fullness, and diarrhea, especially at the start of therapy. Some research attributes the weight loss experienced early in the course of treatment with these side effects. These effects are all usually self-limiting and can be lessened by starting with low dosages, titrating up slowly, and taking the medication with food. Less common adverse effects with metformin are a metallic taste, hypoglycemia, and a reduction in vitamin B_{12} levels after long-term use. Lactic acidosis is an extremely rare complication with metformin, but the risk increases with very high blood glucose levels and/or clinical conditions predisposing to hypoxemia. Lactic acidosis is lethal in up to 50% of cases. Symptoms of lactic acidosis include hyperventilation, cold and clammy skin, muscle pain, abdominal pain, dizziness, and irregular heartbeat.

Interactions

Drug interactions with metformin are listed in Table 32-5. In addition, the use of metformin with iodinated (iodine-containing) radiologic contrast media has been associated with both acute renal failure and lactic acidosis. For these reasons, metformin therapy is to be discontinued the day of the test and for at least 48 hours after the patient undergoes any radiologic study that requires the use of such contrast media.

Dosages

For dosage information on metformin, see the table on p. 521.

DOSAGES

Selected Oral Antidiabetic Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
acarbose (Precose) (B)	Alpha-glucosidase inhibitor	PO: 25-100 mg three times daily, taken with first bite of meal	Diabetes mellitus type 2
♦ glipizide (Glucotrol, Glucotrol XL) (C)	Second-generation sulfonylurea	PO: 5-10 mg daily (max daily dose 20 mg)	
glimepiride (Amaryl) (C)	Second-generation sulfonylurea	PO: 1-4 mg daily (max daily dose 8 mg)	
♦ metformin (Glucophage, Glucophage XR) (B)	Biguanide	PO: 1000 mg twice daily or 850 mg twice daily; max daily dose 2550 mg for adults and 2000 mg for pediatric patients age 10-16 yr	
♦ pioglitazone (Actos) (C)	Thiazolidinedione	PO: 15-45 mg once daily	
♦ repaglinide (Prandin) (C)	Meglitinide	PO: 0.5-4 mg three times daily; best taken 15 min before a meal	
sitagliptin (Januvia) (B)	DPP-IV Inhibitor	PO: 100 mg daily	
Combination Oral Drugs			
glipizide/metformin (Metaglip) (C)	Combination sulfonylurea/biguanide	PO: 1-2 tabs twice daily	
pioglitazone/metformin (ACTOplus Met) (C)	Combination thiazolidinedione/biguanide	PO: 1 tab twice daily	
sitagliptin/metformin (Janumet) (C)	Combination incretin mimetic/biguanide	PO: 1 tab twice daily	
saxagliptin/metformin (Kombiglyze) (C)	Combination incretin mimetic/biguanide	PO: 1 tab twice daily	

SULFONYLUREAS

Mechanism of Action and Drug Effects

The sulfonylureas are the oldest group of oral antidiabetic drugs. The drugs currently used are considered second-generation drugs and have a better potency and adverse effect profile than first-generation drugs (e.g., acetazolamide and tolbutamide), which are no longer used clinically. Second-generation drugs include glipizide (Glucotrol), glyburide (Diabeta), and glimepiride (Amaryl). Sulfonylureas bind to specific receptors on beta cells in the pancreas to stimulate the release of insulin. In addition, sulfonylureas appear to secondarily decrease the secretion of glucagon. For this class of drugs to be effective, the patient must still have functioning beta cells in the pancreas. Thus, these drugs work best during the early stages of type 2 diabetes and are not used in type 1 diabetes.

Indications

The ADA guidelines currently recommend sulfonylureas as second-step drugs for patients with type 2 diabetes whose A1C levels remain elevated after metformin is initiated. Because they have different mechanisms of action, sulfonylureas can be used in conjunction with metformin and thiazolidinediones. Sulfonylureas should not be used in patients with advanced diabetes dependent on insulin administration, because the beta cells in such patients are no longer able to produce insulin. Once insulin is started, sulfonylurea medication is stopped.

Contraindications

Contraindications include hypoglycemia or conditions that can predispose to hypoglycemia, such as reduced caloric intake (e.g., NPO), ethanol use, or advanced age. There is a potential for cross-allergy in patients who are allergic to sulfonamide antibiotics. Although such an allergy is listed as a contraindication by the manufacturer, most clinicians will prescribe sulfonylureas for such patients. However, be aware of the potential for cross-allergy, and inform patients of the possibility.

Adverse Effects

The most common adverse effect of the sulfonylureas is hypoglycemia, the degree to which depends on the dose, eating habits, and presence of hepatic or renal disease. Another predictable adverse effect is weight gain because of the stimulation of insulin secretion. Other adverse effects include skin rash, nausea, epigastric fullness, and heartburn.

Interactions

Drug interactions with the second-generation sulfonylureas are listed in Table 32-5.

Dosages

For dosage information on sulfonylureas, see the table on this page.

GLINIDES

Mechanism of Action and Drug Effects

Repaglinide (Prandin) and nateglinide (Starlix) are currently the only two drugs in the glinide class. They are structurally different from the sulfonylureas but have a similar mechanism of action in that they also increase insulin secretion from the pancreas. However, they have a much shorter duration of action and must be given with each meal.

Indications

Like the sulfonylureas, the glinides are indicated for treatment of type 2 diabetes. They may be particularly useful for diabetic patients with high postprandial glucose levels who have low levels of circulating insulin. Glinides can be used along with metformin and thiazolidinediones, but not combined with sulfonylureas, because they share a similar mechanism of action.

Contraindications

Contraindications are similar to those for the sulfonylureas.

Adverse Effects

The most commonly reported adverse effect of the glinides is hypoglycemia, which can occur particularly if food is not eaten after a dose. Weight gain is also commonly reported.

Interactions

Drug interactions with the glinides are similar to those with the sulfonylureas.

Dosages

For dosage information on the glinides, see the table on p. 521.

THIAZOLIDINEDIONES (GLITAZONES)

Mechanism of Action and Drug Effects

The third major drug category to emerge for the oral treatment of type 2 diabetes mellitus is the thiazolidinediones, most commonly referred to as *glitazones*. This class of drugs acts by regulating genes involved in glucose and lipid metabolism. The first drug in this class to be used in the United States was troglitazone (Rezulin). In 2000, it was removed from the market because of concerns about liver toxicity. In 2011, rosiglitazone (Avandia) was essentially removed from the market due to cardiac problems. It is no longer available in retail pharmacies. It can only be obtained through specialized manufacturer programs. Pioglitazone (Actos) is the only glitazone currently available and is widely used.

Glitazones are referred to as *insulin-sensitizing drugs*. They work to decrease insulin resistance by enhancing the sensitivity of insulin receptors. These drugs are also known to directly stimulate peripheral glucose uptake and storage, as well as to inhibit glucose and triglyceride production in the liver. Because glitazones affect gene regulation, they have a slow onset of activity over several weeks, and maximal activity may not be evident for several months. Some amount of preservation of beta cell function has also been reported with glitazone administration, thereby slowing disease progression in type 2 diabetes.

Indications

Thiazolidinediones (glitazones) are indicated for the management of type 2 diabetes. Because of their cost, adverse effect profile, and slow onset of action, they are usually reserved for patients who cannot tolerate or cannot achieve glucose control with metformin or the sulfonylureas. They may also be combined with metformin or a sulfonylurea for a synergistic effect. Pioglitazone can be used with insulin.

Contraindications

Thiazolidinediones are contraindicated for use in patients with New York Heart Association class III or IV heart failure and are to be used with caution in patients with liver or kidney disease.

Adverse Effects

The glitazones increase the risk of heart failure and are not recommended for use in patients with symptoms of heart failure. The glitazones also commonly cause peripheral edema and weight gain. The weight gain may be due to both water retention and an increase in adipose tissue. Their use has also been associated with reduced bone mineral density and an increased risk of fractures.

Interactions

Pioglitazone is partly metabolized by cytochrome P-450 enzyme 3A4 (CYP3A4). Serum concentrations of pioglitazone may be increased if the drug is taken concurrently with a CYP3A4 inhibitor such as ketoconazole or erythromycin.

Dosages

For dosage information on thiazolidinediones, see the table on p. 521.

ALPHA-GLUCOSIDASE INHIBITORS

Mechanism of Action and Drug Effects

Less commonly used oral drugs are the alpha-glucosidase inhibitors, acarbose (Precose) and miglitol (Glyset). As the name implies, these drugs work by reversibly inhibiting the enzyme alpha-glucosidase that is found in small intestine. This enzyme is responsible for the hydrolysis of oligosaccharides and disaccharides to glucose. When this enzyme is blocked, glucose absorption is delayed. The timing of administration of the alpha-glucosidase inhibitors is important, and they must be taken with food. When an alpha-glucosidase inhibitor is taken with a meal, excessive postprandial blood glucose elevation (a glucose "spike") can be prevented or reduced, making these medications impractical for directly lowering fasting blood glucose.

Indications

The alpha-glucosidase inhibitors are used to treat type 2 diabetes, usually in combination with another oral hypoglycemic drug. They may be particularly effective in controlling high postprandial glucose levels.

Contraindications

Because of their adverse gastrointestinal effects, alpha-glucosidase inhibitors are not recommended for use in patients with inflammatory bowel disease, malabsorption syndromes, or intestinal obstruction.

Adverse Effects

These drugs can cause a high incidence of flatulence, diarrhea, and abdominal pain. At high dosages, they may also elevate levels of hepatic enzymes (transaminases). Unlike sulfonylureas, they do not cause hypoglycemia or weight gain. In the rare instance that a patient develops hypoglycemia from these drugs, complex carbohydrates cannot be used because alpha-glucosidase is blocked; IV or oral glucose must be administered.

Interactions

The bioavailability of digoxin, ranitidine, and propranolol may be reduced when they are taken with alpha-glucosidase inhibitors.

Dosages

For dosage information on alpha-glucosidase inhibitors, see the table on p. 521.

DIPEPTIDYL PEPTIDASE IV (DPP-IV) INHIBITORS

Mechanism of Action and Drug Effects

Dipeptidyl peptidase-IV (DPP-IV) inhibitors work by delaying the breakdown of incretin hormones (see Incretin Mimetics) by inhibiting the enzyme DPP-IV. Incretin hormones are released throughout the day and are increased after a meal. When blood glucose concentrations are normal or high, the incretin hormones increase insulin synthesis and lower glucagon secretion. By inhibiting the enzyme responsible for incretin breakdown (DPP-IV), the DPP-IV inhibitors reduce fasting and postprandial glucose concentrations. Currently there are three DPP-IV inhibitors: sitagliptin (Januvia), saxagliptin (Onglyza), and linagliptin (Tradjenta). There are several DPP-IV inhibitors currently under investigation. This class of drugs is commonly referred to as the *gliptins*.

Indications

The DPP-IV inhibitors are indicated as an adjunct to diet and exercise to improve glycemic control in adults with type 2 diabetes mellitus.

Contraindications

The DPP-IV inhibitors are contraindicated in patients with known drug allergy.

Adverse Effects

The most common effects are upper respiratory tract infection, headache, and diarrhea. Hypoglycemia can occur and is more common if used in conjunction with a sulfonylurea. Cases of pancreatitis have been reported.

Interactions

Sitagliptin may increase digoxin levels. Concurrent use of sulfonylureas and insulin may increase the risk of hypoglycemia. The metabolism of saxagliptin is inhibited by strong CYP4A inhibitors. Rifampin may decrease the efficacy of linagliptin.

Dosages

The recommended dosage of sitagliptin is 100 mg daily; saxagliptin is 5 mg daily; and linagliptin is 5 mg daily.

DRUG PROFILES

acarbose

Acarbose (Precose) is one of the two currently available alpha-glucosidase inhibitors. The other drug in this drug category is miglitol (Glyset). These drugs work by blunting the elevation of blood glucose levels after a meal. To work optimally, they are to be taken with the first bite of each meal. They also may be taken along with sulfonylurea drugs or with metformin. Acarbose use is contraindicated in patients with a hypersensitivity to alpha-glucosidase inhibitors, DKA, cirrhosis, inflammatory bowel disease, colonic ulceration, partial intestinal obstruction, or chronic intestinal disease.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-1.5 hr	2 hr	2-3 hr	Unknown

♦ glipizide

Glipizide (Glucotrol) is a second-generation sulfonylurea drug. In contrast to another second-generation sulfonylurea, glimepiride, it has a very rapid onset and short duration of action, with no active metabolites. The rapid onset of action allows it to function much like the body normally does in response to meals when greater levels of insulin are required rapidly to deal with the increased glucose in the blood. When a patient with type 2 diabetes mellitus takes glipizide, it rapidly stimulates the pancreas to release insulin. This, in turn, facilitates the transport of excess glucose from the blood into the cells of the muscles, liver, and adipose tissues.

Glipizide use is contraindicated in cases of known drug allergy as well as in type 1 or brittle type 2 diabetes. Unlike most other oral antidiabetic drugs, it is not contraindicated in patients with severe renal failure. It works best if given 30 minutes before meals, usually before breakfast. This allows the timing of the insulin secretion induced by the glipizide to correspond with the elevation in blood glucose level induced by the meal in much the same way as endogenous insulin levels are raised in a person without diabetes. The extended-release dosage form of glipizide can be given once daily.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	1-3 hr	2-5 hr	6-8 hr

♦ metformin

Metformin (Glucophage) is currently the only biguanide oral antidiabetic drug. It works primarily by inhibiting hepatic glucose production and increasing the sensitivity of peripheral tissue to insulin. Because its mechanism of action differs from that of sulfonylurea drugs, it may be given along with these drugs.

Metformin use is contraindicated in patients with a known hypersensitivity to biguanides, hepatic or renal disease, alcoholism, or cardiopulmonary disease.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Less than 1 hr	1-3 hr	1.5-5 hr	24 hr

♦ pioglitazone

Pioglitazone (Actos) is classified as a glitazone or thiazolidinedione derivative. It is marketed for the treatment of patients

with type 2 diabetes. Pioglitazone is used alone or with a sulfonylurea, metformin, or insulin. It works by decreasing insulin resistance. It can worsen or precipitate heart failure and is best avoided in patients with cardiac disease. The safety of these drugs for use in pregnant women and children has not been established.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Delayed	2 hr	3-7 hr	Unknown

♦ repaglinide

Repaglinide (Prandin) is one of two antidiabetic drugs classified as *glinides*, the other being nateglinide (Starlix). These drugs have a mechanism of action similar to that of the sulfonylureas in that they also stimulate the release of insulin from pancreatic beta cells. They are especially helpful in the treatment of patients who have erratic eating habits, because the drug dose is skipped when a meal is missed. Contraindications include known drug allergy.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	15-60 min	1 hr	2-3 hr	4-6 hr

♦ sitagliptin

Sitagliptin (Januvia) was the first DPP-IV inhibitor approved. It is an oral drug that selectively inhibits the action of DPP-IV, thus increasing concentrations of the naturally occurring incretins GLP-1 and GIP. Sitagliptin is indicated for management of type 2 diabetes, either as monotherapy or in combination with metformin, a sulfonylurea, or a glitazone, but not with insulin. Clinical trials have demonstrated A1C reductions of 0.6% to 0.8%, which is less than the reductions seen with traditional oral antidiabetic drugs. Significant hypoglycemia may occur when the drug is combined with a sulfonylurea. There have been no significant adverse effects. However, in September 2009, the FDA received postmarketing cases of acute pancreatitis and advised health care providers to monitor patients closely for the development of pancreatitis after both initiation and dose increases. Sitagliptin is given once daily as a 100-mg tablet with or without food. It is classified as a pregnancy category B drug.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	15-30 min	1 hr	12 hr	Unknown

INJECTABLE ANTIDIABETIC DRUGS

AMYLIN AGONISTS

Mechanism of Action and Drug Effects

Amylin is a natural hormone secreted by the beta cells of the pancreas along with insulin in response to food. It functions to decrease postprandial plasma glucose levels, which it accomplishes in the following three ways:

1. Slows gastric emptying
2. Suppresses glucagon secretion and hepatic glucose production
3. Increases satiety (sense of having eaten enough)

When given before major meals, the amylin agonists work by mimicking the action of the natural hormone amylin.

Indications

Pramlintide (Symlin; pregnancy category C) is the only available amylin agonist. It is available only as a subcutaneous injection. It is indicated for use in patients with type 1 or type 2 diabetes receiving mealtime insulin who failed to achieve optimal glucose control with insulin. Pramlintide was the first drug approved for use in type 1 diabetes since insulin was discovered in the early twentieth century.

Contraindications

Pramlintide is contraindicated in patients with gastroparesis or those taking drugs that alter gastrointestinal motility.

Adverse Effects

Adverse effects include nausea, vomiting, anorexia, and headache.

Interactions

Pramlintide itself does not cause hypoglycemia, but if the patient is taking any preprandial rapid- or short-acting insulin product, the insulin dose usually needs to be reduced by 50%. It can delay the oral absorption of any drug taken at the same time and needs to be given at least 1 hour before other medications.

Dosages

Recommended dosage ranges are from 15 to 60 mcg for management of type 1 diabetes and 60 to 120 mcg for management of type 2 diabetes, taken before any major meal.

INCRETIN MIMETICS

Mechanism of Action and Drug Effects

Incretins are hormones released by the gastrointestinal tract in response to food. Incretins do the following:

1. Stimulate insulin secretion
2. Reduce postprandial glucagon production
3. Slow gastric emptying
4. Increase satiety

The most important incretin hormones that have been identified so far are glucagon-like peptide 1 (GLP-1) and gastric inhibitory peptide (GIP). These hormones are rapidly deactivated by the enzyme DPP-IV. The incretin mimetics

enhance glucose-dependent insulin secretion, suppress elevated glucagon secretion, and slow gastric emptying. Currently, there are two incretin mimetics: exenatide and liraglutide.

Indications

Exenatide (Byetta; pregnancy category C) was approved by the FDA in 2005 as the first incretin mimetic drug. Exenatide is a long-acting analogue of GLP-1 that was initially derived from the salivary gland of the Gila monster. This drug is available only as a subcutaneous injection and is indicated only for patients with type 2 diabetes who have been unable to achieve blood glucose control with metformin, a sulfonylurea, and/or a glitazone. It cannot be used with insulin. It is best given 60 minutes before a meal. Liraglutide (Victoza) is similar to exenatide.

Contraindications

These drugs are contraindicated in patients who are allergic to either drug.

Adverse Effects

Adverse effects include nausea, vomiting, and diarrhea. Rare cases of hemorrhagic or necrotizing pancreatitis have also been reported. Patients may experience weight loss of 5 to 10 pounds.

Interactions

The incretin mimetics can delay absorption of other orally administered drugs by slowing gastric emptying. In patients taking sulfonylurea drugs, the dose may need to be reduced if hypoglycemia appears on initiation of exenatide therapy.

Dosages

The usual starting dosage of exenatide is 5 mcg within 1 hour of both the morning and evening meals. If necessary, the dosage may be increased after 1 month to 10 mcg twice daily before meals. The dose of liraglutide is 0.6 mg titrated up to 1.2 or 1.8 mg daily.

GLUCOSE-ELEVATING DRUGS

Hypoglycemia is an abnormally low blood glucose level (generally below 50 mg/dL). When the cause is organic and the effects are mild, treatment usually consists of dietary modifications (a higher intake of protein and lower intake of carbohydrates), to prevent a rebound postprandial hypoglycemic effect. Hypoglycemia is also a common adverse effect of many antidiabetic drugs when their pharmacologic effects are greater than expected. Because the brain needs a constant amount of glucose to function, early symptoms of hypoglycemia include the central nervous system (CNS) manifestations of confusion, irritability, tremor, and sweating. Later symptoms include hypothermia and seizures. Without adequate restoration of normal blood and CNS glucose levels, coma and death will occur.

Oral forms of concentrated glucose are available for patients to use in the event of a hypoglycemic crisis. Dosage forms include rapidly dissolving buccal tablets and semisolid gel forms designed for oral use and rapid mucosal absorption. Table sugar, which is sucrose, will not produce as rapid an effect as the glucose products intended for use by diabetic patients. This is because sucrose is a disaccharide (two-molecule) sugar that must first be digested in the body to yield glucose as a monosaccharide (one-molecule) by-product. In the hospital setting or when the patient is unconscious, intravenous glucose is an obvious option to treat hypoglycemia. Concentrations of up to 50% dextrose in water ($D_{50}W$) are most often used for this purpose.

In addition to oral and/or intravenous glucose, glucagon, a natural hormone secreted by the pancreas, is available as a subcutaneous injection to be given when a quick response to severe hypoglycemia is needed. Because glucagon injection may induce vomiting, roll an unconscious patient onto his or her side before injection. Glucagon is useful in the unconscious hypoglycemic patient without established intravenous access.

TEAMWORK AND COLLABORATION: PHARMACOKINETIC BRIDGE TO NURSING PRACTICE

Continuous subcutaneous insulin infusion has been used in patients with type 1 diabetes for over a quarter of a century and is increasing. Provision of insulin therapy by continuous subcutaneous insulin infusion (CSII) is becoming an option for selected diabetic patients in an attempt to minimize the risks and complications of the disease. One previously used option for achieving tight control of blood glucose levels was multiple daily injections of insulin (MDI). With CSII, normal serum glucose levels are maintained by the continuous delivery of basal insulin, and then with food intake—primarily carbohydrate consumption—bolus doses of insulin are given. Use of an insulin pump (i.e., CSII) leads to a more rapid, consistent absorption of the drug and a reduction in the occurrence of hypoglycemia. Research has also shown that use of an insulin pump helps to decrease the occurrence of elevated pre-breakfast serum glucose levels, often called the *dawn phenomenon* (referring to the dawn of the day). Because the insulin pump delivers insulin through the subcutaneous route and the infusion is a continuous one, fewer problems occur than with once- or twice-daily injections. Patients using CSII achieve mean serum glucose and A1C levels that remain somewhat lower than those associated with MDI, so that the risk for hypoglycemia is decreased. Understanding new and different drugs and their pharmacokinetic properties allows you to help patients achieve better quality of life, minimize risks, and maximize wellness.

NURSING PROCESS

ASSESSMENT

Before administering any type of antidiabetic drug, assess the patient's knowledge about the disease and recommended treatment. Complete a head-to-toe physical assessment, medication history taking, and nursing assessment and document the findings. With *insulin*, as well as other antidiabetic drugs, a thorough medication history includes a list of the patient's current medications, including over-the-counter drugs, herbals, and

supplements. Review the appropriate laboratory test results (e.g., fasting blood glucose level, A1C level) for any abnormalities compared with baseline levels. Assess the prescriber's order for insulin, so that the correct drug, route, type of insulin (i.e., rapid acting, short acting, intermediate acting, short- and intermediate-acting mixtures, long acting), and dosage are implemented correctly. Assess the specific insulin, paying additional attention to the specific pharmacokinetics such as onset of action, peak, and duration of action. Knowing this information prior to giving the insulin is key to patient safety because these drug properties actually define parameters within which reactions, adverse effects, or problems versus therapeutic effects potentially occur. With insulin, it is also important to assess the prescriber's order for type of insulin. If more than one insulin type is prescribed, mixing of insulins may be ordered. It is important for you to know the chemically compatible combinations (see Table 32-4) so as to avoid an undesirable altered glycemic effect. Additionally, with all insulin orders, perform a second check of the prepared insulin dosage against the medication order with another registered nurse, or perform per facility policy and document.

Assess blood glucose levels prior to administering insulin to avoid giving the drug to a patient who is already hypoglycemic. The 2012 ADA guidelines identify the key diagnostic criterion for diabetes as being a fasting plasma glucose of greater than 126 mg/dL or a hemoglobin AIC greater than 6.5% (see Box 32-1). Furthermore, the ADA recommends the following control criteria for the diabetic patient: fasting blood glucose within the range of 70 to 130 mg/dL and/or a hemoglobin A1C less than 7%. Keep in mind that allergic reactions are less likely to occur with recombinant human insulins because of their similarity with endogenous insulin; however, allergies may still occur and have to be considered in the assessment. Contraindications and cautions associated with insulin have been previously discussed. Significant drug interactions are presented in Table 32-5, but it is important to remember the drugs that work against the effect of insulin, include corticosteroids, thyroid drugs, and diuretics. Drugs that increase the hypoglycemic effects of insulin include, alcohol, sulfa antibiotics, and salicylates.

Oral antidiabetic drugs also require close assessment for contraindications, cautions, and drug interactions, so obtain a thorough medication and patient history. Make sure to know the patient's history because type 2 diabetes can be treated with oral antidiabetic drugs, most of which require functioning beta cells in the pancreas. Functioning beta cells are not present in type 1 diabetes. With *biguanides*, be aware that elderly or malnourished patients may react adversely to this group of drugs. Contraindications, cautions, and interactions for this drug class have been previously discussed, but it is important to patient safety to emphasize the interaction between metformin and the iodine-containing radiologic contrast media used for certain diagnostic purposes (e.g., computed tomography with contrast). This interaction is associated with an increased risk for acute renal failure and lactic acidosis. If the patient is taking *metformin*, closely assess and monitor for this scenario so that the metformin may be discontinued the day of the test and for at least 48 hours afterwards. See Table 32-5 for more drug interactions associated with the oral antidiabetic drugs.

With *sulfonylureas,* it is important to know baseline glucose levels as well as conditions that may predispose the patient to hypoglycemia, such as a drop in caloric intake, alcohol use, or advanced age. Assessment of allergic reaction to sulfonamide antibiotics is important, as well, because of a potential for cross-allergic reactions. With *glinides,* cautions, contraindications, and drug interactions are similar to those for sulfonylureas. With *thiazolidinediones (glitazones),* a major contraindication is with class III or IV heart failure (as per the New York Heart Association classification); the FDA has essentially removed rosiglitazone (Avandia) from the market due to these cardiac problems. It is only available through specialized manufacturing programs. With *alpha-glucosidase inhibitors* (e.g., acarbose and miglitol), assess for contraindications, such as inflammatory bowel disease or malabsorption syndromes. With *second-generation sulfonylureas,* assess the patient's type of diabetes because these drugs are contraindicated in type 1 diabetes.

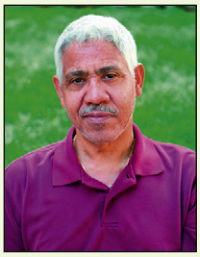
Newer antidiabetic drugs include the *amylin mimetics* (see pharmacology section). These drugs are contraindicated in patients with gastroparesis or in patients who are taking medications that alter GI motility. Assessing for the type of diabetes is important because the drug pramlintide is indicated for both patients with type 1 or type 2 diabetes with particular mealtime needs and who are not able to achieve optimal blood glucose level control with insulin. Exenatide, an *incretin mimetic,* requires assessment of the patient's diagnosis because the drug is used for patients with type 2 diabetes and an inability to control blood glucose levels with metformin, a sulfonylurea, and/or a glitazone. It should not be used with insulin.

With diabetes mellitus, unstable serum glucose levels require immediate attention, so assess the patient for any signs and symptoms of hypoglycemia (e.g., acute onset of confusion, irritability, tremor, and sweating, with progression to possible hypothermia and seizures, and blood glucose level of less than 50 mg/dL) or of hyperglycemia (e.g., polyuria, polydipsia, polyphagia, glucosuria, weight loss, and fatigue, with a fasting blood glucose levels of 126 mg/dL or higher or a nonfasting blood glucose level of 200 mg/dL or higher). Assessment is even more critical for a diabetic patient who is also under stress, has an infection or is ill, is pregnant or lactating, or is experiencing trauma or any serious change in health status. With treatment, diabetic patients are at risk of hypoglycemia with the potential danger of loss of consciousness; therefore, constantly assess serum glucose levels and neurologic status. Along with assessment of the therapeutic regimen and patient adherence to treatment, note any cultural factors, socioeconomic factors, and family support, and follow throughout therapy.

Glucose-elevating drugs are to be given only after thorough assessment of the patient's presenting clinical picture and a thorough collection of data, including laboratory values, medication and patient history, as well as a list of current medications. Assess for level of consciousness as well, because glucagon injection may induce vomiting and precautions must be implemented to prevent aspiration.

CASE STUDY

Diabetes Mellitus: Lispro Insulin



B.G., age 58, was diagnosed with type 2 adult-onset diabetes mellitus 10 years ago. Although he has type 2 diabetes mellitus, he has needed to take insulin for the last 2 years. He has been recovering, without complications, from a laparoscopic cholecystectomy, but his blood glucose levels have shown some wide fluctuations over the past 24 hours. The physician has changed his insulin from regular to lispro (Humalog) to see if it will provide better control of his blood glucose levels.

1. Before his surgery, B.G.'s hemoglobin A1C level was 9%. What does this value imply regarding his glycemic control?
2. While reviewing the instructions for the lispro insulin, B.G. states, "I took my regular insulin shots about 30 minutes before my meals. Hopefully I can keep that same routine." How will the nurse respond to this statement?
3. After his discharge, B.G. wakes up one morning feeling nauseated. He gives himself the lispro insulin injection, but then after eating breakfast he vomits and cannot keep any food down. What must he do at this time?

For answers, see http://evolve.elsevier.com/Lilley.

NURSING DIAGNOSES

1. Imbalanced nutrition, less than body requirements, related to the body's inability to use glucose (for type 1)
2. Ineffective family therapeutic regimen management related to lack of experience with a significant daily treatment regimen of diabetes mellitus
3. Risk for unstable glucose due to recent onset of possible signs and symptoms of diabetes mellitus

PLANNING

GOALS

1. Patient maintains adequate and balanced nutrition with stable weight and improved dietary habits in the overall management of diabetes.
2. Patient and family state the importance of adherence to medication regimens, lifestyle changes, dietary restrictions, and avoidance of high-risk behaviors.
3. Patient begins to understand the etiology of unstable glucose levels and its management.

OUTCOME CRITERIA

1. Patient adheres to the diet recommended by the ADA or other dietary advisor per the orders of the prescriber or nutritional consultant.
   - Patient eats a healthy diet, gets sufficient rest and relaxation, and notifies the prescriber if any unusual problems occur when customary activities are changed.
2. Patient and family report increase in therapeutic regimen management as noted by support (by family), keeping all scheduled appointments with the prescriber to monitor therapeutic effectiveness, diet, and lifestyle change implementation and awareness for the complications of therapy.
3. Patient takes medication as scheduled, monitors blood glucose levels as prescribed, and watches for any signs and symptoms of hyperglycemia or hypoglycemia.
   - Patient's fasting blood glucose (fasting is considered to be no food/meals/snacks for 8 hours) goal is to be within the range of 70 to 130 mg/dL and/or hemoglobin A1C less than 7%.

IMPLEMENTATION

With any patient who is taking *insulin* (or *oral antidiabetic drugs*), always check serum glucose levels (and other related laboratory values, as ordered) before giving the drug so that accurate baseline glucose levels are obtained and documented. Do not shake NPH (cloudy) and premixed insulin mixtures, but roll between the hands before administering the prescribed dose. The rolling helps to avoid air in the syringe and inaccurate dose administration. Administer insulins at room temperature. Insulin may be stored at room temperature if used within 1 month; otherwise, refrigeration is needed. Refrigeration is also recommended in warm or hot climates and with any major changes in environmental temperatures from cold to hot. Never use expired or discolored insulin. For information about the handling, mixing, storage, and administration of insulin, see Box 32-2.

Administer *insulin* subcutaneously at a 90-degree angle unless the patient is emaciated, in which case you may give the insulin at a 45-degree angle. Only regular insulin may be administered intravenously and is often used in intensive care settings. Only use insulin syringes for subcutaneous injections or when drawing up insulin dosage amounts. These syringes are easy to identify because of their orange caps and calibration in units, not milliliters. These syringes have preattached needles that are 29 gauge and ½ inch in length. When insulins are mixed (if ordered), withdraw the regular or rapid-acting insulin (unmodified and clear) first, followed by withdrawing the intermediate-acting or NPH insulin (modified and cloudy). Only do this after the appropriate amount of air has been injected into the vials. The amount of air to inject into the vials equals the prescribed number of units. Inject air into the intermediate-acting insulin vial first. Next, inject air into the regular or rapid- or short-acting insulin vial. This technique helps keep the intermediate-acting insulin from contaminating the rapid-acting insulin vial. This contamination would lead to a change in the regular, short-acting, unmodified insulin by the NPH, intermediate-acting, modified insulin. The net effect is an interference of the activity of the regular insulin (no longer considered modified), thus impacting its effect in the patient (see Table 32-4 and Chapter 9).

Understanding the action of the insulin and its related pharmacokinetics (e.g., onset, peak, duration) is critical for safe care and patient education. For example, it is important to know that the rapid-acting insulins (insulin lispro, insulin aspart, and insulin glulisine) have an onset of action of about 15 minutes and must be given 15 minutes before meals, compared with 30 minutes before meals for regular insulin or a short-acting insulin, which has an onset of action of 30 to 60 minutes. If lispro insulin is to be mixed with NPH (intermediate-acting) insulin, give the combination 15 minutes before meals. Always double-check

BOX 32-2 ADMINISTRATION, HANDLING, AND STORAGE OF INSULIN

Dosages, Storage, Handling, and Mixing

1. Individualize insulin dosages, and monitor closely for adequate control of hypoglycemia and hyperglycemia. Follow guidelines for basal/bolus insulin therapy or sliding scale, depending on specific regimen identified in the hospital setting.
2. Adjust dosages, as ordered, to achieve the prescriber's specific fasting blood glucose level for the patient. Using the ADA 2012 guidelines, this would be a fasting blood glucose level of 70 to 130 mg/dL and/or hemoglobin A1C less than 7% for the diabetic patient.
3. Store insulin for current use at room temperature. Avoid extreme temperatures and exposure to sunlight, because the insulin's protein structure will be permanently denatured. Extra vials not in use may be kept in the refrigerator. Vials being used in high environmental temperatures need to be stored in the refrigerator, but never give cold insulin. Never freeze insulin. To maintain drug stability, only store insulin for up to 1 month at room temperature or up to 3 months in the refrigerator.
4. Discard unused vials if they have not been used for several weeks (or follow hospital policy). Do not use any insulin that does not have the proper clarity or color (e.g., clear for regular, cloudy for NPH).
5. Store prefilled insulin syringes in the refrigerator for up to 1 week.
6. Always check expiration dates of insulin and all equipment.

Administration

1. Administer insulin subcutaneously (see Chapter 9); however, regular insulin may be given intravenously in special situations (e.g., intravenous drip in patient with diabetic ketoacidosis; in postoperative patients), if ordered.
2. Roll the cloudy drug vial gently between the hands without shaking to avoid bubble formation in the vial, which may lead to inaccurate dosage withdrawal. Give freshly mixed insulins within 5 minutes of mixing to avoid binding of the solution and subsequent altered activity of the drugs.
3. Administer insulin at the recommended times, but always with meals or meal trays ready. Give insulin lispro and other rapid-acting insulins approximately 15 minutes before meals (it has a quicker onset of action) and only after monitoring the patient's fasting serum glucose level (as with all insulin administration). Give regular insulin (short-acting insulin) 30 minutes before meals, and NPH intermediate insulin 30 to 60 minutes before meals.
4. When giving regular and NPH insulin at the same time (if ordered), mix the two appropriately (see discussion of mixing insulins in the Implementation subsection under Nursing Process).
5. Administer insulin subcutaneously at a 90-degree angle. However, if the patient is emaciated, the injection may be given at a 45-degree angle. Only use insulin syringes (see text discussion and Chapter 9).
6. Instruct patients using insulin injections to rotate sites within the same general location for about 1 week before moving to a new location (e.g., all injections for a week in the upper right thigh before moving a little lower on the right thigh). This technique allows for better insulin absorption. Each injection site should be at least ½ to 1 inch away from the previous injection site. If this practice is followed, it will be approximately 6 weeks before the patient will have to rotate to a totally new area of the body. Note the following sites for subcutaneous insulin injections: thigh areas (front and back), outer areas of the upper arm (middle third of the upper arm between the shoulder and the elbow), and the abdominal area using the iliac crests as landmarks and using the fatty part of the abdomen, but not within 2 inches of umbilicus or incision/stoma (see Chapter 9).
7. Continuous subcutaneous insulin infusion and/or multiple daily injections may be ordered for tight glucose control.

the prescriber's orders for clarification of the dosage and drug as well as of any change in dietary intake, such as a possible increase in carbohydrates and decrease in fat to avoid postprandial hypoglycemia. A meal high in fat can delay carbohydrate absorption while rapid-acting insulin is already in its peak action.

Regardless of the specific type of recombinant human insulin used, understanding the peak, onset, and duration of action of the insulin to be used (e.g., rapid acting versus short acting versus intermediate acting versus long acting) will help determine when food or meals are to be given. The intermediate-acting insulin (NPH) has an onset of action of 1 to 2 hours, so serve meals at least 30 to 45 minutes prior to its administration. Many combination products of rapid- and short-acting with intermediate-acting insulin are available; give these combination insulins 15 to 30 minutes before meals. In the hospital setting, be sure that meal trays have arrived on the unit before giving insulin to avoid time lapses and subsequent hypoglycemic episodes. Also be sure that other forms of allowed foods are available to the patient in case meals are delayed and insulin has already been administered.

Patients may require dosing by a sliding-scale or a basal-bolus method in a hospital setting. Sliding scale has historically been the method for administering subcutaneous regular insulin doses adjusted according to serum glucose test results. Although controversial (see previous pharmacology discussion), sliding-scale dosing may be used for hospitalized diabetic patients experiencing drastic changes in serum glucose levels due to physical and/or emotional stress, infections, surgery, acute illness, inactivity, or variable caloric intake, as well as for patients needing intensive insulin therapy or patients—even if nondiabetic—receiving total parenteral nutrition (TPN) with a high glucose concentration. When this insulin regimen is used, measure blood glucose levels several times per day (e.g., every 4 hours, every 6 hours, or at specified times such as 7 AM, 11 AM, 4 PM, and midnight) to obtain fasting and/or premeal blood glucose values. The newer method, basal-bolus insulin dosing, is now the preferred method of treatment for hospitalized diabetic patients; orders for the dosages and frequency will be issued by the prescriber. A long-acting insulin (insulin glargine) is used to mimic the basal secretion of a healthy pancreas and constant delivery of an amount of insulin, and then the bolus is used (insulin lispro or insulin apart) to control increases in daily blood glucose levels. Bolus insulin is divided into meal and correction boluses (see pharmacology discussion). Monitor blood glucose levels frequently when using these methods.

Oral antidiabetic drugs are usually given at least 30 minutes before meals, as ordered. With any antidiabetic drug or insulin, it is important for both you and the patient to know what to do if symptoms of hypoglycemia occur—for example, the patient needs to take glucagon; eat glucose tablets or gel, corn syrup, or honey; drink fruit juice or a nondiet soft drink; or eat a small snack such as crackers or half a sandwich. If the patient receiving metformin is to undergo diagnostic studies with contrast dye, the prescriber will need to discontinue the drug prior to the procedure and restart it after the tests, but only after reevaluation of the patient's renal status. During therapy with metformin, the risk of lactic acidosis is possible, so it is important to monitor for and then report

hyperventilation, cold and clammy skin, muscle pain, abdominal pain, dizziness, and irregular heartbeat. Some of the sulfonylureas are to be taken with breakfast; the alpha-glucosidase inhibitors are always taken with the first bite of each main meal, and the thiazolidinediones are given once daily or in two divided doses. Always check the exact timing of the dose against the prescriber's order and with consideration of the drug's onset of action.

It is critical to the safe and efficient use of oral antidiabetics to be sure that food will be or is being tolerated before the dose is given. If the oral drug is taken and no meal is consumed or it is consumed at a later time than usual, hypoglycemia may be problematic and result in negative health consequences and even unconsciousness. Because the glitazones (e.g., rosiglitazone and pioglitazone) may both cause moderate weight gain and edema, it is important to weigh the patient daily at the same time every day and in the same amount of clothing. Several combination oral antidiabetic drug products are available (see the pharmacology discussion) and need to be given exactly as prescribed. Pramlintide needs to be given before any major meal. Exenatide is given by subcutaneous injection in patients with type 2 diabetes and cannot be used with insulin. Sitagliptin is not to be used with insulin and may be taken with or without food.

In special situations, such as when the patient has been ordered to have nothing by mouth (NPO status) and is taking either an oral antidiabetic drug or insulin, it is crucial to follow the prescriber's orders regarding drug administration. If there are no written orders about this situation, contact the prescriber for further instructions. If a patient is on NPO status but is receiving an intravenous solution of dextrose, the prescriber may still order insulin, but always clarify this (with the prescriber). Contact the prescriber if a patient becomes ill and unable to take the usual dosage of an oral antidiabetic drug (or insulin). Encourage the patient to always wear a medical alert bracelet or necklace giving the diagnosis, list of medications, and emergency contact information.

It is also very important to stay informed and up to date about the latest research on diabetes and to keep patients and family members well informed. For example, as previously discussed in the pharmacology section, macrovascular and microvascular problems are now being recognized to occur at fasting blood glucose levels as low as 126 mg/dL. See the Evidence-Based Practice box for more information on specific nursing research.

In summary, there are many nursing considerations related to drug therapy in patients with diabetes mellitus. Patient education is also very important and needs to begin the moment the patient has entered into the health care system or upon diagnosis. Instruction that is tailored to the patient's educational level and that uses appropriate teaching-learning concepts and teaching aids is important to patient adherence with the treatment regimen. In addition, be sure that all necessary resources are made available to patients (e.g., financial assistance, visual assistance, dietary plans, daily menus, ADA information, transportation assistance, and Meals on Wheels and other community services). See the Patient Teaching Tips for more information.

EVIDENCE-BASED PRACTICE

Sensor-Augmented Insulin Pump Therapy Trumps Multiple Daily Injections

Review

In patients with type 1 diabetes and poor glycemic control, a sensor-augmented insulin pump is significantly improving glycated hemoglobin levels as compared with regimens with multiple daily insulin injections. This research was presented at the American Diabetes Association 70th Scientific Session on June 29, 2010. Research has confirmed that the use of these pumps has demonstrated more effective control than the use of multiple daily injections.

Type of Evidence

Some 329 adults and 156 children were randomly assigned to either pump therapy with the MiniMed Paradigm REAL-Time system (Medtronic) or to continue with their regimen of multiple daily injections under close supervision for the duration of the study that lasted for one year. Patients in the study received intensive diabetes management education and training including carbohydrate counting and the administration of correction doses of insulin. Once patients were randomized to insulin pump therapy, they were placed on it for 2 weeks. After they had become comfortable with the pump, the glucose sensor was added. This group used the insulin aspart, and the injection therapy group used both insulin aspart and insulin glargine. All patients were seen at 3, 6, 9, and 12 months and used Carelink, which is a diabetes-management software program. This program was used to relay the patients' glucose data to communicate with their health care providers from home. It is important to know that the sensor-augmented pump therapy uses the two technologies of an insulin pump and continuous glucose monitoring all in one system. This pump allows patients and their physicians to monitor treatment and their response through Internet-based software. The patients needed to have computer access to participate in the study.

Results of Study

At 1 year, the researchers found that the patients on pump therapy had hemoglobin A1C levels that were significantly lower than the injection-therapy group. The baseline mean glycated hemoglobin level, which was 8.3% in the two groups, decreased to 7.5% in the pump therapy group as compared to 8.1% in the injection therapy group. Among the adults, the absolute reduction in the mean glycated hemoglobin level was 1.0% ± 0.7% in the pump-therapy group and 0.4% ± 0.8% in the injection-therapy group. The between-group difference in the pump-therapy group was –0.6%. The occurrence of hypoglycemia and diabetic ketoacidosis were similar in both groups. There was no significant weight gain in adult or child participants.

Link of Evidence to Nursing Practice

This study has been identified as one of the longest and largest randomized controlled study of sensor-augmented insulin pump therapy in type 1 diabetic patients. Another significant point to this study was the comparison of two therapeutic approaches. For nursing and for the care of diabetic patients, the impact of this study is important in that patients may be able to achieve better control of their diabetes with improved outcomes and safety. Having the positive results without the occurrence of increased hypoglycemia represents even larger breakthroughs in the care of these patients as well as the possibility of increased adherence to treatment. This study holds great promise in the treatment of type 1 diabetic patients and for evidenced-based nursing practice. The possibility of enhanced quality of life and prevention of complications in the treatment of patients with chronic illnesses, such as type 1 diabetes, is truly exciting and promising.

EVALUATION

It is important to understand current therapeutic guidelines. The prevailing key diagnostic criterion for diabetes mellitus is hyperglycemia with a fasting blood glucose level of 126 mg/dL or higher or a nonfasting blood glucose level of 200 mg/dL or higher; however, the therapeutic response to insulin and any of the oral antidiabetic drugs is a decrease in blood glucose to the level prescribed by the prescriber or to near-normal levels. Most often, fasting blood glucose levels are used to measure the degree of glycemic control. To provide a picture of the patient's adherence to the therapy regimen for the previous several months, the level of A1C is measured. This value reflects how well the patient has been doing with diet and drug therapy.

Patients with diabetes need to be monitored frequently by their prescribers (as well as at home) to make sure they are adhering to the therapy regimen as evidenced by normalization of blood test results. It is important to monitor the patient for indications of hypoglycemia or hyperglycemia and insulin allergy as well. With short-acting insulins such as lispro, the onset of action is more rapid than with regular insulin and the duration of action is shorter, so monitor blood glucose levels very closely until the dosage is regulated and blood glucose is at the level the prescriber desires. If a patient is switched from one insulin or oral antidiabetic drug to another, advise the patient that glucose levels must be monitored very closely at home or by the prescriber. Always evaluate whether identified goals and outcome criteria are being met, and plan nursing care accordingly.

PATIENT TEACHING TIPS

- Encourage the patient to keep medical alert jewelry or a medical alert card on his or her person at all times and to keep medical information in clear view on the refrigerator at home.
- Provide instructions and demonstrations regarding the proper storage of insulin, the equipment needed for administration, the drawing up and mixing of insulins (if ordered), technique for insulin injections, and rotation of subcutaneous insulin injection sites. Provide the opportunity for return demonstrations from the patient, including rotation of sites. (see Chapter 9 for more information about insulin injections). Emphasize that insulin may be stored at room temperature unless the heat is extreme or the patient is traveling.
- Encourage the keeping of a daily dietary intake and blood glucose journal.
- Educate about the need to have serum glucose levels monitored. Emphasize instructions that are specific to the patient's glucometer. Stress the importance of exercise, hygiene, foot care, dietary plan, and weight control in the management of diabetes.
- Pay attention to and assess the patient's economic situation when teaching about the frequency of blood glucose monitoring. If the patient must pay for supplies, each blood glucose check costs over $1. This expense can add up quickly, especially for those who are economically disadvantaged.
- Advise the patient to avoid smoking and alcohol consumption (with oral antidiabetic drugs) and maintain strict adherence to dietary instructions. Instruct the patient to avoid skipping meals or skipping doses of insulin or oral antidiabetic drugs, and to contact the prescriber for further instructions when needed.
- Explain the difference between hypoglycemia and hyperglycemia (see earlier discussion for specific signs and symptoms), with emphasis on the treatment of each (e.g., having on hand quick sources of glucose, such as candy, sugar packets, over-the-counter glucose tablets, sugar cubes, honey, corn syrup, orange juice, or nondiet soda beverages for hypoglycemia, and having more insulin on hand for hyperglycemia, as ordered). Encourage the patient to keep quick dosage forms of glucose in possession at all times!
- Educate the patient about situations or conditions that lead to altered serum glucose levels, such as fever, illness, stress, increased activity or exercise, surgery, and emotional distress. Encourage the patient to contact the prescriber for any questions or concerns about maintaining glucose control.
- Educate about the importance of knowing premeal serum glucose levels before taking insulin and the importance of timing meals related to the type of insulin.
- Emphasize the importance of having adequate supplies of insulin and equipment at all times and planning ahead for vacations. Instruct the patient to keep all medications and related equipment out of the reach of children. If needed, magnifying attachments are available for syringes and vials. Specialized syringes are available for those with impaired vision. Patients using these types of syringes learn to rely on the sound the syringe makes when a dosage is selected; for example, with Novologpen, 5 clicks equals 5 units.
- Encourage the diabetic patient to report any yellow discoloration of the skin, dark urine, fever, sore throat, weakness, or unusual bleeding or easy bruising.
- Emphasize the importance of A1C monitoring (e.g., at least two times per year for those with good glycemic control and quarterly for patients who are not at target values, have changed their therapy, or are not adhering to the therapy regimen) (Table 32-6). Review with the patient lifestyle modifications, including weight control and glucose level maintenance with diet, exercise, and/or drug therapy. Patients with type 2 diabetes have a greater therapeutic response to diet and exercise and glucose level control than patients with type 1 diabetes. ADA recommendations for fasting serum glucose level measurement need to be followed. Educate the patient about the importance of engaging in supervised exercise, as prescribed, and as a lifelong lifestyle change. A nutritional consult with specific menu planning may help the patient with changes in intake (e.g., low-fat diet with 160 to 300 g of carbohydrates). The ADA has also encouraged the "Create Your Plate" method of meal planning. (Visit www.diabetes.org/food-and-fitness/food/planning-meals/create-your-plate/ for specific information.) The

TABLE 32-6 DIABETES CARE: CORRELATION OF GLYCOSYLATED HEMOGLOBIN LEVELS WITH MEAN SERUM GLUCOSE LEVELS

HEMOGLOBIN A1C (%)	MEAN SERUM GLUCOSE LEVEL (mg/dL)	MEAN SERUM GLUCOSE LEVEL (mmol/L)
6	126	7.0
7	154	8.6
8	183	10.2
9	212	11.8
10	240	13.4
11	269	14.9
12	298	16.5

Data from American Diabetes Association: Executive summary: standards of medical care in diabetes, *Diabetes Care* 35(Suppl 1): S4-S10, 2012.

"Create Your Plate" method has six simple steps as a means of getting larger portions of nonstarchy vegetables and smaller portions of starchy foods. An imaginary line is drawn down the middle of the plate, creating two sections. One side is split into two equal smaller sections so there are now three total sections on the plate. The largest section (one side of the plate) is filled with nonstarchy vegetables. One of the small sections is filled with starchy foods. The other small section is filled with meat or meat substitutes. An 8-oz glass of nonfat or low-fat milk is also added.

- Emphasize the importance of the American Heart Association recommendations for diabetic patients, including 30 minutes of exercise daily with use of a treadmill, prolonged walking, swimming or aquatic aerobics, bicycling, rowing, chair exercises, arm exercises, and non–weight-bearing exercises. It is recommended to use a pedometer and to exercise for 150 minutes per week.
- Emphasize that therapy will be lifelong and that strict blood glucose control, drug therapy, and lifestyle changes are critical to reducing complications.
- Stress the need for strict foot care to the patient and those involved in the patient's care. Begin with the need for a daily basic assessment of the feet and toes to check for sores, lesions, cuts, bruises, ingrown toenails, and any other changes. Foot care is needed to enhance circulation and prevent infections. It may include soaking the feet daily or as ordered in lukewarm water (the temperature of the water must be checked) and then adequate drying of the feet and application of moisturizing lotion; checking the feet and legs for abnormal changes in color (e.g., purplish or reddish discoloration), cool temperature of the feet to the touch, swelling of the extremities or feet, and the appearance of any drainage. Emphasize the importance of contacting the prescriber for further instructions if there is suspicion of any type of wound or alteration in skin integrity. Frequent pedicures and nail trimming by a podiatrist or other licensed, certified individual may be indicated.
- Some of the oral antidiabetic drugs cause photosensitivity, so instruct the patient on wearing protective sunscreen and proper clothing when exposed to the sun. Advise against the use of tanning beds.

KEY POINTS

- Insulin normally facilitates removal of glucose from the blood and its storage as glycogen in the liver.
- Type 1 diabetes mellitus was formerly known as *insulin-dependent diabetes* or *juvenile-onset diabetes*. Little or no endogenous insulin is produced by individuals with type 1 diabetes. It is much less common than type 2 diabetes and affects only about 10% of all diabetic patients. Patients with type 1 diabetes usually are not obese. Because insulin therapy is required for type 1 diabetics, type 1 patients who have the cognitive and financial ability need to be encouraged to consider adding an insulin pump with continuous glucose monitoring as part of their therapy.
- The primary treatment for type 1 diabetes mellitus is insulin therapy. Patients with type 2 diabetes are managed with lifestyle changes (dietary changes, exercise, smoking cessation) and oral drug therapy (one or more drugs). If normal blood glucose levels are not achieved after 2 to 3 months of lifestyle changes, treatment with oral antidiabetic drugs is often added to the regimen.
- Insulin was originally isolated from cattle and pigs, but bovine and porcine insulins are associated with a higher incidence of allergic reactions and insulin resistance than human insulin and are no longer available in the U.S. market.
- Complications associated with diabetes include retinopathy, neuropathy, nephropathy, hypertension, cardiovascular disease, and coronary artery disease. Annual screening with an ophthalmologist specializing in retinopathies is needed in the care of diabetic patients for screening purposes. Because of the renal complications (e.g., nephropathies), annual urinalysis screening and renal function studies are also recommended for diabetic patients.
- All rapid-acting, short-acting, and long-acting insulin preparations are clear solutions. Intermediate-acting insulins are cloudy solutions. Mixtures of short- and intermediate-acting insulin still look uniformly cloudy. The cloudy appearance of these mixtures is due to the presence of the intermediate-acting insulin. Insulin vials are to be rolled in the hands instead of shaken, when used.
- Always carefully check the exact timing of the dose of insulin or oral antidiabetic drug against the prescriber's order. Take into consideration the drug's pharmacokinetics, including onset peak, and duration of action.
- Nursing care must be individualized with patient education focused on the patient's needs and learning abilities. Include pertinent and age-appropriate information on the disease process, drug therapy, and lifestyle modifications.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 Which is the most appropriate timing regarding the nurse's administration of a rapid-acting insulin to a hospitalized patient?
- **a** Give it 15 minutes before the patient begins a meal.
- **b** Give it ½ hour before a meal.
- **c** Give it 1 hour after a meal.
- **d** The timing of the insulin injection does not matter with insulin lispro.

2 Which statement is appropriate for the nurse to include in patient teaching regarding type 2 diabetes?
- **a** "Insulin injections are never used with type 2 diabetes."
- **b** "You don't need to measure your blood glucose levels because you are not taking insulin injections."
- **c** "A person with type 2 diabetes still has functioning beta cells in his or her pancreas."
- **d** "Patients with type 2 diabetes usually have better control over their diabetes than those with type 1 diabetes."

3 The nurse monitoring a patient for a therapeutic response to oral antidiabetic drugs will look for
- **a** fewer episodes of diabetic ketoacidosis (DKA).
- **b** weight loss of 5 pounds.
- **c** hemoglobin A1C levels of less than 7%.
- **d** glucose levels of 150 mg/dL.

4 A patient with type 2 diabetes is scheduled for magnetic resonance imaging (MRI) with contrast dye. The nurse reviews the orders and notices that the patient is receiving metformin (Glucophage). Which action by the nurse is appropriate?
- **a** Proceed with the MRI as scheduled.
- **b** Notify the radiology department that the patient is receiving metformin.
- **c** Expect to hold the metformin the day of the test and for 48 hours after the test is performed.
- **d** Call the prescriber regarding holding the metformin for 2 days before the MRI is performed.

5 A patient with type 2 diabetes has a new prescription for repaglinide (Prandin). After 1 week, she calls the office to ask what to do, because she keeps missing meals. "I work right through lunch sometimes, and I'm not sure whether I need to take it. What do I need to do?" What is the nurse's best response?
- **a** "You need to try not to skip meals, but if that happens, you will need to skip that dose of Prandin."
- **b** "We will probably need to change your prescription to insulin injections because you can't eat meals on a regular basis."
- **c** "Go ahead and take the pill when you first remember that you missed it."
- **d** "Take both pills with the next meal, and try to eat a little extra to make up for what you missed at lunchtime."

6 When checking a patient's fingerstick blood glucose level, the nurse obtains a reading of 42 mg/dL. The patient is awake but states he feels a bit "cloudy-headed." After double-checking the patient's glucose level and getting the same reading, which action by the nurse is most appropriate?
- **a** Administer two packets of table sugar.
- **b** Administer oral glucose in the form of a semisolid gel.
- **c** Administer 50% dextrose IV push.
- **d** Administer the morning dose of lispro insulin.

7 A patient is taking metformin for new-onset type 2 diabetes mellitus. When reviewing potential adverse effects, the nurse will include information about: (Select all that apply.)
- **a** Abdominal bloating
- **b** Nausea
- **c** Diarrhea
- **d** Headache
- **e** Weight gain
- **f** Metallic taste

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the normal anatomy, physiology, and related functions of the adrenal glands, including specific hormones released from the glands.
2 Briefly compare the hormones secreted by the adrenal medulla with those secreted by the adrenal cortex.
3 Contrast Cushing's syndrome, Addison's disease, and addisonian crisis.
4 Compare the glucocorticoids and mineralocorticoids with regard to the roles they perform in normal bodily functions, the diseases that alter them, how they are used in pharmacotherapy, and their basic properties.
5 Contrast the mechanisms of action, indications, dosages, routes of administration, cautions, contraindications, drug interactions, and adverse effects of glucocorticoids, mineralocorticoids, and antiadrenal drugs.
6 Develop a nursing care plan that includes all phases of the nursing process for patients taking adrenal and antiadrenal drugs.

DRUG PROFILES

- **aminoglutethimide, p. 539**
- **fludrocortisone, p. 538**
  methylprednisolone, p. 538
- **prednisone, p. 538**

- *Key drug*

KEY TERMS

Addison's disease A potentially life-threatening condition caused by partial or complete failure of adrenocortical function, with resulting decrease in glucocorticoid, mineralocorticoid, and androgenic hormones. It is a chronic disease of hyposecretion of steroids. (p. 535)

Adrenal cortex The outer portion of the adrenal gland. (p. 534)

Adrenal crisis An acute, life-threatening state of profound adrenocortical insufficiency requiring immediate medical management. It is characterized by glucocorticoid deficiency, a drop in extracellular fluid volume, hyponatremia, and hyperkalemia. (p. 540)

Adrenal medulla The inner portion of the adrenal gland. (p. 534)

Aldosterone A mineralocorticoid hormone produced by the adrenal cortex that acts on the renal tubule to regulate sodium and potassium balance in the blood. (p. 534)

Cortex The general anatomic term for the outer layers of a body organ or other structure. (p. 534)

Corticosteroids Any of the natural or synthetic adrenocortical hormones; those produced by the cortex of the adrenal gland (adrenocorticosteroids). (p. 534)

Cushing's syndrome A metabolic disorder characterized by abnormally increased secretion of the adrenocorticosteroids. (p. 534)

KEY TERMS—cont'd

Epinephrine An endogenous hormone secreted into the bloodstream by the adrenal medulla; also a synthetic drug that is an adrenergic vasoconstrictor and also increases cardiac output. (p. 534)

Glucocorticoids A major group of corticosteroid hormones that regulate carbohydrate, protein, and lipid metabolism and inhibit the release of adrenocorticotropic hormone (corticotropin). (p. 534)

Hypothalamic-pituitary-adrenal (HPA) axis A negative feedback system involved in regulating the release of corticotropin-releasing hormone by the hypothalamus, adrenocorticotropic hormone (corticotropin) by the pituitary gland, and corticosteroids by the adrenal glands. Suppression of the HPA may lead to Addison's disease and possible adrenal crisis or addisonian crisis. This suppression results from chronic disease or exogenous sources, such as long-term glucocorticoid therapy. (p. 534)

Medulla A general anatomic term for the most interior portions of an organ or structure. (p. 534)

Mineralocorticoids A major group of corticosteroid hormones that regulate electrolyte and water balance; in humans the primary mineralocorticoid is aldosterone. (p. 534)

Norepinephrine An adrenergic hormone, also secreted by the adrenal medulla, that increases blood pressure by causing vasoconstriction but does not appreciably affect cardiac output; it is the immediate metabolic precursor to epinephrine. (p. 534)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

ADRENAL SYSTEM

The adrenal gland is an endocrine organ that sits on top of the kidney like a cap. It is composed of two distinct parts called the **adrenal cortex** and the **adrenal medulla;** both are structurally and functionally different from one another. In general, the term **cortex** refers to the outer layers of various organs (e.g., cerebral cortex), whereas the term **medulla** refers to the most internal layers. The adrenal cortex composes roughly 80% to 90% of the entire adrenal gland; the remainder is the medulla. The adrenal cortex is made up of regular endocrine tissue (hormone driven). The adrenal medulla is made up of neurosecretory endocrine tissue (driven by both hormones and peripheral autonomic nerve impulses). Therefore, the adrenal gland actually functions as two different endocrine glands, each secreting different hormones.

The adrenal medulla secretes two important hormones, both of which are catecholamines. These are **epinephrine,** which accounts for about 80% of the secretion, and **norepinephrine,** which accounts for the other 20%. (Both of these hormones are discussed in Chapter 18 and are not described further in this chapter in any detail.) Characteristics of the adrenal cortex and the adrenal medulla and the various hormones secreted by each are presented in Table 33-1.

The hormones secreted by the adrenal cortex, which are the focus of this chapter, are broadly referred to as **corticosteroids.** They arise from the cortex and are made from the steroid known as *cholesterol.* There are two types of corticosteroids—**glucocorticoids** and **mineralocorticoids.** They are secreted by two different layers, or zones, of the cortex. The *zona glomerulosa,* which is the outer layer, secretes the mineralocorticoids, and the *zona fasciculata,* which lies under the zona glomerulosa, secretes the glucocorticoids. A third, inner layer, the *zona reticularis,* secretes small amounts of sex hormones. All the hormones secreted by the adrenal cortex are steroid hormones; that is, they have the steroid chemical structure.

The mineralocorticoids get their name from the fact that they play an important role in regulating mineral salts (electrolytes) in the body. In humans, the only physiologically important mineralocorticoid is **aldosterone.** Its primary role is to maintain normal levels of sodium in the blood (sodium homeostasis) by causing sodium to be resorbed from the urine back into the blood in exchange for potassium and hydrogen ions. In this way aldosterone not only regulates blood sodium levels but also influences the potassium levels in the blood and blood pH.

The corticosteroids are necessary for many vital bodily functions. Some of the more important ones are listed in Box 33-1. Without these hormones, life-threatening consequences may arise.

Adrenal corticosteroids are synthesized as needed; the body does not store them as it does other hormones. The body levels of these hormones are regulated by the **hypothalamic-pituitary-adrenal (HPA) axis** in much the same way that the levels of hormones secreted by the pancreas, thyroid, and pituitary are regulated. As the name implies, this axis consists of a very organized system of communications between the adrenal gland, the pituitary gland, and the hypothalamus. As is the case for the other endocrine glands, it uses hormones as the messengers and a negative feedback mechanism as the controller and maintainer of the process. This feedback mechanism operates as follows: When the level of a particular corticosteroid is low, corticotropin-releasing hormone is released from the hypothalamus into the bloodstream and travels to the anterior pituitary gland, where it triggers the release of adrenocorticotropic hormone (ACTH; also called *corticotropin).* The ACTH is then transported in the blood to the adrenal cortex, where it stimulates the production of the corticosteroids. Corticosteroids are then released into the bloodstream. When they reach peak levels, a signal (negative feedback) is sent to the hypothalamus, and the HPA axis is inhibited until the level of corticosteroids again falls below physiologic threshold, whereupon the axis is stimulated once again.

The oversecretion (hypersecretion) of adrenocortical hormones can lead to a group of signs and symptoms called **Cushing's syndrome.** This hypersecretion of glucocorticoids results in

TABLE 33-1 ADRENAL GLAND: CHARACTERISTICS

TYPE OF TISSUE	TYPE OF HORMONE SECRETED	HORMONES SECRETED AND RELATED DRUGS
Adrenal Cortex		
Endocrine	Glucocorticoids	Adrenocorticotropic hormone, betamethasone, cortisone, dexamethasone, hydrocortisone, methylprednisolone, prednisolone, triamcinolone
	Mineralocorticoids	Aldosterone, desoxycorticosterone, fludrocortisone
Adrenal Medulla		
Neuroendocrine	Catecholamines	Epinephrine, norepinephrine

BOX 33-1 ADRENAL CORTEX HORMONES: BIOLOGIC FUNCTIONS

Glucocorticoids
Antiinflammatory actions
Carbohydrate and protein metabolism
Fat metabolism
Maintenance of normal blood pressure
Stress effects

Mineralocorticoids
Blood pressure control
Maintenance of serum potassium levels
Maintenance of pH levels in the blood
Sodium and water resorption

the redistribution of body fat from the arms and legs to the face, shoulders, trunk, and abdomen, which leads to the characteristic "moon face." Such a glucocorticoid excess can be due to several causes, including ACTH-dependent adrenocortical hyperplasia or tumor, ectopic ACTH-secreting tumor, or excessive administration of steroids. The hypersecretion of aldosterone, or primary aldosteronism, leads to increased retention of water and sodium, which causes muscle weakness due to the potassium loss.

The undersecretion (hyposecretion) of adrenocortical hormones causes a condition known as **Addison's disease.** It is associated with decreased blood sodium and glucose levels, increased potassium levels, dehydration, and weight loss. The combination of a mineralocorticoid (fludrocortisone) and a glucocorticoid (prednisone or some other suitable drug) is used for treatment.

PHARMACOLOGY OVERVIEW

ADRENAL DRUGS

All of the naturally occurring corticosteroids are available as exogenous drugs. There are also higher-potency synthetic analogues. The adrenal glucocorticoids are an extremely large

TABLE 33-2 AVAILABLE SYNTHETIC CORTICOSTEROIDS

TYPE OF HORMONE	METHOD OF ADMINISTRATION	INDIVIDUAL DRUGS
Adrenal steroid inhibitor	Systemic	Aminoglutethimide
Glucocorticoid	Topical	Alclometasone, betamethasone, clobetasol dexamethasone, fluocinolone, halobetasol hydrocortisone, mometasone, triamcinolone
	Systemic	Betamethasone, cortisone, dexamethasone, hydrocortisone, methylprednisolone, prednisolone, prednisone, triamcinolone
	Inhaled	Beclomethasone, dexamethasone, flunisolide, triamcinolone, fluticasone
	Nasal	Beclomethasone, dexamethasone, flunisolide, triamcinolone, fluticasone
Mineralocorticoid	Systemic	Fludrocortisone

group of steroids and can be categorized in various ways. They can be classified by whether they are a natural or synthetic corticosteroid, by the method of administration (e.g., systemic, topical), by their salt and water retention potential (mineralocorticoid activity), by their duration of action (i.e., short, intermediate, or long acting), or by some combination of these methods. The only corticosteroid drug with exclusive mineralocorticoid activity is fludrocortisone. Its uses are much more specific than those of the glucocorticoids and are discussed in the drug profile for fludrocortisone. The currently available synthetic adrenal hormones and adrenal steroid inhibitors are listed in Table 33-2.

Mechanism of Action and Drug Effects

The action of the corticosteroids is related to their involvement in the synthesis of specific proteins. There are several steps to this process. Initially the steroid hormone binds to a receptor on the surface of a target cell to form a steroid-receptor complex, which is then transported through the cytoplasm to the nucleus of that target cell. Once inside the nucleus, the complex stimulates the cell's deoxyribonucleic acid (DNA) to produce messenger ribonucleic acid (mRNA), which is then used as a template for the synthesis of a specific protein. It is these proteins that exert specific effects.

Most of the corticosteroids exert their effects by modifying enzyme activity; therefore, their role is more intermediary than direct. The naturally occurring mineralocorticoid aldosterone affects electrolyte and fluid balance by acting on the distal renal tubule. It promotes sodium resorption from the nephron into the blood, which pulls water and fluid along with it. In doing so, it causes fluid and water retention, which leads to edema and

hypertension. It also increases urinary excretion of potassium and hydrogen via the kidney.

The glucocorticoid drugs hydrocortisone (called *cortisol* in its naturally occurring form) and cortisone have some mineralocorticoid activity and therefore have some of the same effects as aldosterone (i.e., fluid and water retention). However, their main effect is the inhibition of inflammatory and immune responses. Glucocorticoids inhibit or help control the inflammatory response by stabilizing the cell membranes of inflammatory cells called *lysosomes,* decreasing the permeability of capillaries to the inflammatory cells, and decreasing the migration of white blood cells into already inflamed areas. They may lower fever by reducing the release of interleukin-1 from white blood cells. They also stimulate the *erythroid cells* that eventually become red blood cells. The glucocorticoids also promote the breakdown (catabolism) of protein, the production of glycogen in the liver (glycogenesis), and the redistribution of fat from peripheral to central areas of the body. In addition, they have the following effects on various bodily functions: increasing levels of blood sugar, increasing the breakdown of proteins to amino acids, inducing lipolysis, stimulating bone demineralization, and stabilizing mast cells.

Indications

All of the systemically administered glucocorticoids have a similar clinical efficacy but differ in their potency and duration of action and in the extent to which they cause salt and water retention (Table 33-3). These drugs have broad indications, including the following:

- Adrenocortical deficiency
- Adrenogenital syndrome
- Bacterial meningitis (particularly in infants)
- Cerebral edema
- Collagen diseases (e.g., systemic lupus erythematosus)
- Dermatologic diseases (e.g., exfoliative dermatitis, pemphigus)
- Endocrine disorders (thyroiditis)
- Gastrointestinal (GI) diseases (e.g., ulcerative colitis, regional enteritis)
- Exacerbations of chronic respiratory illnesses such as asthma and chronic obstructive pulmonary disease
- Hematologic disorders (reduce bleeding tendencies)
- Ophthalmic disorders (e.g., nonpyogenic inflammations)
- Organ transplantation (decrease immune response to prevent organ rejection)
- Leukemias and lymphomas (palliative management)
- Nephrotic syndrome (remission of proteinuria)
- Spinal cord injury

Glucocorticoids are also administered by inhalation for the control of steroid-responsive bronchospastic states. However, glucocorticoid inhalers are not used as rescue inhalers for acute bronchospasm. Nasally administered glucocorticoids are used to manage rhinitis and to prevent the recurrence of polyps after surgical removal (see Chapter 36). Topical steroids are used in the management of inflammation of the eye, ear, and skin. Prednisone is the most commonly used oral drug, followed by dexamethasone. Methylprednisolone is the most commonly used injectable glucocorticoid, followed by hydrocortisone and dexamethasone. Betamethasone is the drug of choice for women in premature labor to accelerate fetal lung maturation.

Contraindications

Contraindications to the administration of glucocorticoids include drug allergy and may include cataracts, glaucoma, peptic ulcer disease, mental health problems, and diabetes mellitus. The adrenal drugs may intensify these diseases. For example, one common adverse effect seen in hospitalized patients is an increase in blood glucose levels, often requiring insulin. This is not to say that diabetic patients who require glucocorticoids should not receive them, but be aware of the potential increases in blood glucose levels. Because of their immunosuppressant properties, glucocorticoids are often avoided in the presence of any serious infection, including septicemia, systemic fungal infections, and varicella. One exception is tuberculous meningitis, for which glucocorticoids may be used to prevent inflammatory central nervous system damage. Caution is emphasized in treating any patient with gastritis, reflux disease, or ulcer disease because of the potential of these drugs to cause gastric perforation, as well as any patient with cardiac, renal, and/or liver dysfunction because of the associated alterations in elimination.

Adverse Effects

The potent metabolic, physiologic, and pharmacologic effects of the corticosteroids can influence every body system, so these drugs can produce a wide variety of significant undesirable

TABLE 33-3 SYSTEMIC GLUCOCORTICOIDS: A COMPARISON

DRUG	ORIGIN	DURATION OF ACTION	EQUIVALENT DOSE (mg)*	SALT AND WATER RETENTION POTENTIAL
betamethasone	Synthetic	Long	0.75	Very low
cortisone	Natural	Short	25	High
dexamethasone	Synthetic	Long	0.75	Very low
hydrocortisone	Natural	Short	20	High
methylprednisolone	Synthetic	Intermediate	4	Low
prednisolone	Synthetic	Intermediate	5	Low
prednisone	Synthetic	Intermediate	5	Low
triamcinolone	Synthetic	Intermediate	4	Very low

*Drugs with higher potency require smaller milligram doses than those with lower potency. This column lists the approximate dose equivalency between different drugs that is expected to achieve a comparable therapeutic effect.

effects. The more common of these are summarized in Table 33-4. Moon facies is a very common adverse effect of long-term use. Two of the adverse effects most commonly seen in hospitalized patients are hyperglycemia and psychosis. The most serious adverse effect of glucocorticoids is adrenal (or HPA) suppression, which is discussed in the drug profiles. Glucocorticoids should be used with caution in patients with heart failure, due to their ability to cause fluid retention.

Interactions

Systemically administered corticosteroids can interact with many drugs:

TABLE 33-4 CORTICOSTEROIDS: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Heart failure, edema, hypertension—all due to electrolyte imbalances (e.g., hypokalemia, hypernatremia)
Central nervous	Convulsions, headache, vertigo, mood swings, psychic impairment, nervousness, insomnia
Endocrine	Growth suppression, Cushing's syndrome, menstrual irregularities, carbohydrate intolerance, hyperglycemia, hypothalamic-pituitary-adrenal axis suppression
Gastrointestinal	Peptic ulcers with possible perforation, pancreatitis, ulcerative esophagitis, abdominal distension
Integumentary	Fragile skin, petechiae, ecchymosis, facial erythema, poor wound healing, hirsutism, urticaria
Musculoskeletal	Muscle weakness, loss of muscle mass, osteoporosis
Ocular	Increased intraocular pressure, glaucoma, cataracts
Other	Weight gain

- Their use with non–potassium-sparing diuretics (e.g., thiazides, loop diuretics) can lead to severe hypocalcemia and hypokalemia.
- Their use with aspirin, other nonsteroidal antiinflammatory drugs, and other ulcerogenic drugs produces additive GI effects and an increased chance of gastric ulcer development.
- Their use with anticholinesterase drugs produces weakness in patients with myasthenia gravis.
- Their use with immunizing biologics inhibits the immune response to the biologic.
- Their use with antidiabetic drugs may reduce the hypoglycemic effects of the latter and result in elevated blood glucose levels.

Many other drugs can interact with glucocorticoids, including thyroid hormones and antifungal drugs (such as fluconazole), which can decrease renal clearance of the adrenal drug. Barbiturates and hydantoins can increase the metabolism of prednisone and similar drugs. Oral anticoagulants interact with adrenal drugs in ways that can affect the international normalized ratio. Oral contraceptives can increase the half-life of adrenal drugs. Various other drug interactions may be possible between adrenal drugs and over-the-counter drugs and herbals.

Dosages

For dosage information on adrenal drugs, see the table below.

DRUG PROFILES

CORTICOSTEROIDS

The systemic corticosteroids consist of 13 chemically different but pharmacologically similar hormones. They all exert varying degrees of glucocorticoid and mineralocorticoid effects.

DOSAGES

Selected Antiadrenal and Corticosteroid Drugs

DRUG	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ aminoglutethimide	Adrenal corticosteroid inhibitor (antiadrenal drug)	**Adult** PO: 250 mg q6h; titrate in increments of 250 mg to a max daily dose of 2000 mg	Cushing's syndrome
♦ fludrocortisone (Florinef)	Synthetic mineralocorticoid	**Adult and pediatric** (including infant) PO: 0.05-0.2 mg q24h	Addison's disease; salt-losing adrenogenital syndrome
methylprednisolone (Solu-Medrol)	Systemic corticosteroid	**Adult** IV: 10-120 mg every 6 hr **Pediatric** IV: 0.5 mg/kg every 6 hr	Wide variety of endocrine disorders (including adrenocortical insufficiency) and rheumatic, collagen, dermatologic, allergic, ophthalmic, respiratory, hematologic, neoplastic, GI, and nervous system disorders; edematous states
♦ prednisone (Deltasone, Sterapred, Liquid Pred, others)	Synthetic intermediate-acting glucocorticoid	**Adult** PO: 5-60 mg/day **Pediatric** PO: 0.05-2 mg/kg/day divided daily qid	Wide variety of endocrine disorders (including adrenocortical insufficiency) and rheumatic, collagen, dermatologic, allergic, ophthalmic, respiratory, hematologic, neoplastic, GI, and nervous system disorders; edematous states

GI, Gastrointestinal; *IV,* intravenous; *PO,* oral.

Their differences are due to slight changes in their chemical structures.

Corticosteroid drugs can cross the placenta and produce fetal abnormalities. For this reason, they are classified as pregnancy category C drugs. They can also be secreted in breast milk and cause abnormalities in the nursing infant. Their use is contraindicated in patients who have exhibited hypersensitivity reactions to them in the past as well as in patients with fungal or bacterial infections. Short- or long-term use can lead to a condition known as *steroid psychosis.* One very important point about long-term use of steroids is that they must not be stopped abruptly. These drugs require a tapering of the daily dose, because the administration of these drugs causes the endogenous (body's own) production of the hormones to stop. This is referred to as *HPA* or *adrenal suppression.* This suppression can cause impaired stress response and place the patient at risk of developing hypoadrenal crisis (shock, circulatory collapse) in times of increased stress (i.e., surgery, trauma). Adrenal suppression can occur as early as 1 week after a corticosteroid is started. HPA suppression typically does not occur in patients taking prednisone 5 mg/day (or equivalent) or less. Tapering of daily doses allows the HPA axis the time to recover and to start stimulating the normal production of the endogenous hormones. Patients on long-term steroid therapy who are taking at least 10 mg/day (or equivalent) of prednisone and who undergo trauma or require surgery will need replacement doses of steroids (also known as *stress doses*).

♦ fludrocortisone

Fludrocortisone (Florinef) is the most commonly prescribed mineralocorticoid. It is used as partial replacement therapy for adrenocortical insufficiency in Addison's disease and in the treatment of salt-losing adrenogenital syndrome. It is contraindicated in cases of systemic fungal infection. Adverse effects generally relate to water retention and include heart failure, hypertension, and elevated intracerebral pressure (e.g., leading to seizures). Other potential adverse effects involve several body systems and include skin rash, menstrual irregularities, peptic ulcer, hyperglycemia, hypokalemia, muscle pain and weakness, compression bone fractures, glaucoma, and thrombophlebitis, among others. Drugs with which fludrocortisone interacts include anabolic steroids (increased edema); barbiturates, hydantoins, and rifamycins (increased fludrocortisone clearance); estrogens (reduced fludrocortisone clearance); amphotericin B and thiazide and loop diuretics (hypokalemia); anticoagulants (enhanced or reduced anticoagulant activity); antidiabetic drugs (reduced activity leading to hyperglycemia); digoxin (increased risk for dysrhythmias due to fludrocortisone-induced hypokalemia); salicylates (reduced efficacy); and vaccines (increased risk of neurologic complications). Fortunately, adverse effects and serious drug interactions secondary to fludrocortisone therapy are uncommon due to the relatively small dosages of the drug that are normally prescribed. This drug is available only in oral form as a 0.1-mg tablet. It is classified as a pregnancy category C drug. Recommended dosages are given in the table on p. 537.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	10-20 min	1.7 hr	18-36 hr	Unknown

♦ prednisone

Prednisone is one of the four intermediate-acting glucocorticoids; the others are methylprednisolone, prednisolone, and triamcinolone. These drugs have half-lives that are more than double those of the short-acting corticosteroids (2 to 5 hours), and therefore they have longer durations of action. Prednisone is the preferred oral glucocorticoid for antiinflammatory or immunosuppressant purposes. Along with methylprednisolone and prednisolone, it is also used to treat exacerbations of chronic respiratory illnesses such as asthma and chronic bronchitis. Prednisone has only minimal mineralocorticoid properties and therefore alone is inadequate for the management of adrenocortical insufficiency (Addison's disease).

Prednisolone, a prednisone metabolite, is also the liquid drug form of prednisone. Prednisone itself comes in solid form. It is classified as a pregnancy category C drug. Recommended dosages are given in the table on p. 537.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	1-2 hr	18-36 hr	36 hr

methylprednisolone

Methylprednisolone (Solu-Medrol) is the most commonly used injectable glucocorticoid drug. It is used primarily as an antiinflammatory or immunosuppressant drug. It is usually given intravenously. It is available in a long-acting (depot) formulation as well. Like prednisone, it is classified as a pregnancy category C drug. Most injectable formulations contain a preservative (benzyl alcohol) that cannot be given to children younger than 28 days of age.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Immediate	30 min	3-4 hr	24-36 hr

ANTIADRENAL DRUG

Aminoglutethimide is an adrenal steroid inhibitor. Aminoglutethimide obstructs the normal actions of the adrenal cortex by inhibiting the conversion of cholesterol into adrenal corticosteroids. Aminoglutethimide is indicated for the treatment of Cushing's syndrome, which results from an overproduction of corticosteroids by the adrenal gland. Use of antiadrenals is contraindicated in patients who have shown a previous hypersensitivity reaction to them. The most common adverse effects are nausea, anorexia, dizziness, and skin rash. Adverse effects for which to monitor include jaundice, skin lesions, hypotension, headache, lethargy, weakness, GI upset, and hepatotoxicity.

♦ aminoglutethimide

Aminoglutethimide is used in the treatment of Cushing's syndrome, metastatic breast cancer, and adrenal cancer (see Chapters 45 and 46). It is available only in oral form. Aminoglutethimide is classified as a pregnancy category D drug. Recommended dosages are given in the table on p. 537.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	Unknown	9 hr	Unknown

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Look-Alike/Sound-Alike Drugs: Solu-Cortef and Solu-Medrol

Be careful about sound-alike, look-alike drugs! Medication errors often occur when drug names are similar.

Solu-Cortef is a trade name for hydrocortisone; Solu-Medrol is a trade name for methylprednisolone. Both are commonly used glucocorticoids and are given intravenously. However, 4 mg of Solu-Medrol is equivalent to 20 mg of Solu-Cortef; therefore, Solu-Medrol is five times stronger than Solu-Cortef. Despite the similar names, these drugs are not interchangeable!

NURSING PROCESS

ASSESSMENT

Before administering any of the *adrenal* or *antiadrenal drugs,* perform a thorough physical assessment to determine the patient's baseline nutritional, hydration, and immune statuses as well as document baseline weight, intake and output, vital signs (especially blood pressure ranges), and the patient's skin condition (noting bruising, fragility, turgor, and color). Assess important baseline laboratory values, including serum sodium, serum potassium, and serum glucose. These specific laboratory tests are important because of the potential drug-related adverse effects (see Table 33-4). For instance, serum potassium levels usually decrease and blood glucose levels increase when a glucocorticoid (e.g., prednisone) is given. In addition, assess and document the patient's muscle strength and body stature. In your assessment, include the identification of potential contraindications, cautions, and drug interactions including interactions with prescription drugs, over-the-counter drugs, and herbals.

For *adrenal drugs,* lifespan considerations include concern about their use during pregnancy and lactation. Growth suppression may occur in children who are receiving long-term adrenal drug therapy (e.g., glucocorticoids) if the epiphyseal plates of the long bones have not closed. However, there may be situations in which the benefits to the therapy outweigh the risks of the drug's adverse effects. Perform and document baseline height and weight measurements in pediatric patients. Elderly patients are more prone to adrenal suppression with prolonged adrenal therapy and may require dosage alterations by the prescriber to minimize the impact of the drug on muscle mass, blood pressure, and serum glucose and electrolyte levels. Adrenal drugs may exacerbate muscle weakness; produce fatigue; worsen or precipitate osteoporosis, peptic ulcer disease, glaucoma, and cataracts; and increase intraocular pressure. Additionally, because adrenal drugs are associated with the adverse effects of sodium retention, closely assess patients for exacerbation of any preexisting edema and/or cardiac disease. Aminoglutethimide, an antiadrenal drug, requires assessment for contraindications such as noted allergic reaction to the drug. Because of the adverse effects (see previous pharmacology discussion), it is important to assess for history of liver disorders.

NURSING DIAGNOSES

1. Disturbed body image related to the physiologic effects of diseases of the adrenal gland on the body or the cushingoid appearance caused by glucocorticoid therapy (e.g., prednisone)
2. Excess fluid volume related to the fluid retention associated with glucocorticoid and mineralocorticoid use
3. Risk for infection related to the antiinflammatory, immunosuppressive, metabolic, and dermatologic effects of long-term glucocorticoid therapy

PLANNING

GOALS

1. Patient experiences minimal body image disturbances.
2. Patient exhibits normal fluid volume status during management with glucocorticoid and/or mineralocorticoid therapy.
3. Patient is free from infection during adrenal drug therapy.

OUTCOME CRITERIA

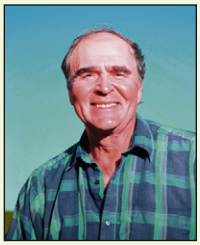
1. Patient openly verbalizes fears about body image disturbances and other changes to health care providers, family, and significant others.
2. Patient experiences minimal problems with fluid volume excess and experiences minimal to no edema.
   - Patient performs and records daily weights.
   - Patient reports to the prescriber an increase in weight of more than 2 pounds in 24 hours or 5 pounds or more in 1 week.
3. Patient notifies the prescriber if body temperature is higher than 100° F (38° C).
   - Patient performs frequent mouth and skin care to prevent infections.

IMPLEMENTATION

It is important to understand how *glucocorticoids* work in the body so that the patient may receive adequate explanations and education to maximize the drug's therapeutic effects and minimize adverse effects. Remember the following points when giving these drugs: (1) Hormone production by the adrenal gland is influenced by time of day and follows a diurnal (daily or 24-hour) pattern with peak levels occurring early in the morning between 6 AM and 8 AM, a decrease during the day,

CASE STUDY

Glucocorticoid Drug Therapy



Mr. J., a 68-year-old farmer, has been in the hospital for 1 week because of an exacerbation of chronic emphysema, which was aggravated by dust from the fall harvesting. He has a history of diabetes mellitus type 2. He says that he stopped smoking "4 years ago" and tries to "watch what I eat." He has no history of drug allergies. He is receiving oxygen at 1 L/min through a nasal cannula. At this time, he is breathing more easily and hopes to be going home soon. His medication orders include the following, among others:

- metformin/glipizide (Metaglip) 500 mg/5 mg twice a day by mouth (PO)
- prednisone (Deltasone), 20 mg, every morning PO
- albuterol (Ventolin) inhaler, 2 puffs every 4 hours

Mr. J. is complaining of a headache. When you check the medication sheet, you see two orders:

- acetaminophen (generic), 650 mg PO every 4 hours as needed for pain
- ibuprofen (generic), 200 mg PO every 6 hours as needed for pain

1. Which medication will you choose to give to Mr. J.? Explain your answer.

In the morning, while assessing Mr. J., you notice that he now has increased edema around his ankles, measured at 2+ bilaterally. When you listen to his lungs, you hear scattered rhonchi but no crackles, and his weight has increased since yesterday by 1 kg. When you call his physician, you receive orders for furosemide (Lasix) 40 mg intravenously now, then 20 mg every morning PO. When you check Mr. J.'s fasting fingerstick blood glucose level, the result is 236 mg/dL. Mr. J. is surprised at this result.

2. Considering Mr. J.'s medications, what could be contributing to this elevated glucose level? What other laboratory values need to be monitored closely during this time?

One week later, Mr. J. is discharged. His prednisone prescription contains instructions for tapering the dose over the next 2 weeks. You provide patient teaching for his medication management, and both Mr. and Mrs. J. demonstrate that they understand the information. However, 3 days later, Mr. J. is back in the emergency department with severe nausea, vomiting, and fatigue. His blood pressure is 92/56 mm Hg, and the results of his stat laboratory tests reflect hyponatremia and hyperkalemia. His wife says that he hates the way the "prednisone makes him look and feel" but she thinks he has been taking his medicine.

3. What do you expect happened to cause these symptoms?
4. What nursing diagnoses are appropriate for Mr. J.?

For answers, see http//evolve.elsevier.com/Lilley.

and a lower peak in the late afternoon between 4 PM and 6 PM. (2) Cortisol levels increase in response to both emotional and physiologic stress. (3) Cortisol levels increase when endogenous levels decrease due to a physiologic negative feedback system. (4) When exogenous glucocorticoids are given, endogenous levels decrease; for endogenous production to resume, exogenous levels must be decreased gradually so that hormone output responds to the negative feedback system. (5) The best time to give exogenous glucocorticoids, if at all possible, is early in the morning (6 AM to 9 AM), to minimize the amount of adrenal suppression. It is important to remember, however, that the patient must not alter dosing or abruptly discontinue medication without consulting with the prescriber.

Prednisone, a synthetic glucocorticoid, and *fludrocortisone,* a synthetic mineralocorticoid, are given orally. It is recommended that oral dosage forms be given with milk and/or food to help minimize GI upset. Another option is for the prescriber to order an H_2 receptor antagonist or a proton pump inhibitor to prevent ulcer formation because these drugs are ulcerogenic. Emphasize to patients the importance of avoiding alcohol, caffeine, and aspirin and other nonsteroidal antiinflammatory drugs to minimize gastric irritation and possible gastric bleeding from the compounding ulcerogenic effects. In long-term therapy, alternate-day dosing of glucocorticoids, if possible, will help minimize the adrenal suppression. Because of delayed wound healing, monitor patients taking these drugs for flulike symptoms, sore throat, and fever. Methylprednisolone, a systemic corticosteroid, is given intravenously. Mix all parenteral forms per manufacturer guidelines, with intravenous doses administered over the recommended time period and in the proper diluent.

With oral and all other forms of glucocorticoids that are given short and/or long term, abrupt withdrawal must be avoided. Abrupt withdrawal of adrenal drugs (e.g., prednisone, methylprednisolone) may lead to a sudden decrease in or no production of endogenous glucocorticoids, resulting in adrenal insufficiency. Signs and symptoms of partial or complete adrenal insufficiency or Addison's disease include fatigue, nausea, vomiting, and hypotension. If left untreated, this condition may lead to an **adrenal crisis** or a life-threatening state of profound adrenocortical insufficiency requiring immediate medical management. Signs and symptoms include a drop in extracellular fluid volume, hyponatremia, and hyperkalemia. This is also referred to as addisonian crisis.

Other adrenal drug dosage forms include those for intraarticular, intrabursal, intradermal, intralesional, and intrasynovial administration (see Table 33-3). Do not overuse intraarticular injections, and if a joint is injected with medication, the patient needs to rest that area for up to 48 hours after the injection is given. Application of cold packs over the injected area may be indicated for up to the first 24 hours to help minimize the discomfort associated with intraarticular injections. Topical dosage forms (e.g., for skin, eye, or inhalation into the bronchial tree) are also available and must be given exactly as ordered. For dermatologic use, clean and dry the skin before application. Wear gloves and apply the medication with either a sterile tongue depressor or a cotton-tipped applicator. Use sterile technique if the skin is not intact. Nasally administered glucocorticoids (e.g., beclomethasone) must also be used exactly as ordered (see Chapter 36). Any written instructions that come with the product must be read and followed carefully. Before using the nasal sprays (see Chapter 9 for more information), the patient needs to first clear the nasal passages and then use the spray per instructions. After the nasal passages are cleared, the container is placed gently inside the nasal passage and the medication is released at the same time that the patient breathes in through the nose, one nasal passage at a time or as ordered. Instructions for use must be followed exactly.

Glucocorticoid inhalers (e.g., beclomethasone, dexamethasone, flunisolide, triamcinolone, fluticasone) are to be used

strictly as ordered; explain the negative consequences of overuse to the patient. Use of these inhaled glucocorticoids may lead to fungal infections (candidiasis) of the oral mucosa and oral cavity, larynx, and pharynx. Therefore, the patient must rinse the mouth and oral mucous membranes with lukewarm water after each use to help prevent fungal overgrowth and further complications. In addition to fungal infections, hoarseness, throat irritation, and dry mouth are also possible adverse effects associated with the use of inhaled glucocorticoids. Occurrence of any of these conditions needs to be reported to the prescriber. See Chapter 9 and Patient Teaching Tips for more information on inhaled dosage forms.

If a patient is receiving long-term maintenance glucocorticoid therapy and requires surgery, recognize the importance of reviewing the patient's medical records for laboratory values, cautions, contraindications, and drug interactions. If the preoperative orders do not include the maintenance dosage of glucocorticoid therapy, contact the surgeon and/or other prescriber and ensure that he or she is aware of the situation and the possible need for a rapid-acting corticosteroid. After surgery, the dosage of steroid may well be increased, with a gradual decrease in dosage over several days until the patient returns to baseline. In addition, you must be constantly aware of the decrease in wound healing in patients taking these drugs on a long-term basis.

In summary, because of their suppressed immune systems, patients taking corticosteroids need to avoid contact with people with known infections and report any fever, increased weakness and lethargy, or sore throat. Monitoring nutritional status, weight, fluid volume, electrolyte status, skin turgor, and glucose levels during therapy is very important to ensure safe and effective therapy. The prescriber needs to be notified if there is any edema, shortness of breath (possible heart failure), joint pain, fever, mood swings, or other unusual symptoms.

EVALUATION

A therapeutic response to *glucocorticoids* includes a resolution of the underlying manifestations of the disease or pathology, such as a decrease in inflammation, increased feeling of well-being, less pain and discomfort in the joints, decrease in lymphocytes, or other improvement in the condition for which the medication was ordered. Adverse effects include weight gain; increased blood pressure; sodium increase and potassium loss; mental status changes such as mood swings, psychic impairment, and nervousness; abdominal distension; ulcer-related symptoms; and changes in vision. Cushing's syndrome occurs with prolonged or frequent use of glucocorticoids and is characterized by moon face, obesity of the trunk area (often referred to as *belly fat*), increase in blood glucose and sodium levels, loss of serum potassium, wasting of muscle mass, buffalo hump, and other features previously discussed. Cataract formation and osteoporosis may also occur with long-term use. Rapid drops in cortisol levels (e.g., from abrupt withdrawal of medication) may lead to Addison's disease and addisonian crisis (see previous discussions). Therapeutic responses to *aminoglutethimide* include a decrease in the size of the tumor and a decrease in Cushing's syndrome. Adverse effects for which to monitor include nausea, anorexia, dizziness, and skin rash. Other adverse effects to report include jaundice, skin lesions, hypotension, lethargy, weakness, GI upset, and liver toxicity.

PATIENT TEACHING TIPS

- Gluccocorticoids are to be taken exactly as ordered and never abruptly discontinued. Contact the prescriber if there are situations that prevent proper dosing. Abrupt withdrawal may precipitate adrenal crisis or Addison's disease and/or possible addisonian crisis.
- If a once-a-day dose of glucocorticoids is missed, the patient needs to take the dose as soon as possible after remembering that the dose was missed. If the patient does *not* remember until close to the time for the next dose, then he or she is usually instructed to skip the dose and resume dosing on the next day without doubling up. If any questions arise, the patient needs to clarify with the prescriber. Educate the patient about the adverse effects of long-term therapy, such as changes in body appearance including acne, buffalo hump, obesity of the trunk area, moon face, and thinning of the extremities.
- With glucocorticoid therapy, emphasize the importance of bone health and ways to prevent falls due to the possibility of osteoporosis with long-term use. Foods high in vitamin D include cod liver oil (amount to be recommended by health care provider) and salmon. Foods high in calcium include milk, cheese, yogurt, and ice cream. Fortified dairy products are high in both vitamin D and calcium. The prescriber may suggest a daily supplement of oral calcium and vitamin D.
- Contact the prescriber immediately if any signs and symptoms of acute adrenal insufficiency appear, such as decreased serum sodium and glucose levels, increased potassium levels, dehydration, and weight loss.
- Fludrocortisone, a mineralocorticoid, is better tolerated if taken with food or milk to minimize GI upset. With any of the adrenal drugs, weight gain of 2 pounds or more in 24 hours or 5 pounds or more in 1 week needs to be reported to the prescriber immediately.
- Encourage the patient to keep a journal to document responses to treatment, blood pressure readings, daily weight measurements, mood changes, and any adverse effects.
- Emphasize the importance of follow-up appointments with the prescriber so that electrolyte levels and adverse effects may be monitored. Also, stress the importance of maintaining a low-sodium and high-potassium diet, if ordered.
- Encourage the patient to wear a medical alert identification bracelet or necklace with the diagnosis and a list of medications and allergies. A medical card with important relevant information needs to be kept on the person at all times and updated frequently.

KEY POINTS

- The adrenal gland is an endocrine organ that is located on top of the kidney and is composed of two distinct tissues: the adrenal cortex and the adrenal medulla. The adrenal medulla secretes two important hormones: epinephrine and norepinephrine; the adrenal cortex secretes two classes of hormones known as *corticosteroids:* glucocorticoids and mineralocorticoids.
- The biologic functions of glucocorticoids include antiinflammatory actions; maintenance of normal blood pressure; carbohydrate, protein, and fat metabolism; and stress effects. The biologic functions of mineralocorticoids include sodium and water resorption, blood pressure control, and maintenance of potassium levels and pH of the blood.
- Patients taking adrenal drugs may receive them by various routes, such as orally, intramuscularly, intravenously, intranasally, intraarticularly, and by inhalation.
- Glucocorticoid inhaled dosage forms are only to be used as prescribed and only after adequate patient education. Rinsing of the mouth after each use is needed to avoid oral fungal infections (oral candidiasis) and oral-pharyngeal irritation.
- Long-term or frequent glucocorticoid use produces increased levels of glucocorticoids, which can lead to Cushing's syndrome. Abrupt withdrawal of glucocorticoids leads to adrenal insufficiency and negative effects on the patient's homeostasis.
- With once-a-day dosing of these drugs, adrenal suppression from corticosteroid therapy can be minimized if the dose is given between 6 AM and 9 AM, but it needs to be given only as ordered.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 When monitoring for a therapeutic response to aminoglutethimide, the nurse will look for which potential outcomes?
- **a** Increase in Cushing's syndrome characteristics
- **b** Decrease in Cushing's syndrome characteristics
- **c** Increased lymphocyte levels
- **d** Growth suppression

2 The nurse has provided teaching about oral corticosteroid therapy to a patient. Which statement by the patient shows a need for more teaching?
- **a** "I will report any fever or sore throat symptoms."
- **b** "I will stay away from anyone who has a cold or infection."
- **c** "I can stop this medication if I have severe adverse effects."
- **d** "I will take this drug with food or milk."

3 During long-term corticosteroid therapy, the nurse will monitor the patient for Cushing's syndrome, which is manifested by
- **a** weight loss.
- **b** moon face.
- **c** hypotension.
- **d** thickened hair growth.

4 When teaching a patient who has been prescribed a daily dose of prednisone (Deltasone), the nurse knows that the patient will be told to take the medication at which time of day to help reduce adrenal suppression?
- **a** In the morning
- **b** At lunchtime
- **c** At dinnertime
- **d** At bedtime

5 Which teaching is appropriate for a patient who is taking an inhaled glucocorticoid for asthma?
- **a** "Exhale while pushing in on the canister of the inhaler."
- **b** "Blow your nose after taking the medication."
- **c** "Rinse your mouth thoroughly after taking the medication."
- **d** "Do not eat immediately after taking the medication."

6 During long-term corticosteroid therapy, the nurse will monitor the patient's laboratory results for adverse effects, such as: (Select all that apply.)
- **a** Increased serum potassium levels
- **b** Decreased serum potassium levels
- **c** Increased sodium levels
- **d** Decreased sodium levels
- **e** Hyperglycemia
- **f** Hypoglycemia

7 The order reads: "Give methyprednisolone (Solu-Medrol) 100 mg IV every 6 hours." The drug is available in vials of 80 mg/mL. How many mL will the nurse draw up for each dose?

1. b, 2. c, 3. b, 4. a, 5. c, 6. b, c, e, 7. 1.25 mL

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the normal anatomy and physiology of the female reproductive system.
2 Describe the normal hormonally mediated feedback system that regulates the female reproductive system.
3 Briefly describe the variety of disorders affecting women's health and the drugs used to treat them.
4 Discuss the rationale for use, indications, adverse effects, cautions, contraindications, drug interactions, dosages, and routes of administration for estrogen, progestins, uterine motility–altering drugs, and osteoporosis drugs.
5 Develop a nursing care plan that includes all phases of the nursing process for patients receiving any of the drugs related to women's health (e.g., estrogens, progestins, uterine mobility–altering drugs, and osteoporosis drugs).

DRUG PROFILES

- ♦ **alendronate, p. 553**
  calcitonin, p. 554
  clomiphene, p. 555
  contraceptive drugs, p. 551
- ♦ **dinoprostone, p. 556**
- ♦ **estrogen, p. 547**
- ♦ **medroxyprogesterone, p. 549**
  megestrol, p. 550
- ♦ **methylergonovine, p. 556**
- ♦ **oxytocin, p. 557**
  raloxifene, p. 554

♦ *Key drug*

KEY TERMS

Chloasma Hyperpigmentation from the melanin in the skin, characterized by brownish macules on the cheeks, forehead, lips, and/or neck; a common dermatologic adverse effect of female hormonal medications (also called *melasma*). (p. 547)

Corpus luteum The structure that forms on the surface of the ovary after every ovulation and acts as a short-lived endocrine organ that secretes progesterone. (p. 545)

Endocrine glands Glands that secrete one or more hormones directly into the blood. (p. 544)

Estrogens The term for a major class of female sex steroid hormones; of the estrogens, estradiol is responsible for most estrogenic physiologic activity. (p. 544)

Fallopian tubes The passages through which ova are carried from the ovary to the uterus. (p. 544)

KEY TERMS—cont'd

Gonadotropin The hormone that stimulates the testes and ovaries. (p. 544)

Hormone replacement therapy (HRT) The term used to describe any replacement of natural body hormones with hormonal drug dosage forms. Most commonly, HRT refers to estrogen replacement therapy for treating symptoms associated with menopause-related estrogen deficiency. It is also referred to as simply hormone therapy. (p. 547)

Implantation The attachment to, penetration of, and embedding of the fertilized ovum in the lining of the uterine wall; it is one of the first stages of pregnancy. (p. 545)

Menarche The first menses in a young woman's life and the beginning of cyclic menstrual function. (p. 545)

Menopause The cessation of menses for 12 consecutive months that marks the end of a woman's childbearing capability. (p. 545)

Menses The normal flow of blood that occurs during menstruation. (p. 544)

Menstrual cycle The recurring cycle of changes in the endometrium in which the decidual layer is shed, regrows, proliferates, is maintained for several days, and is shed again at menstruation unless a pregnancy begins. Also referred to as the *uterine cycle*. (p. 544)

Nucleic acids The term used for specific molecules in the cell that are composed of strings of repeating units that serve to encode information. The two most common ones are DNA and RNA whose functions have to do with the storage and expression of genetic information. (p. 546)

Osteoporosis A condition characterized by the progressive loss of bone density and thinning of bone tissue; it is associated with increased risk of fractures. (p. 551)

Ova Female reproductive or germ cells (singular: *ovum;* also called *eggs*). (p. 544)

Ovarian follicles The location of egg production and ovulation in the ovary; the follicle is the precursor to the corpus luteum. (p. 544)

Ovaries The pair of female gonads located on each side of the lower abdomen beside the uterus. They store the *ova* (eggs) and release ova during the ovulation phase of the menstrual cycle. (p. 544)

Ovulation The rupture of the ovarian follicle, which results in the release of an unfertilized ovum into the peritoneal cavity, from which it normally enters the fallopian tube. (p. 544)

Progesterone A sex hormone that is produced by the corpus luteum and serves to prepare the uterus for possible implantation. (p. 544)

Progestins Synthetic or natural substances that have properties similar to progesterone, but are not considered to be the naturally occurring progesterone that is present in the human female body. (p. 549)

Puberty The period of life when the ability to reproduce begins. (p. 544)

Uterus The hollow, pear-shaped female organ in which the fertilized ovum is implanted (see *implantation)* and the fetus develops. (p. 544)

Vagina The part of the female genitalia that forms a canal from its external orifice through its vestibule to the uterine cervix. (p. 544)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

FEMALE REPRODUCTIVE FUNCTIONS

The female reproductive system consists of the **ovaries, fallopian tubes, uterus, vagina,** and the external structure known as the *vulva.* The development of these primary sex structures, initiation of their subsequent reproductive functions (starting at **puberty**), and their maintenance are controlled by pituitary **gonadotropin** hormones and the female sex steroid hormones—**estrogens** and **progesterone.** Pituitary gonadotropins include follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Both play a primary role in hormonal communication between the pituitary gland (see Chapter 30) and the ovaries in the continuous regulation of the **menstrual cycle** from month to month.

Estrogens are also responsible for stimulating the development of secondary female sex characteristics, including the characteristic breast, skin, and bone development and distribution of body fat and hair. Progesterone helps create optimal conditions for pregnancy in the endometrium just after **ovulation** and also promotes the start of **menses** in the absence of a fertilized ovum.

The ovaries (female gonads) are paired glands located on each side of the uterus. They function both as **endocrine glands** and as reproductive glands. As reproductive glands, they produce mature **ova** within **ovarian follicles,** which are then ovulated or released into the space in the peritoneal cavity between the ovary and the fallopian tube. Fingerlike projections known as *fimbriae* lie adjacent to each ovary and catch the released ovum and guide it into the fallopian tube. Once inside the fallopian tube, the ovum is moved through its lumen to the uterus. This movement is accomplished through the muscular contractions of the tube walls and the actions of ciliated cells inside the lumen of the tube, which "beat" in the direction of the uterus. Fertilization of the ovum, when it occurs, takes place in the fallopian tube.

As endocrine glands, the ovaries are responsible for producing the two sex steroid hormones, estrogen and progesterone. Chemically speaking, the estrogens and progestational hormones include several distinct substances. However, only two of these hormones occur in significant amounts, and have the greatest physiologic activity. These are the estrogen estradiol and the progestational hormone progesterone. Estradiol is the

principal secretory product of the ovary and has several estrogenic effects. One of these effects is the regulation of gonadotropin (FSH and LH) secretion via negative feedback to the pituitary gland. Others include promotion of the development of women's secondary sex characteristics, monthly endometrial growth, thickening of the vaginal mucosa, thinning of the cervical mucus, and growth of the ductal system of the breasts. Progesterone is the principle secretory product of the **corpus luteum** and has progestational effects. These include promotion of tissue growth and secretory activity in the endometrium following the estrogen-driven *proliferative phase* of the menstrual cycle. This important secretory process is required for endometrial egg **implantation** and maintenance of pregnancy. Other progestational effects include induction of menstruation when fertilization has not occurred and, during pregnancy, inhibition of uterine contractions, increase in the viscosity of cervical mucus (which protects the fetus from external contamination), and growth of the alveolar glands of the breasts.

The uterus consists of three layers: the outer protective *perimetrium,* the muscular *myometrium,* and the inner mucosal layer known as the *endometrium.* The myometrium provides the powerful smooth muscle contractions needed for childbirth. The endometrium is the site of the following:

- Implantation of a fertilized ovum and subsequent development of the fetus
- Initiation of labor and birthing of the infant
- Menstruation

The vagina serves as a common passageway for birthing and menstrual flow. In addition, it is a receptacle for the penis during sexual intercourse and for the sperm after male ejaculation.

The menstrual cycle usually takes roughly 1 month to complete. Menstrual cycles begin during puberty with the first menses **(menarche)** and cease at **menopause,** which in most women occurs between 45 and 55 years of age. The hormonally controlled menstrual cycle consists of four distinct but interrelated phases that occur in overlapping sequence. Phase names correspond to activity in either the ovarian follicle or the endometrium (Table 34-1).

- **Phase 1:** the *menstruation phase* (uterine cycle), which initiates the cycle and lasts from 5 to 7 days.
- **Phase 2:** the *follicular phase* (ovarian cycle), during which a mature ovum develops from an ovarian follicle. This phase is also called the *proliferative* or *preovulatory phase* and is characterized by rising estrogen secretion from the ovary and LH secretion from the pituitary gland. It terminates on or about day 14 of the cycle.
- **Phase 3:** the *ovulation phase,* which involves release of the unfertilized ovum from the ovary. This process occurs over a roughly 24- to 48-hour period starting at about day 14. Both estrogen and LH levels peak near this time.
- **Phase 4:** the final phase of the cycle, called the *luteal* or *postovulatory phase.* It is also known as the *secretory phase.* It occurs when the corpus luteum forms from the ruptured ovarian follicle. The corpus luteum is a mass of secretory cells on the surface of the ovary. Its primary function is to produce progesterone, which helps to optimize the endometrial mucosa for implantation of a fertilized ovum. The corpus luteum also serves as an initial source of the progesterone needed during early pregnancy. This function is later assumed by the developing placenta. If fertilization does not occur, the corpus luteum then degenerates causing a fall in progesterone levels. The menstrual cycle begins again on or about day 28.

Figure 34-1 illustrates the sequence of hormone secretions and related events that take place during the menstrual cycle.

TABLE 34-1 PHASES OF THE MENSTRUAL CYCLE

PHASE	OVARIAN FOLLICLE ACTIVITY	ENDOMETRIUM ACTIVITY
Phase 1	Menstruation	Menstruation
Phase 2	Follicular phase (preovulatory)	Proliferative phase
Phase 3	Ovulation	Ovulation
Phase 4	Luteal phase (postovulatory)	Secretory phase

PHARMACOLOGY OVERVIEW

FEMALE SEX HORMONES

ESTROGENS

There are three major endogenous estrogens: estradiol, estrone, and estriol. All are synthesized from cholesterol in the ovarian follicles and have the basic chemical structure of a steroid, known as the *steroid nucleus.* For this reason, they are sometimes referred to as *steroid hormones.* Estradiol is the principal and most active of the three and represents the end product of estrogen synthesis.

Exogenous estrogenic drugs, those used as drug therapy, were developed because most of the endogenous estrogens are inactive when taken orally. These synthetic drugs fall into two categories: steroidal and nonsteroidal. Nonsteroidal estrogen products are no longer available in the United States because major adverse effects occurred when one of them, diethylstilbestrol (DES), was used in obstetrics. Box 34-1 describes this important episode in medical history. The estrogenic drugs currently in use are as follows:

- Conjugated estrogens (Premarin)
- Esterified estrogens (Estratab)
- Estradiol transdermal (Estraderm, Climara, Vivelle)
- Estradiol cypionate (Depo-Estradiol, DepoGen)
- Estradiol valerate (Delestrogen)
- Ethinyl estradiol (Estinyl)
- Estradiol vaginal dosage forms (Vagifem, Estrace Vaginal Cream)
- Estrone (Estrone Aqueous)
- Estropipate (Ogen, Ortho-Est)

The most widely used estrogen product is an estrogen mixture known as *conjugated estrogens.* This mixture contains a combination of natural estrogen compounds equivalent to the average estrogen composition of the urine of pregnant mares, hence its brand name of Premarin. A nonanimal source for this conjugated estrogen mixture is also available. Cenestin is

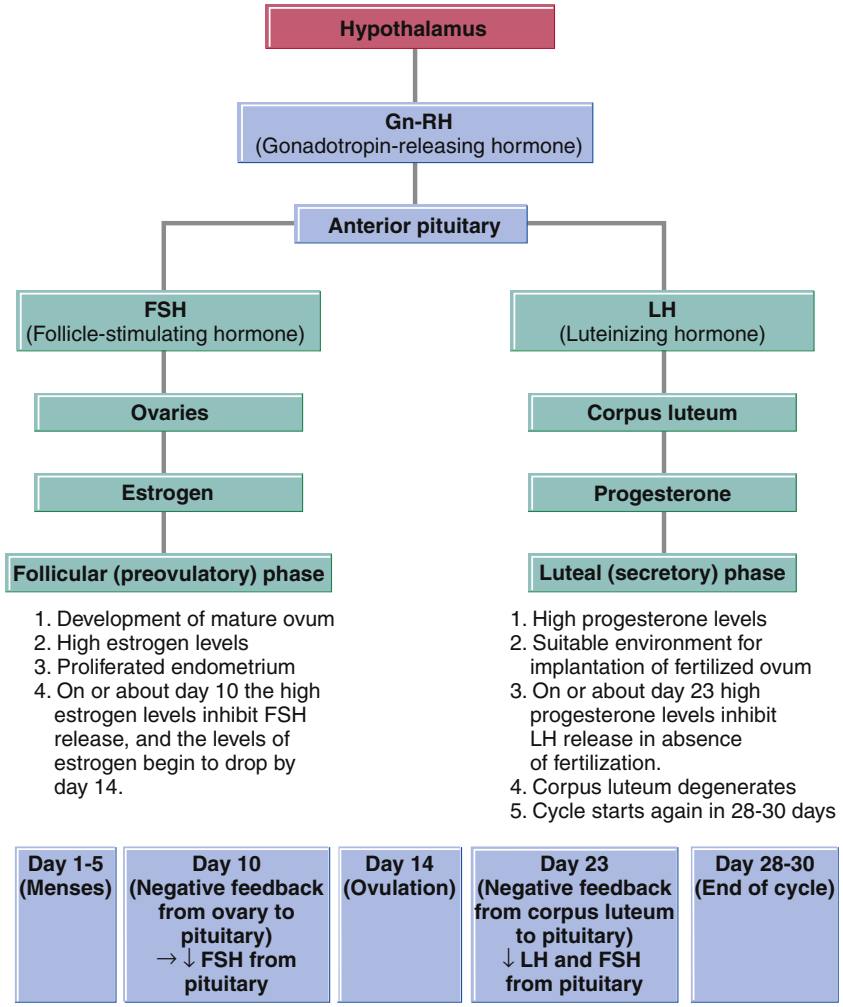

FIGURE 34-1 Hormonal activity during the monthly menstrual cycle. Gonadotropin-releasing hormone (Gn-RH) from the hypothalamus stimulates the pituitary gland, causing it to secrete follicle-stimulating hormone (FSH) early in the cycle (coinciding with the menses) and later luteinizing hormone (LH). FSH stimulates the ovaries to produce estrogen (primarily estradiol). Later in the cycle, the combined surges in the levels of estrogen, Gn-RH, FSH, and LH stimulate ovulation. The corpus luteum then secretes estrogen and progesterone, which provide negative feedback to the hypothalamus and pituitary gland to reduce Gn-RH, FSH, and LH secretions. If the ovum (egg) is not fertilized by a spermatozoon, levels of estrogen and progesterone then fall to their monthly lows, Gn-RH and FSH rise again, and the onset of menses begins a new cycle.

BOX 34-1 DIETHYLSTILBESTROL

Between 1940 and 1971, an estimated 6 million mothers and their fetuses were exposed to diethylstilbestrol (DES). The drug was used to prevent reproductive problems such as miscarriage, premature delivery, intrauterine fetal death, and toxemia. This use resulted in significant complications of the reproductive system in both female and male offspring. Two large groups have been established to monitor these complications: the Registry for Research on Hormonal Transplacental Carcinogenesis and the National Cooperative Diethylstilbestrol Adenosis (DESAD) Project.

composed of various conjugated estrogens obtained from soy and yam plants. This product was developed in response to consumer demand from women who wanted an alternative to an animal-derived product (see the Safety: Herbal Therapies and Dietary Supplements box on p. 547). Some women obtain other natural estrogen products from naturopathic prescribers and prefer these to standard prescription drugs such as Premarin.

Patients report varying degrees of satisfaction with the numerous products available, and it can take both time and patience to find the best choice for a given individual. Ethinyl estradiol is one of the more potent estrogens and is most commonly found in oral contraceptive drugs. Another commonly used form of estrogen is the patch formulation. Several patches exist, all of which are dosed differently, thus patient education is necessary to ensure proper use. The most commonly used patch is Climara (estradiol).

Mechanism of Action and Drug Effects

The binding of estrogen to intracellular estrogen receptors stimulates the synthesis of **nucleic acids** (deoxyribonucleic acid [DNA] and ribonucleic acid [RNA]) and proteins, which

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

***Soy* (Glycine max)**

Overview
Soy is a bean commonly grown throughout the world. The isoflavones in soy are chemically similar to the female hormone estradiol. Some studies have shown soy to be useful in the prevention of menopausal symptoms in perimenopausal women. Estrasorb is a new form of estrogen therapy that is a soy-based emulsion applied like a lotion. Other studies have found that soy reduces both low-density lipoprotein and total cholesterol levels.

Common Uses
Reduction of cholesterol level, relief of menopause symptoms (alternative to hormonal therapy), osteoporosis prevention

Adverse Effects
Nausea, bloating, diarrhea, abdominal pain (ingested forms), and hypersensitivity reaction have been reported from soy. When Estrasorb is used, it has been found that estradiol is still present on the skin up to 8 hours after application and can transfer to men, which results in increased estradiol levels.

Potential Drug Interactions
Orally administered soy may interfere with thyroid hormone absorption (avoid concurrent use).

Contraindications
Allergy to soy products; Estrasorb shares the same contraindications as other estrogen products
Follow manufacturer directions on the label for use of specific preparations.

are the building blocks for all living tissue. Estrogens are also required at puberty for the development and maintenance of the female reproductive system and the development of female secondary sex characteristics, a process known as *feminization.*

Estrogens produce their effects in estrogen-responsive tissues, which have a large number of estrogen receptors. These tissues include the female genital organs, the breasts, the pituitary gland, and the hypothalamus. At the time of puberty, the production of estrogen increases greatly. This causes initiation of the menses, breast development, redistribution of body fat, softening of the skin, and other feminizing changes. Estrogens play a role in the shaping of body contours and development of the skeleton. For instance, long bones are usually inhibited from growing, with the result that females are usually shorter than males.

Indications

Estrogens are used in the treatment or prevention of a variety of disorders that result primarily from estrogen deficiency. These conditions are listed in Box 34-2. **Hormone replacement therapy (HRT)** to counter such estrogen deficiency is most commonly known for its benefits in treating menopausal symptoms (e.g., hot flashes).

Contraindications

Contraindications for estrogen administration include known drug allergy, any estrogen-dependent cancer, undiagnosed abnormal vaginal bleeding, pregnancy, and active thromboembolic disorder (e.g., stroke, thrombophlebitis) or a history of such a disorder.

BOX 34-2 INDICATIONS FOR ESTROGEN THERAPY

- Atrophic vaginitis (shrinkage of the vagina and/or urethra)
- Hypogonadism
- Oral contraception (in combination with a progestin)
- Ovarian failure or castration (or removal of ovaries)
- Uterine bleeding
- Breast or prostate cancer (palliative treatment of advanced inoperable cases)
- Osteoporosis (treatment and prophylaxis)
- Vasomotor symptoms of menopause (e.g., hot flashes)

Adverse Effects

The most serious adverse effects of the estrogens are thromboembolic events. The most common undesirable effect of estrogen use is nausea. Photosensitivity also may occur with estrogen therapy. One common dermatologic effect of note is **chloasma.** Chloasma consists of brownish, macular spots that often occur on the forehead, cheeks, lips, and neck. This and other adverse effects are listed in Table 34-2.

Interactions

Estrogens can decrease the activity of the oral anticoagulants, and the concurrent administration of rifampin and St. John's wort can decrease their estrogenic effect. Their use with tricyclic antidepressants may promote toxicity of the antidepressant. Smoking should be avoided during estrogen therapy, because this, too, can diminish the estrogenic effect and add to the risk for thrombosis.

Dosages

For dosage information on some of the many available estrogen products, see the table on p. 548.

DRUG PROFILE

♦ **estrogen**

Estrogen is indicated for the treatment of many clinical conditions, primarily those resulting from estrogen deficiency (see Box 34-2). Many of these conditions occur around menopause, when the endogenous estradiol level is declining. Any estrogen capable of binding to the estrogen receptors in target organs can alleviate menopausal symptoms. As a general rule, the smallest dosage of estrogen that relieves the symptoms or prevents the condition is used. Although many women receive estrogen or estrogen-progestin therapy for many months or years, some clinicians (and patients) may prefer that the patient be weaned from such therapy in light of the known adverse effects.

Two studies that were performed as part of the Women's Health Initiative (WHI), a large research program sponsored by the National Institutes of Health, demonstrated the possible detrimental effects of estrogen and estrogen-progestin therapy.

DOSAGES

Selected Estrogenic Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ conjugated estrogens (Cenestin, Premarin) (X) and esterified estrogens (Estratab, Menest) (X)	Estrogenic hormone mixture	PO: 0.3-1.25 mg/day	Atrophic vaginitis
		PO: 0.625-1.25 mg/day	Vasomotor symptoms of menopause
		PO: 1.25 mg/day cyclically, 3 wk on, 1 wk off	Female castration, ovarian failure
		PO: 0.3-0.625 mg/day cyclically	Female hypogonadism
		PO: 1.25 mg q4h × 24 hr, then 1.25 mg daily × 7-10 days	Abnormal uterine bleeding
estradiol (Estrace) (X)	Estrogenic hormone	1-2 mg daily	Vasomotor symptoms of menopause, female castration, ovarian failure
		PO: 0.5 mg daily cyclically	Osteoporosis prophylaxis
estradiol transdermal (Estraderm, FemPatch, Vivelle, Climara, Menostar) (X)	Estrogenic hormone	Transdermal patch: 1 patch applied once or twice weekly to lower abdomen (not breast) ranging from 0.025 to 0.1 mg (instructions may vary by product)	Vasomotor symptoms of menopause

PO, Oral.

TABLE 34-2 ESTROGENS: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Hypertension, thrombophlebitis, edema
Gastrointestinal	Nausea, vomiting, diarrhea, constipation
Genitourinary	Amenorrhea, breakthrough uterine bleeding, enlarged uterine fibromyomas
Dermatologic	Chloasma (facial skin discoloration; also called *melasma),* hirsutism, alopecia
Other	Tender breasts, fluid retention, decreased carbohydrate tolerance, headaches

Both studies attempted to determine the value of HRT, if any, in preventing diseases and conditions commonly affecting older women, including breast cancer, heart disease, stroke, and hip fracture. The WHI was launched in 1991 under the direction of the National Heart, Lung, and Blood Institute (NHLBI). In one of the WHI studies of HRT, research subjects who took a certain estrogen-progestin combination product were found to have an increased risk of breast cancer, heart disease, stroke, and blood clots, although their risk of hip fractures and colon cancer was reduced. These preliminary results were so alarming that this study of combined estrogen-progestin therapy was discontinued in 2002.

A part of the WHI investigation focusing on cognitive function, the WHI Memory Study, also identified adverse cognitive effects in women receiving combination estrogen-progestin therapy. These patients showed an increased risk of developing dementia and demonstrated reduced performance on tests of cognitive function. A second HRT study was begun in which women who had undergone hysterectomy received estrogen alone without progestin. In March 2004, however, these participants were advised to stop taking their assigned medication, because the estrogen-only therapy appeared to be associated with an increased risk of stroke. The data also indicated that estrogen therapy had no effect on the rates of coronary heart disease or breast cancer but was associated with a reduced rate of hip fracture.

Since publication of the WHI studies, much confusion and controversy has arisen. One of the biggest challenges to the WHI study is that the majority of the women studied were at least 10 years postmenopause. Recent data have suggested that the use of estrogen in women who are younger is beneficial. Follow-up of the WHI study subjects began in 2010. The North American Menopause Society (NAMS) also updated its position statement in 2010 regarding estrogen use in perimenopausal and postmenopausal women. The updated recommendations support the initiation of HT (hormonal therapy) around the time of menopause to treat menopause-related symptoms and to treat or reduce the risk of certain disorders, such as osteoporosis or fractures. The benefit-risk ratio for menopausal HT is favorable for women who initiate HT close to menopause but decreases in older women and with time since menopause. Hormone replacement is not recommended for women with histories of endometrial cancer. In women with breast cancer, estrogen therapy has not been proven safe and might raise recurrence risk. When hormone therapy is discontinued after several years of use, assess bone-mineral density and begin treatment if indicated. Because this is a topic about which views are so rapidly changing, the reader is referred to the website of the North American Menopause Society at www.menopause.org for the latest position statements.

The pharmacologic effects of all estrogens are similar because there are only slight differences in their chemical structures. These differences yield drugs of different potencies, which in turn make them useful for a variety of indications. They also allow the drugs to be given by different routes of administration and at often highly customized dosages.

Many fixed estrogen-progestin combination products have been developed over the years. Their use is commonly referred to as *continuous combined hormone replacement therapy.* The

use of estrogen therapy alone has been associated with an increased risk of endometrial hyperplasia, a possible precursor of endometrial cancer. The addition of continuously administered progestin to an estrogen regimen reduces the incidence of endometrial hyperplasia associated with unopposed estrogen therapy. Examples of these fixed combinations are conjugated estrogens with medroxyprogesterone, norethindrone acetate with ethinyl estradiol, and estradiol with norethindrone.

PROGESTINS

Available progestational medications, or **progestins,** include both natural and synthetic drugs. Progesterone is the most active natural progestational hormone and is the primary progestin component in most drug formulations. It is produced by the corpus luteum after each ovulation and during pregnancy by the placenta. In addition, there are two other major natural progestational hormones. The first is 17-hydroxyprogesterone, an inactive metabolite of progesterone. The second is pregnenolone, a chemical precursor to all steroid hormones that is synthesized from cholesterol in the ovary. Because orally administered progesterone is relatively inactive and parenterally administered progesterone causes local reactions and pain, chemical derivatives were developed that are effective orally and are also more potent. Their actions are also more specific and of longer duration. The following are some of the most commonly used progestins:

- Hydroxyprogesterone (Hylutin)
- Levonorgestrel (Plan B)
- Medroxyprogesterone (Provera, Depo-Provera)
- Megestrol (Megace)
- Norethindrone acetate (Aygestin)
- Norgestrel (Ovrette, Ovral)
- Progesterone (Prometrium)
- Etonogestrel implant (Implanon)

Mechanism of Action and Drug Effects

All of the progestin products produce the same physiologic responses as those produced by progesterone itself. These responses include induction of secretory changes in the endometrium, including diminished endometrial tissue proliferation; an increase in the basal body temperature; thickening of the vaginal mucosa; relaxation of uterine smooth muscle; stimulation of mammary alveolar tissue growth; feedback inhibition (negative feedback) of the release of pituitary gonadotropins (FSH and LH); and alterations in menstrual blood flow, especially in the presence of estrogen.

Indications

Progestins are useful in the treatment of functional uterine bleeding caused by a hormonal imbalance, fibroids, or uterine cancer; in the treatment of primary and secondary amenorrhea; in the adjunctive and palliative treatment of some cancers and endometriosis; and, alone or in combination with estrogens, in the prevention of conception. They may also be helpful in preventing a threatened miscarriage and alleviating the symptoms of premenstrual syndrome. Medroxyprogesterone is the one most commonly used. Norethindrone and norgestrel are commonly used alone or in combination with estrogens as contraceptives. Megestrol is commonly used as adjunct therapy in the treatment of breast and endometrial cancers. When estrogen replacement therapy is initiated after menopause, progestins are often included to decrease the endometrial proliferation that can be caused by unopposed estrogen in women with an intact uterus. Formulations of progesterone itself are also used to treat female infertility (see Dosages table on p. 550).

TABLE 34-3 PROGESTINS: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Gastrointestinal	Nausea, vomiting
Genitourinary	Amenorrhea, spotting
Other	Edema, weight gain or loss, rash, pyrexia, somnolence or insomnia, depression

Contraindications

Contraindications for progestin are similar to those for estrogens.

Adverse Effects

The most serious undesirable effects of progestin use include liver dysfunction, commonly manifested as jaundice, thrombophlebitis, and thromboembolic disorders such as pulmonary embolism. The more common adverse effects are listed in Table 34-3.

Interactions

There are reports of possible decreases in glucose tolerance when progestins are taken with antidiabetic drugs, and the dosage of the antidiabetic drug may need to be adjusted. The concurrent use of medroxyprogesterone or norethindrone and aminoglutethimide or rifampin induces increased metabolism of the progestin.

Dosages

For recommended dosages of selected progestins, see the Dosages table on p. 550.

DRUG PROFILES

♦ **medroxyprogesterone**

Medroxyprogesterone (Provera, Depo-Provera) inhibits the secretion of pituitary gonadotropins, which prevents follicular maturation and ovulation, stimulates the growth of mammary tissue, and has an antineoplastic action against endometrial cancer. Medroxyprogesterone is used to treat uterine bleeding, secondary amenorrhea, endometrial cancer, and renal cancer and is also used as a contraceptive. Its most common use is to prevent endometrial cancer caused by estrogen replacement therapy. It is also sometimes used as adjunct therapy in certain types of cancer (see Chapter 46). Medroxyprogesterone is available in both oral and parenteral preparations. It is also available in a long-acting injection formulation called Depo-Provera.

DOSAGES

Selected Progestational Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ medroxyprogesterone acetate (Provera, others) (X)	Progestin	PO: 5-10 mg/day for set number of days or cyclically (smaller doses may be given on a continuous daily basis)	Amenorrhea, uterine bleeding
		PO: 5-10 mg/day on last 10-13 days of each month to accompany estrogen dosing	Vasomotor symptoms of menopause
megestrol (Megace) (X)		400-800 mg/day	Severe weight loss in male and female patients with HIV/AIDS
		PO: 40 mg bid-qid	Uterine bleeding

AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus (infection); *PO,* oral.

Depo-Provera is used for birth control, and one shot protects the woman for 3 months. There is concern about its use in women younger than 25 years of age and use for longer than 2 years due to the potential for bone density loss.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IM	Unknown	2-7 hr	14.5 hr	3 mo

megestrol

Megestrol (Megace) is a synthetic progestin that is structurally very similar to progesterone. Although megestrol shares the actions of the progestins, it is primarily used in the palliative management of recurrent, inoperable, or metastatic endometrial or breast cancer. Because it can cause appetite stimulation and weight gain, it is also used in the management of anorexia, cachexia, or unexplained substantial weight loss in patients with acquired immunodeficiency syndrome (AIDS) and in patients with cancer. It is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	6-8 wk	1-3 hr	13-105 hr	4-10 mo

CONTRACEPTIVE DRUGS

Contraceptive drugs are medications used to prevent pregnancy. Contraceptive devices are nondrug methods of pregnancy prevention such as intrauterine devices, male and female condoms, cervical diaphragms, and others, which are beyond the scope of a pharmacology text. Patients must be informed, for their own safety, of the fact that contraceptive drug therapy serves only to prevent pregnancy and does not protect them from sexually transmitted diseases, including human immunodeficiency virus (HIV) infection/AIDS. This includes even spermicidal drugs such as the over-the-counter (OTC) foams for intravaginal use. These products most often contain the spermicide nonoxynol-9, which does kill sperm cells to prevent pregnancy but does not necessarily kill microbes capable of causing sexually transmitted diseases, including HIV infection.

Aside from sexual abstinence, oral contraceptives are the most effective form of birth control currently available. Estrogen-progestin combinations, often referred to as "the pill," are oral contraceptives that contain both estrogenic and progestational steroids. The most common estrogenic component is ethinyl estradiol, a semisynthetic steroidal estrogen. The most common progestin component is norethindrone.

The currently available oral contraceptives may be *biphasic, triphasic,* or *monophasic,* in terms of the doses taken at different times of the menstrual cycle. The newest are the extended-cycle oral contraceptives. The biphasic drugs contain a fixed estrogen dose combined with a low progestin dose for the first 10 days and a higher dose for the rest of the cycle and are available in 21- or 28-day dosage packages. The triphasic oral contraceptives contain three different estrogen-progestin dose ratios that are administered sequentially during the cycle and are provided in 21- or 28-day dosage packages. The triphasic products most closely duplicate the normal hormonal levels of the female cycle. These contraceptives also come in monophasic forms, in which the estrogen and progestin doses are the same throughout the cycle. There are also oral contraceptives that are progestin-only drugs. The monophasic and triphasic oral contraceptives are the most numerous on the market and the most widely prescribed. The extended-cycle oral contraceptives differ from the traditional 21 days on, 7 days off pills by decreasing or eliminating the hormone-free dosing interval. Consecutive days of hormonal therapy may extend to 84 to 365 days. Reasons for switching to an extended-cycle product include improved efficacy in women who forget to restart the pill and patient preference to decrease the frequency of menstrual bleeding. Some patients (e.g., those with menstrual irregularities) may require special assistance in selecting drug products with their prescribers. Three other important contraceptive medications are a long-acting injectable form of medroxyprogesterone, a transdermal contraceptive patch, and, most recently, an intravaginal contraceptive ring.

Mechanism of Action and Drug Effects

Contraceptive drugs prevent ovulation by inhibiting the release of gonadotropins and by increasing uterine mucous viscosity,

which results in (1) decreased sperm movement and fertilization of the ovum, and (2) possible inhibition of implantation (nidation) of a fertilized egg (zygote) into the endometrial lining.

Oral contraceptives have many of the same hormonal effects as those normally produced by endogenous estrogens and progesterone. The contraceptive effect results mainly from the suppression of the hypothalamic-pituitary system, which in turn prevents ovulation. Other incidental benefits to their use are that they improve menstrual cycle regularity and decrease blood loss during menstruation. A decreased incidence of functional ovarian cysts and ectopic pregnancies has also been associated with their use.

Indications

Oral contraceptive drugs are primarily used to prevent pregnancy. In addition, they are used to treat endometriosis and hypermenorrhea and to produce cyclic withdrawal bleeding in patients with amenorrhea. Occasionally combination oral contraceptives are used to provide postcoital emergency contraception. Emergency contraception pills are not effective if the woman is already pregnant (i.e., egg implantation has occurred). They should therefore be taken within 72 hours of unprotected intercourse with a follow-up dose 12 hours after the first dose. They are intended to prevent pregnancy after known or suspected contraceptive failure or unprotected intercourse. Preven, Plan B, Alesse, and Ella are drugs used for this indication. One oral contraceptive of note is Seasonale (extended cycle), which includes both estrogen and progestin components. It is sold in packages containing 3 months' worth of medication, including 1 week's worth of nonhormonal tablets. This is because Seasonale reduces a woman's menstrual cycles to once every 3 months.

Contraindications

Contraindications to the use of oral contraceptives include known drug allergy to a specific product, pregnancy, and known high risk for or history of thromboembolic events such as myocardial infarction, venous thrombosis, pulmonary embolism, or stroke.

Adverse Effects

Common adverse effects associated with the use of oral contraceptives are listed in Table 34-4. These effects include hypertension, thromboembolism, alterations in carbohydrate and lipid metabolism, increases in serum hormone concentrations, and alterations in serum metal and plasma protein levels. It is the estrogen component that appears to be the source of most of these metabolic effects.

Interactions

Several drugs and drug classes can potentially reduce the effectiveness of oral contraceptives, which can possibly result in an unintended pregnancy. Educate patients about the need to use alternative birth control methods for at least 1 month during and after taking any of the following drugs: antibiotics (especially penicillins and cephalosporins), barbiturates, isoniazid, and rifampin. The effectiveness of other drugs, such as anticonvulsants, beta-blockers, hypnotics, antidiabetic drugs, warfarin, theophylline, tricyclic antidepressants, and vitamins, may be reduced when they are taken with oral contraceptives.

TABLE 34-4 ORAL CONTRACEPTIVES: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Hypertension, edema, thromboembolism, pulmonary embolism, myocardial infarction
Central nervous	Dizziness, headache, migraines, depression, stroke
Gastrointestinal	Nausea, vomiting, diarrhea, anorexia, cramps, constipation, increased weight, cholestatic jaundice
Genitourinary	Amenorrhea, cervical erosion, breakthrough bleeding, dysmenorrhea, breast changes

Dosages

For the recommended dosages of oral contraceptives, see the Dosages table on p. 552.

DRUG PROFILE

CONTRACEPTIVE DRUGS

The Dosages table on p. 552 provides selected examples of the many contraceptive drugs available. All work in similar fashion to prevent pregnancy. They are classified as pregnancy category X drugs by the U.S. Food and Drug Administration (FDA). Drugs that are intended for termination of pregnancy are known as *abortifacients* and are discussed later in this chapter.

DRUGS FOR OSTEOPOROSIS

Approximately 8 million women in the United States are currently affected by **osteoporosis,** or low bone mass with increased risk of fracture. Nearly 40% of U.S. women over 50 years of age will develop an osteoporotic fracture, and the annual costs to society equal nearly $11 billion. Risk factors for postmenopausal osteoporosis include white or Asian descent, slender body build, early estrogen deficiency, smoking, alcohol consumption, low-calcium diet, sedentary lifestyle, and family history of osteoporosis. Although osteoporosis is primarily a disorder that affects women, up to 20% of individuals with this condition are men.

Supplementation with calcium and vitamin D are thought to play a role in the prevention of this common bone disorder. Current recommendations are that women, especially those older than age 60, *consider* taking calcium and vitamin D supplements for bone health.

Several drug classes are used for the treatment of existing osteoporosis: the bisphosphonates, the selective estrogen receptor modulators (SERMs), the hormones calcitonin and teripartide, and most recently, denosumab. Currently available bisphosphonates used for osteoporosis prevention and treatment include alendronate, ibandronate, risedronate, and the once-a-year injection zoledronic acid. Raloxifene and tamoxifen

DOSAGES

Selected Contraceptive Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
Oral Contraceptives			
norethindrone and ethinyl estradiol (Ortho-Novum, Necon, Jenest, others) (X)	Biphasic: fixed estrogen–variable progestin 21- or 28-day products	For the most reliable contraceptive action, the patient must take all preparations according to instructions from prescriber or patient information product insert, at intervals not to exceed 24 hr	Prevention of pregnancy
norethindrone and ethinyl estradiol (Loestrin, Modicon, Necon, others) (X)	Monophasic: fixed estrogen-progestin combinations; 21- or 28-day products; 28-day products contain 7 inert tabs		
norethindrone and ethinyl estradiol (Ortho-Novum 7/7/7, Estrostep, Tri-Norinyl, others) (X)	Triphasic: 3 or 4 monthly phases of variable estrogen and progestin combinations; 21- or 28-day products; 28-day products contain 7 inert tabs		
levonorgestrel and ethinyl estradiol (Seasonale, Yaz, Lybrel, others)	Extended-cycle products		
Injectable Contraceptives (Depot)			
medroxyprogesterone (Depo-Provera) (X)	Progestin-only injectable contraceptive	IM: 150 mg q3mo	
Transdermal Contraceptives			
norelgestromin and ethinyl estradiol (X)	Fixed-combination estrogen-progestin transdermal contraceptive	Transdermal patch: 1 patch applied weekly × 3 wk each month, scheduled around menses in wk 4	
Intravaginal Contraceptives			
etonogestrel–ethinyl estradiol vaginal ring (NuvaRing) (X)	Fixed-combination estrogen-progestin intravaginal contraceptive	1 ring inserted into vagina by patient and left in place for 3 wk, followed by removal for 1 wk; new ring is then inserted	

IM, Intramuscular.

are the currently available SERMs. Tamoxifen is primarily used in oncology settings and is discussed further in Chapter 46. Raloxifene is indicated for use in the prevention and treatment of osteoporosis. A drug form of the hormone calcitonin is also commonly used. Teripartide stimulates bone formation, while denosumab (Prolia) prevents bone resorption.

Mechanism of Action and Drug Effects

Bisphosphonates

The bisphosphonates work by inhibiting osteoclast-mediated bone resorption, which in turn indirectly enhances bone mineral density. *Osteoclasts* are bone cells that break down bone, causing calcium to be reabsorbed into the circulation; this resorption eventually leads to osteoporosis if not controlled or countered by adequate new bone formation. Strong clinical evidence indicates reversal of lost bone mass and reduction of facture risk, and, as a result, these drugs are considered drugs of choice for this condition.

Selective Estrogen Receptor Modulators

Raloxifene helps prevent osteoporosis by stimulating estrogen receptors on bone and increasing bone density in a manner similar to that of the estrogens themselves.

Calcitonin

Like the natural thyroid hormone, calcitonin directly inhibits osteoclastic bone resorption.

Teriparatide

In contrast to the other therapies described thus far, which inhibit bone resorption, teriparatide is the first and currently the only drug available that acts by stimulating bone formation. It is a derivative of parathyroid hormone and works to treat osteoporosis by modulating the body's metabolism of calcium and phosphorus in a manner similar to that of the natural parathyroid hormone.

Denosumab

Denosumab (Prolia) is a monoclonal antibody that blocks osteoclast activation, thereby preventing bone resorption. It is given as a subcutaneous injection once every 6 months along with daily calcium and vitamin D. Denosumab is used in the treatment of osteoporosis and bone metastases.

Indications

Raloxifene is primarily used for the prevention of postmenopausal osteoporosis. The bisphosphonates are used in both the

prevention and treatment of osteoporosis. Teriparatide is used primarily for the subset of osteoporosis patients at highest risk of fracture (e.g., those with prior fracture), and calcitonin is used for treatment of osteoporosis.

Contraindications

Bisphosphonates

Contraindications to bisphosphonate use include drug allergy, hypocalcemia, esophageal dysfunction, and the inability to sit or stand upright for at least 30 minutes after taking the medication.

Selective Estrogen Receptor Modulators

The use of SERMs is contraindicated in women with a known allergy to these drugs, in women who are or may become pregnant, and in women with a venous thromboembolic disorder, including deep vein thrombosis, pulmonary embolism, and retinal vein thrombosis, or with a history of such a disorder.

Calcitonin

Contraindications to calcitonin use include drug allergy or allergy to salmon (the drug is salmon derived).

Teriparatide

Contraindications to the use of teriparatide include drug allergy.

Denosumab

Contraindications to the use of denosumab are hypocalcemia, renal impairment or failure, and infection.

Adverse Effects

The primary adverse effects of SERMs are hot flashes and leg cramps. They can increase the risk of venous thromboembolism and are teratogenic. Leukopenia may also occur and predispose the patient to various infections. The most common adverse effects of bisphosphonates are headache, gastrointestinal (GI) upset, and joint pain. However, the bisphosphonates are usually well tolerated. There is a risk of esophageal burns with these medications if they become lodged in the esophagus before reaching the stomach. For this reason the patient must take these medications with a full glass of water and must remain sitting upright or standing for at least 30 minutes afterward. Several case reports of osteonecrosis of the jaw in patients taking bisphosphonates have been released. The FDA issued a public health advisory in January 2008 alerting practitioners to the possible association between bisphosphonate use and the development of severe (possibly incapacitating) bone, muscle, and/or joint pain, as well as low energy fractures when taking bisphosphates for long periods. Common adverse effects of calcitonin include flushing of the face, nausea, diarrhea, and reduced appetite. Common adverse effects of teriparatide include chest pain, dizziness, hypercalcemia, nausea, and arthralgia. Infections occur more frequently in those taking denosumab.

Interactions

Cholestyramine and ampicillin decrease the absorption of raloxifene, and raloxifene can decrease the effects of warfarin. Calcium supplements and antacids can interfere with the absorption of the bisphosphonates, and therefore they need to be spaced 1 to 2 hours apart to avoid this interaction. Calcium supplements, although often needed by patients with osteoporosis, are also more likely to cause hypercalcemia in patients receiving calcitonin. Aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs) have the potential for additive GI irritation if taken with bisphosphonates.

Dosages

For the recommended dosages of osteoporosis drugs, see the Dosages table on this page.

DRUG PROFILES

♦ alendronate

Alendronate (Fosamax) is an oral bisphosphonate and the first nonestrogen nonhormonal option for preventing bone loss. This drug works by inhibiting and/or reversing osteoclast-mediated bone resorption. Recall that *osteoclasts* are the bone cells that cause breakdown or *resorption* of bone tissue as part of their normal physiologic action. However, unchecked osteoclastic activity often leads to osteoporosis if not managed, so this drug class represents a major breakthrough in the treatment of osteoporosis. It is indicated for the prevention and treatment of osteoporosis in men and in postmenopausal women. It is also indicated for the treatment of glucocorticoid-induced osteoporosis in men and for the treatment of Paget disease in women.

Data show that alendronate therapy may reduce the risk of hip fracture by 51%, of spinal fracture by 47%, and of wrist fracture by 48%. Take precautions in patients with dysphagia, esophagitis,

DOSAGES

Selected Drugs Used Specifically for Osteoporosis

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
♦ alendronate (Fosamax) (C)	Bisphosphonate	PO: 5 mg/day or 35 mg/wk PO: 10 mg/day or 70 mg/wk	Osteoporosis prevention Osteoporosis treatment
calcitonin, salmon (Calcimar, Miacalcin, others) (C)	Calcitonin hormonal substitute derived from salmon	IM/subcut: 100 units/day Nasal spray: 200 units (1 spray)/day	Osteoporosis treatment
raloxifene (Evista) (X)	Selective estrogen receptor modulator	PO: 60 mg/day	Osteoporosis prevention and treatment

IM, Intramuscular; *PO,* oral; *subcut,* subcutaneous.

esophageal ulcer, or gastric ulcer, because the drug can be very irritating. Case reports of esophageal erosions have been published. It is recommended that alendronate be taken with an 8-oz glass of water immediately upon arising in the morning and that the patient not lie down for at least 30 minutes after taking it. When patients whose condition has been stabilized on alendronate are hospitalized and cannot comply with these recommendations, the medication is often withheld. Alendronate has an extremely long half-life, so going several days without taking a dose will do little to reduce the therapeutic efficacy of the drug. There is debate on how long a woman should remain on bisphosphonate therapy, with most experts recommending roughly 5 years.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	3 wk	Unknown	Longer than 10 yr due to storage in bone tissue	Unknown

raloxifene

Raloxifene (Evista) is a SERM. It is used primarily for the prevention of postmenopausal osteoporosis. Interestingly, raloxifene has positive effects on cholesterol level, but it is not normally used specifically for this purpose. It may not be the best choice for women near menopause, because use of the drug is associated with the adverse effect of hot flashes. It is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	8 wk	Unknown	28 hr	Unknown

calcitonin

Calcitonin, in its drug forms, is derived from salmon (fish) sources. Although it is available in both injectable form and nasal spray, the nasal spray (Miacalcin) is now more commonly used.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Inhalation (nasal spray)	Unknown	30-40 min	43 min	Unknown

DRUGS RELATED TO PREGNANCY, LABOR, DELIVERY, AND THE POSTPARTUM PERIOD

FERTILITY DRUGS

Infertility in women is often the result of absence of ovulation (anovulation), which is normally due to various imbalances in female reproductive hormones. Such imbalances can occur at the level of the hypothalamus, the pituitary gland, the ovary, or any combination of these. Exogenous administration of estrogens or progestins may be used to fortify the blood levels of these hormones when ovarian output is inadequate. The use of drug forms of these hormones was described earlier in this chapter.

Hormone deficiencies at the hypothalamic and pituitary levels are often treated with gonadotropin ovarian stimulants. These drugs stimulate increased secretion of gonadotropin-releasing hormone (Gn-RH) from the hypothalamus, which then results in increased secretion of FSH and LH from the pituitary gland. These hormones, in turn, stimulate the development of ovarian follicles and ovulation. They also stimulate ovarian secretion of the estrogens and progestins that are part of the normal ovulatory cycle. Proper selection and dosage adjustment of fertility drugs often requires the expertise of a fertility specialist. The various medical techniques used in the treatment of infertility, including drug therapy, are now collectively referred to as assisted reproductive technology. One particularly common specific technique is in vitro fertilization, during which a woman's ovum is fertilized with her partner's sperm in a laboratory and the fertilized ovum is then medically implanted into the woman's uterus. Infants born through the use of this technique used to be referred to as "test tube babies." The success of such fertilization techniques may be further aided with the use of medications such as those described earlier. Representative examples of ovulation stimulants include the drugs clomiphene, menotropins, and choriogonadotropin alfa.

Mechanism of Action and Drug Effects

Clomiphene is a nonsteroidal ovulation stimulant that works by blocking estrogen receptors in the uterus and brain. This results in a false signal of low estrogen levels to the brain. The hypothalamus and pituitary gland then increase their production of Gn-RH (from the hypothalamus) and FSH and LH (from the pituitary), which stimulates the maturation of ovarian follicles. Ideally this leads to ovulation and increases the likelihood of conception in a previously infertile woman.

Menotropins is the drug name for a standardized mixture of FSH and LH that is derived from the urine of postmenopausal women. The FSH component stimulates the development of ovarian follicles, which leads to ovulation. The LH component stimulates the development of the corpus luteum, which supplies female sex hormones (estrogens and progesterone) during the first trimester of pregnancy. Choriogonadotropin alfa is a recombinant form (i.e., developed using recombinant DNA technology) of the hormone human chorionic gonadotropin. This hormone is naturally produced by the placenta during pregnancy and can be isolated from the urine of pregnant women. It is an analogue of LH and can provide a substitute for the natural LH surge that promotes ovulation. It does this by binding to LH receptors in the ovary and stimulating the rupture of mature ovarian follicles and the subsequent development of the corpus luteum. Human chorionic gonadotropin also maintains the viability of the corpus luteum during early pregnancy. This is critical,

because the corpus luteum provides the supply of estrogens and progesterone necessary to support the first trimester of pregnancy until the placenta assumes this role. Choriogonadotropin alfa is often given in a carefully timed fashion after FSH-active therapy such as menotropins or clomiphene therapy, when patient monitoring indicates sufficient maturation of ovarian follicles.

Indications

These drugs are used primarily for the promotion of ovulation in anovulatory female patients. They may also be used to promote spermatogenesis in infertile men. As was mentioned in the section on progestins, progesterone formulations are also used to treat female infertility.

Contraindications

Contraindications to the use of the ovarian stimulants include known drug allergy to a specific product and may also include primary ovarian failure, uncontrolled thyroid or adrenal dysfunction, liver disease, pituitary tumor, abnormal uterine bleeding, ovarian enlargement of uncertain cause, sex hormone–dependent tumors, and pregnancy.

Adverse Effects

The most common adverse effects of the ovulation stimulants are listed in Table 34-5.

Interactions

Few drugs interact with fertility drugs. The most notable are the tricyclic antidepressants, the butyrophenones (e.g., haloperidol), the phenothiazines (e.g., promethazine), and the antihypertensive drug methyldopa. When any of these drugs is taken with the fertility drugs, prolactin concentrations may be increased, which may impair fertility.

TABLE 34-5 FERTILITY DRUGS: MOST COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Tachycardia, deep vein thrombosis, hypovolemia
Central nervous	Dizziness, headache, flushing, depression, restlessness, anxiety, nervousness, fatigue
Gastrointestinal	Nausea, bloating, constipation, vomiting, anorexia
Other	Urticaria, ovarian hyperstimulation, multiple pregnancy (twins or more), blurred vision, diplopia, photophobia, breast pain

Dosages

For recommended dosages of clomiphene, see the Dosages table on this page.

DRUG PROFILE

clomiphene

Clomiphene (Clomid) is primarily used to stimulate the production of pituitary gonadotropins, which in turn induces the maturation of the ovarian follicle and eventually ovulation. It is currently available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	4-12 days	Unknown	5 days	30 days

UTERINE STIMULANTS

A variety of medications are used to alter the dynamics of uterine contractions either to promote or to prevent the start or progression of labor. In the immediate postpartum period, medications may be used to promote rapid shrinkage (involution) of the uterus to reduce the risk of postpartum hemorrhage.

Four types of drugs are used to stimulate uterine contractions: ergot derivatives, prostaglandins, the progesterone antagonist mifepristone (RU-486), and the hormone oxytocin. These drugs all act on the uterus, a highly muscular organ that has a complex network of smooth muscle fibers and a large blood supply. These drugs are often collectively referred to as *oxytocics,* after the naturally occurring hormone oxytocin, whose action they mimic. The uterus undergoes several changes during normal gestation and childbirth that at different times make it either resistant or susceptible to various hormones and drugs. Oxytocin is one of the two hormones secreted by the posterior lobe of the pituitary gland. The other is vasopressin, which is also known as *antidiuretic hormone* (see Chapter 30).

Mechanism of Action and Drug Effects

The uterus of a woman who is not pregnant is relatively insensitive to oxytocin, but during pregnancy the uterus becomes more sensitive to this hormone and is most sensitive at term (the end of gestation).

During childbirth, oxytocin stimulates uterine contraction, and during lactation it promotes the movement of milk

DOSAGES

Selected Fertility Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
clomiphene (Clomid, Serophene) (X)	Ovulation stimulant	PO: 50-100 mg daily × 5 days; repeatable cycle depending on response	Female infertility in selected patients

PO, Oral.

from the mammary glands to the nipples. Another class of oxytocic drugs is the prostaglandins, natural hormones involved in regulating the network of smooth muscle fibers of the uterus. This network is known as the myometrium. The prostaglandins cause very potent contractions of the myometrium and may also play a role in the natural induction of labor. When the prostaglandin concentrations increase during the final few weeks of pregnancy, mild myometrial contractions, commonly known as Braxton Hicks contractions, are stimulated. The third major class of oxytocic drugs is the ergot alkaloids, which are also potent simulators of uterine muscle. These drugs increase the force and frequency of uterine contractions. One of the most politically charged prescription drug approvals ever made by the FDA was approval of the progesterone antagonist mifepristone (Mifeprex), also known as the "abortion pill." This drug also stimulates uterine contractions and is used to induce elective termination of pregnancy.

Indications

Oxytocin is available in a synthetic injectable form (e.g., Pitocin). This drug is used to induce labor at or near full-term gestation and to enhance labor when uterine contractions are weak and ineffective. Oxytocin is also used to prevent or control uterine bleeding after delivery, to induce completion of an incomplete abortion (including miscarriages), and to promote milk ejection during lactation.

The prostaglandins may be used therapeutically to induce labor by softening the cervix (cervical ripening) and enhancing uterine muscle tone. They may also be used to stimulate the myometrium to induce abortion during the second trimester when the uterus is resistant to oxytocin. Examples of these drugs are dinoprostone and misoprostol. Misoprostol is an oral tablet and is also used as a stomach protectant (see Chapter 45). Misoprostol is used off-label for cervical ripening and is administered orally or intravaginally. It offers the advantage of costing pennies as opposed to the hundreds of dollars paid for dinoprostone. Because of this, misoprostol is widely used in third-world countries as well as throughout the United States. Be aware that the prescribing information states that misoprostol should not be used in this way; however it is common to see it used clinically.

Ergot alkaloids are used after delivery of the infant and placenta to prevent postpartum uterine atony (lack of muscle tone) and hemorrhage.

Mifepristone is used to induce abortion and is often given with the synthetic prostaglandin drug misoprostol for this purpose.

Contraindications

Contraindications to the use of labor-inducing uterine stimulants include known drug allergy to a specific product and may include pelvic inflammatory disease, cervical stenosis, uterine fibrosis, high-risk intrauterine fetal positions before delivery, placenta previa, hypertonic uterus, uterine prolapse, or any condition in which vaginal delivery is contraindicated (e.g., increased bleeding risk). Contraindications to the use of abortifacients include known drug allergy as well as the presence of an intrauterine device, ectopic pregnancy, concurrent anticoagulant therapy or bleeding disorder, inadequate access to emergency health care, or the inability to understand or comply with follow-up instructions.

Adverse Effects

The most common undesirable effects of oxytocic drugs are listed in Table 34-6.

Interactions

Few clinically significant drug interactions occur with the oxytocic drugs. The most common and important of these involve sympathomimetic drugs. Combining drugs that produce vasoconstriction, such as sympathomimetics, with the oxytocic drugs can result in severe hypertension.

Dosages

For the recommended dosages of selected oxytocic drugs, see the Dosages table on p. 557.

DRUG PROFILES

♦ dinoprostone

Dinoprostone (Prostin E_2, Cervidil, Prepidil) is a synthetic derivative of the naturally occurring hormone prostaglandin E_2. It is used for the termination of pregnancy from the twelfth through the twentieth gestational weeks, for evacuation of the uterine contents in the management of missed abortion or intrauterine fetal death up to 28 weeks of gestational age, for the management of nonmetastatic gestational trophoblastic disease, and for ripening of an unfavorable cervix in pregnant women at or near term when there is a medical or obstetric need for labor induction. It is available only for vaginal use in various dosage forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Topical gel	Rapid	30-45 min	Unknown	Not available

♦ methylergonovine

The ergot alkaloid methylergonovine (Methergine) is used primarily in the immediately postpartal period to enhance myometrial tone and reduce the likelihood of postpartum uterine hemorrhage. Its use is contraindicated in patients with a known hypersensitivity to ergot medications and in those with pelvic

IV	Immediate	Immediate	3-5 min	1 hr

DRUGS FOR PRETERM LABOR MANAGEMENT

Preterm labor is defined as substantial uterine contractions which could progress to delivery and occur prior to the 37th week of pregnancy. When contractions of the uterus begin before term, it may be desirable to stop labor, because premature birth increases the risk of neonatal death. Postponing delivery increases the likelihood of the infant's survival. However, this measure is generally employed only between weeks 20 to 37 of gestation, because spontaneous labor occurring before the twentieth week is commonly associated with a nonviable fetus and thus is usually not interrupted.

The nonpharmacologic treatment of premature labor includes bed rest, sedation, and hydration. Drugs given to inhibit labor and maintain the pregnancy are called *tocolytics.* Terbutaline is a beta-adrenergic drug (see Chapter 18) and used to be the drug of choice for preterm labor. It works by directly relaxing uterine smooth muscle. In 2011, the FDA stated that terbutaline should not be used to prevent preterm labor or for prolonged treatment due to maternal and fetal safety risks. Concentrated solutions of the electrolyte magnesium sulfate are also used intravenously for this purpose. The efficacy of magnesium sulfate is questionable; however, it is still used clinically by some physicians. Magnesium sulfate is also used in pregnancy induced hypertension. Calcium gluconate must be readily available to reverse magnesium toxicity if it occurs.

The current recommendations for the management of preterm labor include the use of the nonsteroidal antiinflammatory agent, indomethacin (see Chapter 44), and the calcium channel blocker, nifedipine (see Chapter 23). Indomethacin is the most effective tocolytic currently available and works by inhibiting prostaglandin activity. Nifedipine inhibits myometrial activity by blocking calcium influx. The dose of indomethacin is 100 mg load followed by 50 mg every 8 hours. It is given in along with sucralfate (Carafate), which acts to protect the stomach (see Chapter 50). Nifedipine (immediate-release formulation) is dosed as 20 mg, followed by 20 mg after 30 minutes, and if contractions persist, 20 mg every 3 to 8 hours for 48 to 72 hours can be given, with a maximum dose of 160 mg/day. If after 72 hours, maintenance is still required, the sustained-release formulation can be used at doses of 30 to 60 mg daily. When these treatments are ineffective and delivery is proceeding, corticosteroids (betamethasone or dexamethasone) (see Chapter 33) are given to the mother to promote lung maturity in the fetus between 24 to 34 weeks of gestation.

TEAMWORK AND COLLABORATION: PHARMACOKINETIC BRIDGE TO NURSING PRACTICE

Estrasorb is a form of estrogen that is FDA approved to help ease the severity of postmenopausal hot flashes by increasing estrogen levels when these are found to be deficient in the patient. Estrasorb contains estradiol, which is identical to the estrogen produced in the woman's body. The absorption of the topical emulsion dosage form results in measurable levels of estradiol on the skin for up to 8 hours after application. It is important to fully understand this pharmacokinetic property, because the transfer of the drug to another individual may result. In fact, traces of Estrasorb have been found on other individuals from such transfer for up to a 2-day period. This transfer of medication to other individuals may be reduced by allowing the dosage form to fully dry and then covering it with clothing before having contact with another individual. Although no specific investigation of the tissue distribution of the estradiol absorbed from Estrasorb in humans has been conducted, it is known that the distribution of exogenous estrogens is similar to that of endogenous estrogens. The metabolism of exogenous estrogens is also similar to that of endogenous estrogens, with biotransformation taking place mainly in the liver and excretion in the urine. The specific dosage form of an emulsion is desirable because it may be applied easily, once daily to the thighs and/or calves. One dose is contained in two separate foil pouches, and patients need to be fully aware of the application instructions. For example, sunscreen products are not to be applied at the same time, because sunscreen reduces the absorption of Estrasorb.

Knowing the pharmacokinetic properties of Estrasorb is necessary for safe and efficient administration of the drug. It is also important to understand all the pharmacokinetic properties of this drug to be able to fully educate patients about the drug, its effect on the body, and the subsequent implications for its absorption, distribution, metabolism, and excretion.

NURSING PROCESS

ASSESSMENT

In this section, estrogenic and progestational medications (progestins/progesterone drugs) are discussed first, followed by the major drug classes used in treatment of osteoporosis. Next, information on fertility drugs, uterine stimulants, and preterm labor management drugs is discussed. Before initiating therapy with any of the hormonal drugs (e.g., estrogens, progestins) or other women's health-related drugs, obtain the patient's blood pressure and weight and document the findings. Assess and document drug allergies, contraindications, cautions, and drug interactions. Include a thorough medication history, medical history, and menstrual history in your patient assessment. Note the results of the patient's last physical examination, clinician-performed breast examination, and gynecologic examination as well.

Estrogen-only hormones are to only be given after the following disorders and conditions have been ruled out: any estrogen-dependent cancer, undiagnosed abnormal vaginal bleeding, active thromboembolic disorders such as stroke or thrombophlebitis, or a history of these disorders. Include questions about breast examination, breast self-examination practices, and dates of last complete physical examination and Papanicolaou (Pap) smear in the assessment. It is important to assess for potential drug interactions such as with tricyclic antidepressants, which may reach toxic levels if given with estrogens. Advise patients to avoid smoking because of the risk of thrombosis. It has been documented that smoking also decreases the effectiveness of estrogen; hence, take a thorough smoking history. Question about the number of packs smoked per day and the number of years the patient has smoked. Other drug interactions to assess for include oral anticoagulants (decreased effectiveness) as well as rifampin and St. John's wort (decreased estrogen effectiveness). If being used for hormonal replacement therapy for menopausal symptoms, recent changes to older recommendations from the North American Menopause Society include the following: hormonal replacement is not recommended for women with histories of endometrial cancer; in women with breast cancer, estrogen therapy has not been proved safe and may raise recurrence risk. Therefore, perform a thorough assessment for history or diagnosis of endometrial and/or breast cancer. Bone density may also be impacted once hormonal therapy is discontinued; further assessment is needed in these particular patients.

Assess the patient's knowledge about the use of hormones (e.g., estrogens and progestins), whether for contraception or replacement therapy. Also assess the patient's readiness to learn, educational level, and degree of adherence to other medication regimens. The success of treatment with oral contraceptives, hormone replacement medication, and other therapies depends heavily on the patient's understanding instructions. With *oral contraceptive drugs* (e.g., combination estrogen-progestin drugs), perform a pregnancy test and assess for history of vascular and/or thromboembolic disorders (such as myocardial infarction, venous thrombosis, stroke), malignancies of the reproductive tract, and abnormal vaginal bleeding. Closely monitor patients with the following: hypertension, migraine headaches, alterations in lipid and/or carbohydrate metabolism, fluid retention or edema, hair loss, amenorrhea, breakthrough vaginal/uterine bleeding, and uterine fibroids. The concern is for exacerbation of these conditions and the potential for subsequent complications. Closely monitor patients who smoke because of the increased risk of complications (increased risk of thrombosis) with estrogens. Assess for drug interactions, such as with drugs leading to decreased effectiveness of oral contraception—antibiotics (especially penicillins and cephalosporins), barbiturates, isoniazid, and rifampin. Drugs that may have their therapeutic effects decreased if taken concurrently with oral contraceptives include antiepileptic drugs, beta blockers, hypnotics, antidiabetic drugs, warfarin, theophylline, tricyclic antidepressants, and vitamins. When combination oral contraceptives are used in emergency situations for postcoital conception, the same contraindications, cautions, and drug interactions apply, even if the drug is for one-time use.

The chemically derived progestins, such as medroxyprogesterone and megestrol, have the same contraindications as estrogens. Additionally, with progestins, assess for a history of liver/gallbladder disease, thrombophlebitis, and thromboembolic disorders due to possible adverse effects (see Table 34-3). Be mindful that a significant drug interaction occurs with the antidiabetic drugs. Look thoroughly at the patient's medical history in reference to the specific condition for which the progestin is ordered. Some of these include prevention of endometrial cancer caused by estrogen therapy, palliative management of

recurrent endometrial or breast cancer, as well as management of anorexia and cachexia in those with AIDS or cancer.

With the osteoporosis drug class of *bisphosphonates*, there are many contraindications, cautions, and drug interactions. Assessment of the following is therefore important to patient safety: drug allergy, esophageal dysfunction, hypocalcemia, and the inability to sit or stand upright for at least 30 minutes after taking the medication. Selective estrogen receptor modulators (SERMs) are not to be used in patients who are or may become pregnant and in women with thromboembolic disorders including deep vein thrombosis. Assess for allergies to salmon with the use of calcitonin because the drug is derived from this fish. Drug interactions to assess for include ampicillin and cholestyramine because they decrease the absorption of raloxifene. Raloxifene also decreases the effects of warfarin. Assess patients for the drug interaction between bisphosphonates and calcium supplements and/or antacids (decreased absorption) as well as aspirin and NSAIDs (potential for additive GI irritation).

Use of *clomiphene* requires assessment of the patient's medical and medication history with attention to the patient's menstrual history. Medical history is critical, especially reproductive and uterine status, because use of the drug may result in multiple pregnancy (twins or more) and compromise maternal health status. Assess family stability and economic status because of the additional family and financial stressors associated with a multiple birth. Assess thoroughly for possible contraindications such as primary ovarian failure, adrenal and/or thyroid dysfunction, liver disease, and abnormal uterine bleeding. Assess also for potential drug interactions with tricyclic antidepressants, haloperidol, phenothiazines, and methyldopa (an antihypertensive drug). Fertility may be impaired if clomiphene is given with these drugs.

Before administering *uterine stimulants* (e.g., oxytocin or prostaglandins), assess and document the patient's blood pressure, pulse, and respiration. Also determine the fetal heart rate and contraction-related fetal heart rates and document findings. Contraindications to the use of labor-inducing uterine stimulants in early pregnancy include the presence of an intrauterine device for birth control, ectopic pregnancy, use of anticoagulants, bleeding disorders, and inability to understand and then comply with instructions. Assess for the concurrent use of sympathomimetics because of enhanced vasoconstrictive effects, possibly leading to severe hypertension. For labor and delivery, the patient's cervix must be ready for induction. (Consult a current maternal child health or obstetric nursing textbook for more information on the rating of the cervix.) Perform continuous monitoring of maternal blood pressure, pulse, contractions, and fluid status, as well as fetal heart rate. Oxytocin is *not* used during the first trimester except in some cases of spontaneous or induced abortion.

With the ergot alkaloid methylergonovine maleate, assess the medication order after vital signs and note that the first dose is given after delivery of the placenta to help stimulate the uterus to contract and decrease blood loss after delivery in special situations. Continue to assess blood pressure during the drug's administration. Assess for contraindications such as pregnancy, labor, liver/renal disease, cardiac disease, and pregnancy induced hypertension. Assess for any history of seizures. If this drug is given to hypertensive women, it may precipitate seizures or a stroke. The use of dinoprostone or other *prostaglandin E_2* drugs is indicated in specific situations requiring termination of pregnancy. Question the patient about the presence of any contraindications, cautions, and drug interactions. Misoprostol is also used intravaginally in an "off label" use for cervical ripening.

Terbutaline was formerly the drug of choice for the management of preterm labor but has been identified as having maternal and fetal risks. Instead, patients may receive indomethacin (see Chapter 44), nifedipine (see Chapter 23), or magnesium sulfate. Take baseline maternal vital signs, and assess fetal heart rate prior to administering any drug indicated for preterm labor. Assess the maternal history for estimated gestation as these medications are generally used between weeks 20 to 37. Spontaneous labor before the twentieth week is commonly associated with a nonviable fetus, and the labor is not interrupted. With indomethacin, additional concerns to assess for include a history of coagulation disorders, chronic hypertension, heart failure, impaired liver function, and cardiovascular disease. With nifedepine, a history of hypotension and cardiovascular problems are contraindications.

PATIENT-CENTERED CARE: CULTURAL IMPLICATIONS

Racial Disparities between Black Women and White Women in the Incidence, Treatment, and Prognosis of Endometrial Cancer

An estimated 40,100 new cases of uterine cancer were diagnosed in 2008, with the majority of the cases occurring in white women. The incidence of endometrial cancer was at 33% in black women and thought to be due partially to an underestimation of the cancer in this population. Over 7400 women with endometrial cancer died of their disease in 2008, with the mortality rate about 80% higher in black women (with the cancer) as compared with white women. Some 14% of endometrial cancer–related deaths occur in black women, while only 7% of newly diagnosed patients with endometrial cancer are black. Even though the number of new cases presenting each year has remained relatively stable, the number of deaths per year, especially among blacks, is increasing. A survey of recent literature published in the English language was performed by Allard and Maxwell (2009). This survey of literature serves as the basis of this information regarding racial disparities. The cause of racial disparity among black women with endometrial cancer appears to be multifaceted and most likely the result of barriers to the access of care, increasing incidence of comorbidities among black women, inequalities in their surgical care/radiation and/or adjuvant chemotherapy, and biological or genetic differences associated with more aggressive cancerous tumors developing in black women.

Data from Allard JE, Maxwell GL: Race disparities between black and white women in the incidence, treatment and prognosis of endometrial cancer, *Cancer Control* 16(1): 53-56, 2009.

NURSING DIAGNOSES

1. Decisional conflict related to the risks versus benefits of postmenopausal estrogen replacement therapy
2. Acute pain related to adverse effects and improper dosing of SERM
3. Noncompliance related to lack of information and experience with daily dosing of oral contraceptives

PLANNING

GOALS

1. Patient makes informed decision regarding the use of estrogen replacement therapy.
2. Patient experiences minimal pain (epigastric) associated with SERMs.
3. Patient remains compliant with oral contraceptive therapy.

OUTCOME CRITERIA

1. Patient correctly self-administers estrogen replacement therapy daily after decision to opt for pharmacologic treatment.
2. Patient remains without esophageal pain after taking SERM as ordered and with the full ability to sit or stand upright for at least 30 minutes after taking the oral dosage form to avoid/prevent esophageal irritation/erosion.
3. Patient is compliant with oral contraceptive therapy, states rationale for daily use (effectiveness based on taking medication daily), and contacts health care provider with any high incidence of adverse effects.

IMPLEMENTATION

When administering *estrogens,* directions need to be followed exactly. Provide precise and thorough instructions to patients when self-administration of the hormone is ordered. Oral dosage forms are best taken at the same time every day and with meals or a snack to minimize GI upset.

It is also important to understand the indication and rationale for the use of estrogen so that accurate facts about the drug are given to the patient. If estradiol is being given, vasomotor symptoms of menopause are generally the indication, and the drug is to be given daily at the same time. If the estradiol transdermal patch is given, it is to be applied as ordered, which is usually one patch applied once or twice weekly to the lower abdomen and not to the breast and chest areas. See the Patient Teaching Tips for more information.

Use of *progestins* is indicated for birth control, such as the use of Depo-Provera with one IM injection every 3 months. Depo-Provera, however, remains controversial in women of any reproductive age because of the associated bone density loss. Give these injections in deep muscle mass and rotate sites. Oral forms of medroxyprogesterone acetate are used for amenorrhea and uterine bleeding. Doses are to be taken exactly as ordered, such as for a specific number of days or cyclically. Megestrol, a synthetic progestin, is often indicted for palliative reasons or for management of anorexia, cachexia, or weight loss that is unexplained in AIDS patients. It is given orally as ordered and given to maximize appetite. It is recommended, however, that the lowest dosage possible of either *estrogens* and/or *progestins* be used and titrated as needed, but only as ordered.

Oral contraception is available in various formulations based on doses that are taken at different times of the menstrual cycle (see pharmacology discussion). Progestin-only oral contraceptive pills are taken daily. It is important for the patient to take this oral contraceptive at the same time every day so that effective hormone serum levels are maintained. Because use of the progestin-only pill leads to a higher incidence of ovulatory cycles, there is an increased rate and risk of contraceptive failure if not taken as per instructions. Be aware that this type of pill is usually prescribed for those women who cannot tolerate estrogens or for whom estrogens are contraindicated. Often it is more effective in women who are older than 35 years of age and women who are breastfeeding. Combination estrogen-progestin pills contain low doses of the hormones. Biphasic forms contain fixed estrogen and variable progestin for 21- or 28-day products. The low-dose monophasic (fixed estrogen-progestin combination) types are provided as 21 or 28 days of pills, with the 28-day products containing 7 inert tablets. Triphasic products offer 3 or 4 phases of variable estrogen and progestin combinations, and there are also new extended-cycle products available. Make sure the patient fully understands how to take the medication. Emphasize that the reduction in the level of estrogen has been associated with a decrease in adverse effects and a decrease in the risk for complications; however, more breakthrough bleeding may occur.

The success of therapy with *bisphosphonates* depends on providing thorough patient teaching and ensuring that the patient understands all aspects of the drug regimen. With oral bisphosphonates, emphasize the need to take the medication upon rising in the morning with a full glass (6 to 8 oz) of water at least 30 minutes before the intake of any food, other fluids, or other medication. In addition, emphasize that the patient remain upright in either a standing or sitting position for approximately 30 minutes after taking the drug to help prevent esophageal erosion or irritation. Inform the patient taking the *SERM* raloxifene that the drug must be discontinued 72 hours before and during prolonged immobility. Therapy may be resumed, as ordered, once the patient becomes fully ambulatory. See the Patient Teaching Tips for more information.

Fertility drugs (e.g., clomiphene) are often self-administered. Provide specific instructions regarding how to administer the drug at home and how to monitor drug effectiveness to improve the success of treatment. Journal tracking of the medication regimen is helpful to those involved in the care of the infertile patient or couple. See the Patient Teaching Tips for more information.

With *tocolytics,* either indomethacin (Indocin) or nifedipine (Procardia) will be used. It is important to note, however, that magnesium sulfate may also be used. Follow the dosing and routes exactly as determined by the prescriber. Long-term dosing of indomethacin is not recommended due to birth defects. Nifedipine may lead to potentially life-threatening maternal-fetal problems. Discontinue both medications, as ordered, once contractions cease. Monitor vital signs and fetal heart rates closely with these drugs. Placement of the patient in the left lateral recumbent position minimizes hypotension, increases renal blood flow, and increases blood flow to the fetus.

Administer *oxytocin* only as ordered, and strictly follow any instructions or protocols. The cervix must be ripe (see earlier discussion). *Prostaglandin E_2* may be instilled vaginally to help accomplish this if the mother's cervix is not ripe or at a Bishop score of 5 or higher. Because oxytocin has vasopressive and antidiuretic properties, the patient is at risk for hypertensive episodes as well as fluid retention; continuously monitor maternal blood

CASE STUDY

Bisphosphonate Drug Therapy for Osteoporosis

Mrs. S. is a relatively healthy 73-year-old retired clerk who has recently been diagnosed with postmenopausal osteoporosis. She has been prescribed treatment with ibandronate (Boniva), 150 mg each month. She has many questions, and you are reviewing the drug and its use with her.

1. Mrs. S. tells you that she likes to have breakfast, take her morning medicines, then lie down on the couch to read the morning newspaper. She asks whether the ibandronate will fit into her routine. What will you tell her?
2. Mrs. S. calls the clinic to ask what to use for headaches. "I have several different types of headache pills, so aren't they all the same?" How will you respond?
3. A few months later, Mrs. S. comes in for a follow-up visit. She tells you that she is due for her next osteoporosis pill next week, but she has been having some jaw pains ever since she went to the dentist 2 weeks earlier to have a tooth pulled. She is worried that her osteoporosis has affected her jaw. What could be the reason for this pain? What do you think will be done about it?

For answers, see http://evolve.elsevier.com/Lilley.

pressure and pulse rate as well as fetal heart rate. Report any of the following to the prescriber immediately if they occur: strong contractions, edema, and any changes in fetal heart rate. Administer intravenous infusions (via infusion pump) of oxytocin with the proper dilutional fluid and at the proper rate. To minimize the adverse effects of the drug, intravenous piggyback dosing is often ordered so that the diluted oxytocin solution can be discontinued immediately if maternal and/or fetal decline occurs while an intravenous line with hydration is maintained. Doses are generally titrated as ordered and are based on the progress of labor and degree of fetal tolerance of the drug. If the labor progresses at 1 cm/hr, oxytocin may no longer be needed. This decision is made by the prescriber and on an individual basis. Generally speaking, with oxytocin therapy, if there are hypertensive responses or major changes in the maternal vital signs *or* if the fetal heart rate shows any indication of fetal intolerance of labor, contact the prescriber immediately. Hyperstimulation may also occur. If contractions are more frequent than every 2 minutes and last longer than 1 minute (and are accompanied by changes in other parameters), stop the infusion and contact the prescriber immediately. If this does occur, place the patient in a side-lying position, maintain administration of intravenous fluids, give oxygen as ordered (generally via tight face mask at 10 to 12 L/min), and monitor patient and fetus closely. If there is concern about overstimulation, discuss concerns with the prescriber and document actions thoroughly.

When misoprostol is used, give orally or intravaginally for cervical ripening and only as ordered.

Dinoprostone is given by vaginal suppository to patients who are 12 to 20 weeks pregnant and are seeking termination and/or to those in whom evacuation of the uterus is needed for the management of incomplete spontaneous abortion or intrauterine fetal death (up to 28 weeks). Give the drug exactly as ordered and monitor the patient closely.

EVALUATION

Measure therapeutic responses to the various drugs discussed in this chapter by evaluating whether goals and outcome criteria have been met. Many drugs have been discussed, often with several indications for use; thus, the therapeutic response will be the occurrence of the indicated therapeutic effect. Monitor the patient for adverse effects and/or toxicity as well.

Therapeutic effects of *estrogens* may range from prevention of pregnancy to a decrease in menopausal symptoms to a reduction in the size of a tumor. Adverse effects of estrogens may include hypertension, thromboembolism, edema, amenorrhea, nausea, vomiting, facial skin discoloration, hirsutism, breast tenderness, and headaches. Therapeutic responses to *progestins* include a decrease in abnormal uterine bleeding and the disappearance of menstrual disorders (e.g., amenorrhea). The adverse effects of progestins include jaundice, thrombophlebitis, liver dysfunction, and thromboembolic disorders. Adverse effects associated with oral contraceptives include hypertension, edema, thromboembolism, headaches, migraines, depression, stroke, nausea, vomiting, amenorrhea, and breakthrough bleeding.

Therapeutic effects of oxytocin and other *uterine stimulants* include stimulation of labor and control of postpartum bleeding. Adverse effects may include hypotension or hypertension, chest pain, nausea, vomiting, blurred vision, and fainting. The primary therapeutic effect of tocolytics includes absence of preterm labor. Adverse maternal effects may include vasodilation and increase in heart rate, and fetal side effects include possible intrauterine growth retardation.

The therapeutic effects of *fertility drugs* include successful conception. Adverse reactions include tachycardia, deep vein thrombosis, hypovolemia, CNS depression, nausea, vomiting, ovarian hyperstimulation, blurred vision, and photophobia. Therapeutic effects of *osteoporosis drugs* include increased bone density and prevention or management of osteoporosis. Adverse effects of SERMs are hot flashes, leg cramps, leukopenia, headache, GI upset, joint pain, and esophageal burns if the drug is lodged in the esophagus before reaching the stomach.

PATIENT TEACHING TIPS

- Hormonal drugs are better tolerated if taken with food or milk to minimize GI upset.
- With the use of oral contraceptives as well as any form of hormonal replacement therapy (HRT) with estrogens and/or progestins, encourage the patient to openly discuss concerns about the medications. Assure the patient that, although risks may be associated with HRT, the prescriber will weigh each case individually and make a recommendation based on the benefits versus risks, but with the ultimate decision resting with the patient.
- With estrogens and progestins, advise the patient to report the following conditions to the prescriber immediately: hypertension, edema, thromboembolism, migraines, depression, and breakthrough bleeding.
- Instruct the patient to report a weight gain of 2 pounds or more in 24 hours or 5 pounds or more in 1 week, as well as any breakthrough bleeding or a change in menstrual flow.
- Instruct the patient to take oral contraceptives exactly as ordered and to keep all appointments for follow-up examinations (e.g., pelvic examination, Pap smear, and practitioner-performed breast examination).
- Instruct the patient on the importance of and technique for monthly breast self-examinations during the ideal time—that is, 7 to 10 days after the start of menstruation or 2 to 5 days after menses ends. Stress the need for follow-up appointments and annual examinations by a health care provider.
- Hormones make the patient sensitive to sunlight and tanning beds. Emphasize that the patient must use the appropriate sun protection at all times.
- If the patient is using progesterone-only intravaginal gel with other gels, advise the patient to be sure to insert the other gels at least 6 hours before or after the progesterone-based product.
- Slow-release progesterone intrauterine devices are placed in the uterine cavity by a health care provider. Provide thorough education that inserts are left in place for 5 years (after insertion) and then must be replaced. Advise the patient to report abnormal uterine bleeding, cramping, abdominal pain, or amenorrhea immediately.
- Instruct the patient using an estrogen/progestin vaginal ring for contraception on what to expect with its insertion. Use of this contraceptive device requires thorough teaching and follow-up, including instruction on insertion and removal techniques and a return demonstration before the patient leaves the prescriber's office. Inform the patient that menstruation will follow in 2 to 3 days after the ring is removed and to replace the used ring in its foil pouch and discard it in the trash rather than flushing it down the commode.
- Oral contraceptive hormones must be taken at the same time every day and exactly as prescribed. If one dose is missed, advise the patient to take the dose as soon as it is remembered; however, if it is close to the next dose time, advise the patient not to double up and to use a backup form of contraception in these situations. Provide more specific instructions regarding the omission of more than one pill and/or 1 day's dose depending on the specific oral contraceptive drug prescribed. These specific instructions will most likely include the following: If the patient misses one "active" tablet in weeks 1, 2, or 3, the tablet needs to be taken as soon as she remembers. If the patient misses two "active" tablets in week 1 or week 2, the patient needs to take two tablets the day she remembers and two tablets the next day, then continue taking one tablet a day until the pack is finished. The patient needs to be instructed to use a backup method of birth control such as condoms if she has sex in the 7 days after missing pills. If the patient misses two "active" tablets in the third week or misses three or more "active" tablets in a row, the patient needs to throw out the rest of the pack and start a new pack that same day. Instruct the patient to use a backup method of birth control if she has sex in the seven 7 days after missing pills.
- Stress the importance of using condoms with oral contraception to prevent sexually transmitted diseases.
- Emphasize to the patient that backup contraception (e.g., condom use) is needed when antibiotics, barbiturates, griseofulvin, isoniazid, rifampin , or St. John's wort is taken with oral contraceptives. These drugs and herbs diminish the effectiveness of oral contraception.
- Estrasorb is generally applied once daily to the thighs and calves, as ordered, with one dose provided in two separate pouches. Do not apply sunscreen and other lotions at the same time because they interfere with the drug. To reduce the chance of transfer of this medication to other individuals, allow the application areas to dry completely before covering them with clothing. The drug contained in this dosage form, estradiol, has been found to be present on the skin up to 8 hours after application.
- Conjugated estrogens are used for menopausal symptoms and are given orally every day; however, other uses of these estrogens may require different doses and a different dosage schedule/regimen. Emphasize the expected adverse effects such as edema, nausea, diarrhea/constipation, breakthrough uterine bleeding, chloasma (facial skin discoloration), hirsutism, tender breasts, and headaches. Encourage the patient to report the following conditions: elevated blood pressure, severe headaches with changes in vision and vomiting, abdominal pain, and edema.
- Bisphosphonates (e.g., alendronate) are to be taken exactly as prescribed; that is, the drug is taken at least 30 minutes before the first morning beverage, food, or other medication and with at least 6 to 8 oz of water. Emphasize the importance of remaining upright for at least 30 minutes after taking the medication to prevent esophageal and GI adverse effects. Esophageal irritation, dysphagia, severe heartburn, and retrosternal pain must be reported to the prescriber immediately to help prevent severe reactions.
- Patients taking bisphosphonates may also require supplemental calcium and vitamin D, as ordered by the prescriber.
- Educate the patient about making lifestyle changes as recommended, such as engaging in weight-bearing exercise (e.g., walking), stopping smoking, and limiting or eliminating alcohol intake. These measures will help encourage fewer adverse effects of oral contraception and/or drug therapy with hormones.

KEY POINTS

- Three major estrogens are synthesized in the ovaries: estradiol (the principal estrogen), esterone, and estriol. Exogenous estrogens can be classified into two main groups: steroidal estrogens (e.g., conjugated estrogens, esterified estrogens, estradiol) and nonsteroidal estrogens (e.g., chlorotrianisene, dienestrol, diethylstilbestrol).
- Progestins have a variety of uses, including treatment of uterine bleeding and amenorrhea and adjunctive and palliative treatment of some cancers.
- Oral contraceptives containing a combination of estrogens and progestins are the most effective forms of reversible contraception currently available.
- Uterine stimulants (sometimes called *oxytocic drugs*) include ergot derivatives, prostaglandins, and oxytocin.
- Uterine relaxants (often called *tocolytic drugs*) are used to stop preterm labor and maintain pregnancy by halting uterine contractions.
- A thorough nursing assessment is necessary to ensure the safe and effective use of female reproductive drugs. Obtain information on the patient's past medical problems, history of menses and problems with the menstrual cycle, medications taken (prescribed and OTC), number of pregnancies and miscarriages, last menstrual period, and any related surgical or medical treatments.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is assessing a patient who is to receive dinoprostone (Prostin E_2). Which condition would be a contraindication to the use of this drug?
   - **a** Pregnancy at 15 weeks' gestation
   - **b** GI upset or ulcer disease
   - **c** Ectopic pregnancy
   - **d** Incomplete abortion

2 When teaching a patient who is taking oral contraceptive therapy for the first time, the nurse relates that adverse effects may include which of the following?
   - **a** Dizziness
   - **b** Nausea
   - **c** Tingling in the extremities
   - **d** Polyuria

3 The nurse is reviewing the use of obstetric drugs. Which situation is an indication for an oxytocin (Pitocin) infusion?
   - **a** Termination of a pregnancy at 12 weeks
   - **b** Hypertonic uterus
   - **c** Cervical stenosis in a patient who is in labor
   - **d** Induction of labor at full term

4 The nurse has provided patient education regarding therapy with the SERM raloxifene (Evista). Which statement from the patient reflects a good understanding of the instruction?
   - **a** "When I take that long flight to Asia, I will need to stop taking this drug at least 3 days before I travel."
   - **b** "I can continue this drug even when traveling as long as I take it with a full glass of water each time."
   - **c** "After I take this drug, I must sit upright for at least 30 minutes."
   - **d** "One advantage of this drug is that it will reduce my hot flashes."

5 The nurse is discussing therapy with clomiphene (Clomid) with a husband and wife who are considering trying this drug as part of treatment for infertility. It is important that they be informed of which possible effect of this drug?
   - **a** Increased menstrual flow
   - **b** Increased menstrual cramping
   - **c** Multiple pregnancy (twins or more)
   - **d** Sedation

6 A patient calls the clinic because she realized she missed one dose of an oral contraceptive. Which statement from the nurse is appropriate? (Select all that apply.)
   - **a** "Go ahead and take the missed dose now, along with today's dose."
   - **b** "Don't worry, you are still protected from pregnancy."
   - **c** "Please come to the clinic for a reevaluation of your therapy."
   - **d** "Wait 7 days, and then start a new pack of pills."
   - **e** "You will need to use a backup form of contraception concurrently for 7 days."

7 The order reads: "Give calcitonin (Miacalcin) 50 international units subcut daily." The medication is available in a vial that contains 200 international units/mL. How many milliliters will the nurse draw up in the syringe for this dose?

1. c, 2. b, 3. d, 4. a, 5. c, 6. a, e, 7. 0.25 mL

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the normal anatomy, physiology, and functions of the male reproductive system.
2 Compare the various men's health drugs, with discussion of their rationale for use, dosages, and dosage forms.
3 Describe the mechanisms of action, dosages, adverse effects, cautions, contraindications, drug interactions, and routes of administration for the various men's health drugs.
4 Develop a nursing care plan that includes all phases of the nursing process for patients receiving men's health drugs for treatment of benign prostatic hyperplasia, sexual dysfunction, hormone deficiency, or prostate cancer.

DRUG PROFILES

finasteride, p. 568
♦ **sildenafil, p. 569**
♦ **testosterone, p. 569**

♦ *Key drug*

KEY TERMS

Anabolic activity Any metabolic activity that promotes the building up of body tissues, such as the activity produced by testosterone that causes the development of bone and muscle tissue; also called *anabolism*. (p. 565)

Androgenic activity The activity produced by testosterone that causes the development and maintenance of the male reproductive system and male secondary sex characteristics. (p. 565)

Androgens Male sex hormones responsible for mediating the development and maintenance of male sex characteristics. Chief among these are testosterone and its various biochemical precursors. (p. 565)

Benign prostatic hyperplasia (BPH) (also called *hypertrophy*) Nonmalignant (noncancerous) enlargement of the prostate gland. (p. 566)

Catabolism The opposite of anabolic activity; any metabolic activity that results in the breakdown of body tissues. Examples of conditions in which catabolism occurs are debilitating illnesses such as end-stage cancer and starvation. (p. 565)

Erythropoietic effect The effect of stimulating the production of red blood cells (erythropoiesis). (p. 565)

Prostate cancer A malignant tumor within the prostate gland. (p. 566)

Testosterone The main androgenic hormone. (p. 565)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

MALE REPRODUCTIVE SYSTEM

The male reproductive system consists of several structures; two of these structures, the testes and seminiferous tubules, produce the primary male hormones. The *testes,* a pair of oval glands located in the scrotal sac, are the male gonads. The testes produce male sex hormones. The *seminiferous tubules,* which are channels in the testes, are the site of spermatogenesis, which is the process by which mature sperm cells are produced.

Androgens are the group of male sex hormones (primarily testosterone) that mediate the normal development and maintenance of the primary and secondary male sex characteristics. Secondary male sex characteristics include advanced development of the prostate, seminal vesicles (two glands adjacent to the prostate), penis, and scrotum, as well as male hair distribution, laryngeal enlargement, thickening of the vocal cords, and male body musculature and fat distribution. Androgens must be secreted in adequate amounts for these characteristics to appear. The most important androgen is **testosterone,** which is produced from clusters of interstitial cells located between the seminiferous tubules. Besides having **androgenic activity,** testosterone is also involved in the development of bone and muscle tissue; inhibition of protein **catabolism** (metabolic breakdown); and retention of nitrogen, phosphorus, potassium, and sodium. These functions contribute to its **anabolic activity.** The hormone initiates the synthesis of specific proteins needed for androgenic and anabolic activity by binding to chromatin (strands of deoxyribonucleic acid [DNA]) in the nuclei of interstitial cells. In addition, testosterone appears to have an **erythropoietic effect** in that it stimulates the production of red blood cells (see Chapter 54).

PHARMACOLOGY OVERVIEW

ANDROGENS AND OTHER DRUGS PERTAINING TO MEN'S HEALTH

Testosterone deficiency is treated with exogenous testosterone. There are several synthetic derivatives of testosterone that have improved pharmacokinetic and pharmacodynamic characteristics over the naturally occurring hormone. This is accomplished by combining various esters with testosterone, which prolongs the duration of action of the hormone. For example, testosterone propionate is formulated as an oily solution, and its hormonal effects last for 2 to 3 days; the effects of testosterone cypionate and testosterone enanthate in oil last for up to 2 to 4 weeks. Orally administered testosterone has very poor absorption, because most of the dose is metabolized and destroyed by the liver before it can reach the circulation (first-pass effect; see Chapter 2). To circumvent this problem, researchers developed methyltestosterone (Android) and fluoxymesterone (Halotestin). Both are synthetic dosage forms (tablets or capsules) designed to be effective following oral administration. Methyltestosterone is also available in a buccal tablet, which is dissolved in the buccal cavity (the space in the mouth between the cheek and teeth) and in an injectable form. Transdermal dosage forms of testosterone, including skin patches and a gel, have provided another way to circumvent the first-pass effect that occurs with oral administration of this hormone.

There are other chemical derivatives of testosterone known as *anabolic steroids.* These are synthetic drugs that closely resemble the natural hormone but possess high anabolic activity. Currently three anabolic steroid drug products are commercially available. These include oxymetholone (Anadrol-50), oxandrolone (Oxandrin), and nandrolone (Deca-Durabolin). Approved indications include anemia, hereditary angioedema, and metastatic breast cancer. Unlabeled (non–FDA-approved) uses for oxandrolone include treatment of human immunodeficiency virus (HIV)–associated wasting syndrome (debilitation related to disease-induced nutritional malabsorption) and alcoholic hepatitis. Oxandrolone is also used in hospitalized patients to stimulate weight gain. Anabolic steroids have a great potential for misuse by athletes, especially bodybuilders and weight lifters, because of their muscle-building properties. Improper use of these substances can have many serious consequences, such as sterility, cardiovascular diseases, and even liver cancer. For this reason, anabolic steroids are currently classified as Schedule III controlled substances by the U.S. Drug Enforcement Administration. This classification implies that misuse of these drugs can lead to psychological or physical dependence or both.

Another synthetic androgen is danazol (Danocrine). Its labeled uses include treatment of hereditary angioedema, and, in women, endometriosis and fibrocystic breast disease.

Mechanism of Action and Drug Effects

The natural and synthetic androgens and the synthetic anabolic steroids have effects similar to those of the endogenous androgens. These include stimulation of the normal growth and development of the male sex organs (primary sex characteristics) and development and maintenance of the secondary sex characteristics. Androgens stimulate the synthesis of ribonucleic acid (RNA) at the cellular level, thereby promoting cellular growth and reproduction. They also retard the breakdown of amino acids. These properties contribute to an increased synthesis of body proteins, which aids in the formation and maintenance of muscle tissue. Another potent anabolic effect of androgens is the retention of nitrogen, also essential for protein synthesis. Nitrogen also promotes the storage of inorganic phosphorus, sulfate, sodium, and potassium, all of which have important metabolic roles, including protein synthesis, nerve impulse conduction, and muscular contractions. All of these effects result in weight gain and an increase in muscular strength. Finally, androgens also stimulate the production of erythropoietin by the kidney, which leads to enhanced erythropoiesis (red blood cell synthesis; see Chapter 54). However, the administration of exogenous androgens causes the release of endogenous testosterone to be inhibited as a result of the feedback inhibition of pituitary luteinizing hormone. Large doses of exogenous androgens may also suppress sperm production as a

result of the feedback inhibition of pituitary follicle-stimulating hormone, which leads to infertility.

Androgen inhibitors block the effects of naturally occurring (endogenous) androgens. This is accomplished via inhibition of a specific enzyme, 5-alpha reductase. For this reason, these drugs are also called *5-alpha reductase inhibitors*. For unknown reasons, normal male physiology often results in an enlargement of the prostate known as **benign prostatic hyperplasia (BPH).** This process begins as early as 30 years of age and is present in at least 85% of men by 80 years of age. The most troubling symptom is usually varying degrees of obstructed urinary outflow. Although surgical treatment by *transurethral resection of the prostate (TURP)* is a common strategy, BPH is also often treatable with a 5-alpha reductase inhibitor. There are currently two such drugs: finasteride and dutasteride. Finasteride (Proscar), the prototypical drug for this class, works by inhibiting this enzyme, which normally converts testosterone to 5-alpha dihydrotestosterone (DHT). DHT is a more potent type of testosterone and is the principal androgen responsible for stimulating prostatic growth, as well as the expression of other male primary and secondary sex characteristics. Finasteride can dramatically lower the prostatic DHT concentrations, which helps to reduce the size of the prostate to ease the passage of urine. Fortunately, finasteride does not cause antiandrogen adverse effects that might be expected, such as loss of muscle strength, and fertility.

The effects of finasteride are limited primarily to the prostate, but this drug may also affect 5-alpha reductase–dependent processes elsewhere in the body, such as in the hair follicles, skin, and liver. Research has demonstrated that the pharmacologic inhibition of 5-alpha reductase prevents the thinning of hair caused by increased levels of DHT. It has been noted that men taking finasteride experience increased hair growth. Therefore, finasteride is also indicated for the treatment of male-pattern baldness as Propecia. Finasteride is indicated for the treatment of baldness only in men, not in women. Finasteride can be teratogenic in pregnant women, and its use in women of any age (pregnant or not) is not recommended. Women need to wear gloves when handling finasteride. Another medication, minoxidil (Rogaine), can be used topically to treat baldness in both men and women. It is discussed in more detail in Chapter 56.

Another class of drugs that may be used to help alleviate the symptoms of obstruction due to BPH are the alpha$_1$-adrenergic blockers. These drugs are discussed in greater detail in Chapter 19. The alpha$_1$-adrenergic blockers that are most commonly used for symptomatic relief of obstruction secondary to BPH are terazosin (Hytrin), doxazosin (Cardura), tamsulosin (Flomax), alfuzosin (Uroxatral), and silodosin (Rapaflo). Tamsulosin, alfuzosin, and silodosin appear to have a greater specificity for the alpha$_1$-receptors in the prostate and thus may cause less hypotension. These drugs have clinical effects of prostate shrinkage immediately, as opposed to the 5-alpha reductase inhibitors, which may take up to 6 months of continual therapy.

There are also two other classes of androgen inhibitors. The first includes the androgen receptor blockers flutamide (Eulexin), nilutamide (Nilandron), and bicalutamide (Casodex). These drugs work by blocking the activity of androgen hormones at the level of the receptors in target tissues (e.g., prostate). For this reason, these drugs are used in the treatment of **prostate cancer** (see Chapter 46). The second class is the gonadotropin-releasing hormone (Gn-RH) analogues, including leuprolide (Lupron), goserelin (Zoladex), and triptorelin (Trelstar). These drugs work by inhibiting the secretion of pituitary gonadotropin, which eventually leads to a decrease in testosterone production. Both androgen receptor blockers and Gn-RH analogues are used most commonly to treat prostate cancer and are discussed in further detail in Chapter 46.

PATIENT-CENTERED CARE: CULTURAL IMPLICATIONS

Men's Health Concerns: Prostate Cancer and Its Occurrence and Mortality

It is estimated that 217,730 men will be diagnosed in 2010 with prostate cancer and 32,050 will die of the cancer. During the years 2004 to 2008, the median age at diagnosis for prostate cancer was 67 years of age. Incidence rates by race per 100,000 men are as follows (from cases diagnosed from 2004 to 2008): 156 per 100,000 for all races, 149.5 for whites, 233.8 for African Americans, 88.3 for Asians and Pacific Islanders, 75.3 for Native Americans and Alaska Natives, and 107.4 per 100,000 for Hispanics. Prostate cancer is the most common nonskin malignancy in men and the second leading cause of cancer-related death in men in the United States. African-American men have a higher incidence and at least double the mortality rates as compared with men from other racial ethnic groups.

Data from Howlader N, Noone AM, Krapcho M, et al, editors: *SEER cancer statistics review, 1975-2008,* Bethesda, MD, 2011, National Cancer Institute, available at http://seer.cancer.gov/csr/1975_2008/. Accessed May 25, 2011; National Cancer Institute at the National Institutes of Health: Prostate cancer, available at www.cancer.gov/cancertopics/types/prostate. Accessed May 25, 2011.

Phosphodiesterase inhibitors are used in the treatment of erectile dysfunction. Sildenafil (Viagra) was the first oral drug approved for the treatment of erectile dysfunction. Sildenafil works by inhibiting the action of the enzyme phosphodiesterase. This in turn allows the buildup in the penis of the chemical cyclic guanosine monophosphate, which causes relaxation of the smooth muscle in the corpora cavernosa (erectile tubes) of the penis and permits the inflow of blood. Nitric oxide is also released inside the corpora cavernosa during sexual stimulation and contributes to the erectile effect. Two drugs that are similar but have a longer duration of action are vardenafil (Levitra) and tadalafil (Cialis). Collectively, these drugs are referred to as *erectile dysfunction drugs.* Sildenafil is also used to treat pulmonary hypertension (see Chapter 22) under the trade name Revatio.

A second type of drug used to treat erectile dysfunction is the prostaglandin alprostadil (Caverject). This drug must be given by injecting it directly into the erectile tissue of the penis or pushing a suppository form of the drug into the urethra.

A list of all of the men's health drugs mentioned in the chapter appears in Box 35-1. More information on selected drugs can be found in the Drug Profiles section.

BOX 35-1 CURRENTLY AVAILABLE MEN'S HEALTH DRUGS

Alpha$_1$-Adrenergic Blockers
doxazosin
tamsulosin
terazosin
alfuzosin

Anabolic Steroids
nandrolone
oxandrolone
oxymetholone

Other Androgens
danazol
fluoxymesterone
methyltestosterone
testosterone

Antiandrogens
bicalutamide
flutamide
nilutamide

5-Alpha Reductase Inhibitors
finasteride
dutasteride

Gonadotropin-Releasing Hormone Analogues
goserelin
leuprolide
triptorelin

Peripheral Vasodilator
minoxidil

Drugs for Erectile Dysfunction
sildenafil
tadalafil
vardenafil
alprostadil

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

Sildenafil: Use and Concerns

- One in 10 men in the world has erectile dysfunction (ED). Some 30 million men in the U.S. have erectile dysfunction. Fifty percent of men with diabetes experience erectile dysfunction. The incidence of ED increases with age, with 39% at 40 years of age and 65% older than 65 years of age.
- Sildenafil (Viagra) is a prescription medication that is commonly ordered to treat ED, but it is not without concerns and cautions for the patient. This is especially true for elderly patients who generally have other medical conditions (e.g., renal disorders, hypertension, diabetes) and are usually taking more than one other prescribed medication.
- Liver function declines with age; therefore, drugs may not be metabolized as effectively in older adults as they are in younger adults. In addition, sildenafil is highly protein bound, which causes it to stay in the body longer and thus increases the possibility for drug interactions and toxicity.
- A decreased dosage of sildenafil is generally indicated for patients older than 65 years of age and for those with liver or renal impairment.
- Adverse effects to be concerned about in all patients, particularly older patients, include headache, flushing, and dyspepsia.
- Sildenafil must be used cautiously in patients who have cardiac disease and angina, because these patients are at greater risk for complications, especially if they are taking nitrates for their cardiovascular disease. Severe hypotension may occur.
- Discussing topics of a sexual nature may be comfortable for some patients but very anxiety producing for others. Be aware of cultural and gender differences in how individuals perceive their own sexuality and how they generally deal with sexual performance issues. Be respectful of each individual's beliefs and feelings and their sexual beliefs and practices. This requires knowledge, sensitivity, and objectivity.

TABLE 35-1 MEN'S HEALTH DRUGS: INDICATIONS

DRUG	INDICATION
danazol and stanozolol	Hereditary angioedema
finasteride	Benign prostatic hyperplasia
	Male androgenetic alopecia
fluoxymesterone and methyltestosterone	Male hypogonadism, inoperable breast cancer
methyltestosterone	Postpubertal cryptorchidism
minoxidil	Hypertension
	Female and male androgenetic alopecia
oxandrolone	Weight gain
sildenafil, tadalafil, vardenafil	Erectile dysfunction
testosterone	Primary or secondary hypogonadism

Indications

The primary use for androgens is as hormone replacement therapy. Indications for other types of drugs discussed in this chapter are listed in Table 35-1.

Contraindications

Contraindications to the use of androgenic drugs include known androgen-responsive tumors. Use of sildenafil, vardenafil, and tadalafil is also contraindicated in men with major cardiovascular disorders, especially if they use nitrate medications such as nitroglycerin. Concurrent use of erectile dysfunction drugs and nitrates may cause severe hypotension, which may not respond to treatment. Use of finasteride is contraindicated in women (especially pregnant women) and children.

Adverse Effects

Although rare, some of the most devastating effects of androgenic steroids occur in the liver, where they cause the formation of blood-filled cavities, a condition known as *peliosis of the liver*. This condition is a possible consequence of the long-term administration of androgenic anabolic steroids and can be life-threatening. Other serious hepatic effects are hepatic neoplasms (liver cancer), cholestatic hepatitis, jaundice, and abnormal liver function. Fluid retention is another undesirable effect of androgens and may account for some of the weight gain seen. The serious adverse effects that can be caused by the androgens far outweigh the advantages to be gained from their use by those seeking improved athletic ability. Other less serious adverse effects of androgens are listed in Table 35-2.

Sildenafil, vardenafil, and tadalafil appear to have relatively favorable adverse effect profiles. In patients with preexisting cardiovascular disease, especially those taking nitrates (e.g., nitroglycerin, isosorbide mononitrate, or dinitrate), these drugs can lower blood pressure substantially, potentially leading to more serious adverse events. Headache, flushing, and dyspepsia are the most common adverse effects reported. *Priapism* or abnormally prolonged penile erection is a relatively uncommon, but possible, adverse effect of both the erectile dysfunction drugs

TABLE 35-2 MEN'S HEALTH DRUGS: SELECTED ADVERSE EFFECTS

DRUG CLASS	ADVERSE EFFECTS
Alpha$_1$-adrenergic blockers	Tachycardia, hypotension, syncope, depression, drowsiness, rash, impotence, urinary frequency, dyspnea, visual changes, headache
Androgens (including anabolic steroids)	Headache, changes in libido, anxiety, depression, acne, male pattern baldness, hirsutism, nausea, abnormal liver function test results, priapism, elevated cholesterol level
5-Alpha reductase inhibitors	Reduced libido, hypotension, dizziness, drowsiness
Peripheral vasodilator (topical minoxidil)	With topical route, usually limited to localized dermatologic reactions, including erythema, dermatitis, eczema, pruritus
Drugs for erectile dysfunction	Dizziness, headache, muscular pain, chest pain, hypertension or hypotension, rash, dry mouth, nausea, vomiting, diarrhea, priapism

and the androgens. This condition is a medical emergency and warrants urgent medical attention. It is simply due to an excessive therapeutic drug response. Phosphodiesterase inhibitors can also cause unexplained visual loss.

Finasteride has been reported to cause loss of libido, loss of erection, ejaculatory dysfunction, hypersensitivity reactions, gynecomastia, and severe myopathy. The drug has also caused a 50% decrease in prostate-specific antigen (PSA) concentrations. Pregnant women must not handle crushed or broken tablets on a regular basis because of the possibility of topical absorption, which can lead to teratogenic effects.

Interactions

Androgens, when used with oral anticoagulants, can significantly increase or decrease anticoagulant activity (see Chapter 26). Concurrent use of androgens with cyclosporine (see Chapter 48) increases the risk of cyclosporine toxicity and is not recommended. Sildenafil, vardenafil, and tadalafil may cause severe hypotension when given together with nitrates such as nitroglycerin, isosorbide mononitrate, or isosorbide dinitrate (see Chapter 23). Alpha blockers can cause additive hypotension when given with other drugs that lower blood pressure (see Chapter 22). Effects of tamsulosin may be increased when it is taken with azole antifungal drugs, erythromycin and clarithromycin (see Chapter 38), cardiac drugs such as propranolol and verapamil (see Chapters 19 and 25), and protease inhibitors (see Chapter 40).

Dosages

For dosage information on the men's health drugs, see the table below.

DRUG PROFILES

finasteride

Finasteride (Proscar) is available in two tablet forms of 1- and 5-mg strengths. The lower strength is indicated for androgenetic alopecia in men. The higher strength is indicated for BPH, with clinical effects of prostate shrinkage in approximately 3 to 6 months of continual therapy. A similar drug, dutasteride (Avodart), is also indicated for BPH and is currently available in 0.5-mg capsule form. Both drugs are contraindicated in patients who have shown hypersensitivity and in pregnant women and children. It is considered potentially dangerous for a pregnant woman even to handle crushed or broken tablets. Both drugs are classified as pregnancy category X. Recommended dosages are given in the table on this page.

DOSAGES

Selected Men's Health Drugs

DRUG	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
finasteride (Propecia, Proscar)	5-Alpha reductase inhibitor	**Adult** PO: 1 mg daily (Propecia) PO: 5 mg daily (Proscar)	Androgenetic alopecia (baldness) (males only) Benign prostatic hyperplasia
♦ sildenafil (Viagra)	Phosphodiesterase inhibitor	**Adult (males only)** PO: 25-100 mg 1 hr before intercourse, no more than once daily	Erectile dysfunction
♦ testosterone cypionate (Depo-Testosterone)	Androgenic hormone	**Adult and adolescent** IM: 50-400 mg q2-4wk	Delayed puberty or hypogonadism (in males)
♦ testosterone, transdermal (Testoderm, Androderm, AndroGel)	Androgenic hormone	**Adult and adolescent** Testoderm patch (applied only to scrotal skin): 4-6 mg/day Androderm patch (applied to skin of back, abdomen, upper arms, or thighs): 2.5-5 mg/day AndroGel (applied to shoulders, arms, or abdominal skin): 5 g daily (delivers 50 mg of testosterone)	Male hypogonadism

IM, Intramuscular; *PO,* oral.

Pharmacokinetics (finasteride)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	3-12 mo	8 hr	4-15 hr	Unknown

♦ sildenafil

Sildenafil (Viagra) is approved for the treatment of erectile dysfunction. Other erectile dysfunction drugs with longer durations of action include vardenafil and tadalafil. Sildenafil potentiates the physiologic sexual response, causing penile erection after sexual arousal by relaxing smooth muscle and increasing blood flow into the penis.

Sildenafil use is contraindicated in patients with a known hypersensitivity to it. Sildenafil can potentiate the hypotensive effects of nitrates, and its administration to patients who are using organic nitrates in any form, either regularly or intermittently, is therefore contraindicated. Recommended dosages are given in the table on p. 568.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	0.5-1 hr	1 hr	4 hr	4-6 hr

♦ testosterone

Testosterone (Androderm) is a naturally occurring anabolic steroid. It is used for primary and secondary hypogonadism but may also be used to treat oligospermia in men as well as inoperable breast cancer in women, where its purpose is to counteract tumor-enhancing estrogen activity. When it is used as hormone replacement therapy, a transdermal product is desirable. There are presently two transdermal patch formulations. They attempt to mimic the normal circadian variation in testosterone concentration seen in young healthy men, in whom the maximum testosterone levels occur in the early morning hours and the minimum concentrations occur in the evening. Of the two available transdermal delivery systems, Testoderm is always applied to the scrotal skin, whereas Androderm is always applied to skin elsewhere on the body and never to the scrotal skin. Educate patients to wash their hands and cover the area where testosterone is applied, as transfer to others can occur.

Testosterone use is contraindicated in patients with severe renal, cardiac, or hepatic disease; male breast cancer; prostate cancer; hypersensitivity; or genital bleeding, as well as in pregnant or lactating women. Testosterone is considered a Schedule III controlled substance under the Anabolic Steroids Control Act. It is available as intramuscular injections, transdermal gel, transdermal patches, and even implantable pellets. It is classified as a pregnancy category X drug. Recommended dosages are given in the table on p. 568.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Topical	1-2 hr	2-4 hr	10-100 min	2-4 wk

TEAMWORK AND COLLABORATION: PHARMACOKINETIC BRIDGE TO NURSING PRACTICE

Drugs used to manage erectile dysfunction (e.g., sildenafil) essentially work in the same way as the body to assist the male patient in achieving an erection. The related pharmacokinetics must be understood so that the drug is taken safely and effectively. Sildenafil is a rapidly absorbed drug with onset of action within 1 hour, peak plasma concentrations within 1 hour, and duration of action of up to 4 to 6 hours. If the drug is taken with a high-fat meal, absorption will be delayed, and it may take an additional 60 minutes for the drug to reach peak levels. This is yet another example of how specific drug pharmacokinetics may be affected by variables in a patient's everyday life, such as eating habits. Another pharmacokinetic consideration is that patients who are 65 years of age or older have reduced clearance of sildenafil and may experience increased plasma concentrations of free (or pharmacologically active) drug. This could possibly lead to drug accumulation and/or toxicity.

NURSING PROCESS

ASSESSMENT

Before any drug is given to a male patient for the treatment of benign or malignant diseases of the male reproductive tract, thoroughly assess presenting symptoms and obtain a complete history of past and present medical diseases or conditions. In addition, assess the patient's urinary elimination patterns and any difficulties, and document the findings. The health care provider usually performs a rectal examination to palpate for enlargement of the prostate or for other possible pathology. If enlargement exists, a serum PSA test will most likely be ordered, especially prior to any treatment, and the test may also be ordered during treatment. PSA levels may be increased in pathologic conditions such as prostate cancer. Monitor levels for baseline and comparative reasons. PSA levels are expected to decrease with effective therapeutic regimens. More recent research encourages the use of a PSA value of less than 2.5 or 3 ng/mL as the criterion for normal levels, especially for younger patients.

With *testosterone* and related drugs, assess the patient for liver disease because formation of blood-filled cavities may occur. This condition, also called *peliosis,* is associated with long-term therapy and may be life-threatening. Perform liver function studies (e.g., LDH, CPK, and bilirubin levels) as ordered to monitor for the possible adverse effect of abnormal liver function and jaundice. Because edema is also a problem with these drugs, recording baseline weights, intake and output, and history of any cardiovascular diseases is important. Another contraindication to assess for is that of a history of known androgen-responsive tumors.

Finasteride requires baseline assessment of urinary patterns with attention to frequency, urgency, and flow of urine with micturation. As the tissue responds to the drug and there is a reduction in the size of the prostate gland and thus improvement in the symptoms of BPH, urinary flow will be increased. With potentially teratogenic drugs such as finasteride, follow special handling precautions and advise any pregnant caregiver or partner to do the same. Finasteride is not to be given in women. Assessment of the patient's sexual

functioning and libido is important due to possible interference from the drug.

Before *drugs for erectile dysfunction* are given, the prescriber will perform a physical examination. You will need to perform a thorough nursing assessment including vital signs, and obtain a thorough medication history. Take a thorough cardiac history and assess for contraindications with the use of phosphodiesterase inhibitors (e.g., sildenafil, vardenafil [Levitra], and tadalafil [Cialis]), such as major cardiovascular disorders or the use of nitrate medications (nitroglycerin, isosorbide mononitrate, or dinitrate). The erectile dysfunction drugs and nitrates may lead to severe hypotension that may not respond to treatment.

NURSING DIAGNOSES

1. Decreased cardiac output related to drug interaction between erectile dysfunction drug and nitrates
2. Ineffective sexuality pattern related to the effects of treatment with androgen and/or therapy with phosphodiesterase inhibitors
3. Deficient knowledge related to lack of information about drug therapy and disease process of BPH as well as drug interactions with finasteride

PLANNING

GOALS

1. Patient maintains normal and adequate cardiac output.
2. Patient maintains or regains effective sexual patterns and functioning.
3. Patient displays adequate knowledge regarding disease process and recommended drug therapy.

OUTCOME CRITERIA

1. Patient maintains blood pressure within normal limits with at least 120/80 mmHg readings.
   - Patient experiences minimal drop in systolic and diastolic blood pressure during drug therapy with erectile dysfunction drugs or androgens.
   - Patient avoids potential interactions with medication regimen (e.g., nitrates not to be taken with erectile dysfunction drugs) as well as situations that may exacerbate hypotension, such as saunas, alcohol, and hot climates.
   - Patient reports continued low blood pressure readings, dizziness, or feelings of lightheadedness to prescriber.
2. Patient openly verbalizes feelings of inadequacies associated with changes in libido or sexual functioning and seeks out help from health care provider.
   - Patient takes medication as prescribed to minimize adverse effects and maximize therapeutic effects.
   - Patient implements suggestions for improving libido and sexual functioning as recommended by prescriber.
   - Patient verbalizes the ability to sustain and maintain an erection or complete the act of coitus.
3. Patient states understanding of the rationale for drug therapy.

IMPLEMENTATION

The therapeutic effects of *testosterone* are maximized when the drug is taken as ordered and at regular intervals so that steady levels are maintained. If the drug is being used for hypogonadism or induction of puberty, dosages may be managed differently, so that at the end of the growth spurt the patient is placed on maintenance dosages. Instruct patients to apply Testoderm transdermal patches as ordered, which is usually to clean, dry scrotal skin that has been shaved for optimal skin contact and replaced every day. Advise the patient to follow instructions for application and time of duration per prescriber's orders. Educate patients that Androderm patches are to be applied to clean, dry skin on the back, abdomen, upper arms, or thighs; the scrotum and bony areas (shoulder, hip) are not to be used with this particular drug. Be sure the proper patch is being used and that drugs are not confused. AndroGel is to be applied to shoulders, arms, or abdominal skin as ordered. If testosterone is being given intramuscularly, it is usually given every 2 to 4 weeks as prescribed. Mix the vial of medication thoroughly by agitating it before withdrawing the prescribed amount of medication.

Finasteride may be given orally without regard to meals. When used for treatment of the urinary symptoms of BPH, finasteride and related drugs may be ordered for approximately 3 to 6 months with a reevaluation of the condition at that time. Advise the patient to protect the drug from exposure to light and heat. Due to the teratogenic effects of finasteride, emphasize that it must not be handled in any form by a pregnant woman. Recommend that female nurses/members of the health care team wear gloves when handling this medication. Women need to wear gloves when handling this medication.

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

Saw Palmetto (Serenoa repens, Sabal serrulata)

Overview
Saw palmetto comes from a tree that is also known as the American dwarf palm. The therapeutically active part of the tree is its ripe fruit. Saw palmetto is believed to inhibit dihydrotestosterone and 5-alpha reductase. A prostatic-specific antigen test and digital rectal examination should be performed before initiation of treatment with saw palmetto for benign prostatic hyperplasia.

Common Uses
Diuretic, urinary antiseptic, treatment of benign prostatic hyperplasia, treatment of alopecia

Adverse Effects
Gastrointestinal upset, headache, back pain, dysuria

Potential Drug Interactions
Nonsteroidal antiinflammatory drugs, hormones such as estrogen replacement therapy and oral contraceptives, immunostimulants

Contraindications
None

It is recommended that women of any age do not take this medication. See the Safety: Herbal Therapies and Dietary Supplements box for a description of saw palmetto, an herbal supplement that is often taken to relieve symptoms of an enlarged prostate.

For patients taking *erectile dysfunction drugs*, alert them to the drug interaction-related serious adverse effect of severe drops in blood pressure if taken with nitrates. When taking sildenafil, vardenafil, or tadalafil, priapism, which is the abnormally prolonged erection of the penis, may occur; it is considered a medical emergency and requires immediate and urgent medical attention. See the Patient Teaching Tips for more information.

EVALUATION

The therapeutic effects of drugs related to the male reproductive tract include improvement of the condition and/or signs and symptoms for which the patient is being treated, such as hypogonadism, sexual dysfunction, erectile dysfunction, and urinary elimination problems caused by BPH. The therapeutic effects of some drugs (e.g., finasteride) may not be seen for 3 to 6 months, so it is important to observe and monitor the patient for the intended effects of the drugs. In addition, evaluate for the adverse effects of these medications (see the pharmacology section for specific adverse effects). Always evaluate goals and outcome criteria to see if the patient's needs have been met.

CASE STUDY

Erectile Dysfunction Drugs

Mr. S., a 63-year-old college professor, is in the office for a yearly checkup. He feels he is generally healthy, and he does not take any medications. He does say that he has one problem that he wants to discuss with the physician. During his physical examination, he tells the physician, "I have something embarrassing to ask. I want to try one of those drugs that can help my sex life." The physician reassures Mr. S. that he does not need to be embarrassed to ask about this. The physician then assesses Mr. S.'s sexual difficulties. At the end of the examination and assessment, Mr. S. is given a prescription for sildenafil (Viagra).

1. What teaching is important for Mr. S. before he starts this medication?
2. Eleven months later, Mr. S. is admitted to the emergency department with chest pains. After a thorough examination, including a cardiac catheterization, he is diagnosed with mild coronary artery disease and is started on isosorbide dinitrate, sustained-release, 40 mg every 12 hours. He is given a follow-up appointment with his physician in 1 week. What specific teaching is important at this time?
3. Mr. S. comes to the office for the follow-up appointment and tells the nurse that he wants to try saw palmetto for his prostate health. He has a neighbor who takes it and has no problems with it, and he has noticed that he has had a slight increase in difficulty with urination. He is also upset about what he was told in the hospital about his medications. How will the nurse respond to Mr. S., and what assessments are needed at this time?

For answers, see http://evolve.elsevier.com/Lilley.

PATIENT TEACHING TIPS

- With finasteride, provide education at the patient's educational level about the drug's therapeutic effects as well as adverse effects (see the pharmacology discussion for more information). Educate female family members, significant others, and caregivers who are pregnant or of childbearing age about the need to avoid exposure during handling of this drug, including *not* touching any broken or crushed tablets, which could result in exposure to the drug and the risk of teratogenic effects. Emphasize the need to wear gloves when handling the medication.
- Finasteride may be given orally without regard to meals. Instruct patients to protect the drug from exposure to light and heat.
- Sildenafil is usually prescribed to be taken about 1 hour before sexual activity. This drug, and other drugs for erectile dysfunction, should not be taken with nitrates because it may lead to significant hypotensive consequences that could be life-threatening.
- Inform the patient that drug therapy for erectile dysfunction is not effective without sexual stimulation and arousal.
- With testosterone, educate the patient about all therapeutic and adverse effects. Emphasize the importance of follow-up appointments, which are crucial to evaluating the therapeutic effectiveness of the medication (as well as with any drugs discussed in this chapter).
- Prolonged erections (i.e., longer than 4 hours) must be reported immediately and are considered to be a medical emergency.
- Testosterone is not be withdrawn abruptly except under the supervision of the prescriber. Weaning is usually done over several weeks.

KEY POINTS

- The most commonly used drugs related to male health and the male reproductive tract are finasteride, sildenafil, and testosterone. It is important to know the way these drugs work and their adverse effects, contraindications, cautions, and drug interactions to ensure their safe and effective use.
- Testosterone is responsible for the development and maintenance of the male reproductive system and secondary sex characteristics. Oral testosterone has very poor pharmacokinetic and pharmacodynamic characteristics, and therefore it is recommended that testosterone be administered via injection (parenteral route) or a transdermal patch.
- Methyltestosterone was developed to circumvent the problems associated with the oral administration of testosterone.
- Finasteride is usually indicated to stop growth of the prostate in men with BPH and to treat men with androgenic alopecia.
- Warn patients taking drugs for erectile dysfunction (e.g., sildenafil) about potential adverse effects, such as hypotension, headache, and heartburn.
- There are major concerns about heart-related deaths associated with concurrent use of nitrates and drugs used for erectile dysfunction. Focus patient education on the prevention of drug interactions and related adverse effects and complications.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A patient has been taking finasteride (Proscar) for almost a year. The nurse knows that which is most important to evaluate at this time?
- **a** Complete blood count
- **b** PSA levels
- **c** Blood pressure
- **d** Fluid retention

2 The nurse is performing an assessment of a patient who is asking for a prescription for sildenafil (Viagra). Which finding would be a contraindication to its use?
- **a** Age of 65 years
- **b** History of thyroid disease
- **c** Medication list that includes nitrates
- **d** Medication list that includes saw palmetto

3 During a counseling session for a group of teenage athletes, the use of androgenic steroids is discussed. The nurse will explain that which problem is a rare but devastating effect of androgenic steroid use?
- **a** Peliosis of the liver
- **b** Bradycardia
- **c** Kidney failure
- **d** Tachydysrhythmias

4 The nurse is teaching a patient about the possible adverse effect of priapism, which may occur when taking erectile dysfunction drugs. The nurse emphasizes that, if this occurs, the most important action is to
- **a** stay in bed until the erection ceases.
- **b** apply an ice pack for 30 minutes.
- **c** turn toward his left side and rest.
- **d** seek medical attention immediately.

5 A patient is asking about the use of saw palmetto for prostate health. The nurse tells him that drugs that interact with saw palmetto include:
- **a** acetaminophen (Tylenol).
- **b** nitrates.
- **c** nonsteroidal antiinflammatory drugs.
- **d** antihypertensive drugs.

6 When the Testoderm form of testosterone is ordered to treat hypogonadism in a teenage boy, which instructions by the nurse are correct? (Select all that apply.)
- **a** Place the patch on clean, dry skin on the back, upper arms, abdomen, or thighs.
- **b** Place the patch on clean, dry scrotal skin that has been shaved.
- **c** Place the patch on clean, dry scrotal skin, but do not shave the skin first.
- **d** Place the patch on any clean, dry, nonhairy area of the body.
- **e** Remove the old patch before applying a new patch.

7 A 16-year-old male is to receive testosterone cypionate (Depo-Testosterone), 50 mg IM every 2 weeks. The medication is available in 100-mg/mL containers. How many mL will the nurse draw up in the syringe to administer for each dose?

1. b, 2. c, 3. a, 4. d, 5. c, 6. b, e, 7. 0.5 mL per dose

PART 6

Drugs Affecting the Respiratory System

Study Skills Tips

Study on the Run • PURR

STUDY ON THE RUN, PURR

The basic approach in applying Study on the Run (SOTR) is to make use of small blocks of time that are otherwise nonproductive. Plan, Rehearse, and Review do not require that the entire chapter be covered in one study session. These steps produce their benefits by promoting repetition of learning.

Where Is the Time?

SOTR time is everywhere. In the course of a single day, you might have an hour or more that can be used for SOTR activities. It is just a matter of becoming aware of little bits and pieces of your day that can ordinarily slip away without being productive. Small blocks of time are everywhere in your day; it just takes a little creativity on your part to become aware of them. Finishing an examination early, standing in the checkout line, waiting for the teakettle to boil, or even waiting for the washing machine to finish the last spin before you change loads can be time used for SOTR. Get creative and be flexible. Remember, every minute of time you use this way is a minute of time you will not have to find later.

SOTR and Plan

Remember the importance of questioning as an essential component in Plan. Look at the chapter objectives for Chapter 37. There are five objectives presented for this chapter. Work on the questions for as many of these objectives as can be covered in the time you have. If you complete questions for only two objectives, do not look upon it as failure to complete something. Instead, learn to view what you have done as that much less to do later. The time you spend now frees up that much more time during your large blocks of study time for intense study reading.

Will you forget the questions you generated in this session before you have the opportunity to read the chapter? If you make it a habit to ask questions as a continuing part of all study, you will find that you remember the focus questions very well. If you have trouble remembering your own questions, write the questions in the margins of the text. Gradually you will find that questioning becomes such an automatic procedure that you will be able to dispense with writing questions. You will remember them.

SOTR and Vocabulary

One of the most challenging aspects of a course like this is the almost overwhelming vocabulary load. If the new vocabulary load were not enough, there is also the need

to keep reviewing previous parts and chapters because some term that was introduced three chapters ago has reappeared and you do not remember it clearly. Creating your own vocabulary cards is a perfect SOTR activity.

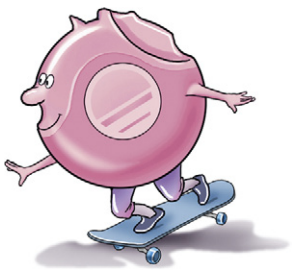
The basic card model is simple. The word, common form, prefix, or suffix appears on the card front. The back of the card may have just a little information (the minimum being a definition of what is on the front) or may contain considerable information. I recommend that you include part, chapter, and page number on the back so that you can locate the term quickly if the need arises. In addition, you may want to add a specific example from the text or of your own creation to help clarify the term. Put as much information on the back as you find useful.

Creating Vocabulary Cards with SOTR

Use the time between classes to create several personal vocabulary cards. Grab your text and your blank note cards. Open to the next chapter you will be studying. Flip over to the key terms pages. Write the first word from the key terms on the front of a blank note card. Turn the card over. Write the part and chapter numbers and the page number for the key term on the card. Pick a standard location for this. Put these numbers in a top or bottom corner, but make sure you put them in the same corner every time. Eventually this becomes a habit and makes the preparation process faster. It also helps when you are making use of the cards, because you will know exactly what information you put on the card and where you put it. Put this card aside and repeat the process with the next term. In those few minutes before you go to class you can have completed the basic preparation for a full set of cards covering, for example, the 17 key terms in Chapter 36.

Notice that all I proposed was that you copy the term and the location information. I did not tell you to copy the definition listed in the key terms at this time. The term used in the context of a sentence and a paragraph may be much easier to understand. If, as you read the chapter, you feel that the glossary definition is also useful to have on this card, you can always flip back by using the location information you put on the card.

SOTR and Vocabulary Review



Your vocabulary cards are ideal for SOTR action. Carry a pack of cards with you at all times. Whenever you have even a minute or two, you can pull out a stack of cards from previous chapters or the current chapter. Use the oral ask-and-answer method discussed in the *Study Guide*. For instance, the first key term in Chapter 37 is *allergen*. Ask yourself aloud, "What is an allergen?" Then try to answer the question aloud. Answer: "An allergen is a substance that produces an allergic reaction." It is not necessary to recall the exact answer presented in the key terms and/or chapter. What is important is that you respond with a clear and meaningful answer. The answer given earlier is not exactly the same as that stated in the key terms, but the general concept is the same. Once you have stated your answer, turn the card over and check to make sure that you were correct. Each time you do this with a term, you are strengthening your long-term memory, and you will find that it takes less and less time to recall the terms you need.

Vocabulary cards can also be used with your study group. You may want to give oral quizzes to each other. This is one sure way to check that your answer is stated clearly.

SOTR and Chapter Review

Chapter review can be overwhelming if you think that review means rereading the material and that you therefore need large blocks of uninterrupted time. There is a much more efficient way to review, and it works well in short time blocks, which makes it a perfect technique for SOTR.

Look at the first page of Chapter 36. You should instantly see a number of visible structures that make it easy to review key terms and concepts without rereading the entire block of material. First, there is the chapter title: Antihistamines, Decongestants, Antitussives, and Expectorants. What are antihistamines? This is a question you would have generated when you were engaged in the Plan step of PURR. Now that you have read the chapter, repeat the question and answer it aloud. Answer aloud because you will hear what you say and will either know the material or need to mark it to come back and reread. Now ask more complex questions: "What is the role of antihistamines? What do they do?" Now try to answer these questions. If you can, then you do not need to reread to find out what antihistamines are. Next, looking at p. 576, you will notice some terms in **bold blue print.** Apply the same process. Using these words and phrases as stimuli, ask questions and try to answer them to your own satisfaction. If you cannot develop a satisfactory answer, then you know that some rereading is needed. However, it should be very focused. You are not trying to reread everything on the page, but only the material right there that is associated with the term.

On p. 576 you will see a bulleted list. Look at the sentence preceding the list: "The release of excessive amounts of histamine can lead to anaphylaxis and severe allergic symptoms and may result in any or all of the following physiologic changes…" Ask questions. If you can answer them, no reading is necessary. If you cannot answer, you know that the answers are found immediately after this sentence in the bulleted list. Use the structures in the chapter to accomplish focused review. Comprehension is improved and long-term memory is strengthened, and your test grades will reflect this.

The benefits of SOTR are enormous. There are no drawbacks. You are using time that otherwise would be "wasted," and this time now becomes productive study time. The more active you become in looking for SOTR opportunities, the more you will find. The more SOTR time you spend, the better student you will become.

CHAPTER

36

Antihistamines, Decongestants, Antitussives, and Expectorants

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Provide specific examples of the drugs categorized as antihistamines (both sedating and nonsedating), decongestants, antitussives, and expectorants.
2 Discuss the mechanisms of action, indications, contraindications, cautions, drug interactions, adverse effects, dosages, and route of administration for antihistamines, decongestants, antitussives, and expectorants.
3 Develop a nursing care plan that includes all phases of the nursing process for patients taking any of the antihistamines, decongestants, antitussives, and/or expectorants.

DRUG PROFILES

benzonatate, p. 583
codeine, p. 583
♦ **dextromethorphan, p. 583**
♦ **diphenhydramine, p. 580**
♦ **guaifenesin, p. 584**
♦ **loratadine, p. 580**
naphazoline, p. 582

♦ *Key drug*

KEY TERMS

Adrenergics (sympathomimetics) Drugs that stimulate the sympathetic nerve fibers of the autonomic nervous system that use epinephrine or epinephrine-like substances as neurotransmitters. (p. 580)

Antagonists Drugs that exert an action opposite to that of another drug or compete for the same receptor sites. (p. 577)

Anticholinergics (parasympatholytics) Drugs that block the action of acetylcholine and similar substances at acetylcholine receptors, which results in inhibition of the transmission of parasympathetic nerve impulses. (p. 580)

Antigens Substances that are capable of inducing specific immune responses and reacting with the specific products of those responses, such as antibodies and specifically sensitized T lymphocytes. Antigens can be soluble (e.g., a foreign protein) or particulate or insoluble (e.g., a bacterial cell). (p. 577)

Antihistamines Substances capable of reducing the physiologic and pharmacologic effects of histamine. (p. 577)

Antitussive A drug that reduces coughing, often by inhibiting neural activity in the cough center of the central nervous system. (p. 582)

KEY TERMS—cont'd

Corticosteroids Any of the hormones produced by the adrenal cortex, either in natural or synthetic drug form. They control many key processes in the body, such as carbohydrate and protein metabolism, the maintenance of serum glucose levels, electrolyte and water balance, and the functions of the cardiovascular system, skeletal muscle, kidneys, and other organs. (p. 580)

Decongestants Drugs that reduce congestion or swelling, especially of the upper or lower respiratory tract. (p. 580)

Empiric therapy A method of treating disease based on observations and experience, rather than a knowledge of the precise cause for the disorder. (p. 576)

Expectorants Drugs that increase the flow of fluid in the respiratory tract, usually by reducing the viscosity of secretions, and facilitate their removal by coughing. (p. 584)

Histamine antagonists Drugs that compete with histamine for binding sites on histamine receptors. (p. 577)

Influenza A highly contagious infection of the respiratory tract caused by a myxovirus and transmitted by airborne droplets. (p. 576)

Nonsedating antihistamines Medications that primarily work peripherally to block the actions of histamine and therefore do not generally have the central nervous system effects of many of the older antihistamines; also called *second-generation antihistamines* and *peripherally acting antihistamines.* (p. 580)

Reflex stimulation An irritation of the respiratory tract occurring in response to an irritation of the gastrointestinal tract. (p. 583)

Rhinovirus Any of about 100 serologically distinct ribonucleic acid (RNA) viruses that cause about 40% of acute respiratory illnesses. (p. 576)

Sympathomimetic drugs A class of drugs whose effects mimic those resulting from the stimulation of the sympathetic nervous system. (p. 581)

Upper respiratory tract infection (URI) Any infectious disease of the upper respiratory tract, including the common cold, laryngitis, pharyngitis, rhinitis, sinusitis, and tonsillitis. (p. 576)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Common colds result from a viral infection, most often infection with a **rhinovirus** or an **influenza** virus. These viruses invade the tissues (mucosa) of the upper respiratory tract (nose, pharynx, and larynx) to cause an **upper respiratory tract infection (URI).** The inflammatory response elicited by these viruses stimulates excessive mucus production. This fluid drips behind the nose, down the pharynx, and into the esophagus and lower respiratory tract, which leads to symptoms typical of a cold: sore throat, coughing, and upset stomach. Irritation of the nasal mucosa often triggers the sneeze reflex and also causes the release of several inflammatory and vasoactive substances, which results in the dilation of the small blood vessels in the nasal sinuses and leads to nasal congestion. Treatment of the common symptoms of URI involves the combined use of antihistamines, nasal decongestants, antitussives, and expectorants.

In 2008, the U.S. Food and Drug Administration (FDA) issued recommendations that over-the-counter (OTC) cough and cold products not be given to children younger than 2 years of age. This followed numerous case reports of symptoms such as oversedation, seizures, tachycardia, and even death in toddlers. There is also evidence that such medications are simply not effective in small children, and parents are advised to consult their pediatrician on the best ways to manage these illnesses. A 2010 study showed a dramatic decrease in young children emergency room visits since the FDA recommendation.

Many antihistamines, nasal decongestants, antitussives, and expectorants are available without prescription. However, these drugs can only relieve the symptoms of a URI. They can do nothing to eliminate the causative pathogen. Antiviral drugs are currently the only drugs that are effective; however, treatment with these mediations is often hampered by the fact that the viral cause cannot be readily identified. Because of this, the treatment rendered can only be based on what is believed to be the most likely cause, given the presenting clinical symptoms. Such treatment is called **empiric therapy.** Some patients seem to gain benefit from the use of herbal products and other supplements, such as vitamin C, to prevent the onset of cold signs and symptoms or at least to decrease their severity. Herbal products commonly used for colds are echinacea and goldenseal (see the Safety: Herbal Therapies and Dietary Supplements boxes on p. 577). There is limited research data regarding the efficacy of herbal products, and some can have significant drug-drug or drug-disease interactions.

PHARMACOLOGY OVERVIEW

ANTIHISTAMINES

Histamine is a substance that performs many functions. It is involved in nerve impulse transmission in the central nervous system (CNS), dilation of capillaries, contraction of smooth muscle, stimulation of gastric secretion, and acceleration of the heart rate. There are two types of cellular receptors for histamine. Histamine 1 (H_1) receptors mediate smooth muscle contraction and dilation of capillaries; histamine 2 (H_2) receptors mediate acceleration of the heart rate and gastric acid secretion. The release of excessive amounts of histamine can lead to anaphylaxis and severe allergic symptoms and may result in any or all of the following physiologic changes:

- Constriction of smooth muscle, especially in the stomach and lungs
- Increase in body secretions

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

Echinacea (Echinacea)

Overview
The three species of echinacea used medicinally are *Echinacea angustifolia, Echinacea pallida,* and *Echinacea purpurea.* Echinacea has been shown in clinical trials to reduce cold symptoms and recovery time when taken early in the illness. This is believed to be due to its immunostimulant effects. At this time, there is no strong research evidence to warrant recommending the herb for urinary tract infections, wound healing, or prevention of colds; further study is needed to provide evidence of its therapeutic effects and indications.

Common Uses
Stimulation of the immune system, antisepsis, treatment of viral infections and influenza-like respiratory tract infections, promotion of healing of wounds, and chronic ulcerations

Adverse Effects
Dermatitis, upset stomach or vomiting, dizziness, headache, unpleasant taste

Potential Drug Interactions
Amiodarone, cyclosporine, phenytoin, methotrexate, ketoconazole, barbiturates; tolerance likely to develop if used for more than 8 weeks. Because some preparations have a high alcohol content, they may cause acetaldehyde syndrome in patients taking disulfiram (Antabuse) to prevent alcohol abuse (see Chapter 17).

Contraindications
Contraindicated for patients with acquired immunodeficiency syndrome, tuberculosis, connective tissue diseases, multiple sclerosis

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

Goldenseal (Hydrastis canadensis)

Overview
Goldenseal is found in wooded areas from the northeastern to midwestern United States. It is the dried root of the plant that is most commonly used for its various biologically active alkaloids. These components have been shown to have antibacterial, antifungal, and antiprotozoal activity. The alkaloid berberine has both anticholinergic and antihistaminic activity.

Common Uses
Treatment of upper respiratory tract infections, allergies, nasal congestion, and numerous genitourinary, skin, ophthalmic, and otic conditions

Adverse Effects
Gastrointestinal (GI) distress, emotional instability, mucosal ulceration (e.g., when used as a vaginal douche)

Potential Drug Interactions
Gastric acid suppressors (including antacids, histamine H_2 blockers [e.g., ranitidine], proton pump inhibitors [e.g., omeprazole]): theoretically reduced effectiveness due to acid-promoting effect of herb
Antihypertensives: theoretically reduced effectiveness due to vasoconstrictive activity of herb

Contraindications
Acute or chronic GI disorders; pregnancy (has uterine stimulant properties); should be used with caution by those with cardiovascular disease

Data from Skidmore-Roth L: *Mosby's handbook of herbs and natural supplements,* ed 4, St Louis, 2010, Mosby.

- Vasodilatation and increased capillary permeability, which results in the movement of fluid out of the blood vessels and into the tissues and thus causes a drop in blood pressure and edema

Antihistamines are drugs that directly compete with histamine for specific receptor sites. For this reason, they are also called **histamine antagonists.** Antihistamines that compete with histamine for the H_2 receptors are called H_2 **antagonists** or *H_2 blockers* and include cimetidine (Tagamet), ranitidine (Zantac), famotidine (Pepcid), and nizatidine (Axid). Because they act on the gastrointestinal (GI) system, they are discussed in detail in Chapter 50. This chapter focuses on the H_1 antagonists (also called *H_1 blockers*); they are the drugs commonly known as *antihistamines.* They are very useful drugs, because approximately 10% to 20% of the general population is sensitive to various environmental allergens. Histamine is a major inflammatory mediator in many allergic disorders, such as allergic rhinitis (e.g., hay fever and mold, dust allergies), anaphylaxis, angioedema, drug fevers, insect bite reactions, and urticaria (itching).

H_1 antagonists include drugs such as diphenhydramine (Benadryl), chlorpheniramine (generic), fexofenadine (Allegra), loratadine (Claritin), and cetirizine (Zyrtec). They are of greatest value in the treatment of nasal allergies, particularly seasonal hay fever. They are also given to relieve the symptoms of the common cold, such as sneezing and runny nose. In this regard they are palliative, not curative; that is, they can help alleviate the symptoms of a cold but can do nothing to destroy the virus causing it.

The clinical efficacy of the different antihistamines is very similar, although they have varying degrees of antihistaminic, anticholinergic, and sedating properties. The particular actions and indications for a particular antihistamine are determined by its specific chemical makeup. All antihistamines compete with histamine for the H_1 receptors in the smooth muscle surrounding blood vessels and bronchioles. They also affect the secretions of the lacrimal, salivary, and respiratory mucosal glands, which are the primary anticholinergic actions of antihistamines. These drugs differ from each other in their potency and adverse effects, especially in the degree of drowsiness they produce. The antihistaminic, anticholinergic, and sedative properties of some of the more commonly used antihistamines are summarized in Figure 36-1. Because of their antihistaminic properties, they are indicated for the treatment of allergies. They are also useful for the treatment of problems such as vertigo, motion sickness, insomnia, and cough. Several classes of antihistamines are listed in Table 36-1, along with their various anticholinergic and sedative effects.

Mechanism of Action and Drug Effects

During allergic reactions, histamine and other substances are released from mast cells, basophils, and other cells in response to **antigens** circulating in the blood. Histamine molecules then bind to and activate other cells in the nose, eyes, respiratory tract, GI tract, and skin, producing the characteristic allergic signs and symptoms. For example, in the respiratory tract histamine causes extravascular smooth muscle (e.g., in the bronchial tree) to contract, whereas antihistamines cause it to relax. Also, histamine causes pruritus by stimulating nerve endings. Antihistamines can prevent or alleviate this itching.

Circulating histamine molecules bind to histamine receptors on basophils and mast cells. This stimulates further release of histamine stored within these cells. Antihistamine drugs work by blocking the histamine receptors on the surfaces of basophils and mast cells, thereby preventing the release and actions of histamine stored within these cells. They do not push off histamine that is already bound to a receptor but compete with histamine for unoccupied receptors. Therefore, they are most beneficial when given early in a histamine-mediated reaction, before all of the free histamine molecules bind to cell membrane receptors. The binding of H_1 blockers to these receptors prevents the adverse consequences of histamine binding: vasodilation; increased GI, respiratory, salivary, and lacrimal secretions; and increased capillary permeability with resultant edema. The various drug effects of antihistamines are listed in Table 36-2.

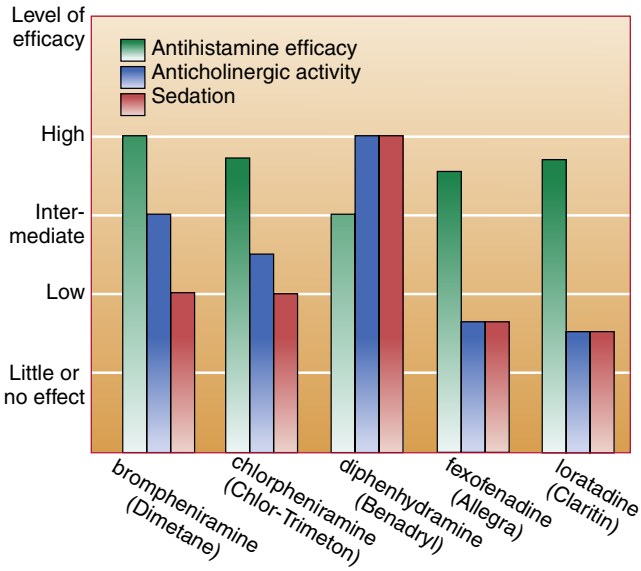

FIGURE 36-1 Comparison of the efficacy and adverse effects of selected antihistamines.

Indications

Antihistamines are indicated for the management of nasal allergies, seasonal or perennial allergic rhinitis (e.g., hay fever), and

TABLE 36-2 ANTIHISTAMINES: DRUG EFFECTS

BODY SYSTEM	HISTAMINE EFFECTS	ANTIHISTAMINE EFFECTS
Cardiovascular (small blood vessels)	Dilates blood vessels, increases blood vessel permeability (allows substances to leak into tissues)	Reduces dilation of blood vessels and increased permeability
Immune (release of various substances commonly associated with allergic reactions)	Released from mast cells along with several other substances, which results in allergic reactions	Does not stabilize mast cells or prevent the release of histamine and other substances, but does bind to histamine receptors and prevent the actions of histamine
Smooth muscle (on exocrine glands)	Stimulates salivary, gastric, lacrimal, and bronchial secretions	Reduces salivary, gastric, lacrimal, and bronchial secretions

TABLE 36-1 EFFECTS OF VARIOUS ANTIHISTAMINES

CHEMICAL CLASS	ANTICHOLINERGIC EFFECTS	SEDATIVE EFFECTS	COMMENTS
Alkylamines			
brompheniramine	Moderate	Low	Cause less drowsiness and more CNS stimulation; suitable for daytime use.
chlorpheniramine	Moderate	Low	
dexchlorpheniramine	Moderate	Low	
Ethanolamines			
clemastine	High	Moderate	Substantial anticholinergic effects; commonly cause sedation; at usual dosages, drowsiness occurs in about 50% of patients; diphenhydramine and dimenhydrinate also used as antiemetics.
diphenhydramine	High	High	
dimenhydrinate	High	High	
Phenothiazine			
promethazine	High	High	Drugs in this class are principally used as antipsychotics; promethazine is useful as an antihistamine and antiemetic.
Piperidines			
cyproheptadine	Moderate	Low	Commonly used in the treatment of motion sickness; hydroxyzine is used as a tranquilizer, sedative, antipruritic, and antiemetic.
hydroxyzine	Moderate	Moderate	
Miscellaneous			
fexofenadine	Low to none	Low to none	Very few adverse anticholinergic or sedative effects; almost exclusively antihistaminic effects; can be taken during the day because no sedative effects occur; they are longer acting and have fewer adverse effects than other classes.
loratadine	Low	Low to none	

CNS, Central nervous system; *GI,* gastrointestinal.

some of the typical symptoms of the common cold. They are also useful in the treatment of allergic reactions, motion sickness, Parkinson's disease (due to their anticholinergic effects), and vertigo. In addition, they are sometimes used as sleep aids.

Contraindications

Use of antihistamines is contraindicated in cases of known drug allergy. They are not to be used as the sole drug therapy during acute asthmatic attacks. In such cases, a rapidly acting bronchodilator such as albuterol, or in extreme cases epinephrine, is the most urgently needed medication. Other contraindications may include narrow-angle glaucoma, cardiac disease, kidney disease, hypertension, bronchial asthma, chronic obstructive pulmonary disease, peptic ulcer disease, seizure disorders, benign prostatic hyperplasia, and pregnancy. Fexofenadine is not recommended for those with renal impairment. Desloratadine is not recommended for pediatric patients. Loratadine is not recommended for children younger than 2 years of age. Antihistamines should be used with caution in patients with impaired liver function or renal insufficiency, as well as in lactating mothers.

Adverse Effects

Drowsiness is usually the chief complaint of people who take antihistamines, but the sedative effects vary from class to class (see Table 36-1). Fortunately, sedative effects are much less common, although still possible, with the newer "nonsedating" drugs. The anticholinergic (drying) effects of antihistamines can cause adverse effects such as dry mouth, changes in vision, difficulty urinating, and constipation. Reported adverse effects of the antihistamines are listed in Table 36-3.

Interactions

Drug interactions of antihistamines are listed in Table 36-4. An allergist will usually recommend discontinuation of antihistamine drug therapy at least 4 days prior to allergy testing.

Dosages

For dosage information on selected antihistamines, see the table on this page.

TABLE 36-3 ANTIHISTAMINES: REPORTED ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Dysrhythmias, hypotension, palpitations, syncope
Central nervous	Sedation, dizziness, muscular weakness, paradoxical excitement, restlessness, nervousness, seizures
Gastrointestinal	Nausea, vomiting, diarrhea, constipation, hepatitis
Other	Dryness of mouth, nose, and throat; urinary retention; vertigo; visual disturbances; tinnitus; headache

TABLE 36-4 ANTIHISTAMINES: DRUG INTERACTIONS

DRUG	INTERACTING DRUG	MECHANISM	RESULT
fexofenadine	Erythromycin and other CYP450 inhibitors	Inhibit metabolism	Increased fexofenadine levels
	Phenytoin	Increased metabolism	Decreased fexofenadine levels
loratadine	Ketoconazole, cimetidine, erythromycin	Inhibit metabolism	Increased loratadine levels
diphenhydramine, cetirizine	Alcohol, MAOIs, CNS depressants	Additive effects	Increased CNS depression

CNS, Central nervous system; *CYP450,* cytochrome P-450; *MAOI,* monoamine oxidase inhibitor.

DOSAGES

Selected Antihistamines

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
Nonsedating Antihistamine			
♦ loratadine (Claritin) (B)	H_1 antihistamine	**Adult and pediatric 6 yr and older** PO: 10 mg once daily **Pediatric 2-5 yr** PO: 5 mg once daily	Allergic rhinitis, chronic urticaria
Traditional Antihistamine (More Commonly Associated with Sedation)			
♦ diphenhydramine (Benadryl) (B)	H_1 antihistamine	**Pediatric more than 10 kg** PO/IM/IV: 12.5-25 mg tid-qid **Adult and pediatric 12 yr and older** PO: 25-50 mg qhs **Adult only** PO/IM/IV: 25-50 mg tid-qid **Adult only** PO: 25-50 mg tid-qid	Allergic disorders, nighttime insomnia, motion sickness Nighttime insomnia Allergic disorders, PD symptoms Motion sickness

IM, Intramuscular; *IV,* intravenous; *PD,* Parkinson's disease; *PO,* oral.

DRUG PROFILES

Although some antihistamines are prescription drugs, most are available over the counter. Antihistamines are available in many dosage forms to be administered orally, intramuscularly, intravenously, or topically.

NONSEDATING ANTIHISTAMINES

A major advance in antihistamine therapy occurred with the development of the **nonsedating antihistamines** loratadine, cetirizine, and fexofenadine. These drugs were developed to eliminate many of the unwanted adverse effects (mainly sedation) of the older antihistamines. These drugs work peripherally to block the actions of histamine and therefore have significantly less of the CNS effects of many older antihistamines. For this reason, these drugs are also called *peripherally acting antihistamines* because they do not readily cross the blood-brain barrier, unlike their traditional counterparts. Another advantage of the nonsedating antihistamines is that they have longer durations of action, which allow for once daily dosing. This increases patient adherence to therapy. The original nonsedating antihistamines terfenadine and astemizole were withdrawn from the U.S. market in the 1990s following the occurrence of several cases of fatal drug-induced cardiac dysrhythmias. Fexofenadine is the active metabolite of terfenadine but is not associated with such severe cardiac effects, nor are loratadine or cetirizine.

♦ loratadine

Loratadine (Claritin) is a nonsedating antihistamine and is taken only once a day. It is structurally similar to cyproheptadine, but it does not readily distribute into the CNS, which diminishes the sedative effects associated with traditional antihistamines. However, at higher doses, central side effects such as drowsiness, headache, and fatigue can be seen. Loratadine is used to relieve the symptoms of seasonal allergic rhinitis (e.g., hay fever) as well as chronic urticaria. Loratadine has recently been converted to OTC status. However, a drug containing its primary active metabolite, desloratadine is currently available only by prescription.

Drug allergy is the only contraindication to the use of loratadine. The drug is available in oral form as a 10-mg tablet, as a 1-mg/mL syrup, as a 10-mg rapidly disintegrating tablet, and in a combination tablet with the decongestant pseudoephedrine. It is classified as a pregnancy category B drug. Recommended dosages are given in the table on p. 579.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-3 hr	8-12 hr	8-24 hr	24 hr

TRADITIONAL ANTIHISTAMINES

The traditional antihistamines are older drugs that work both peripherally and centrally. They also have anticholinergic effects, which in some cases make them more effective than nonsedating antihistamines. Some of the commonly used older drugs are diphenhydramine, brompheniramine, chlorpheniramine, dimenhydrinate, meclizine, and promethazine. They are used either alone or in combination with other drugs in the symptomatic relief of many disorders ranging from insomnia to motion sickness. Many patients respond to and tolerate the older drugs quite well, and because many are generically available, they are much less expensive. These drugs are available both OTC and by prescription.

♦ diphenhydramine

Diphenhydramine (Benadryl) is a traditional antihistamine that works both peripherally and centrally. It also has anticholinergic and sedative effects. In fact, it is used as a hypnotic drug because of its sedating effects. Its use is not generally advised in elderly patients, however, because of the "hangover" effect and increased potential for falls. Diphenhydramine is one of the most commonly used antihistamines, in part because of its excellent safety profile and efficacy. It has the greatest range of therapeutic indications of any antihistamine available. It is used for the relief or prevention of histamine-mediated allergies, motion sickness, the treatment of Parkinson's disease (due to its anticholinergic effects; see Chapter 15), and the promotion of sleep (see Chapter 12). It is also used in conjunction with epinephrine in the management of anaphylaxis and in the treatment of acute dystonic reactions.

Diphenhydramine is classified as a pregnancy category B drug, and its use is contraindicated in patients with a known hypersensitivity to it. It is to be used with caution in nursing mothers, neonates, and patients with lower respiratory tract symptoms. It is available in oral, parenteral, and topical preparations. In oral form, diphenhydramine is available as capsules, tablets, and liquid, as well as in several combination products that contain other cough and cold medications. It is also available as an injection. In topical form, diphenhydramine is available as a cream, gel, and spray. It also is available in combination with several other drugs that are commonly given topically, such as calamine, camphor, and zinc oxide. These combination preparations come in the form of aerosols, creams, gels, and lotions. Recommended dosages for the oral and injectable forms are given in the table on p. 579.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	15-30 min	2-4 hr	2-7 hr	4 hr

DECONGESTANTS

Nasal congestion is due to excessive nasal secretions and inflamed and swollen nasal mucosa. The primary causes of nasal congestion are allergies and URIs, especially the common cold. There are three separate groups of nasal **decongestants: adrenergics (sympathomimetics),** which are the largest group; **anticholinergics (parasympatholytics),** which are somewhat less commonly used; and selected topical **corticosteroids** (intranasal steroids).

Decongestants can be taken orally to produce a systemic effect, can be inhaled, or can be administered topically to the nose. Each

method of administration has its advantages and disadvantages. Decongestants administered by the oral route include pseudoephedrine, which is available OTC. A commonly used nasal decongestant spray is phenylephrine, which is also OTC.

Drugs administered by the oral route produce prolonged decongestant effects, but the onset of action is more delayed and the effect less potent than for decongestants applied topically. However, the clinical problem of rebound congestion associated with topically administered drugs is almost nonexistent with oral dosage forms. Rebound congestion occurs because of the very rapid absorption of drug through mucous membranes followed by a more rapid decline in therapeutic activity. This rebound congestion can cause overuse and dependence to the nasal spray, as patients take it frequently due to the rapid decline in activity. This is in contrast to oral dosage forms, which provide a more gradual increase and decline in pharmacologic activity due to the time required for GI absorption. Decongestants suitable for nasal inhalation include ephedrine, oxymetazoline, phenylephrine, and tetrahydrozoline.

Inhaled intranasal steroids and anticholinergic drugs are not associated with rebound congestion and are often used prophylactically to prevent nasal congestion in patients with chronic upper respiratory tract symptoms. Commonly used intranasal steroids include the following:

- beclomethasone dipropionate (Beconase)
- budesonide (Rhinocort)
- flunisolide (Nasalide)
- fluticasone (Flonase)
- triamcinolone (Nasacort)
- ciclesonide (Omnaris)

The only intranasal anticholinergic drug in use is ipratropium nasal spray (Atrovent).

Mechanism of Action and Drug Effects

Nasal decongestants are most commonly used for their ability to shrink engorged nasal mucous membranes and relieve nasal stuffiness. Adrenergic drugs (e.g., ephedrine, oxymetazoline) accomplish this by constricting the small arterioles that supply the structures of the upper respiratory tract, primarily the blood vessels surrounding the nasal sinuses. When these blood vessels are stimulated by alpha-adrenergic drugs, they constrict. Once these blood vessels shrink, the nasal secretions in the swollen mucous membranes are better able to drain, either externally through the nostrils or internally through reabsorption into the bloodstream or lymphatic circulation. Because stimulation of the sympathetic nervous system produces the same effect, these drugs are also referred to as *sympathomimetics.*

Nasal steroids are aimed at the inflammatory response elicited by invading organisms (viruses and bacteria) or other antigens (e.g., allergens). The body responds to these antigens by producing inflammation in an effort to isolate or wall off the area and by attracting various cells of the immune system to consume and destroy the offending antigens. Steroids exert their antiinflammatory effect by causing these cells to be turned off or rendered unresponsive. The goal is *not* complete immunosuppression of the respiratory tract but rather to reduce the inflammatory symptoms to improve patient comfort and air exchange. The drug effects of intranasal steroids are discussed in more detail in Chapter 33.

Indications

Nasal decongestants reduce the nasal congestion associated with acute or chronic rhinitis, the common cold, sinusitis, and hay fever or other allergies. They may also be used to reduce swelling of the nasal passages and to facilitate visualization of the nasal and pharyngeal membranes before surgery or diagnostic procedures.

Contraindications

Contraindications to the use of decongestants include drug allergy. Adrenergic drugs are contraindicated in narrow-angle glaucoma, uncontrolled cardiovascular disease, hypertension, diabetes, hyperthyroidism, and prostatitis. They are also contraindicated in situations in which the patient is unable to close his or her eyes (such as after a cerebrovascular accident), as well as in patients with a history of cerebrovascular accident or transient ischemic attacks, cerebral arteriosclerosis, long-standing asthma, benign prostatic hyperplasia, or diabetes.

Adverse Effects

Adrenergic drugs are usually well tolerated. Possible adverse effects of these drugs include nervousness, insomnia, palpitations, and tremor. The most common adverse effects of intranasal steroids are localized and include mucosal irritation and dryness.

Although a topically applied adrenergic nasal decongestant can be absorbed into the bloodstream, the amount absorbed is usually too small to cause systemic effects at normal dosages. Excessive dosages of these medications are likely to cause systemic effects elsewhere in the body. These may include cardiovascular effects such as hypertension and palpitations and CNS effects such as headache, nervousness, and dizziness. These systemic effects are the result of alpha-adrenergic stimulation of the heart, blood vessels, and CNS.

Interactions

There are few significant drug interactions with nasal decongestants. Systemic **sympathomimetic drugs** and sympathomimetic nasal decongestants are likely to cause drug toxicity when given together. Monoamine oxidase inhibitors (MAOIs) may result in additive pressor effects (e.g., raising of the blood pressure) when given with sympathomimetic nasal decongestants. Other interacting drugs include methyldopa and urinary acidifiers and alkalinizers.

Dosages

For dosage information on naphazoline, see the table on p. 582.

DRUG PROFILE

Many of the decongestants are OTC drugs, but the more potent drugs that can cause serious adverse effects are available only by prescription. Although nasal steroids are relatively safe, their use is also contraindicated in some circumstances, including in patients with nasal mucosal infections (because of their ability

DOSAGES

Selected Decongestant, Expectorant, and Antitussive Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
naphazoline (Privine) (C)	Alpha-adrenergic vasoconstrictor	**Adult and pediatric 12 yr and older** 1 or 2 drops or sprays in each nostril q6h prn, usually for no more than 3-5 days	Nasal congestion
benzonatate (Tessalon Perles) (C)	Nonopioid antitussive	**Adult and pediatric older than 10 yr** PO: 100-200 mg tid	Cough
codeine (as part of a combination product such as Dimetane-DC, Tussar SF, Novahistine DH, Robitussin A-C, others) (C)	Opioid antitussive	**Adult and pediatric older than 12 yr** PO: 10-20 mg q4-6h, max 120 mg/24 hr **Pediatric 6-12 yr** PO: 5-10 mg q4-6h, max 60 mg/24 hr **Pediatric 2-5 yr** PO: 2.5-5 mg q4-6h, max 30 mg/24 hr	Cough
♦ dextromethorphan (as part of a combination product such as Vicks Formula 44, Robitussin DM, others) (C)	Nonopioid antitussive	**Adult and pediatric older than 12 yr** PO: 10-30 mg q4-8h, max 120 mg/24 hr **Pediatric 6-12 yr** PO: 5-10 mg q4h or 15 mg q6-8h, max 60 mg/24 hr **Pediatric 2-6 yr** PO: 2.5-7.5 mg q4-8h, max 30 mg/24 hr	Cough
♦ guaifenesin (glyceryl guaiacolate) (Guiatuss, Humibid, Robitussin, Mucinex, others) (C)	Expectorant	**Adult and pediatric 12 yr and older** PO: 100-400 mg q4h, max 2400 mg/24 hr **Pediatric 6-12 yr** PO: 100-200 mg q4h, max 1200 mg/24 hr **Pediatric 2-6 yr** PO: 50-100 mg q4h, max 600 mg/24 hr	Respiratory congestion, cough

to depress the body's immune response as part of their antiinflammatory effect) or known drug allergy.

Many inhaled corticosteroids (e.g., beclomethasone, dexamethasone, flunisolide) are discussed in greater detail in Chapter 33. The adrenergic drugs (e.g., naphazoline) are discussed in this chapter. Both of these drug categories are generally first-line drugs for the treatment of chronic nasal congestion.

naphazoline

Naphazoline (Privine) is chemically and pharmacologically similar to the other sympathomimetic drugs oxymetazoline and tetrahydrozoline. During a cold, the blood vessels that surround the nasal sinus are dilated and engorged with plasma, white blood cells, mast cells, histamines, and many other blood components that are involved in fighting infections of the respiratory tract. This swelling, or dilation, blocks the nasal passages, which results in nasal congestion. When these drugs are administered intranasally, they cause dilated arterioles to constrict, which reduces nasal blood flow and congestion. Naphazoline is classified as a pregnancy category C drug and has the same contraindications as the other nasal decongestants. Naphazoline for nasal administration is available as a 0.05% solution and is meant to be instilled into each nostril. Recommended dosages are given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Intranasal	5-10 min	Unknown	Unknown	2-6 hr

ANTITUSSIVES

Coughing is a normal physiologic function and serves the purpose of removing potentially harmful foreign substances and excessive secretions from the respiratory tract. The cough reflex is stimulated when receptors in the bronchi, alveoli, and pleura (lining of the lungs) are stretched. This causes a signal to be sent to the cough center in the medulla of the brain, which in turn stimulates the cough. Most of the time coughing is a beneficial response; however, there are times when it is not useful and may even be harmful (e.g., after a surgical procedure such as hernia repair or in cases of nonproductive or "dry" cough). In these situations, the use of an **antitussive** drug may enhance patient comfort and reduce respiratory distress. There are two main categories of antitussive drugs: opioid and nonopioid.

Although all opioid drugs have antitussive effects, only codeine and its semisynthetic derivative hydrocodone are used as antitussives. Both drugs are effective in suppressing the cough reflex, and if they are taken in the prescribed manner, their use does not generally lead to dependency. These two drugs are commonly incorporated into various combination formulations with other respiratory drugs and are rarely used alone for the purpose of cough suppression.

Nonopioid antitussive drugs are less effective than opioid drugs and are available either alone or in combination with other drugs in an array of OTC cold and cough preparations. Dextromethorphan is the most widely used of the nonopioid antitussive drugs and is a derivative of the synthetic opioid levorphanol. Benzonatate is another nonopioid antitussive.

Mechanism of Action and Drug Effects

The opioid antitussives codeine and hydrocodone suppress the cough reflex through direct action on the cough center in the CNS (medulla). Opioid antitussives also provide analgesia and have a drying effect on the mucosa of the respiratory tract, which increases the viscosity of respiratory secretions. This helps to reduce symptoms such as runny nose and postnasal drip. The nonopioid cough suppressant dextromethorphan works in the same way. Because it is not an opioid, however, it does not have analgesic properties, nor does it cause CNS depression. Another nonopioid antitussive is benzonatate. Its mechanism of action is entirely different from that of the other drugs. Benzonatate suppresses the cough reflex by anesthetizing (numbing) the stretch receptor cells in the respiratory tract, which prevents **reflex stimulation** of the medullary cough center.

Indications

Although they have other properties, such as analgesic effects for the opioid drugs, antitussives are used primarily to stop the cough reflex when the cough is nonproductive and/or harmful.

Contraindications

The only absolute contraindication to the antitussives is drug allergy. Relative contraindications include opioid dependency (for opioid antitussives) and high risk for respiratory depression (e.g., in frail elderly patients). Patients with these conditions are often able to tolerate lower medication dosages and still experience some symptom relief.

Additional contraindications and cautions include the following:

- Benzonatate: no known contraindications but cautious use in those with productive cough
- Dextromethorphan: contraindications of hyperthyroidism, advanced cardiac and vessel disease, hypertension, glaucoma, and use of MAOIs within the past 14 days
- Diphenhydramine: see antihistamines
- Codeine and hydrocodone: contraindicated with alcohol use; cautious use required with CNS depression, anoxia, high serum levels of carbon dioxide (hypercapnia), and respiratory depression; increased intracranial pressure, impaired renal function, liver diseases, benign prostatic hyperplasia, Addison's disease, and chronic obstructive pulmonary disease

Adverse Effects

The following are the common adverse effects of selected antitussive drugs:

- Benzonatate: dizziness, headache, sedation, nausea, constipation, pruritus, and nasal congestion
- Codeine and hydrocodone: sedation, nausea, vomiting, lightheadedness, and constipation
- Dextromethorphan: dizziness, drowsiness, and nausea
- Diphenhydramine: sedation, dry mouth, and other anticholinergic effects

Interactions

Very few drug interactions occur with benzonatate. Opioid antitussives (codeine and hydrocodone) may potentiate the effects of other opioids, general anesthetics, tranquilizers, sedatives and hypnotics, tricyclic antidepressants, alcohol, and other CNS depressants.

Dosages

For dosage information on selected antitussive drugs, see the table on p. 582.

DRUG PROFILES

Antitussives come in many oral dosage forms and are available both with and without a prescription. Most of the opioid antitussives are available only by prescription because of the associated abuse potential. Dextromethorphan is the most popular nonopioid antitussive available OTC.

benzonatate

Benzonatate (Tessalon Perles) is a nonopioid antitussive drug that is thought to work by anesthetizing or numbing the cough receptors. It is available in oral form as a 100- and 200-mg capsules. Its use is contraindicated in patients with a known hypersensitivity to it. It is classified as a pregnancy category C drug. Recommended dosages are given in the table on p. 582.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	15-20 min	Unknown	Unknown	3-8 hr

codeine

Codeine is a popular opioid antitussive drug. It is used in combination with many other respiratory medications to control coughs. Because it is an opioid, it is potentially addictive and can depress respirations as part of its CNS depressant effects. For this reason, codeine-containing cough suppressants are controlled substances. Many states allow persons over 18 years of age to purchase at least one oral liquid combination product without a prescription. However, most codeine antitussive products are obtained with a prescription. Codeine alone, without being combined with other drugs, is a Schedule II drug. Codeine-containing cough suppressants are Schedule V. They are available in many oral dosage forms: solutions, tablets, capsules, and suspensions. Their use is contraindicated in patients with a known hypersensitivity to opiates and in those who have respiratory depression, increased intracranial pressure, seizure disorders, or severe respiratory disorders. It is classified as a pregnancy category C drug. Recommended dosages are given in the table on p. 582.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	15-30 min	34-45 min	2.5-4 hr	4-6 hr

♦ dextromethorphan

Dextromethorphan is a nonopioid antitussive that is available alone or in combination with many other cough and cold preparations. It is widely used because it is safe and nonaddicting and

does not cause respiratory or CNS depression when used in recommended dosages. Dextromethorphan has become a popular drug of abuse and is discussed in detail in Chapter 17. Its use is contraindicated in cases of drug allergy, asthma or emphysema, or persistent headache. Dextromethorphan is available as lozenges, solution, liquid-filled capsules, granules, tablets (chewable, extended-release, and film-coated), and extended-release suspension. It is classified as a pregnancy category C drug. Recommended dosages are given in the table on p. 582.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	15-30 min	2.5 hr	Unknown	3-6 hr

EXPECTORANTS

Expectorants aid in the expectoration (i.e., coughing up and spitting out) of excessive mucus that has accumulated in the respiratory tract by breaking down and thinning out the secretions. They are administered orally either as single drugs or in combination with other drugs to facilitate the flow of respiratory secretions by reducing the viscosity of secretions. The clinical effectiveness of expectorants is somewhat questionable. Placebo-controlled clinical evaluations have failed to confirm that expectorants reduce the viscosity of sputum. Despite this, expectorants are popular drugs, are contained in most OTC cold and cough preparations, and provide symptom relief for many users. The most common expectorant in OTC products is guaifenesin.

Mechanism of Action and Drug Effects

Expectorants have one of two different mechanisms of action, depending on the drug. The first is reflex stimulation, in which loosening and thinning of respiratory tract secretions occurs in response to an irritation of the GI tract produced by the drug. Guaifenesin is the only such drug currently available. The second mechanism of action is direct stimulation of the secretory glands in the respiratory tract.

Indications

Expectorants are used for the relief of productive cough commonly associated with the common cold, bronchitis, laryngitis, pharyngitis, pertussis, influenza, and measles. They may also be used for the suppression of coughs caused by chronic paranasal sinusitis. By loosening and thinning sputum and the bronchial secretions, they may also indirectly diminish the tendency to cough.

Contraindications

Guaifenesin is contraindicated if drug allergy is present.

Adverse Effects

The adverse effects of expectorants are minimal. Guaifenesin may cause nausea, vomiting, and gastric irritation.

Interactions

There are no known significant interactions involving guaifenesin.

Dosages

For dosage information on guaifenesin, the only expectorant profiled, see the table on p. 582.

DRUG PROFILE

♦ **guaifenesin**

Guaifenesin (Mucinex) is a commonly used expectorant that is available in several different oral dosage forms: capsules, tablets, solutions, and granules. It is used in the symptomatic management of coughs of varying origin. It is beneficial in the treatment of productive coughs because it thins mucus in the respiratory tract that is difficult to cough up. There are few published pharmacokinetic data on guaifenesin, but its half-life is estimated to be approximately 1 hour. This short half-life helps to explain why it is usually dosed several times throughout the day. However, there are sustained-release products that are given once or twice daily. Although this drug remains popular, there is some evidence in the literature to suggest that it has no greater therapeutic activity than water in terms of loosening respiratory tract secretions. It is classified as a pregnancy category C drug. For dosage information on guaifenesin, see the table on p. 582.

NURSING PROCESS

ASSESSMENT

When the patient is to be given drugs to treat symptoms related to the respiratory tract, begin the assessment by gathering data about the condition and determining if symptoms are caused by an allergic reaction. Obtaining the patient's medical history and medication profile, completing a thorough head-to-toe physical assessment, and taking a nursing history are critical to understanding possible causes, risks, or links to diseases or conditions such as allergy, a cold, or flu. For example, if an allergic reaction to a drug, food, or substance has occurred, the patient may be experiencing signs and symptoms such as hives, wheezing or bronchospasm, tachycardia, or hypotension (requiring immediate medical attention). However, if the cause is a cold or flu, the symptoms are different and treated completely differently. The drug of choice is then selected based on the type and severity of the symptoms.

Most *nonsedating antihistamines* (e.g., fexofenadine, loratadine, cetirizine) are contraindicated in those with known allergies to the drugs. Remember with the traditional and nontraditional antihistamines that if allergy testing is to be performed, these medications are usually discontinued at least 4 days before the testing, but only on a prescriber's order and as directed. Assess for the following possible drug interactions that need to be avoided: fexofenadine given with erythromycin and other CYP450 inhibitors, leading to increased antihistamine levels; fexofenadine and phenytoin, leading to decreased fexofenadine levels; loratadine given with some antifungals, cimetidine, and erythromycin, leading to increased antihistamine levels; and diphenhydramine and cetirizine given with alcohol, MAOIs, and CNS depressants, leading to increased CNS depression.

Before administering the *traditional antihistamines* such as diphenhydramine, chlorpheniramine, or brompheniramine,

ensure that the patient has no allergies to this group of medications, even though these drugs are used for allergic reactions. Assess contraindications, cautions, and drug interactions with these and all other drugs. Use of these antihistamines is of concern in patients who are experiencing an acute asthma attack and in those who have lower respiratory tract disease or are at risk for pneumonia. The rationale for not using these drugs in these situations is that antihistamines (and nonsedating antihistamines) dry up secretions; if the patient cannot expectorate the secretions, the secretions may become viscous (thick), occlude airways, and lead to atelectasis, infection, or occlusion of the bronchioles. It is also important to know that these drugs may lead to paradoxical reactions in elderly patients, with subsequent irritability as well as dizziness, confusion, sedation, and hypotension.

Use of *decongestants* requires assessment of contraindications, cautions, and drug interactions. Because decongestants are available in oral, nasal drop and spray, and eyedrop dosage forms, any condition that could affect the functional structures of the eye or nose may be a possible caution or contraindication. Decongestants may increase blood pressure and heart rate, so assess and document the patient's blood pressure, pulse, and other vital parameters. Because so many of these drugs are found in OTC cough and cold products and have been associated with numerous cases of oversedation, seizures, tachycardia, and even in death, their use warrants extreme caution. Contraindications to the use of decongestants include drug allergy, narrow-angle glaucoma, uncontrolled cardiovascular disease, hypertension, diabetes, and prostatitis. Topically applied adrenergic nasal decongestants may be absorbed into the circulation; however, the dosage amount absorbed is usually too small to cause systemic effects. If there are excessive dosages (e.g., excessive use or amounts), these may precipitate cardiovascular effects such as increase in blood pressure and CNS stimulation with headache, nervousness, or dizziness. Some drug interactions include the use of systemic sympathomimetics and sympathomimetic nasal decongestants with possible toxicity when given together. Other drug interactions to assess for with nasal decongestants include their use with MAOIs.

Inhaled intranasal steroids are contraindicated in situations in which the patient is experiencing a nasal mucosal infection or drug allergy. Chapter 33 discusses some of the inhaled corticosteroids. With the use of any decongestant, always perform a thorough assessment of signs and symptoms before and after use of these drugs. Include description of cough, secretions, and breath sounds in this assessment.

With *antitussive* therapy, assessment is tailored to the patient and the specific drug. Most of these drugs result in sedation, dizziness, and drowsiness, so assessment of the patient's safety is very important. Complete an assessment for allergies, contraindications, cautions, and drug interactions, and document the findings. In the respiratory assessment (as for all of the drugs in this chapter), include rate, rhythm and depth, as well as breath sounds, presence of cough, and description of cough and sputum if present. For individuals with chronic respiratory disease, the prescriber may order further studies to determine the safety of using these drugs without causing further respiratory concerns or depression. Pulse oximetry readings with measurement of vital signs may be used to provide more information. Assess for potential drug interactions including alcohol, MAOIs, and antihistamines. With use of codeine and hydrocodone antitussives, there are contraindications with alcohol and other opioid drugs; these drugs must be used cautiously with CNS depression, anoxia, hypercapnia, respiratory depression, and impaired renal function and in those with chronic obstructive pulmonary disease such as emphysema. With the nonopioid antitussive dextromethorphan, monitor its use carefully because it is a popular drug of abuse (see Chapter 17).

Expectorants are generally tolerated well, and the only contraindication is with drug allergy. There are no known drug interactions to assess for with use of the expectorant guaifenesin (Mucinex).

CASE STUDY

Decongestants

A 22-year-old college student has suffered with allergy symptoms since moving into his dormitory. When he calls the student health center, he is told to try an over-the-counter (OTC) nasal decongestant spray. He tries this and is excited about the relief he experiences at first, but 2 weeks later, he calls the student health center again. "I am congested all the time again, and I have to use the spray more and more to get any relief, but it does not last very long." He is upset because his symptoms are now worse.

1. What explanation do you have for the worsening symptoms?
2. What patient education is important when this type of drug is used?
3. What other over-the-counter drugs and nonpharmacologic measures could be suggested for this situation?

For answers, see http://evolve.elsevier.com/Lilley.

NURSING DIAGNOSES

1. Impaired gas exchange related to the disorder, condition, or disease affecting the respiratory system and various respiratory-related signs and symptoms
2. Ineffective airway clearance related to diminished ability to cough and/or a suppressed cough reflex (with antitussives)
3. Deficient knowledge related to the effective use of cold medications and other related products due to lack of information and patient teaching

PLANNING

GOALS

1. Patient experiences improved gas exchange with drug therapy.
2. Patient has improved airway clearance and relief of symptoms.
3. Patient displays improved knowledge about drug therapy.

OUTCOME CRITERIA

1. Patient experiences improved oxygen exchange and breath sounds and a return to normal respiratory rate and rhythm.
2. Patient takes medications exactly as prescribed to enhance airway clearance.
   - Patient increases fluid intake to thin secretions and increase expectoration of mucus.

- Patient's breath sounds clear with expectoration of secretions and return to a respiratory rate of 12 to 20 breaths/min.
- Patient reports to the prescriber immediately the following symptoms: increase in cough, congestion, shortness of breath, chest pain, fever (above 100.4° F or 38° C), or any change in sputum production or color (i.e., if not clear or if a change from baseline).

3. Patient states rationale for therapy as well as adverse effects to expect while on drug therapy.
   - Patient remains compliant with the antihistamine, antitussive, decongestant, or expectorant medication regimen until symptoms are resolved or the prescriber orders discontinuation.

IMPLEMENTATION

If patients are receiving a *nonsedating antihistamine,* advise them to take the drug as directed. Reduced dosages may be needed for patients who are elderly or have decreased renal function. The H_1 receptor antagonist drugs do not cross the blood-brain barrier as readily as do older antihistamines and are therefore less likely to cause sedation. They are generally very well tolerated with minimal adverse effects.

Instruct patients taking *traditional antihistamines* (e.g., diphenhydramine) to take the medications as prescribed. Most of these medications, including the OTC antihistamines, are best tolerated when taken with meals. Although food may slightly decrease absorption of these drugs, it has the benefit of minimizing the GI upset these drugs may cause. Encourage patients who experience dry mouth to chew or suck on candy (sugar-free if needed) or OTC throat, cough, or cold lozenges, or to chew gum, as well as to perform frequent mouth care to ease the dryness and related discomfort. Other OTC or prescribed cold or cough medications must not be taken with antihistamines unless they were previously approved or ordered by the prescriber because of the potential for serious drug interactions. Dosage amounts and routes may vary depending on whether the patient is elderly, an adult, or younger than 12 years of age, so encourage proper dosing and usage. Monitor blood pressure and other vital signs as needed. Monitor the elderly and children for any paradoxical reactions, which are common with these drugs.

Patients taking *decongestants* are generally using the drugs for nasal decongestion. These drugs come in oral dosage forms, including sustained-release and chewable forms. Educate patients that all dosage forms are to be taken as instructed and with an increase in fluid intake of up to 3000 mL per day, unless contraindicated. The fluid helps to liquefy secretions, assists in breaking up thick secretions, and makes it easier to cough up secretions. Counsel patients to use nasal decongestant dosage forms exactly as ordered and with no increase in frequency. Excessive use of decongestant nasal sprays/drops may lead to rebound congestion. See the Patient Teaching Tips for further information.

With *antitussives,* instruct patients that the various dosage forms of the drugs are to be used exactly as ordered. Drowsiness or dizziness may occur with the use of antitussives; therefore, caution patients against driving a car or engaging in other activities that require mental alertness until they feel back to normal. If the antitussive contains codeine, the CNS depressant effects of the narcotic opiate may further depress breathing and respiratory effort. Other antitussives, such as dextromethorphan, as well as the codeine-containing drugs are to be given at evenly spaced intervals so that the drug reaches a steady state.

EVALUATION

A therapeutic response to drugs given to treat respiratory conditions, such as *antihistamines, decongestants, antitussives,* and *expectorants,* includes resolution of the symptoms for which the drugs were originally prescribed or taken. These symptoms may include cough; nasal, sinus, or chest congestion; nasal, salivary, and lacrimal gland hypersecretion; motion sickness; sneezing; watery, red, or itchy eyes; itchy nose; allergic rhinitis; and allergic symptoms. Monitor for the adverse effects of excessive dry mouth, nose, and throat; urinary retention; drowsiness; oversedation; dizziness; paradoxical excitement; nervousness; restlessness; dysrhythmias; palpitations; nausea; diarrhea or constipation; and headache, depending on the drug prescribed.

PATIENT TEACHING TIPS

- Provide the patient with education about the sedating effects of traditional antihistamines. The patient needs to avoid activities that require mental alertness until tolerance to sedation occurs or until he or she accurately judges that the drug has no impact on motor skills or responses to motor activities. Include a list of drugs the patient must avoid, such as alcohol and CNS depressants.
- With traditional and nonsedating antihistamines, a humidifier may be needed to help liquefy secretions, making expectoration of sputum easier. Encourage intake of fluids, unless contraindicated.
- Educate patients with upper or lower respiratory symptoms or disease processes of the impact of the environment on their symptoms or condition, and instruct patients to avoid dry air, smoke-filled environments, and allergens.
- Encourage the patient to always check for possible drug interactions because of the many OTC and prescription drugs that could lead to adverse effects if taken concurrently with any of the antihistamines, decongestants, antitussives, or expectorants.
- Advise the patient to take the medication with food to avoid GI upset.
- Any difficulty breathing, palpitations or unusual adverse effects must be reported to the prescriber immediately.
- Instruct the patient to take antitussives with caution and to report to the prescriber any fever, chest tightness, change in sputum from clear to colored, difficult or noisy breathing, activity intolerance, or weakness.
- With decongestants, emphasize the importance of only taking the medication as ordered and adhering to

PATIENT TEACHING TIPS—cont'd

instructions regarding dose and frequency. Emphasize that frequent, long-term, or excessive use of decongestants (whether oral forms or nasal inhaled forms) may lead to rebound congestion in which the nasal passages become more congested as the effects of the drug wear off. When this occurs, the patient generally uses more of the drug, precipitating a vicious cycle with more congestion. Advise the patient to report to the prescriber any excessive dizziness, heart palpitations, weakness, sedation, or excessive irritability.

- Patients taking expectorants must avoid alcohol and products containing alcohol and should not use these medications for longer than 1 week. If cough or symptoms continue, the patient should contact the prescriber for further instructions or assessment. Encourage intake of fluids, unless contraindicated, to help thin secretions for easier expectoration.
- Decongestants and expectorants are recommended to treat cold symptoms, but the patient must report a fever of higher than 100.4° F (38° C), cough, or other symptoms lasting longer than 3 to 4 days.

KEY POINTS

- There are two types of histamine blockers: H_1 blockers and H_2 blockers. H_1 blockers are the drugs to which most people are referring when they use the term *antihistamine*. H_1 blockers prevent the harmful effects of histamine and are used to treat seasonal allergic rhinitis, anaphylaxis, reactions to insect bites, and so forth. H_2 blockers are used to treat gastric acid disorders, such as hyperacidity or ulcer disease.
- Educate the patient about the purposes of the medication regimen, the expected adverse effects, and any drug interactions. A list of all medications (prescription, over-the-counter, and herbal) needs to be provided to all health care providers.
- Decongestants work by causing constriction of the engorged and swollen blood vessels in the sinuses, which decreases pressure and allows mucous membranes to drain. It is important to understand the action of these drugs and know other important information such as significant adverse effects, including cardiac and CNS-stimulating effects.
- Nonopioid antitussive drugs may also cause sedation, drowsiness, or dizziness. Patients should not drive a car or engage in other activities that require mental alertness if these adverse effects occur. Codeine-containing antitussives may lead to CNS depression; these drugs are to be used cautiously and are not to be mixed with anything containing alcohol.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 When assessing a patient who is to receive a decongestant, the nurse will recognize that a potential contraindication to this drug would be which condition?
- **a** Glaucoma
- **b** Fever
- **c** Peptic ulcer disease
- **d** Allergic rhinitis

2 When giving decongestants, the nurse must remember that these drugs have alpha-adrenergic–stimulating effects that may result in which effect?
- **a** Fever
- **b** Bradycardia
- **c** Hypertension
- **d** CNS depression

3 The nurse is reviewing a patient's medication orders for prn (as necessary) medications that can be given to a patient who has bronchitis with a productive cough. Which drug will the nurse choose?
- **a** An antitussive
- **b** An expectorant
- **c** An antihistamine
- **d** A decongestant

4 The nurse knows that an antitussive cough medication would be the best choice for which patient?
- **a** A patient with a productive cough
- **b** A patient with chronic paranasal sinusitis
- **c** A patient who has had recent abdominal surgery
- **d** A patient who has influenza

5 A patient is taking a decongestant to help reduce symptoms of a cold. The nurse will instruct the patient to observe for which possible symptom, which may indicate an adverse effect of this drug?
- **a** Increased cough
- **b** Dry mouth
- **c** Slower heart rate
- **d** Heart palpitations

6 The nurse is giving an antihistamine and will observe the patient for which side effects? (Select all that apply.)
- **a** Hypertension
- **b** Dizziness
- **c** "Hangover" effect
- **d** Drowsiness
- **e** Tachycardia
- **f** Dry mouth

7 The order for a 4-year-old patient reads: "Give guaifenesin, 80 mg PO, every 4 hours as needed for cough. Maximum of 600 mg/24 hours." The medication comes in a bottle that has 100 mg/5 mL. How many milliliters will the nurse give per dose?

1. a, 2. c, 3. b, 4. c, 5. d, 6. b, c, d, f, 7. 4 mL

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Describe the anatomy and physiology of the respiratory system.
2 Discuss the impact of respiratory drugs on various lower and upper respiratory tract diseases and conditions.
3 List the classifications of drugs used to treat diseases and conditions of the respiratory system, and provide specific examples.
4 Discuss the mechanisms of action, indications, contraindications, cautions, drug interactions, dosages, routes of administration, adverse effects, and toxic effects of the bronchodilators and other respiratory drugs.
5 Develop a nursing care plan that includes all phases of the nursing process for patients who use bronchodilators and other respiratory drugs.

DRUG PROFILES

♦ **albuterol, p. 593**
fluticasone propionate, p. 599
ipratropium, p. 594
methylprednisolone, p. 599
♦ **montelukast, p. 597**
♦ **salmeterol, p. 593**
theophylline, p. 595

♦ *Key drug*

KEY TERMS

Allergen Any substance that evokes an allergic response. (p. 589)

Allergic asthma Bronchial asthma caused by hypersensitivity to an allergen or allergens. (p. 589)

Alveoli Microscopic sacs in the lungs where oxygen is exchanged for carbon dioxide; also called *air sacs.* (p. 589)

Antibodies Immunoglobulins produced by lymphocytes in response to bacteria, viruses, or other antigenic substances. (p. 590)

Antigen A substance (usually a protein) that causes the formation of an antibody and reacts specifically with that antibody. (p. 590)

Asthma attack The onset of wheezing together with difficulty breathing. (p. 589)

Bronchial asthma The general term for recurrent and reversible shortness of breath resulting from narrowing of the bronchi and bronchioles; it is often referred to simply as *asthma.* Key characteristics are inflammation, bronchial smooth muscle spasticity, and sputum production; inflammation is the most important. (p. 589)

Bronchodilators Medications that improve airflow by relaxing bronchial smooth muscle cells (e.g., xanthines, adrenergic agonists). (p. 591)

KEY TERMS—cont'd

Chronic bronchitis Chronic inflammation and low-grade infection of the bronchi. (p. 589)

Emphysema A condition of the lungs characterized by enlargement of the air spaces distal to the bronchioles. (p. 589)

Immunoglobulins Proteins belonging to any of five structurally and antigenically distinct classes of antibodies present in the serum and external secretions of the body; they play a major role in immune responses; *immunoglobulin* is often abbreviated *Ig.* (p. 590)

Lower respiratory tract (LRT) The division of the respiratory system composed of organs located almost entirely within the chest. (p. 589)

Status asthmaticus A prolonged asthma attack. (p. 589)

Upper respiratory tract (URT) The division of the respiratory system composed of organs located outside the chest cavity (thorax). (p. 589)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

The main function of the respiratory system is to deliver oxygen to, and remove carbon dioxide from, the cells of the body. To perform this deceptively simple task requires a very intricate system of tissues, muscles, and organs called the respiratory system. It consists of two divisions or tracts: the upper and lower respiratory tracts. The **upper respiratory tract (URT)** is composed of the structures that are located outside of the chest cavity or thorax. These are the nose, nasopharynx, oropharynx, laryngopharynx, and larynx. The **lower respiratory tract (LRT)** is located almost entirely within the thorax and is composed of the trachea, all segments of the bronchial tree, and the lungs. The URT and LRT have four main accessory structures that aid in their overall function. These are the oral cavity (mouth), the rib cage, the muscles of the rib cage (intercostal muscles), and the diaphragm. The upper and lower respiratory tracts together with the accessory structures make up the respiratory system. Elements of this system are in constant communication with each other as they perform the vital function of respiration and the exchange of oxygen for carbon dioxide.

The air we breathe is a mixture of many gases. During inhalation, oxygen molecules from the air diffuse across the semipermeable membranes of the **alveoli,** where they are exchanged for carbon dioxide molecules, which are then exhaled. The lungs also filter, warm, and humidify the air. Oxygen is then delivered to the cells by the blood vessels of the circulatory system, where the respiratory system transfers the oxygen it has extracted from inhaled air to the hemoglobin protein molecules contained within red blood cells. Also within the circulatory system, the cellular metabolic waste product carbon dioxide is collected from the tissues by the red blood cells. This waste is then transported back to the lungs via the circulatory system, where it diffuses back across the alveolar membranes and is then exhaled into the air. The respiratory system also plays a central role in speech, smell, and regulation of pH (acid-base balance).

PATHOPHYSIOLOGY OF DISEASES OF THE RESPIRATORY SYSTEM

Several diseases impair the function of the respiratory system. Those that affect the URT include colds, rhinitis, and hay fever. These conditions and the drugs used to treat them are discussed in Chapter 36. The major diseases that impair the function of the LRT include asthma, **emphysema,** and **chronic bronchitis.** All of these diseases have one feature in common; they all involve the obstruction of airflow through the airways. Chronic obstructive pulmonary disease (COPD) is the name applied collectively to emphysema and chronic bronchitis, because the obstruction is relatively constant. Asthma that is persistent and present most of the time despite treatment is also considered a COPD. Cystic fibrosis and infant respiratory distress syndrome are other disorders that affect the LRT, but they are not a focus of discussion in this chapter because treatment for them places more emphasis on nonpharmacologic than on pharmacologic measures.

Asthma

Bronchial asthma is defined as a recurrent and reversible shortness of breath and occurs when the airways of the lung (bronchi and bronchioles) become narrow as a result of bronchospasm, inflammation and edema of the bronchial mucosa, and the production of viscous (sticky) mucus. The alveolar ducts and alveoli distal to the bronchioles remain open, but the obstruction to the airflow in the airways prevents carbon dioxide from getting out of the air spaces and oxygen from getting in. Symptoms include wheezing and difficulty breathing. When an episode has a sudden and dramatic onset, it is referred to as an **asthma attack.** Most asthma attacks are short, and normal breathing is subsequently recovered. However, an asthma attack may be prolonged and may not respond to typical drug therapy. This is a condition known as **status asthmaticus** and requires hospitalization. The onset of asthma occurs before 10 years of age in 50% of patients and before 40 years of age in about 80% of patients.

There are different types of asthma: intrinsic (occurring in patients with no history of allergies), extrinsic (occurring in patients exposed to a known allergen), exercise induced, and drug induced. **Allergic asthma,** or extrinsic asthma, is caused by a hypersensitivity to an allergen or allergens in the environment. An **allergen** is any substance that elicits an allergic reaction. In patients with seasonal asthma, the allergen is a substance such as pollen or mold, which is present only periodically (seasonally). The offending allergens in patients with nonseasonal asthma are substances such as dust, mold, and

BOX 37-1 STEPS INVOLVED IN AN ATTACK OF ALLERGIC ASTHMA

1. The offending allergen provokes the production of hypersensitive antibodies (most commonly immunoglobulin E [IgE]) that are specific to the allergen. This immunologic response initiates patient sensitivity.
2. The IgE antibodies are homocytotropic and collect on the surface of mast cells, thus sensitizing the patient to the allergen.
3. Subsequent allergen contact provokes the antigen-antibody reaction on the surface of mast cells.
4. Mast cell integrity is then violated, and these cells release chemical mediators stored in the cell. They also synthesize and then release other chemical mediators. These mediators include bradykinin, eosinophil chemotactic factor of anaphylaxis, histamine, prostaglandins, and slow-reacting substance of anaphylaxis (SRS-A).
5. The released chemical mediators, especially histamine and SRS-A, trigger bronchial constriction and an asthma attack.

BOX 37-2 CLASSIFICATIONS OF DRUGS USED TO TREAT ASTHMA

Long-Term Control

Leukotriene receptor antagonists
Mast cell stabilizers
Inhaled corticosteroids
Anticholinergic agents
Long-acting beta$_2$ agonists (LABA)
theophylline
Long-acting beta$_2$ agonists in combination with inhaled corticosteroids

Quick Relief

Intravenous systemic corticosteroids
Short-acting inhaled beta$_2$ agonists (rescue agents)

TABLE 37-1 STEPWISE THERAPY FOR THE MANAGEMENT OF ASTHMA

STEP	DRUG CLASSIFICATION
Step 1	Short-acting inhaled beta$_2$ agonist as needed
Step 2	Preferred: low-dose inhaled corticosteroid (ICS) Alternative: cromolyn, nedocromil, leukotriene receptor antagonist (LTRA), or theophylline
Step 3	Preferred: low-dose ICS and long-acting beta$_2$ agonist (LABA) or medium-dose ICS Alternative: low-dose ICS and either LTRA, theophylline, or zileuton
Step 4	Preferred: medium-dose ICS plus LABA Alternative: medium-dose ICS plus either LTRA, theophylline, or zileuton
Step 5	High-dose ICS and LABA, and consider omalizumab for patients with allergies
Step 6	High-dose ICS and LABA and oral corticosteroid, and consider omalizumab for patients with allergies

Adapted from National Institutes of Health: Expert Panel Report 3: guidelines for the diagnosis and management of asthma, 2007, U.S. Department of Health and Human Services, available at www.nhlbi.nih.gov/guidelines/asthma. Accessed December 3, 2011.

animal dander, which are present in the environment throughout the year. Cigarette smoke, from either smoking or exposure to secondhand smoke, is another common allergen. Examples of common food allergens include nuts, eggs, and corn. Exposure to the offending allergen in a patient with allergic asthma causes an immediate allergic reaction in the form of an asthma attack. This attack is mediated by antibodies already present in the patient's body that chemically recognize the allergen to be a foreign substance, or **antigen.** These **antibodies** are specialized immune system proteins known as **immunoglobulins.** The antibody in individuals with asthma is usually immunoglobulin E (IgE), which is one of the five types of antibodies in the body (the others are IgG, IgA, IgM, and IgD). On exposure to the allergen, the patient's body responds by mounting an immediate and potent antigen-antibody reaction (immune response). This reaction occurs on the surfaces of cells such as mast cells that are rich in histamines, leukotrienes, and other substances involved in the immune response. These substances are collectively known as inflammatory mediators, and they are released from the mast cells as part of the immune response. This in turn, as described in Chapter 36, triggers the mucosal swelling and bronchoconstriction that are characteristic of an allergic asthma attack. The sequence of events that occurs in a patient with allergic asthma is shown in Box 37-1.

The specific cause of intrinsic, or idiopathic, asthma is unknown. It is not mediated by IgE, and there is often no family history of allergies in affected patients. However, certain factors have been noted to precipitate asthma attacks in these patients, including respiratory infections, stress, and cold weather. Patients with exercise-induced asthma have bronchospasm at the beginning of exercise, and symptoms stop when exercise is halted. Drug-induced asthma can be the result of different drugs including NSAIDs (see Chapter 44), beta blockers (see Chapters 22 and 24), sulfites, or certain foods. Patients with any type of asthma who know their suspected "triggers," whether an allergen, the weather, or another factor, are advised to avoid these triggers as much as is feasible as part of managing their disease. When it is not feasible or advisable to avoid a certain trigger (e.g., exercise), patients need to work with their prescribers to prevent the response to these triggers through appropriate drug therapy (e.g., use of a bronchodilator inhaler before exercise or other strenuous activity).

The National Asthma Education and Prevention Panel (NAEPP) of the National Heart, Lung, and Blood Institute has maintained ongoing guidelines for the diagnosis and management of asthma since 1989. The current guideline revision was published in 2007. In general, these guidelines classify asthma medications as either for long-term symptom control or rapid symptom relief. The specific drugs in each classification are listed in Box 37-2. The guidelines advocate the use of a stepwise approach in the treatment of asthma. The particular steps and recommended drug classifications for treatment at each step are listed in Table 37-1.

Chronic Bronchitis

Chronic bronchitis is a continuous inflammation and low-grade infection of the bronchi. The inflammation in the associated

bronchioles (smaller bronchi) is responsible for most of the airflow obstruction. Chronic bronchitis involves the excessive secretion of mucus and certain pathologic changes in the bronchial structure. The disease can arise as a result of repeated episodes of acute bronchitis or in the context of chronic generalized diseases. It is usually precipitated by prolonged exposure to bronchial irritants. One of the most common is cigarette smoke. Some patients acquire the disease because of other predisposing factors such as viral or bacterial pulmonary infections during childhood. Others may have mild impairment of the ability to inactivate proteolytic (protein-destroying) enzymes, which then damage the airway mucosal tissues. Unknown genetic characteristics may be responsible as well.

Emphysema

Emphysema is a condition in which the air spaces enlarge as a result of the destruction of the alveolar walls. This appears to be caused by the effect of proteolytic enzymes released from leukocytes in response to alveolar inflammation. Because the alveolar walls are partially destroyed, the surface area available for oxygen and carbon dioxide exchange is reduced, which impairs effective respiration. As with chronic bronchitis, cigarette smoke appears to be the primary irritant responsible for precipitating the underlying inflammation that leads to the development of emphysema. There is also an associated genetic deficiency of the enzyme alpha$_1$-antitrypsin.

TREATMENT OF DISEASES OF THE LOWER RESPIRATORY TRACT

In the past, the treatment of asthma and other COPDs was focused primarily on the use of drugs that cause the airways to dilate. Now there is a greater understanding of the pathophysiology of these diseases. The emphasis of research has shifted from the bronchoconstriction component of the disease to the inflammatory component. This is also reflected in the various medication classes used to treat COPDs, although bronchodilators still play an important role. A synopsis of the mechanisms of action of the various classes of antiasthmatic drugs is provided in Table 37-2. Figure 37-1 gives an overview of the various drugs used in asthma.

TABLE 37-2 MECHANISMS OF ANTIASTHMATIC DRUG ACTION

ANTIASTHMATIC	MECHANISM IN ASTHMA RELIEF
Anticholinergics	Block cholinergic receptors, thus preventing the binding of cholinergic substances that cause bronchoconstriction and increase secretions
Leukotriene receptor antagonists	Modify or inhibit the activity of leukotrienes, which decreases arachidonic acid–induced inflammation and allergen-induced bronchoconstriction
Beta agonists and xanthine derivatives	Raise intracellular levels of cyclic adenosine monophosphate, which in turn produces smooth muscle relaxation and dilates the constricted bronchi and bronchioles
Corticosteroids	Prevent the inflammation commonly provoked by the substances released from mast cells
Mast cell stabilizers (cromolyn and nedocromil)	Stabilize the cell membranes of the mast cells in which the antigen-antibody reactions take place, thereby preventing the release of substances such as histamine that cause constriction

PHARMACOLOGY OVERVIEW

BRONCHODILATORS

Bronchodilators are an important part of the pharmacotherapy for all respiratory diseases. These drugs relax bronchial smooth muscle, which causes dilation of the bronchi and bronchioles that are narrowed as a result of the disease process. There are three classes of such drugs: beta adrenergic agonists, anticholinergics, and xanthine derivatives.

BETA-ADRENERGIC AGONISTS

The beta adrenergic agonists are a group of drugs that are commonly used during the acute phase of an asthmatic attack to quickly reduce airway constriction and restore airflow to normal. They are agonists, or stimulators, of the adrenergic receptors in the sympathetic nervous system. The beta and alpha adrenergic receptors are discussed in Chapters 18 and 19. The beta agonists imitate the effects of norepinephrine on beta receptors. For this reason, they are also called *sympathomimetic* bronchodilators. The beta agonists are categorized by their onset of action. Short-acting beta agonist (SABA) inhalers include albuterol (Ventolin), levalbuterol (Xopenex), pirbuterol (Maxair), terbutaline (Brethine), and metaproterenol (Alupent). Long-acting beta agonist (LABA) inhalers include arformoterol (Brovana), formoterol (Foradil, Perforomist), and salmeterol (Serevent). Because the LABAs have a longer onset of action, they must never be used for acute treatment. Patients must be taught to use the SABAs as rescue treatment.

Mechanism of Action and Drug Effects

The beta agonists dilate airways by stimulating the beta$_2$-adrenergic receptors located throughout the lungs.

There are three subtypes of these drugs, based on their selectivity for beta$_2$ receptors:

1. Nonselective adrenergic drugs, which stimulate the beta, beta$_1$ (cardiac), and beta$_2$ (respiratory) receptors. Example: epinephrine. (NOTE: Epinephrine inhalers were taken off the market in 2012 because they did not comply with FDA requirements; they may return to the market in the future.) Epinephrine is available as a prefilled syringe for self-administration by patients with severe allergic reactions and is called Epipen (Figure 37-2.)
2. Nonselective beta-adrenergic drugs, which stimulate both beta$_1$ and beta$_2$ receptors. Example: metaproterenol.
3. Selective beta$_2$ drugs, which primarily stimulate the beta$_2$ receptors. Example: albuterol.

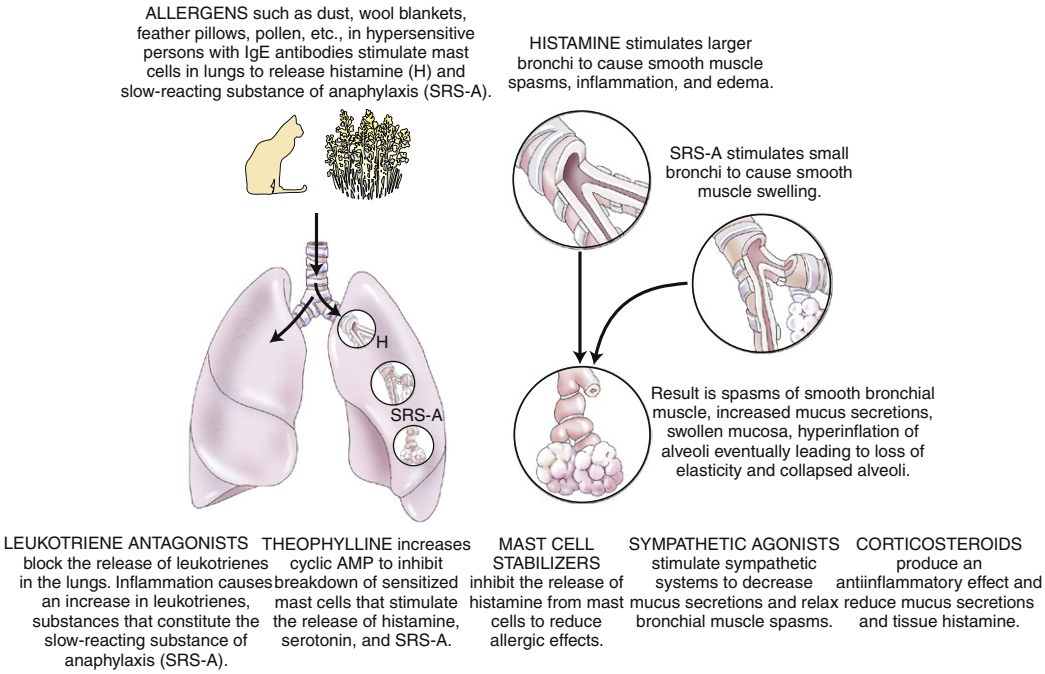

FIGURE 37-1 Overview of the effects of various antiasthmatic medications. (From McKenry LM, Tessier E, Hogan M: *Mosby's pharmacology in nursing,* ed 22, St Louis, 2006, Mosby.)

FIGURE 37-2 The EpiPen Auto-Injector (epinephrine) is used for immediate treatment of anaphylaxis (allergic emergencies). The EpiPen is given into the outer thigh, through the clothing. Anaphylactic emergencies also require emergency medical services in addition to the EpiPen. Additional information is available at www.epipen.com. (Copyright Mylan Specialty, L.P. Used with permission.)

TABLE 37-3 BETA AGONIST BRONCHODILATORS

DRUG	TYPE	TRADE NAMES	ADMINISTRATION
Short Acting			
albuterol	$Beta_2$	Proventil, Ventolin	PO, inhalation
ephedrine	Alpha/beta	None (various generic)	IM, IV, subcut
epinephrine	Alpha/beta	Adrenalin	Subcut, IM
metaproterenol	$Beta_1/beta_2$	Alupent	PO, inhalation
levalbuterol	$Beta_2$	Xopenex	Inhalation
metaproterenol	$Beta_1/beta_2$	Alupent, Metaprel	PO, inhalation
pirbuterol	$Beta_2$	Maxair	Inhalation
terbutaline	$Beta_2$	Brethine	PO, subcut, inhalation
Long Acting			
salmeterol	$Beta_2$	Serevent, Serevent Diskus	Inhalation
formoterol	$Beta_2$	Foradil, Perforomist	Inhalation
arformoterol	$Beta_2$	Brovana	Inhalation

IM, Intramuscular; *IV,* intravenous; *PO,* oral; *subcut,* subcutaneous.

These drugs can also be categorized according to their routes of administration as oral, injectable, or inhaled. The various beta agonist bronchodilators are listed in Table 37-3.

The bronchioles are surrounded by smooth muscle. When the smooth muscle contracts, the airways are narrowed and the amount of oxygen and carbon dioxide exchanged is reduced. The action of beta agonist bronchodilators begins at the specific receptor stimulated and ends with the dilation of the airways. However, many reactions must take place at the cellular level for this bronchodilation to occur. When a $beta_2$-adrenergic receptor is stimulated by a beta agonist, adenylate cyclase is activated and produces cyclic adenosine monophosphate (cAMP). Adenylate cyclase is an enzyme needed to make cAMP. The increased levels of cAMP cause bronchial smooth muscles to

DOSAGES

Bronchodilators

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ albuterol (Proventil, Proventil Repetabs, Ventolin, others) (C)	Short-acting beta$_2$ agonist (SABA)	**Pediatric 2-6 yr** PO: 0.1-0.2 mg/kg 3 times daily **Pediatric 7-11 yr** PO: 2 mg 3-4 times daily **Adult and pediatric 12 yr and older** PO: 2-4 mg 3-4 times daily **Adult and pediatric 4 yr and older** MDI: 2 puffs q4-6h Inhalation solution: 2.5 mg 3-4 times daily	Asthma, bronchospasm
ipratropium (Atrovent) (B)	Anticholinergic	**Adult and pediatric 12 yr and older** MDI: 2 puffs 4 times daily Nasal spray, 0.03%: 2 sprays 2-3 times daily Nasal spray, 0.06%: 2 sprays 3-4 times daily Inhalation solution: 500 mcg 3-4 times daily	
♦salmeterol* (Severent) (C)	Long-acting beta$_2$ agonist (LABA)	**Adult** 1 puff twice a day	Asthma, COPD

IM, Intramuscular; *IV,* intravenous; *MDI,* metered-dose inhaler; *PO,* oral.
*Long-acting beta agonists are no longer recommended to be used alone; they need to be combined with an asthma controlling medication such as an inhaled corticosteroid (e.g., Advair inhaler [fluticasone and salmeterol]).

relax, which results in bronchial dilation and increased airflow into and out of the lungs.

Nonselective adrenergic agonist drugs such as epinephrine also stimulate alpha-adrenergic receptors, causing constriction within the blood vessels. This vasoconstriction reduces the amount of edema or swelling in the mucous membranes and limits the quantity of secretions normally produced by these membranes. In addition, these drugs stimulate beta$_1$ receptors, which results in cardiovascular adverse effects such as an increase in heart rate, force of contraction, and blood pressure, as well as central nervous system (CNS) effects such as nervousness and tremor.

Drugs such as albuterol that predominantly stimulate the beta$_2$ receptors have more specific drug effects and cause less adverse effects. By primarily stimulating the beta$_2$-adrenergic receptors of the bronchial and vascular smooth muscles, they cause bronchodilation and may also have a dilating effect on the peripheral vasculature, which results in a decrease in diastolic blood pressure.

Indications

The primary therapeutic effect of the beta agonists is the prevention or relief of bronchospasm related to bronchial asthma, bronchitis, and other pulmonary diseases. However, they are also used for effects outside the respiratory system. Because some of these drugs have the ability to stimulate both beta$_1$- and alpha-adrenergic receptors, they may be used to treat hypotension and shock (see Chapter 18).

Contraindications

Contraindications include known drug allergy, uncontrolled hypertension or cardiac dysrhythmias, and high risk of stroke (because of the vasoconstrictive drug action).

Adverse Effects

Mixed alpha/beta agonists produce the most adverse effects because they are nonselective. These include insomnia, restlessness, anorexia, cardiac stimulation, hyperglycemia, tremor, and vascular headache. The adverse effects of the nonselective beta agonists are limited to beta-adrenergic effects, including cardiac stimulation, tremor, anginal pain, and vascular headache. The beta$_2$ drugs can cause both hypertension and hypotension, vascular headaches, and tremor. Overdose management may include careful administration of a beta blocker while the patient is under close observation due to the risk of bronchospasm. Because the half-life of most adrenergic agonists is relatively short, the patient may just be observed while the body eliminates the medication.

Interactions

When nonselective beta blockers are used with the beta agonist bronchodilators, the bronchodilation from the beta agonist is diminished. The use of beta agonists with monoamine oxidase inhibitors and other sympathomimetics is best avoided because of the enhanced risk for hypertension. Patients with diabetes may require an adjustment in the dosage of their hypoglycemic drugs, especially patients receiving epinephrine, because of the increase in blood glucose levels that can occur.

Dosages

For dosage information on selected beta agonists, see the table on this page.

DRUG PROFILES

♦ albuterol

Albuterol (Proventil) is a short-acting beta$_2$-specific bronchodilating beta agonist. Other similar drugs include bitolterol

(Tornalate), levalbuterol (Xopenex), pirbuterol (Maxair), and terbutaline (Brethine). Albuterol is the most commonly used drug in this class. If albuterol is used too frequently, dose-related adverse effects may be seen, because albuterol loses its $beta_2$-specific actions, especially at larger dosages. As a consequence, the $beta_1$ receptors are stimulated, which causes nausea, increased anxiety, palpitations, tremors, and an increased heart rate.

Albuterol is available for both oral and inhalational use. Inhalational dosage forms include metered-dose inhalers (MDIs) as well as solutions for inhalation. The levorotatory isomeric form of albuterol, levalbuterol, is sometimes prescribed as an albuterol alternative for patients with certain risk factors (e.g., tachycardia, including tachycardia associated with albuterol treatment).

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Inhalation	Immediate	10-25 min	3-4 hr	3-4 hr

♦ salmeterol

Salmeterol (Serevent) is a long-acting $beta_2$ agonist bronchodilator. Other long-acting inhalers include formoterol (Foradil, Perforomist) and arformoterol (Brovana). The long-acting inhalers are never to be used for acute treatment. Salmeterol is used for the maintenance treatment of asthma and COPD and is used in conjunction with an inhaled corticosteroid. It is given twice daily for maintenance treatment only. In 2006, a large randomized clinical trial showed that use of salmeterol was associated with an increase in asthma-related deaths (when added to usual asthma therapy). The risk appears to be higher in African-American patients. Adverse effects include immediate hypersensitivity reactions, headache, hypertension, and neuromuscular and skeletal pain. Salmeterol should never be given more than twice daily nor should the maximum daily dose (one puff twice daily) be exceeded. It is available as a powder for inhalation either alone (Serevent Diskus) or combined with a corticosteroid (Advair). The long-acting inhalers, including salmeterol, are not to be used alone, but in combination with other drugs such as the inhaled corticosteroids. Advair (salmeterol and fluticasone) is a very popular inhaler for COPD. Symbicort, a newer inhaler consisting of the corticosteroid budesonide and the bronchodilator formoterol, is similar to Advair.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Inhalation	Asthma: 30-48 min COPD: 2 hr	Asthma: 2-4 hr COPD: 3-4.5 hr	5.5 hr	12 hr

ANTICHOLINERGICS

Currently there are two anticholinergic drugs used in the treatment of COPD: ipratropium (Atrovent) and tiotropium (Spiriva).

Mechanism of Action and Drug Effects

On the surface of the bronchial tree are receptors for acetylcholine (ACh), the neurotransmitter for the parasympathetic nervous system (PSNS). When the PSNS releases ACh from its nerve endings, it binds to the ACh receptors on the surface of the bronchial tree, which results in bronchial constriction and narrowing of the airways. Anticholinergic drugs block these ACh receptors to prevent bronchoconstriction. This indirectly causes airway dilation. Anticholinergic agents also help reduce secretions in COPD patients.

Indications

Because their actions are slow and prolonged, anticholinergics are used for prevention of the bronchospasm associated with chronic bronchitis or emphysema and not for the management of acute symptoms.

Contraindications

The only usual contraindication to the use of bronchial anticholinergic drugs is drug allergy, including allergy to atropine or to soy lecithin (found in some of the inhalational formulations), or allergy to related food products such as peanut oils, peanuts, soybeans, and other legumes (beans). There have been reported cases of severe anaphylactic reactions to ipratropium inhalers in patients with peanut allergy, and such use is to be avoided. Caution is necessary in patients with acute narrow-angle glaucoma and prostate enlargement.

Adverse Effects

The most commonly reported adverse effects of ipratropium and tiotropium therapy are related to the drugs' anticholinergic effects and include dry mouth or throat, nasal congestion, heart palpitations, gastrointestinal (GI) distress, urinary retention, increased intraocular pressure, headache, coughing, and anxiety. Ipratropium is classified as a pregnancy category B drug; tiotropium is classified as pregnancy category C.

Drug Interactions

Possible additive toxicity may occur when anticholinergic bronchodilators are taken with other anticholinergic drugs.

Dosages

For dosage information on anticholinergic drugs, see the table on p. 593.

DRUG PROFILE

ipratropium

Ipratropium (Atrovent) is the oldest and most commonly used anticholinergic bronchodilator. It is pharmacologically very similar to atropine (see Chapter 21). It is available both as a liquid aerosol for inhalation and as a multidose inhaler; both forms are usually dosed twice daily. Tiotropium (Spiriva) is a similar drug but is formulated for once-daily dosing. Many patients also benefit from taking both a $beta_2$ agonist and an anticholinergic drug, with the most popular combination being albuterol and ipratropium. Although many patients receive the two drugs separately, two combination products are available containing both of these drugs: Combivent (an MDI) and DuoNeb (an inhalation solution).

DOSAGES

Theophylline Salts

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATION
theophylline (Elixophyllin, Theo-Dur, Uniphyl, others) (C)	Xanthine-derived bronchodilator	**Adult** PO: 400-600 mg/day in 1-4 divided doses	Asthma

Pharmacokinetics (ipratropium)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Inhalation	5-15 min	1-2 hr	1.6 hr	4-5 hr

XANTHINE DERIVATIVES

The natural xanthines consist of the plant alkaloids caffeine, theobromine, and theophylline, but only theophylline and caffeine are currently used clinically. Synthetic xanthines include aminophylline and dyphylline. Caffeine, which is actually a metabolite of theophylline, has other uses described later.

Mechanism of Action and Drug Effects

Xanthines cause bronchodilation by increasing the levels of the energy-producing substance cAMP. They do this by competitively inhibiting phosphodiesterase, the enzyme responsible for breaking down cAMP. In patients with COPD, cAMP plays an integral role in the maintenance of open airways. Higher intracellular levels of cAMP contribute to smooth muscle relaxation and also inhibit IgE-induced release of the chemical mediators that drive allergic reactions (histamine, slow-reacting substance of anaphylaxis, and others).

Theophylline is metabolized to caffeine in the body, whereas aminophylline is metabolized to theophylline. Theophylline and other xanthines also stimulate the CNS, but to a lesser degree than caffeine. This stimulation of the CNS has the beneficial effect of acting directly on the medullary respiratory center to enhance respiratory drive. In large doses, theophylline may stimulate the cardiovascular system, which results in both an increased force of contraction (positive inotropy) and an increased heart rate (positive chronotropy). The increased force of contraction raises cardiac output and hence blood flow to the kidneys. This, in combination with the ability of the xanthines to dilate blood vessels in and around the kidney, increases the glomerular filtration rate, which produces a diuretic effect.

Indications

Xanthines are used to dilate the airways in patients with asthma, chronic bronchitis, or emphysema. They may be used in mild to moderate cases of acute asthma and as an adjunct drug in the management of COPD. Xanthines are now deemphasized as treatment for milder asthma because of their greater potential for drug interactions and the greater interpatient variability in therapeutic drug levels in the blood. Because of their relatively slow onset of action, xanthines are more often used for the prevention of asthmatic symptoms than for the relief of acute asthma attacks. However, they are also used as adjunct bronchodilators for patients with chronic bronchitis or emphysema.

Caffeine is used without prescription as a CNS stimulant, or analeptic (see Chapter 13), to promote alertness (e.g., for long-duration driving or studying). It is also used as a cardiac stimulant in infants with bradycardia and for enhancement of respiratory drive in infants in neonatal intensive care units. It is not normally used clinically in adults for these purposes, although theoretically it would have similar effects.

Contraindications

Contraindications to therapy with xanthine derivatives include known drug allergy, uncontrolled cardiac dysrhythmias, seizure disorders, hyperthyroidism, and peptic ulcers.

Adverse Effects

The common adverse effects of the xanthine derivatives include nausea, vomiting, and anorexia. In addition, gastroesophageal reflux has been observed to occur during sleep in patients taking these drugs. Cardiac adverse effects include sinus tachycardia, extrasystole, palpitations, and ventricular dysrhythmias. Transient increased urination and hyperglycemia are other possible adverse effects. Overdose and other toxicity of xanthine derivatives are usually treated by the repeated administration of doses of activated charcoal.

Interactions

The use of xanthine derivatives with any of the following drugs causes an increase in the serum level: allopurinol, cimetidine, macrolide antibiotics (e.g., erythromycin), quinolones (e.g., ciprofloxacin), influenza vaccine, and oral contraceptives. Their use with sympathomimetics, or even caffeine, can produce additive cardiac and CNS stimulation. Rifampin increases the metabolism of theophylline, which results in decreased theophylline levels. St. John's wort *(Hypericum perforatum)* enhances the rate of xanthine drug metabolism; thus, higher dosages of theophylline and other xanthine derivatives may be needed. Cigarette smoking has a similar effect because of the enzyme-inducing effect of nicotine. Interacting foods include charcoal-broiled, high-protein, and low-carbohydrate foods. These foods may reduce serum levels of xanthines through various metabolic mechanisms.

Dosages

For dosage information on selected theophylline salts, see the table on this page.

DRUG PROFILE

theophylline

Theophylline is the most commonly used xanthine derivative, albeit not often used. It is available in oral, rectal, injectable (as aminophylline), and topical dosage forms. Besides theophylline, which occurs in various salt forms, the other xanthine bronchodilator used clinically for the treatment of bronchoconstriction is aminophylline. Aminophylline is a prodrug of theophylline; it is metabolized to theophylline in the body. Aminophylline is sometimes given intravenously to patients with status asthmaticus who have not responded to fast-acting beta agonists such as epinephrine.

The beneficial effects of theophylline can be maximized by maintaining blood levels within a certain target range. If these levels become too high, unwanted adverse effects can occur. If the levels become too low, the patient receives little therapeutic benefit. Although the optimal level may vary from patient to patient, most standard references have suggested that the therapeutic range for theophylline blood level is 10 to 20 mcg/mL. However, most clinicians now advise levels between 5 and 15 mcg/mL. Laboratory monitoring of drug blood levels is common to ensure adequate dosage, especially in the hospital setting.

Pharmacokinetics

NONBRONCHODILATING RESPIRATORY DRUGS

Bronchodilators (beta-adrenergic agonists and xanthines) are just one type of drug used to treat asthma, chronic bronchitis, and emphysema. There are also other drugs that are effective in suppressing the various underlying causes of some of these respiratory illnesses. These include leukotriene receptor antagonists (montelukast, zafirlukast, and zileuton) and corticosteroids (beclomethasone, budesonide, dexamethasone, flunisolide, fluticasone, ciclesonide, and triamcinolone). Another drug class known as *mast cell stabilizers* is now rarely used. However, these drugs are still listed in the national guidelines as *alternative* therapy and include cromolyn and nedocromil; they are sometimes used for exercise-induced asthma. As their class name implies, they work by stabilizing the cell membranes of mast cells to prevent the release of inflammatory mediators such as histamine.

LEUKOTRIENE RECEPTOR ANTAGONISTS

When they became available in the 1990s, the leukotriene receptor antagonists (LTRAs) were the first new class of asthma medications to be introduced in the United States in more than 20 years.

Before the development of LTRAs, most asthma treatments focused on relaxing the contraction of bronchial muscles with bronchodilators. More recently, researchers have begun to understand how asthma symptoms are caused by the immune system at the cellular level. A chain reaction starts when a trigger allergen, such as cat hair or dust, initiates a series of chemical reactions in the body. Several substances are produced, including a family of molecules known as *leukotrienes.* In people with asthma, leukotrienes cause inflammation, bronchoconstriction, and mucus production. This in turn leads to coughing, wheezing, and shortness of breath.

Mechanism of Action and Drug Effects

Currently two subclasses of LTRAs are available. These subclasses differ in the mechanism by which they block the inflammatory process in asthma. The first subclass of LTRAs acts by an indirect mechanism and inhibits the enzyme 5-lipoxygenase, which is necessary for leukotriene synthesis. Zileuton (Zyflo) is the only drug of this type currently available. Drugs in the second subclass of LTRAs act more directly by binding to the D_4 leukotriene receptor subtype in respiratory tract tissues and organs. These drugs include montelukast (Singulair) and zafirlukast (Accolate).

The drug effects of LTRAs are primarily limited to the lungs. As their name implies, LTRAs prevent leukotrienes from attaching to receptors located on circulating immune cells (e.g., lymphocytes in the blood) as well as local immune cells within the lungs (e.g., alveolar macrophages). This alleviates asthma symptoms in the lungs by reducing inflammation. They prevent smooth muscle contraction of the bronchial airways, decrease mucus secretion, and reduce vascular permeability (which reduces edema) through their reduction of leukotriene synthesis. Other antileukotriene effects of these drugs include prevention of the mobilization and migration of such cells as neutrophils and lymphocytes into the lungs. This also serves to reduce airway inflammation.

Indications

The LTRAs montelukast, zafirlukast, and zileuton are used for the prophylaxis and long-term treatment and prevention of asthma in adults and children 12 years of age and older. Because it is dosed once daily, montelukast is the most widely used of these drugs and has also been approved for treatment of allergic rhinitis, a condition discussed in Chapter 36. These drugs are not meant for the management of acute asthmatic attacks. Improvement with their use is typically seen in about 1 week.

Contraindications

Known drug allergy or other previous adverse drug reaction is the primary contraindication to the use of these drugs. Allergy to povidone, lactose, titanium dioxide, or cellulose derivatives is also important to note, because these are inactive ingredients in these drugs.

Adverse Effects

The adverse effects of LTRAs differ depending on the specific drug. The most commonly reported adverse effects of zileuton include headache, nausea, dizziness, and insomnia. The most common adverse effects of zafirlukast include headache, nausea, and diarrhea. Both drugs may also lead to liver dysfunction. For this reason, monitor liver enzyme levels regularly in patients taking these drugs, especially early in the course of therapy.

Interactions

Montelukast has fewer drug interactions than zafirlukast or zileuton. Phenobarbital and rifampin, both of which are enzyme

DOSAGES

Selected Antileukotriene Drug

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ montelukast (Singulair) (B)	Leukotriene receptor antagonist	**Pediatric 2-5 yr** 4 mg daily in evening **Pediatric 6-14 yr** 5 mg daily in evening **Adult and pediatric 15 yr and older** 10 mg daily in evening	Asthma (prophylaxis and maintenance treatment)

inducers, decrease montelukast concentrations. For information on the drugs that interact with zafirlukast and zileuton, see Table 37-4.

Dosages

For dosage information on montelukast, see the table on this page.

DRUG PROFILE

LTRAs are used primarily for oral prophylaxis and long-term treatment of asthma. The three drugs currently available are zileuton, zafirlukast, and montelukast. These drugs are not recommended for treatment of acute asthma attacks.

♦ montelukast

Montelukast (Singulair) belongs to the same subcategory of LTRAs as zafirlukast. Montelukast and zafirlukast work by blocking leukotriene D_4 receptors to augment the inflammatory response. Montelukast offers the advantage of being approved for use in children 2 years of age and older. It also has fewer adverse effects and drug interactions than zafirlukast. Use of montelukast is contraindicated in patients with a known hypersensitivity to it. It is available only for oral use. It is classified as a pregnancy category B drug. Recommended dosages are given in the table on this page.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30 min	3-4 hr	2.7-5 hr	24 hr

CORTICOSTEROIDS

Corticosteroids, also known as *glucocorticoids,* are either naturally occurring or synthetic drugs used in the treatment of pulmonary diseases for their antiinflammatory effects. All have actions similar to those of the natural steroid hormone cortisol, which is chemically the same as the drug hydrocortisone. Synthetic steroids are more commonly used in drug therapy. They can be given by inhalation, orally, or even intravenously in severe cases of asthma. Corticosteroids administered by inhalation have an advantage over orally administered corticosteroids in that their action is relatively limited to the topical site in the lungs. This generally limits, although does not totally prevent, systemic effects. The chemical structures of the corticosteroids given by inhalation have also been slightly altered to limit their systemic absorption from the respiratory tract. The corticosteroids administered by inhalation include the following:

- beclomethasone dipropionate (Beclovent)
- budesonide (Pulmicort Turbuhaler)
- dexamethasone sodium phosphate (Decadron Phosphate Respihaler)
- flunisolide (AeroBid)
- fluticasone (Flovent)
- triamcinolone acetonide (Azmacort)
- ciclesonide (Omnaris)

The systemic use of corticosteroids was described in Chapter 33. The systemic corticosteroids most commonly used for respiratory illness include the following:

- prednisone (oral)
- methylprednisolone (intravenous or oral)

TABLE 37-4 DRUG INTERACTIONS: LEUKOTRIENE RECEPTOR ANTAGONISTS

DRUG	INTERACTING DRUGS	MECHANISM	RESULT
montelukast (Singulair)	phenobarbital, rifampin	Increased metabolism	Decreased montelukast levels
zafirlukast (Accolate)	aspirin	Decreased clearance	Increased zafirlukast levels
	erythromycin	Decreased bioavailability	Decreased zafirlukast levels
	warfarin	Decreased clearance	Increased warfarin levels
zileuton (Zyflo)	propranolol	Decreased clearance	Increased propranolol levels
	theophylline	Decreased clearance	Increased theophylline levels
	warfarin	Decreased clearance	Increased warfarin levels

TABLE 37-5 WHITE BLOOD CELLS (LEUKOCYTES)

WBC TYPE*	ROLE IN INFLAMMATION	CORTICOSTEROID EFFECT
Granulocytes		
Neutrophils (65%)	Contain powerful lysosomes (very small bodies that hold cellular digestive enzymes); release chemicals that destroy invading organisms and also attack other WBCs	Stabilize cell membranes so that inflammation-causing substances are not released
Eosinophils (2%-5%)	Function mainly in allergic reactions and protect against parasitic infections; ingest inflammatory chemicals and antigen-antibody complexes	Little effect if any
Basophils (0.5%-1%)	Contain histamine, an inflammation-causing substance, and heparin, an anticoagulant	Stabilize cell membranes so that histamine is not released
Agranulocytes		
Lymphocytes (25%)	Two types: T lymphocytes and B lymphocytes; T cells attack infecting microbial or cancerous cells; B cells produce antibodies against specific antigens	Decrease activity of the lymphocytes
Monocytes (3%-5%)	Produce macrophages, which can migrate out of the bloodstream to such places as mucous membranes, where they are capable of engulfing large bacteria or virus-infected cells	Inhibit macrophage accumulation in already inflamed areas, thus preventing more inflammation

WBC, White blood cell.
*Value in parentheses is the percentage of all leukocytes represented by the given type.

Mechanism of Action and Drug Effects

Although the exact mechanism of action of the corticosteroids has not been determined, it is thought that they have the dual effect of both reducing inflammation and enhancing the activity of beta agonists. The corticosteroids produce their antiinflammatory effects through a complex sequence of actions. The overall effect is to prevent various nonspecific inflammatory processes. These include the accumulation of inflammatory mediators as well as altered vascular permeability (which causes edema).

Corticosteroids essentially work by stabilizing the membranes of cells that normally release bronchoconstricting substances. These cells include leukocytes, which is another name for white blood cells (WBCs). There are five different types of WBC, each with its own specific characteristics. The five types of WBC, their role in the inflammatory process, and the way in which corticosteroids inhibit their normal action, combat inflammation, and produce bronchodilation are summarized in Table 37-5. Inflammatory mediators are primarily released by lymphocytes in the circulation as well as by mast cells and alveolar macrophages. These latter two cell types are stationary (noncirculating) inflammatory cells that remain localized in the various tissues and organs of the respiratory tract.

Corticosteroids have also been shown to restore or increase the responsiveness of bronchial smooth muscle to beta-adrenergic receptor stimulation, which results in more pronounced stimulation of the $beta_2$ receptors by beta agonist drugs such as albuterol. It may take several weeks of continuous therapy before the full therapeutic effects of the corticosteroids are realized.

Indications

Inhaled corticosteroids are used for the primary treatment of bronchospastic disorders to control the inflammatory responses that are believed to be the cause of these disorders; they are indicated for persistent asthma. They are often used concurrently with the beta-adrenergic agonists. In respiratory illnesses, systemic corticosteroids are generally used only to treat acute exacerbations, or severe asthma. Their long-term use is associated with adverse effects (see later). The NAEPP recommends long-term use in cases of truly disabling illness (Step 6 of the recommended therapeutic approach) in which the benefits of this drug therapy arguably outweigh the adverse effects. When a more pronounced antiinflammatory effect is needed, however, as in an acute exacerbation of asthma or other COPD, intravenous corticosteroids (e.g., methylprednisolone) are often used.

Contraindications

Drug allergy is the primary contraindication and is usually due to other ingredients in the drug formulation. These drugs are not intended as sole therapy for acute asthma attacks. Inhaled corticosteroids are contraindicated in patients who are hypersensitive to glucocorticoids, in patients whose sputum tests positive for *Candida* organisms, and in patients with systemic fungal infection, as the corticosteroids can suppress the immune system.

Adverse Effects

The main undesirable local effects of typical doses of inhaled corticosteroids in the respiratory system include pharyngeal irritation, coughing, dry mouth, and oral fungal infections. Instruct patients to rinse their mouths after use of an inhaled corticosteroid. Most of the drug effects of inhaled corticosteroids are limited to their topical site of action in the lungs. Because of the chemical structure of these inhaled dosage forms, there is relatively little systemic absorption of the drugs when they are administered by inhalation at normal therapeutic dosages. However, the degree of systemic absorption is more likely to be increased in patients who require higher inhaled dosages. When there is significant

DOSAGES

Selected Corticosteroids

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
fluticasone propionate (Flovent, Flonase) (C)	Synthetic glucocorticoid	**Adult and pediatric 12 yr and older** Flovent MDI, 3 strengths available: 88-880 mcg twice daily **Pediatric 4-11 yr** Flovent inhalation powder, 3 strengths available: 50-100 mcg twice daily	Asthma (prophylaxis and maintenance treatment)
		Adult and pediatric 12 yr and older Flovent inhalation powder, 3 strengths available: 100-1000 mcg twice daily	Seasonal allergic rhinitis
methylprednisolone (Solu-Medrol injection, Medrol tablets) (C)	Synthetic glucocorticoid	Dosage varies as above, but usually 40-125 mg IV, 1-3 times daily, usually tapered down Oral taper: usually from 24 to 2 mg daily	Exacerbations of asthma or COPD

COPD, Chronic obstructive pulmonary disease; *IV,* intravenous; *MDI,* metered-dose inhaler.

systemic absorption, which is most likely with high-dose intravenous or oral administration, corticosteroids can affect any of the organ systems in the body. Some of these systemic drug effects include adrenocortical insufficiency, increased susceptibility to infection, fluid and electrolyte disturbances, endocrine effects, CNS effects (insomnia, nervousness, seizures), and dermatologic and connective tissue effects, including brittle skin, bone loss, osteoporosis, and Cushing's syndrome (see Chapter 33).

It is important to remember that when patients are switched to inhaled corticosteroids after receiving systemic corticosteroids, especially at high dosages for an extended period, adrenal suppression (Addisonian crisis) may occur when the systemically administered corticosteroid is not tapered slowly. Patient deaths have been reported due to adrenal gland failure in such cases when the switch to inhaled corticosteroids is made quickly and the dosage of systemic corticosteroids is not reduced gradually. Prevention of this occurrence requires careful monitoring with slow tapering of systemic drug dosages. The patient who is dependent on systemic corticosteroids may need up to 1 year of recovery time after discontinuation of systemic therapy. There is evidence that bone growth is suppressed in children and adolescents taking corticosteroids. This suppression is more apparent in children receiving larger systemic (versus inhaled) dosages over longer treatment durations. Growth needs to be tracked (e.g., with standardized charts) and medications reevaluated if growth suppression becomes evident. In some cases, supplemental growth hormone may be prescribed.

Interactions

Drug interactions are more likely to occur with systemic (versus inhaled) corticosteroids. These drugs may increase serum glucose levels, possibly requiring adjustments in dosages of antidiabetic drugs. Because of interactions related to metabolizing enzymes, they may also raise blood levels of the immunosuppressants cyclosporine and tacrolimus. Likewise, the antifungal drug itraconazole may reduce clearance of the steroids, whereas phenytoin, phenobarbital, and rifampin may enhance clearance. There is also greater risk for hypokalemia with concurrent use of potassium-depleting diuretics such as hydrochlorothiazide and furosemide.

Dosages

For dosage information on selected corticosteroids, see the table on this page.

DRUG PROFILES

fluticasone propionate

Fluticasone is administered intranasally (Flonase) (one inhalation in each nostril daily) and by oral inhalation (Flovent) (usually one inhalation by mouth twice daily). Fluticasone is also available in a combination formulation with the bronchodilator salmeterol (Advair). Advair is one of the most commonly used inhalers, but because it contains a long-acting beta agonist, it must never be used for acute treatment.

Pharmacokinetics

CASE STUDY

Bronchodilators and Corticosteroids for COPD

Ms. B. is a 73-year-old woman who worked in the local traffic tunnel for about 25 years and has had chronic obstructive pulmonary disease (COPD) for 10 years, caused by exposure to environmental pollutants while on the job and by cigarette smoking. She is now retired and is frequently admitted to the hospital for treatment of her condition. She quit smoking about 8 years ago. Ms. B. is now in the hospital for treatment of an acute exacerbation of her COPD and an upper respiratory tract infection. The physician has ordered the following: Oxygen per nasal cannula at 2 L/min, methylprednisolone (Solu-Medrol), 125 mg IVPB, then 80 mg IVPB every 6 hours; Advair 50 mcg/250 mcg, 1 puff every 12 hours; albuterol (Accuneb) 2.5 mg by nebulizer every 4 hours for 2 days, then every 4 hours as needed; piperacillin/tazobactam (Zosyn) antibiotic therapy, 3.375 g intravenously every 6 hours; measurement of intake and output; daily weight measurement; assessment of vital signs with breath sounds and pulse oximetry every 2 hours until stable; chest physiotherapy twice a day and as needed.

1. What is in Advair, and what does the "50 mcg/250 mcg" mean? Explain the class and purposes of the drug(s) it contains.

Within 2 days, Ms. B's condition stabilizes, and the methylprednisolone dose is gradually reduced. After 1 week, the IV corticosteroid is discontinued and she is started on oral prednisone (generic) 40 mg daily. Her discharge medications include the following:

prednisone (generic) 40 mg PO daily for 3 days, then taper and discontinue by reducing the dose by 5 mg daily. (Prescription calls for 5-mg tablets.)

Advair 50 mcg/250 mcg, 1 puff every 12 hours

albuterol (Proventil HFA) metered-dose inhaler, 90 mcg/spray, every 4 hours as needed

2. What is the reason for tapering the methylprednisolone and prednisone before they are discontinued?
3. Ms. B states, "This is confusing! How do I know how many tablets to take? It's different each day!" What can you do to help her with the tapering dosage of prednisone?
4. While going over the medications, Ms. B asks you, "So which inhaler do I take if I feel short of breath? The Advair or the albuterol? Aren't they the same thing?" What is the nurse's best response?

For answers, see http://evolve.elsevier.com/Lilley.

PHOSPHODIESTERASE-4 INHIBITOR

In 2011, the FDA approved roflumilast (Daliresp), which is a selective inhibitor of the enzyme called *phophodiesterase type 4 (PDE4)*. It is indicated to prevent coughing and excess mucus from worsening and to decrease the frequency of life-threatening COPD exacerbations. It is not intended to treat acute bronchospasm. The most commonly reported adverse effects include nausea, diarrhea, headache, insomnia, dizziness, weight loss, and psychiatric symptoms. The FDA requires a medication guide that informs patients of the potential risk of psychiatric adverse effects. Further information can be found at www.daliresp.com.

MONOCLONAL ANTIBODY ANTIASTHMATIC

Omalizumab (Xolair) is the newest antiasthmatic medication to become available. It is a monoclonal antibody that selectively binds to the immunoglobulin IgE, which in turn limits the release of mediators of the allergic response. Omalizumab is given by injection and has the potential for producing anaphylaxis. Patients receiving omalizumab must be monitored closely for hypersensitivity reactions.

NURSING PROCESS

ASSESSMENT

The net drug effect of beta agonists, xanthine derivatives, anticholinergics, LTRAs, and corticosteroids is improved airflow in airway passages and increased oxygen supply. Thoroughly assess for cautions, contraindications, and drug interactions. Before administering these drugs, assess the patient's skin color, temperature, respiration rate (at a rate of 12-24 breaths/min) respiration depth and rhythm, breath sounds, blood pressure, and pulse rate. Determine if the patient is having problems with cough, dyspnea, orthopnea, or hypoxia, or has other signs or symptoms of respiratory distress. If a cough is present, assess its character, frequency, presence or absence of sputum, as well as the color of the sputum. Assess the patient for presence of any of the following: sternal retractions, cyanosis, restlessness, activity intolerance, cardiac irregularities, palpitations, hypertension, tachycardia, and use of accessory muscles to breathe, indicating significant respiratory compromise. Determine the anterior-posterior diameter of the thorax. Note pulse oximetry reading to determine oxygen saturation levels.

Obtain a complete medication history that includes information about prescription and over-the-counter (OTC) drugs, herbal products, alternative therapies, use of nebulizers and/or humidifiers, use of a home air conditioner, and intactness of the heating and air conditioning system. Collect information about environmental allergies such as to dust, mold, pollen, mildew, seasonal allergies, as well as food allergies. Note the characteristics of any respiratory symptoms (e.g., seasonally induced, exercise- or stress-induced) and any family history of respiratory diseases. Identify any environmental exposures, such as to chemicals or irritants, as well as precipitating and alleviating factors for any respiratory symptoms and/or disease processes. Assess smoking habits because smoking exacerbates respiratory symptoms, and nicotine interacts with many respiratory drugs.

Cardiac status may be compromised due to respiratory distress and respiratory illnesses; thus closely assess the patient's blood pressure, pulse rate, heart sounds, and electrocardiogram, as ordered. Blood gas analysis may be indicated with attention to the patient's pH, oxygen, carbon dioxide, and serum bicarbonate levels. Assess nail beds for abnormalities (e.g., clubbing, cyanosis) and the area around the lips for cyanotic changes. Restlessness is often the first sign of hypoxia, so frequent assessment before, during, and after drug treatment is needed. If hypoxia present, it needs to be reported to the prescriber. If chest radiographs, scans, or magnetic resonance images have been ordered, review the findings. Along with a physical assessment, perform a psychosocial and emotional assessment, because anxiety, stress, and fear may only further compromise the patient's respiratory status and oxygen levels. Be sure to note the age of

the patient because of increased drug sensitivity in the very young and the elderly.

For the *beta agonists* (e.g., albuterol and salmeterol), cautions, contraindications, and drug interactions associated with these drugs must be noted. A respiratory assessment is needed to assess for allergies to the fluorocarbon propellant in inhaled dosage forms. Assess for the contraindications in patients with dysrhythmias and those at risk for stroke. Assess the patient's intake of caffeine (e.g., chocolate, tea, coffee, candy, and sodas) and use of OTC medications containing caffeine (e.g., appetite suppressants, pain relievers). The intake of caffeine is important to determine, because of its sympathomimetic effects and possible potentiation of adverse effects along with albuterol and other beta agonists (e.g., restlessness, cardiac stimulation, tremor, hyperglycemia and vascular headache; hypotension/hypertension with $beta_2$ drugs). Assess the patient's medication history because these drugs are not to be taken with monoamine oxidase inhibitors because of the enhanced risk for hypertension. Assess educational level and readiness to learn.

With use of the nonselective adrenergic agonist drug EpiPen (0.3 mg epinephrine) or EpiPen Jr (0.15 mg epinephrine) Auto-Injectors, assess for the main indication (which is emergency use with severe allergic reactions caused by allergens, exercise, and unknown triggers) and for those individuals who are considered at increased risk for these reactions.

Specific to the use of *anticholinergics* is the need to assess for allergies to atropine, soy lecithin, peanut oils, peanuts, soybeans, and other legumes, as there have been reported cases of severe anaphylactic reactions to ipratropium inhalers in patients with these type of allergies. In your assessments for patients taking anticholinergics, include any history of heart palpitations, GI distress, benign prostatic hyperplasia and/or urinary retention, and glaucoma due to the adverse effects of the drugs, leading to potentiation of these conditions or symptoms. Ipratropium and its aerosol forms have been associated with bronchospasm, so assess for any preexisting problems with the use of MDIs. If a combination product containing both ipratropium and albuterol is prescribed, perform an assessment appropriate to the use of both of these drugs.

In patients taking *xanthine derivatives* (e.g., theophylline), identify any contraindications and cautions. Perform a careful cardiovascular assessment, noting heart rate, blood pressure, and history of cardiac disease. This is important because of the adverse effects of sinus tachycardia and palpitations. GI reflux may also occur with these drugs. Assess bowel patterns and for preexisting disease, such as gastroesophageal reflux and/or ulcers. Because of possible drug-induced transient urinary frequency, conduct a baseline assessment of urinary patterns. Assessment needs to also include the patient's medication history to assess for possible drug interactions such as with allopurinol, cimetidine, erythromycin, ciprofloxacin, oral contraceptives, caffeine, and sympathomimetics. Perform a dietary assessment, including questions about consumption of a low-carbohydrate, high-protein diet and intake of charcoal-broiled meat. These dietary practices may lead to increased theophylline elimination and decrease the therapeutic levels of the drug. Note caffeine-containing foods, beverages, prescription drugs, OTC drugs, and herbals because of additional interactions.

With *LTRAs,* assess for contraindications, cautions, and drug interactions. Determine liver functioning because of specific concerns about the use of these drugs in patients with altered hepatic function. As with other medications, elderly patients are more sensitive to these drugs.

PATIENT-CENTERED-CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

Xanthine Derivatives

- Administer xanthine derivatives cautiously with careful monitoring in the elderly because sensitivity to these drugs is increased in this patient population due to decreased drug metabolism.
- Assess for signs and symptoms of xanthine toxicity, which include nausea, vomiting, restlessness, insomnia, irritability, and tremors. Discriminating the cause of restlessness (e.g., hypoxia versus drug toxicity) is important to patient safety.
- Instruct elderly patients to never chew or crush sustained-released dosage forms and to remain aware of drug interactions, especially interactions with other asthma-related drugs/bronchodilators. Advise elderly patients to avoid omitting and/or doubling up on doses. If a dose is missed, the prescriber must be contacted for further instructions.
- Monitoring of serum levels during follow-up visits is important to avoid possible toxicity and ensure therapeutic blood levels.
- Lower dosages may be necessary initially in elderly patients, not only because of their increased sensitivity to the drug but also because of the possibility of decreased liver and renal functioning. Close monitoring for adverse effects and toxicity should be part of everyday therapy. Note and report any palpitations and increased blood pressure (from cardiovascular and central nervous system stimulation).

With *corticosteroids* (also known as *glucocorticoids*), perform a baseline assessment of vital signs, breath sounds, and heart sounds. Assessment for underlying adrenal disorders is important because of the adrenal suppression that occurs with the use of these medications. Age is important to consider because corticosteroids may be problematic for the pediatric patient if long-term therapy and/or high dosage amounts are used. The systemic impact on the pediatric patient is suppressed growth (see the Pharmacology Overview section for further discussion). As with the other drugs in this chapter, awareness of basic information about these drugs, especially their action, is very important for safe use and prevention of medication errors. For example, glucocorticoids are used for their antiinflammatory effects, beta agonists and xanthines for their bronchodilating effects, and anticholinergics for their blockage of cholinergic receptors. Knowing what drugs do and why they are used helps to prevent or decrease medication errors and adverse effects. Significant drug interactions to assess for, especially with systemic versus inhaled corticosteroids, include antidiabetic drugs, antifungals, phenytoin, phenobarbital, rifampin, and

potassium-sparing diuretics. See Chapter 33 for more information on these antiinflammatory adrenal drugs.

With the *PDE4 inhibitors,* assess for presenting symptoms as well as any baseline psychiatric issues or disorders. Note that these drugs are not for acute bronchospasms. Omalizumab, a *monoclonal antibody antiasthmatic drug,* requires additional assessment of known risks associated with certain malignancies. Taking a thorough nursing history will help identify any of these risks. Assess also for signs and symptoms of hypersensitivity due to an increased incidence.

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Oral Ingestion of Capsules for Inhalation Devices

Some inhalation products use capsules and a device that pierces the capsules to allow the powdered medication to be inhaled with a special inhaler. Two products, Foradil Aerolizer (formoterol fumarate inhalation powder) and Spiriva HandiHaler (tiotropium bromide inhalation powder) contain such capsules. Even though these capsules are packaged with inhaler devices, they closely resemble oral capsules. The U.S. Food and Drug Administration (FDA) has received reports that the capsules have been taken orally by patients, which can potentially result in adverse effects. If the capsules are swallowed instead of taken using the inhalation device, the medication's onset of action may be delayed, the efficacy is reduced, and as a result the patient receives inadequate drug delivery. The FDA has taken steps to work with the drug manufacturers to mark the packaging clearly. Be certain to instruct patients on the proper use and correct route of administration for these inhaled drugs to prevent their confusion with oral products.

Data from FDA: Public health advisory: important information on the correct use of Spiriva and Foradil capsules, 2008, available at www.fda.gov/Drugs/DrugSafety/PostmarketDrugSafetyInformationforPatientsandProviders/DrugSafetyInformationforHeathcareProfessionals/PublicHealthAdvisories/ucm051132.html. Accessed March 13, 2012.

NURSING DIAGNOSES

1. Impaired gas exchange related to pathophysiologic changes caused by respiratory disease
2. Fatigue related to the disease process and lack of oxygen saturation
3. Noncompliance with the medication regimen related to undesirable adverse effects of drug therapy

PLANNING

GOALS

1. Patient experiences improved gas exchange due to improved disease process and symptomatology.
2. Patient exhibits improved energy and less fatigue.
3. Patient remains compliant with the medication regimen and with the nonpharmacologic therapies.

OUTCOME CRITERIA

1. Patient briefly describes measures to improve gas exchange such as use of deep breathing, use of medications as described, and avoiding precipitating factors.
   - Patient shows evidence of improved oxygen levels with an SpO_2 greater than or equal to 95% (depending on pathology).
2. Patient is well rested and allows time for frequent rest periods during activities of daily living while minimizing oxygen demands.
3. Patient states the importance of taking the medication as prescribed, the reasons for not increasing or decreasing the dosage of the drug, and the importance of not stopping the drug therapy abruptly to prevent complications and exacerbations of the disease.
   - Patient takes medication(s) as prescribed to improve oxygenation and prevent exacerbation of symptoms.

IMPLEMENTATION

Nursing interventions that apply to patients with respiratory disease processes (e.g., COPD, asthma, other upper and lower respiratory tract disorders) include patient education and an emphasis on compliance and prevention, in addition to the specific actions related to the prescribed drug therapy. Emphasize measures that help to prevent, relieve, or decrease the manifestations of the disease. A resource that provides excellent information as well as photographs and slideshows can be found at http://www.medicinenet.com/asthma.

Bronchodilators and other respiratory drugs must be given exactly as prescribed and by the prescribed route (e.g., parenterally, orally, by intermittent positive pressure breathing, or by inhalation). Demonstrate the proper method for administering the inhaled forms of these drugs to the patient (see Chapter 9). Provide time for a return demonstration. Emphasize the importance of taking only the prescribed dose of the *beta agonists, anticholinergics, xanthines, LTRAs,* and *other respiratory drugs* because of the possible adverse effects, such as cardiac stimulation, hypertension or hypotension, vascular headaches, heart palpitations, GI distress, urinary retention, gastroesophageal reflux, dysrhythmias, nausea, and dizziness.

The use of MDIs requires coordination to inhale the medication correctly and to obtain approximately 10% of drug delivery to the lungs. If a second puff of the same drug is ordered, instruct the patient to wait 1 to 2 minutes between puffs. If a second type of inhaled drug is ordered, instruct the patient to wait 2 to 5 minutes between the medications or to take as prescribed. Use of a spacer may be indicated to increase the amount of drug delivered. See the Teamwork and Collaboration: Legal and Ethical Principles box for information concerning the environmental hazards associated with MDIs. Dry powder inhalers are small handheld devices that deliver a specific amount of dry micronized powder with each inhaled breath. A nebulizer dosage form delivers small amounts of misted droplets of the drug to the lungs through a small mouthpiece or mask. Although a nebulizer may take a longer time to deliver the drug to the lungs than the inhalers, the nebulizer dosage form may be more effective for some patients. See Chapter 9 for more information on these dosage routes.

TEAMWORK AND COLLABORATION: LEGAL AND ETHICAL PRINCIPLES

Inhaled Medications and the Environment

A method of delivery or route of administration for inhalers poses concern for the environment. These inhaled medications are often used by people who have asthma or other breathing problems, such as chronic obstructive pulmonary disease. Traditionally, many inhalers have contained chlorofluorocarbons (CFCs), a propellant that damages the protective ozone layer. However, these CFC inhalers are being phased out and replaced with more environmentally friendly inhalers. Depending on the specific type of product being used and where one lives geographically, inhalers and aerosol products may be thrown into household trash or recyclables, or may be considered hazardous waste and require special handling. Read the handling instructions on the label, as some inhalers should not be punctured or thrown into a fire or incinerator. To ensure safe disposal, contact your local trash and recycling facility. For more information, visit www.fda.gov.

Modified from the U.S. Food and Drug Administration: How to dispose of unused medications, *FDA Consumer Updates,* April 14, 2011, available at www.fda.gov/forconsumers/consumerupdates/ucm101653.htm. Accessed March 13, 2012.

Beta agonists must be taken exactly as prescribed because overdosage may be life-threatening. Educate patients not to crush or chew oral sustained-release tablets and to take them with food to decrease GI upset. Instructions for inhaled dosage forms are presented in Chapter 9. See Figure 37-2 for instructions for use of the EpiPen Auto-Injector. Reassess the respiratory status and breath sounds before, during, and after therapy with these drugs to determine therapeutic effectiveness.

Anticholinergic drugs used for respiratory diseases (e.g., ipratropium) are to be taken daily as ordered and with appropriate use of the MDI. See the Patient Teaching Tips for more information on the administration of these drugs. It is important that the patient waits from 1 to 2 minutes (or as prescribed) before inhaling the second dose of the drug to allow for maximal lung penetration. Encourage rinsing the mouth with water immediately after use of any inhaled or nebulized drug to help prevent mucosal irritation and dryness.

Xanthine derivatives are also to be given exactly as prescribed. If they are to be administered parenterally, determine the correct diluent, compatibility, and rate of administration. Use intravenous infusion pumps to ensure dosage accuracy and help prevent toxicity. Too rapid an infusion may lead to profound hypotension with possible syncope, tachycardia, seizures, and even cardiac arrest. Oral forms are to be taken with food to decrease GI upset. To prevent a sudden increase in drug release and irritating effects on the gastric mucosa, instruct patients not to crush or chew timed-release preparations. Educate patients that suppository forms of the drug need to be refrigerated, and to notify the prescriber if rectal burning, itching, or irritation occurs. Continue to monitor the patient for respiratory status and improvement in baseline condition during drug therapy.

The *LTRAs,* specifically zileuton, montelukast, and zafirlukast, are given orally. Of most concern are the montelukast chewable tablets, which contain aspartame and approximately 0.842 mg of phenylamine per 5-mg tablet. Some patients may need to avoid these substances. Emphasize that these drugs are indicated for treatment of chronic, not acute, asthma attacks. Stress that these drugs are to be taken as ordered and on a continuous schedule, even if symptoms improve. Increase fluid intake, as with all the respiratory drugs, to help in decreasing the viscosity of secretions.

Inhaled *corticosteroids* (glucocorticoids) are yet another group of drugs that must be used as prescribed and with cautions regarding overuse. Advise the patient to take the medication as ordered every day, regardless of whether or not he or she is feeling better. Often these drugs (e.g., flunisolide) are used as maintenance drugs and are taken twice daily for maximal response. An inhaled $beta_2$ agonist may be used before the inhaled corticosteroid to provide bronchodilation before administration of the antiinflammatory drug. The bronchodilator inhaled drug is generally taken 2 to 5 minutes (or as ordered) before the corticosteroid aerosol. Stress the importance of keeping all equipment (inhalers or nebulizers) clean, cleaning and changing filters (nebulizers), and maintaining it in good working condition. Use of a spacer may be indicated, especially if success with inhalation is limited. Recommend rinsing the mouth immediately after use of the inhaler or nebulizer dosage forms of corticosteroids to help prevent overgrowth of oral fungi and subsequent development of oral candidiasis (thrush). Pediatric patients may need a prescriber's order to have these medications on hand, at school, and during athletic events or physical education. Peak flow meter use is also encouraged to help patients of all ages better regulate their disease. A peak flow meter is a handheld device used to monitor a patient's ability to breath out air and reflects the airflow through the bronchi and thus the degree of obstruction in the airways. Encourage journaling to record peak flow levels, signs and symptoms of the disease, any improvement, and the occurrence of adverse effects associated with therapy. For pediatric patients, use of systemic forms of corticosteroids is a concern. Specifically in children, the use of systemic forms of these drugs may lead to suppression of the hypothalamic-pituitary-adrenal axis and subsequent growth stunting. However, the benefits are considerable when compared to the risks. Inhaled forms are often combined with short-term systemic therapy in pediatric patients. Continue to monitor the patient's condition during therapy with a focus on the respiratory, cardiac, and central nervous systems.

With *PDE4 inhibitor drugs*, educate the patient about the importance of reporting any change in psychiatric status to the prescriber immediately. The *monoclonal antibody antiasthmatic drug* omalizumab is to be taken exactly as ordered. Since it is given as a subcutaneous injection, instruct the patient in self-injection, or alert the patient that frequent visits to the prescriber, nurse, or other health care provider to receive the injection are necessary. This drug is usually given every 2 to 4 weeks. Omalizumab is not indicated for acute asthma attacks, and it may be used in conjunction with other acute-acting asthma medications. Closely monitor the patient for any allergic or hypersensitivity reactions.

EVALUATION

The therapeutic effects of any of the drugs used to improve the control of acute or chronic respiratory diseases and to

treat or help prevent respiratory symptoms include the following: decreased dyspnea, wheezing, restlessness, and anxiety; improved respiratory patterns with return to normal rate and quality; improved oxygen saturation levels; improved activity tolerance and arterial blood gas levels; improved quality of life; and decreased severity and incidence of respiratory symptoms. The therapeutic effects of *bronchodilators* (e.g., *xanthines, beta agonists*) include decreased symptoms and increased ease of breathing. Blood levels of theophylline need to be between 5 and 15 mcg/mL and need to be frequently monitored. Peak flow meters are easy to use and help reveal early decreases in peak flow caused by bronchospasm. They also aid in monitoring treatment effectiveness. Other respiratory drugs produce therapeutic effects as related to the specific drug. Adverse effects for which to monitor during therapy include the following: *beta agonists*—headache, insomnia, cardiac stimulation, and tremor; *anticholinergics*—headache, GI distress, urinary retention, and increased intraocular pressure; *xanthines*—nausea, vomiting, or palpitations; *LTRAs*—dyspepsia, headaches, and insomnia; and *corticosteroids*—adrenocortical insufficiency, increased susceptibility to infection, fluid and electrolyte disturbances, and insomnia. With corticosteroids, adrenal suppression may occur with high doses for an extended period of time. See the previous discussion for a complete listing of adverse effects.

PATIENT TEACHING TIPS

Beta Agonists

- Educate the patient about any potential drug interactions.
- Encourage patients with asthma, bronchitis, or COPD to avoid precipitating events such as exposure to conditions or situations that may lead to bronchoconstriction and/or worsening of the disorder (e.g., allergens, stress, smoking, and/or air pollutants).
- Provide instructions about the proper use and care of MDIs, dry powder inhalers, and other such devices. See Chapter 9 for more specific information.
- Emphasize the importance of not overusing the medication due to the risk of rebound bronchospasm.

Xanthines

- Educate the patient about the interaction between smoking and xanthines (e.g., smoking decreases the blood concentrations of aminophylline and theophylline). Xanthines also interact with charcoal-broiled foods and may lead to decreased serum levels of xanthine drugs.
- Instruct patients about food and beverage items that contain caffeine (e.g., chocolate, coffee, cola, cocoa, tea), because their consumption can exacerbate CNS stimulation.
- Encourage the patient that he or she needs to take medications around the clock to maintain steady-state drug levels. Extended-released dosage forms and other oral dosage forms are not to be crushed or chewed. Advise patients that any worsening of adverse effects, such as epigastric pain, nausea, vomiting, tremors, and headache, must be reported immediately.
- Encourage the patient to keep follow-up appointments because of the importance in monitoring therapeutic levels of medications and therapeutic effectiveness.
- Some patients may need to learn to take their own pulse rate. Demonstrate proper technique.

Anticholinergics

- Educate patients that ipratropium is used prophylactically to decrease the frequency and severity of asthma and must be taken as ordered and generally year round for therapeutic effectiveness. This drug must be avoided in patients with existing allergy to soybeans, peanuts, or other legumes.
- Encourage forcing fluids, unless contraindicated, to decrease the viscosity of secretions and increase the expectoration of sputum.
- When inhaled forms of these drugs (and other respiratory drugs) are used, instruct the patient to take the prescribed number of puffs of the inhaler and no more than two puffs with one dosing or as ordered. Educate the patient about how to properly use an MDI with or without a spacer, how to use a dry powder inhaler, and how to properly clean and store the equipment (see Chapter 9). Instruct the patient to wait 2 to 5 minutes (or as prescribed) before using additional different inhaled medications.

Leukotriene Receptor Antagonists

- Educate the patient about the action and purpose of LTRAs and how they work differently by preventing leukotriene formation and thus preventing/decreasing inflammation, bronchoconstriction, and mucus production. Emphasize that these drugs are indicated for prevention, not treatment, of acute asthmatic attacks.

Corticosteroids (Glucocorticoids)

- In addition to adhering to the specified dose and frequency of these drugs, if inhaled forms are used, the patient must practice good oral hygiene (e.g., rinsing of the mouth) after the last inhalation. Rinsing the mouth with water is appropriate and necessary to prevent oral fungal infections. Instruct the patient about keeping the inhaler clean, including weekly removing of the canister from the plastic casing and washing the casing in warm, soapy water. Once the casing is dry, the canister and mouthpiece may be put back together and the cap applied. The glucocorticoid may predispose the patient to oral fungal overgrowth. Provide implicit instructions for mouth care after each use and for the cleaning of inhaled devices.
- Instruct the patient to keep track of the doses left in the MDI. Many inhalers have built-in counters, but if not, the patient can do the following: Divide the number of doses in the canister by

PATIENT TEACHING TIPS—cont'd

the number of puffs used per day. For example, assume that two puffs are taken four times a day, and the inhaler has a capacity of 200 inhalations. Two puffs four times a day equals eight inhalations per day. Eight divided into 200 yields 25; that is, the inhaler will last approximately 25 days. The MDI may then be marked with the date it will be empty and a refill obtained a few days before that date. Note that using extra doses will alter the refill date. Advise the patient to always check expiration dates.

- Stress the importance of journaling, which should include notation of how the patient feels, medications being taken, adverse effects, and precipitators/alleviators/symptoms of the asthma/illness.
- Counsel the patient to wear a medical alert bracelet or necklace at all times and to keep a medical card with the diagnoses and list of medications and allergies on his or her person at all times. Emergency contact persons and phone numbers must also be listed.
- With intranasal dosage forms, instruct the patient to clear nasal passages before administration. The patient needs to tilt his or her head slightly forward and insert the spray tip into one nostril and point toward the inflamed nasal turbinates. Instruct the patient to pump the medication into the nasal passage as the patient sniffs inward while holding the other nostril closed. This procedure may then be repeated in the other nostril. It is recommended to discard any unused portion after 3 months or by the expiration date.
- Educate the patient about the fact that excess levels of systemic corticosteroids may lead to Cushing's syndrome with symptoms such as moon face, acne, an increase in fat pads, and swelling. Although use of inhaled forms helps to minimize this problem, education about it remains important to patient safety. As noted previously, the risk of occurrence of these signs and symptoms is higher when these drugs are given systemically (e.g., oral or parenteral dosage forms).
- Educate the patient about the possibility of Addisonian crisis, which may occur if a systemic corticosteroid is abruptly discontinued. These drugs require weaning prior to discontinuation of the medication. Addisonian crisis may be manifested by nausea, shortness of breath, joint pain, weakness, and fatigue, and the patient must contact the prescriber immediately if these occur.
- Educate the patient about the importance of reporting to the prescriber any weight gain of 2 pounds or more in 24 hours or 5 pounds or more in 1 week.

Phosphodiesterase-4 Inhibitor

- Emphasize that the patient report any change in mood or emotions to the prescriber immediately.

Monoclonal Antibody Antiasthmatic Drugs

- Omalizumab is used for the treatment of moderate to severe asthma and not for aborting acute asthma attacks. The patient needs to provide return demonstrations of subcutaneous injection techniques. Instruct the patient to keep medications and needles, syringes, and other equipment out of the reach of children and to use puncture-proof needle waste containers. Each needle is used for only one injection.

KEY POINTS

- The beta agonists stimulate $beta_1$ and $beta_2$ receptors. The $beta_2$ agonists are specific for the lungs.
- Xanthines, such as theophylline, help to relax the smooth muscles of the bronchioles by inhibiting phosphodiesterase. Phosphodiesterase breaks down cAMP, which is needed to relax smooth muscles.
- Anticholinergic drugs are used for maintenance and not for relief of acute bronchospasm and work by blocking the bronchoconstrictive effects of ACh.
- Corticosteroids (e.g., beclomethasone, dexamethasone, flunisolide, triamcinolone) have many indications and work by stabilizing the membranes of cells that release harmful bronchoconstricting substances.
- The LTRAs, such as zileuton and zafirlukast, are given orally. Adverse effects include headache, dizziness, insomnia, and dyspepsia.
- Omalizumab, a monoclonal antibody antiasthmatic drug, works by preventing the release of mediators that lead to allergic responses. It is given for preventative purposes.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A patient who has a history of asthma is experiencing an acute episode of shortness of breath and needs to take a medication for immediate relief. The nurse will choose which medication that is appropriate for this situation?
   - **a** A beta agonist, such as albuterol
   - **b** An leukotriene receptor antagonist, such as montelukast
   - **c** A corticosteroid, such as fluticasone
   - **d** An anticholinergic, such as ipratropium

2 After a nebulizer treatment with the beta agonist albuterol, the patient complains of feeling a little "shaky," with slight tremors of the hands. The patient's heart rate is 98 beats/min, increased from the pretreatment rate of 88 beats/min. The nurse knows that this reaction is an
   - **a** expected adverse effect of the medication.
   - **b** allergic reaction to the medication.

NCLEX® EXAMINATION REVIEW QUESTIONS—cont'd

c indication that he has received an overdose of the medication.
d idiosyncratic reaction to the medication.

3 A patient has been receiving an aminophylline (xanthine derivative) infusion for 24 hours. The nurse will assess for which adverse effect when assessing the patient during the infusion?
a CNS depression
b Sinus tachycardia
c Increased appetite
d Temporary urinary retention

4 During a teaching session for a patient who will be receiving a new prescription for the LTRA montelukast (Singulair), the nurse will tell the patient that the drug has which therapeutic effect?
a Improves the respiratory drive
b Loosens and removes thickened secretions
c Reduces inflammation in the airway
d Stimulates immediate bronchodilation

5 After the patient takes a dose of an inhaled corticosteroid, such as fluticasone (Flovent), what is the most important action the patient needs to do next?
a Hold the breath for 60 seconds.
b Rinse out the mouth with water.
c Follow the corticosteroid with a bronchodilator inhaler, if ordered.
d Repeat the dose in 15 minutes if the patient feels short of breath.

6 The nurse is teaching a patient about the inhaler Advair (salmeterol/fluticasone). Which statements by the patient indicate a correct understanding of this medication? Select all that apply.
a "I will rinse my mouth with water after each dose."
b "I need to use this inhaler whenever I feel short of breath, but not less than 4 hours between doses."
c "This medication is taken twice a day, every 12 hours."
d "I can take this inhaler if I get short of breath while exercising."
e "I will call my doctor if I notice white patches inside my mouth."

7 A patient has been given an MDI of albuterol and is instructed to take two puffs three times a day, with doses 6 hours apart. The inhaler contains 200 actuations, but does not have a dose counter. Calculate how many days the inhaler will deliver this ordered dose.

puffs/day divided into 200)

1. a, 2. a, 3. b, 4. c, 5. b, 6. a, c, e, 7. Approximately 33 days (6

PART 7

Antiinfective and Antiinflammatory Drugs

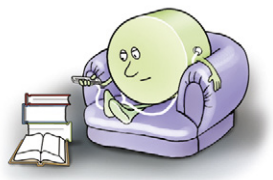
STUDY SKILLS TIPS

Nursing Process • Assessment • Nursing Diagnoses • Evaluation

NURSING PROCESS

This study model focuses on the Nursing Process section in Chapter 38. Since there is a Nursing Process section at the end of each chapter, the discussion of the example in Chapter 38 is applicable to all chapters.

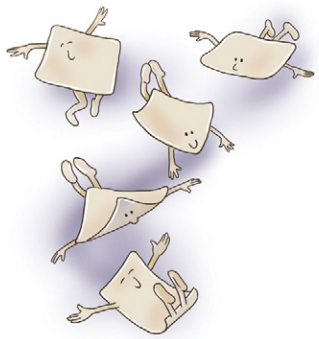
ASSESSMENT



What is the purpose of this section? Each time you begin to read the Nursing Process section of a chapter, you need to ask this question. What are you supposed to learn? What are you supposed to know? What are you supposed to be able to do? All these questions relate to your role as a nurse. Consider the following sentence from this section in Chapter 38.

> *In general, before the administration of any antibiotic, it is crucial to gather data regarding a history of or symptoms indicative of hypersensitivity or allergic reactions (from mild reactions with rash, pruritus, or hives to severe reactions with laryngeal edema, bronchospasm, hypotension, and possible cardiac arrest).*

Assessment clearly has to do with patient care. You are assessing the patient in relation to the pharmacologic interventions that this chapter discusses.



Notice the use of the word *crucial* in the first line. Something is so important at this point that it cannot be ignored. Immediately the questioning process should be activated. What is crucial? The answer follows immediately in the sentence. You must assess for history of or symptoms indicative of hypersensitivity or allergic reactions. The sentence goes on to identify the kind of data that should be available, and the sentence makes it clear that these data must be obtained *before the administration* of any drug. Each of the data factors is important, and each relates to other parts and chapters in this text. The next item to notice is hypersensitivity. Some individuals are *allergic* to certain antibiotics. It would be dangerous and possibly fatal, however, to administer an antibiotic to a patient if he or she is hypersensitive.

Another data item specifies *rash, pruritus, or hives* and *laryngeal edema, bronchospasms, hypotension, and possible cardiac arrest.* As you read this,

you should instantly think of the reactions to which they refer. Then you should try to recall information from this chapter that related the specific antibiotics to these reactions. Learning is cumulative. The Nursing Process section assumes you have read and understood what was presented earlier in the chapter.

Often you will encounter standard medical abbreviations. As you read on in the Assessment section, you find this sentence:

> *Also determine the patient's age, weight, and baseline vital signs with body temperature. Examine the results of any laboratory tests that have been ordered, such as liver function studies (AST and ALT levels), kidney function studies (usually BUN and creatinine levels), cardiac function studies (pertinent laboratory tests, electrocardiogram), ultrasonography (if indicated), culture and sensitivity tests, CBC, and platelet and clotting tests.*

In earlier Study Skills Tips, it has been suggested that you prepare vocabulary cards for these abbreviations to help you in a situation such as this. When you see abbreviations such as AST, ALT, BUN, and CBC, you may refer to the Abbreviations for Diagnostic and Laboratory Tests table on the inside back cover of this text. However, you need to know what these abbreviations mean, what they measure, and how they relate to appropriate and effective administration of antibiotics. If these letters are not meaningful to you, then you will not be able to link what you know about the antibiotics with what you must know about administering them as a nurse. Many test questions on nursing examinations use the standard abbreviations, and you must know them instantly and be able to relate them to the situation covered. As you look at antibiotic administration and CBC, think what a test question might ask about this data element in a real application in patient care. This is what the nursing process is all about.

NURSING DIAGNOSES

The same first question applies here as in every other section. What am I supposed to learn? Since the focus is on administration of antibiotics, the expectation you should bring to this is an awareness of your role in diagnosis. What should you look for in working with patients that affects the administration of antibiotics?

This same procedure should be applied to the Planning, Goals, Outcome Criteria, and Implementation sections. Consider what each of these headings suggests about the nursing process, and read and evaluate the information, relating it to what you have already learned. Also consider the implications of the information as possible test questions that may ask you to do more than recall specific facts. As an example, consider the following case:

> *Patient A, age 23, has bronchitis and a fever of 100.8° F (38.2° C). She was admitted yesterday and delivered a healthy infant 8 hours ago. She is breastfeeding the newborn. What antibiotics might be administered for the bronchitis? What specific antibiotics should be used with caution or eliminated from consideration?*

This case demonstrates the need to read and think critically. Not only do you need to remember the specific facts from the chapter, but you should also be able to take a case study example and apply those facts to that specific situation.

EVALUATION

Evaluation is the final section under Nursing Process. What are you supposed to evaluate?

> *Include monitoring of goals, outcome criteria, therapeutic effects, and adverse effects in the evaluation. Therapeutic effects of antibiotics include a decrease in the signs and symptoms of the infection; a return to normal vital signs, including temperature; negative results on culture and sensitivity tests; normal results for CBC; and improved appetite, energy level, and sense of well-being. Evaluation for adverse effects includes monitoring for specific drug-related adverse effects (see each drug profile).*

First you should look for the positive responses (therapeutic effects) set forth in the preceding text sample that indicate the patient is responding favorably to the treatment. However, then you read, "Evaluation for adverse effects includes…." This says that part of your role in evaluation is to monitor the patient for negative responses and be prepared to educate the patient about the effects he or she is experiencing and possible steps to help alleviate the symptoms.

The Nursing Process section in each chapter should be read carefully and thoughtfully, because it is in this section where you begin to see how the complex pharmacologic material presented earlier in the chapter fits into your role as a nurse. This material should be read with the same concern and care that you have given to the highly complex material earlier in the chapter, because this is the section in which you must think about *application* of all you have learned. Your thinking process may be stimulated when you review this section with your study group. Each person brings his or her understanding and experience to the discussion. The insights can be richer and the learning more complete as you exchange ideas. Apply the PURR model with a study group or alone and be an active questioner and reader, and you will be successful in working with the Nursing Process section in each chapter.

- Review Questions for the NCLEX® Examination
- Unfolding Case Studies

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the general principles of antibiotic therapy.
2 Explain how antibiotics work to rid the body of infection.
3 Briefly compare the characteristics and uses of antiseptics and disinfectants.
4 List the most commonly used antiseptics and disinfectants.
5 Discuss any nursing-related considerations associated with the environmental use of antiseptics and disinfectants.
6 Discuss the pros and cons of antibiotic use with attention to the overuse or abuse of antibiotics and the development of drug resistance.
7 Classify the various antibiotics by general category, including sulfonamides, penicillins, cephalosporins, macrolides, and tetracyclines.
8 Discuss the mechanisms of action, indications, cautions, contraindications, routes of administration, and drug interactions for the sulfonamides, penicillins, cephalosporins, macrolides, and tetracyclines.
9 Identify drug-specific adverse effects and toxic effects of each of the antibiotic classes listed earlier, and cite measures to decrease their occurrence.
10 Briefly discuss superinfection, including its etiology and prevention.
11 Develop a nursing care plan that includes all phases of the nursing process for patients receiving drugs in each of the following classes of antibiotic: sulfonamides, penicillins, cephalosporins, macrolides, and tetracyclines.

KEY TERMS

Antibiotic Having the ability to destroy or interfere with the development of a living organism. The term is used most commonly to refer to antibacterial drugs. (p. 611)

Antiseptic One of two types of topical antimicrobial agents; a chemical that inhibits the growth and reproduction of microorganisms without necessarily killing them. Antiseptics are also called *static agents*. (p. 612)

Bactericidal antibiotics Antibiotics that kill bacteria. (p. 616)

Bacteriostatic antibiotics Antibiotics that do not actually kill bacteria but rather inhibit their growth. (p. 614)

Beta-lactam The designation for a broad class of antibiotics that includes four subclasses: penicillins, cephalosporins, carbapenems, and monobactams; so named because of the beta-lactam ring that is part of the chemical structure of all drugs in this class. (p. 616)

Beta-lactamase Any of a group of enzymes produced by bacteria that catalyze the chemical opening of the crucial beta-lactam ring structures in beta-lactam antibiotics. (p. 616)

Beta-lactamase inhibitors Medications combined with certain penicillin drugs to block the effect of beta-lactamase enzymes. (p. 616)

Colonization The establishment and growth of microorganisms on the skin, open wounds, or mucous membranes, or in secretions without causing an infection. (p. 611)

Community-associated infection An infection that is acquired by persons who have not been hospitalized or had a medical procedure recently. (p. 611)

Definitive therapy The administration of antibiotics based on known results of culture and sensitivity testing identifying the pathogen causing infection. (p. 612)

Disinfectant One of two types of topical antimicrobial agents; a chemical applied to nonliving objects to kill microorganisms. Also called *cidal agents*. (p. 612)

Empiric therapy The administration of antibiotics based on the practitioner's judgment of the pathogens most likely to be causing an apparent infection; it involves the presumptive treatment of an infection to avoid treatment delay before specific culture information has been obtained. (p. 612)

Glucose-6-phosphate dehydrogenase (G6PD) deficiency An inherited disorder in which the red blood cells are partially or completely deficient in glucose-6-phosphate dehydrogenase, a critical enzyme in the metabolism of glucose. Certain medications can cause hemolytic anemia in patients with this disorder. This is an example of a host factor related to drug therapy. (p. 614)

Health care–associated infection An infection that is acquired during the course of receiving treatment for another condition in a health care facility. The infection is not present or incubating at the time of admission; also known as a *nosocomial infection*. (p. 611)

Host factors Factors that are unique to a particular patient that affect the patient's susceptibility to infection and response to various antibiotic drugs. Examples include a low neutrophil count or a lack of immunoglobulins in the blood that carry antibodies. (p. 613)

Infections Invasions and multiplications of microorganisms in body tissues. (p. 611)

Microorganisms Microscopic living organisms (also called *microbes*). (p. 610)

Prophylactic antibiotic therapy Antibiotics taken before anticipated exposure to an infectious organism in an effort to prevent the development of infection. (p. 612)

Pseudomembranous colitis A potentially-necrotizing inflammatory bowel condition that is often associated with antibiotic therapy; often caused by the bacteria *Clostridium difficile*. A more general term that is also used is *antibiotic-associated colitis*. (p. 613)

Slow acetylation A common genetic host factor in which the rate of metabolism of certain drugs is reduced. (p. 614)

Subtherapeutic Generally refers to blood levels below therapeutic levels due to insufficient dosing. Also refers to antibiotic treatment that is ineffective in treating a given infection. Possible causes include inappropriate drug therapy, insufficient drug dosing, and bacterial drug resistance. (p. 612)

Superinfection (1) An infection occurring during antimicrobial treatment for another infection, resulting from overgrowth of an organism not susceptible to the antibiotic used. (2) A secondary microbial infection that occurs in addition to an earlier primary infection, often due to weakening of the patient's immune system function by the first infection. (p. 613)

Teratogens Substances that can interfere with normal prenatal development and cause one or more developmental abnormalities in the fetus. (p. 614)

Therapeutic Referring to antibiotic therapy that is given in sufficient doses so that the concentration of the drug in the blood or other tissues renders it effective against specific bacterial pathogens. (p. 612)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

MICROBIAL INFECTION

Microorganisms are everywhere, both in the external environment and in parts of the internal environment of our bodies. They can be harmful to humans, or they can be beneficial under normal circumstances but become harmful when conditions are altered in some way. A person is normally able to remain healthy and resistant to infectious **microorganisms** because of the existence of certain host defenses. These defenses include actual physical barriers, such as intact skin or the ciliated respiratory mucosa, or physiologic defenses, such as the gastric acid

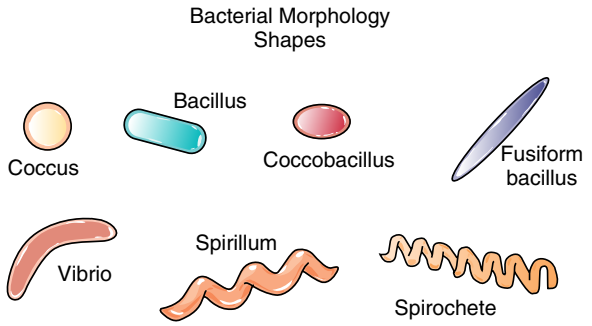

FIGURE 38-1 General morphology of bacteria. (From Murray PR, Rosenthal KS, Pfaller MA: *Medical microbiology,* ed 6, St Louis, 2009, Mosby.)

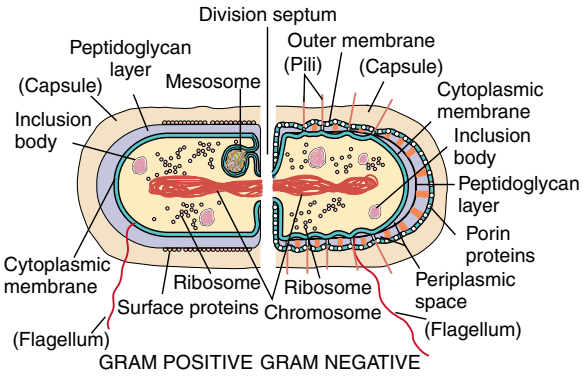

FIGURE 38-2 Gram-positive and gram-negative bacteria. A gram-positive bacterium has a thick layer of peptidoglycan *(left).* A gram-negative bacterium has a thin peptidoglycan layer and an outer membrane *(right).* Structures in parentheses are not found in all bacteria. (From Murray PR, Rosenthal KS, Pfaller MA: *Medical microbiology,* ed 6, St Louis, 2009, Mosby.)

in the stomach and immune factors such as antibodies. Other defenses are the phagocytic cells (macrophages and polymorphonuclear neutrophils) that are part of the mononuclear phagocyte system.

Every known major class of microbes contains organisms that can infect humans. This includes bacteria, viruses, fungi, and protozoans. The focus of this chapter is common bacterial **infections.**

Recall from microbiology that bacteria may take a number of different shapes. This property of bacteria is called their morphology (Figure 38-1), and they are often grouped based on this property. Bacteria may also be grouped according to other common recognizable characteristics. One of the most important ways of categorizing different bacteria is on the basis of their response to the Gram stain procedure. Bacterial species that stain purple with Gram staining are classified as *gram-positive* organisms. Bacteria that stain red are classified as *gram-negative* organisms. This seemingly simple difference proves to be very significant in guiding the choice of **antibiotic** therapy.

Gram-positive organisms have a very thick cell wall, known as peptidoglycan, and they also have a thick outer capsule. Gram-negative organisms have a cell wall structure that is more complex, with a smaller outer capsule and peptidoglycan layer and two cell membranes: an outer and an inner membrane (Figure 38-2). These differences usually make gram-negative bacterial infections more difficult to treat, because the drug molecules have a harder time penetrating the more complex cell walls of gram-negative organisms.

When the normal host defenses are somehow compromised, that person becomes susceptible to infection. The microorganisms invade and multiply in the body tissues, and if the infective process overwhelms the body's defense system, the infection becomes clinically apparent. The patient usually manifests some of the following classic signs and symptoms of infection: fever, chills, sweats, redness, pain and swelling, fatigue, weight loss, increased white blood cell (WBC) count, and the formation of pus. Not all patients will exhibit signs of the infection. This is especially true in elderly and immunocompromised patients.

To help the body and its normal host defenses combat an infection, antibiotic therapy is often required. Antibiotics are most effective when their actions are combined with functioning bodily defense mechanisms. Oftentimes patients will become colonized with bacteria. Although bacteria are present in open wounds, in secretions, on mucous membranes, or on the skin, these patients do not have any overt signs of infection. **Colonization** does not require antibiotic treatment. However, it is not uncommon for these colonizations to be treated, which may be one way in which drug-resistant organisms emerge.

Health Care–Associated Infection

A **community-associated infection** is defined as an infection that is acquired by a person who has not recently (within the past year) been hospitalized or had a medical procedure (e.g., dialysis, surgery, catheterization). A **health care–associated infection,** previously known as a *nosocomial infection,* is defined as an infection that a patient acquires during the course of receiving treatment for another condition in a health care facility. The infection was not present or incubating at the time of admission but occurs greater than 48 hours after admission. Health care–associated infections are one of the top ten leading causes of death in the United States. They tend to be more difficult to treat because the causative microorganisms have been exposed to strong antibiotics in the past and are the most drug resistant and the most virulent. The particular organisms that cause hospital-associated infections have changed over time, with methicillin-resistant *Staphylococcus aureus* (MRSA) now being the most common. Other serious pathogens include *Enterococcus, Klebsiella, Acinetobacter,* and *Pseudomonas aeruginosa.* Most of these microorganisms are now resistant to many of the commonly used antibiotics.

Health care–associated infections develop in approximately 10% of hospitalized patients, and the cost of treating these infections amounts to $4 to $11 billion annually. Most of these infections (70% or more) are either urinary tract infections (UTIs) or postoperative wound infections. Often they are acquired from various devices, such as mechanical ventilators, intravenous (IV) infusion lines, catheters, and dialysis equipment. Areas of the hospital associated with the greatest risk for acquiring a hospital-associated infection are the critical care, dialysis, oncology, transplant, and burn units. This is because the host

TABLE 38-1 ANTISEPTICS VERSUS DISINFECTANTS

	ANTISEPTICS	DISINFECTANTS
Where used	Living tissue	Nonliving objects
Potency	Lower	Higher
Activity against organisms	Primarily inhibits growth (bacteriostatic)	Kills (bactericidal)

defenses of the patients in these areas are typically compromised, which makes them more vulnerable to infection. Over 70% of hospital-associated infections are preventable. The most common mode of transmitting hospital-associated infections is by direct contact. Handwashing is the single most important thing health care professionals can do to prevent the spread of these potentially deadly infections. Because health care–associated infections cause numerous deaths and cost billions of dollars, The Joint Commission has made the prevention of health care associated–infections a national patient safety goal. In addition, they have added prevention of catheter-associated UTIs as a 2012 national patient safety goal.

Other methods of reducing hospital-associated infections include the use of disinfectants and antiseptics. A **disinfectant** is able to kill organisms and is used only on nonliving objects to destroy organisms that may be present. Disinfectants are sometimes called *cidal agents*. An **antiseptic** generally only inhibits the growth of microorganisms but does not necessarily kill them and is applied exclusively to living tissue. Antiseptics are also called *static agents*. The differences between antiseptics and disinfectants in a clinical sense are summarized in Table 38-1. Topical antimicrobial drugs are discussed further in Chapter 56.

PHARMACOLOGY OVERVIEW

The selection of antimicrobial drugs requires clinical judgment and detailed knowledge of pharmacologic and microbiologic factors. Antibiotics have three general uses: empiric therapy, definitive therapy, and prophylactic or preventative therapy. Antibiotic drug therapy begins with a clinical assessment of the patient to determine whether he or she has the common signs and symptoms of infection. The patient is assessed during and after antibiotic therapy to evaluate the effectiveness of the drug therapy, monitor for adverse drug effects, and make sure the infection is not recurring.

Often the signs and symptoms of an infection appear long before a causative organism can be identified. When this happens and the risk of life-threatening or severe complications is high (e.g., suspected acute meningitis), an antibiotic is given to the patient immediately. The antibiotic selected is one that can best kill the microorganisms known to be the most common causes of the infection. This is called **empiric therapy.** Before the start of empiric antibiotic therapy, specimens are obtained from suspected areas of infection to be cultured in an attempt to identify a causative organism. It must be emphasized that culture specimens must be obtained before drug therapy is initiated whenever possible. Otherwise, the presence of antibiotics in the tissues may result in misleading culture results. However, sometimes it is not possible to obtain a sample (especially sputum) in a reasonable amount of time, and antibiotic therapy is begun without a sample in that situation. If an organism is identified in the laboratory, it is then tested for susceptibility to various antibiotics. The results of these tests can confirm whether the empiric therapy chosen is appropriate for eradicating the organism identified. If not, therapy can be adjusted to optimize its efficacy against the specific infectious organism(s). Once the results of culture and sensitivity testing are available (usually in 48 to 72 hours), the antibiotic therapy is then tailored to treat the identified organism by using the most narrow-spectrum, least toxic drug based on sensitivity results. This is known as **definitive therapy.** Broad-spectrum antibiotics are those that are active against numerous organisms (gram-positive, gram-negative, and anaerobic). Narrow-spectrum antibiotics are effective against only a few organisms. Once the results of culture and sensitivity testing are available, it is always better to use an antibiotic that targets the specific organism identified (i.e., a narrow-spectrum antibiotic). Overuse of broad-spectrum antibiotics contributes to resistance. The goal of therapy is to use the most narrow-spectrum drug when possible based on sensitivity results.

Antibiotics are also given for prophylaxis. This is often the case when patients are scheduled to undergo a procedure (i.e., surgery) in which the likelihood of dangerous microbial contamination is high during or after the procedure. **Prophylactic antibiotic therapy** is used to prevent an infection. The risk of infection varies depending on the procedure being performed. For example, the risk of infection in a patient undergoing coronary artery bypass surgery (with standard preoperative cleansing of the body) is relatively low compared with that in a person undergoing intraabdominal surgery for the treatment of injuries sustained in a motor vehicle accident. In the latter case, contamination with bacteria from the gastrointestinal (GI) tract is more likely to be present in the abdominal cavity. This would constitute a contaminated or "dirty" surgical field, and therefore the likelihood of clinically serious infection would be much higher. Antibiotic therapy would likely be required for a longer period after the procedure. To be effective, prophylactic antibiotics need to be given before the procedure, generally 30 minutes before the incision to ensure adequate tissue penetration. The Surgical Care Improvement Project (SCIP) is a national performance improvement project that provides hospitals with evidence-based recommendations on the administration of prophylactic antibiotics. More information can be found at www.jointcommission.org/surgical_care_improvement_project/.

To optimize antibiotic therapy, the patient is continuously monitored for both **therapeutic** efficacy and adverse drug effects. A therapeutic response to antibiotics is one in which there is a decrease in the specific signs and symptoms of infection compared with the baseline findings (e.g., fever, elevated WBC count, redness, inflammation, drainage, pain). Antibiotic therapy is said to be **subtherapeutic** when these signs and symptoms do not improve. This can result from use of an

incorrect route of drug administration, inadequate drainage of an abscess, poor drug penetration to the infected area, insufficient serum levels of the drug, or bacterial resistance to the drug. Antibiotic therapy is considered toxic when the serum levels of the antibiotic are too high or when the patient has an allergic or other major adverse reaction to the drug. These reactions include rash, itching, hives, fever, chills, joint pain, difficulty breathing, or wheezing. Relatively minor adverse drug reactions such as nausea, vomiting, and diarrhea are quite common with antibiotic therapy and are usually not severe enough to require drug discontinuation.

Superinfection can occur when antibiotics reduce or completely eliminate the normal bacterial flora, which consist of certain bacteria and fungi that are needed to maintain normal function in various organs. When these bacteria or fungi are killed by antibiotics, other bacteria or fungi are permitted to take over and cause infection. An example of a superinfection caused by antibiotics is the development of a vaginal yeast infection when the normal vaginal bacterial flora is reduced by antibiotic therapy and yeast growth is no longer kept in balance. Antibiotic use is strongly associated with the potential for the development of diarrhea. Antibiotic-associated diarrhea is a common adverse effect of antibiotics. However, it becomes a serious superinfection when it causes antibiotic-associated colitis, also known as **pseudomembranous colitis** or simply *C. difficile infection.* This happens because antibiotics disrupt the normal gut flora and can cause an overgrowth of *Clostridium difficile.* The most common symptoms of *C. difficile* colitis are watery diarrhea, abdominal pain, and fever. Whenever a patient who was previously treated with antibiotics develops watery diarrhea, the patient needs to be tested for *C. difficile* infection. If the results are positive, the patient will need to be treated for this serious superinfection. Infections with *C. difficile* are increasingly becoming resistant to standard therapy.

Another type of superinfection occurs when a second infection closely follows the initial infection and comes from an external source (as opposed to normal body flora). A common example is a case in which a patient who has a viral respiratory infection develops a secondary bacterial infection. This is likely due to weakening of the patient's immune system function by the primary viral infection. Although the viral infection will not respond to antibiotic therapy, antibiotics may be needed to treat the secondary bacterial infection. This situation calls for some diagnostic finesse on the part of the prescriber, who needs to avoid prescribing unnecessary antibiotics for a viral infection. The presence of colored sputum (e.g., green or yellow) may or may not be a sign of a bacterial superinfection during a viral respiratory illness. Patients will often expect to receive an antibiotic prescription even when they show no signs of a bacterial superinfection. From their perspective, they know they are "sick" and want "some medicine" to expedite their recovery from illness. This can create both diagnostic confusion and an emotional dilemma for the prescriber.

Over the decades, many easily treatable bacterial infections have become resistant to antibiotic therapy. One major cause of this phenomenon is considered to be the overprescribing of antibiotics, often in the clinical situations described earlier. Antibiotic resistance is now considered one of the world's most pressing public health problems. Another factor that contributes to this problem is the tendency of many patients not to complete their antibiotic regimen. Patients must be counseled to take the entire course of prescribed antibiotic drugs, even if they feel that they are no longer ill.

Food-drug and drug-drug interactions are common problems when antibiotics are taken. One of the more common food-drug interactions is that between milk or cheese and tetracycline, which results in decreased GI absorption of tetracycline. An example of a drug-drug interaction is that between quinolone antibiotics and antacids or multivitamins with iron, which leads to decreased absorption of quinolones. This is especially important, as will be discussed later, because quinolone antibiotics are used orally to treat serious infections. If they are not absorbed, treatment failure is likely to ensue.

Other important factors that must be understood to use antibiotics appropriately are host-specific factors, or **host factors.** These are factors that pertain specifically to a given patient, and they can have an important bearing on the success or failure of antibiotic therapy. Some of these host factors are age, allergy history, kidney and liver function, pregnancy status, genetic characteristics, site of infection, and host defenses.

Age-related host factors are those that apply to patients at either end of the age spectrum. For example, infants and children may not be able to take certain antibiotics such as tetracyclines, which affect developing teeth or bones; quinolones, which may affect bone or cartilage development in children; and sulfonamides, which may displace bilirubin from albumin and precipitate kernicterus (hyperbilirubinemia) in neonates. The aging process affects the function of various organ systems. As people age, there is a gradual decline in the function of the kidneys and liver, the organs primarily responsible for metabolizing and eliminating antibiotics. Therefore, depending on the level of kidney or liver function of a given older adult, dosage adjustments may be necessary. Pharmacists often play a role in evaluating the dosages of antibiotics and other medications to ensure optimal dosing for a given patient's level of organ function.

A patient history of allergic reaction to an antibiotic is important in the selection of the most appropriate antibiotic. Penicillins and sulfonamides are two broad classes of antibiotic to which many people have allergic anaphylactic reactions. Symptoms of anaphylaxis include flushing, itching, hives, anxiety, fast irregular pulse, and throat and tongue swelling. The most dangerous such reaction is anaphylactic shock, in which a patient can suffocate from drug-induced respiratory arrest. Although this outcome is the most extreme, the potential for it does underscore the importance of consistently assessing patients for drug allergies and documenting any known allergies clearly in the medical record. All reported drug allergies are to be taken seriously and investigated further before a final decision is made about whether to administer a given drug. Many patients will say that they are "allergic" to a medication when in fact what they experienced was a common mild adverse effect such as stomach upset or nausea. Patients who report drug allergies need to be asked open-ended questions to elicit descriptions of prior allergic reactions so that the actual severity of the

reaction can be assessed. The most common severe reactions to any medication that need to be noted in the patient's chart are any difficulty breathing; significant rash, hives, or other skin reaction; and severe GI intolerance. Although some antibiotics are ideally taken on an empty stomach, eating a small amount of food with the medication may be sufficient to help the patient tolerate it and realize its therapeutic benefits.

Pregnancy-related host factors are also important to the selection of appropriate antibiotics, because several antibiotics can pass through the placenta and cause harm to the developing fetus. Drugs that cause development abnormalities in the fetus are called **teratogens.** Their use by pregnant women can result in birth defects.

Some patients also have certain genetic abnormalities that result in various enzyme deficiencies. These conditions can adversely affect drug actions in the body. Two of the most common examples of such genetic host factors are **glucose-6-phosphate dehydrogenase (G6PD) deficiency** and **slow acetylation.** The administration of antibiotics such as sulfonamides, nitrofurantoin, and dapsone to a person with G6PD deficiency may result in the *hemolysis,* or destruction, of red blood cells. Patients who are slow acetylators have a physiologic makeup that causes certain drugs to be metabolized more slowly than usual in a chemical step known as *acetylation.* This can lead to toxicity from drug accumulation (see Chapter 4).

The anatomic site of the infection is a very important host factor to consider when deciding not only which antibiotic to use but also the dosage, route of administration, and duration of therapy. Some antibiotics do not penetrate into the site of infection, such as the lung or bone or abscesses, which can lead to treatment failures.

Consideration of these host factors helps prescribers and pharmacists to ensure optimal drug selection for each individual patient. Continued patient assessment and proper monitoring of antibiotic therapy increase the likelihood that this therapy will be safe and effective.

ANTIBIOTICS

Antibiotics are classified into broad categories based on their chemical structure. The common categories include sulfonamides, penicillins, cephalosporins, macrolides, quinolones, aminoglycosides, and tetracyclines. In addition to chemical structure, other characteristics that distinguish classes of drugs include antibacterial spectrum, mechanism of action, potency, toxicity, and pharmacokinetic properties. The four most common mechanisms of antibiotic action are: (1) interference with bacterial cell wall synthesis, (2) interference with protein synthesis, (3) interference with replication of nucleic acids (deoxyribonucleic acid [DNA] and ribonucleic acid [RNA]), and (4) antimetabolite action that disrupts critical metabolic reactions inside the bacterial cell. Figure 38-3 portrays these mechanisms in combating bacterial infections and indicates which mechanism is used by several major antibiotic classes.

Perhaps the greatest challenge in understanding antimicrobial therapy is remembering the types and species of microorganisms against which a given drug can act. The list of microorganisms that a given drug has activity against can be quite extensive and can seem daunting to the inexperienced practitioner. Most antimicrobials have activity against only one type of microbe (e.g., bacteria, viruses, fungi, protozoans). However, a few drugs do have activity against more than one class of organisms.

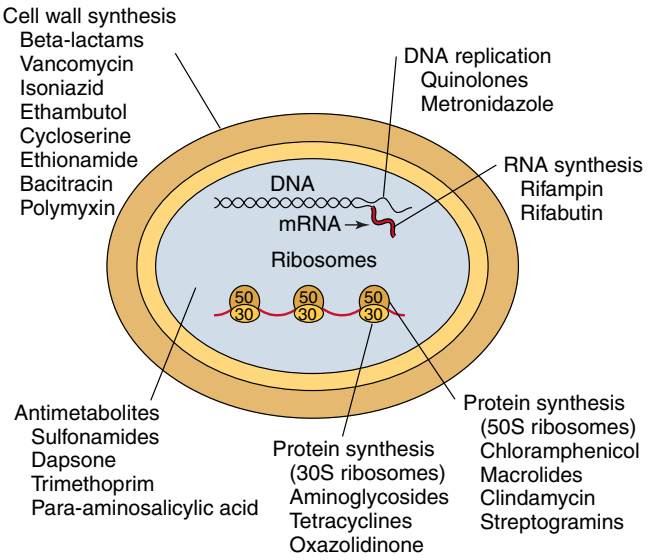

FIGURE 38-3 Basic sites of antibiotic activity. *DNA,* Deoxyribonucleic acid; *mRNA,* messenger ribonucleic acid; *RNA,* ribonucleic acid. (From Murray PR, Rosenthal KS, Pfaller MA: *Medical microbiology,* ed 6, St Louis, 2009, Mosby.)

The field of infectious disease treatment is continually evolving, largely because of the continual emergence of resistant bacterial strains. For this reason, drug indications change frequently, often from year to year, as various bacterial species become resistant to previously effective antiinfective therapy. It is always appropriate to check the most current reference materials or consult with colleagues (e.g., nurses, pharmacists, prescribers) when questions remain. Pharmacists are excellent resources regarding antibiotics. Many hospitals now have pharmacists who are specially trained in the treatment of infectious diseases.

SULFONAMIDES

Sulfonamides were one of the first groups of drugs used as antibiotics. Although there are many compounds in the sulfonamide family, only sulfamethoxazole combined with trimethoprim (a nonsulfonamide antibiotic), known as Bactrim, Septra, or co-trimoxazole and often abbreviated as SMX-TMP, is used commonly in clinical practice. Sulfisoxazole combined with erythromycin (a macrolide antibiotic) is occasionally used in pediatrics. Sulfasalazine, another sulfonamide, is used to treat ulcerative colitis and rheumatoid arthritis and is not used as an antibiotic.

Mechanism of Action and Drug Effects

Sulfonamides do not actually destroy bacteria but rather inhibit their growth. For this reason, they are considered **bacteriostatic antibiotics.** They inhibit the growth of susceptible bacteria by

preventing bacterial synthesis of folic acid. Folic acid is a B-complex vitamin that is required for the proper synthesis of purines, one of the chemical components of nucleic acids (DNA and RNA). Chemical components of folic acid include paraaminobenzoic acid (PABA), pteridine, and glutamic acid. Specifically, in a process known as competitive inhibition, sulfonamides compete with PABA for the bacterial enzyme tetrahydropteroic acid synthetase, which incorporates PABA into the folic acid molecule. Because sulfonamides are capable of blocking a specific step in a biosynthetic pathway, they are also considered antimetabolites. Microorganisms that require exogenous folic acid (not synthesized by the bacterium itself) are not affected by sulfonamide antibiotics. Therefore, these drugs do not affect folic acid metabolism in human cells. Trimethoprim, although not a sulfonamide, works via a similar mechanism, inhibiting dihydrofolic acid reduction to tetrahydrofolate, which results in inhibition of the enzymes of the folic acid pathway.

Indications

Sulfonamides have a broad spectrum of antibacterial activity, including activity against both gram-positive and gram-negative organisms. These antibiotics achieve very high concentrations in the kidneys, through which they are eliminated. Therefore, sulfamethoxazole/trimethoprim is often used in the treatment of UTIs. The combination of these two drugs allows for a synergistic (see Chapter 2) antibacterial effect. Commonly susceptible organisms include strains of *Enterobacter* species (spp.), *Escherichia coli, Klebsiella* spp., *Proteus mirabilis, Proteus vulgaris,* and *S. aureus.* Unfortunately, however, resistant bacterial strains are a growing problem, as is the case with other antibiotic classes. Results of culture and sensitivity testing help to optimize drug selection in individual cases. This combination drug is also used for respiratory tract infections. However, it is now less effective against streptococci infecting the upper respiratory tract and pharynx. Another specific use for sulfamethoxazole/trimethoprim is prophylaxis and treatment of opportunistic infections in patients with human immunodeficiency virus (HIV) infection, especially infection by *Pneumocystis jirovecii,* a common cause of HIV-associated pneumonia. Sulfamethoxazole/trimethoprim is also a drug of choice for infection caused by the bacterium *Stenotrophomonas maltophilia.* Sulfamethoxazole/trimethoprim has become common treatment for outpatient *Staphylococcus* infections, due to the high rate of community-acquired methicillin-resistant *S. aureus* (MRSA) infections. MRSA and other resistant organisms are discussed in Chapter 39.

Contraindications

Use of sulfonamides is contraindicated in cases of known drug allergy to sulfonamides. Chemically related drugs such as the sulfonylureas (used to treat diabetes; see Chapter 32), thiazide and loop diuretics (see Chapter 28), and carbonic anhydrase inhibitors (see Chapter 28) are generally considered relatively safe in a patient who has a sulfonamide allergy. However, the cyclooxygenase-2 inhibitor celecoxib (Celebrex) should not be used (see Chapter 44) in patients with a known sulfonamide allergy. It is important to differentiate between sulfites and sulfonamides. Sulfites are commonly used as preservatives in everything from wine to food to injectable drugs. A person allergic to sulfonamide drugs may or may not also be allergic to sulfite preservatives. The use of sulfonamides is also contraindicated in pregnant women at term and in infants younger than 2 months of age.

TABLE 38-2 SULFONAMIDES: REPORTED ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Blood	Agranulocytosis, aplastic anemia, hemolytic anemia, thrombocytopenia
Gastrointestinal	Nausea, vomiting, diarrhea, pancreatitis, hepatotoxicity
Integumentary	Epidermal necrolysis, exfoliative dermatitis, Stevens-Johnson syndrome, photosensitivity
Other	Convulsions, crystalluria, toxic nephrosis, headache, peripheral neuritis, urticaria, cough

Adverse Effects

Sulfonamide drugs are a common cause of allergic reaction. Patients will sometimes refer to this as "sulfa allergy" or even "sulfur allergy." Although immediate reactions can occur, sulfonamides typically cause delayed cutaneous reactions. These reactions frequently begin with fever followed by a rash (morbilliform eruptions, erythema multiforme, or toxic epidermal necrolysis). Photosensitivity reactions are another type of skin reaction that is induced by exposure to sunlight during sulfonamide drug therapy. In some cases, such reactions can result in severe sunburn. Such reactions are also common with the tetracycline class of antibiotics discussed later in this chapter, as well as with various other drug classes and may occur immediately or have a delayed onset. Other reactions to sulfonamides include mucocutaneous, GI, hepatic, renal, and hematologic complications, all of which may be fatal in severe cases. It is believed that sulfonamide reactions are immune mediated and involve the production of reactive drug metabolites in the body. Reported adverse effects of the sulfonamides are listed in Table 38-2.

Interactions

Sulfonamides can have clinically significant interactions with a number of other medications. Sulfonamides may potentiate the hypoglycemic effects of sulfonylureas in diabetes treatment, the toxic effects of phenytoin, and the anticoagulant effects of warfarin, which can lead to hemorrhage. Sulfonamides may increase the likelihood of cyclosporine-induced nephrotoxicity. Patients receiving any of the above drug combinations may require more frequent monitoring. Sulfonamides, and all antibiotics, may also reduce the efficacy of oral contraceptives. Instruct patients taking these drugs to use additional contraceptive methods.

Dosages

For dosage information on selected sulfonamides, see the table on p. 616.

DOSAGES

Selected Sulfonamide Combination Drug Products

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE*	INDICATIONS
Sulfamethoxazole/trimethoprim (co-trimoxazole, SMX-TMP, SMZ-TMP) (Bactrim, Septra) (C)	Sulfonamide and folate antimetabolite	**Adult and pediatric** IV/PO: 8-20 mg/kg/day divided twice a day (dose is in terms of trimethoprim component)	UTI, shigellosis enteritis; higher doses for nocardiosis and *Pneumocystis jirovecii* infection
		Adult PO: 160 mg TMP/800 mg SMX twice daily (every 12 hr)	*P. jirovecii* prophylaxis, acute exacerbation of chronic bronchitis
		Pediatric PO: 6-10 mg/kg/day (trimethoprim component)	Otitis media

IV, Intravenous; *PO,* oral; *TMP,* trimethoprim; *UTI,* urinary tract infection.
*Dosage ranges are typical but are not necessarily exhaustive due to space limitations. Clinical variations may occur. Check current drug handbook for exact dosages for specific indications.

DRUG PROFILE

Sulfonamides work by interfering with bacterial synthesis of the essential nutrient folic acid. Most sulfonamide therapy today uses the combination drug sulfamethoxazole/trimethoprim.

sulfamethoxazole/trimethoprim (co-trimoxazole)

Co-trimoxazole (Bactrim) is a fixed-combination drug product containing a 5:1 ratio of sulfamethoxazole to trimethoprim. It is available in both oral and injectable dosage forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	2-4 hr	7-12 hr	12 hr

BETA-LACTAM ANTIBIOTICS

The **beta-lactam** antibiotics are very commonly used drugs. They are so named because of the beta-lactam ring that is part of their chemical structure (Figure 38-4). This broad group of drugs includes four major subclasses: penicillins, cephalosporins, carbapenems, and monobactams. They share a common structure and mechanism of action: they inhibit the synthesis of the bacterial peptidoglycan cell wall.

Some bacterial strains produce the enzyme **beta-lactamase.** This enzyme provides a mechanism for bacterial resistance to these antibiotics. The enzyme can break the chemical bond between the carbon (C) and nitrogen (N) atoms in the structure of the beta-lactam ring. When this happens, all beta-lactam drugs lose their antibacterial efficacy. Because of this, additional drugs known as **beta-lactamase inhibitors** are added to several of the penicillin antibiotics to make the drug more powerful against beta-lactamase–producing bacterial strains. Each of the four classes of beta-lactam antibiotics is examined in detail in the following sections.

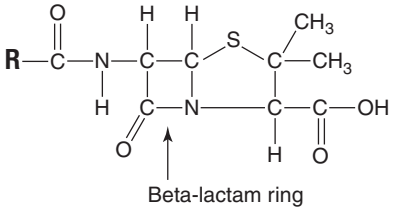

FIGURE 38-4 Chemical structure of penicillins showing the beta-lactam ring. **R,** Variable portion of drug chemical structure.

PENICILLINS

The penicillins are a very large group of chemically related antibiotics that were first derived from a mold (fungus) often seen on bread or fruit. The penicillins can be divided into four subgroups based on their structure and the spectrum of bacteria they are active against: natural penicillins, penicillinase-resistant penicillins, aminopenicillins, and extended-spectrum penicillins. Examples of antibiotics in each subgroup and a brief description of their characteristics are given in Table 38-3.

Penicillins are **bactericidal antibiotics,** meaning they kill a wide variety of gram-positive and some gram-negative bacteria. However, some bacteria have acquired the capacity to produce enzymes capable of destroying penicillins. These enzymes are called *beta-lactamases,* and they can inactivate the penicillin molecules by opening the beta-lactam ring. The beta-lactamases that specifically inactivate penicillin molecules are called *penicillinases.* Bacterial strains that produce these drug-inactivating enzymes were a therapeutic obstacle until drugs were synthesized that inhibit these enzymes. Three of these beta-lactamase inhibitors are clavulanic acid (also called *clavulanate*), tazobactam, and sulbactam. These drugs bind with the beta-lactamase enzyme itself to prevent the enzyme from breaking down the penicillin molecule, although they are not always effective. The following are examples of currently available combinations of a penicillin and a beta-lactamase inhibitor:

- ampicillin/sulbactam (Unasyn)
- amoxicillin/clavulanic acid (Augmentin)

TABLE 38-3 CLASSIFICATION OF PENICILLINS

SUBCLASS	GENERIC DRUG NAMES	DESCRIPTION
Natural penicillins	penicillin G, penicillin V	Although many modifications of the original natural (mold-produced) structure have been made, these are the only two in current clinical use. Penicillin G is the injectable form for IV or IM use; penicillin V is a PO dosage form (tablet and liquid).
Penicillinase-resistant drugs	cloxacillin, dicloxacillin, nafcillin, oxacillin	Stable against hydrolysis by most staphylococcal penicillinases (enzymes that normally break down the natural penicillins).
Aminopenicillins	amoxicillin, ampicillin	Have an amino group attached to the basic penicillin structure that enhances their activity against gram-negative bacteria compared with natural penicillins.
Extended-spectrum drugs	piperacillin, ticarcillin, carbenicillin, piperacillin/tazobactam	Have wider spectra of activity than do all other penicillins.

IM, Intramuscular; *IV,* intravenous; *PO,* oral.

- ticarcillin/clavulanic acid (Timentin)
- piperacillin/tazobactam (Zosyn)

Mechanism of Action and Drug Effects

The mechanism of action of penicillins involves the inhibition of bacterial cell wall synthesis. Once distributed by the patient's bloodstream to infected areas, penicillin molecules slide through bacterial cell walls to get to their site of action. Some penicillins, however, are too large to pass through the openings in the cell walls, and because they cannot get to their site of action they cannot kill the bacteria. Some bacteria make the openings in their cell walls small so that the penicillin cannot get through to kill them. The penicillin molecules that do gain entry into the bacterium must then find the appropriate binding sites. These are known as *penicillin-binding proteins.* By binding to these proteins, the penicillin molecules interfere with normal cell wall synthesis, causing the formation of defective cell walls that are unstable and easily broken down (see Figure 38-3). Bacterial death usually results from lysis (rupture) of the bacterial cells due to this drug-induced disruption of cell wall structure.

Indications

Penicillins are indicated for the prevention and treatment of infections caused by susceptible bacteria. The microorganisms most commonly destroyed by penicillins are gram-positive bacteria, including *Streptococcus* spp., *Enterococcus* spp., and *Staphylococcus* spp. Most natural penicillins have little if any ability to kill gram-negative bacteria. However, the extended-spectrum penicillins (i.e., piperacillin/tazobactam [Zosyn]) have excellent gram-positive, gram-negative, and anaerobic coverage. Because of this, the extended-spectrum penicillins are used to treat many hospital-associated infections, including pneumonia, intraabdominal infections, and sepsis.

Contraindications

Penicillins are usually safe and well-tolerated medications. The only usual contraindication is known drug allergy. It is very important to obtain an accurate history regarding the type of reaction that occurs in patients who state they are allergic to penicillins. It is also important to note that often drugs are referred to by their trade names, and these don't always end in "*cillin*" (e.g., Zosyn, Augmentin). Many medication errors have occurred when a penicillin drug called by its trade name is given to a patient with a penicillin allergy (see the Safety and Quality Improvement: Preventing Medication Errors box).

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Do You Know Your Penicillins?

Medication errors have occurred when nurses gave penicillin products to patients who were allergic to penicillin. In these cases, the drugs were referred to by their trade names, which lack the *"cillin"* suffix. Examples of these drugs are Zosyn and Unasyn. Both drugs contain a form of penicillin and a beta-lactamase inhibitor. Zosyn is a combination of piperacillin and tazobactam; Unasyn is a combination of ampicillin and sulbactam. Analysis of these errors revealed that the person administering the drug did not realize that the drug with the non-*"cillin"* name was a penicillin.

These errors illustrate why is it important to use both trade and generic names when ordering medications for patients. It is essential to know what you are administering to your patients! Be sure to check both names of the medications you give, and check the patient's allergies.

Adverse Effects

Allergic reactions to the penicillins occur in 0.7% to 4% of treatment courses. The most common reactions are urticaria, pruritus, and angioedema. A wide variety of idiosyncratic (unpredictable) drug reactions can occur, such as maculopapular eruptions, eosinophilia, Stevens-Johnson syndrome, and exfoliative dermatitis. Maculopapular rash occurs in about 2% of treatment courses with natural penicillin and 5.2% to 9.5% of those with ampicillin. Anaphylactic reactions are much less common, occurring in 0.004% to 0.015% of patients. Severe reactions are much more common with injected than with orally administered penicillin, as is the case with most antibiotics. Patients who are allergic to penicillins have an increased risk of allergy to other beta-lactam antibiotics. The incidence of cross-reactivity between cephalosporins and penicillins is reported to be between 1% and 4%. Patients reporting penicillin allergy need to describe their prior allergic reaction. It is very important to document the type of reaction. The decision to treat with cephalosporin therapy in such cases is often a matter of clinical judgment, based on the severity of reported prior reactions to penicillin drugs, the nature of the infection, the drug susceptibility of the infective organism if known, and the availability and patient tolerance of other alternative antibiotics. Generally

speaking, only those patients with a history of throat swelling or hives from penicillin should not receive cephalosporins. Some patients may require skin testing and desensitization.

Penicillins are generally well tolerated and associated with very few adverse effects. As with many drugs, the most common adverse effects involve the GI system. The intravenous (IV) formulations of some penicillins contain large amounts of sodium and/or potassium. Doses must be adjusted for patients with renal dysfunction. The most common adverse effects of the penicillins are listed in Table 38-4.

Interactions

Many drugs interact with penicillins; some have positive effects, and others have harmful effects. The most common and clinically significant drug interactions associated with penicillin use are listed in Table 38-5.

Dosages

For dosage information on selected penicillins, see the table on p. 619.

DRUG PROFILES

Penicillins are classified as pregnancy category B drugs. They are very safe antibiotics. Their use is contraindicated in patients with a hypersensitivity to them, but because of their relatively good adverse effects profile, there are otherwise very few contraindications to their use.

NATURAL PENICILLINS

♦ penicillin G and penicillin V potassium

Penicillin G has three salt forms: benzathine, procaine, and potassium. All of these forms are given by injection, either IV or intramuscularly (IM). The benzathine and procaine salts are used as longer-acting IM injections. They are formulated into a thick, white, pastelike material that is designed for prolonged dissolution and absorption from the IM site of injection. Never give these preparations IV, however, because their consistency is too thick for IV administration, and such use can be fatal. The IM formulations can be especially helpful for treating the sexually transmitted disease syphilis, because often only one injection is needed. Penicillin G potassium is formulated for IV use. Penicillin V potassium is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	30-60 min	30 min	4-6 hr
IV	Variable	30 min	24-54 min	4-6 hr

PENICILLINASE-RESISTANT PENICILLINS

nafcillin

Nafcillin is one of the four currently available penicillinase-resistant penicillins; the other three are cloxacillin, dicloxacillin, and oxacillin. Nafcillin is available only in injectable form, whereas cloxacillin and dicloxacillin are available only in oral form. Oxacillin is available in both oral and injectable forms. The penicillinase-resistant penicillins are able to resist breakdown by the penicillin-destroying enzyme (penicillinase) commonly produced by bacteria such as staphylococci. For this reason, they may also be referred to as *antistaphylococcal penicillins.* The chemical structure of these drugs features a large, bulky side chain near the beta-lactam ring. This side chain serves as a barrier to the penicillinase enzyme, preventing it from breaking the beta-lactam ring, which would inactivate the drug. There are, however, certain strains of staphylococci, specifically *S. aureus,* that are resistant to these drugs. Such bacteria therefore require alternative antibiotic regimens.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Variable	15-30 min	30-60 min	6 hr

AMINOPENICILLINS

There are two aminopenicillins: amoxicillin and ampicillin. They are so named because of the presence of a free amino group ($^{-}NH^{2}$) in their chemical structure. This structural feature gives aminopenicillins enhanced activity against gram-negative bacteria against which the natural and penicillinase-resistant

TABLE 38-4 PENICILLINS: REPORTED ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Central nervous	Lethargy, anxiety, depression, seizures
Gastrointestinal	Nausea, vomiting, diarrhea, taste alterations, oral candidiasis
Hematologic	Anemia, bone marrow depression, granulocytopenia
Metabolic	Hyperkalemia, hypernatremia, alkalosis
Skin	Pruritus, hives, rash

TABLE 38-5 PENICILLINS: DRUG INTERACTIONS

DRUG INTERACTING WITH PENICILLINS	MECHANISM	RESULT
Aminoglycosides (IV) and clavulanic acid	Additivity	More effective killing of bacteria
methotrexate	Decreased renal elimination of methotrexate	Increased methotrexate levels
NSAIDs	Compete for protein binding	More free and active penicillin (may be beneficial)
Oral contraceptives	Uncertain	May decrease efficacy of the contraceptive
probenecid	Competes for elimination	Prolongs the effects of penicillins
rifampin	Inhibition	May inhibit the killing activity of penicillins
warfarin	Reduced vitamin K from gut flora	Enhanced anticoagulant effect of warfarin

IV, Intravenous; *NSAIDs,* nonsteroidal antiinflammatory drugs.

DOSAGES

Selected Penicillins

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ amoxicillin (Amoxil, generics) (B)	Aminopenicillin	**Pediatric** PO: 45-90 mg/kg/day divided q8-12h **Adult** PO: 250-500 mg q8h	Otitis media; sinusitis; various susceptible respiratory, skin, and urinary tract infections; dental prophylaxis for bacterial endocarditis; *Helicobacter pylori* infection
ampicillin (generic only) (B)	Aminopenicillin	**Adult** PO/IV/IM: 1-12 g/day divided q4-6h **Pediatric** 25-50 mg/kg/day divided q6h (doses up to 300 mg/kg/day may be required for meningitis and other serious infections)	Primarily infection with gram-negative organisms such as *Shigella, Salmonella, Escherichia, Haemophilus, Proteus,* and *Neisseria* spp.; infection with some gram-positive organisms
nafcillin (generic only) (B)	Penicillinase-resistant penicillin	**Adult** IV/IM: 500-1000 mg q4-6h **Pediatric** IV/IM: 50-200 mg/kg/day divided q6h	Infection with penicillinase-producing staphylococci
♦ penicillin V potassium (Pen-Vee K) (B)	Natural penicillin	**Adult and pediatric** PO: 125-500 mg q6-8h	Primarily infection with gram-positive organisms such as Streptococcus (including *Streptococcus pneumoniae*)

IM, Intramuscular; *IV,* intravenous; *PO,* oral; *spp.,* species.

penicillins are relatively ineffective. The aminopenicillins are also effective against some gram-positive organisms. Amoxicillin is an analogue of ampicillin.

♦ amoxicillin

Amoxicillin is a very commonly prescribed aminopenicillin. Amoxicillin is used to treat infections caused by susceptible organisms in the ears, nose, throat, genitourinary tract, skin, and skin structures. Pediatric dosages are sometimes higher than in the past because of the development of increasingly resistant *Streptococcus pneumoniae* organisms. The drug is available only for oral use and can be given with or without food.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	0.5-1 hr	1-2 hr	1-1.5 hr	6-8 hr

ampicillin

Ampicillin is available in three different salt forms: anhydrous, trihydrate, and sodium. The different salt forms are administered by different routes. Ampicillin anhydrous and trihydrate are both administered orally, whereas ampicillin sodium is given parenterally. This drug is still currently available, although it is now used less frequently than before because of resistance.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	1-2 hr	1-1.5 hr	4-6 hr
IV	Variable	5 min	1-1.8 hr	6-8 hr

EXTENDED-SPECTRUM PENICILLINS

By making a few changes in the basic penicillin structure, drug developers produced another generation of penicillins that have a wider spectrum of activity than that possessed by either of the other two classes of semisynthetic penicillins (penicillinase-resistant penicillins and aminopenicillins) or by the natural penicillins. Currently three extended-spectrum penicillins are available: carbenicillin, piperacillin, and ticarcillin; however, they are rarely used by themselves. Both ticarcillin and piperacillin are available in fixed-combination products that include beta-lactamase inhibitors. The ticarcillin fixed-combination product (Timentin) includes clavulanate potassium. Piperacillin is available in combination with tazobactam (a combination called Zosyn). These beta-lactamase–inhibiting products allow for enhanced multiorganism coverage, especially against anaerobic organisms that are common in intestinal infections and *Pseudomonas* spp., which are common in hospital-acquired infections. Zosyn is commonly used in hospitalized patients with suspected or documented serious infections. Because of its broad spectrum of activity (gram positive, gram negative, and anaerobic), it is often used as empiric therapy. Zosyn and Timentin are available only by injection.

CEPHALOSPORINS

Cephalosporins are semisynthetic antibiotics widely used in clinical practice. They are structurally and pharmacologically related to the penicillins. Like penicillins, cephalosporins are bactericidal and work by interfering with bacterial cell wall synthesis. They also bind to the same penicillin-binding proteins inside bacteria that were described earlier for the penicillins. Although there are a variety of such proteins, they are collectively referred to as penicillin binding regardless of the type of beta-lactam drug involved.

TABLE 38-6 CEPHALOSPORINS: PARENTERAL AND ORAL PREPARATIONS

FIRST GENERATION		SECOND GENERATION		THIRD GENERATION		FOURTH GENERATION	FIFTH GENERATION
IV	PO	IV	PO	IV	PO	IV	IV
cefazolin cephradine	cefadroxil cephalexin cephradine	cefoxitin cefuroxime cefotetan loracarbef	cefaclor cefuroxime axetil* cefprozil	cefotaxime ceftizoxime ceftriaxone ceftazidime	cefpodoxime ceftibuten cefdinir	cefepime	ceftaroline

IV, Intravenous; *PO,* oral.
*Prodrug salts that aid in drug delivery into the gastrointestinal tract.

TABLE 38-7 CEPHALOSPORINS: DRUG INTERACTIONS

INTERACTING DRUG	MECHANISM	RESULT
Ethanol (alcohol)	Accumulation of acetaldehyde metabolite of ethanol	Acute alcohol intolerance (disulfiram-like reaction) after drinking alcoholic beverages within 72 hr of taking cefotetan. Symptoms include stomach cramps, nausea, vomiting, diaphoresis, pruritus, headache, and hypotension.
Antacids, iron	Decreased absorption of certain oral cephalosporins (cefdinir, cefditoren)	Decreased effectiveness of drug
probenecid	Decreased renal excretion	Increased cephalosporin levels
Oral contraceptives (OCs)	Enhanced OC metabolism	Increased risk for unintended pregnancy

Cephalosporins can destroy a broad spectrum of bacteria, and this ability is directly related to the chemical changes that have been made to their basic cephalosporin structure. Modifications to this chemical structure by pharmaceutical scientists have given rise to five generations of cephalosporins. Depending on the generation, these drugs may be active against gram-positive, gram-negative, or anaerobic bacteria. They are not active against fungi and viruses. The different drugs of each generation have certain chemical similarities, and thus they can kill similar spectra of bacteria. In general, the level of gram-negative coverage increases with each successive generation. The first-generation drugs have the most gram-positive coverage, and the later generations have the most gram-negative coverage. Anaerobic coverage is found only with the second-generation drugs. Cefepime, cefdinir, and cefditoren pivoxil are the oral third-generation cephalosporins. Ceftaroline, the newest cephalosporin, often referred as the fifth generation, has a broad spectrum and covers gram-positive (including MRSA) and gram-negative organisms. The currently available parenteral and oral cephalosporin antibiotics are listed in Table 38-6. As is often the case, injectable drugs produce higher serum concentrations than drugs administered by the oral route and thus are used to treat more serious infections.

The safety profiles, contraindications, and pregnancy ratings of the cephalosporins are very similar to those of the penicillins. The most commonly reported adverse effects are mild diarrhea, abdominal cramps, rash, pruritus, redness, and edema. Because cephalosporins are chemically very similar to penicillins, a person who has had an allergic reaction to penicillin may also have an allergic reaction to a cephalosporin. This is referred to as cross-sensitivity. Various investigators have observed that the incidence of cross-sensitivity between penicillins and cephalosporins is between 1% and 4%. However, only those patients who have had a serious anaphylactic reaction to penicillin must not be given cephalosporins. As a class, the cephalosporins are very safe and effective antibiotics.

Penicillins and cephalosporins are practically identical in their mechanism of action, drug effects, therapeutic effects, and adverse effects. For this reason, this information is not repeated for the cephalosporins, and the reader is referred to the pertinent discussions in the section on the penicillin drugs. Cephalosporins of all generations are very safe drugs that are classified as pregnancy category B drugs. Their use is contraindicated in patients who have shown a hypersensitivity to them and in any patient with a history of life-threatening allergic reaction to penicillins. Drug interactions are listed in Table 38-7.

Dosages

For the dosage information on selected cephalosporins, see the table on p. 621.

DRUG PROFILES

FIRST-GENERATION CEPHALOSPORINS

First-generation cephalosporins are usually active against gram-positive bacteria and have limited activity against gram-negative bacteria. They are available in both parenteral and oral forms. Currently available first-generation cephalosporins include cefadroxil, cefazolin, cephalexin, and cephradine.

♦ cefazolin

Cefazolin (Ancef) is a prototypical first-generation cephalosporin. As with all first-generation cephalosporins, it provides excellent coverage against gram-positive bacteria but limited coverage against gram-negative bacteria. It is available only for

DOSAGES

Selected Cephalosporins

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ cefazolin (Kefzol, Ancef) (B)	First-generation cephalosporin	**Adult** IV/IM: 500-2000 mg q8h **Pediatric** IV/IM: 25-100 mg/kg/day divided q6-8h	Infections due to gram positive organisms, some penicillinase-producing organisms, and some gram-negative organisms; preoperative and post-operative surgical prophylaxis
♦ cefoxitin (Mefoxin) (B)	Second-generation cephalosporin	**Adult** IV/IM: 3-12 g/day divided q6-8h **Pediatric** IV/IM: 80-160 mg/kg/day divided q4-6h, not to exceed 12 g/day	Infections; less coverage of gram-positive organisms, greater coverage of gram-negative and anaerobic organisms
cefuroxime (Kefurox, Zinacef); cefuroxime axetil* (Ceftin, tablet form) (B)	Second-generation cephalosporin	**Adult** PO (tabs): 125-500 mg bid IV/IM: 750-1500 mg q8h **Pediatric** PO: 20-30 mg/kg/day divided bid IV/IM: 50-150 mg/kg/day, divided q8h	Comparable to those for cefazolin, and provides more coverage of gram-negative organisms
ceftazidime (Fortaz, Tazidime) (B)	Third-generation cephalosporin	**Adult** IV/IM: 250-2000 mg q6-12h **Pediatric** IV/IM: 30-50 mg/kg/day divided q8-12h	Infections; more extensive coverage of gram-negative organisms, including *Pseudomonas* spp.
♦ ceftriaxone (Rocephin) (B)	Third-generation cephalosporin	**Adult** IV/IM: 1-2 g given once daily except for meningitis, for which it is given twice daily **Pediatric** IV/IM: 50-100 mg/kg/day divided daily-bid (as above)	Comparable to those for ceftazidime
cefepime (Maxipime) (B)	Fourth-generation cephalosporin	**Adult** IV/IM: 250-2000 mg daily-bid **Pediatric** IV/IM: 50 mg/kg q12h	Infections; provides more extensive coverage of gram-negative organisms and better gram-positive coverage than third generation, including organisms causing intraabdominal infections

IM, Intramuscular; *IV,* intravenous; *PO,* oral; *spp.,* species.
*Cefuroxime axetil and cefditoren pivoxil are both prodrugs for PO use that are hydrolyzed into the active ingredient in the fluids of the gastrointestinal tract.

parenteral use. It is used commonly for surgical prophylaxis and for susceptible staphylococcal infections.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Variable	5 min	1.2-2.5 hr	8 hr

♦ cephalexin

Cephalexin (Keflex) is a prototypical oral first-generation cephalosporin. It also provides excellent coverage against gram-positive bacteria but limited coverage against gram-negative bacteria. It is available only for oral use. Cephradine is another oral first-generation cephalosporin.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	1 hr	0.6-2 hr	6-12 hr

SECOND-GENERATION CEPHALOSPORINS

Second-generation cephalosporins have coverage against gram-positive organisms similar to that of the first-generation cephalosporins but have enhanced coverage against gram-negative bacteria. Both parenteral and oral formulations are available. Currently available second-generation cephalosporins include cefaclor, cefoxitin, cefuroxime, cefotetan, cefprozil, and loracarbef. These drugs differ slightly with regard to their antibacterial coverage. Cefoxitin and cefotetan are often referred to as *cephamycins* and have better coverage against various anaerobic bacteria such as *Bacteroides fragilis, Peptostreptococcus* spp., and *Clostridium* spp. than the other drugs in this class.

♦ cefoxitin

Cefoxitin (Mefoxin) is a parenteral second-generation cephalosporin. It provides excellent gram-positive coverage and better gram-negative coverage than the first-generation drugs. Cefoxitin has been used extensively as a prophylactic antibiotic in patients undergoing abdominal surgery because it can effectively kill intestinal bacteria, including anaerobes. Normal

intestinal flora include gram-positive, gram-negative, and anaerobic bacteria.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Variable	0.5 hr	1 hr	8 hr

cefuroxime

Cefuroxime sodium (Zinacef) is the parenteral form of this second-generation cephalosporin. The oral form is a different salt, cefuroxime axetil (Ceftin). It has more activity against gram-negative bacteria than first-generation cephalosporins but a narrower spectrum of activity against gram-negative bacteria than third-generation cephalosporins. It differs from the cephamycins such as cefoxitin in that it does not kill anaerobic bacteria. Cefuroxime axetil is a prodrug. It has little antibacterial activity until it is hydrolyzed in the liver to its active cefuroxime form. It is available only for oral use. Cefuroxime sodium is available only in injectable form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	2-3 hr	1.3 hr	6-8 hr
IV	Variable	30 min	1-2 hr	6-8 hr

THIRD-GENERATION CEPHALOSPORINS

The available third-generation cephalosporins include cefotaxime, cefpodoxime, ceftazidime, ceftibuten, cefdinir, ceftizoxime, and ceftriaxone. These are the most potent of the first three generations of cephalosporins in fighting gram-negative bacteria, but they generally have less activity than first- and second-generation drugs against gram-positive organisms.

Because of specific changes in the basic cephalosporin structure, ceftazidime has activity against *Pseudomonas* spp. However resistance is beginning to limit its usefulness. Cefpodoxime, cefdinir, and ceftibuten are currently the only third-generation cephalosporins available for oral use. All the other third-generation drugs are available only in parenteral forms.

♦ ceftriaxone

Ceftriaxone (Rocephin) is an extremely long-acting third-generation drug that can be given only once a day for the treatment of most infections. It also has the unique characteristic of being able to pass easily through the blood-brain barrier. For this reason, it is one of the few cephalosporins that is indicated for the treatment of meningitis, an infection of the meninges of the brain. The spectrum of activity of ceftriaxone is similar to that of the other third-generation drugs cefotaxime and ceftizoxime. It can be given both IV and IM. In some cases of infection, one IM injection can eradicate the infection. Ceftriaxone is 93% to 96% bound to plasma protein, a proportion higher than that of many of the other cephalosporins. This drug is also unique in that it is metabolized in the intestine after biliary excretion. Ceftriaxone is not given to hyperbilirubinemic neonates or to patients with severe liver dysfunction. It should not be administered with calcium infusions. Ceftriaxone is available only for injection.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Variable	1.5-4 hr	4.3-8.7 hr	24 hr

ceftazidime

Ceftazidime (Ceptaz, Fortaz, Tazidime) is a parenterally administered third-generation cephalosporin with activity against difficult-to-treat infections with gram-negative bacteria such as *Pseudomonas* spp. It is the third-generation cephalosporin of choice for many indications because of its excellent spectrum of activity and safety profile; however, resistance is beginning to limit its usefulness, and it is generally given in combination with an aminoglycoside (discussed in Chapter 39). Ceftazidime is available only in injectable form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV/IM	Variable	1 hr	2 hr	8-12 hr

FOURTH-GENERATION CEPHALOSPORINS

cefepime

Cefepime (Maxipime) is the prototypical fourth-generation cephalosporin. Cefepime is a broad-spectrum cephalosporin that most closely resembles ceftazidime in its spectrum of activity. It differs from ceftazidime in that it has increased activity against many *Enterobacter* spp. (gram-negative) as well as gram-positive organisms. Cefepime is indicated for the treatment of uncomplicated and complicated UTIs, uncomplicated skin and skin structure infections, and pneumonia. It is available only in injectable form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	0.5 hr	0.5-1.5 hr	2 hr	8-12 hr

FIFTH-GENERATION CEPHALOSPORINS

Cefaroline (Teflaro) is the newest cephalosporin. It has a broader spectrum of activity than the current cephalosporins. It is effective against a wide variety of organisms, including methicillin-resistant *S. aureus* (MRSA), making it the only cephalosporin that treats MRSA. Cefaroline is indicated for acute skin and skin structure infections and community-acquired pneumonia. The dose needs to be adjusted for decreased renal function. It is available only in injectable form.

CARBAPENEMS

Carbapenems have the broadest antibacterial action of any antibiotics to date. They are bactericidal and inhibit cell wall synthesis. Because of this, they are often reserved for complicated body cavity and connective tissue infections in acutely ill hospitalized patients. They are also effective against many gram-positive organisms. One hazard of carbapenem use is drug-induced seizure activity, which occurs in a relatively small percentage of patients. However, the risk of seizures can be reduced by proper dosage adjustment in impaired patients. There is a small risk of cross-allergenicity in patients with penicillin allergies. Only those patients with anaphylactic-type reactions to penicillins must not receive a carbapenem. Currently available carbapenems include imipenem/cilastatin, meropenem, ertapenem, and doripenem. Carbapenems must be infused over 60 minutes.

DRUG PROFILE

♦ imipenem/cilastatin

Imipenem/cilastatin (Primaxin) is a fixed combination of imipenem, which is a semisynthetic carbapenem antibiotic similar to beta-lactam antibiotics, and cilastatin, an inhibitor of an enzyme that breaks down imipenem. Imipenem has a wide spectrum of activity against gram-positive and gram-negative aerobic and anaerobic bacteria. Cilastatin is a unique drug in that it inhibits an enzyme in the kidneys called *dehydropeptidase,* which would otherwise quickly break down the imipenem. Cilastatin also blocks the renal tubular secretion of imipenem, which impairs imipenem from being excreted by the kidneys, the primary route of elimination of the drug.

Imipenem/cilastatin exerts its antibacterial effect by binding to penicillin-binding proteins inside bacteria, which in turn inhibits bacterial cell wall synthesis. Unlike many of the penicillins and cephalosporins, imipenem/cilastatin is very resistant to the antibiotic-inhibiting actions of beta-lactamases. Drugs with which it potentially interacts include cyclosporine, ganciclovir, and probenecid, all of which may potentiate the central nervous system (CNS) adverse effects (including seizures) of imipenem. The most serious adverse effect associated with imipenem/cilastatin therapy is seizures, which have been reported in up to 1.5% of patients receiving less than 500 mg every 6 hours. In patients receiving high dosages of the drug (more than 500 mg every 6 hours), however, there is a 10% incidence of seizures. Seizures are more likely in elderly and renally impaired patients. Seizures have been associated with all of the carbapenems, but the data suggest that they are most likely to occur with imipenem/cilastatin.

Imipenem/cilastatin is indicated for the treatment of bone, joint, skin, and soft-tissue infections; bacterial endocarditis caused by *S. aureus;* intraabdominal bacterial infections; pneumonia; UTIs and pelvic infections; and bacterial septicemia caused by susceptible bacterial organisms. The IM form of imipenem/cilastatin contains lidocaine, and its use is therefore contraindicated in patients with a known drug allergy to lidocaine or related local anesthetics. All dosage forms contain the same number of milligrams of both imipenem and cilastatin.

Meropenem (Merrem) is the second drug in the carbapenem class of antibiotics. Compared with imipenem/cilastatin, meropenem appears to be somewhat less active against gram-positive organisms, more active against *Enterobacteriaceae,* and equally active against *P. aeruginosa.* However, meropenem is the only carbapenem currently indicated for treatment of bacterial meningitis. Ertapenem (Invanz) has a spectrum of activity comparable to that of imipenem/cilastatin, although it is not active against *Enterococcal* or *Pseudomonas* spp. Doripenem (Doribax) is the newest carbapenem. It has less seizure potential than imipenem/cilastatin. It is indicated for intraabdominal infections, pyelonephritis, UTIs, and pneumonia. Recommended dosages of imipenem/cilastatin are given in the table on p. 624.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Variable	2 hr	2-3 hr	6-8 hr

MONOBACTAMS

DRUG PROFILE

aztreonam

Aztreonam (Azactam) is the only monobactam antibiotic to be developed thus far. It is a synthetic beta-lactam antibiotic that is primarily active against aerobic gram-negative bacteria, including *E. coli, Klebsiella* spp., and *Pseudomonas* spp. Aztreonam is a bactericidal antibiotic. It destroys bacteria by inhibiting bacterial cell wall synthesis, which results in lysis. Aztreonam is indicated for the treatment of moderately severe systemic infections and UTIs. It is often combined with other antibiotics for the treatment of intraabdominal and gynecologic infections. Aztreonam is available only in injectable form. Its use is contraindicated in patients with a known drug allergy, although it is believed to have less allergic cross-reactivity with other beta-lactam antibiotics. Common adverse effects include rash, nausea, vomiting, and diarrhea. Recommended dosages for this monobactam are given in the table on p. 624.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV/IM	Variable	1 hr	1.5-2.1 hr	6-12 hr

MACROLIDES

The macrolides are a large group of antibiotics that first became available in the early 1950s with the introduction of erythromycin. Macrolides are considered bacteriostatic; however, in high enough concentrations they may be bactericidal to some susceptible bacteria. There are three macrolide antibiotics: azithromycin, clarithromycin, and erythromycin. Azithromycin and clarithromycin are currently the most widely used of the macrolides. Although the spectra of antibacterial activity of both azithromycin and clarithromycin are similar to that of

DOSAGES

Selected Carbapenems and Monobactams

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
aztreonam (Azactam) (B)	Monobactam	**Adult** IV/IM: 500-2000 mg q6-12h **Pediatric** IV/IM: 30 mg/kg q6-8 hr	Primarily UTI caused by gram-negative organisms, severe systemic infections
♦ imipenem/cilastatin (Primaxin) (C)	Carbapenem	**Adult** IV: 250-500 mg q6-8h IM: 500-750 mg q12h **Pediatric** 15-25 mg/kg q6 hr	Infection with gram-positive, gram-negative, and aerobic bacteria, including *Pseudomonas aeruginosa;* includes infections of bone, joint, skin, or soft tissue and endocarditis, pneumonia, UTI, intraabdominal and pelvic infections, and septicemia

IM, Intramuscular; *IV,* intravenous; *UTI,* urinary tract infection.

erythromycin, the former have longer durations of action than erythromycin, which allows them to be given less often. They produce fewer and milder GI tract adverse effects than erythromycin, and azithromycin is usually dosed over a shorter length of time than many of the erythromycin products. Azithromycin and clarithromycin also exhibit better efficacy in eradicating various bacteria and are capable of better tissue penetration. Because erythromycin has a bitter taste and is quickly degraded by the acidity of the stomach, several salt forms and many dosage formulations were developed to circumvent these problems. Fidaxomicin (Dificid) is the newest macrolide antibiotic. It is indicated only for the treatment of *Clostridium difficile*–associated diarrhea. The most common adverse effects are nausea, vomiting, and GI bleed. It is pregnancy category B. It has minimal absorption and, as such, there are known drug interactions.

Mechanism of Action and Drug Effects

Macrolide antibiotics are bacteriostatic drugs that inhibit protein synthesis by binding reversibly to the 50S ribosomal subunits of susceptible microorganisms. Macrolides are effective in the treatment of a wide range of infections. These include various infections of the upper and lower respiratory tract, skin, and soft tissue caused by some strains of *Streptococcus* and *Haemophilus;* spirochetal infections such as syphilis and Lyme disease; gonorrhea; and *Chlamydia, Mycoplasma,* and *Corynebacterium* infections. Gonorrheal infections have become increasingly difficult to treat with macrolide monotherapy, so these drugs are sometimes used in combination with other antibiotics such as cephalosporins. Macrolides are also somewhat unique among antibiotics in that they are especially effective against several bacterial species that often reproduce inside host cells instead of just in the bloodstream or interstitial spaces. Common examples of such bacteria, some of which were previously listed, are *Listeria, Chlamydia, Legionella* (one species of which causes Legionnaires' disease), *Neisseria* (one species of which causes gonorrhea), and *Campylobacter.*

Indications

Infections caused by *Streptococcus pyogenes* (group A beta-hemolytic streptococci) are inhibited by macrolides, as are mild to moderate upper and lower respiratory tract infections caused by *Haemophilus influenzae.* Spirochetal infections that are treated with erythromycin and other macrolides are syphilis and Lyme disease. Various forms of gonorrhea and *Chlamydia* and Mycoplasma infections are also susceptible to the effects of macrolides.

A therapeutic effect of erythromycin outside its antibiotic actions is its ability to irritate the GI tract, which stimulates smooth muscle and GI motility. This may be of benefit to patients who have decreased GI motility, such as delayed gastric emptying in diabetic patients (known as *diabetic gastroparesis*). It has also been shown to be helpful in facilitating the passage of feeding tubes from the stomach into the small bowel. Azithromycin and clarithromycin are approved for the prevention and treatment of *Mycobacterium avium-intracellulare (MAC)* complex infections. This is a common *opportunistic infection* often associated with HIV infection/acquired immunodeficiency syndrome (AIDS) (see Chapter 40). Clarithromycin also has been approved for use in combination with omeprazole and amoxicillin for the treatment of patients with active ulcer associated with *Helicobacter pylori* infection.

Contraindications

The only usual contraindication to macrolide use is known drug allergy. Macrolides are often used as alternative drugs for patients with allergies to beta-lactam antibiotics.

Adverse Effects

Erythromycin formulations cause many GI-related adverse effects, especially nausea and vomiting. Azithromycin and clarithromycin seem to be associated with a lower incidence of these GI tract complications. Reported adverse effects are listed in Table 38-8.

Interactions

There are a number of potential drug interactions with the macrolides. The macrolides possess two properties that can cause drug interactions: they are highly protein bound and they are metabolized in the liver. For drugs metabolized in the liver, drug interactions arise from competition between the different drugs for metabolic enzymes, specifically the enzymes known as the *cytochrome P-450 complex* (see Chapter 2). Such

TABLE 38-8 MACROLIDES: REPORTED ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Palpitations, chest pain, QT prolongation
Central nervous	Headache, dizziness, vertigo
Gastrointestinal	Nausea, hepatotoxicity, heartburn, vomiting, diarrhea, flatulence, cholestatic jaundice, anorexia, abnormal taste
Integumentary	Rash, urticaria, phlebitis at intravenous site
Other	Hearing loss, tinnitus

enzymatic effects generally lead to more pronounced drug interactions than competition for protein binding. The result is a delay in the metabolic clearance of one or more interacting drugs and thus a prolonged and possibly toxic drug effect. Examples of some especially common drugs that compete for hepatic metabolism with the macrolides are carbamazepine, cyclosporine, theophylline, and warfarin. When macrolides are given with these drugs, the results are enhanced effects and possible toxicity of the latter drugs, and patients must be monitored. Macrolides can also reduce the efficacy of oral contraceptives. Clarithromycin and erythromycin are not to be used with moxifloxacin, pimozide, thioridazine, or other drugs that prolong the QT interval, because malignant dysrhythmias can occur. Concurrent use of simvastatin or lovastatin with clarithromycin or erythromycin is not recommended. Azithromycin is not as prone to such interactions as are the other macrolides, because of its minimal effects on the cytochrome P-450 enzymes.

Dosages

For dosages information on selected macrolide antibiotics, see the table below.

DRUG PROFILES

Macrolide antibiotics are used to treat a variety of infections. Azithromycin and clarithromycin have fewer adverse effects and a better pharmacokinetics profile than erythromycin.

Macrolide use is contraindicated in patients with known drug allergy. Because these drugs are significantly protein bound and are metabolized in the liver, they may interact with other drugs that are also highly protein bound or hepatically metabolized.

♦ erythromycin

Erythromycin, which goes by many product names, was for many years the most commonly prescribed macrolide antibiotic. However, other macrolides are now more commonly used. The drug is available in several different salt and dosage forms for oral use that were developed to circumvent some of the drawbacks it has chemically. An injectable form is also available for IV use. Erythromycin is also available in topical forms for dermatologic use (see Chapter 56) and in ophthalmic dosage forms (see Chapter 57). The absorption of oral erythromycin is enhanced if it is taken on an empty stomach, but because of the high incidence of stomach irritation associated with its use, many of these drugs are taken with a meal or snack.

♦ azithromycin and clarithromycin

Azithromycin (Zithromax) and clarithromycin (Biaxin) are semisynthetic macrolide antibiotics that differ structurally from erythromycin and as a result have advantages over it. These include better adverse effect profiles, including less GI tract irritation, and more favorable pharmacokinetic properties. Both have very similar spectra of activity that differ only slightly from that of erythromycin. The two drugs are used for the treatment of both upper and lower respiratory tract and skin structure infections.

DOSAGES

Selected Macrolides

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ azithromycin (Zithromax) (B)	Semisynthetic macrolide	**Adult** PO: 500 mg × 1 dose, then 250 mg daily × 4 days IV: 500 mg q day **Pediatric** PO: 5-12 mg/kg once a day × 4 days or as 30 mg/kg single dose (max dose 500 mg) IV: 10 mg/kg × 1 day then 5 mg/kg/day × 4 days	Comparable to those for erythromycin, but especially GU and respiratory tract infections, including MAC infections
♦ clarithromycin (Biaxin) (C)	Semisynthetic macrolide	**Adult** PO: 500 mg twice daily **Pediatric** PO: 7.5 mg/kg bid (max 500 mg/dose)	Comparable to those for erythromycin, but especially GU and respiratory tract infections, including MAC infections
♦ erythromycin (E-mycin, EryPed, Eryc, E.E.S., many others) (B)	Natural macrolide	**Adult*** PO: 250-500 mg qid **Pediatric*** 25-50 mg/kg/day divided qid	Infections of respiratory and GI tracts and skin caused by various gram-positive, gram-negative, and miscellaneous organisms

GI, Gastrointestinal; *GU,* genitourinary; *IV,* intravenous; *MAC, Mycobacterium avium-intracellulare* complex; *PO,* oral.
*There are many dosage forms, and dosages may vary from those listed.

Azithromycin has excellent tissue penetration, so that it can reach high concentrations in infected tissues. It also has a long duration of action, which allows it to be dosed once daily. It is usually given in a regimen of 500 mg on day 1 and then 250 mg/day for four days. Taking the drug with food decreases both the rate and extent of GI absorption. The drug is available in oral and injectable forms.

Clarithromycin is given orally twice daily in adults and children older than 6 months of age. It can be given with or without food. The extended-release preparation must not be crushed.

Pharmacokinetics (azithromycin)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	2.5-4 hr	60-70 hr	Up to 24 hr

Pharmacokinetics (clarithromycin)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	2-4 hr	3-7 hr	Up to 12 hr

KETOLIDES

Telithromycin (Ketek) is currently the only drug in a new class known as ketolides. It is derived from erythromycin A and has better acid stability and better antibacterial coverage than the macrolides. Its mechanism of action is also similar to that of the macrolides. However, telithromycin has been associated with severe liver damage, and its use is very limited.

TETRACYCLINES

The tetracyclines are bacteriostatic drugs that inhibit bacterial protein synthesis by binding to the 30S bacterial ribosome. The three naturally occurring tetracyclines are demeclocycline, oxytetracycline, and tetracycline. The two semisynthetic tetracyclines are doxycycline and minocycline. The newest tetracycline antibiotic is tigecycline (Tygacil). Tigecycline is indicated for skin and soft-tissue infections, intraabdominal infections, and pneumonia. It is effective against many resistant bacteria. The available tetracycline antibiotics are listed in Box 38-1.

Tetracyclines are chemically and pharmacologically similar to one another. The most significant chemical characteristic of these drugs is their ability to bind to (chelate) divalent (Ca^{++}, Mg^{++}) and trivalent (Al^{+++}) metallic ions to form insoluble complexes. Therefore, their coadministration with milk, antacids, or iron salts causes a considerable reduction in the oral absorption of the tetracycline. In addition, their strong affinity for calcium usually precludes their use in pediatric patients younger than 8 years of age, because it can result in significant tooth discoloration. These drugs must be avoided in pregnant women and nursing mothers. The drugs do pass into breast milk, and this can be another route of exposure leading to tooth discoloration in nursing children.

Tetracyclines primarily differ from one another in the following ways:

- *Oral absorption:* All except tigecycline are adequately absorbed, but doxycycline and minocycline have the best absorption.
- *Body tissue penetration:* Doxycycline and minocycline possess the best penetration potential (brain and cerebrospinal fluid).
- *Half-life and resulting dosage schedule:* See the Dosages table on p. 627 and pharmacokinetics information in the Drug Profiles section.

BOX 38-1 AVAILABLE TETRACYCLINE ANTIBIOTICS

demeclocycline
oxytetracycline
tetracycline
doxycycline
minocycline
tigecycline

Mechanism of Action and Drug Effects

Tetracyclines work by inhibiting protein synthesis in susceptible bacteria. They inhibit the growth of and kill a very wide range of *Rickettsia, Chlamydia,* and *Mycoplasma* organisms, as well as a variety of gram-negative and gram-positive bacteria. They are also useful in the treatment of spirochetal infections, such as syphilis and Lyme disease, and pelvic inflammatory disease. Demeclocycline possesses a unique drug effect in that it inhibits the action of antidiuretic hormone, which makes it useful in the treatment of the syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

Indications

Tetracyclines have a wide range of activity, and all drugs in this class are effective against essentially the same spectrum of microbes. They inhibit the growth of many gram-negative and gram-positive organisms and even of some protozoans. Traditionally used to treat acne in adolescents and adults, they are also considered the drugs of choice for the treatment of the following infections caused by susceptible organisms:

- *Chlamydia:* lymphogranuloma venereum, psittacosis, and nonspecific endocervical, rectal, and urethral infections
- *Mycoplasma: Mycoplasma* pneumonia
- *Rickettsia:* Q fever, rickettsial pox, Rocky Mountain spotted fever, and typhus
- *Other bacteria:* acne, brucellosis, chancroid, cholera, granuloma inguinale, shigellosis, spirochetal relapsing fever, Lyme disease, *H. pylori* infections associated with peptic ulcer disease (used as part of the treatment regimen), syphilis (used as an alternative drug to treat patients with penicillin allergy); tetracyclines are now unreliable in treating gonorrhea due to the development of resistant bacterial strains
- *Protozoa:* balantidiasis

Contraindications

The only usual contraindication is known drug allergy. However, tetracyclines must be avoided in pregnant and nursing women and not given to children younger than 8 years of age.

DOSAGES

Selected Tetracyclines

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
demeclocycline (Declomycin) (D)	Tetracycline	**Adult** PO: 150 mg qid or 300 mg bid **Pediatric older than 8 yr*** 7-13 mg/kg divided bid-qid	Infections; provides broad antibacterial coverage, including treatment of skin infections and respiratory, GI, and GU tract infections
♦ doxycycline (Vibramycin, others) (D)	Tetracycline	**Adult** PO: 100 mg bid first day, then 100 mg daily thereafter **Pediatric older than 8 yr*** PO/IV: 2.2-4.4 mg/kg/day in 1-2 divided doses	Comparable to those for demeclocycline
tigecycline (Tygacil) (D)	Glycylcycline	**Adult** IV: 100 mg × 1, then 50 mg q12h	Skin and skin structure infections, MRSA infections, intraabdominal infections

GI, Gastrointestinal; *GU,* genitourinary; *IV,* intravenous; *MRSA,* methicillin-resistant *Staphylococcus aureus; PO,* oral.
*Use of tetracyclines is contraindicated in children younger than 8 years of age and in pregnant women because of the risk of significant tooth discoloration in children.

Adverse Effects

All tetracyclines cause similar adverse effects. They can cause discoloration of the permanent teeth and tooth enamel hypoplasia in both fetuses and children and possibly retard fetal skeletal development if taken during pregnancy. Other clinically significant undesirable effects include photosensitivity, which is most frequent in patients taking demeclocycline; alteration of the intestinal and vaginal flora, which can result in diarrhea or vaginal candidiasis; reversible bulging fontanelles in neonates; thrombocytopenia, possible coagulation irregularities, and hemolytic anemia; and exacerbation of systemic lupus erythematosus. Other effects include gastric upset, enterocolitis, and maculopapular rash.

Interactions

There are several significant drug interactions associated with the use of tetracyclines. When tetracyclines are taken with antacids, antidiarrheal drugs, dairy products, calcium, enteral feedings, or iron preparations, the oral absorption of the tetracycline is reduced. Tetracyclines can potentiate the effects of oral anticoagulants, which necessitates more frequent monitoring of anticoagulant effect and possible dosage adjustment. They can also antagonize the effects of bactericidal antibiotics and oral contraceptives. In addition, depending on the dosage, they can cause blood urea nitrogen levels to be increased.

Dosages

For dosage information on selected tetracyclines, see the table on this page.

DRUG PROFILES

Tetracyclines were one of the first classes of antibiotic capable of providing coverage against a broad spectrum of microorganisms. Their use is contraindicated in patients who have had hypersensitivity reactions to them in the past and in lactating women. Resistance to one tetracycline implies resistance to all tetracyclines.

demeclocycline

Demeclocycline (Declomycin) is a naturally occurring tetracycline antibiotic that is derived from strains of *Streptomyces.* It is used both for its antibacterial action and for its ability to inhibit the action of antidiuretic hormone in SIADH. Demeclocycline has all the characteristics of this class of tetracyclines. It is available only for oral use.

♦ doxycycline

Doxycycline (Doryx) is a semisynthetic tetracycline antibiotic. It is useful in the treatment of rickettsial infections such as Rocky Mountain spotted fever, chlamydial and mycoplasmal infections, spirochetal infections, and many infections with gram-negative organisms. It can also be used for the prevention and treatment of anthrax and malaria. Doxycycline may also be used in the treatment of acne. It is available in both oral and injectable forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	1.5-4 hr	14-24 hr	Up to 10-12 hr

tigecycline

Tigecycline (Tygacil) is the newest tetracycline, referred to as a *glycylcycline.* It differs from other tetracyclines in that it is effective against many organisms resistant to others in its class. It is indicated for the treatment of complicated skin and skin structure infections caused by susceptible organisms, including MRSA and vancomycin-sensitive *Enterococcus faecalis,* and for the treatment of complicated intraabdominal infections. Tigecycline is given by injection only. Nausea and vomiting are the most common adverse effects, occurring in 20% to 30% of patients.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Immediate	Immediate after infusion	27 hr	12 hr

The remaining antibiotic classes are discussed in Chapter 39.

NURSING PROCESS

ASSESSMENT

In general, before the administration of any *antibiotic,* it is crucial to gather data regarding a history of or symptoms indicative of hypersensitivity or allergic reactions (from mild reactions with rash, pruritus, or hives to severe reactions with laryngeal edema, bronchospasm, hypotension, and possible cardiac arrest). Also, determine the patient's age, weight, and baseline vital signs with body temperature. Examine the results of any laboratory tests that have been ordered, such as liver function studies (AST and ALT levels), kidney function studies (usually BUN and creatinine levels), cardiac function studies (pertinent laboratory tests, electrocardiogram), ultrasonography (if indicated), culture and sensitivity tests, CBC, and platelet and clotting tests. Assess intake and output measurements, if appropriate (e.g., more than 30 mL/hr or 600 mL/day). Record baseline neurologic assessment findings because of the possibility of CNS adverse effects from the various antibiotics. Assess bowel sounds and patterns because of potential antibiotic-related GI tract adverse effects. Further assessment needs to include checking for contraindications, cautions, and drug interactions. Obtain a complete list of all medications, including over-the-counter drugs, herbals, and dietary supplements. Cultural assessment is also important because of the well-documented variations in responses among different racial and ethnic groups as well as some patients' use of folk remedies or alternative therapies to try and alleviate infections. Assess learning preparedness, willingness to learn, and educational level because of the importance of patient education to safe medication administration. Note baseline findings from assessment of the oral mucosa, respiratory tract, GI tract, and genitourinary tract because of the risk of superinfection in these areas. Superinfections are often evidenced by fever, lethargy, mouth sores, perineal itching, and other system-related symptoms. Because antibiotic resistance is so prevalent, pose questions about long-term use, overuse, or abuse of antibiotics to the patient or caregiver. Assessment information related to each group of antibiotics is presented in the following paragraphs.

For patients taking *sulfonamides,* a careful assessment for drug allergies to sulfa-type drugs and/or sulfites, such as oral sulfonylureas (antidiabetic drugs) and thiazide diuretics, is important to patient safety (see pharmacology discussion). Perform a thorough skin assessment during drug therapy because of the potential for occurrence of the adverse effect of Stevens-Johnson syndrome (see Table 38-2). Assess red blood cell count before beginning sulfonamide therapy because of the possibility of drug-related anemias. With frequent or long-term therapy, assess renal function due to the potential for drug-related crystalluria. Check the patient's medication and medical history for any manifestations of G6PD and slow acetylation (see Chapters 2 and 4).

With *penicillins,* because of the high incidence of hypersensitivity, determine if there are drug allergies before initiation of therapy. Potential drug interactions are presented in Table 38-5. In addition, assess the patient for a history of asthma, sensitivity to multiple allergens, aspirin allergy, and sensitivity to cephalosporins, because these are associated with a higher risk for penicillin allergy. If procaine penicillin is to be given, also assess for procaine hypersensitivity. Note results of culture and sensitivity testing as soon as they are available to confirm the appropriateness of therapy. Because of possible CNS and/or GI adverse effects, complete a thorough neurologic, abdominal, and bowel assessment. Especially important for patients with electrolyte disturbances, cardiac disease, and/or renal disease is assessment of serum sodium and potassium levels, primarily because of the high sodium and potassium ion concentrations in some penicillin preparations. For example, penicillin G contains 1.7 mEq of potassium ion per million units and 2 mEq of sodium ion per million units. With these particular preparations, if a patient has heart failure, fluid overload, or cardiac dysrhythmias, a high sodium or potassium level (hypernatremia or hyperkalemia) can lead to exacerbation of these problems. With any dosage form of the penicillins, it is important to patient safety to assess for the possibility of an immediate, accelerated, or delayed allergic reaction. Also, assess the medication order and be aware that many times these drugs are referred to by their trade names and don't always end in "*cillin,*" such as with Zosyn and Augmentin (see the Safety and Quality Improvement: Preventing Medication Errors box).

With *cephalosporins,* conduct a thorough assessment of allergies, including allergy to penicillins, because of possible cross-sensitivity. Because of the similarity in their mechanism of action to penicillins, assessment data is also similar. Obtain information about the specific drug and note the generation of cephalosporins to which it belongs. Each of the five drug generations has distinctive adverse effects and/or complications in addition to commonalities with the other groups.

Carbapenems are used when there are complicated connective tissue infections in acutely ill patients who are hospitalized. Assess patients for a history of seizure activity because of the potential seizure-type, drug-induced reaction.

With *macrolides,* assessment of baseline cardiac function with documentation of vital signs is important because these drugs may lead to palpitations, chest pain, and ECG changes. Note baseline hearing status because of drug-induced hearing loss and tinnitus. Assess liver function and history of liver disease due to possible hepatotoxicity and jaundice. Drug interactions have been discussed previously, but special consideration should be given to concurrent use of a macrolide with warfarin, digoxin, or theophylline, resulting in possible toxicity of the latter drugs. Macrolides also reduce the effectiveness of oral contraceptives.

With *tetracyclines,* carefully assess culture and sensitivity reports as with all antibiotic therapy. There is concern regarding the use of these drugs in patients younger than 8 years of age because of the problem of permanent mottling and discoloration of the teeth. Use of these drugs in pregnancy may also pose problems for the fetus. Assess for any whitish sore patches on the oral

BOX 38-2 BRIEF SUMMARY OF NURSING CONSIDERATIONS FOR ANTISEPTICS AND DISINFECTANTS

- Check for allergies to any of the chemicals or compounds contained in the antiseptic or disinfectant before use. These include alcohol, chlorine, and hydrogen peroxide.
- If the agent is iodine based (e.g., povidone-iodine), be sure to ask about any allergies to iodine or seafood. If allergies exist, then the agent must not be used. There is a higher risk for reactions to antiseptics if there have been previous allergic reactions to antibacterial topical drugs. Use of disinfectants may also be associated with allergic reactions.
- Research the product or chemical and be aware of specific instructions and application technique.
- Always follow Standard Precautions. Dispose of any soiled bandages in a biohazard bag.
- With antiseptics, always research the product and any special application instructions or directions. If the skin is intact, nonsterile gloves are recommended for use unless otherwise indicated. If integrity is broken and the skin is not intact, use sterile gloves and/or sterile technique.
- With antiseptics, cleanse the site of any debris (e.g., pus, drainage) and any residual medication. Use normal saline or lukewarm soap and water for cleansing. Use a tongue blade, cotton-tipped applicator, or gloved finger to apply the antiseptic solution or product. Document any unusual findings at the site of use, such as swelling, redness, or drainage.
- Always follow the instructions related to each specific disinfectant agent.
- Adverse effects of antiseptics may include excessive dryness of the skin, burns to the skin or mucous membranes, blistering, and skin staining.
- Instruct patients to report any increase in redness, drainage, pain, swelling, and/or fever associated with the use of antiseptics, as deemed appropriate.

mucosa (due to candidiasis or yeast infection) as well as any vaginal itching, pain, and/or cottage cheese–like discharge (due to vaginal candidiasis) for early identification and early treatment of superinfections (see previous discussion). Assess for significant drug interactions, including simultaneous use of antacids, antidiarrheal drugs, dairy products, calcium, enteral feedings, and iron preparations. These medications may lead to reduced absorption of the tetracycline. Tetracyclines may also decrease the effectiveness of oral contraceptives. Assess the patient taking oral anticoagulants more closely due to possible potentiation of bleeding.

Antiseptics and disinfectants have also been put in this chapter. See Box 38-2 for a brief summary of nursing-related considerations for these agents.

NURSING DIAGNOSES

1. Noncompliance with the treatment regimen related to lack of information and/or inability to pay for and obtain the necessary medication
2. Deficient knowledge related to lack of information about the disease process and the medication regimen
3. Risk for infection related to the patient's possible development of a compromised immune status (due to use of sulfonamides)

CASE STUDY

Antibiotic Therapy

Mr. G. has been a resident of an assisted care facility since experiencing a left-sided stroke 5 years ago. Presently his cardiovascular status and cerebrovascular status are stable. However, he has had a productive cough and a low-grade fever for 2 days. After physical assessment and chest radiographic examination, the prescriber diagnoses pneumonia of the left lower lobe of the lung. The prescriber instructs that a sputum specimen be obtained and orders intravenous piperacillin/tazobactam (Zosyn) 2.25 g every 8 hours and oral theophylline (Theo-Dur) 300 mg every 12 hours. Mr. G. also takes warfarin (Coumadin) 2 mg every evening. Maalox 30 mL has been ordered as needed for GI upset, and oral ibuprofen 400 mg can be given as needed for pain. The prescriber also asks the nurse to start the antibiotic "as soon as possible."

1. Explain the rationale behind the use of tazobactam with piperacillin in the Zosyn.
2. Which order will the nurse implement first? Explain your answer.
3. What concerns or drug interactions will the nurse be aware of with the use of Zosyn and the other medications ordered for Mr. G.?
4. What parameters need to be monitored to determine whether the Zosyn is working? Explain your answer.

For answers, see http://evolve.elsevier.com/Lilley.

PLANNING

GOALS

1. Patient remains compliant with the antibiotic therapy regimen for the full duration of treatment.
2. Patient demonstrates an increase in knowledge and information about the disease process and related drug therapy.
3. Patient maintains homeostasis and a healthy immune system, and is free from risk for infection.

OUTCOME CRITERIA

1. Patient describes the rationale for the specific antibiotic therapeutic regimen, associated adverse effects, as well as measures to decrease these adverse effects.
   - Patient takes specific antibiotic with attention to instructions about whether to take with meals and/or increased fluids and foods, medications, and beverages to avoid while on antibiotic regimen.
   - Patient briefly describes the importance to therapeutic effectiveness of taking the antibiotic for the duration of therapy and as prescribed.
2. Patient takes medication exactly as prescribed and for the full time prescribed.
   - Patient understands the importance to therapeutic effectiveness of taking the medication exactly as prescribed and until the full prescription is taken.
   - Patient reports adverse effects that are unresolved and are of concern such as jaundice, excessive fatigue, elevated temperature, increase in pain associated with the infection, and severe GI distress, nausea, or diarrhea.

3. Patient remains free of elevated WBC count and maintains temperature, pulse rate, and respiratory rate within normal ranges with negative culture and sensitivity reports.

IMPLEMENTATION

General nursing interventions that apply to antibiotics include the following: (1) Give oral antibiotics within the recommended time frames and fluids/foods as indicated. (2) All medication is to be taken as ordered and in full and around the clock to maintain effective blood levels unless otherwise instructed by the prescriber. (3) Doses are not to be omitted or doubled up. (4) Oral antibiotics are not to be given at the same time as antacids, calcium supplements, iron products, laxatives containing magnesium, or some of the antilipemic drugs (see pharmacology listing of drug interactions). (5) Herbal products and dietary supplements are to be used only if they do not interact with the antibiotic. (6) Continually monitor for hypersensitivity reactions past the initial assessment phase because immediate reactions may not occur for up to 30 minutes, accelerated reactions may occur within 1 to 72 hours, and delayed responses may occur after 72 hours. These are characterized by wheezing; shortness of breath; swelling of the face, tongue, or hands; itching; or rash. (7) If there are signs of a possible hypersensitivity reaction, the first thing to do is stop the dosage form immediately (if IV, stop the infusion), contact the prescriber, and monitor the patient closely.

Sulfonamides need to be avoided in patients with G6PD and slow acetylation. Encourage forcing of fluids (2000 to 3000 mL/24 hr) to prevent drug-related crystalluria. Oral dosage forms are to be taken with food to minimize GI upset. Encourage patients to immediately report the following to the prescriber: worsening abdominal cramps, stomach pain, diarrhea, blood in the urine, severe or worsening rash, shortness of breath, and fever. These may indicate adverse reactions to these drugs; remember that the mucocutaneous, GI, hepatic, and hematologic complications may be of a fatal nature.

With *penicillins,* as with other antibiotics, the natural flora in the GI tract may be killed off by the antibiotic. Unaffected GI bacteria such as *C. difficile* may overgrow (see pharmacology discussion for more information). This process may be prevented by the consumption of probiotics, such as products containing *Lactobacillus,* supplements, or cultured dairy products like yogurt, buttermilk, and kefir. Kefir is prepared using milk from sheep, goats, and cows. Soy milk kefirs are now also commercially available. Keep in mind the following important points when giving various penicillin formulations: (1) Advise patients to take oral penicillins with at least 6 oz of water (not juices); juices are acidic fluids and may nullify the drug's antibacterial action. (2) Penicillin V, amoxicillin, and amoxicillin/clavulanate are given with water and 1 hour before or 2 hours after meals to maximize absorption; however, because of GI upset, these medications may need to be taken with a snack or meals. (3) Procaine and benzathine salt penicillins are thick solutions; give them as ordered IM, using at least a 21-gauge needle, and into a large muscle mass, rotating sites as needed. (4) Reconstitute IM imipenem/cilastatin in sterile saline, with plain lidocaine—as ordered and if the patient has no allergy to it—give into a large muscle mass. (5) With IV penicillins (e.g., ampicillin), as with any IV therapy, use the proper diluent and infuse the medication over the recommended time. Monitor the IV site frequently for swelling, tenderness, heat, redness, leaking, and pain. Calculate IV rates to deliver the prescribed amount per minute/hour. Change IV sites per facility protocol. (6) Check for compatibilities of IV fluids and drugs prior to infusion. (7) If the patient experiences an anaphylactic reaction to a penicillin (or any drug), give epinephrine and other emergency drugs as ordered, and have supportive treatment (e.g., oxygen) available at all times.

Orally administered *cephalosporins* may be given with food to decrease GI upset. Alcohol and alcohol-containing products are to be avoided due to the potentiation of a disulfiram-like reaction (known as *acute alcohol intolerance*) with some of the cephalosporins. This may occur up to 72 hours after taking cefotetan. Symptoms that may occur include stomach cramping, nausea, vomiting, headache, diaphoresis, pruritus, and hypotension. With the newer cephalosporins, as with many drug groups, check the drug names carefully to ensure patient safety. Many drug names sound alike, and this could lead to medication errors.

Macrolides need to be administered with the same precautions as used with other antibiotics. Macrolides are *not* to be given with or immediately before or after fruit juices to avoid interaction with the drug. Inform the patient about the many drug interactions (discussed in the pharmacology section), including those with over-the-counter drugs, herbal products, and dietary supplements. Encourage patients to report the following to their prescriber immediately: chest pain, palpitations, dizziness, jaundice, rash, and hearing loss.

Tetracyclines cause photosensitivity, so advise the patient to take precautions to avoid sun exposure and tanning bed use. Encourage the patient to take oral doses with at least 8 oz of fluids and food to minimize GI upset. However, warn the patient *not* to take tetracyclines with calcium, magnesium, and iron. These chemicals *chelate* or bind with the tetracycline, leading to a significant reduction in the oral absorption, and thus the effectiveness, of this group of antibiotics. Therefore, concurrent use of dairy products, antacids, or iron needs to be avoided. The patient may take these interacting foods and drugs 2 hours before or 3 hours after the tetracycline to avoid this interaction. IV doxycycline is very irritating to the veins, so check the IV infusion site frequently. Remember that tetracyclines can cause discoloration of the permanent teeth and tooth enamel in fetuses and children. They may also retard fetal skeletal growth if taken during pregnancy. Continually monitor for diarrhea or vaginal yeast infections due to altered intestinal and/or vaginal flora.

EVALUATION

Include monitoring of goals, outcome criteria, therapeutic effects, and adverse effects in the evaluation. Therapeutic effects of *antibiotics* include a decrease in the signs and symptoms of the infection; a return to normal vital signs, including temperature; negative results on culture and sensitivity tests; normal results for CBC; and improved appetite, energy level, and sense of well-being. Evaluation for adverse effects includes monitoring for specific drug-related adverse effects (see each drug profile).

PATIENT TEACHING TIPS

- Provide the patient with a list of foods and beverages that may interact negatively with antibiotics, such as alcohol, acidic fruit juices, and dairy products.
- Advise the patient to report severe adverse effects to the prescriber and to keep any follow-up visits so that the effectiveness of therapy may be monitored. Laboratory tests (e.g., CBC) may also be performed at these visits.
- Foods that may help prevent superinfections (e.g., vaginal yeast infections) include yogurt, buttermilk, and kefir. New yogurts, termed *probiotics,* are available for reestablishing the natural flora of the GI tract.
- Educate patients who are taking oral contraceptives for birth control, about the interactions between them and certain antibiotics. This is because the effectiveness of oral contraceptives may be decreased with certain antibiotics. Reliable backup methods of contraception must be used in addition to the oral contraception during antibiotic use.
- Recommend wearing of a medical alert bracelet or necklace if there are drug allergies, especially if anaphylactic in nature. It is recommended that drug allergy information and a listing of medical diagnoses and list of all medications be kept on the patient's person at all times.
- For *sulfonamides,* the medication is to be taken with plenty of fluids (2000 to 3000 mL/24 hr) and taken with food to decrease GI adverse effects.
- For *penicillins,* medications are to be taken exactly as prescribed and for the full duration indicated, as with all antibiotics. Doses are to be spaced at regularly scheduled intervals. Instruct the patient to take oral dosage forms with water, avoiding the following beverages: caffeine-containing beverages, citrus fruit, cola beverages, fruit juices, and tomato juice (decrease effectiveness of the antibiotic). If the patient must take a penicillin drug four times a day, encourage the patient to set up a reminder system (with cell phone alarms or a watch) so that blood levels remain steady.
- For *cephalosporins,* advise the patient to report unresolved GI upset, such as diarrhea and nausea. Alcohol must be avoided.
- For *tetracyclines,* advise patients to avoid exposure to tanning beds and direct sunlight or to use sunscreen and/or wear protective clothing because of drug-related photosensitivity. These photosensitive effects may be noticed within a few minutes to hours after taking the drug and may last up to several days after the drug has been discontinued.
- For *macrolides,* instruct the patient to take the drug as directed, and check for interactions with other drugs being taken at the same time, especially interactions between erythromycin and other medications. For some drugs in this class (e.g., azithromycin), newer dosage forms are available in 3-day and 1-day dose packs rather than the 5-day dose pack. Always be sure that the patient knows the proper dosage and instructions for the drug the patient is taking.

KEY POINTS

- Antibiotics are either bacteriostatic or bactericidal. Bacteriostatic antibiotics inhibit the growth of bacteria but do not directly kill them. Bactericidal antibiotics directly kill the bacteria.
- Most antibiotics work by inhibiting bacterial cell wall synthesis in some way. Bacteria have survived over the ages because they can adapt to their surroundings. If a bacterium's environment includes an antibiotic, over time it can mutate in such a way that it can survive an attack by the antibiotic. The production of beta-lactamases is one way in which bacteria can fend off the effects of antibiotics.
- Be aware of the most common adverse effects of antibiotics, which include nausea, vomiting, and diarrhea. Inform patients that antibiotics should be taken for the prescribed length of time.
- Each class of antibiotics is associated with specific cautions, contraindications, drug interactions, and adverse effects that must be carefully assessed for and monitored by the nurse.
- Because normally occurring bacteria are killed during antibiotic therapy, superinfections may arise during treatment. These may be manifested by the following signs and symptoms: fever, perineal itching, oral lesions, vaginal irritation and discharge, cough, and lethargy.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A patient is scheduled for colorectal surgery tomorrow. He does not have sepsis, his WBC count is normal, he has no fever, and he is otherwise in good health. However, there is an order to administer an antibiotic on call before he goes to surgery. The nurse knows that the rationale for this antibiotic order is to
- **a** provide empiric therapy.
- **b** provide prophylactic therapy.
- **c** treat for a superinfection.
- **d** reduce the number of resistant organisms.

2 A teenage patient is taking a tetracycline drug as part of treatment for severe acne. When the nurse teaches this patient about drug-related precautions, which is the most important information to convey?
- **a** When the acne clears up, the medication may be discontinued.
- **b** This medication needs to be taken with antacids to reduce GI upset.
- **c** The patient needs to use sunscreen or avoid exposure to sunlight, because this drug may cause photosensitivity.
- **d** The teeth should be observed closely for signs of mottling or other color changes.

3 A newly admitted patient reports a penicillin allergy. The prescriber has ordered a second-generation cephalosporin as part of the therapy. Which nursing action is appropriate?
- **a** Call the prescriber to clarify the order because of the patient's allergy.
- **b** Give the medication, and monitor for adverse effects.
- **c** Ask the pharmacy to change the order to a first-generation cephalosporin.
- **d** Administer the drug with a nonsteroidal antiinflammatory drug to reduce adverse effects.

4 During patient education regarding an oral macrolide such as erythromycin, the nurse will include which information?
- **a** If GI upset occurs, the drug will have to be stopped.
- **b** The drug needs to be taken with an antacid to avoid GI problems.
- **c** The patient needs to take each dose with a sip of water.
- **d** The patient may take the drug with a small snack to reduce GI irritation.

5 A woman who has been taking an antibiotic for a UTI calls the nurse practitioner to complain of severe vaginal itching. She has also noticed a thick, whitish vaginal discharge. The nurse practitioner suspects that
- **a** this is an expected response to antibiotic therapy.
- **b** the UTI has become worse instead of better.
- **c** a superinfection has developed.
- **d** the UTI is resistant to the antibiotic.

6 The nurse is reviewing the orders for wound care, which include use of an antiseptic. Which statements best describe the use of antiseptics? (Select all that apply.)
- **a** Antiseptics are appropriate for use on living tissue.
- **b** Antiseptics work by sterilizing the surface of the wound.
- **c** Antiseptics are applied to nonliving objects to kill microorganisms.
- **d** The patient's allergies must be assessed before using the antiseptic.
- **e** Antiseptics are used to inhibit the growth of microorganisms on the wound surface.

7 The order for a child reads: "Give cefoxitin (Mefoxin) 160 mg/kg/day, IVPB, divided into doses given every 6 hours." The child weighs 55 lb. How much will the patient receive each day? For each dose?

1. b, 2. c, 3. a, 4. d, 5. c, 6. a, d, e, 7. 4000 mg/day; 1000 mg/dose

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Review the general principles of antibiotic therapy and all of the antibiotics covered previously in Chapter 38 in preparation for discussion of the following antibiotics or antibiotic classes: aminoglycosides, quinolones, clindamycin, metronidazole, nitrofurantoin, vancomycin, and several other miscellaneous antibiotics.

2 Describe the advantages and disadvantages associated with the use of antibiotics, including overuse and abuse of antibiotics, development of drug resistance, superinfections, and antibiotic-associated colitis.

3 Discuss the indications, cautions, contraindications, mechanisms of action, adverse effects, toxic effects, routes of administration, and drug interactions for the aminoglycosides, fluoroquinolones, clindamycin, metronidazole, nitrofurantoin, vancomycin, and miscellaneous antibiotics.

4 Develop a nursing care plan that includes all phases of the nursing process for the patient receiving antibiotics.

DRUG PROFILES

amikacin, p. 638
♦ **ciprofloxacin, p. 640**
♦ **clindamycin, p. 640**
colistimethate, p. 643
daptomycin, p. 643
♦ **gentamicin, p. 638**
levofloxacin, p. 640
linezolid, p. 641
♦ **metronidazole, p. 642**
neomycin, p. 638
nitrofurantoin, p. 642
quinupristin/dalfopristin, p. 642
telavancin, p. 644
tobramycin, p. 638
♦ **vancomycin, p. 643**

♦ *Key drug*

KEY TERMS

Concentration-dependent killing A property of some antibiotics, especially aminoglycosides, whereby achieving high plasma drug concentrations, even if briefly, results in the most effective bacterial kill (compare *time-dependent killing*). (p. 635)

Extended-spectrum beta-lactamases (ESBLs) A group of beta-lactamase enzymes produced by some organisms that makes the organism resistant to all beta-lactam antibiotics (penicillins and cephalosporins) and aztreonam. Patients who are infected by such organisms must be in contact isolation;

KEY TERMS—cont'd

proper handwashing is key to preventing the spread of these organisms. (p. 634)

Klebsiella pneumoniae carbapenemase (KPC) An enzyme first found in isolates of the bacterium *Klebsiella pneumoniae* that renders the organism resistant to all carbapenem antibiotics as well as beta-lactam antibiotics and monobactams. Such organisms produce a very serious resistant infection. (p. 634)

Methicillin-resistant *Staphylococcus aureus* (MRSA) A strain of *Staphylococcus aureus* that is resistant to the beta-lactamase penicillin known as *methicillin.* Originally, the abbreviation MRSA referred exclusively to methicillin-resistant *S. aureus.* It is now used more commonly to refer to strains of *S. aureus* that are resistant to several drug classes, and therefore, depending on the context or health facility, it may also stand for "multidrug-resistant *S. aureus.*" (p. 634)

Microgram One millionth of a gram. Be careful not to confuse it with milligram (one thousandth of a gram), which is one thousand times greater than 1 microgram. Confusion of these two units sometimes results in drug dosage errors. (p. 635)

Minimum inhibitory concentration (MIC) A laboratory measure of the lowest concentration of a drug needed to kill a certain standardized amount of bacteria. (p. 635)

Multidrug-resistant organisms Bacteria that are resistant to one or more classes of antimicrobial drugs. These include multidrug-resistant *Staphylococcus aureus,* extended-spectrum beta-lactamase–producing organisms, and *Klebsiella pneumoniae* carbapenemase–producing organisms. (p. 634)

Nephrotoxicity Toxicity to the kidneys, often drug induced and manifesting as compromised renal function; usually reversible upon withdrawal of the offending drug. (p. 635)

Ototoxicity Toxicity to the ears, often drug induced and manifesting as varying degrees of hearing loss that is likely to be permanent. (p. 635)

Postantibiotic effect A period of continued bacterial suppression that occurs after brief exposure to certain antibiotic drug classes, especially aminoglycosides (discussed in this chapter) and carbapenems (see Chapter 38). The mechanism of this effect is uncertain. (p. 636)

Pseudomembranous colitis A necrotizing inflammatory bowel condition that is often associated with antibiotic therapy. Some antibiotics (e.g., clindamycin) are more likely to produce it than others. More commonly referred to as *antibiotic-associated colitis* or *Clostridium difficile diarrhea* or *C. difficile infection*. (p. 641)

Synergistic effect Drug interaction in which the bacterial killing effect of two antibiotics given together is greater than the sum of the individual effects of the same drugs given alone. (p. 636)

Therapeutic drug monitoring Ongoing monitoring of plasma drug concentrations and dosage adjustment based on these values as well as other laboratory indicators such as kidney and liver function test results; it is often carried out by a pharmacist in collaboration with medical, nursing, and laboratory staff. (p. 635)

Time-dependent killing A property of most antibiotic classes whereby prolonged high plasma drug concentrations are required for effective bacterial kill (compare *concentration-dependent killing*). (p. 635)

Vancomycin-resistant *Enterococcus* (VRE) *Enterococcus* species that are resistant to beta-lactam antibiotics and vancomycin. Most commonly refers to *Enterococcus faecium*. (p. 634)

This chapter is a continuation of Chapter 38 and focuses on additional classes of antibiotics, which are used for more serious and harder-to-treat infections. Most of the drugs discussed in this chapter are given by the *parenteral* (injection) route only, a route generally reserved for treating more clinically serious infections. Also included are miscellaneous drugs that are unique in their class, as well as newer drugs and drug classes. This chapter also focuses on multidrug-resistant organisms, specifically **methicillin-resistant *Staphylococcus aureus* (MRSA)**, **vancomycin-resistant *Enterococcus* (VRE)**, organisms producing **extended-spectrum beta-lactamases (ESBLs)**, and organisms producing ***Klebsiella pneumoniae* carbapenemase (KPC).**

PATHOPHYSIOLOGY OF RESISTANT INFECTIONS

Organisms that are resistant to one or more classes of antimicrobial drugs are referred to as **multidrug-resistant organisms.** These include MRSA, VRE, and ESBL- and KPC-producing organisms. MRSA has been around for many years, and fortunately new antibiotics have been developed to treat MRSA. However, the threat of MRSA becoming resistant to all antibiotics currently available is all too real. MRSA is no longer seen just in hospitals; it has spread to the community setting, and approximately 50% of staphylococcal infections contracted in the community involve MRSA, depending on location. Local community and hospital MRSA strains vary. VRE is usually seen in urinary tract infections. Some newer antibiotics have been developed to successfully treat VRE, as well as MRSA. Unfortunately, ESBL- and KPC-producing bacteria are the newest players in this saga. Organisms that produce ESBL are resistant to all beta-lactam antibiotics and aztreonam, and can be treated only with carbapenems or sometimes quinolones. In our noble effort to treat infection with ESBL-producing organisms, the use of carbapenems increased, and unfortunately in response, bacteria created a new means of resistance, namely, the ability to produce KPC. When patients become infected with KPC-producing bacteria, there are only two known antibiotics that can be used, tigecycline and colistimethate. Reports of

resistance to these antibiotics have been described, which leaves the patient untreatable. Multidrug-resistant organisms are one of the world's top health problems. When patients become infected with such an organism, they must be placed in contact isolation. Many hospitals are placing all patients infected with KPC-producing bacteria in one area, and some hospitals have been shut down due to this organism. Proper handwashing is of the utmost importance. These organisms are spread by contact, so all health care professionals must wash their hands before and after all patient contact. Some research indicates that patterns of antibiotic resistance for a certain class of antibiotics are influenced by the prescription of antibiotics in other, previously-assumed unrelated classes. (For example, quinolone use may influence the emergence of resistance to other antibiotic classes.)

PHARMACOLOGY OVERVIEW

AMINOGLYCOSIDES

The aminoglycosides are a group of natural and semisynthetic antibiotics that are classified as bactericidal drugs (see Chapter 38). They are potent antibiotics, which makes aminoglycosides the drugs of choice for the treatment of particularly virulent infections. The aminoglycoside antibiotics available for clinical use are listed in Table 39-1. These drugs can be given by several different routes, but they are not given orally because of their poor oral absorption. An exception to this is neomycin (see Drug Profiles). The three aminoglycosides most commonly used for the treatment of systemic infections are amikacin, gentamicin, and tobramycin. Serum levels of these drugs are routinely monitored in patients' blood samples. Dosages are adjusted to maintain known optimal levels that maximize drug efficacy and minimize the risk for toxicity. This process is known as **therapeutic drug monitoring.** Aminoglycoside therapy is monitored in this way due to the **nephrotoxicity** and **ototoxicity** associated with these drugs. Most commonly, dosing is adjusted to the patient's level of renal function, based on estimates of creatinine clearance calculated from serum creatinine values. This task is often carried out by a hospital pharmacist, consulting for the prescriber. Not only are serum levels measured to prevent toxicity, but it has been shown that for the aminoglycosides to be effective, the serum level needs to be at least eight times higher than the **minimum inhibitory concentration (MIC).** The MIC for any antibiotic is a measure of the lowest concentration of drug needed to kill a certain standard amount of bacteria. This value is determined *in vitro* (in the laboratory) for each drug. It has been shown that other classes of antibiotics, such as beta-lactams, act through **time-dependent killing,** that is, the amount of time the drug is above the MIC is critical for maximal bacterial kill. However, aminoglycosides work primarily through **concentration-dependent killing;** that is, achieving a drug plasma concentration that is a certain level above the MIC, even for a brief period of time, results in the most effective bacterial kill. For this reason, although these drugs were originally given in three daily intravenous doses, the current predominant practice is once-daily aminoglycoside dosing. Dosages of 5 to 7 mg/kg/day are used. Several clinical studies have shown that once-daily dosing provides a sufficient plasma drug concentration for bacterial kill, along with equal or lower risk for toxicity compared with multiple daily dosing regimens. Use of a once-daily regimen instead of the traditional three-times-daily regimen also reduces the nursing care time required and often allows for outpatient or even home-based aminoglycoside drug therapy.

Peak (highest) drug levels for once-daily regimens are usually not measured as it is assumed that the peak level for a single daily dose will be short lived and will drop within a reasonable time frame. However, trough (lowest) levels are routinely measured to ensure adequate renal clearance of the drug and avoid toxicity. For dosage information on selected aminoglycosides, see the table on p. 637. Dosage regimens and ranges for serum levels may vary for different institutions.

With once-daily dosing, the blood sample for trough measurement is drawn at least 8 to 12 hours after completion of dose administration. The therapeutic goal is a trough concentration at or below 1 mcg/mL (which is considered undetectable). Trough levels above 2 mcg/mL are associated with greater risk for both *ototoxicity* and *nephrotoxicity*. Ototoxicity (toxicity to the ears) often manifests as some degree of temporary or permanent hearing loss. Nephrotoxicity (toxicity to the kidneys) manifests as varying degrees of reduced renal function. This is generally indicated by laboratory test results such as serum creatinine level. A rising serum creatinine level suggests reduced creatinine clearance by the kidneys and is indicative of declining renal function. Trough levels are normally monitored initially, and then once every 5 to 7 days until drug therapy is discontinued. The patient's serum creatinine level is measured at least every 3 days as an index of renal function,

TABLE 39-1 AMINOGLYCOSIDE ANTIBIOTICS

	PEAK		TROUGH	
SERUM DRUG LEVELS	MULTIPLE DAILY DOSING*	ONCE-DAILY DOSING	MULTIPLE DAILY DOSING	ONCE-DAILY DOSING
amikacin	15-30 mcg/mL†	Usually not measured	5-10 mcg/mL	Less than 10 mcg/mL
gentamicin and tobramycin	4-10 mcg/mL	Usually not measured	1-2 mcg/mL	Less than 1 mcg/mL

*q8h or q12h.

†*mcg,* **microgram**; note that 1 microgram = 1/1000 (one thousandth) of a milligram or 1/1,000,000 (one millionth) of a gram. Also note that microgram is abbreviated *mcg,* while milligram is abbreviated *mg.*

and drug dosages are adjusted as needed for any changes in renal function.

Traditional dosing of aminoglycosides (i.e., three times a day) can still be used. When an aminoglycoside is given in this manner, both peak and trough levels are measured. Samples for measurement of peak levels are drawn 30 minutes after a 30-minute infusion, and samples for measurement of trough levels are drawn just before the next dose. Pharmacists can adjust the dose based on a pharmacokinetic evaluation of these levels. When the drug is given in the traditional manner, the desired peak levels vary depending on the type of organism and the site of infection. Higher levels are needed when treating pneumonia, as opposed to treating a urinary tract infection. Because the aminoglycosides are eliminated by the kidney, the drug concentrates in the urine, so lower dosages can be used to treat urinary tract infections. Regardless of the infection being treated, however, it is desirable to keep the trough levels below 2 mcg/mL. Table 39-1 lists the traditional desired drug levels for these drugs.

Mechanism of Action and Drug Effects

Aminoglycosides work in a way that is similar to that of the tetracyclines in that they bind to ribosomes, specifically the 30S ribosome, and thereby prevent protein synthesis in bacteria (see Figure 38-3). Aminoglycosides are most often used in combination with other antibiotics such as beta-lactams or vancomycin in the treatment of various infections, because the combined effect of the two antibiotics is greater than the sum of the effects of each drug acting separately. This is known as a **synergistic effect.** When aminoglycosides are used in combination with beta-lactam antibiotics (i.e., penicillins, cephalosporins, monobactams [see Chapter 38]), the beta-lactam antibiotic is given first. This is because the beta-lactams break down the cell wall of the bacteria and allow the aminoglycoside to gain access to the ribosomes where they work. Aminoglycosides also have a property known as the **postantibiotic effect.** This is a period of continued bacterial growth suppression that occurs *after* short-term antibiotic exposure, as in once-daily aminoglycoside dosing (see earlier). Carbapenems are another antibiotic class with a postantibiotic effect. The postantibiotic effect is enhanced with higher peak drug concentrations and concurrent use of beta-lactam antibiotics.

As is the case with most antibiotic drug classes, various bacterial mechanisms of resistance to aminoglycosides have emerged among both gram-positive and gram-negative species previously more susceptible to these drugs. The prevalence and strength of such resistance varies for different drugs, organisms, patient populations, disease states, and geographic prescribing patterns.

Indications

The toxicity associated with aminoglycosides limits their use to treatment of serious gram-negative infections and specific conditions involving gram-positive cocci, in which case gentamicin is usually given in combination with a penicillin. Gram-negative infections commonly treated with aminoglycosides include those caused by *Pseudomonas* species (spp.) and several organisms belonging to the Enterobacteriaceae family (facultatively anaerobic gram-negative rods), including *Escherichia coli, Proteus* spp., *Klebsiella* spp., and *Serratia* spp. Such infections are often treated with a suitable aminoglycoside and an extended-spectrum penicillin, third-generation cephalosporin, or carbapenem. Gram-positive infections treated with aminoglycosides may include infections due to *Enterococcus* spp. and *S. aureus,* and bacterial endocarditis, which is usually streptococcal in origin. A regimen of three daily doses is more common when treating gram-positive infections, because this often enhances synergy with other antibiotics that are used. Aminoglycosides are never used alone to treat gram-positive infections. Aminoglycosides are also used for prophylaxis in procedures involving the gastrointestinal (GI) or genitourinary (GU) tract, because such procedures carry a high risk for enterococcal bacteremia. They are also commonly given in combination with either ampicillin or vancomycin (for penicillin-allergic patients) to surgical patients with a history of valvular heart disease, because diseased heart valves are also more prone to enterococcal infection.

Aminoglycosides are to be administered with caution in premature and full-term neonates. Because of the renal immaturity of these patients, prolonged actions of the aminoglycosides and a greater risk for toxicities may result. Serious pediatric infections for which aminoglycosides are used include pneumonia, meningitis, and urinary tract infections. Drug selection for both pediatric and adult patients is based on the susceptibility of the causative organism. Refer to Table 39-2 for more information on the antibacterial spectra of specific aminoglycosides. A few aminoglycosides have more specific indications. Streptomycin is active against *Mycobacterium* spp. (see Chapter 41), whereas paromomycin is used to treat amebic dysentery, a protozoal intestinal disease (see Chapter 43).

TABLE 39-2 AMINOGLYCOSIDES: COMPARATIVE SPECTRA OF ANTIMICROBIAL ACTIVITY

AMINOGLYCOSIDE	SPECTRUM OF ACTIVITY
amikacin	*Acinetobacter* spp., *Enterobacter aerogenes, Escherichia coli, Klebsiella pneumoniae, Proteus* spp., *Providencia* spp., *Pseudomonas* spp., *Serratia* spp., Staphylococcus
gentamicin	*E. aerogenes, E. coli, K. pneumoniae, Proteus* spp., *Pseudomonas* spp., *Salmonella* spp., *Serratia* spp. (nonpigmented), *Shigella* spp.
neomycin	Toxicity limits use to gastrointestinal tract (hepatic coma, *E. coli* diarrhea, and antisepsis) and as a topical antibacterial
streptomycin	*Klebsiella granulomatis* (granuloma inguinale), *Yersinia pestis* (plague), *Francisella tularensis* (tularemia), *Mycobacterium tuberculosis* (tuberculosis), *Streptococcus* spp. (nonhemolytic endocarditis)
tobramycin	*Citrobacter* spp., *Enterobacter* spp., *E. coli, Klebsiella* spp., *Proteus* spp., *Providencia* spp., *P. aeruginosa, Serratia* spp.

GI, Gastrointestinal; *spp.,* species.

Aminoglycosides are inactive against fungi, viruses, and most anaerobic bacteria.

Contraindications

The only usual contraindication is known drug allergy. The pregnancy categories of these drugs range from C to D. Aminoglycosides have been shown to cross the placenta and cause fetal harm when administered to pregnant women. There have been several case reports of total irreversible bilateral congenital deafness in the children of women receiving aminoglycosides during pregnancy. Therefore, aminoglycosides are used in pregnant women only in the event of life-threatening infections when safer drugs are ineffective. These drugs are also distributed in breast milk. They should not be used by lactating women to avoid the risk of drug toxicity in nursing infants.

Adverse Effects

Aminoglycosides are very potent antibiotics and are capable of potentially serious toxicities, especially to the kidneys (nephrotoxicity) and to the ears (ototoxicity), in which they can affect hearing and balance functions. Duration of drug therapy needs to be as short as possible, based on sound clinical judgment and monitoring of the patient's progress. Nephrotoxicity typically occurs in 5% to 25% of patients and is usually manifested by urinary casts (visible remnants of destroyed renal cells), proteinuria, and increased blood urea nitrogen (BUN) and serum creatinine levels. It is usually reversible, but the patient's renal function test results must be monitored throughout therapy. In contrast, ototoxicity is less common, occurring in 3% to 14% of patients, and often is not reversible. It can result in varying degrees of permanent hearing loss, depending on the dosage and duration of drug therapy. It is believed to result from injury to the eighth cranial nerve (CN VIII, also called the *cochleovestibular nerve* or *auditory nerve*) and involves both cochlear damage (hearing loss) and vestibular damage (disrupted sense of balance). Symptoms include dizziness, tinnitus, a sense of fullness in the ears, and hearing loss. Other less common effects include headache, paresthesia, vertigo, skin rash, fever, overgrowth of nonsusceptible organisms, and neuromuscular paralysis (very rare and reversible). The risk for these toxicities is greatest in patients with preexisting renal impairment, patients already receiving other renally toxic drugs, and patients receiving high-dose or prolonged aminoglycoside therapy.

Interactions

The risk for nephrotoxicity can be increased with concurrent use of other nephrotoxic drugs such as vancomycin, cyclosporine, and amphotericin B. Concurrent use with loop diuretics increases the risk for ototoxicity. In addition, because aminoglycosides, like many other antibiotics, kill intestinal bacterial flora, they also reduce the amount of vitamin K produced by these gut bacteria. These normal flora normally serve to balance the effects of oral anticoagulants such as warfarin (Coumadin). Therefore, aminoglycosides can potentiate warfarin toxicity. Concurrent use with neuromuscular blocking drugs may prolong the duration of action of the neuromuscular blockade.

Dosages

For dosages information on selected aminoglycosides, see the table on this page.

DOSAGES

Selected Aminoglycosides

DRUG (PREGNANCY CATEGORY)	USUAL DOSAGE RANGE	INDICATIONS/USES
amikacin (generic only) (D)	**Adult and pediatric** IV: 15 mg/kg/day divided 2-3 times daily or 15-20 mg/kg once daily **Neonatal*** IV: 10 mg/kg load, then 7.5 mg/kg q12h	Primarily infection with gentamicin- and tobramycin-resistant gram-negative organisms along with severe staphylococcal infections
♦ gentamicin (generic only) (C)	**Adult** IV/IM: 2-6 mg/kg/day divided 1-4 times daily or 5-7 mg/kg once daily **Pediatric and neonatal** IV/IM: 2-2.5 mg/kg q8h	Primarily gram-negative infections along with severe staphylococcal infections
neomycin (C)	**Adult** PO/PR: 3000-9000 mg divided between 3-9 doses	Preoperative bowel cleansing (also used with different dosage regimens for hepatic encephalopathy)
tobramycin (generic, TOBI) (D)	**Adult** IV/IM: 3-6 mg/kg/day divided 1-3 times daily or 5-7 mg/kg once daily **Pediatric** IV/IM: 6-7.5 mg/kg/day divided 3-4 times daily **Neonatal*** IV/IM: 3 mg/kg q24h or 2 mg/kg q12h	Primarily gram-negative infections along with severe staphylococcal infections

IM, Intramuscular; *IV,* intravenous; *PO,* oral; *PR,* rectal.
*Dosing and frequency vary depending on age of patient.

DRUG PROFILES

Historically, the aminoglycoside antibiotics were used primarily to treat gram-negative infections. However, they are now used as a synergistic drug in the treatment of gram-positive infections as well. They are normally given intravenously or intramuscularly, but neomycin is administered only orally, rectally, or topically. Topical dosage forms of both gentamicin and tobramycin are also available for dermatologic (see Chapter 56) and ophthalmic (see Chapter 57) use. Currently available aminoglycosides include amikacin, gentamicin, kanamycin, neomycin, streptomycin, and tobramycin. Dosage and other information are given in the table on p. 637.

♦ amikacin

Amikacin is a semisynthetic aminoglycoside antibiotic that is often used to treat infections that are resistant to gentamicin or tobramycin. It is available only in injectable form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Variable	1 hr	2-3 hr	8-12 hr
IM	Variable	30 min-2 hr	2-3 hr	8-12 hr

♦ gentamicin

Gentamicin is the most commonly used aminoglycoside in clinical practice today. It can be given either intravenously or intramuscularly, and the dosage is the same for both routes. It is indicated for the treatment of infection with several susceptible gram-positive and gram-negative bacteria. Gentamicin is available in several dosage forms, including injections, topical ointments, and ophthalmic drops and ointments.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Variable	30 min	2-3 hr	Up to 24 hr
IM	Variable	30-90 min	2-3 hr	Up to 24 hr

tobramycin

Tobramycin has dosages, routes of administration, and indications that are comparable to those for gentamicin for generalized infections. In addition, it is commonly used to treat recurrent pulmonary infections in patients with cystic fibrosis by both injectable and inhaled dosing. When used for inhalation, it goes by the trade name of TOBI. It is also available in topical and ophthalmic dosage forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Variable	30 min	2-3 hr	Up to 24 hr
IM	Variable	30-90 min	2-3 hr	Up to 24 hr

neomycin

Neomycin is most commonly used for bacterial decontamination of the GI tract before surgical procedures, and it is given both orally and rectally (as an enema) for this purpose. Other uses include topical application for skin infections, bladder irrigation, and treatment of *E. coli* diarrhea, hepatic encephalopathy, and eye infections. In hepatic encephalopathy, the drug helps reduce the number of ammonia-producing bacteria in the GI tract. The subsequent reduced blood ammonia levels sometimes result in improvement of neurologic symptoms of the hepatic illness. This drug is not available in injectable form but instead is available in tablets, solutions, and powders for oral, topical, or irrigation administration.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	1-4 hr	3 hr	Up to 24 hr

QUINOLONES

Quinolones, sometimes referred to as *fluoroquinolones,* are very potent bactericidal broad-spectrum antibiotics. Currently available quinolone antibiotics include norfloxacin, ciprofloxacin, levofloxacin, and moxifloxacin. With the exception of norfloxacin, these antibiotics have excellent oral absorption. In most cases, the extent of oral absorption is comparable to that of intravenous injection.

Mechanism of Action and Drug Effects

Quinolone antibiotics destroy bacteria by altering their deoxyribonucleic acid (DNA) (see Figure 38-3). They accomplish this by interfering with the bacterial enzymes DNA gyrase and topo-isomerase IV. Quinolones do not inhibit the production of human DNA.

The quinolones kill susceptible strains of mostly gram-negative and some gram-positive organisms. Some quinolones are also believed to diffuse into and concentrate themselves in human neutrophils, killing bacteria such as *S. aureus, Serratia marcescens,* and *Mycobacterium fortuitum* that sometimes accumulate in these cells. Bacterial resistance to quinolone antibiotics has been identified among several bacterial species, including *Pseudomonas aeruginosa, S. aureus, Pneumococcus* spp., *Enterococcus* spp., and the broad Enterobacteriaceae family that includes *E. coli.*

Indications

Quinolones are active against a wide variety of gram-negative and selected gram-positive bacteria. Most are excreted primarily by the kidneys as unchanged drug. This characteristic, together with the fact that they have extensive gram-negative coverage, makes them suitable for treating complicated urinary tract infections. They are also commonly used to treat respiratory, skin, GI, and bone and joint infections.

Ciprofloxacin (Cipro) was the first quinolone to enjoy widespread use. Resistance was soon seen in *Pseudomonas*

BOX 39-1 OVERVIEW OF QUINOLONE-SUSCEPTIBLE ORGANISMS

- Gram-positive: *Streptococcus* (including *Streptococcus pneumoniae*), *Staphylococcus, Enterococcus, Listeria monocytogenes*
- Gram-negative: *Neisseria gonorrhea, Neisseria meningitidis, Haemophilus influenzae, Haemophilus parainfluenzae,* Enterobacteriaceae (including *Escherichia coli, Enterobacter, Klebsiella, Proteus mirabilis, Salmonella, Shigella), Acinetobacter, Pseudomonas aeruginosa, Pasteurella multocida, Legionella, Mycoplasma pneumoniae, Chlamydia*
- Anaerobes: *Bacteroides fragilis, Peptococcus, Peptostreptococcus* (moxifloxacin is strongest)
- Other: *Rickettsia* (ciprofloxacin only)

and some *Streptococcus* spp. Ciprofloxacin and levofloxacin are available both orally and by injection and are both available in generic form, which means that it costs significantly less than brand name quinolones. Levofloxacin (Levaquin) is somewhat more active than ciprofloxacin against gram-positive organisms such as *Streptococcus pneumoniae,* including penicillin-resistant strains, as well as *Enterococcus* and *S. aureus.* Moxifloxacin is also effective against *S. pneumoniae* as well as some strains of *S. aureus* and enterococci. However, MRSA and VRE are generally also resistant to moxifloxacin. The activity of moxifloxacin against many enteric gram-negative bacteria and *P. aeruginosa* is similar to that of levofloxacin and less than that of ciprofloxacin. Moxifloxacin often has stronger anaerobic bacterial coverage. Norfloxacin has limited oral absorption and is available only in oral form, and its use is limited to GU tract infections. Quinolones are often combined with aminoglycosides to treat *P. aeruginosa* infections. Moxifloxacin also has some *in vitro* activity against anaerobes.

The use of quinolones in prepubescent children is not generally recommended, because these drugs have been shown to affect cartilage development in laboratory animals. However, more recent evidence suggests that judicious use in children might be less of a risk than previously thought, and in fact these drugs are used commonly in children with cystic fibrosis. Box 39-1 lists selected microbes commonly susceptible to quinolone therapy in general, but there is some variation in spectra among drugs. Table 39-3 gives common indications for individual drugs.

Contraindications

The only true contraindication is known drug allergy.

Adverse Effects

Quinolones are capable of causing a variety of adverse effects, the most common of which are listed in Table 39-4. Bacterial overgrowth is another possible complication of quinolone therapy, but this is more commonly associated with long-term use. More worrisome is a cardiac effect that involves prolongation of the QT interval on the electrocardiogram (ECG). Dangerous cardiac dysrhythmias are more likely to occur when quinolones are taken by patients who are also receiving class Ia and class III antidysrhythmic drugs, such as disopyramide and amiodarone.

TABLE 39-3 QUINOLONES: COMMON INDICATIONS FOR SPECIFIC DRUGS

GENERIC NAME (TRADE NAME, YEAR OF FDA APPROVAL)	ANTIBACTERIAL SPECTRUM	COMMON INDICATIONS
norfloxacin (Noroxin, 1986)	Extensive gram-negative and selected gram-positive coverage	Urinary tract infections, prostatitis, STIs
ciprofloxacin (Cipro, 1987)	Comparable to that of norfloxacin	Anthrax (inhalational, post-exposure); respiratory, skin, urinary tract, prostate, intraabdominal, GI, bone, and joint infections; typhoid fever; selected nosocomial pneumonias
levofloxacin (Levaquin, 1996)	Comparable to that of ciprofloxacin with better gram-positive coverage	Respiratory and urinary tract infections; prophylaxis in various transrectal and transurethral prostate surgical procedures
moxifloxacin (Avelox, 1999)	Comparable to that of levofloxacin plus anaerobic coverage	Respiratory and skin infections; CAP caused by PRSP; anaerobic infections
gemifloxacin (Factive, 2004)	Comparable to ciprofloxacin	CAP, exacerbation of COPD

CAP, Community-acquired pneumonia; *COPD,* chronic obstructive pulmonary disease; *FDA,* U.S. Food and Drug Administration; *GI,* gastrointestinal; *PRSP,* penicillin-resistant streptococcal pneumonia; *STI,* sexually transmitted infection.

TABLE 39-4 QUINOLONES: REPORTED ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Central nervous	Headache, dizziness, insomnia, depression, restlessness, convulsions
Gastrointestinal	Nausea, constipation, increased AST and ALT levels, flatulence, heartburn, vomiting, diarrhea, oral candidiasis, dysphagia
Integumentary	Rash, pruritus, urticaria, flushing
Other	Ruptured tendons and tendonitis (black box warning added in 2008), fever, chills, blurred vision, tinnitus

ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase.

For this reason, such drug combinations are best avoided. A black box warning is required by the U.S. Food and Drug Administration for all quinolones because of the increased risk of tendinitis and tendon rupture with use of these drugs. This effect is more common in elderly patients, patients with renal failure, and those receiving concurrent glucocorticoid therapy (e.g., prednisone). Central nervous system stimulation (i.e., seizures) has been reported. Quinolones must be infused over 1 to 1.5 hours.

DOSAGES

Selected Quinolones

DRUG	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATION/USES
♦ ciprofloxacin (Cipro) (C)	Fluoroquinolone	**Adult*** IV: 200-400 mg q12h PO: 250-750 mg q8-12h	Broad gram-positive and gram-negative coverage for infections throughout the body
levofloxacin (Levaquin) (C)	Fluoroquinolone	**Adult only** IV/PO: 250-750 mg once daily	Various susceptible bacterial infections

IV, Intravenous; *PO,* oral.
*Not normally recommended for children younger than 18 years of age due to finding of adverse musculoskeletal effects in studies of immature animals.

Interactions

There are several drugs that interact with quinolones. Concurrent use of quinolones with antacids, calcium, magnesium, iron, zinc preparations or sucralfate causes a reduction in the oral absorption of the quinolone. Patients need to take the interacting drugs at least 1 hour before or after taking quinolones. Dairy products also reduce the absorption of quinolones and should be separated as stated previously for interacting drugs. Enteral tube feedings can also reduce the absorption of quinolones. Probenecid can reduce the renal excretion of quinolones. Nitrofurantoin (which is discussed later in the chapter) can antagonize the antibacterial activity of the quinolones, and oral anticoagulants are to be used with caution in patients receiving quinolones because of the antibiotic-induced alteration of the intestinal flora, which affects vitamin K synthesis.

Dosages

For dosage information on selected quinolones, see the table on this page.

DRUG PROFILES

♦ ciprofloxacin

Ciprofloxacin (Cipro) was one of the first of the broad-coverage, potent quinolones to become available. It was first marketed in an oral form but is also available in injectable, ophthalmic (see Chapter 57), and otic (see Chapter 58) formulations. Because of its excellent bioavailability, it can work orally as well as many intravenous antibiotics. It is capable of killing a wide range of gram-negative bacteria and is even effective against traditionally difficult-to-kill gram-negative bacteria such as *Pseudomonas.* Some anaerobic bacteria as well as atypical organisms such as *Chlamydia, Mycoplasma,* and *Mycobacterium* can also be killed by ciprofloxacin. It is also a drug of choice for the treatment of anthrax (infection with *Bacillus anthracis*).

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	30 min	1 hr	3-4.8 hr	Up to 12 hr
PO	Variable	1-2 hr	3-4.8 hr	Up to 12 hr

levofloxacin

Levofloxacin (Levaquin) is one of the most widely used quinolones. It has a broad spectrum of activity similar to that of ciprofloxacin, but it has the advantage of once-daily dosing. Levofloxacin is available in both oral and injectable forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Variable	1-2 hr	6-8 hr	Up to 24 hr
PO	Variable	2 hr	6-8 hr	Up to 24 hr

MISCELLANEOUS ANTIBIOTICS

There are a number of antibiotics that do not fit into any of the previously described broad categories. Most have somewhat unique indications or are especially preferred for a particular type of infection. Although they may not be used as commonly as drugs from the other major classes, they are still of clinical importance. Several of these drugs are described individually in the following drug profiles. Dosage information for these drugs is given in the table on p. 641.

DRUG PROFILES

♦ clindamycin

Clindamycin (Cleocin) is a semisynthetic antibiotic. Clindamycin can be either bactericidal or bacteriostatic (see Chapter 38), depending on the concentration of the drug at the site of infection and on the infecting bacteria. It inhibits protein synthesis in bacteria (see Figure 38-3). It is indicated for the treatment of chronic bone infections, GU tract infections, intraabdominal infections, anaerobic pneumonia, septicemia caused by streptococci and staphylococci, and serious skin and soft-tissue infections caused by susceptible bacteria. Most gram-positive bacteria, including staphylococci, streptococci, and pneumococci, are susceptible to clindamycin's actions. It also has the special advantage of being active against several anaerobic organisms and is most often used for this purpose. However, resistant strains of gram-positive, gram-negative, and anaerobic organisms do exist. Also, all Enterobacteriaceae are resistant to clindamycin.

DOSAGES

Selected Miscellaneous Antibiotics

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ clindamycin (Cleocin) (B)	Lincosamide	**Adult** IV/PO: 300-900 mg bid-qid **Pediatric** IV/PO: 8-20 mg/kg/day divided tid-qid	Anaerobic infections; streptococcal and staphylococcal infections of bone, skin, respiratory, and GU tract
colistimethate (Colisitin) (C)	Polypeptide	2.5-5 mg/kg/day; infuse over 3-5 min	Treatment of KPC-producing organisms; renal and neurotoxicity common
daptomycin (Cubicin) (B)	Lipopeptide	**Adult only** IV: 4-6 mg/kg once daily × 7-14 days	Complicated skin and soft-tissue infections
linezolid (Zyvox) (C)	Oxazolidinone	**Adult only** IV/PO: 600 mg q12h	VRE infections; skin and respiratory infections caused by various *Staphylococcus* and *Streptococcus* spp.
♦ metronidazole (Flagyl) (B)	Nitroimidazole	**Adult*** IV/PO: 250-500 mg q6-12h	Primarily anaerobic and gram-negative infections of abdominal cavity, skin, bone, and respiratory and GU tracts
nitrofurantoin (Macrodantin, Furadantin) (B)	Nitrofuran	**Adult** PO: 50-100 mg qid **Pediatric** PO: 1-2 mg/kg/day	Primarily UTIs caused by gram-negative organisms and *Staphylococcus aureus*
quinupristin/dalfopristin (Synercid) (B)	Streptogramins	**Adult and pediatric** IV: 7.5 mg/kg q8-12h	VRE infections; skin infections caused by streptococcal and staphylococcal infections
telavancin (Vibativ) (C)	Lipoglycopeptides	**Adult** IV: 7.5 mg/kg/day	Serious gram-positive infections caused by MRSA and VRE
vancomycin (Vancocin, Vancoled) (B, oral; C injection)	Tricyclic glycopeptide	**Adult** IV: 15 mg/kg/day (frequency dependent on renal function) PO†: 500 mg q6h **Pediatric**‡ IV/PO†:10-15 mg/kg q6h	Severe staphylococcal infections, including MRSA infections; other serious gram-positive infections, including streptococcal infections

GU, Genitourinary; *IV,* intravenous; *KPC, Klebsiella pneumoniae* carbapenemase; *MRSA,* methicillin-resistant *Staphylococcus aureus; PO,* oral; *spp.,* species; *UTI,* urinary tract infection; *VRE,* vancomycin-resistant *Enterococcus.*

*Not normally used in children except to treat amebiasis.

†Oral is not absorbed and is used only for *C. difficile* diarrhea.

‡Dosing varies depending on age of patient.

Clindamycin is contraindicated in patients with a known hypersensitivity to it, those with ulcerative colitis or enteritis, and infants younger than 1 month of age. GI tract adverse effects are the most common and include nausea, vomiting, abdominal pain, diarrhea, pseudomembranous colitis, and anorexia. **Pseudomembranous colitis** (also known as antibiotic-associated colitis, *C. difficile* diarrhea, or *C. difficile* infection) is a necrotizing inflammatory bowel condition that is often associated with antibiotic therapy, especially clindamycin therapy. Clindamycin is available in oral, injectable, and topical (see Chapter 56) forms.

Clindamycin is also known to have some neuromuscular blocking properties that may enhance the actions of neuromuscular drugs used in perioperative and intensive care settings, such as vecuronium (see Chapter 11). Patients receiving both drugs need to be monitored for excessive neuromuscular blockade and respiratory paralysis, and appropriate ventilatory support provided as needed.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30 min	45 min	2-3 hr	6 hr
IM/IV	Variable	IM: 3 hr	2-3 hr	IM: 8-12 hr

linezolid

Linezolid (Zyvox) is the first antibacterial drug in a new class of antibiotics known as oxazolidinones. This drug works by inhibiting bacterial protein synthesis. Linezolid was originally developed to treat infections associated with vancomycin-resistant *Enterococcus faecium,* more commonly referred to as VRE. VRE infection is notoriously difficult to treat and often occurs as a *nosocomial* (hospital-acquired) infection. Linezolid is commonly used to treat hospital-acquired pneumonia; complicated skin and skin structure infections, including cases caused by MRSA; and gram-positive infections in infants and children. MRSA is a virulent organism and stands for "methicillin-resistant *S. aureus.*" However, methicillin, a penicillinase-resistant penicillin, has recently been removed from the U.S. market. Nonetheless, *MRSA* is still the term used, although oxacillin is now the test drug for this organism. To confuse things even further, oxacillin is rarely used for therapy, and nafcillin is the most commonly used drug for methicillin-susceptible *S. aureus.* MRSA is notorious for causing serious infections, especially in the hospital setting. Linezolid is also approved for treatment of community-acquired pneumonia and uncomplicated skin and skin structure infections.

The most commonly reported adverse effects attributed to linezolid are headache, nausea, diarrhea, and vomiting. It has also been shown to decrease platelet count. Linezolid is contraindicated in patients with a known hypersensitivity to it. It is available in oral and injectable forms. It has excellent oral absorption, which allows patients to continue oral therapy at home for serious infections that would otherwise require hospitalization. With regard to drug interactions, linezolid has the potential to strengthen the vasopressor (prohypertensive) effects of various vasopressive drugs (see Chapter 18) such as dopamine by an unclear mechanism. Also, there have been postmarketing case reports of this drug causing serotonin syndrome when used concurrently with serotonergic drugs such as the selective serotonin reuptake inhibitor (SSRI) antidepressants (see Chapter 16). It is recommended that the SSRI be stopped while the patient is receiving linezolid therapy; however, oftentimes this is not realistic and patients must be watched carefully for signs of serotonin syndrome. Finally, tyramine-containing foods such as aged cheese or wine, soy sauce, smoked meats or fish, and sauerkraut can interact with linezolid to raise blood pressure.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	1-2 hr	5 hr	12 hr
IV	Variable	Immediate	6-7 hr	8-12 hr

♦ metronidazole

Metronidazole (Flagyl) is an antimicrobial drug of the class nitroimidazole. It has especially good activity against anaerobic organisms and is widely used to treat intraabdominal and gynecologic infections that are caused by such organisms. Examples of the anaerobes against which it is active are *Peptostreptococcus* spp., *Eubacterium* spp., *Bacteroides* spp., and *Clostridium* spp. Metronidazole is also indicated for the treatment of protozoal infections such as amebiasis and trichomoniasis (see Chapter 43). It works by interfering with microbial DNA synthesis, and in this regard is similar to the quinolones (see Figure 38-3). It is used orally to treat antibiotic-associated colitis; however, resistance is being noted. Metronidazole is contraindicated in cases of known drug allergy. It is available in both oral and injectable forms. Metronidazole is classified as a pregnancy category B drug, although it is not recommended for use during the first trimester of pregnancy. Adverse effects include dizziness, headache, GI discomfort, nasal congestion, and reversible neutropenia and thrombocytopenia. Drug interactions include acute alcohol intolerance when it is taken with alcoholic beverages, due to the accumulation of acetaldehyde, the principal alcohol metabolite. Patients must avoid alcohol for 24 hours before initiation of therapy and for at least 36 hours after the last dose of metronidazole. Metronidazole may also increase the toxicity of lithium, benzodiazepines, cyclosporine, calcium channel blockers, various antidepressants (e.g., venlafaxine), warfarin, and other drugs. In contrast, phenytoin and phenobarbital may reduce the effects of metronidazole. These interactions occur because of various enzymatic effects involving the cytochrome P-450 liver enzymes that result in altered drug metabolism when these drugs are taken concurrently with metronidazole.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	1-2 hr	8 hr	Unknown
IV	Variable	1 hr	8 hr	Unknown

nitrofurantoin

Nitrofurantoin (Macrodantin) is an antibiotic drug of the class nitrofuran. It is indicated primarily for urinary tract infections caused by *E. coli, S. aureus, Klebsiella* spp., and *Enterobacter* spp. It works by interfering with the activity of enzymes that regulate bacterial carbohydrate metabolism and also by disrupting bacterial cell wall formation. It is contraindicated in cases of known drug allergy and also in cases of significant renal function impairment, because the drug concentrates in the urine. The drug is available only for oral use. Adverse effects include GI discomfort, dizziness, headache, skin reactions (mild to severe reported), blood dyscrasias, ECG changes, possibly irreversible peripheral neuropathy, and hepatotoxicity. Although hepatotoxicity is rare, it is often fatal. Interacting drugs are few and include probenecid, which can reduce renal excretion of nitrofurantoin, and antacids, which can reduce the extent of its GI absorption. The dose must be reduced for elderly patients or those with decreased renal function. Another drug that is approved for urinary tract infections is fosfomycin (Monurol). It is given as a one-time dose and maintains high concentrations in the urine for up to 48 hours.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2.5-4.5 hr	30 min	0.5-1 hr	5-8 hr

quinupristin/dalfopristin

Quinupristin and dalfopristin (Synercid) are two streptogramin antibacterials marketed in a 30:70 fixed combination. The combination drug is approved for intravenous treatment of bacteremia and life-threatening infection caused by VRE and for treatment of complicated skin and skin structure infections caused by *S. pyogenes* and *S. aureus,* including MRSA.

Common adverse effects are arthralgias and myalgias, which may become severe. Adverse effects related to the infusion site, including pain, inflammation, edema, and thrombophlebitis, have developed in approximately 75% of patients treated through a peripheral intravenous line. The drug is contraindicated in patients with a known hypersensitivity to it. It is available only in injectable form. Drug interactions are limited, the most serious being potential increase in levels of cyclosporine. Quinupristin/dalfopristin must be infused with 5% dextrose in water (D_5W) only and cannot be mixed with saline or heparin, including heparinized flushes.

Pharmacokinetics (quinupristin/dalfopristin)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	1-2 hr	3-4 hr	1-3 hr	8-12 hr

♦ vancomycin

Vancomycin is a natural bactericidal antibiotic that is structurally unrelated to any other commercially available antibiotics. It destroys bacteria by binding to the bacterial cell wall, producing immediate inhibition of cell wall synthesis and death (see Figure 38-3). This mechanism differs from that of the beta-lactam antibiotics.

Vancomycin is the antibiotic of choice for the treatment of MRSA infection and infections caused by many other gram-positive bacteria. It is not active against gram-negative bacteria, fungi, or yeast. Oral vancomycin is indicated for the treatment of antibiotic-induced colitis *(Clostridium difficile)* and for the treatment of staphylococcal enterocolitis. Because the oral formulation is poorly absorbed from the GI tract, it is used for its local effects on the surface of the GI tract. The parenteral form is indicated for the treatment of bone and joint infections and bacterial bloodstream infections caused by *Staphylococcus* spp. Resistance to vancomycin has been noted with increasing frequency in patients with infections caused by *Enterococcus* organisms. These strains have been isolated most often from GI tract infections but have also been isolated from skin, soft tissue, and bloodstream infections. Resistance to MRSA has been rarely reported to occur with vancomycin.

Vancomycin is contraindicated in patients with a known hypersensitivity to it. It should be used with caution in those with preexisting renal dysfunction or hearing loss, as well as in elderly patients and neonates. Vancomycin is similar to the aminoglycosides in that there are very specific drug levels in the blood that are safe. If the levels are too low (less than 5 mcg/mL), the dosage may be subtherapeutic with reduced antibacterial efficacy. If the blood levels are too high (over 50 mcg/mL), toxicities may result, the two most severe of which are ototoxicity (hearing loss) and nephrotoxicity (kidney damage). Nephrotoxicity is more likely to occur with concurrent therapy with other nephrotoxic drugs such as aminoglycosides, cyclosporine, and contrast media used for CT scans. Vancomycin can also cause additive neuromuscular blocking effects in patients receiving neuromuscular blockers. Another common adverse effect that is bothersome but usually not harmful is known as *red man syndrome.* This syndrome is characterized by flushing and/or itching of the head, face, neck, and upper trunk area. It is most commonly seen when the drug is infused too rapidly. It can usually be alleviated by slowing the rate of infusion of the dose to at least 1 hour. Rapid infusions may also cause hypotension. Optimal blood levels of vancomycin are a peak level of 18 to 50 mcg/mL and a trough level of 10 to 20 mcg/mL. Measurement of peak levels is no longer routinely recommended, and only trough levels are commonly monitored. Blood samples for measurement of trough levels are drawn immediately before administration of the next dose. Because of the increase in resistant organisms, many clinicians use a trough level of 15 to 20 mcg/mL as their goal.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Variable	1 hr	4-6 hr	Up to 24 hr Longer in renal dysfunction

daptomycin

Daptomycin (Cubicin) is currently the only drug of the new class known as *lipopeptides.* Its mechanism of action is not completely known, but it binds to gram-positive cells in a calcium-dependent process and disrupts the cell membrane potential. It is used to treat complicated skin and soft-tissue infections caused by susceptible gram-positive bacteria, including MRSA and VRE. It can also be used to treat vancomycin-intermediate or vancomycin-resistant strains of MRSA. This drug is contraindicated in cases of known drug allergy. It is available only in injectable form. Adverse reactions include hypotension or hypertension (low incidence for both), headache, dizziness, rash, GI discomfort, elevated liver enzyme levels, local injection site reaction, renal failure, dyspnea, and fungal infection. The precise mechanisms for these reactions are uncertain, but all occur in a relatively small percentage of patients (fewer than 5%). Major drug interactions have yet to be identified; however, there is a theoretical risk of increased myopathy when daptomycin is given in conjunction with hydroxymethylglutaryl–coenzyme A (HMG-CoA) reductase inhibitors, commonly referred to as *statins.*

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Unknown	30 min	8-9 hr	Unknown

colistimethate

Colistimethate (Coly-Mycin) is a polypeptide antibiotic that penetrates and disrupts the bacterial membrane of susceptible strains of gram-negative bacteria. It is commonly referred to as *colistin*. It is an old drug that fell out of clinical use when newer, less toxic drugs became available. Unfortunately, due to the emergence of infections with KPC-producing organisms, it is now being used again, often as one of the only drugs available to treat KPC. Colistin is available for intravenous, intramuscular, and inhalational administration. It has serious adverse effects, including renal failure and neurotoxic effects such as paresthesia, numbness, tingling, vertigo, dizziness, and impairment of speech. It can cause acute respiratory failure when administered by inhalation. Colistin crosses the placenta and needs to be used with caution in pregnant women. Colistin is infused over 3 to 5 minutes.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Unknown	10 min	2-3 hr	8-12 hr

telavancin

Telavancin (Vibativ) is a new drug and the only one in the class called the *lipoglycopeptides*. It is indicated for the treatment of skin and skin structure infections caused by susceptible gram-positive organisms. It is effective against MRSA and VRE. It must not be used in pregnant women, and the dose needs to be adjusted for renal dysfunction. Most common adverse effects include renal toxicity, infusion-related reactions, and QT prolongation.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Variable	1 hr	8-9 hours	Up to 24 hr

NURSING PROCESS

ASSESSMENT

Many of the antibiotics discussed in this chapter, in contrast to those in Chapter 38, are the types of drugs that are often reserved for treatment of more potent infections and are mainly administered by parenteral routes; thus, they demand more skillful and thorough assessment of the patient and the specific drug. These antibiotics all require a critical assessment for any history of or current symptoms indicative of hypersensitivity or allergic reactions, with symptoms ranging from mild reactions with rash, pruritus, or hives to severe reactions with laryngeal edema, bronchospasm, hypotension to possible cardiac arrest. Further assessment associated with these groups of antibiotics in general includes conducting a nursing physical examination and recording age, weight, and baseline vital sign values. Diagnostic and laboratory studies that may be ordered include the following: (1) AST and ALT levels for assessing liver function; (2) urinalysis, BUN, and serum creatinine levels for assessing renal function; (3) ECG, echocardiography, ultrasonography, and/or cardiac enzyme levels for assessing cardiac function; (4) culture and sensitivity of infected tissue or blood samples for assessing sensitivity of the bacteria to the antibiotic; and (5) white blood cell (WBC) count, hemoglobin level, hematocrit, RBC count, platelet count, and clotting values for baseline blood count levels. In the baseline neurologic assessment, note baseline sensory and motor intactness and/or assessment of any alterations in neurologic functioning—for example, altered sensorium and level of consciousness—because of the potential for central nervous system adverse effects. Baseline abdominal and GI assessments are important, with a focus on bowel patterns and bowel sounds because of the possibility of GI adverse effects. Note contraindications, cautions, and drug interactions, and obtain a complete list of the patient's medications, including over-the-counter drugs, herbals, and dietary supplements. Perform a cultural assessment because of the various responses of certain racial and ethnic groups to specific drugs as well as the potential use of alternative healing practices.

With any antibiotic, assess for *superinfection,* or a secondary infection that occurs with the destruction of normal flora during antibiotic therapy (see Chapter 38). Fungal superinfections may be evidenced by fever, lethargy, perineal itching, and other anatomically related symptoms. Assess the patient's immune system status and overall condition because if there is a deficiency (e.g., in patients with cancer, autoimmune disorders such as lupus, acquired immunodeficiency syndromes, and any chronic illness), the patient's ability to physically resist infection may be diminished. Antibiotic resistance is a continual concern with antibiotic drug therapy, especially in pediatrics and in large health care institutions and long-term care facilities. You must consider this possibility of resistance to certain antibiotics when assessing patients for symptoms of infection and superinfection.

With *aminoglycosides,* assess for hypersensitivity and preexisting conditions. Obtain a list of all medications the patient is taking because of the many cautions, contraindications, and drug interactions associated with these drugs. The aminoglycosides are known for their ototoxicity and nephrotoxicity; therefore, if deemed appropriate, perform baseline hearing tests and assessment of vestibular function. Nephrotoxicity is at an increased risk with the use of other nephrotoxic drugs, such as cyclosporine and the intravenous contrast used for CT scan. For patients requiring a CT scan with contrast who are also on a nephrotoxic medication, alert the prescriber to the situation so that the dose may be adjusted and additional fluids and/or medications ordered. Additionally, perform renal function studies (BUN level, urinalysis, serum and urine creatinine levels), as ordered, and document all results. If renal baseline functioning is decreased the prescriber may need to adjust the dosage amounts because of the risk of nephrotoxicity. Complete a thorough neuromuscular assessment because of the potential for drug-related neurotoxicity and higher risk for complications in those with impaired neurologic functioning. For example, patients with myasthenia gravis or Parkinson's disease may experience worsening of muscle weakness because of the drug's neuromuscular blockade. Neonates (because of the immaturity of the nervous and renal systems) and the elderly (because of decreased neurologic and renal functioning) are also at higher risk for nephrotoxicity, neurotoxicity, and ototoxicity and require careful assessment before and during drug therapy. Assess hydration status. The toxicities of these drugs are greater in those with preexisting renal impairment, those receiving other renal toxic drugs, and in those patients taking the aminoglycoside for a long period of time or on high-dose therapy.

Quinolones, such as ciprofloxacin, require careful assessment for preexisting central nervous system conditions (e.g., seizure or stroke disorders) that may be exacerbated by the concurrent use of these drugs. Assess for a cardiac history, and note if the patient is taking certain antidysrhythmics because of the potential for dangerous cardiac irregularities. Significant drug interactions include antacids, iron, zinc preparations, and sucralfate as they affect the absorption of the quinolone.

Oral anticoagulants also interact with and alter the antibacterial activity of quinolones (see pharmacology discussion).

If *clindamycin* is being used, assess for hypersensitivity to the drug or related compounds. Clindamycin is not to be used in patients with ulcerative colitis or in those younger than 1 month of age. Perform a thorough assessment of GI disorders because of the possibility of drug-induced pseudomembranous colitis, vomiting, and diarrhea (see pharmacology discussion). Assess bowel sounds as well as bowel patterns prior to giving this drug. Preoperatively, or if the patient is in an intensive care setting and receiving clindamycin, assess for the concurrent use of neuromuscular blocking drugs because of clindamycin's excessive blockade of neuromuscular functioning and respiratory paralysis. These patients, if in need of clindamycin, would need ventilator support.

Linezolid is used to treat hospital-acquired infections, pneumonia, and complicated skin infections, including MRSA. Use of methicillin (removed from the market) and oxacillin are no longer options for treatment, so this drug offers another pharmacotherapeutic option. Assess for the concurrent use of serotonergic drugs (e.g., SSRIs [antidepressants]) because of drug-induced serotonin syndrome (see Chapter 17). Additionally, assess for intake of tyramine-containing foods (e.g., aged cheese or wine, soy sauce, and smoked fish or meat) because of the risk of elevated blood pressure.

Assess patients taking *metronidazole* for allergy to the drug and to other nitroimidazole derivatives. As with all medications, assess for contraindications, cautions, and drug interactions, and document the findings (see the pharmacology discussion). It is important for patient safety to review culture and sensitivity reports before therapy is initiated. However, it may be necessary to start the medication regimen (due to clinical presentation) prior to results being obtained and then medications can be changed as dictated by the culture and sensitivity results. Baseline assessments are needed of the neurologic system (noting any dizziness, numbness, tingling, and other sensory and motor abnormalities), GI system (checking bowel sounds, problems, and patterns), and GU system (documenting urinary patterns, color of urine, and intake and output). Inquire about alcohol intake because of the interaction of alcohol with the drug and subsequent acute alcohol intolerance. Assess for potential drug interactions, such as with benzodiazepines, calcium channel blockers, various antidepressants, and warfarin.

Assessment of drug allergies is important with *nitrofurantoin.* Renal and liver functions are also important to assess due to the possibility of hepatotoxic adverse effects and the need for a decrease in dosage amounts in the elderly with renal function impairment. Complete a baseline assessment of any sensory or motor problems because of the possible adverse effect of peripheral neuropathy, which may be irreversible. Assess the patient's skin color, turgor, intactness, and presence of rash due to the possibility of drug-related mild to severe skin reactions. With *quinupristin/dalfopristin,* assess vital signs as well as for any muscular aches and pains due to drug-induced arthralgia and myalgia.

With *vancomycin,* ask questions about other medications the patient is taking, especially drugs that are nephrotoxic or ototoxic. Assess the patient for a history of preexisting renal disease or hearing loss due to the possibility of nephrotoxicity or ototoxicity. Note the baseline hearing status because of the risk of hearing loss. Part of the prescriber's order will be to order trough levels of vancomycin. These labs will be drawn immediately before the next dose. Assessment of these levels will be important to patient safety. Peak levels are no longer utilized. The color of the patient's skin is important to assess because of the risk for red man syndrome. This syndrome is bothersome but usually not harmful, and is characterized by flushing of the face, head, neck, and upper trunk areas. Red man syndrome is seen when infusions are administered too rapidly, so always assess and monitor IV rates to be sure the drug is administered over at least 1 hour. Assess vital signs with attention to blood pressure because too rapid infusions may precipitate hypotension. Because of multiple drug and diluent incompatibilities, as with several of the other parenteral antibiotics mentioned previously in this chapter, always assess for potential fluid and medication interactions.

Daptinomycin is a drug now indicated for complicated cases of skin and soft tissue infections caused by MRSA. Assess vital signs and blood pressure prior to and during infusion of this drug.

With the emergence of multidrug-resistant organisms (e.g., MRSA, VRE, and ESBL- and KPC-producing organisms), ensure that proper handwashing techniques are used by health care providers and caregivers.

CASE STUDY

Vancomycin

Mr. M., a 45-year-old quadriplegic, is being treated for an infected stage IV sacral pressure ulcer. The wound cultures have indicated the presence of multidrug-resistant *Staphylococcus aureus* (MRSA). The physician has ordered intravenous vancomycin to be given every 12 hours, application of wet-to-dry dressings (twice a day) as part of the treatment, as well as a referral to the enterostomal therapist. In addition, Mr. M. is placed on contact precautions because of the MRSA.

1. What will you assess before starting the vancomycin infusion?
2. Two days later, Mr. M. complains of feeling "hot" in his face and neck, and itching in those same areas. His face and neck are flushed. What do you suspect is happening?
3. What can you do to minimize complications during vancomycin infusions?
4. The physician orders measurement of vancomycin blood levels. What is the therapeutic goal when vancomycin levels are monitored?
5. What is the single best action you can take to prevent the spread of Mr. M.'s MRSA infection?

For answers, see http://evolve.elsevier.com/Lilley.

NURSING DIAGNOSES

1. Deficient knowledge related to lack of information and experience with the medication regimen
2. Risk for infection related to the patient's compromised immune status before and during treatment
3. Risk for injury (compromised organ function) related to adverse effects of medications (e.g., ototoxicity and nephrotoxicity) and weakened physical state

PLANNING

GOALS

1. Patient demonstrates adequate knowledge base about the antibiotic therapeutic regimen.
2. Patient remains free from infection and has improved immune status during antibiotic therapy.
3. Patient remains free from injury.

OUTCOME CRITERIA

1. Patient states action and rationale for use of antibiotic therapy.
   - Patient understands the need to take the antibiotic exactly as ordered and for the duration of therapy.
2. Patient experiences an increased sense of well-being and improved immune status while taking antibiotics.
   - Patient remains without fever, pain, and malaise.
   - Patient experiences increased comfort and improved energy levels.
   - Patient experiences minimal adverse effects of antibiotic therapy.
3. Patient remains free from injury as related to adverse effects such as minimal to no problems with GI upset, diarrhea, nausea, and hearing loss.
   - Patient states measures to minimize adverse effects associated with antibiotic therapy, such as taking medications with yogurt, increasing fluids, eating well-balanced meals, and following instructions associated with safe use of the specific antibiotic.

IMPLEMENTATION

Aminoglycosides, as well as any antibiotics, need to be given exactly as ordered and with adequate hydration. Encourage fluid intake of up to 3000 mL/day unless contraindicated, especially with oral dosage forms. Parenteral dosage forms are the most commonly used. Neomycin is the only oral dosage form available for this class of antibiotic. Oral neomycin is generally used in special situations such as preoperative bowel preparation, treatment of diarrhea caused by *E. coli,* and treatment of hepatic encephalopathy. It is to be given exactly as ordered. Because of the potential for nephrotoxicity and ototoxicity, determine and monitor the patient's renal function during therapy. Dosing is adjusted based on estimates of creatinine clearance calculated from the patient's serum creatinine level. This assists in keeping a close watch on the patient's renal function and thus helps to prevent toxicity. Also monitor BUN levels and glomerular filtration rate (GFR) during therapy. Alteration in auditory, vestibular, or renal function may indicate the need for a possible dosage adjustment or withdrawal of the drug. Consumption of yogurt or buttermilk may help prevent antibiotic-induced superinfections (see Chapter 38).

With *aminoglycosides,* instruct the patient to report to the prescriber any changes in hearing, ringing in the ears (tinnitus), or a full feeling in the ears. Nausea, vomiting with motion, ataxia, nystagmus, and dizziness should also be reported immediately and may indicate issues with the vestibular nerve. With ophthalmic dosage forms, redness, burning, and itching of the eyes may indicate an adverse reaction to ophthalmic forms, and redness over the skin area may indicate an adverse reaction to topical forms. Check intramuscular administration sites for induration. If noted, report it immediately to the prescriber, and do not reuse the site. Monitor intravenous sites for heat, swelling, redness, pain, or red streaking over the vein (phlebitis), and initiate measures as per institutional protocol or policy. Keep in mind the following special considerations for gentamicin: (1) Intramuscular: Give deeply and slowly into muscle mass (ventrogluteal) to minimize discomfort; and (2) Intravenous: Check for incompatibilities with other drugs, and give only clear or very slightly yellow solutions that have been diluted with either normal saline (NS) or D_5W, infusing at the correct rate.

Quinolones, as with any antibiotics that are self-administered, are to be taken exactly as prescribed and for the full course of treatment. Instruct the patient not to take these medications with antacids, iron, zinc preparations, multivitamins, or sucralfate because the absorption of the antibiotic will be decreased. If the patient needs to take calcium or magnesium, instruct the patient to take it 1 hour before or after the quinolone. Forcing of fluids is recommended, unless contraindicated. See the Patient Teaching Tips for more information.

With *clindamycin,* instruct the patient to take the medication as ordered. Oral dosage forms are to be taken with 8 oz of water or other fluid. With topical forms, advise patients to avoid the simultaneous use of peeling or abrasive acne products, soaps, or alcohol-containing cosmetics to prevent cumulative effects; however, some products combine clindamycin with anti-acne medications (e.g., Acayna). Topical forms are to be applied in a thin layer to the affected area. Infuse intravenous dosage forms by piggyback technique and as ordered. Most references state *never* to give these drugs via parenteral intravenous push. Dilute doses of the drug, and infuse per manufacturer guidelines. Too rapid intravenous infusion can lead to severe hypotension and possible cardiac arrest. Give intramuscular dosage forms deep into a large muscle mass (see Chapter 9).

Linezolid is generally given orally or intravenously, which makes it advantageous for those requiring an antibiotic with a spectrum similar to vancomycin for an extended period or on an outpatient basis. Oral doses are to be evenly spaced around the clock, as ordered, and given with food or milk

to decrease the possibility of GI upset. Oral suspension forms must be used within 21 days of reconstitution. Protect intravenous doses from light, and infuse over 30 to 120 minutes; do not mix with any other medication. Foods that may increase blood pressure while taking linezolid and need to be avoided include aged cheeses, wine, soy sauce, smoked meats or fish, and sauerkraut due to their tyramine content.

Oral forms of *metronidazole* need to be given with food or meals to help decrease GI upset. Educate patients not to chew extended-release dosage. Intravaginal doses are recommended to be administered at bedtime. Topical creams, ointments, or lotions are to be applied thinly to the affected area. An applicator should be used for intravaginal dosages. Gloves are worn to protect from undue exposure to the medication and as a part of Standard Precautions. Do not apply topical forms close to the eyes to avoid irritation. Store intravenous dosage forms, which are supplied in a ready-to-use infusion bag, at room temperature.

Nitrofurantoin is available in oral forms and should be given with plenty of fluids, food, or milk to decrease GI upset. Do not crush tablets to help prevent tooth staining and GI upset. Because of the risk for superinfection, hepatotoxicity, and peripheral neuropathy (which may be irreversible), constantly monitor for signs and symptoms of these adverse effects and document the findings. Be aware that jaundice, itching, rash, and liver enlargement may indicate toxic effects to the liver, whereas numbness and tingling may occur with peripheral neuropathy.

For *quinupristin/dalfopristin,* only intravenous dosage forms are available. Reconstitute the drug using only D_5W. Use a gentle swirling action instead of shaking to mix the drug (to help minimize foaming). A diluted infusion bag of the drug is stable for up to 6 hours, or 54 hours if refrigerated. These characteristics are important to know to help prevent untoward complications. Infusions are generally given over at least 60 minutes. Implement the same measures, as with other antibiotics, to monitor for superinfection.

Vancomycin may be used orally but is poorly absorbed by this route, and is only used to treat microbes in the GI tract (e.g., staphylococcal enterocolitis). Parenteral dosage forms must be used to treat infection outside of the intima of the GI tract. Reconstitute intravenous dosage forms as recommended (e.g., with either D_5W or NS) and infuse over at least 60 minutes. Too rapid an infusion of vancomycin or administration by intravenous push may lead to severe hypotension and red man syndrome. Extravasation may cause local skin irritation and damage, so frequently monitor the infusion, and in particular the intravenous site. Constant monitoring for drug-related neurotoxicity, nephrotoxicity, ototoxicity, and superinfection remain critical to patient safety. In addition, adequate hydration (at least 2 L of fluids every 24 hours unless contraindicated) is important to prevent nephrotoxicity. Trough levels need to be ordered prior to the third or fourth dose; peak levels are no longer used (see the pharmacology discussion for more information).

If the new drug *telavancin* is ordered, use it very carefully and as ordered, especially if the patient has renal dysfunction. When this drug is infused, give it exactly as ordered while also watching for ECG changes, such as changes in the QT segment.

Because of the significant issue of multidrug-resistant organisms, encourage patients and family members not to abuse or overuse antibiotics and to report immediately to the prescriber any signs and symptoms of an infection that is not resolving or responding to antibiotic therapy. Regardless of drug management, in today's health care settings (acute and long-term facilities, medical offices, urgent care centers, emergency departments) as well as in the home setting and abroad, teach and demonstrate proper and thorough handwashing technique. Handwashing must be performed often, especially during cold and flu season, before and after preparing food, and after engaging in any of the following activities: going to the bathroom or changing diapers; touching bare human body parts; coughing, sneezing, or using a handkerchief or disposable tissue; eating or drinking; using tobacco; using the telephone; shaking hands; and playing with pets. The Centers for Disease Control and Prevention (CDC) recommend the following as the proper handwashing technique: Wash hands with warm running water and soap; lather well by rubbing hands vigorously for at least 15 to 20 seconds; pay attention to the wrist area, backs of the hands, areas between the fingers, and under the fingernails; and rinse well. Allow the water to run while drying hands with a paper towel and then use a dry paper towel as a barrier between the faucet and clean hands while turning off the water. If soap and water are not available and hands are not visibly soiled, gel hand sanitizers or alcohol-based hand wipes containing at least 60% ethyl alcohol or isopropanol may be used. Once the gel is applied and all surfaces covered, rub hands until gel is dry and do not towel gel off. It is also imperative to educate patients and family members as well as the community at large that taking antibiotics excessively and when not needed may lead to problems of antibiotic resistance!

EVALUATION

Once antibiotic therapy has been initiated, evaluation that is focused on goals, outcome criteria, therapeutic effects, and adverse effects must always be ongoing. Ask patients to report a decrease in symptoms (e.g., infection) as well as absence of injury to self and a decrease in pain. Therapeutic goals include a return to normal of all blood counts and vital signs, negative results on culture and sensitivity testing, and improved appetite, energy level, and sense of well-being. Signs and symptoms of the infection will begin to resolve once therapeutic levels of antibiotics are achieved. Another aspect of evaluation is monitoring for adverse effects of therapy such as superinfections, antibiotic-associated colitis, nephrotoxicity, ototoxicity, neurotoxicity, hepatotoxicity, and other drug-specific adverse effects.

PATIENT TEACHING TIPS

Aminoglycosides

- Educate the patient about the drug, its purpose, and its adverse effects, including the risk of hearing loss, which may occur after completion of therapy. Advise the patient to report to the prescriber any change in hearing.
- Forcing fluids up to 3000 mL/day, unless contraindicated, is important with any medication but especially with antibiotics to maximize absorption of oral doses, minimize some of the adverse effects, and ensure adequate hydration.
- Instruct the patient to report to the prescriber any persistent headache, nausea, or vertigo. Educate the patient about the signs and symptoms of superinfection, such as diarrhea; vaginal discharge; stomatitis; loose and foul-smelling stools; and cough.

Quinolones

- Educate about the importance of avoiding exposure to the sun and tanning beds. Recommend the use of sunglasses and sunscreen protection.
- Advise the patient to report to the prescriber any headache, dizziness, restlessness, diarrhea, vomiting, oral candidiasis, flushing of the face, and/or inflammation of the tendons.
- Educate about drug interactions that may occur with the following drugs: calcium, magnesium, probenecid, nitrofurantoin, oral anticoagulants, antacids, iron, sucralfate, and zinc preparations. Instruct the patient to take calcium and magnesium supplements at least 1 hour before or after taking the quinolone. Probenecid may reduce the excretion of the antibiotic and cause toxicity. Since quinolones may alter the intestinal flora and thus vitamin K synthesis, oral anticoagulants must be used with caution in patients taking these antibiotics.
- Instruct the patient to take ciprofloxacin and levofloxacin, both quinolones, exactly as ordered.

Clindamycin

- Instruct the patient not to use topical forms near the eyes or near any abraded areas to avoid irritation.
- When vaginal dosage forms are used, the patient needs to be advised not to engage in sexual intercourse for the duration of therapy. The full course of antibiotics are to be taken as ordered to obtain maximal therapeutic benefit.
- If cream dosage forms get into the eyes accidentally, instruct the patient to rinse the eyes immediately with copious amounts of cool tap water.

Linezolid

- Instruct the patient to continue therapy for the full prescribed length of treatment (as with all antibiotics).
- Educate the patient to avoid tyramine-containing foods (e.g., red wine, aged cheeses) while taking the drug.
- Instruct the patient to report to the prescriber immediately any severe abdominal pain, fever, severe diarrhea, and/or worsening of signs and symptoms of infection.

Metronidazole

- Caution the patient to avoid alcohol and any alcohol-containing products (e.g., cough preparations and elixirs) while taking the drug because of the risk for a disulfiram-like reaction (e.g., severe vomiting).
- Educate the patient about the purpose of the drug, such as its use as either an antibacterial or an antifungal medication, because this knowledge is crucial to achieving therapeutic effects and preventing adverse effects.

Nitrofurantoin

- Advise the patient to report to the prescriber any abdominal cramping, dizziness, severe skin reactions, or jaundice.

Vancomycin

- Instruct the patient to report any changes in hearing such as ringing in the ears or a feeling of fullness in the ears. Any nausea, vomiting, unsteady gait, dizziness, generalized tingling (usually after intravenous dosing), chills, fever, rash, and/or hives must also be reported.
- Monitor therapeutic serum levels throughout therapy; this monitoring is key to prevention of toxicity. Trough levels are usually monitored throughout therapy. Stress to the patient that follow-up appointments are important for monitoring serum drug levels and identifying possible toxic effects.

KEY POINTS

- Over the years, bacteria have developed enzymes and mechanisms to interact with antibiotics and render the antibiotic ineffective. Multidrug resistance is a significant health issue, and such resistant organisms include ESBL- and KPC-producing bacteria, MRSA, and VRE.
- The aminoglycosides are a group of natural and semisynthetic antibiotics that are classified as *bactericidal* drugs, are very potent, and are capable of potentially serious toxicities (e.g., nephrotoxicity, ototoxicity).
- Quinolones are very potent, bactericidal, broad-spectrum antibiotics and include norfloxacin, ciprofloxacin, levofloxacin, and moxifloxacin.
- Clindamycin is a semisynthetic derivative of lincomycin, an older antibiotic.
- Linezolid is an antibacterial drug used to treat infections associated with vancomycin-resistant *Enterococcus faecium,* more commonly referred to as VRE. VRE is a difficult infection to treat and often occurs as a *nosocomial* (hospital-acquired) infection.
- Metronidazole (Flagyl) is an antimicrobial drug of the class nitroimidazole, has good activity against anaerobic organisms, and is widely used for intraabdominal and gynecologic infections; it is also used to treat protozoal infections (e.g., amebiasis, trichomoniasis).
- Nitrofurantoin (Macrodantin) is an antibiotic drug of the class *nitrofuran.* It is indicated primarily for urinary tract infections caused by *E. coli, S. aureus, Klebsiella* spp., and *Enterobacter* spp.
- Quinupristin and dalfopristin (Synercid) are two streptogramin antibacterials approved for intravenous treatment of bacteremia and life-threatening infection caused by VRE and for treatment of complicated skin and skin structure infections caused by *S. aureus* and *S. pyogenes.*
- Daptomycin (Cubicin) is used to treat complicated skin and soft-tissue infections. Telavancin is a newer drug that is effective against MRSA and VRE and is indicated in the treatment of skin and skin structure infections.
- Use of these antibiotics requires a critical assessment for any history or current symptoms indicative of hypersensitivity or allergic reactions (from mild reactions with rash, pruritus, and hives to severe reactions with laryngeal edema, bronchospasm, hypotension, and possible cardiac arrest).
- With use of any antibiotic, it is important to assess for superinfection, or a secondary infection that occurs because of the destruction of normal flora during antibiotic therapy. Superinfections may occur in the mouth, respiratory tract, GI and GU tracts, and on the skin. Fungal infections are evidenced by fever, lethargy, perineal itching, and other anatomically related symptoms.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 While assessing a woman who is receiving an antibiotic for community acquired pneumonia, the nurse notes that the patient has a thick, white vaginal discharge. The patient is also complaining about perineal itching. The nurse suspects that the patient has
   - **a** resistance to the antibiotic.
   - **b** an adverse effect of the antibiotic.
   - **c** a superinfection.
   - **d** an allergic reaction.

2 A patient has been admitted for treatment of an infected leg ulcer and will be started on intravenous linezolid. The nurse is reviewing the list of the patient's current medications. Which type of medication, if listed, would be of most concern if taken with the linezolid?
   - **a** Beta blocker
   - **b** Oral anticoagulant
   - **c** Selective serotonin reuptake inhibitor antidepressant
   - **d** Thyroid replacement hormone

3 When administering vancomycin, the nurse knows that which of these is most important to assess before giving the medication?
   - **a** Renal function
   - **b** WBC count
   - **c** Liver function
   - **d** Platelet count

4 During therapy with an intravenous aminoglycoside, the patient calls the nurse and says, "I'm hearing some odd sounds, like ringing, in my ears." What is the nurse's priority action at this time?
   - **a** Reassure the patient that these are expected adverse effects.
   - **b** Reduce the rate of the intravenous infusion.
   - **c** Increase the rate of the intravenous infusion.
   - **d** Stop the infusion immediately.

5 When giving intravenous quinolones, the nurse needs to keep in mind that these drugs may have serious interactions with which drugs?
   - **a** Selective serotonin reuptake inhibitor antidepressants
   - **b** Nonsteroidal antiinflammatory drugs
   - **c** Oral anticoagulants
   - **d** Antihypertensives

6 The nurse is administering an intravenous aminoglycoside to a patient who has had gastrointestinal surgery. Which nursing measures are appropriate? (Select all that apply.)
   - **a** Report a trough drug level of 0.8 mcg/mL, and hold the drug.
   - **b** Enforce a strict fluid restriction.
   - **c** Monitor serum creatinine levels.
   - **d** Instruct the patient to report dizziness or a feeling of fullness in the ears.
   - **e** Warn the patient that the urine may turn darker in color.

7 The order reads: "Give vancomycin, 1250 mg in 250 mL NS, IVPB, every 12 hours. Infuse over 90 minutes." The nurse will set the infusion pump to what setting for mL/hour?

1. c, 2. c, 3. a, 4. d, 5. c, 6. c, d, 7. 167 mL/hour

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the effects of the immune system with attention to the various types of immunity.
2 Describe the effects of viruses in the human body.
3 List specific drugs categorized as non–human immunodeficiency virus (HIV) antivirals and HIV antivirals or antiretrovirals.
4 Discuss the process of immunosuppression in patients with viral infections, specifically those with HIV infection.
5 Describe the stages of acquired immunodeficiency syndrome (AIDS) and various drugs used to manage the illness.
6 Discuss the mechanism of action, indications, contraindications, cautions, routes, adverse effects, and toxic effects of the various non-HIV antiviral and HIV antiviral drugs.
7 Develop a nursing care plan that includes all phases of the nursing process for patients receiving non-HIV and HIV antiviral drugs.

DRUG PROFILES

♦ *Key drug*

KEY TERMS

Acquired immunodeficiency syndrome (AIDS) Infection caused by the *human immunodeficiency virus (HIV),* which weakens the host's immune system, giving rise to opportunistic infections. (p. 652)

Antibodies Immunoglobulin molecules that have an antigen-specific amino acid sequence and are produced by the humoral immune system (antibodies produced from B lymphocytes) in response to exposure to a specific antigen, the purpose of which is to attack and destroy molecules of this antigen. (p. 652)

Antigen A substance, usually a protein, that is foreign to a host and causes the formation of an antibody that reacts specifically with that antibody. Examples of antigens include bacterial exotoxins, viruses, and allergens. An allergen (e.g., dust, pollen, mold) is a specific type of antigen that causes allergic reactions (see Chapter 36). (p. 652)

Antiretroviral drugs A specific term for antiviral drugs that work against retroviruses such as HIV. (p. 654)

KEY TERMS—cont'd

Antiviral drugs A general term for drugs that destroy viruses, either directly or indirectly by suppressing their replication. (p. 653)

Cell-mediated immunity One of two major parts of the immune system. It consists of nonspecific immune responses mediated primarily by T lymphocytes (T cells) and other immune system cells (e.g., monocytes, macrophages, neutrophils) but not by antibody-producing cells (B lymphocytes). (p. 652)

Deoxyribonucleic acid (DNA) A nucleic acid composed of nucleotide units that contain molecules of the sugar deoxyribose, phosphate groups, and purine and pyrimidine bases. DNA molecules transmit genetic information and are found primarily in the nuclei of cells. (Compare with *ribonucleic acid [RNA].*) (p. 651)

Fusion The process by which viruses attach themselves to, or fuse with, the cell membranes of host cells, in preparation for infecting the cell for purposes of viral replication. (p. 651)

Genome The complete set of genetic material of any organism; it may consist of multiple chromosomes (groups of DNA or RNA molecules) in higher organisms; a single chromosome, as in bacteria; or one or two DNA or RNA molecules, as in viruses. (p. 651)

Herpesviruses Several different types of viruses belonging to the family Herpesviridae that cause various forms of herpes infection. (p. 653)

Host Any organism that is infected with a microorganism, such as bacteria or viruses. (p. 651)

Human immunodeficiency virus (HIV) The retrovirus that causes AIDS. (p. 652)

Humoral immunity One of two major parts of the immune system. It consists of specific immune responses in the form of antigen-specific antibodies produced from B lymphocytes. (p. 653)

Immunoglobulins Synonymous with immune globulins. Glycoproteins produced and used by the humoral immune system to attack and kill any substance (antigen) that is foreign to the body. An immunoglobulin with an antigen-specific amino acid sequence is called an antibody and is able to recognize and inactivate molecules of a specific antigen. (p. 653)

Influenza viruses The viruses that cause influenza, an acute viral infection of the respiratory tract. There are three types of influenza virus: A, B, and C. Currently, medications are available only to treat types A and B. (p. 653)

Nucleic acids A general term referring to DNA and RNA. These complex biomolecules contain the genetic material of all living organisms, which is passed to future generations during reproduction. (p. 652)

Nucleoside A structural component of nucleic acid molecules (DNA or RNA) that consists of a purine or pyrimidine base attached to a sugar molecule. (p. 654)

Nucleotide A nucleoside that is attached to a phosphate unit, which makes up the side chain "backbone" of a DNA or an RNA molecule. (p. 654)

Opportunistic infections Infections caused by any type of microorganism that occur in an immunocompromised host but normally would not occur in an immunocompetent host. (p. 653)

Protease An enzyme that breaks down the amino acid structure of protein molecules by chemically cleaving the peptide bonds that link together the individual amino acids. (p. 659)

Replication Any process of duplication or reproduction, such as that involved in the duplication of nucleic acid molecules (DNA or RNA) during the reproduction processes of all living organisms. This is also the term used most often to describe the entire process of viral reproduction, which occurs only inside the cells of an infected host organism. (p. 652)

Retroviruses Viruses belonging to the family Retroviridae. These viruses contain RNA (as opposed to DNA) as their genome and replicate using the enzyme reverse transcriptase. Currently the most clinically significant retrovirus is HIV. (p. 653)

Reverse transcriptase An RNA-directed DNA polymerase enzyme. It promotes the synthesis of a DNA molecule from an RNA molecule, which is the reverse of the usual process. HIV replicates in this manner. (p. 659)

Ribonucleic acid (RNA) A nucleic acid composed of nucleotide units that contain molecules of the sugar ribose, phosphate groups, and purine and pyrimidine bases. RNA molecules transmit genetic information and are found in both the nuclei and cytoplasm of cells. (Compare with deoxyribonucleic acid [DNA].) (p. 651)

Virion A mature virus particle. (p. 651)

Viruses The smallest known class of microorganisms; viruses can only replicate inside host cells. (p. 651)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

GENERAL PRINCIPLES OF VIROLOGY

Viruses are very small microorganisms, usually many times smaller than bacteria. Unlike bacteria, viruses can replicate only inside the cells of their **host.** In this respect, all viruses are obligate intracellular parasites. It must be emphasized that viruses are not cells, per se, but instead are particles that infect and replicate inside of cells. A mature virus particle is known as a **virion.** Compared with other organisms, virions have a relatively simple structure that consists of the genome, the capsid, and the envelope. The **genome** is the inner core of the virion, which is composed of single- or double-stranded **deoxyribonucleic acid (DNA)** or **ribonucleic acid (RNA)** molecules, but not both.

Viruses are the simplest of all organisms. The cells of more complex organisms have much larger nucleic acid strands or multiple strands, which make up chromosomes. The viral capsid is a protein coat that surrounds and protects the genome. It also plays a role in the process of **fusion** between the virions

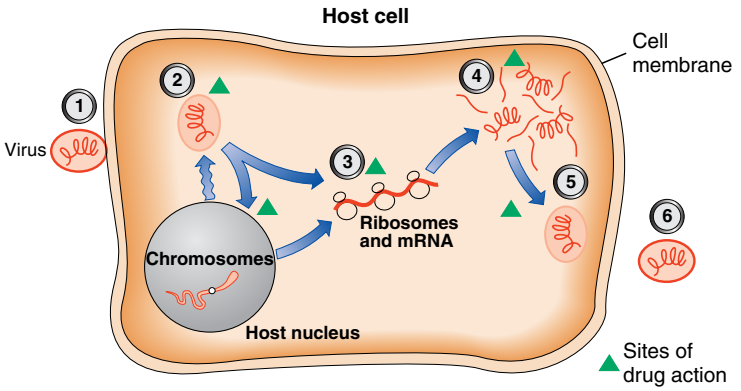

FIGURE 40-1 Virus replication. Some viruses integrate into host chromosome and enter a period of latency. *mRNA,* Messenger RNA. (Modified from Brody TM, Larner J, Minneman KP: *Human pharmacology: molecular to clinical,* ed 5, St Louis, 2010, Mosby.)

and the host cells. Fusion occurs when virions attach themselves to host cells in preparation for infecting the cells. The envelope is the outermost layer of the virion and is present in some, but not all, viruses. It has a lipoprotein structure containing viral antigens that are often chemically specific for various proteins on the surface of the host cell membranes. This biochemical specificity, when present, also facilitates the fusion process. The **human immunodeficiency virus (HIV),** which causes **acquired immune deficiency syndrome (AIDS),** functions in this manner.

Viruses can enter the body through at least four routes: inhalation through the respiratory tract, ingestion via the gastrointestinal (GI) tract, transplacentally via mother to infant, and inoculation via skin or mucous membranes. The inoculation route can take several forms, including sexual contact, blood transfusions, sharing of syringes or needles, organ transplantation, and bites (including human, animal, insect, spider, and others). Once inside the body, the virus particles, or virions, begin to attach themselves to the outer membranes of host cells (cell membranes or plasma membranes) as illustrated in Figure 40-1.

The viral genome then passes through the plasma membrane into the cytoplasm of the host cell. It later enters the cell nucleus, where the **replication** process begins. The virion may use its own or host enzymes (or both) to direct the replication process. In the host cell nucleus, the viral genome uses the cell's genetic material (the **nucleic acids** RNA and DNA) to synthesize viral nucleic acids and proteins. These are then used to construct complete new virions. These new virions then exit the infected host cell by budding through the plasma membrane and go on to infect other host cells, where the replication process continues. The changes in the cell associated with viral replication are known as the *cytopathic effect* and usually result in the destruction of the host cell. Repeated over time, host cell destruction gives rise to the pathologic effects of the virus, which can eventually impair or even kill the host organism.

Although this cytopathic effect is the most common outcome, there are other possible outcomes of viral infection. One is viral transformation, which involves mutation of the host cell DNA or RNA and can result in malignant (cancerous) host cells. Viruses that can induce cancer in this way are known as oncogenic viruses. More common is latent, or dormant, infection in which the virions remain inside host cells but do not actively replicate to any significant degree. For example, HIV infection may have a lengthy dormant phase of 10 years or longer before giving rise to AIDS in an infected person. HIV infection is discussed in greater detail later in the chapter in the section on retroviruses.

Viruses are ubiquitous (widespread) in the environment, and most viral infections may not even be noticed before they are eliminated by the host's immune system. These are referred to as "silent" viral infections. Although the host's immune system acts to neutralize viral infection, it can become overwhelmed, depending on how virulent the virus is and how rapidly it replicates inside host cells. In most cases, however, a person's immune system is able to arrest and eliminate the virus. Host immune responses to viral infections are classified as either *nonspecific* or *specific*. Nonspecific immune responses include phagocytosis (eating) of viral particles by leukocytes such as neutrophils, macrophages, monocytes, and T lymphocytes (T cells). Another nonspecific immune response is the release of cytokines from these leukocytes. Cytokines are biochemical substances (e.g., histamine, tumor necrosis factor) that stimulate other protective immune functions. In addition, these activated immune system cells may also phagocytize infected host cells to curb the growth and spread of infection. These types of immune responses are collectively referred to as **cell-mediated immunity.** Cell-mediated immunity is nonspecific in the sense that it does not involve **antibodies** that are specific for a given **antigen.** In contrast, specific immune responses include the production of antibodies from B lymphocytes (B cells). These are immune-system proteins (immunoglobulins) that are chemically specific for viral antigens. This type of immune response

is also called **humoral immunity.** Immune system function is discussed in more detail in Chapters 48 and 49.

OVERVIEW OF VIRAL ILLNESSES AND THEIR TREATMENT

There are at least 6 classes of DNA viruses and at least 14 classes of RNA viruses that are known to infect humans. Some of the more prominent viral illnesses include smallpox (poxviruses), sore throat and conjunctivitis (adenoviruses), warts (papovaviruses), influenza (orthomyxoviruses), respiratory infections (coronaviruses, rhinoviruses), gastroenteritis (rotaviruses, Norwalk-like viruses), HIV/AIDS **(retroviruses),** herpes **(herpesviruses),** and hepatitis (hepadnaviruses). Effective drug therapy is currently available only for a relatively small number of active viral infections. The drug therapy for hepatitis is discussed further in Chapter 47. HIV belongs to the relatively unique viral class known as *retroviruses* and is discussed in more detail in a separate section of this chapter.

Fortunately, many viral illnesses are survivable (e.g., chickenpox), albeit bothersome and uncomfortable. The incidence of some of these illnesses has been reduced by the development of effective vaccines (e.g., vaccines for polio, smallpox, measles, chickenpox). Vaccines are discussed in more detail in Chapter 49. However, many other viral illnesses are either fatal or have much more severe long-term outcomes (e.g., hepatitis, HIV infection).

Antiviral drugs are chemicals that kill or suppress viruses by either destroying virions or inhibiting their ability to replicate. Even the best medications currently available never fully eradicate a virus completely from its host. However, the body's immune system has a better chance of controlling or eliminating a viral infection when the ability of the virus to replicate itself is suppressed. Drugs that actually destroy virions include various disinfectants and immunoglobulins. Disinfectants such as povidone-iodine (Betadine) are virucides and are commonly used to disinfect medical equipment. Such drugs are discussed further in Chapter 38.

Immunoglobulins are concentrated antibodies that can attack and destroy viruses. They are isolated and pooled from human or animal blood. Their activity may be either nonspecific (e.g., human gamma globulin) or specific (e.g., rabies immunoglobulin, varicella-zoster immunoglobulin). Although such substances can technically be considered as antiviral drugs, they are more commonly thought of as immunizing drugs and are therefore discussed in more detail in Chapter 49. A few antiviral drugs, such as the interferons, stimulate the body's immune system to kill the virions directly. These drugs are discussed in Chapter 47.

The current antiviral drugs are all synthetic compounds that work indirectly by inhibiting viral replication as opposed to directly by destroying mature virions themselves. Only relatively few of the known viruses can be controlled by current drug therapy. Some of the viruses in this group are the following:

- Cytomegalovirus (CMV)
- Hepatitis viruses
- Herpesviruses
- HIV
- **Influenza viruses** ("flu" viruses)
- Respiratory syncytial virus

Active viral infections are usually more difficult to eradicate than those caused by bacteria. One reason is that viruses replicate only inside host cells rather than replicating independently in the bloodstream or in other tissues. Most antiviral drugs must therefore enter these cells to disrupt viral replication. The need to develop antiviral drugs that are not overly toxic to host cells is one reason that there are relatively few effective antiviral medications on the market. However, the HIV/AIDS epidemic that began in the early 1980s strongly boosted antiviral drug research. This has increased the number of available antiviral drugs to treat HIV and other viral infections such as influenza, CMV infection, and varicella-zoster virus (VZV) infection. Many drugs for the treatment of HIV are approved by the U.S. Food and Drug Administration (FDA) via an accelerated process, which means that they are approved faster than other drugs, because of the nature of the illness. Because of the rapid addition of HIV drugs to the market, it is beyond the scope of this book to list every available drug. The reader is referred to the FDA website on approved AIDS drugs at www.fda.gov/ForConsumers/byAudience/ForPatientAdvocates/HIVandAIDSActivities/ucm118915.html for the most recently approved AIDS drugs.

Another reason viral illnesses are difficult to treat is that the virus has often replicated itself many thousands or even millions of times before symptoms of illness appear. Therefore, one goal in the field of infectious disease is to be able to diagnose viral illnesses before an infecting virus has undergone widespread replication in a human host. This would theoretically allow the dual benefit of both early drug therapy and easier elimination of the virus by the host's immune system. This has happened to some degree with HIV infection, with relatively early diagnosis made possible by blood tests to screen for HIV antibodies. Of course, the patient must also be alerted of the need to seek medical care before serious illness develops.

Recall that for a virus to replicate, virions must first attach themselves to host cell membranes in a process known as *fusion.* Once inside the cell, the viral genome makes nucleic acids and proteins, which are then used to build new viral particles, or virions (see Figure 40-1). All virions contain a genome that consists of either DNA or RNA, but not both. Antiviral drugs inhibit this replication process in various ways. Most antiviral drugs enter the same cells that the viruses enter. Once inside, these antiviral drugs interfere with viral nucleic acid synthesis. Other antiviral drugs work by preventing the fusion process itself.

The best responses to antiviral drug therapy are usually seen in patients with competent immune systems. The immune system can work synergistically with the drug to eliminate or suppress viral activity. Patients who are immunocompromised (have weakened immune systems) are at greater risk for **opportunistic infections,** which are infections caused by organisms that would not normally harm an immunocompetent person. The most common examples of immunocompromised patients are cancer patients, organ transplant recipients, and patients

with AIDS. These patients are prone to frequent and often severe opportunistic infections of many types, including those caused by other (non-HIV) viruses, bacteria, fungi, and protozoans. Such infections often require long-term prophylactic antiinfective drug therapy to control the infection and prevent its recurrence because of compromised host immune functions.

Recall that there are two types of nucleic acid found in living organisms: DNA and RNA. There are also five organic bases that are the structural components of these nucleic acids. DNA consists of long chains of deoxyribose sugar molecules, phosphate groups, and purine (adenine or guanine) and pyrimidine (cytosine or thymine) bases. RNA consists of long chains of ribose sugar molecules linked to phosphate groups, together with purine (adenine or guanine) and pyrimidine (cytosine or uracil) bases. A **nucleoside** is a single unit consisting of a base and its attached sugar molecule. Nucleosides have names similar to their bases with minor spelling modifications (e.g., adenosine, guanosine, cytidine, thymidine). A **nucleotide** is a nucleoside plus its attached phosphate molecule. Most antiviral drugs are synthetic purine or pyrimidine nucleoside or nucleotide analogues. Some pharmacology texts categorize the antiviral drugs based on their nucleoside-nucleotide activity. However, for ease of learning, this book divides antiviral drugs into drugs that treat HIV infections and those that treat non-HIV viral infections. **Antiretroviral drugs** are indicated specifically for the treatment of infections caused by HIV, the virus that causes AIDS. The effectiveness of antiviral drugs varies widely among patients and even over time in the same patient.

HERPES SIMPLEX VIRUS AND VARICELLA-ZOSTER VIRUS INFECTIONS

The family of viruses known as Herpesviridae includes those viruses that cause all kinds of herpes infection. There are several specific types of such viruses. Herpes simplex virus type 1 (HSV-1) causes mucocutaneous herpes—usually in the form of perioral blisters ("fever blisters" or "cold sores"). Herpes simplex virus type 2 (HSV-2) causes genital herpes. Human herpesvirus 3 (HHV-3) causes both chickenpox and shingles. This virus is more commonly known as *herpes zoster virus* or *varicella-zoster virus (VZV).* Human herpesvirus 4 (HHV-4), more frequently known as Epstein-Barr virus, is associated with illnesses such as infectious mononucleosis ("mono") and chronic fatigue syndrome. Human herpesvirus 5 (HHV-5) is more commonly known as *cytomegalovirus (CMV)* and is the cause of CMV retinitis (a serious viral infection of the eye) and CMV disease, which is most commonly seen in immunocompromised patients. Human herpesviruses 6 and 7 are not especially clinically significant, and infection with these viruses may be more likely to occur in immunocompromised patients. Human herpesvirus 8, also known as *Kaposi's sarcoma herpesvirus,* is an oncogenic (cancer-inducing) virus believed to cause Kaposi's sarcoma, an AIDS-associated cancer. All of these viruses occur, often asymptomatically, in varying percentages of the population. Types 3 through 7 normally do not cause diseases that require medication, except in the case of immunocompromised patients. However, the HSVs (types 1 and 2) and VZV (HHV-3) commonly cause illnesses that are now routinely treated with prescription medications.

Herpes Simplex Viruses

Although there can be anatomic overlap between the two types of herpesviruses, HSV-1 infection is most commonly associated with perioral blisters and is therefore often thought of as *oral herpes.* In contrast, HSV-2 infection is most commonly associated with blisters on both male and female genitalia and is therefore commonly referred to as *genital herpes.* Although they usually do not cause serious or life-threatening illness, both infections are annoying and highly transmissible through close physical contact (e.g., kissing, sexual intercourse). Outbreaks of painful skin lesions occur intermittently, with periods of latency (no sores or other symptoms) occurring between acute outbreaks. Although antiviral medications are not always required and are *not* curative, they can speed up the process of remission and reduce the duration of painful symptoms. This is especially true if the medications are started early in a given outbreak. Patients may be prescribed an ongoing lower dose of antiviral drug for prophylaxis of outbreaks. HSV infections can become serious, even life-threatening, when the patient is immunocompromised or a newborn infant. Neonatal herpes is often a life-threatening infection, and babies with this disease are often treated in neonatal intensive care units with intravenous antiviral drugs. However, treatments may fail, causing infant death and/or permanent disability. Therefore, the best strategy is to prevent transmission to the newborn infant. For this reason, obstetricians will usually recommend delivery by cesarean section ("C-section") for any mother with active genital herpes lesions.

Varicella-Zoster Virus

Varicella-zoster virus (VZV) is a type of herpesvirus (HHV-3) that most commonly causes chickenpox (varicella) in childhood, remains dormant for many years, and can then reemerge in later adulthood as painful herpes zoster lesions known as *shingles.*

Chickenpox is usually an uncomfortable but self-limiting disease of childhood. However, it is highly contagious and easily spread by either direct contact with weeping lesions or via droplet inhalation. It may also lead to significant scarring. The serious condition known as *Reye's syndrome* (fatty liver damage with encephalopathy) may also complicate varicella, as can other viral infections such as influenza. Herpes zoster, more commonly known as shingles, is caused by the reactivation of VZV from its dormant state, often decades after a case of childhood chickenpox. It is also referred to simply as *zoster.* Its most common manifestation is in the form of skin lesions that follow nerve tracts, known as *dermatomes,* along the skin surface. The most common site of these lesions is around the side of the trunk, although they can appear in other areas (e.g., along trigeminal nerve dermatomes of the face). Zoster lesions are often quite painful, and some patients even require opioids for pain control. In addition, postherpetic neuralgias (long-term nerve pain) remain following shingles outbreaks in up to 50% of elderly patients. Early administration of antiviral drugs such

as acyclovir may speed recovery, but this effect is usually not dramatic. The best results are generally seen when the antiviral drug is started within 72 hours of symptom onset.

Active childhood varicella (chickenpox) infections are usually self-limiting and are not normally treated with antiviral drugs, except in high-risk (e.g., immunocompromised) pediatric patients. The varicella virus vaccine was approved in 1995 and is now routinely recommended for healthy children older than 1 year of age who have not had chickenpox. A new vaccine, Zostavax, is available for prevention of herpes shingles in patients 50 years of age or older (see Chapter 49).

In a small percentage of shingles cases, skin lesions may progress beyond the usual dermatome regions, and the virus can cause solid organ infections such as pneumonitis, hepatitis, encephalitis, and optic neuritis (infection of the optic nerve). Such infections are uncommon, with elderly and immunocompromised patients being the most vulnerable. Rarely, these serious infections can be caused by first-time exposure to varicella (chickenpox). In general, these more serious infections require intravenous antiviral drugs, especially in high-risk patients. Intravenous acyclovir is the most commonly used drug, and it may prevent fatalities or disability. Less serious infections are usually treated orally with acyclovir, valacyclovir, or famciclovir. Topical dosage forms of some of these drugs are also available and are discussed further in Chapter 56. Although VZV reactivation is comparable in pathology to that of HSV (e.g., oral or genital herpes lesions), VZV reactivation occurs much less regularly than does HSV reactivation because of a lack of reactivation genes. Secondary bacterial infections (e.g., group A *Streptococcus* skin infection) are common with VZV exacerbations, so antibiotics may also be needed. This is especially true in cases of ophthalmic involvement.

PHARMACOLOGY OVERVIEW

ANTIVIRALS (NON-HIV)

The drugs discussed in this section include those used to treat non-HIV viral infections such as those caused by influenza viruses, HSV, VZV, and CMV. There are also antiviral drugs used to treat infections with hepatitis A, B, and C viruses. However, hepatitis treatment is covered in detail in Chapter 47 because it involves some additional unique drug therapy.

Mechanism of Action and Drug Effects

Most of the current antiviral drugs work by blocking the activity of a polymerase enzyme that normally stimulates the synthesis of new viral genomes. The result is impaired viral replication, which results in viral concentrations low enough to allow elimination of the virus by the patient's immune system. If this does not occur, the virus may either enter a dormant state or remain at a low level of replication with continuous drug therapy.

Indications

The antivirals discussed in this section are those used to treat HSV, VZV, and CMV infections and are listed in Table 40-1.

TABLE 40-1 EXAMPLES OF ANTIVIRAL DRUGS (NON-HIV)

DRUG	INDICATIONS
Drugs to Treat Herpesviruses	
acyclovir, valacyclovir	Herpes simplex types 1 and 2, herpes zoster, chickenpox
trifluridine	Herpes simplex keratitis
Drugs to Treat Influenza Viruses	
amantadine	Influenza A
rimantadine	Influenza A
zanamivir, oseltamivir	Influenza A and B
Miscellaneous Antivirals	
ribavirin	Respiratory syncytial virus infection
cidofovir	Cytomegalovirus infection
foscarnet	Cytomegalovirus infection, acyclovir herpes simplex infections

HIV, Human immunodeficiency virus.

Contraindications

Most of the antiviral drugs used to treat non-HIV viral infections are surprisingly well tolerated. The only usual contraindication for most of these drugs is known severe drug allergy. However, a small number of contraindications are listed for a few of the antiviral drugs. Amantadine is contraindicated in lactating women, children younger than 12 months of age, and patients with an eczematous rash. Famciclovir is contraindicated in cases of allergy to the drug itself or to a similar drug called *penciclovir,* which is used topically to treat herpes labialis (perioral sores). Cidofovir has a strong propensity for renal toxicity, and it is contraindicated in patients who already have severely compromised renal function as well as those receiving concurrent drug therapy with other highly nephrotoxic drugs. It is also contraindicated in cases of allergy to probenecid, because probenecid is recommended as concurrent drug therapy with cidofovir to help alleviate its nephrotoxicity. Ribavirin also has additional specific contraindications besides drug allergy. Because of the drug's teratogenic potential, it is also contraindicated in pregnant women and even in their male sexual partners. The aerosol form must not be used by pregnant women or by women who may become pregnant during exposure to the drug. This includes health care providers administering the drug in aerosol form, because of the potential for second-hand inhalation on the part of the health care provider.

Adverse Effects

The adverse effects of the antiviral drugs are as different as the drugs themselves. Each has its own specific adverse effect profile. Because viruses reproduce in human cells, selective killing is difficult, and consequently many healthy human cells, in addition to virally infected cells, may be killed in the process, which results in more serious toxicities for these drugs. However, this effect is usually not as pronounced as in cancer chemotherapy, which often kills many more healthy cells. The more serious adverse effects are listed by drug in Table 40-2.

TABLE 40-2 SELECTED ANTIVIRAL DRUGS: ADVERSE EFFECTS

DRUG	ADVERSE EFFECTS
acyclovir	Nausea, diarrhea, headache, burning when topically applied
amantadine, rimantadine	Insomnia, nervousness, lightheadedness, anorexia, nausea, anticholinergic effects, orthostatic hypotension, blurred vision
didanosine	Pancreatitis, peripheral neuropathies, seizures
foscarnet	Headache, seizures, electrolyte disturbances, acute renal failure, bone marrow suppression, nausea, vomiting, diarrhea
ganciclovir	Bone marrow toxicity, nausea, vomiting, headache, seizures
indinavir	Nausea; abdominal, back, or flank pain; headache; diarrhea; vomiting; weakness; taste changes; acid regurgitation; nephrolithiasis
nevirapine	Rash, fever, nausea, headache, elevation in liver enzyme levels
ribavirin	Rash, conjunctivitis, anemia, mild bronchospasm
trifluridine	Ophthalmic effects: burning, swelling, stinging, photophobia, pain
vidarabine	Ophthalmic effects: burning, lacrimation, keratitis, foreign body sensation, pain, photophobia, uveitis
zalcitabine	Peripheral neuropathy, rash, ulcers
zidovudine	Bone marrow suppression, nausea, headache

Interactions

Significant drug interactions that occur with the antiviral drugs arise most often when they are administered via systemic routes such as intravenously and orally. Many of these drugs are also applied topically to the eye or body, however, and the incidence of drug interactions associated with these routes of administration is much lower. Selected common drug interactions for both antiviral and antiretroviral drugs are listed in Table 40-3.

Dosages

For dosage information on some of the commonly used antiviral drugs, see the table on this page.

DRUG PROFILES

amantadine and rimantadine

Amantadine (Symmetrel), one of the earliest antiviral drugs, has a narrow antiviral spectrum in that it is active only against influenza A viruses. It has been used both prophylactically and therapeutically. However, the most recent guidelines of the Centers for Disease Control and Prevention (CDC) do not recommend the use of amantadine or rimantadine to prevent or

DOSAGES

Antiviral Drugs (Non-HIV)

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ acyclovir (Zovirax) (B)	Antiherpesvirus	**Pediatric younger than 12 yr** IV: 10-20 mg/kg q8h × 7-10 days **Pediatric 12 yr to adult** IV: 5-10 mg/kg q8h × 7-10 days PO: 200-800 mg q4h 5 times daily × 7-10 days PO: 20 mg/kg (max 800 mg/dose) 5 times daily × 5 days	HSV-1 and HSV-2 infection, including genital herpes, mucocutaneous herpes, herpes encephalitis; herpes zoster (shingles); higher-dose therapy for acute episodes; lower-dose therapy for viral suppression Chickenpox (varicella)
amantadine (Symmetrel) (C)	Antiinfluenza	**Pediatric 1-9 yr** 4.4-8.8 mg/kg/day divided once or twice daily **Pediatric 9-12 yr** 100 mg twice daily **Adolescent and adult 13-64 yr** 200 mg/day or divided bid **Adult older than 65 yr** 100 mg daily	Influenza A
ganciclovir (Cytovene) (C)	Antiviral	**Adult** IV: 5-10 mg/kg/day PO: 1000 mg tid	CMV retinitis treatment or maintenance
oseltamivir (Tamiflu) (C)	Antiinfluenza	**Pediatric 1-12 yr*** 30-60 mg twice daily, depending on weight **More than 40 kg or 13 yr to adult** 75 mg twice daily	Influenza A or B
ribavirin (Virazole) (X)	Anti-RSV	**Pediatric** Aerosol: 6 g reconstituted to 20 mg/mL via continuous aerosol 12-18 hr/day for 3-7 days	Severe RSV infection in hospitalized infants and toddlers
zanamivir (Relenza) (C)	Antiinfluenza	**Pediatric 7 yr to adult** Inhalation*: 10 mg (two 5-mg powder doses) twice daily; first day's doses must be at least 2 hr apart and q12h thereafter	Influenza A or B

NOTE: When pediatric dosages are not provided, dosing guidelines for pediatric patients are not firmly established for the drug in question and are based on the careful clinical judgment of a qualified prescriber.
HIV, Human immunodeficiency virus; *HSV-1, HSV-2,* herpes simplex virus types 1 and 2; *IV,* intravenous; *PO,* oral; *RSV,* respiratory syncytial virus.
*Use bronchodilator inhaler first if applicable.

TABLE 40-3 SELECTED ANTIVIRAL DRUGS: INTERACTIONS

DRUG	INTERACTING DRUGS	INTERACTION
Non-HIV Drugs		
acyclovir	interferon	Additive antiviral effects
	probenecid	Increased acyclovir levels due to decreasing renal clearance
	zidovudine	Increased risk for neurotoxicity
amantadine	Anticholinergic drugs	Increased adverse anticholinergic effects
	CNS stimulants	Additive CNS stimulant effects
ganciclovir	foscarnet	Additive or synergistic effect against CMV and HSV type 2
	imipenem	Increased risk for seizures
	zidovudine	Increased risk for hematologic toxicity (i.e., bone marrow suppression)
ribavirin	Nucleoside reverse transcriptase inhibitors	Increased risk for hepatotoxicity and lactic acidosis
HIV Drugs		
indinavir	Drugs metabolized by the CYP3A4 hepatic microsomal enzyme system (azole antifungals, clarithromycin, doxycycline, erythromycin, isoniazid, nefazodone, nicardipine, protease inhibitors, quinidine, statins, telithromycin, and verapamil)	Competition for metabolism resulting in elevated blood levels and potential toxicity
	rifabutin and ketoconazole	Increased plasma concentrations of rifabutin and ketoconazole
	rifampin	Increased metabolism of indinavir
nevirapine	Drugs metabolized by the CYP3A4 hepatic microsomal enzyme system (see indinavir)	Increased metabolism of these drugs
	Oral contraceptives	Decreased plasma concentrations of oral contraceptives
	Protease inhibitors	Decreased plasma concentrations of protease inhibitors
	rifampin and rifabutin	Decreased nevirapine serum concentration
tenofovir	acyclovir, cidofovir, ganciclovir, valacyclovir	May increase serum concentrations of tenofovir
	Protease inhibitors	Increased serum concentrations of tenofovir
maraviroc	CYP3A4 inhibitors (see indinavir)	May increase maraviroc toxicity
	CYP3A4 inducers (phenytoin, carbamazepine, rifampin)	May decrease effects of maraviroc
	St. John's wort	May decrease effects of maraviroc
raltegravir	atazanavir (with or without ritonavir)	May increase effects of raltegravir
	rifampin	May decrease effects of raltegravir
zidovudine	acyclovir	Increased neurotoxicity
	interferon beta	Increased serum levels of zidovudine
	Cytotoxic drugs	Increased risk for hematologic toxicity
	didanosine and zalcitabine	Additive or synergistic effect against HIV
	ganciclovir and ribavirin	Antagonize the antiviral action of zidovudine

CMV, Cytomegalovirus; *CNS,* central nervous system; *CYP3A4,* cytochrome P-450 enzyme 3A4; *HIV,* human immunodeficiency virus.

treat the flu. The recommendations on the use of amantadine change yearly based on the type of influenza that is prevalent. The reader is referred to www.cdc.gov/flu/professionals/antivirals/ for the latest recommendations.

Rimantadine is a structural analogue of amantadine that has the same spectrum of activity, mechanism of action, and clinical indications. However, it differs from amantadine in that it has a longer half-life and causes fewer central nervous system adverse effects such as dizziness and blurred vision. Rimantadine has GI adverse effects similar to those of amantadine. Both medications may be used in children. Both drugs are available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Within 48 hr	1-4 hr	17 hr	12-24 hr

♦ acyclovir

Acyclovir (Zovirax) is a synthetic nucleoside analogue that is used mainly to suppress the replication of HSV-1, HSV-2, and VZV. Acyclovir is considered the drug of choice for the treatment of both initial and recurrent episodes of these viral infections.

Acyclovir is available in oral, topical, and injectable formulations. Its topical use is discussed in Chapter 56. Other similar antiviral drugs include valacyclovir and famciclovir. However, these latter two drugs are currently available only for oral use and are indicated for the treatment of less serious infections. Note the slight inconsistencies in the spelling of these drug names. Valacyclovir is a prodrug that is metabolized to acyclovir in the body. It has the advantage of greater oral bioavailability and less frequent dosing (three times daily versus five times daily for acyclovir). It may also provide more effective relief of pain from zoster lesions.

Pharmacokinetics (acyclovir)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1.5-2 hr	1.5-2 hr	2-3 hr	10-15 hr
IV	Variable	1 hr	3 hr	8 hr

♦ ganciclovir

Like acyclovir, ganciclovir (Cytovene) is a synthetic nucleoside analogue of guanosine, but it has a much different spectrum of antiviral activity. It is indicated for the treatment of infections caused by CMV. CMV is carried by up to 50% of the adult population and normally causes no harm. However, in immunocompromised patients (including premature infants), it can cause life-threatening or disabling opportunistic infections. Valganciclovir (Valcyte), foscarnet (Foscavir), and cidofovir (Vistide) are three other antiviral drugs that are used in the treatment of CMV infection. Of these three antiviral drugs, ganciclovir is the one most often used for this purpose. A common site of CMV infections in the immunocompromised patient is the eye, and it can result in CMV retinitis, a devastating viral infection that can lead to blindness. Ganciclovir is most commonly administered intravenously or orally. However, there is also an ophthalmic form (Vitrasert) for treating active CMV retinitis, which must be surgically inserted. Ganciclovir is also administered to prevent CMV disease (generalized infection) in high-risk patients, such as those receiving organ transplants.

The dose-limiting toxicity of ganciclovir treatment is bone marrow suppression, whereas that of foscarnet and cidofovir is renal toxicity. These toxicities must be kept in mind when deciding which drug is more appropriate in a particular patient. For example, a heart transplant recipient who contracts CMV retinitis is immunocompromised because of immunosuppressant drug therapy and is most likely taking cyclosporine, which is nephrotoxic. Therefore, using foscarnet in this patient may be more dangerous than using ganciclovir. On the other hand, a patient who contracts a CMV infection and is immunocompromised because of a bone marrow transplant might be better treated using foscarnet.

Valganciclovir is a prodrug of ganciclovir, formulated for oral use, that is metabolized to ganciclovir in the body. As in the case described previously for valacyclovir and acyclovir, the prodrug provides greater oral bioavailability and allows less frequent daily dosing. Cidofovir and foscarnet are available only in injectable form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	24 hr	4.8 hr	Variable

oseltamivir and zanamivir

Oseltamivir (Tamiflu) and zanamivir (Relenza) belong to one of the newest classes of antiviral drugs known as *neuraminidase inhibitors*. These drugs are active against influenza virus types A and B. They are indicated for the treatment of uncomplicated acute illness caused by influenza infection in adults. They have been shown to reduce the duration of influenza infection by several days. The neuraminidase enzyme enables budding virions to escape from infected cells and spread throughout the body. Neuraminidase inhibitors are designed to stop this process in the body, speeding recovery from infection.

The most commonly reported adverse events with oseltamivir are nausea and vomiting; those with zanamivir are diarrhea, nausea, and sinusitis. Oseltamivir is available only for oral use. The drug is indicated for prophylaxis and treatment of influenza infection. Zanamivir is available in dry powder for inhalation. It is currently indicated only for treatment of active influenza illness. Treatment with oseltamivir and zanamivir needs to begin within 2 days of symptom onset.

Pharmacokinetics (oseltamivir)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	1-2 hr	1-3 hr	5-15 hr

Pharmacokinetics (zanamivir)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	1-2 hr	2-5 hr	10-24 hr

ribavirin

Ribavirin (Virazole) is a synthetic nucleoside analogue of guanosine, as are many of the other antiviral drugs, but it has a spectrum of antiviral activity that is broader than that of other currently available antiviral drugs. It interferes with both RNA and DNA synthesis and as a result inhibits both protein synthesis and viral replication overall.

The inhalational form (Virazole) is used primarily in the treatment of hospitalized infants with severe lower respiratory tract infections caused by respiratory syncytial virus. This drug was first available only in inhalational form. More recently, oral dosage forms have become available for use in the treatment of hepatitis C; these are discussed in Chapter 47.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Inhalation	Unknown	End of inhalation	1.4-2.5 hr	Variable
PO	Unknown	2-3 hr	120-170 hr	Unknown

PATHOPHYSIOLOGY OVERVIEW

HIV INFECTION AND AIDS

The first U.S. cases of acquired immune deficiency syndrome (AIDS) were recognized in 1981 in 31 previously healthy homosexual men in Los Angeles and New York City. These first patients mysteriously developed *Pneumocystis carinii* pneumonia

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Look-Alike/Sound-Alike Drugs: Zostrix and Zovirax

An incident was reported that involved the confusion of the two similarly named drugs Zostrix and Zovirax. A physician prescribed Zostrix cream with the directions, "Apply to affected area four times a day." There were no other specific instructions for the medication. The pharmacist mistakenly entered "Zovirax" into the pharmacy computer, and the nursing staff did not catch the error. The next day, the physician saw the tube of Zovirax in the patient's room instead of Zostrix. The sound-alike drug names can be easily confused.

Zostrix is capsaicin, derived from hot chili peppers, and is used topically for the treatment of arthritic pain, muscle strains, and joint sprains. In this case, it was ordered for neuralgic pain. Zovirax 5% ointment is a topical form of acyclovir, an antiviral medication, and is used for the management of initial genital herpes.

This incident illustrates how important it is to clarify the instructions in a medication order (e.g., application to a *specific* site) and how the use of generic names can help to avoid a medication error. In addition, it shows how important it is for nurses to be familiar with the indications of the drugs they are administering.

Data from ISMP Medication Safety Alert, *Nurse Advise-ERR,* May 2004, Volume 2, Issue 5, available at http://www.ismp.org/newsletters/nursing/issues/nurseadviseerr200405.pdf. Accessed April 12, 2012.

(PCP) or Kaposi's sarcoma, both normally extremely rare illnesses. (PCP is now known as *Pneumocystis jirovecii* pneumonia). Within months, similar disease patterns were recognized in intravenous drug users and in hemophiliac patients who had been transfused with blood-derived clotting factors. Other cases began to occur in hospitalized patients transfused with a variety of blood-derived products. In 1983 human T-cell lymphotropic virus type 3 (HTLV-3) was isolated from a patient with lymphadenopathy (swollen lymph nodes), and in 1984 this virus was demonstrated to be the cause of AIDS. The virus was later renamed *human immunodeficiency virus (HIV)*, a member of the retrovirus family. There are two recognized types of HIV: human immunodeficiency virus type 1 (HIV-1) and human immunodeficiency virus type 2 (HIV-2). Both cause AIDS, but HIV-2 is primarily localized in western Africa, with HIV-1 causing the majority of the HIV pandemic in the rest of the world. By 1985, a laboratory technique known as *enzyme-linked immunosorbent assay (ELISA)* was developed. This technique allowed the detection of HIV exposure based on the presence of human antibodies to the virus in blood samples. This diagnostic breakthrough led to an appreciation of the enormity of HIV prevalence both in U.S. high-risk groups and as an emerging world pandemic, especially in developing countries. This laboratory screening technique also helped to restore the safety of the transfusion blood supply, although it is not 100% reliable.

The retrovirus family got its name upon discovery of a unique feature of its replication process. Retroviruses are all RNA viruses and are unique in their use of the enzyme **reverse transcriptase** during their replication process. This enzyme promotes the synthesis of complementary (mirror image) DNA molecules from the viral RNA genome. A second enzyme, integrase, promotes the integration of this viral DNA into the host

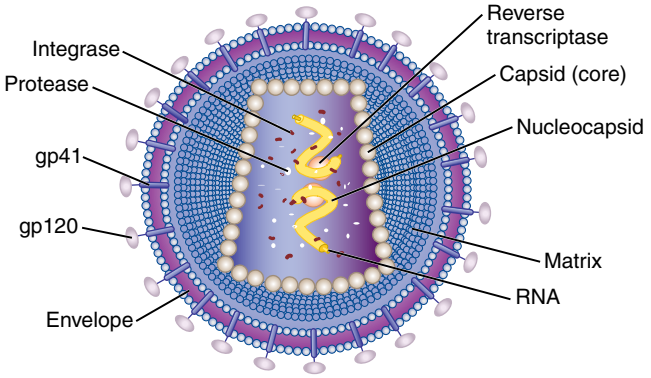

FIGURE 40-2 Human immunodeficiency virus. Within the core capsid, the diploid, single-stranded, positive-sense RNA is complexed to nucleoprotein. *gp,* Glycoprotein. (From *Dorland's illustrated medical dictionary,* ed 32, Philadelphia, 2012, Saunders.)

cell DNA. This hybrid DNA complex is known as a *provirus*. It produces new viral RNA genomes and proteins, which in turn combine to make mature HIV virions that infect other host cells. Another important enzyme is **protease,** which serves to chemically separate the new viral RNA from viral protein molecules. These components are initially synthesized into one large macromolecular strand, and the protease enzyme carefully breaks up this strand into its key components. Figure 40-2 shows the major structural features of the HIV virion, and Figure 40-3 illustrates the steps in its replication process. Reverse transcriptase is not normally found in host cells—both reverse transcriptase and integrase are carried by the virus itself. "Reversal" of the usual replication processes led to the name *reverse transcriptase* for this enzyme and also to the name *retrovirus* for this family of viruses. Furthermore, the fact that retroviruses synthesize DNA from viral RNA molecules is also a reversal of the norm, because in most other organisms, RNA molecules are synthesized from DNA molecules as part of the reproductive process. Reverse transcriptase has a high rate of errors when stringing together the purine and pyrimidine bases during transcription of the viral RNA genome into a DNA molecule in the replication process. This allows more frequent genetic mutations among HIV virions and often results in viral strains that are resistant to both medications and the patient's immune system. Such mutations also hamper the development of an effective vaccine against the virus. Drugs used to treat HIV are called *antiretrovirals.*

The most common routes of transmission of HIV are sexual activity, intravenous drug use, and perinatal transfer from mother to child. According to the most recent data, over 33 million people worldwide are infected with HIV, with 2.7 million cases newly diagnosed in 2008. Transmission was most common in homosexual or bisexual men followed by high-risk heterosexual intercourse and intravenous drug use for 12% of cases. African-American males and females had a rate of HIV infection seven times higher than that seen in white Americans. Cases of sexual transmission via oral mucosa have also been documented. However, no solid evidence to date confirms transmission of HIV by more casual contact, including hugging, kissing, coughing, sneezing, swimming in pools, and sharing of food, water, eating utensils, or toilet facilities. HIV

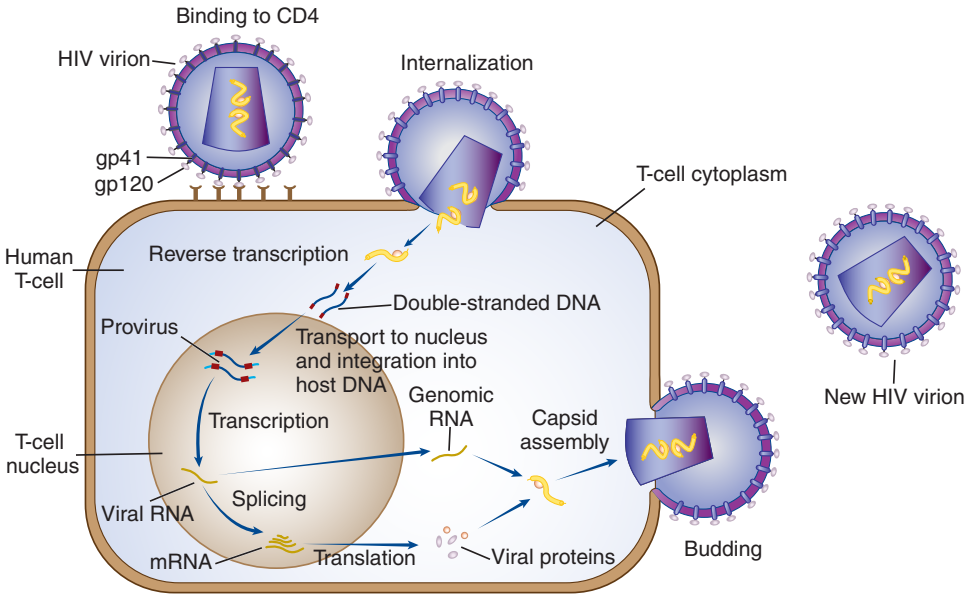

FIGURE 40-3 Life cycle of the human immunodeficiency virus (HIV). The extracellular envelope protein gp120 binds to CD4 on the surface of T lymphocytes or mononuclear phagocytes, while the transmembrane protein gp41 mediates the fusion of the viral envelope with the cell membrane. *gp,* Glycoprotein; *mRNA,* messenger RNA. (From *Dorland's illustrated medical dictionary,* ed 32, Philadelphia, 2012, Saunders.)

also is not transmitted by insect bites, unlike some other viral illnesses. Although HIV can be isolated from almost any body fluid, including tears, sweat, saliva, and urine, its concentrations in these fluids are much lower than those in blood and genital secretions. In approximately 6% of cases, specific risk factors cannot be determined. The risk for transmission to health care workers via percutaneous (needlestick) injuries is currently calculated at approximately 0.3%. Performing hand hygiene and maintaining Standard Precautions to avoid contact with all body fluids during patient care dramatically reduces the risk for caregiver infection (see Box 9-1).

The rate of new infections is rising more rapidly in minority populations, especially among African Americans and Hispanics. Patients in underdeveloped countries often lack access to adequate drug therapy. Untreated HIV-infected pregnant women transmit the virus to their infants in 15% to 30% of pregnancies. This can occur transplacentally, causing infection in utero, or during birth. When the first antiretroviral drugs were developed in the 1980s, it was feared that they would be too toxic and even teratogenic if given to pregnant women. However, prophylactic antiretroviral treatment of infected mothers has been shown to reduce infant infection by at least two thirds and is not normally harmful to either mother or infant. Medication may also be given prophylactically to the newborn infant, typically for the first 6 weeks of life. Infants and children with established HIV infection must usually continue taking medication indefinitely. Breast milk can transmit the virus to the infant in 10% to 20% of cases, and therefore breastfeeding is contraindicated in developed countries. In developing countries, however, breastfeeding may be the only available source of nutrition for the infant and therefore worth the risk. Box 40-1 summarizes the key epidemiologic concepts related to HIV/AIDS.

BOX 40-1 EPIDEMIOLOGY OF HIV INFECTION

Disease Viral Factors
- Developed virus is easily inactivated and must be transmitted in body fluids
- Disease has a long prodromal or incubation period
- Virus can be shed before development of identifiable symptoms

Transmission
- Virus is present in blood, semen, and vaginal secretions

Groups at Risk
- Intravenous drug abusers; sexually active people with many partners (homosexual and heterosexual); prostitutes; newborns of HIV-positive mothers
- Blood and organ transplant recipients and hemophiliacs: before 1985 (before screening programs)

Geographic Factors
- Continuously expanding epidemic worldwide
- No particular seasonal pattern of infection (i.e., unlike influenza)

Modes of Control
- Antiviral drugs limit progression of disease.
- Vaccines for prevention and treatment are in trials.
- Monogamous sex using safe sexual practices helps limit spread.
- Sterile injection needles need to be used.
- Large-scale screening programs have been developed to test blood for transfusions, organs for transplantation, and clotting factors given to hemophiliacs.

Data from U.S. Department of Health and Human Services: AIDSinfo (AIDS information website), available at www.aidsinfo.nih.gov.
HIV, Human immunodeficiency virus.

HIV infection that is untreated or treatment resistant eventually leads to severe immune system failure, with death occurring secondary to opportunistic infections. AIDS often progresses over a period of several years. Various health organizations, including the CDC and the World Health Organization (WHO), have published classification systems describing the various "stages" of this infection. The most recent WHO model lists four stages as follows:

- Stage 1: asymptomatic infection
- Stage 2: early, general symptoms of disease
- Stage 3: moderate symptoms
- Stage 4: severe symptoms, often leading to death

Stage 1 refers to the first few weeks or months after initial exposure to the virus. Patients may be asymptomatic but may show signs of persistent generalized lymphadenopathy or swollen lymph nodes ("swollen glands"). Persistent generalized lymphadenopathy is more specifically defined as inflammation of the lymph nodes in at least two sites outside the inguinal (groin) area that lasts for some months. During this time, the virus is present in the blood at low levels and has a low rate of replication. An important measure of immune function, the CD4 count, is usually still within normal limits at 350 cells/mm^3 of blood. CD4 refers to the protein on the cell surface of helper T lymphocytes, to which HIV virions attach themselves. Helper T cells normally function by releasing cytokines. Cytokines are chemicals that activate and modulate cell-mediated immunity, which is a general term for all immune system actions other than those involving antibodies. Immune system function is described further in Chapters 47 to 49. Helper T cells circulate in the blood and are the primary target cells for HIV. It is ultimately through widespread destruction of these helper T cells in the blood that HIV infection weakens the patient's immune system.

Stage 2 involves continued lymphadenopathy along with other symptoms, including fever, rash, sore throat, night sweats, malaise, diarrhea, idiopathic thrombocytopenia, oral candidiasis, and herpes zoster (shingles). In the early years of the epidemic (early 1980s), this stage was also known as AIDS-related complex or ARC. These symptoms may actually resolve spontaneously about the time of seroconversion, which is when the patient's own antibodies to the virus (HIV antibodies) begin to appear in blood samples. Seroconversion usually occurs 3 weeks to 3 months after exposure. At this point, the patient is said to be HIV positive. However, the patient may not have further progression of symptoms for 1 to 10 years. During this stage, the CD4 T-cell count begins to drop, and HIV antibody levels rise as part of an attempt by the patient's own immune system to neutralize the virus. The virus begins to multiply in the body but does not necessarily produce disabling symptoms. This stage is often the first presenting sign of HIV infection, and stage 1 may not have been noticed or reported by the patient.

During stage 3, the infection progresses to a moderately symptomatic state. Weight loss, chronic diarrhea, and fever continue, and CD4 counts continue to drop. Opportunistic infections begin, including severe bacterial pneumonias and pulmonary tuberculosis (TB). Pulmonary TB is usually more severe in persons with AIDS and is currently the leading cause of death worldwide for HIV-infected patients. Opportunistic infections are so named because the destruction by HIV of the patient's immune system gives the "opportunity" for normally harmless microorganisms in the body to proliferate to cause serious infections. These infections may become life-threatening or produce significant disability (e.g., blindness from CMV retinitis).

In stage 4, viral replication increases dramatically, which results in increasing destruction of helper T cells and a corresponding decrease in CD4 counts. At this point, there is a major decline in immune system function, and the illness begins to seriously affect the entire body. When the CD4 count drops below 200 cells/mm^3, fever, night sweats, and malaise resume and are now accompanied by increasingly severe opportunistic infections, such as *Mycobacterium avium-intracellulare* complex infection and *Pneumocystis jirovecii* pneumonia. Other common opportunistic infections include parasitic infections such as cryptosporidial diarrhea and toxoplasmosis encephalitis; viral infections such as HSV mouth ulcers, disseminated extrapulmonary tuberculosis, esophagitis, pneumonitis, CMV pneumonia, and CMV retinitis; and fungal infections, such as candidiasis of the GI and respiratory tracts, and invasive aspergillosis of the lungs. Similarly opportunistic disorders are HIV-associated neoplasms. The most common of these are Kaposi's sarcoma and various types of lymphoma. There is also some evidence that cervical cancer is more likely to be diagnosed in advanced stages in HIV-infected women. HIV wasting syndrome is yet another defining condition of the disease and involves major weight loss, chronic diarrhea, more frequent or even constant fever, and chronic fatigue. In addition to attacking helper T cells and macrophages, the HIV virus can also cause pathologic changes in organs such as the brain (HIV-induced encephalopathy and dementia), bone marrow, lungs (recurrent pneumonia), and skin. Death is most likely when the CD4 count falls below 50 cells/mm^3. The viral load, which is measured as the number of viral RNA copies per milliliter of blood, also continues to rise uncontrollably. If this condition persists, death often ensues. All of these manifestations are said to be the defining conditions of AIDS. Box 40-2 lists several such conditions.

Figure 40-4 illustrates events that roughly correlate with these four stages of HIV infection. This figure shows the hypothetical natural course of the disease through the previously described stages in patients *without* treatment. Patients who are effectively treated with drug therapy usually do not progress through all of these stages, or at least such progression is slowed considerably (by years). In fact, advances in antiretroviral drug therapy have given rise to increasingly greater numbers of long-term survivors of HIV infection. Highly active antiretroviral therapy (HAART) refers to combinations of antiretroviral drugs ("cocktails") that are now standard for treating HIV-infected patients. This combination therapy (HAART) is normally begun immediately upon confirmation of HIV infection. Opportunistic infections are treated with infection-specific antimicrobial drugs (see corresponding chapters) as they arise. Prophylactic treatment for opportunistic infections is also common and is most frequently given when a patient's

BOX 40-2 INDICATOR DISEASES OF AIDS

Opportunistic Infections

Protozoal

- Toxoplasmosis of the brain
- Cryptosporidiosis with diarrhea
- Isosporiasis with diarrhea

Fungal

- Candidiasis of the esophagus, trachea, and lungs
- *Pneumocystis jirovecii* pneumonia
- Cryptococcosis (extrapulmonary)
- Histoplasmosis (disseminated)
- Coccidioidomycosis (disseminated)

Viral

- Cytomegalovirus disease
- Herpes simplex virus infection (persistent or disseminated)
- Progressive multifocal leukoencephalopathy
- Hairy leukoplakia caused by Epstein-Barr virus

Bacterial

- *Mycobacterium avium-intracellulare* complex infection (disseminated)
- Any atypical mycobacterial disease
- Extrapulmonary tuberculosis
- *Salmonella* septicemia (recurrent)
- Pyogenic bacterial infections (multiple or recurrent)

Opportunistic Neoplasias

- Kaposi's sarcoma
- Primary lymphoma of the brain
- Other non-Hodgkin's lymphomas

Others

- HIV wasting syndrome
- HIV encephalopathy
- Lymphoid interstitial pneumonia

AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus.
Data from Mandell GL, Bennett JE, Dolin R, et al: *Mandell, Douglas, and Bennett's principles and practices of infectious diseases,* ed 7, Philadelphia, 2010, Churchill Livingstone.

CD4 count falls below 200 cells/mm^3. Opportunistic malignancies, such as Kaposi's sarcoma and lymphomas, are also treated with specific antineoplastic medications, which are discussed in Chapters 45 and 46, as well as with radiation and/or surgery as indicated. Long-term survival is defined as living with HIV infection for at least 10 to 15 years after infection. Some particularly remarkable patients have lived for several years with CD4 counts remaining at levels considered fatal. Improved drug therapy against both HIV and opportunistic infections is believed to play an important role in these unusual cases. Other remarkable patients are the long-term nonprogressors. These are long-term survivors who have maintained normal CD4 counts and low HIV viral loads despite not receiving *any* anti-HIV drug treatment. These patients are usually able to mount especially strong cell-mediated and humoral immune responses that prevent progression of the viral infection. They are also the subject of much research to identify the mechanisms of their survival and hopefully to find ways to share these advantages

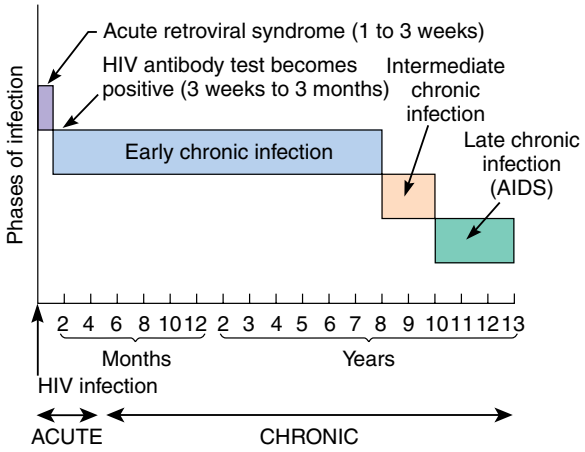

FIGURE 40-4 Timeline for the spectrum of untreated HIV infection. The timeline represents the course of untreated illness from the time of infection to clinical manifestations of disease. (From Lewis SL, Dirksen SR, Heitkemper MM, et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 8, Philadelphia, 2011, Elsevier.)

with other patients. Research attempts to develop an effective anti-HIV vaccine are also underway throughout the world. Human clinical trials have been conducted since 1990, primarily in non–HIV-infected research volunteers. However, vaccines are also being studied in HIV-positive patients. Despite encouraging data regarding potential benefits, the design of an effective HIV vaccine continues to remain elusive.

PHARMACOLOGY OVERVIEW

DRUGS USED TO TREAT HIV INFECTION

Much has happened in medical science since the AIDS virus was first identified in the early 1980s. The increasing urgency and public awareness of the HIV epidemic have stimulated much research in the fields of immunology and pharmacology. This has resulted in the development of several effective antiretroviral drugs, as well as of antiviral drugs in general. Although new drug combinations have prolonged lives, these medications often carry significant toxicities. Furthermore, HIV/AIDS is still not considered to be a curable disease. There are currently five classes of antiretroviral drugs, including the reverse transcriptase inhibitors, the protease inhibitors, the fusion inhibitors, and the newest classes, the entry inhibitor–CCR5 co-receptor antagonists and the HIV integrase strand transfer inhibitors. There are currently two subclasses of reverse transcriptase inhibitors: nucleoside reverse transcriptase inhibitors (NRTIs) and the nonnucleoside reverse transcriptase inhibitors (NNRTIs). Drugs from many of these drug classes are combined together into a single drug dosage form for ease of use. Table 40-4 lists these drugs and their respective classes. In 2012, the FDA approved Truvada for the prevention of HIV in high-risk patients. HIV drug therapy is rapidly changing, and the reader is referred to various websites including the FDA's website at www.fda.gov/ForConsumers/byAudience/ForPatientAdvocates/HIVandAIDSActivities/ucm118915.htm for the most up-to-date listing.

TABLE 40-4 EXAMPLES OF ANTIRETROVIRALS USED TO TREAT HIV

GENERIC NAME	TRADE NAME
Nucleoside Reverse Transcriptase Inhibitors	
abacavir	Ziagen
abacavir/lamivudine	Epzicom
abacavir/zidovudine/lamivudine	Trizivir
didanosine (enteric coated)	Videx EC
didanosine (dideoxyinosine)	Videx
emtricitabine	Emtriva
lamivudine	Epivir
stavudine (d4t)	Zerit
tenofovir	Viread
tenofovir/emtricitabine	Truvada
zalcitabine	Hivid
zidovudine	Retrovir
Nonnucleoside Reverse Transcriptase Inhibitors	
delavirdine	Rescriptor
efavirenz	Sustiva
etravirine	Intelence
nevirapine	Viramune
Protease Inhibitors	
amprenavir	Agenerase
atazanavir	Reyataz
darunavir	Prezista
fosamprenavir	Lexiva
indinavir	Crixivan
lopinavir/ritonavir	Kaletra
nelfinavir	Viracept
ritonavir	Norvir
saquinavir mesylate	Invirase
tipranavir	Aptivus
Fusion Inhibitor	
Enfuvirtide	Fuzeon
Entry Inhibitor–CCR5 Coreceptor Antagonist (Also Known as CCR5 Kntagonist)	
maraviroc	Selzentry
HIV Integrase Strand Transfer Inhibitor (Also Known as Integrase Inhibitor)	
raltegravir	Isentress
Multiclass Combination Products	
efavirenz/emtricitabine/tenofovir	Atripla
abacavir/lamivudine/zidovudine	Trizivir
lamivudine/zidovudine	Combivir
lopinavir/ritonavir	Kaletra

CCR5, Chemokine receptor 5; *HIV,* human immunodeficiency virus.

Mechanism of Action and Drug Effects

Although HIV/AIDS is a very complex illness, the mechanisms of action of the various drug classes are fortunately straightforward and distinct. The name of each class of medication provides a reminder of its role in suppressing the viral replication process. Thus, reverse transcriptase inhibitors work by blocking activity of the enzyme reverse transcriptase. Reverse transcriptase promotes the synthesis of new viral DNA molecules from the RNA genome. The protease inhibitors work by inhibiting the protease retroviral enzyme. This enzyme promotes the breakup of chains of protein molecules at designated points, a process necessary for viral replication. There is also one combination protease inhibitor that includes both lopinavir and ritonavir. Both medications are protease inhibitors. The ritonavir component also serves to inhibit cytochrome P-450–mediated enzymatic metabolism of the lopinavir component. There is currently one fusion inhibitor. This compound works by inhibiting viral fusion. This is the process by which an HIV virion attaches to (fuses with) the membrane of a host cell (T lymphocyte) before infecting it in preparation for viral replication. The entry inhibitor–CCR5 co-receptor antagonists, or CCR5 antagonists, work by selectively and reversibly binding to the type 5 chemokine co-receptors located on the CD4 cells that are used by the HIV virion to gain entry to the cells. The integrase strand transfer inhibitors, also referred to as *integrase inhibitors,* work by inhibiting the catalytic activity of the enzyme integrase thus preventing integration of the proviral gene into human DNA.

Single-drug therapy was most common in the early years of the HIV epidemic, partly due to a lack of treatment options. However, both the development of multiple antiretroviral drugs and the emergence of resistant viral strains have given rise to combination drug therapy as the current standard of care. This is the most effective treatment to date and is referred to as highly active antiretroviral therapy (HAART). HAART usually includes at least three medications. The most commonly recommended drug combinations include two or three NRTIs; two NRTIs plus one or two protease inhibitors; or an NRTI plus an NNRTI with one or two protease inhibitors. Despite the effectiveness of HAART, prescribers may still need to alter a given patient's drug regimen in cases of major drug intolerance (see Adverse Effects) or drug resistance. A given patient's HIV strain can still evolve and mutate over time, which allows it to become resistant to any drug therapy, especially when that therapy is used for a prolonged period of time. Evidence of drug resistance includes a falling CD4 count and/or increased viral load in a patient in whom a given drug regimen previously kept these parameters under control.

All antiretroviral drugs have similar therapeutic effects in that they reduce the viral load. A viral load of less than 50 copies/mL is considered to be an undetectable viral load and is a primary goal of antiretroviral therapy. HIV-infected patients need to be followed by practitioners with extensive training and specialization in drug therapy for infectious diseases. These practitioners must often make careful choices and changes in drug therapy over time, based on a given patient's clinical response and severity of any drug-related toxicity. When effective, treatment leads to a significant reduction in mortality and incidence of opportunistic infections, improves patient's physical performance, and significantly increases T-cell counts.

TABLE 40-5 RECOMMENDATIONS FOR OCCUPATIONAL HIV EXPOSURE CHEMOPROPHYLAXIS

TYPE OF EXPOSURE	SOURCE	PROPHYLAXIS	THERAPY
Percutaneous	Blood	Recommended	zidovudine + lamivudine + indinavir; OR zidovudine + lamivudine ± indinavir
	Fluid containing visible blood or other potentially infectious fluid or tissue		
Mucous membrane	Blood	Offer	zidovudine + lamivudine
	Fluid containing visible blood or other potentially infectious fluid or tissue	Offer	zidovudine + lamivudine ± indinavir; OR zidovudine ± lamivudine
Skin (i.e., prolonged contact, extensive area, area without skin integrity)	Blood	Offer	zidovudine + lamivudine ± indinavir

NOTE: Recommendations vary and change often, and the reader is referred to the CDC website (www.cdc.gov) for updated guidelines.
HIV, Human immunodeficiency virus.

Indications

The only usual indication for all of the current antiretroviral drugs is active HIV infection. Prophylactic therapy is also given to individuals such as health care workers and high-risk infants with a known potential exposure to HIV (e.g., via needlestick injuries in hospitals [Table 40-5]).

Contraindications

Because of the potentially fatal outcome of HIV infection, the only usual contraindication to a given medication is known severe drug allergy or other intolerable toxicity. Most of the current antiretroviral drug classes have several alternative drugs to choose from, if a patient is especially intolerant of a given drug.

Adverse Effects

Common adverse effects of selected antiretroviral drugs are listed in Table 40-2. The need to modify drug therapy because of adverse effects is not uncommon. The goal is to find the regimen that will best control a given patient's infection and that has as tolerable an adverse effect profile as possible. Different patients vary widely in their drug tolerance, and their tolerance may change over time. Thus, medication regimens often must be strategically individualized and evolve with the course of the patient's illness.

Approximately 25% of HIV-infected patients in the United States are also infected with hepatitis C virus (HCV), which tends to cause more severe disease in HIV patients. Hepatitis C is the most important cause of chronic liver disease in the United States and is the most common reason for liver transplantation. Unfortunately, HAART is strongly correlated with increased mortality from HCV-induced liver disease, because the anti-HIV drugs produce strain on the liver as these drugs are metabolized via the liver.

A major adverse effect of protease inhibitors is lipid abnormalities, including lipodystrophy, or redistribution of fat stores under the skin. This condition often results in cosmetically undesirable outcomes for the patient, such as a "hump" at the posterior base of the neck and also a skeletonized (bony) appearance of the face. In addition, dyslipidemias such as hypertriglyceridemia can occur, and insulin resistance and type 2 diabetes symptoms can result. It is reported that in these cases, switching a patient from a protease inhibitor to an NNRTI may help to reduce such symptoms without decreasing antiretroviral efficacy.

The increase in long-term antiretroviral drug therapy due to prolonged disease survival has led to the emergence of another long-term adverse effect associated with these medications—bone demineralization and possible osteoporosis. When this condition occurs, it may require treatment with standard medications for osteoporosis, such as calcium, vitamin D, and bisphosphonates (see Chapter 34).

Interactions

Common selected drug interactions involving both antiretrovirals and other antivirals are listed in Table 40-3.

Dosages

Because of rapidly changing antiviral drug therapy and the complexity of dosing and the disease state, only selected dosages are listed in this book (see the Dosages table on p. 665). Refer to an up-to-date drug information handbook for specifics on dosing.

DRUG PROFILES

enfuvirtide

Enfuvirtide (Fuzeon) is the only medication in one of the newest classes of antiretroviral drugs, called *fusion inhibitors.* It works by suppressing the fusion process whereby a virion is attached to the outer membrane of a host T cell before entry into the cell and subsequent viral replication. This mechanism of action serves as yet another example of how antiretroviral drugs are strategically designed to interfere with specific steps of the viral replication process. The use of combinations of drugs that work by different mechanisms improves a patient's chances for continued survival by reducing the likelihood of viral resistance to the drug therapy regimen. Enfuvirtide is indicated for treatment of HIV infection in combination with other antiretroviral drugs. Adult and pediatric patients have shown comparable tolerance of the drug in clinical trials thus far. Use of this drug in combination with other standard antiretroviral drugs has been associated with markedly reduced viral loads, compared with drug regimens that did not include this drug. The drug is currently available only in injectable form.

DOSAGES

HIV/AIDS Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE
enfuvirtide (Fuzeon) (B)	Fusion inhibitor	**Pediatric 6-16 yr** Subcut: 2 mg/kg twice daily **17 yr to adult** Subcut: 90 mg twice daily
♦ indinavir (Crixivan) (C)	Protease inhibitor	**Adult** PO: 800 mg q8h
maraviroc (Selzentry) (B)	CCR5 antagonist	**Adults and children older than 16 yr** 300 mg twice daily
♦ nevirapine (NVP) (Viramune) (C)	Nonnucleoside reverse transcriptase inhibitor	**Pediatric 2 mo-8 yr** PO: 4 mg/kg daily × 14 days, then 7 mg/kg twice daily **8 yr to adult** PO: 4 mg/kg daily × 14 days, then 4 mg/kg twice daily **Adult** PO: 200 mg daily × 14 days, then twice daily
raltegravir (Isentress) (C)	Integrase inhibitor	**Adults and children older than 16 yr** 400 mg twice daily
tenofovir (Viread) (B)	Nucleotide reverse transcriptase inhibitor	**Adult** PO: 300 mg once daily
♦ zidovudine (AZT, ZDV) (Retrovir) (C)	Nucleoside reverse transcriptase inhibitor	**Pediatric 0-3 mo*** PO: 2 mg/kg q6h starting within 12 hr after birth and through 6 wk of age IV: 1.5 mg/kg q6h **Pediatric 6 wk-12 yr** PO: 160 mg/m^2 q8h (max 200 mg/dose) **Adult** PO: 300 mg twice a day IV: 1 mg/kg over 1 hr; 5-6 times daily **Pregnant women** PO: 100 mg 5 times daily during pregnancy until start of labor, then give IV bolus dose of 2 mg/kg over 1 hr followed by an IV infusion of 1 mg/kg/hr until the umbilical cord is clamped

NOTE: Where pediatric dosages are not provided, dosing guidelines for pediatric patients are not firmly established for the drug in question and are based on the careful clinical judgment of a qualified prescriber.

AIDS, Acquired immunodeficiency syndrome; *CCR5,* chemokine receptor 5; *HIV,* human immunodeficiency virus; *IV,* intravenous; *PO,* oral; *subcut,* subcutaneous.

*Drug needs to be continued either IV or PO through at least 6 wk of age.

Pharmacokinetics (enfuvirtide)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Subcut	Unknown	4-8 hr	4 hr	Unknown

♦ indinavir

Indinavir (Crixivan) belongs to the *protease inhibitor* class of antiretroviral drugs. Others include ritonavir (Norvir), nelfinavir (Viracept), amprenavir (Agenerase), fosamprenavir (Lexiva), atazanavir (Reyataz), tipranavir (Aptivus), ritonavir (Norvir), darunavir (Prezista), and the combination product lopinavir/ritonavir (Kaletra). Indinavir can be taken in combination with other anti-HIV therapies or alone. This drug is best dissolved and absorbed in an acidic gastric environment, and the presence of high-protein and high-fat foods reduces its absorption. Therefore, it is recommended that it be administered in a fasting state. Indinavir therapy produces increases in CD4 cell counts and significant reductions in viral load. Protease inhibitors are commonly given in combination with two reverse transcriptase inhibitors to maximize efficacy and decrease the likelihood of viral drug resistance. Indinavir is relatively well tolerated in most patients. Nephrolithiasis (kidney stones) occur in approximately 4% of patients. Patients who take indinavir are encouraged to drink at least 48 oz of liquids every day to maintain hydration and help avoid nephrolithiasis. Indinavir and all other protease inhibitors are available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2 wk to therapeutic effect	0.5-1 hr	1.5-2.5 hr	6 mo

maraviroc

Maraviroc (Selzentry) is the only drug available in a new class of antiretrovirals called *CCR5 antagonists.* Maraviroc works by

selectively and reversibly binding to the chemokine co-receptors located on the CD4 cells. It is used in treatment-experienced patients with evidence of viral replication and HIV-1 strains resistant to multiple antiretroviral therapies. Patients must receive an FDA-approved medication guide before this drug is dispensed. Hepatotoxicity with allergic-type features has been reported. Drug interactions of significance include interactions with cytochrome P-450 3A4 (CYP3A4) inhibitors (azole antifungals, clarithromycin, doxycycline, erythromycin, isoniazid, nefazodone, nicardipine, protease inhibitors, quinidine, telithromycin, and verapamil), which may increase maraviroc toxicity. CYP3A4 inducers, including phenytoin, carbamazepine, nafcillin, and rifampin, may decrease maraviroc's effects. Maraviroc is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	0.5-4 hr	14-18 hr	Unknown

♦ nevirapine

Nevirapine (Viramune) is an NNRTI. This is the second class of antiviral drugs indicated for the treatment of HIV infection. Other currently available NNRTIs include delavirdine (Rescriptor), efavirenz (Sustiva), and etravirine (Intelence). These drugs are often used in combination with NRTIs.

Nevirapine is well tolerated compared with other therapies for HIV. The most common adverse events associated with nevirapine therapy are rash, fever, nausea, headache, and abnormal liver function test results. Nevirapine and the other NNRTIs are available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2 hr	2-4 hr	25-30 hr	24 hr

raltegravir

Raltegravir (Isentress) is the only drug in the new class called *integrase inhibitors.* Raltegravir works by inhibiting the activity of the integrase enzyme, thus preventing integration of the proviral gene into human DNA. Raltegravir is used in treatment-experienced patients with virus that shows multidrug resistance and active replication. Myopathy and rhabdomyolysis have been reported, as well as an immune reconstitution syndrome, which may result in an inflammatory response to a residual opportunistic infection. Raltegravir does not interact with CYP3A4 inducers or inhibitors (as do many other AIDS drugs).

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	3 hr	9 hr	Unknown

tenofovir

Tenofovir (Viread) is one of many NRTIs. Others in this class include emtricitabine (Emtriva), lamivudine (Epivir), stavudine (Zerit), and abacavir (Ziagen), as well as many combination products. Lactic acidosis and severe hepatomegaly have been reported with this drug and others in its class. Tenofovir is indicated for use against HIV infection in combination with other antiretroviral drugs. It is currently available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	4-8 days for therapeutic effect	1 hr	10-14 hr	7 days

♦ zidovudine

Zidovudine (Retrovir), also known as azidothymidine or AZT, is a synthetic nucleoside analogue of thymidine that has had an enormous impact on the treatment and quality of life of patients who have AIDS. It was the very first and, for a long time, the only anti-HIV medication. Zidovudine, along with various other antiretroviral drugs, is given to HIV-infected pregnant women and even to newborn babies to prevent maternal transmission of the virus to the infant.

The major dose-limiting adverse effect of zidovudine is bone marrow suppression, and this is often the reason a patient with HIV infection must be switched to another anti-HIV drug such as zalcitabine or didanosine. Some patients may receive a combination of two of these drugs, in lower dosages, to maximize their combined actions. This strategy may reduce the likelihood of toxicity. Zidovudine is available in both oral and injectable formulations.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	At least 6 mo for therapeutic effect	0.4-1.5 hr	0.8-2 hr	3-5 hr

PATHOPHYSIOLOGY OVERVIEW

OTHER VIRAL INFECTIONS

There are numerous other viral infections; however, four of recent significance include avian flu, West Nile virus (WNV) infection, severe acute respiratory syndrome (SARS), and the novel influenza virus (H1N1).

In 1999, the first North American cases of WNV infection occurred in New York City. WNV is a member of the arbovirus family and is transmitted to humans by mosquitoes. It also infects animals, primarily birds, and has been detected in horses and cows. In humans, WNV infection can lead to meningitis and encephalitis. In 2001, an epidemic occurred with more than 4000 documented human cases, including 284 deaths. Organ

transplant patients constituted one of the key groups infected. The virus can also be transmitted through blood transfusions and has been detected in breast milk. It is currently being investigated to determine whether maternal-fetal transmission can occur during pregnancy. In July 2003, national blood banks began screening blood donations for WNV using newly developed laboratory techniques. There are currently no specific antiviral medications or vaccines available for treatment of human WNV infection. Prevention focuses on reducing mosquito reproduction by eliminating unneeded pools of water near residential environments.

November 2002 marked the emergence of a new, serious viral illness known as severe acute respiratory syndrome (SARS). A large outbreak later occurred in Singapore in March 2003. This outbreak was eventually traced to a traveler returning from Hong Kong. Cases later appeared in Europe and North America. SARS can range from a mild to a life-threatening respiratory illness. The disease usually resolves on its own within 3 to 4 weeks. However, 10% to 20% of patients required mechanical ventilation and intensive care support, and the overall fatality rate is 3%. Although standard antiviral drugs, including oseltamivir, have been used to treat SARS, no specific drug therapy has proved to be definitively helpful. The cause of SARS has been determined to be a coronavirus, which was named the *SARS coronavirus.* Coronaviruses commonly cause mild to moderate upper respiratory tract illnesses in humans, including the common cold.

Avian influenza or "bird flu" is an influenza virus infection that has been shown to infect birds in Europe and both birds and humans in Asia. This disease is caused by an influenza A virus known as *avian influenza A, subtype H5N1.* The virus is carried in the intestines of many wild birds worldwide, often without causing any serious illness. However, more serious infections can be fatal and spread rapidly among an entire flock of birds. Usually, these viruses do not infect humans. However, since 1997, there have been cases of human infection, mostly following contact with infected birds or their secretions or excrement (e.g., in poultry workers). Most of these cases have occurred in Europe and Asia. There have also been one documented case in New York and one in Virginia of infection with H7N2 virus, another avian influenza virus subtype. Human-to-human transmission has been especially rare. Symptoms in humans have ranged from typical flulike symptoms such as fever, cough, sore throat, and muscle aches, to eye infections and acute respiratory illness, sometimes with life-threatening complications. This virus is resistant to amantadine and rimantadine, although it is believed (but remains to be confirmed) that zanamivir and oseltamivir would likely offer some therapeutic benefit for this condition.

Many health experts fear a flu pandemic caused by this virus, if it mutates to a more easily transmissible form. This occurs frequently with influenza viruses in general, which is why a new seasonal flu vaccine must be developed each year. Although no one can predict if and when such a pandemic might occur with this virus, the WHO and other health agencies, including the CDC, are continuously monitoring activity patterns as well as the virus's resistance to other antiviral drugs. Some countries, including the United States, have also implemented a ban on the import of birds from countries where avian influenza has been shown to be prevalent.

In 2009, the WHO signaled that a pandemic was underway with the new influenza virus H1N1 (originally called *swine flu*). The H1N1 virus spreads person to person, much the same way the regular seasonal influenza virus spreads. Symptoms include fever, cough, sore throat, body aches, chills, and fatigue. Severe illness and death have occurred with H1N1. A vaccine was developed and made available in October 2009. Antiviral medications such as oseltamivir or zanamivir are recommended for all patients with suspected or confirmed influenza requiring hospitalization. Prophylactic treatment is considered for patients at high risk for complications.

NURSING PROCESS

ASSESSMENT

Before administering an antiviral drug, perform a thorough head-to-toe physical assessment and take a medical and medication history. Document any known allergies. Assess the patient's nutritional status and baseline vital signs because of the profound effects of viral illnesses on physiologic status, especially if the patient is immune-compromised. Assess for any contraindications, cautions, and drug interactions.

In your assessment related to the use of *non-HIV antivirals,* inquire about the patient's allergy to medications. Ask for a listing of any prescription and over-the-counter drugs, herbals, and dietary supplements. Before initiation of therapy, assess energy levels, any weight loss, vital signs, and the characteristics of any visible lesions. Document the findings for baseline comparison. Age is also important to assess, because amantadine is not to be used in children younger than 12 months of age. Cidofovir requires assessment of renal function and is contraindicated in those with renal compromise or with use of other nephrotoxic drugs. Ribavirin is contraindicated in pregnant women and in their male sexual partners due to its teratogenic properties; it must also not be handled by health care personnel who are or might be pregnant. With ribavirin, analysis of respiratory secretions via sputum specimen will most likely be ordered for diagnostic purposes prior to initiation of drug therapy. With respiratory illness, also assess and document breath sounds, respiratory rate and patterns, cough, sputum production, and vital signs including temperature. A dose-limiting toxicity of ganciclovir treatment is bone marrow suppression; thus, perform a close review of the patient's CBC; CBC includes RBCs, WBCs, and platelets. With foscarnet and cidofovir, assess renal function because of the potential for renal toxicity.

Before giving acyclovir, assess vital signs and take a thorough medication history. Assess pain levels associated with the zoster lesions prior to giving the medication because relief of pain is expected with use of the drug. See Chapter 56 for more information on the topical form of acyclovir.

Famciclovir also requires assessment of allergies. Oseltamivir and zanamivir, useful against influenza virus types A and B, must be given as ordered within 2 days of the onset of flu symptoms. Ganciclovir is associated with bone marrow suppression; therefore, assess blood counts prior to and during use.

With use of *HIV antivirals* or *antiretrovirals,* closely assess allergies, cautions, contraindications, and drug interactions. Because of the severity of HIV infections and potential for a fatal outcome, the main contraindication includes severe drug allergy and other toxicities. Use of protease inhibitors requires assessment of the patient's medical history, vital signs, baseline weight, allergies, medication history, and results of baseline laboratory tests, such as CBC and renal and liver function studies. These laboratory tests are also generally ordered during the different phases of treatment; document results appropriately. A major adverse effect of the protease inhibitors is lipid abnormalities with redistribution of fat stores under the skin, leading to undesirable cosmetic outcomes for the patient. Assess emotional status and support systems due to the impact of this adverse effect on body image. Bone demineralization is yet another adverse effect with long-term use, so assessment of calcium and vitamin D levels is crucial to patient safety before, during, and after therapy.

The antiretroviral drug maraviroc requires assessment of allergies and liver function as well as review of the list of medications the patient is taking because of many interacting drugs. Raltegravir is associated with myopathies and breakdown of muscle cells; thus, baseline notation of skeletal muscle functioning and pain level is crucial to patient safety. Perform a baseline measurement, and frequently monitor vital signs, including temperature, due to the possibility of opportunistic infections. The prescriber may also order CBCs and other laboratory studies before, during, and after therapy. Avoid tenofovir in patients with liver disorders. Bone marrow suppression is a dose-limiting adverse effect of zidovudine, so review blood cell counts and results of clotting studies before and during therapy.

With any of the drugs presented in this chapter, especially those used for the management of HIV infection, assessment of the patient's knowledge about the illness and the need for long-term and often lifelong therapy is crucial. In addition, an assessment of the patient's knowledge about the illness as well as his or her educational level, reading level, the way in which he or she learns best, and familiarity with community resources is important in implementing patient education effectively. Be sure to assess mental status and emotional state because of the psychological impact of chronic illness. Value systems, social patterns, hobbies, support systems, and spiritual beliefs need to also be documented. Perform an assessment of financial status and resources as well. Many patients may need to be referred to social services because of lack of health care insurance and because many of these drugs are lifelong. For patients with chronic illnesses, the synthesis of this information will help ensure the development of a nursing care plan that is complete and holistic.

CASE STUDY

Antiviral Therapy

One of your patients, Z.K., a 33-year-old biology professor, has just begun therapy with lamivudine/zidovudine (Combivir) for a human immunodeficiency virus (HIV) infection. She has many questions about this medication therapy, and you are meeting with her to review her questions.

1. Z.K. asks you why there are two drugs in this particular medication. What is your explanation?
2. While she is receiving this drug therapy, Z.K. is continually monitored for what potential major problem?
3. What will be done to monitor for this problem, and how is it manifested?
4. Develop a patient teaching guide for Z.K., emphasizing any specific cautions and symptoms to report to the health care provider.

For answers, see http://evolve.elsevier.com/Lilley.

NURSING DIAGNOSES

1. Activity intolerance related to weakness secondary to decreased energy from pathology of viral infections
2. Deficient knowledge related to the lack of information about and experience with long-term medication therapy and lack of information about the viral infection, its transmission, and its treatment
3. Risk for injury related to the immunosuppressive effects of viral disease processes and their treatment

PLANNING

GOALS

1. Patient experiences improved energy and activity level while receiving therapy.
2. Patient demonstrates improved knowledge base about the disease process and the need for lifelong therapy.
3. Patient remains free from injury while taking medication for viral disease.

OUTCOME CRITERIA

1. Patient experiences increased periods of comfort with greater participation in care and activities of daily living as a result of successful treatment of viral infection.
   - Patient's energy levels improve to a level greater than what was experienced before antiviral therapy.
2. Patient states the rationale for the treatment regimen and the possibility of lifelong therapy with HIV illnesses.
   - Patient understands the need for taking the medication exactly as prescribed.
   - Patient identifies possible adverse effects associated with the HIV antiviral drugs such as GI upset.
   - Patient identifies financial resources to pay for lifelong medication therapy.
3. Patient states the physical impact of a viral infection on the patient's overall state of health (e.g., compromised

immune system) and the effect of appropriate therapy with either non-HIV antivirals and/or HIV antivirals (antiretrovirals).

- Patient takes appropriate precautions during antiviral therapy such as avoiding others who are ill and staying away from crowds.

IMPLEMENTATION

Nursing interventions pertinent to patients receiving *non-HIV antivirals* include use of the appropriate technique when applying or administering ointments, aerosol powders, and intravenous or oral forms of medication. Wear gloves and wash hands thoroughly before and after the administration of medication to prevent contamination of the site and spread of infection. It is important to the safety of both the patient and you to always begin by performing hand hygiene and maintain Standard Precautions (see Box 9-1). The use of non-HIV antivirals as well as HIV antivirals or antiretrovirals may lead to superimposed infection or superinfection, so constantly monitor for such infections and implement measures for their prevention (see Chapters 38 and 39).

Instruct the patient to take *oral antivirals* with meals to help minimize GI upset. Also advise the patient to store capsules at room temperature and not to crush or break the capsules. Acyclovir is available in various dosage forms, and there are slight inconsistencies in the spelling of the drug names so be sure to double-check the specific drug and dosage form ordered. Topical dosage forms (e.g., acyclovir) must be applied using a finger cot or gloves to prevent autoinoculation. Eye contact must also be avoided. Intravenous acyclovir is stable for 12 hours at room temperature and will often precipitate when refrigerated. Dilute intravenous infusions as recommended (e.g., with 5% dextrose in water or normal saline), and infuse with caution. Infusion over longer than 1 hour is suggested to avoid the renal tubular damage seen with more rapid infusions. Encourage adequate hydration during the infusion and for several hours afterward to prevent drug-related crystalluria. Carefully monitor the intravenous site. Document and report to the prescriber any redness, heat, pain, swelling, or red streaks that may indicate possible phlebitis. Document the characteristics of any lesions. Implement appropriate isolation for individuals with chickenpox or herpes zoster, and give analgesics for comfort, as ordered. Some of the more common adverse effects of acyclovir include nausea, diarrhea, and headache. Comfort measures may need to be implemented.

Amantadine and other antivirals need to be taken for the entire course of therapy, and, if a dose is missed, instruct the patient to take the dose as soon as it is remembered or contact the prescriber for further instructions. If dry mouth occurs due to anticholinergic effects, sucking on sugarless candy or chewing gum might be helpful. Encourage daily mouth care, including the use of dental floss, and regular dental preventive visits. Saliva substitutes may be needed, and if dry mouth continues for longer than 2 weeks, contact the prescriber for further management. Orthostatic hypotension may occur, so it is important to monitor vital signs with postural blood pressures during therapy. If given intravenously, dilute ganciclovir with 5% dextrose in water or normal saline to a concentration and in a time frame indicated by the prescriber and authoritative sources. Administration into large veins is recommended to provide the dilution needed to minimize the risk for vein irritation. When the solution of ganciclovir is being handled, avoid exposure of the eyes, mucous membranes, and skin to the drug, and use latex gloves and safety glasses for handling and preparation. If the drug comes in contact with these areas, flush the eyes with plain water and thoroughly wash other affected areas with soap and water. Laboratory values including blood counts will most likely be monitored during therapy due to possible bone marrow toxicity. Ribavirin may be given by nasal or oral inhalation, but the drug is not to be administered to pregnant women or handled by a health care provider who is (or may be) pregnant. Continually monitor for possible altered breath sounds, as wheezing may occur due to mild bronchospasm. When certain antivirals are given, always check the order closely against the drug being administered, because other drugs are spelled similarly or sound alike. For example, acyclovir may be mistaken for valacyclovir and famciclovir. When the patient is taking oseltamivir and other non-HIV antivirals for influenza, it is important to remember that this medication must be prescribed and is most effective if started within 2 days of the onset of flu symptoms.

Aerosol generators are available from the drug manufacturer. Discard reservoir solutions if levels are low or empty and change every 24 hours. For patients taking ribavirin and similar drugs for treatment of respiratory syncytial virus via a small particle aerosol generator (SPAG) device, provide clear and precise instructions to on how to properly mix and administer the drug. Be sure to reconstitute the drug (e.g., ribavirin powder) as instructed in the manufacturer guidelines. Discard old solutions left in the equipment before adding fresh medication. Drugs given using SPAG equipment are usually administered 12 to 18 hours daily for up to 7 days beginning within 3 days of the onset of symptoms. Much controversy exists about the use of this drug in patients on ventilators, and it is to be administered by only health care providers who are specially trained in this drug and its use. Frequently empty any "rain out" in the tubing of the ventilator, and continually monitor breath sounds in patients receiving inhaled forms of this drug, whether they are receiving artificial ventilation or not. Zanamivir is administered by inhalation using a Diskhaler device. Be sure that the patient exhales completely first; then, while holding the mouthpiece between the teeth with lips snug around it and tongue down and out of the way, the patient needs to inhale deeply through the mouth and then hold the breath as long as possible before exhaling the drug and the breath. Encourage rinsing of the mouth with water to prevent irritation and dryness, and instruct the patient to never exhale into the Diskhaler.

HIV antivirals, or *antiretrovirals,* include numerous drugs. With regard to dosage forms, there are special administration and handling guidelines for some of these drugs. With zidovudine, monitor for the adverse effects of bone marrow suppression by checking RBCs, WBCs, platelets, and other blood counts. If the patient experiences signs and symptoms of an opportunistic infection (e.g., respiratory signs and symptoms, fever, changes in oral mucosa), the prescriber needs to be contacted immediately. The patient may experience

headaches; therefore, provide the appropriate form of analgesia, as ordered. See Table 40-2 for a listing of more adverse effects associated with the various antiviral drugs.

With film-coated oral dosage forms, advise the patient not to alter the drugs in any way. Patients may improve the taste of ritonavir by mixing it with chocolate milk or a nutritional beverage within 1 hour of its dosing. Emphasize to patient and family that ritonavir's dosage form needs to be protected from light. Absorption of oral dosage forms of zidovudine is not impeded by taking the drug with food or milk, but instruct the patient to remain upright or with the head of the bed elevated while administering the medication and for up to 30 minutes afterward to prevent esophageal ulceration. Give intravenous doses only if the solution is clear and does not contain any particulate matter. Be sure to use the appropriate dosage, diluents, and infusion time. Because these drugs often come in oral dosage forms, it is usually recommended that they be given with food. Generally, administer zidovudine and other antiretrovirals at evenly spaced intervals around the clock—as ordered—to ensure steady-state levels. With all oral and parenteral dosage forms of antiretrovirals, observe the patient for nausea and vomiting as well as any changes in weight, anorexia, or changes in bowel activity and patterns. Maraviroc and tenofovir are available for oral dosing and are to be given as prescribed.

Throughout therapy, always remember that the goal of treatment is to find the regimen that provides the best control of the individual patient's infection with the most tolerable adverse effects possible. Because patients vary greatly in their drug tolerance, carefully individualize medication regimens. Other nursing interventions associated with these drugs include: (1) Continually monitor for adverse effects throughout therapy with a focus on the various organ systems, such as GI, neurologic, renal, and hepatic. (2) With oral forms of indinavir and nevirapine, encourage forcing of fluids (unless contraindicated) of at least 6 to 8 glasses of water daily to maintain adequate hydration and help prevent nephrolithiasis. (3) Nevirapine, zidovudine, and similar drugs may be associated with a rash; however, if the rash is accompanied by blistering, fever, malaise, myalgias, oral lesions, swelling or edema, or conjunctivitis, contact the prescriber immediately. (4) If drug therapy results in worsening of signs and symptoms, notify the prescriber immediately. The drug may be discontinued. (5) Continually monitor laboratory testing (e.g., CBC, renal/liver function studies, HIV RNA levels), and report abnormalities to the prescriber. See the Patient Teaching Tips for more information.

EVALUATION

The therapeutic effects of *non-HIV antivirals* and *HIV antivirals* or *antiretrovirals* include elimination of the virus or a decrease in the symptoms of the viral infection. There may be a delayed progression of HIV infection and AIDS as well as a decrease in flulike symptoms and/or the frequency of herpetic flare-ups and other lesion breakouts. With successful therapy, herpetic lesions will crust over, and the frequency of recurrence will decrease. In addition, constantly evaluate for the occurrence of adverse effects and toxicity associated with specific antiviral and antiretroviral drugs. These specific adverse effects are listed in Table 40-2. Continually reevaluate the nursing care plan to ensure that the goals and outcome criteria have been met. Remain constantly attentive in reviewing reports from the CDC, other federal and state health care agencies, and public health care organizations regarding new strains of viruses and flu syndromes (see earlier discussion).

PATIENT TEACHING TIPS

- Alert the patient to the adverse effect of dizziness, and instruct him or her to use caution while driving or participating in activities requiring alertness while taking antiviral drugs. Advise the patient to take all medications exactly as prescribed and for the full course of therapy.
- Inform the patient of all possible drug interactions including over-the-counter medications.
- Advise immunocompromised patients to avoid crowds and persons with infections.
- Advocate standard precautions and safe sex practices for all patients but especially those with sexually transmitted viral diseases, such as HIV-positive individuals. Condom use is a necessity for prevention of these viral infections and other sexually transmitted diseases. The presence of genital herpes requires sexual abstinence.
- It is generally recommended that female patients with genital herpes undergo a Papanicolaou smear test (Pap test) every 6 months or as ordered by the prescriber to monitor the virus and effectiveness of therapy.
- Instruct the patient to report the following adverse reactions to the prescriber: decreased urinary output, seizure activity, syncope, jaundice, wheezing, abnormal sensations in the hands and feet, vomiting, or diarrhea.
- Provide the patient with adequate demonstrations, teaching aids, and instructions for special application procedures (e.g., instillation of ophthalmic drops, use of finger cots or gloves when applying medication to lesions, use of respiratory inhalation forms). Explain that gloves or finger cots are needed for medication application and cleansing to prevent the spread of lesions.
- Encourage forcing fluids up to 3000 mL/24 hr unless contraindicated.
- Educate the patient about the fact that these drugs suppress but do not cure the viral infection.
- Inform the patient that therapy is to be started as prescribed but at the first sign (as with valacyclovir or other antivirals) of a recurrent episode of genital herpes or herpes zoster. In addition, explain that early treatment within 24 to 48 hours of symptom onset is needed to achieve full therapeutic results.
- Instruct the patient to report to the prescriber immediately any difficulty breathing; drastic changes in blood pressure; bleeding; new symptoms; worsening of infection, fever, or chills; or other unusual problems.
- Emphasize the importance of follow-up appointments.

KEY POINTS

- Viruses are difficult to kill and to treat because they live inside human cells, and most antiviral drugs work by inhibiting replication of the virus. In this chapter, antiviral drugs are categorized as either non-HIV antivirals or HIV antivirals (antiretrovirals).
- Non-HIV antivirals include amantadine, rimantadine, acyclovir, ganciclovir, oseltamivir, zanamivir, and ribavirin. HIV antivirals include enfuvirtide, indinavir, maraviroc, nevirapine, raltegravir, tenofovir, and zidovudine.
- Administer antiretroviral drugs only after the prescriber's orders are read and understood and after performing a thorough nursing assessment that includes a review of the patient's nutritional status, weight, baseline vital sign values, and renal and hepatic functioning as well as an assessment of heart sounds, neurologic status, and GI tract functioning.
- Comfort measures and supportive nursing care are to accompany drug therapy. Patients need to drink plenty of fluids and to space medications around the clock, as ordered, to maintain steady blood levels of the drug.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 During treatment with zidovudine, the nurse needs to monitor for which potential adverse effect?
- **a** Retinitis
- **b** Deep vein thromboses
- **c** Kaposi's sarcoma
- **d** Bone marrow suppression

2 After giving an injection to a patient with HIV infection, the nurse accidentally receives a needlestick from a too-full needle disposal box. Recommendations for occupational HIV exposure may include the use of which drug(s)?
- **a** didanosine
- **b** lamivudine and enfuvirtide
- **c** zidovudine, lamivudine, and indinavir
- **d** acyclovir

3 When the nurse is teaching a patient who is taking acyclovir for genital herpes, which statement by the nurse is accurate?
- **a** "This drug will help the lesions to dry and crust over."
- **b** "Acyclovir will eradicate the herpes virus."
- **c** "This drug will prevent the spread of this virus to others."
- **d** "Be sure to give this drug to your partner, too."

4 A patient who has been newly diagnosed with HIV has many questions about the effectiveness of drug therapy. After a teaching session, which statement by the patient reflects a need for more education?
- **a** "I will be monitored for side effects and improvements while I'm taking this medicine."
- **b** "These drugs do not eliminate the HIV, but hopefully the amount of virus in my body will be reduced."
- **c** "There is no cure for HIV."
- **d** "These drugs will eventually eliminate the virus from my body."

5 After surgery for organ transplantation, a patient is receiving ganciclovir, even though he does not have a viral infection. Which statement best explains the rationale for this medication therapy?
- **a** Ganciclovir is used to prevent potential exposure to the HIV virus.
- **b** This medication is given prophylactically to prevent influenza A infection.
- **c** Ganciclovir is given to prevent CMV infection.
- **d** The drug works synergistically with antibiotics to prevent superinfections.

6 The nurse is reviewing the use of multidrug therapy for HIV with a patient. Which statements are correct regarding the reason for using multiple drugs to treat HIV? (Select all that apply.)
- **a** The combination of drugs has fewer associated toxicities.
- **b** The use of multiple drugs is more effective against resistant strains of HIV.
- **c** Effective treatment results in reduced T-cell counts.
- **d** The goal of this treatment is to reduce the viral load.
- **e** This type of therapy reduces the incidence of opportunistic infections.

7 The order for an 11-year-old child who has chickenpox reads: "Give acyclovir (Zovirax) 20 mg/kg PO daily × 5 days. The child weighs 99 pounds. How much is each dose? Is this dose safe for this child?

1. d, 2. c, 3. a, 4. d, 5. c, 6. b, d, e, 7. 900 mg; no, the dose exceeds the 800 mg maximum per dose

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Identify the various first-line and second-line drugs indicated for the treatment of tuberculosis.
2 Discuss the mechanisms of action, dosages, adverse effects, routes of administration, special dosing considerations, cautions, contraindications, and drug interactions of the various antitubercular drugs.
3 Develop a nursing care plan that includes all phases of the nursing process for patients receiving antitubercular drugs.
4 Develop a comprehensive teaching guide for patients and families impacted by the diagnosis and treatment of antitubercular drugs.

DRUG PROFILES

ethambutol, p. 677
♦ **isoniazid, p. 677**
pyrazinamide, p. 678
rifabutin, p. 678
rifampin, p. 678
rifapentine, p. 678
streptomycin, p. 678

♦ *Key drug*

KEY TERMS

Aerobic Requiring oxygen for the maintenance of life. (p. 673)
Antitubercular drugs Drugs used to treat infections caused by *Mycobacterium* bacterial species. (p. 674)
Bacillus A rod-shaped bacterium. (p. 673)
Granulomas Small nodular aggregations of inflammatory cells (e.g., macrophages, lymphocytes); usually characterized by clearly delimited boundaries, as found in tuberculosis. (p. 673)
Isoniazid The primary and most commonly prescribed tuberculostatic drug. (p. 674)
Multidrug-resistant tuberculosis (MDR-TB) Tuberculosis that demonstrates resistance to two or more drugs. (p. 673)
Slow acetylator An individual with a genetic defect that causes a deficiency in the enzyme needed to metabolize isoniazid, the most widely used tuberculosis drug. (p. 677)
Tubercle The characteristic lesion of tuberculosis; a small round gray translucent granulomatous lesion, usually with a caseated (cheesy) consistency in its interior. (See *granuloma.*) (p. 673)
Tubercle bacilli Another common name for rod-shaped tuberculosis bacteria; essentially synonymous with *Mycobacterium tuberculosis.* (p. 673)
Tuberculosis (TB) Any infectious disease caused by species of *Mycobacterium,* usually *Mycobacterium tuberculosis* (adjectives: *tuberculous, tubercular*). (p. 673)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

PATHOPHYSIOLOGY OF TUBERCULOSIS

Tuberculosis (TB) is the medical diagnosis for any infection caused by a bacterial species known as *Mycobacterium.* TB is most commonly characterized by **granulomas** in the lungs. These are nodular accumulations of inflammatory cells (e.g., macrophages, lymphocytes) that are delimited ("walled off" with clear boundaries) and have a center that has a cheesy or caseated consistency. (*Casein* is the name of a protein that is prevalent in cheese and milk.) Although there are two mycobacterial species that can cause TB, *Mycobacterium tuberculosis* and *Mycobacterium bovis,* infections caused by *M. tuberculosis* (abbreviated MTB) are the most common. There are also several other mycobacterial species, including *Mycobacterium leprae,* which causes leprosy, and *Mycobacterium avium-intracellulare* complex, which causes a disease that is similar to TB but often has gastrointestinal symptoms, both of which have varying susceptibility to different drugs used for TB. Infections with these bacteria are much less of a public health problem and hence are not the focus of this chapter.

MTB is an aerobic bacillus, which means that it is a rod-shaped microorganism **(bacillus)** that requires a large supply of oxygen to grow and flourish **(aerobic).** This bacterium's need for a highly oxygenated body site explains why *Mycobacterium* infections most commonly affect the lungs. Other common sites of infection are the growing ends of bones and the brain (cerebral cortex). Less common sites of infection include the kidney, liver, and genitourinary tract, as well as virtually every other tissue and organ in the body.

These **tubercle bacilli** (a common synonym for MTB) are transmitted from one of three sources: humans, cattle (adjective: *bovine,* hence the species name *M. bovis*), or birds (adjective: *avian*), although bovine and avian transmission are much less common than human transmission. **Tubercle** bacilli are conveyed in droplets expelled by infected people or animals during coughing or sneezing and then inhaled by the new host. After these infectious droplets are inhaled, the infection spreads to the susceptible organ sites by means of the blood and lymphatic system. MTB is a very slow-growing organism, which makes it more difficult to treat than most other bacterial infections. Many of the antibiotics used to treat TB work by inhibiting growth (bacteriostatic) rather than by directly killing the organism. The reason why microorganisms that grow slowly are more difficult to kill is because their cells are not as metabolically active as those of faster-growing organisms. Most bactericidal (cell-killing) drugs work by disrupting critical cellular metabolic processes in the organism. Therefore, the most drug-susceptible organisms are those with faster (not slower) metabolic activity.

The first infectious episode is considered the primary TB infection; reinfection represents the more chronic form of the disease. However, TB does not develop in all people who are exposed to the bacteria. In some cases, the bacteria become dormant and walled off by calcified or fibrous tissues. These patients may test positive for exposure but are not necessarily infectious because of this dormancy process. In immunocompromised patients, TB can inflict devastating and irreversible damage. The steps for diagnosis of TB are listed in Box 41-1.

BOX 41-1 DIAGNOSIS OF TUBERCULOSIS

Step 1: Tuberculin skin test (Mantoux test)
Step 2: If skin test results are positive, then chest radiograph
Step 3: If chest radiograph shows signs of tuberculosis, then culture of sputum* or stomach secretions

*The acid-fast bacillus smear test is performed on sputum as a quick method of determining whether tuberculosis treatment and precautions are needed until a more definite diagnosis is made.

TB cases have been reported on a national level in the United States beginning in 1953. Since that time, the TB incidence decreased in most years until about 1985. At that point, the epidemic of human immunodeficiency virus (HIV) infection was growing strongly, and the TB incidence began to rise for the first time in 20 years because of the development of TB in patients co-infected with HIV. Many cities were unprepared to handle this reemergence of TB. After an 18% increase in TB incidence between 1985 and 1991, a 50% decline was recorded from 1992 through 2002, and a 3.1% decline was seen from 2009 to 2010. In 2010, 11,182 new cases were reported in the United States. The rate in 2010 represented the lowest recorded number of cases since 1953. This is attributed to intensified public health efforts aimed at preventing, diagnosing, and treating TB as well as HIV infection, including more effective antiretroviral drug therapy (see Chapter 40). However, the rate of decline has now slowed, primarily due to one contributing factor: the number of **multidrug-resistant tuberculosis (MDR-TB)** cases. An upward trend in drug resistance, especially to isoniazid (abbreviated INH) and rifampin, has been observed since the 1970s. In the 1990s, one third of TB cases in New York City were resistant to at least one drug, and 20% to both isoniazid and rifampin. Fortunately, these numbers have since declined, which has been attributed to stronger TB-related public health efforts.

The prevalence and growth of TB continues to be greater in the larger global community, and TB infects one third of the world's population. It is currently second only to HIV infection in the number of deaths caused by a single infectious organism. MDR-TB is defined as TB that is resistant to both isoniazid and rifampin, according to the World Health Organization. Close contacts of patients with MDR-TB need to be treated as well. Extensively drug-resistant tuberculosis (XDR-TB) is a relatively rare type of MDR-TB. It is resistant to almost all drugs used to treat TB, including the two best first-line drugs, isoniazid and rifampin, as well as to the best second-line medications. Because XDR-TB is resistant to the most powerful first-line and second-line drugs, patients are left with treatment options that are much less effective and often have worse treatment outcomes. XDR-TB is of special concern for patients who have AIDS or are otherwise immunocompromised. Not only are these patients more likely to contract TB, they are also more likely to die of it. At this point, XDR-TB is rare.

Several factors have contributed to this health care crisis, but one very important source of the problem is the increasing numbers of people in groups that are particularly susceptible to the infection—the homeless, undernourished or malnourished individuals, HIV-infected persons, drug abusers, cancer patients, those taking immunosuppressant drugs, and those who live in crowded and poorly sanitized housing facilities. All of these circumstances also favor the acquisition of a drug-resistant infection. Members of racial and ethnic minority groups are at greater risk than white populations and account for two thirds of new cases. Asian and Hispanic immigrants are at particularly high risk, accounting for more than half of all U.S. cases of foreign-acquired TB.

PHARMACOLOGY OVERVIEW

ANTITUBERCULAR DRUGS

The drugs used to treat infections caused by all forms of *Mycobacterium* are called antitubercular drugs, and these drugs fall into two categories: primary or first-line drugs and secondary or second-line drugs. As these designations imply, primary drugs are those tried first, whereas secondary drugs are reserved for more complicated cases, such as those resistant to primary drugs. The antimycobacterial activity, efficacy, and potential adverse and toxic effects of the various drugs determine the class to which they belong. **Isoniazid** is a primary antitubercular drug and is the most widely used. It can be administered either as the sole drug in the prophylaxis of TB or in combination with other antitubercular drugs in the treatment of TB. The various first-line and second-line antibiotic drugs are listed in Box 41-2. There are also two miscellaneous TB-related injections—one diagnostic, the other a vaccine. These are described in Box 41-3.

An important consideration during drug selection is the likelihood of drug-resistant organisms and drug toxicity. Following are other key elements that are important in the planning and implementation of effective therapy:

- Drug-susceptibility tests are performed on the first *Mycobacterium* species that is isolated from a patient specimen (to prevent the development of MDR-TB).
- Before the results of the susceptibility tests are known, the patient is started on a four-drug regimen consisting of isoniazid, rifampin, pyrazinamide (PZA), and ethambutol or streptomycin, which together are 95% effective in combating the infection. The use of multiple medications reduces the possibility of the organism's becoming drug resistant.
- Once drug susceptibility results are available, the regimen is adjusted accordingly.
- Patient adherence to the prescribed drug regimen and any adverse effects of therapy need to be monitored closely, because the incidence of both patient nonadherence and adverse effects is high.
- Despite the availability of many drugs to combat TB and the efforts mounted to detect and treat victims of the disease, treatment has been made difficult by two problems previously mentioned: patient nonadherence with therapy and the growing incidence of drug-resistant organisms.

BOX 41-2 FIRST-LINE AND SECOND-LINE ANTITUBERCULAR DRUGS

First-Line Drugs	Second-Line Drugs
ethambutol	amikacin
isoniazid (INH)	capreomycin
pyrazinamide (PZA)	cycloserine
rifabutin	ethionamide
rifampin	kanamycin
rifapentine	levofloxacin
streptomycin	ofloxacin
	para-aminosalicylic acid (PAS)

BOX 41-3 TUBERCULOSIS-RELATED INJECTIONS

Purified protein derivative (PPD): A diagnostic injection given intradermally in doses of 5 tuberculin units (0.1 mL) to detect exposure to the tuberculosis (TB) organism. It is composed of a protein precipitate derived from TB bacteria. A positive result is indicated by induration (not erythema) at the site of injection and is known as the Mantoux reaction, named for the physician who described it.

Bacille Calmette-Guérin (BCG): A vaccine injection derived from an inactivated strain of *Mycobacterium bovis*. Although it is not normally administered in the United States because the risk is not as high, it is used in much of the world to vaccinate young children against tuberculosis. Although it does not prevent infection, evidence indicates that it reduces active tuberculosis by 60% to 80% and is even more effective at preventing more severe cases involving dissemination of infection throughout the body. The bacille Calmette-Guérin vaccine for tuberculosis can cause false-positive results on the tuberculin skin test.

Mechanism of Action and Drug Effects

The mechanisms of action of the various antitubercular drugs vary depending on the drug. These drugs act on MTB by inhibiting protein synthesis, inhibiting cell wall synthesis, or various other mechanisms. The **antitubercular drugs** are listed in Table 41-1 by their mechanism of action. The major effects of drug therapy include reduction of cough and, therefore, reduction of the infectiousness of the patient. This normally occurs within 2 weeks of the initiation of drug therapy, assuming that the patient's TB strain is drug sensitive.

Indications

Antitubercular medications are indicated for the treatment of TB infections, including both pulmonary and extrapulmonary TB. Most antitubercular drugs have not been fully tested for their effects in pregnant women. However, the combination of isoniazid and ethambutol has been used to treat pregnant women with clinically apparent TB without teratogenic complications. Rifampin is another drug that is usually safe during pregnancy and is a more likely choice for more advanced disease.

Besides being used for the initial treatment of TB, antitubercular drugs have also proved effective in the management of treatment failures and relapses. Infection with species of *Mycobacterium* other than *M. tuberculosis* and atypical mycobacterial

TABLE 41-1 ANTITUBERCULAR DRUGS: MECHANISMS OF ACTION

DRUGS	DESCRIPTION
Inhibit Protein Synthesis	
kanamycin, capreomycin, rifabutin, rifampin, streptomycin	Streptomycin and kanamycin work by interfering with normal protein synthesis and causing the production of faulty proteins. Rifampin and capreomycin act at different points in the protein synthesis pathway than streptomycin and kanamycin. Rifampin inhibits RNA synthesis and may also inhibit DNA synthesis. Human cells are not as sensitive as the mycobacterial cells and are not affected by rifampin except at high drug concentrations. Capreomycin inhibits protein synthesis by preventing translocation on ribosomes.
Inhibit Cell Wall Synthesis	
cycloserine, ethionamide, isoniazid	Cycloserine acts by inhibiting the amino acid (D-alanine) involved in the synthesis of cell walls. Isoniazid and ethionamide also act at least partly to inhibit the synthesis of wall components, but the mechanisms of these two drugs are still not clearly understood.
Other Mechanisms	
ethambutol, ethionamide, isoniazid, para-aminosalicylic acid, pyrazinamide	Isoniazid is taken up by mycobacterial cells and undergoes hydrolysis to isonicotinic acid, which reacts with cofactor NAD to form a defective NAD that is no longer active as a coenzyme for certain life-sustaining reactions in the *Mycobacterium tuberculosis* organism. Ethionamide directly inhibits mycolic acid synthesis, which eventually has the same deleterious effects on the TB organism as isoniazid. Ethambutol affects lipid synthesis, which results in the inhibition of mycolic acid incorporation into the cell wall and thus inhibits protein synthesis. Para-aminosalicylic acid acts as a competitive inhibitor of para-aminobenzoic acid in the synthesis of folate. The mechanism of action of pyrazinamide in the inhibition of TB is unknown. It can be either bacteriostatic or bactericidal, depending on the susceptibility of the particular *Mycobacterium* organism and the concentration of the drug attained at the site of infection.

NAD, Nicotinamide adenine; *TB,* tuberculosis.

infections have also been successfully treated with these drugs. Nontuberculous *Mycobacteria* may also be susceptible to antitubercular drugs. However, in general, antitubercular drugs are not as effective against other species of *Mycobacterium* as they are against MTB. Some of these other species that may be of particular concern in immunocompromised patients such as AIDS patients are *M. avium-intracellulare* complex, *Mycobacterium flavescens, Mycobacterium marinum,* and *Mycobacterium kansasii.* Additional *Mycobacterium* infections that may respond to antitubercular drugs are those caused by *Mycobacterium fortuitum, Mycobacterium chelonae, Mycobacterium smegmatis, Mycobacterium xenopi,* and *Mycobacterium scrofulaceum.* Treatment regimens for these non-TB mycobacterial infections often include the macrolide antibiotics clarithromycin or azithromycin (see Chapter 38), either alone or in combination with one or more antitubercular drugs.

In summary, antitubercular drugs are primarily used for the prophylaxis or treatment of TB. The effectiveness of these drugs depends on the type of infection, adequate dosing, sufficient duration of treatment, adherence to the drug regimen, and selection of an effective drug combination. The indications of the different antitubercular drugs are listed in Table 41-2.

Contraindications

Contraindications to the use of various antitubercular drugs include severe drug allergy and major renal or liver dysfunction. However, it must be recognized that the urgency of treating a potentially fatal infection may have to be balanced against any prevailing contraindications. In extreme cases, patients are sometimes given a drug to which they have some degree of allergy with supportive care that enables them at least to tolerate the medication. Examples of such supportive care are treatment with antipyretics (e.g., acetaminophen), antihistamines (e.g., diphenhydramine), or even corticosteroids (e.g., prednisone, methylprednisolone).

One relative contraindication to ethambutol is optic neuritis. Chronic alcohol use, especially when associated with major liver damage, may also be a contraindication to therapy with any antitubercular drug. Other contraindications for specific drugs, if any, can be found in the drug profiles presented later in the chapter.

Adverse Effects

Antitubercular drugs are fairly well tolerated. Isoniazid, one of the mainstays of treatment, is noted for causing pyridoxine deficiency and liver toxicity. For this reason, supplements of pyridoxine (vitamin B_6; see Chapter 53) are often given concurrently with isoniazid, with a common oral dose of 50 mg daily. The most problematic drugs and their associated adverse effects are listed in Table 41-3.

Interactions

The drugs that can interact with antitubercular drugs can cause significant effects. See Table 41-4 for a listing of selected interactions. Besides these drug interactions, isoniazid can cause false-positive readings on urine glucose tests (e.g., Clinitest) and an increase in the serum levels of the liver function enzymes alanine aminotransferase and aspartate aminotransferase.

Dosages

For dosage information on selected antitubercular drugs, see the table on p. 677.

TABLE 41-2 ANTITUBERCULAR DRUGS: CLINICAL USES

DRUG	CLINICAL USES
amikacin, kanamycin	Used in combination with other antitubercular drugs in the treatment of clinical TB. Not intended for long-term use.
capreomycin	Used with other antitubercular drugs for the treatment of pulmonary TB caused by *Mycobacterium tuberculosis* after first-line drugs fail, drug resistance appears, or drug toxicity occurs.
cycloserine	Used with other antitubercular drugs for treatment of active pulmonary and extrapulmonary TB after failure of first-line drugs.
ethambutol	Indicated as a first-line drug for treatment of TB.
ethionamide	Used with other antitubercular drugs in treatment of clinical TB after failure of first-line drugs and for treatment of other types of mycobacterial infections.
isoniazid	Used alone or in combination with other antitubercular drugs in treatment and prevention of clinical TB.
para-aminosalicylic acid	Used in combination with other antitubercular drugs for treatment of pulmonary and extrapulmonary *M. tuberculosis* infection after failure of first-line drugs.
pyrazinamide	Used with other antitubercular drugs in treatment of clinical TB.
rifabutin	Used to prevent or delay development of *Mycobacterium avium-intracellulare* bacteremia and disseminated infections in patients with advanced HIV infection.
rifampin	Used with other antitubercular drugs in treatment of clinical TB. Used in treatment of diseases caused by mycobacteria other than *M. tuberculosis.* Used for preventive therapy in patients exposed to isoniazid-resistant *M. tuberculosis.* Used to eliminate meningococci from the nasopharynx of asymptomatic *Neisseria meningitidis* carriers when risk for meningococcal meningitis is high. Used for chemoprophylaxis in contacts of patients with HiB infection. Used with at least one other antiinfective drug in the treatment of leprosy. Used in the treatment of endocarditis caused by methicillin-resistant staphylococci, chronic staphylococcal prostatitis, and multiple-antiinfective–resistant pneumococci.
rifapentine	Used with other antitubercular drugs in the treatment of clinical TB.
streptomycin	Used in combination with other antitubercular drugs in the treatment of clinical TB and other mycobacterial diseases.

HiB, Haemophilus influenzae type b; *HIV,* human immunodeficiency virus; *TB,* tuberculosis.

TABLE 41-3 ANTITUBERCULAR DRUGS: COMMON ADVERSE EFFECTS

DRUG	ADVERSE EFFECTS
amikacin, kanamycin	Ototoxicity, nephrotoxicity
capreomycin	Ototoxicity, nephrotoxicity
cycloserine	Psychotic behavior, seizures
ethambutol	Retrobulbar neuritis, blindness
ethionamide	GI tract disturbances, hepatotoxicity
isoniazid	Peripheral neuropathy, hepatotoxicity, optic neuritis and visual disturbances, hyperglycemia
para-aminosalicylic acid	GI tract disturbances, hepatotoxicity
pyrazinamide	Hepatotoxicity, hyperuricemia
rifabutin	GI tract disturbances; rash; neutropenia; red-orange-brown discoloration of urine, feces, saliva, sputum, sweat, tears, skin
rifampin	Hepatitis; hematologic disorders; red-orange-brown discoloration of urine, tears, sweat, sputum
rifapentine	GI upset; red-orange-brown discoloration of tears, sweat, skin, teeth, tongue, sputum, saliva, urine, feces, CSF
streptomycin	Ototoxicity, nephrotoxicity, blood dyscrasias

CSF, Cerebrospinal fluid; *GI,* gastrointestinal.

TABLE 41-4 SELECTED ANTITUBERCULAR DRUGS: DRUG INTERACTIONS

DRUG	INTERACTING DRUGS	MECHANISM	RESULTS
isoniazid	Antacids	Reduce absorption	Decreased isoniazid levels
	cycloserine, ethionamide, rifampin	Have additive effects	Increased central nervous system and hepatic toxicity
	phenytoin, carbamazepine	Decrease metabolism	Increased phenytoin and carbamazepine effects
streptomycin	Nephrotoxic and neurotoxic drugs	Additive effects	Increased toxicity
	Oral anticoagulants	Alter intestinal flora	Increased bleeding tendencies
rifampin	Beta blockers, benzodiazepines, cyclosporine, oral anticoagulants, oral antidiabetics, oral contraceptives, phenytoin, quinidine, sirolimus, theophylline	Increase metabolism	Decreased therapeutic effects of these drugs

DOSAGES

Selected Antitubercular Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
ethambutol (Myambutol) (B)	Synthetic first-line antimycobacterial	**Adult and pediatric** PO: 15-25 mg/kg/day; may also be divided in 2×/wk and 3×/wk dosage regimens with higher doses; no maximum dose listed	Active TB
♦ isoniazid (INH), generic only (C)	Synthetic first-line antimycobacterial	**Adult** PO: 5 mg/kg daily (max 300 mg) or 15 mg/kg 1-3×/wk (max 900 mg/dose) **Pediatric** PO: 10-20 mg/kg/day (max 300 mg)	
pyrazinamide (generic only) (C)	Synthetic first-line antimycobacterial	**Adult and pediatric** PO: 15-30 mg/kg/day (max 2 g)	
rifabutin (Mycobutin) (B)	Semisynthetic first-line antimycobacterial antibiotic	**Adult only** PO: 150-300 mg once daily	
rifampin (Rifadin, Rimactane) (C)	Semisynthetic first-line antimycobacterial antibiotic	**Adult** PO/IV: 10 mg/kg up to 600 mg once daily **Pediatric** PO/IV*: 10-20 mg/kg/day or 2-3×/wk (max 600 mg/dose for all regimens)	
rifapentine (Priftin) (C)	Semisynthetic first-line antimycobacterial antibiotic	**Adult only** PO: 600 mg 2×/wk for first 2 mo; then 1×/wk for 4 mo	
streptomycin (generic) (D)	Aminoglycoside antibiotic used in combination with other drugs for TB	**Adult** Deep IM: 15 mg/kg/day **Pediatric** Deep IM: 20-40 mg/kg/day (Maximum dose: 1 g/day for all)	

IM, Intramuscular; *IV,* intravenous; *PO,* oral; *TB,* tuberculosis.
*Use of intramuscular and subcutaneous injections is contraindicated due to soft-tissue toxicity.

DRUG PROFILES

ethambutol

Ethambutol (Myambutol) is a first-line bacteriostatic drug used in the treatment of TB. It works by diffusing into the mycobacteria and suppressing ribonucleic acid (RNA) synthesis, which thereby inhibits protein synthesis. Ethambutol is included with isoniazid, streptomycin, and rifampin in many TB combination-drug therapies. It may also be used to treat other mycobacterial diseases. It is contraindicated in patients with known optic neuritis, because it can both exacerbate and cause this condition, which can result in varying degrees of vision loss. Ethambutol is also contraindicated in children younger than 13 years of age. It is available only in oral form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	2-4 hr	3.5 hr	24 hr

♦ isoniazid

Isoniazid (also called INH) is the mainstay in the treatment of TB and the most widely used antitubercular drug. It may be given either as a single drug for prophylaxis or in combination with other antitubercular drugs for the treatment of active TB. It is a bactericidal drug that kills the mycobacteria by disrupting cell wall synthesis and essential cellular functions. Isoniazid is metabolized in the liver through a process called *acetylation,* which requires a certain enzymatic pathway to break down the drug. However, some people have a genetic deficiency of the liver enzymes needed for this to occur. Such people are called **slow acetylators.** When isoniazid is taken by slow acetylators, the isoniazid accumulates, because there is not enough of the enzyme to break down the isoniazid. Therefore, the dosages of isoniazid may need to be adjusted downward in these patients.

Isoniazid is most commonly used in oral form, although an injection is available. There is also a combination oral formulation containing both isoniazid and rifampin (Rifamate). Another combination drug product, Rifater, contains rifampin, isoniazid, and pyrazinamide. Isoniazid is contraindicated in those with previous isoniazid-associated hepatic injury or any acute liver disease.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	1-2 hr	1-4 hr	24 hr

pyrazinamide

Pyrazinamide (also called PZA) is an antitubercular drug that can be either bacteriostatic or bactericidal, depending on its concentration at the site of infection and the particular susceptibility of the mycobacteria. It is commonly used in combination with other antitubercular drugs for the treatment of TB. Its mechanism of action is unknown, but it is believed to work by inhibiting lipid and nucleic acid synthesis in the mycobacteria. Pyrazinamide is available only in generic oral form. It is contraindicated in patients with severe hepatic disease or acute gout. It is also not normally used in pregnant patients in the United States, due to a lack of teratogenicity data, although it is often used in pregnant patients in other countries.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	2 hr	9-10 hr	24 hr

rifabutin

Rifabutin is one of three currently available *rifamycin* antibiotics. Although it is considered a first-line TB drug by some clinicians, it is more commonly used to treat infections caused by *M. avium-intracellulare* complex, which includes several non-TB mycobacterial species. This is also the case with the two other rifamycin-derived drugs, rifampin and rifapentine. A notable adverse effect of rifabutin, as well as rifampin (see later in the chapter), is that it can turn urine, feces, saliva, skin, sputum, sweat, and tears a red-orange-brown color. Rifabutin is currently available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	2-4 hr	16-69 hr	1 to several days

rifampin

Rifampin (Rifadin) is the first of the rifamycin class of synthetic macrocyclic antibiotics, which also includes rifabutin and rifapentine. The term *macrocyclic* connotes the very large and complex hydrocarbon ring structure included in all three of the rifamycin compounds. Rifampin has activity against many *Mycobacterium* species, as well as against *Meningococcus, Haemophilus influenzae* type b, and *M. leprae.* It is a broad-spectrum bactericidal drug that kills the offending organism by inhibiting protein synthesis. Rifampin is used either alone in the prevention of TB or in combination with other antitubercular drugs in its treatment. It is available in both oral and parenteral formulations and in combination with isoniazid (Rifamate). Rifampin is contraindicated in patients with known drug allergy to it or to any other rifamycin (i.e., rifabutin, rifapentine). The drug is a potent enzyme inducer and is associated with many drug interactions (see Table 41-4.) Rifampin may cause urine, saliva, tears, and sweat to be red-orange colored.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	2-4 hr	3.5 hr	Up to 24 hr

rifapentine

Rifapentine (Priftin) is a derivative of rifampin. It offers advantages over rifampin in that it has a much longer duration of action and possibly better efficacy. It has been shown to have greater antimycobacterial efficacy and macrophage penetration. Its accumulation into tissue macrophages allows it to work synergistically against bacterial cells that are ingested by the macrophage during phagocytosis ("cell eating"). Rifapentine is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	5-6 hr	13-17 hr	1 to several days

streptomycin

Streptomycin is an aminoglycoside antibiotic currently available only in generic form. Introduced in 1944, it was the very first drug available that could effectively treat TB. Because of its toxicities, it is used most commonly today in combination drug regimens for the treatment of MDR-TB infections. Streptomycin is currently available only in injectable form. It is classified as a pregnancy category D drug and is usually not given to pregnant patients.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IM	Variable	1-2 hr	2-3 hr	Up to 24 hr

NURSING PROCESS

ASSESSMENT

Before administering any of the *antitubercular drugs,* and to ensure the safe and effective use of these medications, obtain a thorough medical history, medication profile, and nursing history. Perform a complete head-to-toe physical assessment. Note any specific history of diagnoses or symptoms of TB. Determine the results of the patient's last purified protein derivative (PPD) or tuberculin skin test and the reaction at the intradermal injection site. Review the most recent chest radiograph and results. Assess the results of liver function studies (e.g., bilirubin level, liver enzyme levels) and kidney function studies (e.g., blood urea nitrogen [BUN], creatinine clearance). As noted earlier, major liver and/or renal dysfunction are contraindications. These values also provide comparative baseline data throughout therapy.

Because some drugs may lead to peripheral neuropathies, note baseline neurologic functioning prior to therapy. Assess

hearing status, especially when streptomycin is to be used, because of its drug-related ototoxicity. A gross eye examination is important due to the drug-induced adverse effect of visual disturbances and optic neuritis with isoniazid, levofloxacin, and ofloxacin. Blindness may occur with the use of ethambutol.

Assessment of age is also important because the likelihood of adverse reactions and toxicity is increased in elderly patients due to age-related liver and kidney dysfunction. Additionally, the safety of these drugs in children 13 years of age and younger has not been established. Assess the patient's complete blood count (CBC) prior to giving isoniazid, streptomycin, and rifampin because of the potential for drug-related hematologic disorders. Renal function studies, such as creatinine clearance and BUN, may be ordered prior to therapy with streptomycin due to the nephrotoxicity associated with its use. Document uric acid baseline levels with use of pyrazinamide due to the drug-induced adverse effect of hyperuricemia and symptoms of gout. Analysis of sputum specimens is usually ordered as well, to aid in determining the appropriate drug regimen. Contraindications, cautions, and drug interactions have been discussed previously.

NURSING DIAGNOSES

1. Ineffective family therapeutic regimen management related to poor compliance with antitubercular drug therapy and lack of knowledge about long-term therapies
2. Deficient knowledge related to the disease process and treatment protocol
3. Risk for injury related to noncompliance with the drug therapy regimen and an overall poor health status

PLANNING

GOALS

1. Patient experiences improved therapeutic regimen management and compliance.
   - Patient, family, and others in home environment understand the disease/infectious process, methods of spread and the need for the patient to remain on therapy, as prescribed.
2. Patient gains increased knowledge about antitubercular medication therapy and takes medication regularly and for the length of time prescribed.
3. Patient remains free from injury related to noncompliance to antitubercular drugs.

OUTCOME CRITERIA

1. Patient shows improvement of disease state with adherence to the drug regimen, including a decrease in cough, fever, and sputum production; return of laboratory values to normal ranges; and no spread of infection to those in the environment/home setting.
   - Patient reports family support and lack of spread of infection (to those in the environment/home setting) while on antitubercular drug therapy.
2. Patient states rationale for antitubercular drug therapy as well as anticipated adverse effects.
   - Patient takes medication as ordered and regularly with acknowledgement of more effective therapy and prevention of complications, relapses, or recurrences.
3. Patient takes antitubercular drugs as ordered and routinely, with stated goal of improved health status.
   - Patient minimizes adverse effects by taking medication as prescribed.
   - Patient reports the following to the prescriber immediately: fever, increase in cough/sputum, hearing loss, severe numbness/tingling of extremities, and altered vision.

CASE STUDY

Antitubercular Drugs

M.C., a 59-year-old homemaker, lives on the farm with her husband, R.C. Recently she has been experiencing weight loss, night sweats, and a chronic cough. When she is given the purified protein derivative (PPD) test, the result is positive, and a chest radiograph indicates areas of consolidation characteristic of tuberculosis. She is hospitalized, and special precautions are initiated to prevent the spread to others.

1. What is the next step in diagnosing the disease?

The physician orders that M.C. be started on a four-drug regimen consisting of isoniazid, rifampin, pyrazinamide, and ethambutol until the final results of testing are back.

2. What is the purpose of the multiple drugs in this order?
3. What needs to be assessed before M.C. begins this medication therapy?

Two weeks later, M.C. is discharged and given a prescription for Rifamate (combination of rifampin and isoniazid). In addition, she is given instructions to take pyridoxine (vitamin B_6).

4. M.C. asks, "Can't I just take my regular multivitamin? Why do I need this one?" What is the nurse's best answer?

For answers, see http://evolve.elsevier.com/Lilley.

IMPLEMENTATION

Because drug therapy is the mainstay of treatment for TB and often lasts for up to 24 months, patient education is critical, with a special emphasis on adherence to the drug regimen. Provide simple, clear, and concise instructions to the patient, with appropriate use of audiovisuals and take-home information. Include the fact that multiple drugs are often used to improve cure rates in the education. The patient needs to be able to state an understanding of all instructions. Because many of the patients affected by tuberculosis may be from other countries and cultures, it is important to have a translator available.

All *antitubercular drugs* need to be taken exactly as ordered and at the same time every day. Consistent use and dosing around the clock are critical to maintaining steady blood levels and minimizing the chances of resistance to the drug therapy. Always emphasize the need for strict adherence to the therapeutic regimen in the instructions to the patient. Additionally, emphasize that the entire prescription must be finished over

the prescribed time and as ordered by a prescriber, even if the patient is feeling better.

Although many drugs are given without food for maximum absorption, antitubercular drugs may need to be taken with food to minimize gastrointestinal upset. Constantly monitor for any signs and symptoms of liver dysfunction such as fatigue, jaundice, nausea, vomiting, dark urine, and anorexia. If these occur, contact the prescriber immediately. Also monitor kidney functioning (e.g., BUN, creatinine), and notify the prescriber if levels are altered. If vision changes occur (e.g., altered color perception, changes in visual acuity), in particular with ethambutol use, these changes must be reported immediately to the prescriber. Monitor uric acid levels during therapy, and advise the patient to report any symptoms of gout such as hot, painful, or swollen joints of the big toe, knee, or ankle. In addition, the prescriber must be notified if there are signs and symptoms of peripheral neuropathy (e.g., numbness, burning, and tingling of extremities). Pyridoxine (vitamin B_6) may be beneficial for isoniazid-induced peripheral neuropathy. If the prescriber has ordered collection of a sputum specimen to test for acid-fast bacilli, it is best to obtain the sample early in the morning. The most common order is for three consecutive morning specimens and a repeat specimen several weeks later. All drugs are to be taken as ordered and without any omission of doses for maximal therapeutic results.

Follow-up visits to the prescriber are important for monitoring therapeutic effects and watching for adverse effects and toxicity. If intravenous dosing of an antitubercular drug is ordered, use the appropriate diluent and infuse over the recommended time. Monitor the intravenous site every hour during the infusion for extravasation with possible tissue inflammation (e.g., redness, heat, and swelling at the intravenous site). See the Patient Teaching Tips for more information on antitubercular drugs.

Cultural considerations associated with these drugs include the fact that when patients have active TB, thorough patient teaching of all family members is required, and some family members may need prophylactic therapy for up to 1 full year. Because some cultural practices include living in close-knit communities or close living quarters, this teaching is critical to make sure the spread of this highly communicable disease is adequately prevented. All family members or those in close contact with the patient must receive the same thorough instructions about maintaining health while taking their medications appropriately, with emphasis on adherence.

EVALUATION

Always document a patient's response, or lack of, to the therapeutic regimen. A therapeutic response to *antitubercular* therapy is manifested by a decrease in the symptoms of TB, such as cough and fever, and by weight gain. The results of laboratory studies (culture and sensitivity tests) and the chest radiographic findings will aid in the confirmation of resolution of the infection along with improved clinical status. Continually evaluate the meeting of goals and outcome criteria to confirm that the infection is being adequately treated and that the drug therapy is providing therapeutic relief without complications or toxicity and with minimal adverse effects. Also monitor patients for the occurrence of adverse reactions to *antitubercular* drugs, such as hearing loss (ototoxicity); nephrotoxicity; seizure activity; altered vision; blindness; extreme GI upset; fatigue; nausea; vomiting; fever; jaundice; numbness, tingling, or burning of the extremities; abdominal pain; and easy bruising. Because of the need for long-term therapy and possible treatment of family or those in close contact, further evaluation of these individuals is important during and after completion of therapy.

PATIENT TEACHING TIPS

- Educate the patient to take medications exactly as ordered by the prescriber with attention to long-term therapy and strict adherence to the drug regimen. Treatment may be ineffective if drugs are taken intermittently or stopped once the patient begins to feel better.
- Stress the importance of follow-up appointments with the prescriber or health clinic so that the infection and therapeutic effectiveness may be closely monitored.
- Instruct the patient to avoid certain medications while taking antitubercular drugs, such as antacids, phenytoin, carbamazepine, beta blockers, benzodiazepines, oral anticoagulants, oral antidiabetic drugs, oral contraceptives, and theophylline. Inform the patient of all drug interactions prior to beginning therapy.
- Pyridoxine (vitamin B_6) may be indicated to prevent isoniazid-precipitated peripheral neuropathies and numbness, tingling, or burning of the extremities.
- Educate the patient taking isoniazid about the occurrence of the following adverse effects: numbness/tingling of extremities, abdominal pain, jaundice, and visual changes.
- Advise the patient taking rifampin to report the occurrence of the following adverse effects to the prescriber immediately: fever, nausea, vomiting, loss of appetite, jaundice, and/or unusual bleeding. These may indicate the possible occurrence of the adverse effects of hepatitis and/or various hematologic disorders.
- Encourage the patient to wear sunscreen and protective clothing during therapy to avoid ultraviolet light exposure. Drug-related photosensitivity reactions may be avoided by preventing exposure to the sun.
- Women taking oral contraceptives who are prescribed rifampin must be switched to another form of birth control. Oral contraceptives become ineffective when given with rifampin.
- During initial periods of the illness, instruct the patient to make every effort to wash hands and cover the mouth when coughing or sneezing. Emphasize methods of proper disposal of secretions.
- Emphasize the importance of proper rest, good sleep habits, adequate nutrition, and maintenance of general health. Advise the patient to always keep antitubercular drugs and other medications out of the reach of children.

PATIENT TEACHING TIPS—cont'd

- Recommend wearing of a medical alert tag or bracelet with a list of allergies, prescription drugs, and medical conditions at all times. Written medical information must also be kept on the patient's person at all times.
- Instruct the patient to contact the prescriber immediately upon any increase in fatigue, cough, sputum production, bloody sputum, chest pain, unusual bleeding, or yellow skin and/or eyes.
- Patients taking rifampin, rifabutin, or rifapentine may experience red-orange-brown discoloration of the skin, sweat, tears, urine, feces, sputum, saliva, and tongue as an adverse effect of the drug. The discoloration reverses with discontinuation of the drug; however, contact lenses may be permanently stained.

KEY POINTS

- All antitubercular drugs are to be taken exactly as prescribed. Emphasize adherence to the therapeutic regimen and long-term dosing combined with healthy living practices.
- Therapeutic effects include resolution of pulmonary and extrapulmonary MTB infections.
- Vitamin B_6 is needed to combat the peripheral neuropathy associated with isoniazid.
- Counsel women taking oral contraceptive therapy who are prescribed rifampin on other forms of birth control because of the ineffectiveness of oral contraception when rifampin is taken.
- Educate the patient about the importance of strict adherence to the drug regimen for improvement or cure of the condition. Provide instructions in written and oral formats about drug interactions and the need to avoid alcohol while taking any of these medications.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is teaching a patient who is starting antitubercular therapy with rifampin. Which adverse effects would the nurse expect to see?
- **a** Headache and neck pain
- **b** Gynecomastia
- **c** Reddish brown urine
- **d** Numbness or tingling of extremities

2 During antitubercular therapy with isoniazid, the patient received another prescription for pyridoxine. Which statement by the nurse best explains the rationale for this second medication?
- **a** "This vitamin will help to improve your energy levels."
- **b** "This vitamin helps to prevent neurologic adverse effects."
- **c** "This vitamin works to protect your heart from toxic effects."
- **d** "This vitamin helps to reduce gastrointestinal adverse effects."

3 The nurse is counseling a woman who is beginning antitubercular therapy with rifampin. The patient also takes an oral contraceptive. Which statement by the nurse is most accurate regarding potential drug interactions?
- **a** "You will need to switch to another form of birth control while you are taking the rifampin."
- **b** "Your birth control pills will remain effective while you are taking the rifampin."
- **c** "You will need to take a stronger dose of birth control pills while you are on the rifampin."
- **d** "You will need to abstain from sexual intercourse while on the rifampin to avoid pregnancy."

4 When counseling a patient who has been newly diagnosed with TB, the nurse will make sure that the patient realizes that he or she is contagious
- **a** during all phases of the illness.
- **b** any time up to 18 months after therapy begins.
- **c** during the postictal phase of TB.
- **d** during the initial period of the illness and its diagnosis.

5 While monitoring a patient, the nurse knows that a therapeutic response to antitubercular drugs would be:
- **a** The patient states that he or she is feeling much better.
- **b** The patient's laboratory test results show a lower white blood cell count.
- **c** The patient reports a decrease in cough and night sweats.
- **d** There is a decrease in symptoms, along with improved chest radiograph and sputum culture results.

6 The nurse is monitoring for liver toxicity in a patient who has been receiving long-term isoniazid therapy. Manifestations of liver toxicity include: (Select all that apply.)
- **a** Orange discoloration of sweat and tears
- **b** Darkened urine
- **c** Dizziness
- **d** Fatigue
- **e** Visual disturbances
- **f** Jaundice

7 The order for isoniazid (INH) reads: "Give 5 mg/kg PO daily." The patient weighs 275 pounds. What is the amount per dose? Is this a safe dose?

1. c, 2. b, 3. a, 4. d, 5. d, 6. b, d, f, 7. 625 mg/dose; no, maximum dose is 300 mg

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Identify the various antifungal drugs.
2 Describe the mechanisms of action, indications, contraindications, routes of administration, adverse and toxic effects, and drug interactions of the various antifungal drugs.
3 Develop a nursing care plan that includes all phases of the nursing process for patients receiving antifungal drugs.

DRUG PROFILES

♦ **amphotericin B, p. 686**
caspofungin, p. 686
♦ **fluconazole, p. 687**
nystatin, p. 688
terbinafine, p. 688
voriconazole, p. 688

♦ *Key drug*

KEY TERMS

Antimetabolite A drug that is a either a receptor antagonist or that resembles a normal human metabolite and interferes with its function in the body, usually by competing for the metabolite's usual receptors or enzymes. (p. 684)
Dermatophyte One of several fungi that are often found in soil and infect the skin, nails, or hair of humans. (p. 683)
Ergosterol The main sterol in fungal membranes. (p. 684)
Fungi A very large, diverse group of eukaryotic microorganisms that require an external carbon source and that form a plant structure known as a *thallus.* Fungi consist of yeasts and molds. (p. 683)
Molds Multicellular fungi characterized by long, branching filaments called *hyphae,* which entwine to form a complex branched structure known as a *mycelium.* (p. 683)
Mycosis The general term for any fungal infection. (p. 683)
Pathologic fungi Fungi that cause mycoses. (p. 683)
Sterols Substances in the cell membranes of fungi to which polyene antifungal drugs bind. (p. 684)
Yeasts Single-celled fungi that reproduce by *budding.* (p. 683)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

FUNGAL INFECTIONS

Fungi are a very large and diverse group of microorganisms that include all yeasts and molds. **Yeasts** are single-celled fungi that reproduce by budding (in which a daughter cell forms by pouching out of and breaking off from a mother cell). These organisms have common practical uses in the baking of breads and the preparation of alcoholic beverages. **Molds** are multicellular and are characterized by long, branching filaments. Some fungi are part of the normal flora of the skin, mouth, intestines, and vagina.

An infection caused by a fungus is called a **mycosis.** A variety of fungi can cause clinically significant infections or *mycoses.* These are called **pathologic fungi,** and the infections they cause range in severity from mild infections with annoying symptoms (e.g., athlete's foot) to systemic mycoses that can become life-threatening. These infections are acquired by various routes: the fungi can be ingested orally; can grow on or in the skin, hair, or nails; and, if the fungal spores are airborne, can be inhaled. There are four general types of mycotic infection: *systemic, cutaneous, subcutaneous,* and *superficial.* The latter three are infections of various layers of the *integumentary* system (skin, hair, or nails). Fungi that cause integumentary infections are known as **dermatophytes,** and such infections are known as *dermatomycoses.* The most severe systemic fungal infections generally affect people whose host immune defenses are compromised. Commonly, these are patients who have received organ transplants and are taking immunosuppressive drug therapy, cancer patients who are immunocompromised as a result of their chemotherapy, and patients with acquired immunodeficiency syndrome (AIDS). In addition, the use of antibiotics, antineoplastics, or immunosuppressants such as corticosteroids may result in colonization of *Candida albicans,* followed by the development of a systemic infection. When the infection affects the mouth, it is referred to as oral *candidiasis,* or thrush. It is common in newborns and immunocompromised patients. Vaginal candidiasis, commonly called a *yeast infection,* often affects pregnant women, women with diabetes mellitus, women taking antibiotics, and women taking oral contraceptives. The characteristics of some of the systemic, cutaneous, and superficial mycotic infections are summarized in Table 42-1.

PHARMACOLOGY OVERVIEW

ANTIFUNGAL DRUGS

Drugs used to treat fungal infections are called *antifungal drugs.* Systemic mycotic infections and some cutaneous or subcutaneous mycoses are treated with oral or parenteral drugs. Antifungals are a fairly small group of drugs. There are few such drugs because the fungi that cause these infections have proved to be very difficult to kill, and research into new and improved drugs has occurred at a slow pace. One difficulty is that often the chemical concentrations required for experimental drugs to be effective cannot be tolerated by human beings. The drugs that proved successful in the treatment of systemic mycoses as well

TABLE 42-1 MYCOTIC INFECTIONS

MYCOSIS	FUNGUS	ENDEMIC LOCATION	RESERVOIR	TRANSMISSION	PRIMARY TISSUE AFFECTED
Systemic Infections					
Aspergillosis	*Aspergillus* spp.	Universal	Soil	Inhalation	Lungs
Blastomycosis	*Blastomyces dermatitidis*	North America	Soil, animal droppings	Inhalation	Lungs
Candidiasis	*Candida albicans, glabrata, krusei, tropicalisis, parapsilosis*	Universal	Humans	Direct contact, overgrowth in response to treatment with antibiotic to which it is nonsusceptible	Blood, lungs
Coccidioidomycosis	*Coccidioides immitis*	Southwestern United States	Soil, dust	Inhalation	Lungs
Cryptococcosis	*Cryptococcus neoformans*	Universal	Soil, bird and chicken droppings	Inhalation	Lungs, meninges of brain
Histoplasmosis	*Histoplasma capsulatum*	Universal		Inhalation	Lungs
Superficial/Topical Infections					
Candidiasis	*Candida albicans*	Universal	Humans	Direct contact, overgrowth in response to treatment with antibiotic to which it is nonsusceptible	Mucous membrane, skin; disseminated (may be systemic)
Dermatophytosis, tinea	*Epidermophyton* spp. *Microsporum* spp. *Trichophyton* spp.	Universal	Humans	Direct and indirect contact with infected persons	Scalp, skin (e.g., groin, feet)
Tinea versicolor	*Malassezia furfur*	Universal	Humans	Unknown*	Skin

spp., Species.
**Malassezia* spp. are a usual part of the normal human flora and appear to cause infection in only select individuals.*

as severe dermatomycoses include amphotericin B, caspofungin, fluconazole, flucytosine, griseofulvin, itraconazole, ketoconazole, micafungin, nystatin, terbinafine, posaconazole, anidulafungin, and voriconazole. These drugs are the focus of this chapter.

Topical antifungal drugs are the most commonly used drugs in this class and are often administered without prescription for the treatment of dermatomycoses as well as oral and vaginal mycoses. Although topical drug therapy is usually sufficient for these conditions, systemic oral medications are sometimes used, especially for more severe or recurrent cases. Antifungal drugs available for topical use are discussed further in Chapter 56. There is also a single antifungal drug (natamycin) for ophthalmic use (see Chapter 57).

Two antifungal drugs, flucytosine and griseofulvin, are individually listed and are not specifically classified according to their chemical structures. The remaining drugs currently include four specific chemical classes: *polyenes* (amphotericin B and nystatin), *imidazoles* (ketoconazole), *triazoles* (fluconazole, itraconazole, voriconazole, and posaconazole), and the *echinocandins* (caspofungin, micafungin, and anidulafungin). The imidazoles and triazoles are sometimes referred to by the more general term *azole antifungals.* Also included in some of these classes are drugs for topical use.

Mechanism of Action and Drug Effects

The mechanisms of action of the various antifungal drugs differ between drug subclasses. Flucytosine, also known as *5-fluorocytosine (5-FC),* acts in much the same way as the antiviral drugs. It is an **antimetabolite,** which is a drug that disrupts critical cellular metabolic pathways of the fungal cell. Once inside a susceptible fungal cell, the drug is deaminated by the enzyme *cytosine deaminase* to 5-fluorouracil (5-FU). Because human cells do not have this enzyme, they are not harmed by this antimetabolite. Once the 5-FU is generated inside the fungal cell, it interferes with fungal deoxyribonucleic acid (DNA) synthesis, which results in both inhibition of cell growth and reproduction, and cell death. 5-FU is also available as an antineoplastic (anticancer) drug and is discussed in more detail in Chapter 45.

Griseofulvin, like flucytosine, is one of the older types of antifungal drugs. It works by preventing susceptible fungi from reproducing. It enters the fungal cell through an energy-dependent transport system and inhibits fungal mitosis (cell division) by binding to key structures known as *microtubules.* It has also been proposed that griseofulvin causes the production of defective DNA, which is then unable to replicate. Although both griseofulvin and flucytosine are still currently available in the U.S. market, their use has been largely replaced by the newer antifungal drug classes.

The polyenes (amphotericin B and nystatin) act by binding to **sterols** in the cell membranes of fungi. The main sterol in fungal membranes is **ergosterol.** Human cell membranes have cholesterol instead of ergosterol. Because polyene antifungals have a strong chemical affinity for ergosterol instead of cholesterol, they do not bind to human cell membranes and therefore do not kill human cells. Once the polyene drug molecule binds to the ergosterol, a channel forms in the fungal cell membrane that allows potassium and magnesium ions to leak out of the fungal cell. This loss of ions causes fungal cellular metabolism to be altered, which leads to death of the cell.

Imidazoles and triazoles (ketoconazole, fluconazole, itraconazole, voriconazole, and posaconazole) act as either fungistatic or fungicidal drugs, depending on their concentration in the fungus. They are most effective in combating rapidly growing fungi and work by inhibiting fungal cell cytochrome P-450 enzymes. These enzymes are needed to produce ergosterol. The allylamine terbinafine is believed to act by a similar mechanism. When the production of ergosterol is inhibited, other sterols called *methylsterols* are produced instead, which results in a defect similar to that caused by the polyene antifungals, namely, a leaky cell membrane that allows needed electrolytes to escape. The fungal cells die because they cannot carry on cellular metabolism.

The echinocandins (caspofungin, micafungin, and anidulafungin) act by preventing the synthesis of glucans, essential components of fungal cell walls that are not present in mammalian cells. This also contributes to fungal cell death. Some of the fungi that are susceptible to these drugs are the pathogens involved in the various mycoses listed in Box 42-1.

Indications

Indications for the use of the various antifungal drugs are specific to the drug. The adverse effects of the newer antifungals are fewer and less serious than those of the older drugs. However, the drug of choice for the treatment of many severe systemic fungal infections remains one of the oldest antifungals, amphotericin B, which does have major adverse effects. Amphotericin B is effective against a wide range of fungi. It is sometimes given with flucytosine in the treatment of *Candida* and cryptococcal infections because of the synergy of the two drugs. Amphotericin B is also effective for treating aspergillosis, blastomycosis, candidiasis, coccidioidomycosis, cryptococcosis, fungal endocarditis, histoplasmosis, zygomycosis, fungal septicemia, and many other systemic fungal infections. The activity of nystatin is similar to that of amphotericin B, but its usefulness is limited because of its toxic effects when given in the dosages required to accomplish

BOX 42-1 FUNGAL SPECIES SUSCEPTIBLE TO CURRENT ANTIFUNGAL DRUGS

Superficial/Topical Mycoses

Epidermophyton spp.
Malassezia furfur (causes tinea versicolor)
Microsporum spp.
Sporothrix spp.
Trichophyton spp.

Systemic Mycoses

Absidia spp.
Aspergillus spp.
Basidiobolus spp.
Blastomyces dermatitidis
Candida spp.
Coccidioides immitis
Conidiobolus spp.
Cryptococcus neoformans
Histoplasma capsulatum
Mucor spp.
Rhizopus spp.
Scedosporium apiospermum spp.

the same antifungal actions as amphotericin B. It is also not available in parenteral form. Nystatin is most commonly used to treat oropharyngeal candidiasis, commonly referred to as *thrush.*

Fluconazole and itraconazole are synthetic azole antifungals. Fluconazole can pass into the cerebrospinal fluid (CSF) and inhibit the growth of cryptococcal fungi. This makes it effective in the treatment of cryptococcal meningitis. Both drugs are active against oropharyngeal and esophageal *Candida* infections. Itraconazole is capable of only poor CSF penetration but can be widely distributed throughout other areas of the body. It is indicated for the treatment of fungal infections in immunocompromised and nonimmunocompromised patients with disseminated candidiasis, histoplasmosis, blastomycosis, and aspergillosis. Ketoconazole, a systemic imidazole, inhibits many dermatophytes and fungi that cause systemic mycoses, but it is not active against *Aspergillus* organisms or *Phycomycetes* (common molds) such as *Mucor* species (spp.). Fortunately, the newest triazole antifungal drug, voriconazole, does have activity against some of these more tenacious fungi, including *Aspergillus* spp. causing invasive infection, *Scedosporium* spp., and *Fusarium* spp.

Of the azole antifungals, fluconazole is the most effective for combating infections with *Candida, Cryptococcus, Blastomyces,* and *Histoplasma* organisms. Fluconazole is very effective against vaginal candidiasis. One dose of 150 mg of fluconazole can cure many vaginal candidal infections.

Flucytosine inhibits *Cryptococcus neoformans, C. albicans,* and many *Cladosporium* and *Phialophora* spp. It does not inhibit *Aspergillus, Sporothrix, Blastomyces,* or *Histoplasma* spp. or *Coccidioides immitis.*

Griseofulvin inhibits dermatophytes of *Microsporum, Trichophyton,* and *Epidermophyton* spp. It has no effect on filamentous fungi such as *Aspergillus,* yeasts such as *Candida* spp., or dimorphic species such as *Histoplasma.* Terbinafine is a synthetic allylamine derivative used in a systemic oral form for treatment of onychomycoses—fungal infections of the fingernails or toenails. Topical forms of terbinafine are also used for various skin infections (see Chapter 56).

Contraindications

Drug allergy, liver failure, kidney failure, and porphyria (for griseofulvin) are the most common contraindications for antifungal drugs. Itraconazole should not be used to treat onychomycoses in patients with severe cardiac problems. Voriconazole can cause fetal harm in pregnant women.

Adverse Effects

The major adverse effects caused by antifungal drugs are encountered most commonly in conjunction with amphotericin B treatment. Drug interactions and hepatotoxicity are the primary concerns in patients receiving other antifungal drugs, but the intravenous administration of amphotericin B is associated with a multitude of adverse effects. The most common and problematic of the adverse effects of the various antifungal drugs are listed in Table 42-2. With amphotericin B treatment in particular, prescribers commonly order various premedications (including antiemetics, antihistamines, antipyretics, and corticosteroids) to prevent or minimize infusion-related reactions. The likelihood of such reactions can also be reduced by using longer-than-average drug infusion times (i.e., 2 to 6 hours) for this particular drug.

Interactions

There are many important drug interactions associated antifungal drugs, some of which can be life-threatening. A common underlying source of the problem is that many of the antifungal drugs, as well as other drugs, are metabolized by the *cytochrome P-450 enzyme system.* The result of the coadministration of two drugs that are both broken down by this system is that they compete for the limited amount of enzymes, and one of the drugs ends up accumulating. Key drug interactions for the systemic antifungal drugs are summarized in Table 42-3.

TABLE 42-2 SELECTED ANTIFUNGAL DRUGS: COMMON ADVERSE EFFECTS AND CAUTIONS

BODY SYSTEM	ADVERSE EFFECTS	CAUTIONS
Amphotericin B (Sy)		
Cardiovascular	Cardiac dysrhythmias	Recheck dosage and type of amphotericin B being administered
Central nervous	Neurotoxicity; tinnitus; visual disturbances; hand or feet numbness, tingling, or pain; convulsions	
Renal	Renal toxicity, potassium loss, hypomagnesemia	
Pulmonary	Pulmonary infiltrates	
Other (infusion related)	Fever, chills, headache, malaise, nausea, occasional hypotension, gastrointestinal upset, anemia	
Fluconazole (Sy)		
Gastrointestinal	Nausea, vomiting, diarrhea, stomach pain	Use with caution in patients with renal or hepatic dysfunction
Other	Increased liver enzyme levels, dizziness	
Caspofungin (Sy)		
Central nervous	Fever, chills, headache	Adjust dose for patients with hepatic dysfunction
Cardiovascular	Hypotension, peripheral edema, tachycardia	
Gastrointestinal	Nausea, vomiting, diarrhea, hepatotoxicity	
Hematologic	Decreased hemoglobin and hematocrit, leukopenia, anemia	
Integumentary	Rash, facial edema, itching	

Continued

TABLE 42-2 SELECTED ANTIFUNGAL DRUGS: COMMON ADVERSE EFFECTS AND CAUTIONS—cont'd

BODY SYSTEM	ADVERSE EFFECTS	CAUTIONS
Voriconazole (Sy)		
Central nervous	Hallucinations	
Gastrointestinal	Nausea, vomiting	
Hepatic	Increased liver enzyme levels	
Integumentary	Rash	
Other	Photophobia, hypokalemia	
Nystatin (T)		
Gastrointestinal	Nausea, vomiting, diarrhea, cramps	Local irritation may occur
Integumentary	Rash, urticaria	
Terbinafine (Sy, T)		
Central nervous	Headache, dizziness	Rarely causes irritation
Gastrointestinal	Nausea, vomiting, diarrhea	
Integumentary	Rash, pruritus	
Other	Alopecia, fatigue	

Sy, Systemic; *T,* topical.

TABLE 42-3 ANTIFUNGAL DRUGS: DRUG INTERACTIONS

DRUG	POSSIBLE EFFECTS
Amphotericin B	
Digitalis glycosides	Amphotericin B–induced hypokalemia may increase the potential for digitalis toxicity
Nephrotoxic drug	Additive nephrotoxicity
Thiazide diuretics	Severe hypokalemia or decreased adrenal cortex response to corticotrophin
Fluconazole, itraconazole	
cyclosporine, phenytoin, sirolimus	Increased plasma concentrations of both drugs
Oral anticoagulants	Increased effects of anticoagulants
Oral hypoglycemics	Reduced metabolism of hypoglycemic drugs
Statins	Reduced metabolism of statins, increased toxicity
Voriconazole	
quinidine	Prolongation of QT interval on electrocardiogram

Dosages

For the dosage information on selected antifungal drugs, see the table on p. 687.

DRUG PROFILES

♦ amphotericin B

Amphotericin B (Fungizone) remains one of the drugs of choice for the treatment of severe systemic mycoses. The main drawback of amphotericin B therapy is that the drug causes many adverse effects. Almost all patients given the drug intravenously experience fever, chills, hypotension, tachycardia, malaise, muscle and joint pain, anorexia, nausea and vomiting, and headache. For this reason, pretreatment with antipyretics, antihistamines, antiemetics, and coricosteroids is common to decrease the severity of the infusion-related reaction.

Lipid formulations of amphotericin B were developed in an attempt to decrease the incidence of its adverse effects and increase its efficacy. There are currently three lipid preparations of amphotericin B: amphotericin B lipid complex (Abelcet), amphotericin B cholesteryl complex (Amphotec), and liposomal amphotericin B (AmBisome). These lipid dosage forms have a much higher cost than conventional amphotericin B and for this reason are often used only when patients are intolerant of or have an infection refractory to nonlipid amphotericin B.

Amphotericin B is contraindicated in patients who have a known hypersensitivity to it and in those with severe bone marrow suppression or renal impairment. However, patients who have life-threatening fungal infections may still be treated with this drug if culture results indicate that no other drug will kill the causative organism. The drug is available in injectable, oral, and topical preparations. Often a 1-mg test dose is given over 20 to 30 minutes to see if the patient will tolerate the drug. Amphotericin has been used as a local irrigant (in bladder irrigation) for the treatment of candidal cystitis and has been used intrapleurally and intraperitoneally for the treatment of fungal infections in those body cavities.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Variable	1 hr	1-15 days	18-24 hr

caspofungin

Caspofungin (Cancidas) was the first echinocandin antifungal drug, approved in 2001. It is used for treatment of severe *Aspergillus* infection (invasive aspergillosis) in patients who are intolerant of or have infections refractory to other drugs. Caspofungin doses need to be reduced in patients with impaired liver function. The drug is available only in injectable form. In 2005, a second echinocandin known as micafungin (Mycamine) was approved, and in 2007, a third, anidulafungin (Eraxis), was approved.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Unknown	1 hr	9-50 hr	Unknown

DOSAGES

Selected Antifungal Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ amphotericin B (Amphocin, Fungizone) (B)	Polyene antifungal	IV: Initial daily dose, 0.25 mg/kg; titrate up to 0.5-1.5 mg/kg/day	Systemic infections with broad spectrum of fungi
		Topical: apply cream or lotion 2-4 times daily	Topical candidiasis
amphotericin B lipid complex; dosages vary with product as follows:	Polyene antifungal	**Adult and pediatric**	Systemic fungal infections
Abelcet (B)		IV: 5 mg/kg once daily, infused at 2.5 mg/kg/hr	
Amphotec (B)		IV: 3-4 mg/kg/day, infused at 1 mg/kg/hr	
AmBisome (B)		IV: 3-5 mg/kg/day, infused over 1-2 hr	
caspofungin (Cancidas) (C)	Echinocandin antifungal	**Adult only**	Invasive aspergillosis in patients who do not tolerate or respond to other drugs
		IV: 70 mg loading dose on day 1, followed by 50 mg/day thereafter; infuse doses over 1 hr	
♦ fluconazole (Diflucan) (C)	Synthetic triazole antifungal	**Adult**	Vaginal candidiasis
		PO: 150 mg in a single dose	
		Adult	Oropharyngeal and esophageal candidiasis, systemic candidiasis
		IV/PO: 100-400 mg/day × 2-5 wk (dose and duration dependent on severity of infection)	
		Pediatric	
		IV/PO: 3-12 mg/kg, same guidelines as for adult	
		Adult	Cryptococcal meningitis
		IV/PO: 200-400 mg/day × 10-12 wk after negative CSF culture results	
		Pediatric	
		IV/PO: 3-12 mg/kg × 10-12 wk after negative CSF culture results	
nystatin (Nilstat, Mycostatin, Nystex) (C)	Polyene antifungal	**Infant**	Oral candidiasis
		PO: 200,000 units (2 mL) oral suspension in oral cavity 4 times daily	
		Adult and pediatric	
		PO: 400,000-600,000 units (4-6 mL) oral suspension in oral cavity 4 times daily	
		Adult and pediatric	
		PO (troche): 200,000-400,000 units (1-2 troches dissolved in mouth) 4-5 times daily	
		Adult only	Intestinal candidiasis
		PO (tab): 500,000-1,000,000 units (1-2 tabs) 3 times daily	
		Topical (cream, lotion, or powder): apply 2-3 times daily	Topical candidiasis
terbinafine (Lamisil) (B)	Synthetic allylamine antifungal	**Adult only**	Onychomycosis (fungal infection of fingernail or toenail)
		PO: 250 mg/day × 6 wk (fingernail) or × 12 wk (toenail)	
		Topical cream or solution: Apply twice daily to affected area × 1-4 wk	Athlete's foot *(tinea pedis),* jock itch *(tinea cruris),* or ringworm *(tinea corporis)*
voriconazole (Vfend) (D)	Synthetic triazole antifungal	**Adult only**	Invasive aspergillosis; other major fungal infections in patients who do not tolerate or respond to other antifungal drugs
		PO: 200 mg q12h	
		IV: 6 mg/kg q12h × 2 doses followed by 4 mg/kg q12h	

CSF, Cerebrospinal fluid; *IV,* intravenous; *PO,* oral.

♦ fluconazole

Fluconazole (Diflucan) has proved to be a significant improvement in the area of antifungal treatment. It has a much better adverse effect profile than that of amphotericin B, and it also has excellent coverage against many fungi. In fact, it is often preferred to amphotericin B because of these qualities. Oral fluconazole has excellent bioavailability, which means that almost the entire dose administered is absorbed into the circulation. Fluconazole is available in both oral and injectable forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	1-2 hr	22-30 hr	Variable

nystatin

Nystatin (Mycostatin) is a polyene antifungal drug that is often applied topically for the treatment of candidal diaper rash, taken orally as prophylaxis against candidal infections during periods of neutropenia in patients receiving immunosuppressive therapy, and used for the treatment of oral and vaginal candidiasis. It is not available in a parenteral form but does come in several oral and topical formulations.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	24 hr	2 hr	Unknown	Unknown

terbinafine

Terbinafine (Lamisil) is classified as an allylamine antifungal drug and is currently the only drug in its class. It is available in a topical cream, gel, and spray for treating superficial dermatologic infections, including *tinea pedis* (athlete's foot), *tinea cruris* (jock itch), and *tinea corporis* (ringworm). A tablet form is also available for systemic use and is used primarily to treat onychomycoses of the fingernails or toenails.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	1-2 hr	22-26 hr	Unknown

voriconazole

Voriconazole (Vfend) is used for treating severe fungal infections caused by *Aspergillus* spp. (invasive aspergillosis). It is also used for a variety of other severe fungal infections, such as those caused by *Scedosporium* and *Fusarium* spp. Voriconazole is contraindicated in patients who have a known drug allergy to it and in patients who are taking certain other drugs metabolized by the cytochrome P-450 enzyme 3A4 (e.g., quinidine) because of the risk for induction of serious cardiac dysrhythmias. It is also the only antifungal drug contraindicated in pregnancy. The drug is available in oral and injectable forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	1-2 hr	Variable	Unknown

NURSING PROCESS

ASSESSMENT

Although topical dosage forms are discussed in detail in Chapter 56, it is important to discuss all *antifungal* dosage forms and their related nursing process. Before initiation of therapy with antifungals, assess and document vital signs, weight, hemoglobin (Hgb) level, hematocrit (Hct), red blood cell (RBC) counts, complete blood counts (CBCs) with differential, liver and renal function test results and culture and sensitivity test results.

Before administering amphotericin B (or any other antifungal drug), identify any contraindications, cautions, and drug interactions (see Tables 42-2 and 42-3). Baseline renal function studies are generally ordered as well as hepatic function tests due to adverse effects of nephrotoxicity and hepatotoxicity. Avoid any concurrent administration of nephrotoxic drugs if at all possible. There is a risk for severe adverse reactions (e.g., cardiac dysrhythmias, headache, chills, malaise, nausea, hypotension, anemia, GI upset) with intravenous amphotericin B administration. Perform an assessment of any special premedication orders for antiemetics, antihistamines, antipyretics, and/or antiinflammatory drugs prior to giving amphotericin B. Bone marrow suppression is another contraindication to the use of amphotericin B.

Caspofungin use requires careful assessment of blood pressure, pulse rate, liver function, RBC counts, and WBC counts due to potential drug-induced adverse effects of hypotension, tachycardia, hepatotoxicity, decreased Hgb and Hct, and leukopenia. Fluconazole requires a close assessment of preexisting GI problems and of renal and/or hepatic functioning due to drug-induced adverse effects impacting these systems. Nystatin lozenges are generally not used in children younger than 5 years of age. See Tables 42-2 and 42-3 for more information about specific adverse effects and drug interactions for all antifungals.

NURSING DIAGNOSES

1. Acute pain related to symptoms of the infectious process
2. Deficient knowledge related to lack of information and experience with the antifungal drug therapy
3. Risk for injury related to adverse effects of the medication treatment regimen

CASE STUDY

Amphotericin B

A.B., a 63-year-old retired delivery driver, has been hospitalized for pneumonia. Since his admission, he has been diagnosed with a severe systemic fungal infection, and an amphotericin B infusion will be started. Before beginning this medication, the nurse assesses the results of his renal and liver function laboratory studies, as well as his complete blood count. The patency of the intravenous line is verified, and the nurse gives A.B. a dose of acetaminophen (Tylenol) as well as an antihistamine before starting the infusion.

1. What is the purpose of the acetaminophen and antihistamine?
2. The nurse stays with the patient for the first 15 minutes of the infusion and monitors A.B.'s vital signs. Explain the rationale for these nursing actions.
3. One hour after the infusion is completed, A.B. calls the nurse and says that he feels as if he may vomit and has chills, yet feels hot at the same time. What does the nurse need to do next?
4. A.B. continues to feel "terrible" the rest of the night, and the next morning his physician, Dr. F., changes the order to liposomal amphotericin B (AmBisome). Why did the physician continue an antifungal medication? What is the rationale behind this order change?

For answers, see http://evolve.elsevier.com/Lilley.

PLANNING

GOALS

1. Patient has minimal to no pain after therapy has been initiated.
2. Patient gains increased knowledge about the antifungal drug, its use, and its adverse effects.
3. Patient experiences minimal to no injury to self as related to the adverse effects of antifungal therapy.

OUTCOME CRITERIA

1. Patient is free of pain associated with the fungal infection once therapy is initiated.
   - Patient's fever and discomfort associated with the infection decreases with therapy.
   - Patient experiences improved health status/energy and well being.
2. Patient demonstrates adequate knowledge about medication regimen by following directions about when and how to take the antifungal drug.
   - Patient experiences minimal to no adverse effects and reports to the prescriber any nausea, vomiting, or gastrointestinal upset if they become unmanageable.
   - Patient remains compliant with the medication regimen, without skipping doses while experiencing relief from the infection, and experiences a return to normal vital signs and negative findings on culture and sensitivity tests after the full course of therapy.
   - Patient experiences improved appetite, energy level, and physical strength and stamina after taking the antifungal drugs for the prescribed period.
3. Patient experiences minimal to no injury to self and is able to manage adverse effects or contact prescriber if they become problematic.
   - Patient takes medication as prescribed.
   - Patient returns to the prescriber regularly as recommended by the prescriber for constant monitoring of the infection and of drug therapy with various blood tests (e.g., CBC with differential, RBC count, hemoglobin level, hematocrit, renal and liver function tests).

IMPLEMENTATION

The nursing interventions appropriate for patients receiving *antifungal* drugs vary depending on the particular drug. With intravenous amphotericin B, do not administer solutions that are cloudy or have precipitates. Use of an intravenous infusion pump is recommended. Once the intravenous infusion has begun, monitor vital signs every 15 minutes, or as needed, to assess for adverse reactions such as cardiac dysrhythmias, visual disturbances, paresthesias (numbness or tingling of the hands or feet), respiratory difficulty, pain, fever, chills, and nausea (see Table 42-2 for a listing of adverse effects). If a severe reaction occurs (e.g., exacerbation of adverse effects and/or a decline in vital signs), discontinue the infusion while continuing to closely monitor the patient. Contact the prescriber immediately. Monitor the intravenous site for signs of phlebitis (e.g., heat, pain, and redness over the vein), as per hospital policy. Continually monitor all laboratory values during therapy (see earlier discussion). Document weight frequently, as indicated, with long-term or at-home therapy. A gain of 2 pounds or more in a 24-hour period or 5 pounds or more in 1 week may indicate possible medication-induced renal damage and the need for prompt medical attention. Follow manufacturer guidelines and the prescriber's order for specific solutions and rates of intravenous administration. See the Patient Teaching Tips for further information.

Only use clear solutions of caspofungin and dilute doses with the recommended amount of normal saline. Liver toxicity may occur, so monitor liver function tests during therapy as ordered. In addition, constantly monitor the patient for the occurrence of tachycardia, hypotension, fever, chills, or headache. Hemoglobin and hematocrit levels must also be monitored frequently because of the possibility of drug-induced anemias. Fluconazole may be given either orally or intravenously, with intravenous dosage forms used if there is a specific indication or if the oral dosage forms are poorly tolerated. Only administer intravenous dosage forms if solution is clear, and do not add other medications. If itching or a rash occurs, stop the infusion, take vital signs, and contact the prescriber immediately. Nystatin may be given orally in the form of lozenges or troches, which the patient should slowly and completely dissolve in the mouth for optimal effects; these should not be chewed or swallowed whole. If a suspension is used, instruct the patient to swish the medication solution thoroughly in the mouth for as long as possible before swallowing. Terbinafine may be given orally or topically. Local skin reactions that need to be reported include blistering, itching, oozing, redness, and swelling. Oral doses of voriconazole are to be given 1 hour before or 1 hour after a meal. Intravenous doses may be diluted with 5% dextrose in water or normal saline, with the accurate dose infused over the recommended time. Monitor visual acuity when this drug is given (especially if ordered for longer than 28 days), and report any visual changes to the prescriber.

EVALUATION

The therapeutic effects of *antifungals* include improvement and eventual resolution of the signs and symptoms of the fungal infection if the patient has remained totally adherent to the therapy regimen. Improved energy levels and improvement in overall sense of well-being with a normal temperature and other vital sign values also indicate a therapeutic response. Specific adverse effects for which to monitor in patients receiving these drugs are listed in Table 42-2. Evaluate goals and outcome criteria in the context of the nursing care plan.

PATIENT TEACHING TIPS

- Instruct female patients taking antifungal medications for the treatment of vaginal infection to abstain from sexual intercourse until the treatment is completed and the infection is resolved, and advise patients to continue to take the medication even if actively menstruating. Tell patients to notify the prescriber if symptoms persist after treatment is completed.
- Some patients receiving amphotericin B may need long-term treatment (i.e., over weeks to months). If so, possible adverse effects include tinnitus, blurred vision, burning and itching at the infusion site, headache, rash, fever, chills, hypokalemia, gastrointestinal upset, and various anemias.
- Instruct patients taking caspofungin to immediately report to the prescriber any problems with shortness of breath, itching, facial swelling, and/or a rash.
- Encourage the patient to practice good hand washing technique.
- Instruct the patient on the proper dosing instructions for nystatin (e.g., for oral solutions, swish and swallow). If vaginal troches are prescribed, use the appropriate applicator with a gloved hand and insert high into the vagina, followed by thorough hand washing (see Chapter 9).
- Encourage the patient to keep affected body areas clean and dry and to wear light and cool clothing. Avoid contact of the topical dosage form with the eyes, mouth, nose, or other mucous membranes.
- Voriconazole is to be taken 1 hour before or 1 hour after meals. Warn the patient about the adverse effect of photophobia with use of this drug.

KEY POINTS

- Fungi are a very large and diverse group of microorganisms and consist of yeasts and molds. Yeasts are single-celled fungi that may be harmful (e.g., causing infections) or helpful (e.g., aiding in baking or brewing beer). Molds are multicellular and are characterized by long, branching filaments called *hyphae.*
- Candidiasis is an opportunistic fungal infection caused by *C. albicans* and occurs in patients taking broad-spectrum antibiotics, antineoplastics, or immunosuppressants, as well as in immunocompromised persons. When candidiasis occurs in the mouth, it is commonly called *oral candidiasis* or *thrush.* Oral candidiasis is more commonly seen in newborns or immunocompromised persons.
- Vaginal candidiasis is a yeast infection and occurs most commonly in individuals with diabetes mellitus, women taking oral contraceptives, and pregnant women.
- Antifungals may be administered either systemically or topically. Some of the most common systemic antifungals are amphotericin B and fluconazole; an example of a topical antifungal is nystatin.
- Before administering antifungals, thoroughly assess for allergies as well as interactions with other drugs patients are taking, including prescription drugs, over-the-counter drugs, and herbals.
- Amphotericin B must be properly diluted according to manufacturer guidelines and administered using an intravenous infusion pump. Tissue extravasation of fluconazole at the intravenous infusion site leads to tissue necrosis; therefore, check the site hourly and document the assessment.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is assessing a patient who is about to receive antifungal drug therapy. Which problem would be of most concern?
   - **a** Endocrine disease
   - **b** Hepatic disease
   - **c** Cardiac disease
   - **d** Pulmonary disease

2 While monitoring a patient who is receiving intravenous amphotericin B, the nurse expects to see which adverse effect(s)?
   - **a** Hypertension
   - **b** Bradycardia
   - **c** Fever and chills
   - **d** Diarrhea and stomach cramps

3 When administering antifungal drug therapy, the nurse knows that an issue that contributes to many of the drug interactions with antifungals is the patient's
   - **a** history of cardiac disease.
   - **b** history of gallbladder surgery.
   - **c** ethnic background.
   - **d** cytochrome P-450 enzyme system.

4 During an infusion of amphotericin B, the nurse knows that which administration technique may be used to minimize infusion-related adverse effects?
   - **a** Forcing of fluids during the infusion
   - **b** Infusing the medication quickly
   - **c** Infusing the medication over a longer period of time
   - **d** Stopping the infusion for 2 hours after half of the bag has infused, then resuming 1 hour later

NCLEX® EXAMINATION REVIEW QUESTIONS—cont'd

5 When teaching a patient who is taking nystatin lozenges for oral candidiasis, which instruction by the nurse is correct?
- **a** "Chew the lozenge carefully before swallowing."
- **b** "Dissolve the lozenge slowly and completely in your mouth."
- **c** "Dissolve the lozenge until it is half the original size, and then swallow it."
- **d** "These lozenges need to be swallowed whole with a glass of water."

6 When monitoring a patient who is receiving caspofungin, the nurse will look for which serious adverse effects? (Select all that apply.)
- **a** Blood dyscrasias
- **b** Hypotension
- **c** Pulmonary infiltrates
- **d** Tinnitus
- **e** Hepatotoxicity

7 The order reads, "Give nystatin (Mycostatin) suspension, 500,000 units by mouth (swish and swallow) 4 times a day for 1 week." The medication is available in a suspension of 100,000 units per mL. How many milliliters will the nurse give per dose?

1. b, 2. c, 3. d, 4. c, 5. b, 6. a, b, e, 7. 5 mL

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Briefly discuss the infectious process associated with malaria, other protozoal infections, and helminth infections.
2 Compare the signs and symptoms of malarial, other protozoal, and helminthic infection processes.
3 Identify the more commonly used antimalarial, antiprotozoal, and anthelmintic drugs.
4 Discuss the mechanisms of action, indications, cautions, contraindications, adverse effects, dosages, drug interactions, and routes of administration of the antimalarial, antiprotozoal, and anthelmintic drugs.
5 Develop a nursing care plan that includes all phases of the nursing process for patients receiving antimalarial, antiprotozoal, or anthelmintic drugs.

DRUG PROFILES

atovaquone, p. 700
♦ **chloroquine and hydroxychloroquine, p. 696**
♦ **mefloquine, p. 697**
♦ **metronidazole, p. 700**
pentamidine, p. 700
praziquantel, p. 702
♦ **primaquine, p. 697**
pyrantel, p. 702
pyrimethamine, p. 697

♦ *Key drug*

KEY TERMS

Anthelmintic A drug that destroys or prevents the development of parasitic worm (helminthic) infections. Also called *antihelmintic* or *vermicide;* notice that the terms for the drug categories are spelled with only one *h,* which appears in the second syllable of the term, whereas the term for worm infection *(helminthic)* is spelled with two *h*'s, appearing in both the first and third syllables of the term. (p. 700)

Antimalarial drugs Drugs that destroy or prevent the development of the malaria parasite (*Plasmodium* sp.) in humans. Antimalarial drugs are a subset of the broader category of antiprotozoal drugs. (p. 694)

Antiprotozoal A drug that destroys or prevents the development of protozoans in humans. (p. 698)

Helminthic infections Parasitic worm infections. (p. 700)

KEY TERMS—cont'd

Malaria A widespread protozoal infectious disease caused by four species of the genus *Plasmodium*. (p. 693)

Parasite Any organism that feeds on another living organism (known as a *host*) in a way that results in varying degrees of harm to the host organism. (p. 693)

Parasitic protozoans Harmful protozoans that live on or in humans or animals and cause disease in the process. (p. 693)

Protozoans Single-celled organisms that are the smallest and simplest members of the animal kingdom. (p. 693)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

There are more than 28,000 known types of **protozoans,** which are single-celled organisms. Those that live on or in humans are called **parasitic protozoans.** Billions of people worldwide are infected with these organisms, and, as a result, these infections are considered a serious public health problem. Some of the more common protozoal infections are malaria, leishmaniasis, trypanosomiasis, amebiasis, giardiasis, and trichomoniasis. They are relatively uncommon in the United States but are becoming increasingly prevalent in immunocompromised individuals, including those with acquired immunodeficiency syndrome (AIDS). Protozoal diseases are especially prevalent among people living in tropical climates because it is easier for protozoans to survive and be transmitted in environments that are warm and humid year round. Although the population of the United States is relatively free of many of these protozoal infections, international travel and the immigration of people from other countries where such infections are endemic are providing opportunities for increased exposure.

PATHOPHYSIOLOGY OF MALARIA

The most significant protozoal disease in terms of morbidity and mortality is **malaria.** Worldwide, it is estimated that 350 to 500 million people are infected, with an annual death rate of 1 million to 2 million people. In Africa alone, malaria accounts for more than 1 million infant deaths per year. The geographic areas with the highest prevalence are sub-Saharan Africa, Southeast Asia, and Latin America. Approximately 1200 cases of malaria are reported in the United States annually, seen mostly in people who traveled to malaria-infested countries. Malaria is caused by a particular genus of protozoans called *Plasmodium,* and there are four species of organisms in this genus, each with its own characteristics and its own ability to resist being killed by antimalarial drugs. These four species are *Plasmodium vivax, Plasmodium falciparum, Plasmodium malariae,* and *Plasmodium ovale.* Although *P. vivax* is the most widespread of the four, *P. falciparum* is nearly as widespread and causes greater problems with drug resistance. The two remaining species are much less common and more geographically limited in their occurrence, but they can still cause serious malarial infections.

Most commonly, malaria is transmitted by the bite of an infected female anopheline mosquito. This type of mosquito is endemic to many tropical regions of the earth. Malaria can also be transmitted by blood transfusions, congenitally from mother to infant via an infected placenta, or through the use of contaminated needles. Despite the combined efforts of many countries to eradicate malaria, it remains one of the most devastating infectious diseases in the world. As is also the case with tuberculosis (see Chapter 41) and AIDS (see Chapter 40), many lives are lost to malaria, and the cost of treating and preventing the disease imposes a tremendous economic burden on the often poor countries where the disease is prevalent.

The *Plasmodium* life cycle is quite complex and involves many stages. The organism has two interdependent life cycles: the *sexual cycle,* which takes place inside the mosquito, and the *asexual cycle,* which occurs in the human host (Figure 43-1). In addition, the asexual cycle of the **parasite** consists of a phase outside the erythrocyte (primarily in liver tissues) called the *exoerythrocytic phase* (or the *tissue phase*) and a phase inside the erythrocyte called the *erythrocytic phase* (or the *blood phase*). The malarial parasite undergoes many changes during these two phases (Figure 43-2).

Malaria signs and symptoms are often described in terms of the *classic malaria paroxysm.* A *paroxysm* is a sudden recurrence or intensification of symptoms. Symptoms include chills and rigors, followed by fever of up to 104° F (40° C) and diaphoresis, frequently leading to extreme fatigue and prolonged sleep. This syndrome often repeats itself periodically in 48- to 72-hour cycles. Other common symptoms include headache, nausea, and joint pain.

PHARMACOLOGY OVERVIEW

ANTIMALARIAL DRUGS

Treatment for malaria is not initiated until the diagnosis has been confirmed by laboratory tests. Once confirmed, appropriate antimalarial treatment must be initiated immediately. Treatment is guided by three main factors: the infecting *Plasmodium* species, the clinical status of the patient, and the drug susceptibility of the infecting parasites as determined by the geographic area where the infection was acquired. Because the resistance patterns are constantly changing, depending on geographic location, the reader is referred to the website of the Centers for Disease Control and Prevention (CDC) at www.cdc.gov/malaria/ for the most up-to-date information. People traveling to different parts of the world may require antimalarial prophylaxis and

need to check with their prescribers and/or the CDC website mentioned above for specific drug therapy.

Antimalarial drugs administered to humans cannot affect the parasite during its sexual cycle when it resides in the mosquito. Instead, these drugs work against the parasite during its asexual cycle, which takes place within the human body. Often these drugs are given in various combinations to achieve an additive or synergistic antimalarial effect. One example is the combination of the two antiprotozoal drugs atovaquone and proguanil (Malarone). The antibiotic combination of pyrimethamine and sulfadoxine (Fansidar) is also commonly used, especially in cases caused by drug-resistant organisms.

Mechanism of Action and Drug Effects

The mechanisms of action of the various antimalarial drugs differ depending on the chemical family to which they belong. The *4-aminoquinoline derivatives* (chloroquine and hydroxychloroquine) work by inhibiting deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) polymerase, enzymes essential to DNA and RNA synthesis by the parasite cells. Parasite protein synthesis is also disrupted, because protein synthesis is dependent on proper nucleic acid (DNA and RNA) function. These drugs also raise the pH within the parasite, which interferes with the parasite's ability to metabolize and use erythrocyte hemoglobin; this is one reason these drugs are ineffective during the

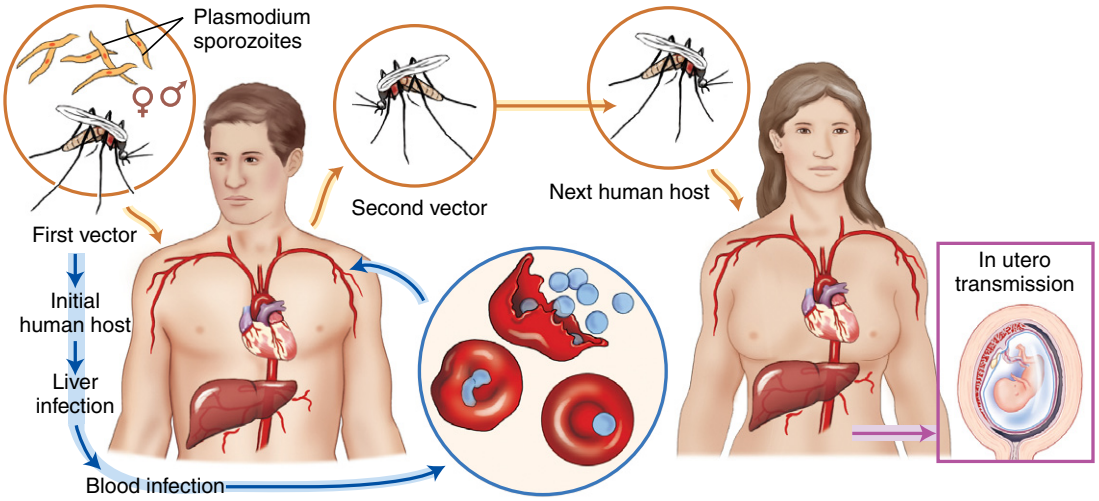

FIGURE 43-1 An infected Anopheles mosquito carries parasites to humans, causing malaria. These parasites mature in the liver before entering the bloodstream and rupturing red blood cells. A pregnant woman infected with malaria may transmit the disease to her unborn child.

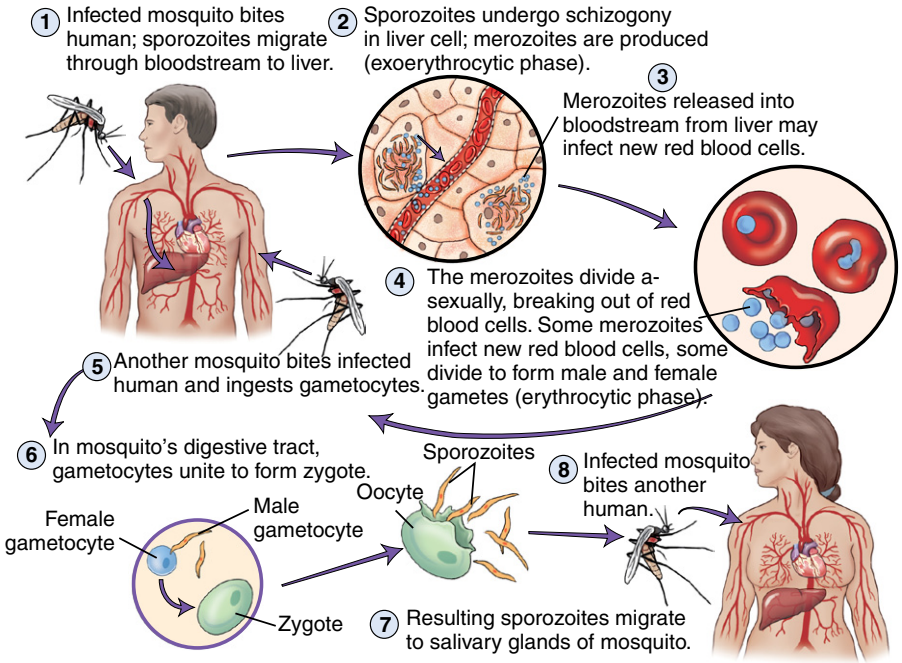

FIGURE 43-2 Life cycle of the malarial parasite. (From Van Meter K, Hubert R: *Microbiology for the healthcare professional,* St Louis, 2010, Mosby.)

exoerythrocytic (tissue) phase of infection. All of these actions contribute to the destruction of the parasite. Quinine, quinidine, and mefloquine are thought to be similar to the 4-aminoquinoline derivatives in their actions in that all are also believed to raise the pH within the parasite.

The *diaminopyrimidines* (pyrimethamine and trimethoprim [see Chapter 38]) work by inhibiting dihydrofolate reductase, an enzyme that is needed for the production of certain vital substances in malarial parasites. Specifically, inhibiting this enzyme blocks the synthesis of tetrahydrofolate, which is a precursor of purines and pyrimidines (nucleic acid components) and certain amino acids (protein components) that are essential for the growth and survival of plasmodia parasites. These two drugs are effective only during the erythrocytic phase. Pyrimethamine and trimethoprim are often used with a sulfonamide (sulfadoxine or dapsone) because of the resulting synergistic effects exerted by such drug combinations. Tetracyclines such as doxycycline (see Chapter 38) and lincomycins such as clindamycin (see Chapter 39) may also be used in combination with some of the other antimalarial drugs because of the synergistic effects resulting from these drug combinations.

Primaquine, an *8-aminoquinoline* that is structurally similar to the 4-aminoquinolines, has the ability to bind to and alter parasitic DNA. It is one of the few drugs that is effective in the exoerythrocytic phase. Atovaquone/proguanil also works by interference with nucleic acid synthesis.

The drug effects of the antimalarial drugs are mostly limited to their ability to kill parasitic organisms, most of which are *Plasmodium* species (spp.). However, some of these drugs have other effects and therapeutic uses. Hydroxychloroquine also has antiinflammatory effects and is sometimes used in the treatment of rheumatoid arthritis and systemic lupus erythematosus. Quinine and quinidine can also decrease the excitability of both cardiac and skeletal muscles. Quinidine is still currently used to treat certain types of cardiac dysrhythmias (see Chapter 25).

Indications

Antimalarial drugs are used to kill *Plasmodium* organisms, the parasites that cause malaria. The various antimalarial drugs work during different phases of the parasite's growth inside the human. The antimalarials that exert the greatest effect on all four *Plasmodium* organisms during the erythrocytic or blood phase are chloroquine, hydroxychloroquine, and pyrimethamine. Other drugs that are known to work during the blood phase are quinine, quinidine, and mefloquine. Because these drugs are ineffective during the exoerythrocytic phase, however, they cannot *prevent* infection. The most effective antimalarial drug for eradicating the parasite during the exoerythrocytic phase is primaquine, which actually works during both phases. Primaquine is indicated specifically for infection with *P. vivax.* Chloroquine and hydroxychloroquine (4-aminoquinolines) are the drugs of choice for the treatment of susceptible strains of malarial parasites. They are highly toxic to all *Plasmodium* spp., except resistant strains of *P. falciparum.*

Quinine is indicated for infection with chloroquine-resistant *P. falciparum,* which can cause a type of malaria that affects the brain. Quinine can be used alone but is more commonly given in combination with pyrimethamine, a sulfonamide, or a tetracycline (such as doxycycline). Pyrimethamine is another antimalarial antibiotic that is commonly used in combination with the sulfonamide antibiotic sulfadoxine (Fansidar) for prophylaxis against chloroquine-resistant *P. falciparum* and *P. vivax.* However, drug resistance in most locations has reduced its use for this purpose. Other antimalarial drugs are generally preferred for the treatment of active disease. Mefloquine is an antimalarial drug that may also be used for both prophylaxis and treatment of malaria caused by *P. falciparum* or *P. vivax.* The drug combination atovaquone and proguanil (Malarone) is also used for prevention and treatment of *P. falciparum* infection.

Contraindications

Contraindications to various antimalarial drugs include drug allergy, tinnitus (ear ringing), and pregnancy (quinine). Severe renal, hepatic, or hematologic dysfunction may also be a contraindication to the use of antimalarial drugs. Other drug-specific contraindications are noted in the drug profiles that follow.

Adverse Effects

Antimalarial drugs cause diverse adverse effects, and these are listed for each drug in Table 43-1.

TABLE 43-1 ANTIMALARIAL DRUGS: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Chloroquine and hydroxychloroquine	
Gastrointestinal	Diarrhea, anorexia, nausea, vomiting
Central nervous	Dizziness, headache, seizure, personality changes
Other	Alopecia, rash, pruritus
Mefloquine	
Central nervous	Headache, fatigue, tinnitus
Gastrointestinal	Stomach pain, anorexia, nausea, vomiting
Other	Fever, chills, rash, myalgia
Primaquine	
Gastrointestinal	Nausea, vomiting, abdominal distress
Other	Headaches, pruritus, dark discoloration of urine, hemolytic anemia due to G6PD deficiency
Pyrimethamine	
Gastrointestinal	Anorexia; vomiting; taste disturbances; soreness, redness, swelling, or burning of tongue; diarrhea; throat pain; swallowing difficulties; sores, ulcerations, or white spots in mouth; sore throat
Other	Malaise, weakness, rash, abnormal skin pigmentation, hemolytic anemia resulting from G6PD deficiency, severe hypersensitivity reactions
Quinine	
Central nervous	Visual disturbances, dizziness, headaches, tinnitus
Gastrointestinal	Diarrhea, nausea, vomiting, abdominal pain
Other	Rash, pruritus, hives, photosensitivity, respiratory difficulties

G6PD, Glucose-6-phosphate dehydrogenase.

Interactions

Some common drug interactions associated with antimalarial drugs are listed in Table 43-2.

Dosages

For dosage information on selected antimalarial drugs, see the table on this page.

TABLE 43-2 ANTIMALARIAL DRUGS: DRUG INTERACTIONS

DRUG	MECHANISM	RESULT
Chloroquine		
divalproex, valproic acid, anthelmintics, beta blockers	Decreased serum levels of target drug	Treatment failures of target drugs
digoxin	Increased serum levels of digoxin	Potential toxicity
Mefloquine		
Beta blockers, calcium channel blockers, quinidine, quinine	Unknown	Increased risk of dysrhythmia, cardiac arrest, seizures
Primaquine		
Other hemolytic drugs	Unknown	Increased risk for myelotoxic effects (monitor for muscle weakness)

DRUG PROFILES

The dosing instructions for several of the antimalarial drugs can be confusing, because tablet strengths listed on the medication packaging often indicate the strength of the tablet in terms of the entire salt form of the drug, not just the active ingredient itself, which is referred to as the *base ingredient*. However, dosing guidelines often list recommended dosages in terms of the base ingredient and not the entire salt. For example, as described later in the drug profile for chloroquine, the tablets come in 250-mg and 500-mg strengths of the salt form of the drug, but these tablets actually only have 150 mg and 300 mg, respectively, of the active ingredient or base. Be mindful of these distinctions.

♦ chloroquine and hydroxychloroquine

Chloroquine (Aralen) is a synthetic antimalarial drug that is chemically classified as a 4-aminoquinoline derivative. In addition to malaria, it is also indicated for treatment of other parasitic infections, such as amebiasis. Hydroxychloroquine is another synthetic 4-aminoquinoline derivative that differs from chloroquine by only one hydroxyl group ($^{-}$OH). Its efficacy in treating malaria is comparable to that of quinine. Both medications also possess antiinflammatory actions and have been used to treat rheumatoid arthritis and systemic lupus erythematosus since the 1950s. However, only hydroxychloroquine (Plaquenil) is now used for these indications.

Contraindications include visual field changes, optic neuritis, and psoriasis, but its use may still be warranted in urgent clinical situations, based on sound clinical judgment.

DOSAGES

Selected Antimalarial Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
♦ chloroquine (Aralen) (C)	Synthetic antimalarial and antiamebic	**Adult***	
		PO: 300 mg base weekly, beginning 2 wk before and continuing for 8 wk after visiting endemic area	Malaria prophylaxis
		PO: 600 mg base on day 1, followed by 300 mg 6 hr later and on days 2 and 3	Malaria treatment
♦ hydroxychloroquine (Plaquenil) (C)	Synthetic antimalarial	**Adult***	
		PO: 310 mg base weekly, beginning 1-2 wk before and continuing through 4 wk after visiting endemic area	Malaria prophylaxis
		PO: 620 mg base on day 1, followed by 310 mg 6 hr later and once daily on days 2 and 3	Malaria treatment
mefloquine (Lariam) (C)	Synthetic antimalarial	**Adult and children weighing over 45 kg**	Malaria prophylaxis
		PO: 250 mg weekly beginning 1-2 wk before travel and continuing until 4 wk after visiting endemic area	
		Pediatric	
		PO: Dosing varies based on weight.	
		Adult	Malaria treatment
		PO: 1250 mg (5 tabs) in a single dose	
		Pediatric	
		PO: 15-25 mg/kg in a single dose, not to exceed 1250 mg	
♦ primaquine (generic only) (C)	Synthetic antimalarial	**Adult**	Malaria prophylaxis
		30 mg PO daily × 14 days after leaving endemic area. Doses vary if dealing with drug-resistant malaria.	

DOSAGES—cont'd

Selected Antimalarial Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
		Adult PO: 15 mg base daily × 14 days **Pediatric** PO: 0.5 mg base/kg/day × 14 days	Malaria treatment
pyrimethamine (Daraprim) (C)	Folic acid antagonist, antimalarial, antitoxoplasmotic	**Adult and pediatric older than 10 yr** PO: 25 mg weekly **Pediatric 4-10 yr** PO: 12.5 mg weekly **Pediatric infant to 3 yr** PO: 6.25 mg weekly	Malaria prophylaxis
		Adult and pediatric older than 10 yr PO: 50 mg daily × 2 days **Pediatric 4-10 yr** PO: 25 mg daily × 2 days	Malaria treatment

PO, oral.
*Only adult dosages are given. Pediatric dosages range from 5 to 10 mg/kg but not to exceed adult dosages.

Chloroquine and hydroxychloroquine are available only for oral use. Both drugs are classified as pregnancy category C drugs, but it is recommended that they be used in pregnant women only in truly urgent clinical situations. These drugs are also distributed into breast milk.

Pharmacokinetics (chloroquine)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	8-10 hr	1-2 hr	3-5 days	Variable

Pharmacokinetics (hydroxychloroquine)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	4 hr	2-3 hr	32-50 days	Variable

mefloquine

Mefloquine (Lariam) is an analogue of quinine that is indicated for the management of mild to moderate acute malaria and for the prevention and treatment of malaria caused by chloroquine-resistant organisms. It is also used to treat multidrug-resistant strains of *P. falciparum,* which, as already noted, is a very difficult species of *Plasmodium* to kill. The drug is commonly used prophylactically by travelers to prevent malarial infection while visiting malaria-endemic areas. The tetracycline antibiotic doxycycline (see Chapter 38) is also commonly used for this purpose. Mefloquine is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Less than 24 hr	7-24 hr	21-22 days	Variable

♦ primaquine

Primaquine is similar in chemical structure and antimalarial activity to the 4-aminoquinolines, but it is classified as an 8-aminoquinoline. It is one of the few antimalarial drugs that can destroy the malarial parasites while they are in their exoerythrocytic phase. Primaquine is indicated for curative therapy in acute cases of *P. vivax, P. ovale,* and to a lesser degree, *P. falciparum* infection.

Primaquine is contraindicated in patients with allergy or any disease states that may cause granulocytopenia (rheumatoid arthritis, systemic lupus erythematosus). Primaquine must be used with caution in patients with methemoglobinemia, porphyria, methemoglobin reductase deficiency, and glucose-6-phosphate dehydrogenase (G6PD) deficiency (see Chapter 2). It is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2 hr	1-3 hr	4-10 hr	24 hr

pyrimethamine

Pyrimethamine (Daraprim) is a synthetic antimalarial drug that is structurally related to trimethoprim (see Chapter 38). Both drugs are chemically subclassified as *diaminopyrimidines.* Fansidar is a commonly used fixed-combination drug product that contains 500 mg of sulfadoxine and 25 mg of pyrimethamine. Pyrimethamine is contraindicated in patients with megaloblastic anemia caused by folate deficiency. It is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	6 hr	2-6 hr	80-123 hours	Up to 2 wk

TABLE 43-3 TYPES OF PROTOZOAL INFECTIONS AND COMMON DRUG THERAPY

INFECTION	DESCRIPTION	ANTIPROTOZOAL DRUG
Amebiasis	Caused by the protozoal parasite *Entamoeba histolytica*. Infection mainly resides in the large intestine but can also migrate to other parts of the body, such as the liver. Usually transmitted in contaminated food or water.	chloroquine, metronidazole, paromomycin, iodoquinol
Giardiasis	Caused by *Giardia lamblia*. The most common intestinal protozoal infection, usually residing in the intestinal mucosa (most commonly the duodenum). May cause diarrhea, bloating, and foul-smelling stools. Transmitted in contaminated food or water or by contact with stool from infected persons.	metronidazole, nitazoxanide, quinacrine, furazolidone, albendazole, paromomycin
Pneumocystosis	Pneumonia caused by *Pneumocystis jirovecii** that occurs exclusively in immunocompromised individuals. Always fatal if left untreated.	trimethoprim/sulfamethoxazole, dapsone, atovaquone, primaquine, pentamidine, clindamycin
Toxoplasmosis	Caused by *Toxoplasma gondii*. Can produce systemic infection in both immunocompetent and immunocompromised hosts. Domesticated animals, usually cats, serve as intermediate host for parasites, passing infective oocysts in their feces.	sulfonamides with pyrimethamine, clindamycin, metronidazole
Trichomoniasis	Sexually transmitted disease caused by *Trichomonas vaginalis*.	metronidazole

* *Pneumocystis jirovecii* is now classified as a fungus.

PATHOPHYSIOLOGY OVERVIEW

OTHER PROTOZOAL INFECTIONS

There are several other common protozoal infections. These include amebiasis (caused by *Entamoeba histolytica*), giardiasis (caused by *Giardia lamblia*), toxoplasmosis (caused by *Toxoplasma gondii*), and trichomoniasis, (caused by *Trichomonas vaginalis*). These diseases are more prevalent in tropical regions. Pneumocystosis, which is caused by *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*), used to be classified as a protozoal infection; however, it is now classified as fungal infection. It is a common infection that complicates HIV and AIDS. It will be discussed in this chapter as opposed to the antifungal chapter (see Chapter 42) because it is treated with drugs discussed in this chapter.

These protozoal infections can be transmitted in a number of ways: from person to person (e.g., via sexual contact), through the ingestion of contaminated water or food, through direct contact with the parasite, or by the bite of an insect (mosquito or tick). These infections can be systemic and occur throughout the body, or they can be localized to a specific region. For example, amebiasis most commonly affects the gastrointestinal tract (e.g., amebic dysentery), whereas pneumocystosis is predominantly a pulmonary infection.

The more common protozoal infections are described briefly in Table 43-3, and the **antiprotozoal** drugs commonly used in their treatment are listed. Only selected drugs are discussed here. Patients whose immune systems are compromised are at particular risk for acquiring a protozoal infection. Often such infections are fatal in these patients.

PHARMACOLOGY OVERVIEW

ANTIPROTOZOAL DRUGS

Several drugs used to treat malaria are also used to treat nonmalarial protozoal infections, including chloroquine, primaquine, pyrimethamine, and atovaquone. Other antiprotozoal drugs normally used against nonmalarial parasites include iodoquinol, metronidazole, paromomycin, and pentamidine.

TABLE 43-4 SELECTED ANTIPROTOZOAL DRUGS: MECHANISMS OF ACTION

DRUG	MECHANISM OF ACTION
atovaquone	Atovaquone selectively inhibits mitochondrial electron transport, reducing synthesis of adenosine triphosphate (required for cellular energy). Also inhibits nucleic acid synthesis.
metronidazole	Interferes with DNA, resulting in inhibition of protein synthesis and cell death in susceptible organisms.
pentamidine	Inhibits production of much-needed substances such as DNA and RNA. Can bind to and aggregate ribosomes. Is directly lethal to *Pneumocystis jirovecii** by inhibiting glucose metabolism, protein and RNA synthesis, and intracellular amino acid transport.

* *Pneumocystis jirovecii* is now classified as a fungus.

Mechanism of Action and Drug Effects

Antiprotozoal drugs work by several different mechanisms. The most commonly used of these drugs, together with brief descriptions of their mechanisms of action, are given in Table 43-4. Pyrimethamine and chloroquine were discussed earlier in this chapter in the section on malaria. The drug effects of antiprotozoal drugs are primarily limited to their ability to kill various forms of protozoal parasites.

Indications

Antiprotozoal drugs are used to treat various protozoal infections, ranging from intestinal amebiasis to pneumocystosis. Indications for selected drugs are summarized in Table 43-5. Atovaquone and pentamidine are used for the treatment of

TABLE 43-5 SELECTED ANTIPROTOZOAL DRUGS: INDICATIONS

DRUG	INDICATIONS
atovaquone	Indicated for treatment of acute mild to moderately severe *Pneumocystis jirovecii* pneumonia in patients who cannot tolerate co-trimoxazole
iodoquinol	Indicated for treatment of intestinal amebiasis in asymptomatic carriers of *Entamoeba histolytica;* also has been used for treatment of *Giardia lamblia* and *Trichomonas vaginalis* infections
metronidazole	Indicated for treatment of bacterial (including anaerobic), protozoal, and helminthic infections
pentamidine	Indicated for treatment of *P. jirovecii** pneumonia

* *Pneumocystis jirovecii* is now classified as a fungus.

TABLE 43-6 SELECTED ANTIPROTOZOAL DRUGS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Atovaquone	
Hematologic	Anemia, neutropenia, leukopenia
Integumentary	Pruritus, urticaria, rash
Gastrointestinal	Anorexia, elevated liver enzymes, nausea, constipation
Central nervous	Dizziness, headache, anxiety, fever
Metabolic	Hyperkalemia, hypoglycemia, hyponatremia
Other	Cough
Iodoquinol	
Hematologic	Agranulocytosis
Integumentary	Rash; pruritus; discolored skin, hair, nails
Central nervous	Headache, agitation, peripheral neuropathy
Eyes, ears, nose, and throat	Blurred vision, sore throat, optic neuritis, blindness
Gastrointestinal	Anorexia, gastritis, nausea, vomiting, diarrhea
Metronidazole	
Central nervous	Headache, dizziness, confusion, fatigue, peripheral neuropathy, weakness
Eyes, ears, nose, and throat	Blurred vision, sore throat, dry mouth, metallic taste, glossitis
Gastrointestinal	Anorexia, vomiting, diarrhea, constipation
Genitourinary	Dysuria, cystitis
Hematologic	Neutropenia
Integumentary	Rash, pruritus, urticaria
Paromomycin	
Gastrointestinal	Stomach cramps, nausea, vomiting, diarrhea
Central nervous	Hearing loss, dizziness, tinnitus
Pentamidine	
Cardiovascular	Hypotension, chest pain, dysrythmias
Hematologic	Leukopenia, thrombocytopenia, neutropenia
Integumentary	Pain at injection site, pruritus, urticaria, rash
Genitourinary	Nephrotoxicity
Gastrointestinal	Increased liver enzyme levels, pancreatitis, metallic taste, nausea, vomiting, diarrhea
Respiratory	Cough, wheezing, dyspnea, pharyngitis
Metabolic	Hypoglycemia followed by hyperglycemia
Other	Fatigue, chills, night sweats

TABLE 43-7 ANTIPROTOZOAL DRUGS: DRUG AND LABORATORY TEST INTERACTIONS

DRUG	MECHANISM	RESULT
atovaquone	Competition for binding on protein, resulting in free, active atovaquone	Highly protein-bound drugs (e.g., warfarin, phenytoin) may increase atovaquone drug concentrations and risk of adverse reactions
iodoquinol	Increase in protein-bound serum iodine concentrations, reflecting a decrease in iodine 131 uptake	May interfere with certain thyroid function test results
metronidazole	Decreased absorption of vitamin K from the intestines due to elimination of the bacteria needed to absorb vitamin K, increased plasma acetaldehyde concentration after ingestion of alcohol	Alcohol causes a disulfiram-like reaction; action of warfarin may be increased (increased bleeding risk)
pentamidine	Additive nephrotoxic effects	Use with an aminoglycoside, amphotericin B, colistin, cisplatin, or vancomycin may result in nephrotoxicity

P. jirovecii infection. Iodoquinol, metronidazole, and paromomycin are all used to treat intestinal amebiasis. Metronidazole is effective against several forms of bacteria, including anaerobic bacteria (see Chapter 39), as well as against protozoans and helminths (parasitic worms). Worm infection (helminthiasis) is discussed later in the chapter.

Contraindications

Contraindications to the use of antiprotozoal drugs include known drug allergy. Additional contraindications may include serious renal, liver, or other illnesses, with the seriousness of the infection weighed against the patient's overall condition.

Adverse Effects

The adverse effects of antiprotozoal drugs vary greatly depending on the drug and are listed in Table 43-6.

Interactions

The common drug and laboratory test interactions associated with the use of antiprotozoal drugs are listed in Table 43-7.

Dosages

For dosage information for selected antiprotozoal drugs, see the table on p. 700.

DOSAGES

Selected Antiprotozoal Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
atovaquone* (Mepron) (C)	Synthetic anti-*Pneumocystis* drug	**Adult and adolescent 13-16 yr** PO: 1500 mg daily with meal × 21 days	Prophylaxis of PJP; treatment of active PJP
♦ metronidazole (Flagyl) (X, first trimester; B, second and third trimesters)	Amebicide, antibacterial, trichomonacide	**Adult** PO: 750 mg 3 times daily × 7-10 days **Pediatric** PO: 35-50 mg/kg (max 750 mg/dose) 3 times daily × 7-10 days	Amebiasis, including amebic liver abscess
		Adult 7-day treatment PO: 250 mg 3 times daily × 5-7 days **Pediatric 7-day treatment** PO: 15 mg/kg/day in 3 divided doses × 5 days	Trichomoniasis, giardiasis
pentamidine (NebuPent, Pentam 300) (C)	Synthetic anti-*Pneumocystis*† drug	**Adult and pediatric** Inhalation aerosol: 300 mg q4wk IV/IM: 4 mg/kg daily × 14-21 days	Prophylaxis of PJP; treatment of active PJP

IM, Intramuscular; *IV,* intravenous; *PO,* oral; *PJP, Pneumocystis jirovecii* pneumonia.
*Note: A combination product containing atovaquone and the drug proguanil is also used against malaria.
†*Pneumocystis jirovecii* is now classified as a fungus.

DRUG PROFILES

atovaquone

Atovaquone (Mepron) is a synthetic antiprotozoal drug indicated for the treatment of mild to moderate *P. jirovecii* pneumonia in patients who cannot tolerate co-trimoxazole (trimethoprim/sulfamethoxazole [see Chapter 38]). It is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	8-24 hr	24-96 hr	2-3 days	Unknown

♦ metronidazole

Metronidazole (Flagyl) is an antiprotozoal drug that also has fairly broad antibacterial activity as well as **anthelmintic** activity. The therapeutic uses of metronidazole are many and range from the treatment of trichomoniasis, amebiasis, and giardiasis to the treatment of anaerobic bacterial infections and antibiotic-induced pseudomembranous colitis (see Chapters 38 and 39). Metronidazole is believed to directly kill protozoans by causing free-radical reactions that damage their DNA and other vital biomolecules. Tinidazole (Tindamax) is a newer, similar drug.

Metronidazole is contraindicated during the first trimester of pregnancy. It is available in both oral and injectable forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	1-2 hr	8 hr	Variable

pentamidine

Pentamidine (NebuPent, Pentam 300) is an antiprotozoal drug that is used mainly for the management of *P. jirovecii* pneumonia (which is actually a fungal infection), although it is sometimes used to treat various protozoal infections. It works by inhibiting protein and nucleic acid synthesis. It is used for the treatment of active pneumocystosis and for prophylaxis of *P. jirovecii* pneumonia in patients at high risk for initial or recurrent *Pneumocystis* infection, such as patients with human immunodeficiency virus (HIV) infection and AIDS.

The only contraindication to pentamidine is known hypersensitivity to the drug. Hypersensitivity is more common when the drug is administered by inhalation. Due to the seriousness of the *Pneumocystis* infection, an allergic reaction to the inhalational form does not preclude its administration by either the intramuscular or intravenous route. The drug needs to be used with caution in patients with blood dyscrasias, hepatic or renal disease, diabetes mellitus, cardiac disease, hypocalcemia, or hypertension. Pentamidine is available as an oral inhalational solution and also in injectable form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Inhalation	0.5-1 hr	Less than 1 hr	6-9 hr	Variable

PATHOPHYSIOLOGY OVERVIEW

HELMINTHIC INFECTIONS

Parasitic **helminthic infections** (worm infections) are a worldwide problem. It has been estimated that one third of the world's population is infected with these parasites, but persons

TABLE 43-8 HELMINTHIC INFECTIONS

INFECTION	ORGANISM AND OTHER FACTS
Nematodes (Various Intestinal and Tissue Roundworms)	
Ascariasis	Caused by *Ascaris lumbricoides* (giant roundworm); worm resides in small intestine; treated with pyrantel or albendazole
Enterobiasis	Caused by *Enterobius vermicularis* (pinworm); worm resides in large intestine; treated with pyrantel or albendazole
Platyhelminthes (Intestinal Tapeworms or Flatworms)	
Diphyllobothriasis	Caused by *Diphyllobothrium latum* (fish worm); acquired from fish; treated with paromomycin, praziquantel, or albendazole
Hymenolepiasis	Caused by *Hymenolepis nana* (dwarf tapeworm); treated with niclosamide, paromomycin, praziquantel, or albendazole
Taeniasis	Caused by *Taenia saginata* (beef tapeworm); acquired from beef; treated with paromomycin, praziquantel, or albendazole
	Caused by *Taenia solium* (pork tapeworm); acquired from pork; treated with paromomycin, praziquantel, or albendazole

living in undeveloped countries where sanitary conditions are often poor are by far the most common victims. The incidence of worm infection in developed countries where sewage treatment is adequate is much lower, and usually only a few select helminthic diseases are the source of the problem. The most prevalent helminthic infection in the United States is enterobiasis, caused by one genus of roundworm, *Enterobius*.

Helminths that are parasitic in humans are classified in the following way:

- Platyhelminthes (flatworms)
- Cestodes (tapeworms)
- Trematodes (flukes)
- Nematodes (roundworms)

The characteristics of a few of the most common of the many helminthic infections are summarized in Table 43-8. These usually first infect the intestines of their host and reside there but can sometimes also migrate to other tissues.

PHARMACOLOGY OVERVIEW

ANTHELMINTIC DRUGS

Unlike protozoans, which are the single-celled members of the animal kingdom, helminths are larger and have complex multicellular structures. Anthelmintic drugs (also spelled *antihelmintic*) work to destroy these organisms by disrupting their structures. The currently available anthelmintic drugs are very specific with regard to the worms they can kill. For this reason, the causative worm in an infected host must be accurately identified before treatment is started. This can usually be done by analyzing samples of feces, urine, blood, sputum, or tissue from the infected host for the presence of ova or larvae of the particular parasite.

TABLE 43-9 ANTHELMINTICS: CLASS OF WORMS KILLED

ANTHELMINTIC DRUG	CESTODES	NEMATODES	TREMATODES
albendazole	Yes	Yes	Yes
ivermectin	No	Yes	No
piperazine and pyrantel	No	Yes (giant worm and pinworm)	No
praziquantel	Yes	No	Yes

Several anthelmintics are commercially available in the United States. These include albendazole (Albenza), ivermectin (Stromectol), praziquantel (Biltricide), and pyrantel (Antiminth).

Other drugs, such as niclosamide and piperazine, may be available either in other countries or by special request from the CDC. Anthelmintics are very specific in their actions. Albendazole can be used to treat both tapeworms and roundworms. Praziquantel is a drug that can kill flukes (trematodes). The most commonly used anthelmintics and the specific class of worms they can effectively kill are summarized in Table 43-9.

Mechanism of Action and Drug Effects

The mechanisms of action of the various anthelmintics vary greatly from drug to drug, although there are some similarities among the drugs used to kill similar types of worms. The various anthelmintic drugs and their respective mechanisms of action are listed in Table 43-10. The drug effects of the anthelmintic drugs are limited to their ability to kill various forms of worms and flukes.

Indications

Anthelmintic drugs are used to treat roundworm, tapeworm, and fluke infections. Specific drugs are used to treat specific helminthic infections.

Contraindications

The only usual contraindication to a specific anthelmintic drug product is known drug allergy. Pyrantel is contraindicated in patients with liver disease. Praziquantel is also contraindicated in patients with *ocular cysticercosis* (tapeworm infection of the eye).

Adverse Effects

The anthelmintic drugs show a remarkable diversity in their drug-specific adverse effects. Common adverse effects are listed in Table 43-11.

Interactions

The concurrent use of pyrantel with piperazine is not recommended, and pyrantel is used cautiously in patients with hepatic impairment. Pyrantel has also been shown to raise blood levels of theophylline in pediatric patients. Dexamethasone and the anthelmintic praziquantel may raise blood levels of albendazole.

TABLE 43-10 ANTHELMINTICS: MECHANISMS OF ACTION

DRUG	MECHANISM OF ACTION	INDICATION
albendazole	Cells of intestinal and tissue-dwelling larvae are selectively destroyed by degenerating cytoplasmic microtubules. This in turn causes secretory substances to accumulate intracellularly, which leads to impaired cholinesterase secretion and glucose. Glycogen becomes depleted, which leads to decreased ATP production and energy depletion, which immobilizes and kills the worm.	Neurocysticercosis, hydatid disease
ivermectin	Potentiates inhibitory signals in the CNS of nematodes, which leads to their paralysis.	Nondisseminated intestinal infection with *Strongyloides* (threadworms)
praziquantel	Increases permeability of the cell membrane of susceptible worms to calcium, which results in the influx of calcium. This causes the worms to be dislodged from their usual site of residence in the mesenteric veins to the liver; they are then killed by host tissue reactions.	Schistosomiasis, opisthorchiasis (liver fluke infection), clonorchiasis (infection with Chinese or Oriental liver fluke), diphyllobothriasis (fish worm infection), hymenolepiasis (dwarf tapeworm infection), neurocysticercosis
pyrantel	Blocks ACh at the neuromuscular junction, which results in paralysis of the worm. The paralyzed worm is then expelled from the GI tract by normal peristalsis.	Ascariasis, enterobiasis, other helminthic infections
thiabendazole	Inhibits the helminth-specific enzyme fumarate reductase.	Cutaneous larva migrans (creeping eruption), strongyloidiasis, trichinosis

ACh, Acetylcholine; *ATP,* adenosine triphosphate; *CNS,* central nervous system; *GI,* gastrointestinal.

TABLE 43-11 ANTHELMINTICS: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Primaquine	
Gastrointestinal	Nausea, vomiting, abdominal distress
Other	Headaches, pruritus, dark discoloration of urine, hemolytic anemia due to glucose-6-phosphate dehydrogenase deficiency
Pyrantel	
Central nervous system	Headache, dizziness, insomnia
Dermatologic	Skin rash
Gastrointestinal	Anorexia, abdominal cramps, diarrhea, nausea, vomiting
Praziquantel	
Central nervous system	Dizziness, headache, drowsiness
Gastrointestinal	Abdominal pain, nausea
Other	Malaise

Histamine H_2 antagonists (e.g., cimetidine, ranitidine) may also raise blood levels of praziquantel.

Dosages

For dosage information on selected anthelmintic drugs, see the table on p. 703.

DRUG PROFILES

Anthelmintics are available only as oral preparations and, with the exception of pyrantel, all require a prescription. Different drugs are selected to treat infection with different helminthic species.

praziquantel

Praziquantel (Biltricide) is one of the primary anthelmintic drugs used for the treatment of various fluke infections. It is also useful against many species of tapeworm. It is contraindicated in patients with ocular worm infestation *(ocular cysticercosis).* It is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	1-3 hr	4-5 hr	Variable

pyrantel

Pyrantel (Pin-X) is a pyrimidine-derived anthelmintic drug that is indicated for the treatment of infection with intestinal roundworms, including ascariasis, enterobiasis, and other helminthic infections. It is the only anthelmintic available in the United States without a prescription. It is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	1-3 hr	Unknown	Unknown

NURSING PROCESS

ASSESSMENT

Before beginning treatment with an *antimalarial drug,* obtain a thorough medication history, perform a head-to-toe physical assessment and measure vital signs. Give special attention to assessment findings of any common manifestations of malaria, such as headache, nausea, and joint pain. Other symptoms include chills and rigors followed by fever of up to 104° F (40° C) frequently leading to extreme fatigue and prolonged sleep. Baseline visual acuity tests may be needed due to the contraindications of visual field problems and optic

DOSAGES

Selected Anthelmintic Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
praziquantel (Biltricide) (B)	Trematode anthelmintic	**Adult and pediatric** PO: approx 20-25 mg/kg 3 times daily × 1 day	Fluke infections
pyrantel (Pin-X) (C)	Nematode anthelmintic	**Adult and pediatric** PO: 11 mg/kg in a single dose (max dose 1 g)	Roundworm infections

PO, oral.

neuritis with chloroquine, quinine, and hydroxychoroquine. Perform a skin assessment as well, because of the contraindication with those individuals with psoriasis. Other drugs, such as mefloquine and primaquine, require assessment of baseline hearing and (with primaquine as well as pryimethamine) assessment of G6PD deficiency due to drug-induced hemolytic anemia. Common drug interactions to assess for are listed in Table 43-2.

Antiprotozoal drugs and their contraindications, cautions, and drug interactions have been previously discussed. Assess baseline renal and liver function as well as overall health status. With atovaquone, determine baseline blood counts due to risk of drug-induced anemia/neutropenia and leukopenia. Assess serum potassium, sodium, and glucose levels as ordered. With iodoquinol, it is important to assess blood counts prior to its use as well as baseline vision and neurologic intactness (e.g., presence of normal sensations). Metronidazole requires assessment for allergy to any of the nitroimidazole derivatives as well as to parabens (for the topical dosage forms). Obtain appropriate specimens for analysis before treatment. Assess blood counts, presence of central nervous system disorders or abnormalities, and bladder function prior to use of metronidazole. Pentamidine is associated with serious cardiac, hematologic, skin, renal, GI, and respiratory adverse effects; therefore, documentation of a thorough assessment of each of these systems is critical to patient safety.

With any of the *anthelmintic drugs,* obtain a thorough history of the foods eaten, especially meat and fish, and their means of preparation. Also assess other individuals in the family household for helminth infection. Obtaining stool specimens is indicated. Assess the patient's energy level, ability to perform activities of daily living, weight, and appetite. Document the findings. Assess for contraindications, such as liver disease and drug allergy, and any cautions. Drug interactions to assess for include theophylline, antiepileptic drugs, and histamine H_2 antagonists.

NURSING DIAGNOSES

1. Imbalanced nutrition, less than body requirements, related to the disease process and adverse effects of medication
2. Deficient knowledge related to the infection and its drug treatment
3. Ineffective family therapeutic regimen management related to poor compliance with treatment and/or lack of knowledge about the infection and its treatment

CASE STUDY

Metronidazole

T.J., a 28-year-old graduate student, just returned from an archeology internship in a third-world country. She has had severe diarrhea for several days and has been diagnosed with intestinal amebiasis. She will receive fluids for rehydration and metronidazole (Flagyl) as part of her treatment.

1. What specific laboratory test must be ordered before initiation of the metronidazole therapy? List other laboratory studies that will be performed.
2. T.J. is started on the intravenous piggyback infusions, and after a day she reports that her diarrhea has decreased and that she feels a little better. During afternoon rounds, she tells the nurse that she feels dizzy and tired, and has some nausea. She asks, "Is this because of my infection?" How will the nurse respond?
3. T.J. is discharged to home with a prescription to take the metronidazole for 2 more weeks. The nurse knows that one serious adverse effect is leukopenia. What symptoms will the nurse tell T.J. to report?
4. A week later, T.J. calls to tell the nurse that she went out to a bar with some friends and became very ill after having a drink. Explain what happened.

For answers, see http://evolve.elsevier.com/Lilley.

PLANNING

GOALS

1. Patient maintains balanced nutrition during drug therapy.
2. Patient, family, and significant others demonstrate adequate knowledge regarding the infection and its treatment.
3. Patient, family, and others in the home environment experience improved therapeutic regimen management and compliance.as well as with family and others in the household.

OUTCOME CRITERIA

1. Patient states measures to enhance balanced nutrition with recommendations for increased caloric and protein intake.
   - Patient identifies menu planning with grocery lists appropriate to meet increased nutritional demands.
   - Patient lists foods to be included in the daily diet with use of MyPlate to improve overall nutritional status along with prescribed dietary changes.
2. Patient states the impact of infectious process on the human body and its daily functioning.
   - Patient states the various measures to prevent worsening of lesions and minimize tissue injury, such as washing hands

thoroughly; reporting worsening of lesions and/or drainage, fever, or joint pain; and taking medication as prescribed.
- Patient states the importance and need for reporting the worsening of symptoms of the infection, such as fever, lethargy, and loss of appetite.
- Patient states the rationale for staying on treatment for the prescribed length of time.
- Patient states the importance of effective family therapeutic management through compliance with therapy, returning for follow-up visits to the prescriber to monitor progress, checking for adverse reactions and reporting any new symptoms in members of the household/family.

IMPLEMENTATION

With *antimalarials,* encourage adequate dietary and fluid intake while the patient is fighting the infection and taking the medications. Take oral doses with at least 6 to 8 oz of water or other fluid. Increase fluids unless contraindicated. Because antimalarials concentrate in the liver first, emphasize to the patient the importance of follow-up visits to the prescriber so that liver function may be monitored during therapy.

Chloroquine and hydroxychloroquine are administered orally and are to be taken exactly as prescribed. Follow dosing orders and instructions as prescribed, with specific attention to the loading doses, subsequent doses, and prophylactic dosing. Photosensitivity may occur with quinine; provide adequate teaching about the use of sunscreen and sun safety. Sun protection must include coverage against UVA and UVB rays. See the Patient Teaching Tips for more information.

Most of the *antiprotozoal drugs* (e.g., atovaquone, metronidazole) are given with food when taken orally. Infuse intravenous doses of metronidazole as ordered. Intravenous (IV) doses are to infuse over 30 to 60 minutes and are never given as an IV bolus. During use of this drug, report to the prescriber any changes in neurologic status (e.g., dizziness, confusion).

All *anthelmintic drugs* are to be administered as ordered and for the prescribed length of time. Warn patients that use of primaquine may lead to dark discoloration of the urine. Perform collection of stool specimens as ordered. The stool must not be in contact with water, urine, or chemicals because of the risk of destroying the parasitic worms and/or altering the test results. See the Patient Teaching Tips for more information on these drugs.

EVALUATION

Monitor the patient for the therapeutic effects of the *antimalarials, antiprotozoals, and anthelmintic* drugs such as improved energy levels and decrease in and/or eventual resolution of all symptoms. Evaluation of proper hygiene and prevention of the spread of the infestation or infection is also important. With these three groups of drugs, evaluate for the adverse effects associated with each type of drug (see Tables 43-1, 43-6, and 43-11). Some *antimalarials and anthelmintics* may precipitate hemolysis in patients with G6PD deficiency (mostly African-American patients and those of Mediterranean ancestry); therefore, closely monitor such patients for this complication during the treatment protocol. See Chapter 2 for further discussion of G6PD deficiency.

PATIENT TEACHING TIPS

- Antimalarials are known to cause gastrointestinal upset; however, this may be decreased if the medication is taken with food. Encourage the patient to contact the prescriber if there is unresolved nausea, vomiting, profuse diarrhea, or abdominal pain. Report immediately any visual disturbances, dizziness, or respiratory difficulties.
- Educate the patient about the need for prophylactic doses of antimalarials, as prescribed, before visiting malaria-infested countries as well as the need to obtain appropriate treatment upon return.
- Keep antimalarials, like all other medications, out of the reach of children.
- Instruct the patient to take the entire course of medication as directed.
- Oral dosage forms of metronidazole to be taken with food.
- Inform the patient taking metronidazole for a sexually transmitted disease to avoid sexual intercourse until the prescriber states otherwise.
- When the patient is taking metronidazole for amebiasis, include in your instructions how to check stool samples correctly and safely and how to dispose of samples properly.
- Apply topical forms of the drug with a finger cot or gloved hand and caution the patient to avoid contact of the drug with the eyes.
- Metronidazole may precipitate dizziness. Encourage the patient to be cautious in all activities until a response to the drug is noted and is consistent.
- Anthelmintics are to be taken exactly as prescribed; emphasize the importance of compliance with the drug regimen.

KEY POINTS

- Malaria is caused by *Plasmodium,* a particular genus of protozoans, and is transmitted by the bite of an infected female mosquito. The drug primaquine attacks the parasite when it is outside the exoerythrocytic (tissue) phase.
- Other common protozoal infections are amebiasis, giardiasis, toxoplasmosis, and trichomoniasis. Protozoans are parasites that are transmitted by person-to-person contact, ingestion of contaminated water or food, direct contact with the parasite, and the bite of an insect (mosquito or tick). Pneumocystosis is now classified as a fungal infection, but it is treated with antiprotozoal drugs.
- Antiprotozoals include atovaquone and pentamidine. Metronidazole is an antibacterial, antiprotozoal, and anthelmintic. The drugs iodoquinol and paromomycin directly kill protozoans such as *Entamoeba histolytica.*
- Anthelmintics are drugs used to treat parasitic worm infections caused by cestodes (tapeworms), nematodes (roundworms), and trematodes (flukes).
- Nursing considerations with the use of any of the antimalarials, antiprotozoals, and anthelmintics include assessment for contraindications, cautions, and drug interactions.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is reviewing the medication history of a patient who is taking hydroxychloroquine. However, the patient's chart does not reveal a history of malaria or travel out of the country. The patient is most likely taking this medication for
   - **a** *Plasmodium.*
   - **b** thyroid disorders.
   - **c** roundworms.
   - **d** rheumatoid arthritis.

2 Which teaching point would be appropriate to include when the nurse is informing a patient about the adverse effects of antimalarials?
   - **a** The skin may turn blotchy while these medications are taken.
   - **b** These medications may cause anorexia and abdominal distress.
   - **c** These medications may cause increased urinary output.
   - **d** The patient may experience periods of diaphoresis and chills.

3 When teaching a patient about the potential drug interactions with antiprotozoal drugs, the nurse will include information about
   - **a** acetaminophen.
   - **b** warfarin.
   - **c** decongestants.
   - **d** antibiotics.

4 Before administering antiprotozoal drugs, the nurse will review which baseline assessment?
   - **a** Complete blood count
   - **b** Serum magnesium level
   - **c** Creatinine clearance
   - **d** Arterial blood gas concentrations

5 The nurse knows that antimalarial drugs are used to treat patients with infections caused by which microorganism?
   - **a** *Plasmodium* spp.
   - **b** *Candida albicans*
   - **c** *Pneumocystis jirovecii*
   - **d** *Mycobacterium*

6 When giving metronidazole, the nurse implements appropriate administration techniques, including which of these? (Select all that apply.)
   - **a** Giving oral forms with food
   - **b** Giving oral forms on an empty stomach with a full glass of water
   - **c** Infusing intravenous doses over 30 to 60 minutes
   - **d** Administering intravenous doses by bolus over 5 minutes
   - **e** Obtaining ordered specimens before starting the medication

7 A 5-year-old patient has been diagnosed with malaria after returning from a trip. The patient is to receive one dose of mefloquine (Lariam), 25 mg/kg PO. The child weighs 44 lb. How much mefloquine will this child receive? Is this a safe dose?

1. d, 2. b, 3. b, 4. a, 5. a, 6. a, c, e, 7. 500 mg; yes

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the inflammatory response and the part it plays in the generation of pain.
2 Compare the disease processes or pathologies that are inflammatory in nature with those of gout.
3 Discuss the mechanisms of action, indications, adverse effects, dosage ranges, routes of administration, cautions, contraindications, drug interactions, and toxicities of the various antiinflammatory and antigout drugs.
4 Develop a nursing care plan that includes all phases of the nursing process for patients receiving antiinflammatory and/or antigout drugs.

DRUG PROFILES

- **aspirin, p. 712**
- **celecoxib, p. 713**
- **colchicine, p. 714**
- **ibuprofen, p. 712**
- **indomethacin, p. 712**
- **ketorolac, p. 712**
- **probenecid, p. 715**

♦ *Key drug*

KEY TERMS

Done nomogram A standard data graph, originally published in 1960 in the journal *Pediatrics,* for rating the severity of aspirin toxicity following overdose. Serum salicylate levels are plotted against time elapsed since ingestion. (p. 710)

Gout Hyperuricemia (elevated blood uric acid level); the arthritis caused by tissue buildup of uric acid crystals. (p. 713)

Inflammation A localized protective response stimulated by injury to tissues that serves to destroy, dilute, or wall off (sequester) both the injurious agent and the injured tissue. (p. 707)

Nonsteroidal antiinflammatory drugs (NSAIDs) A large and chemically diverse group of drugs that possess analgesic, antiinflammatory, and antipyretic (fever-reducing) activity. (p. 707)

Salicylism The syndrome of salicylate toxicity, including symptoms such as tinnitus (ringing sound in the ears), nausea, and vomiting. (p. 710)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Inflammation is defined as a localized protective response stimulated by injury to tissues, which serves to destroy, dilute, or wall off (sequester) both the injurious agent and the injured tissue. Classic signs and symptoms of inflammation include pain, fever, loss of function, redness, and swelling. These symptoms result from arterial, venous, and capillary dilation; enhanced blood flow and vascular permeability; exudation of fluids, including plasma proteins; and leukocyte migration into the inflammatory focus. The inflammatory response is mediated by a host of endogenous compounds, including proteins of the complement system, histamine, serotonin, bradykinin, leukotrienes, and prostaglandins, the latter two being major contributors to the symptoms of inflammation.

Arachidonic acid is released from phospholipids in cell membranes in response to a triggering event (e.g., an injury). It is metabolized in either the prostaglandin pathway or the leukotriene pathway, both of which are branches of the arachidonic acid pathway, as shown in Figure 44-1. Both of these pathways lead to inflammation, edema, headache, and other pain characteristic of the body's response to injury or inflammatory illnesses such as arthritis.

In the prostaglandin pathway, arachidonic acid is converted by the enzyme cyclooxygenase into various prostaglandins. Prostaglandins mediate inflammation by inducing vasodilation and enhancing vasopermeability. These effects in turn potentiate the action of proinflammatory substances such as histamine and bradykinin in the production of edema and pain. These symptoms arise as a result of prostaglandin-induced hyperalgesia (excessive sensitivity). In this situation, stimuli that normally would not be painful, such as simply moving a joint through its natural range of motion, become painful because of the inflammatory process at work. Fever occurs when prostaglandin E_2 is synthesized in the preoptic hypothalamic region, the area of the brain that regulates temperature.

The leukotriene pathway utilizes lipoxygenases to metabolize the arachidonic acid and convert it into various leukotrienes. Although leukotrienes are more newly discovered than prostaglandins and not as well studied, they are also mediators of inflammation, promoting vasoconstriction, bronchospasm, and increased vascular permeability with resultant edema (see Chapter 37).

PHARMACOLOGY OVERVIEW

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Nonsteroidal antiinflammatory drugs (NSAIDs) are among the most commonly prescribed drugs. Every year, over 70 million prescriptions are written for these drugs. This represents more than 5% of all prescriptions. Currently more than 23 different NSAIDs are available in the United States. Some of these are used much more commonly than others. A given patient may respond better to one NSAID than to others, in terms of both symptom relief and adverse effects.

NSAIDs comprise a large and chemically diverse group of drugs that possess analgesic, antiinflammatory, and antipyretic (antifever) activity. They are also used for the relief of mild to moderate headaches, myalgia, neuralgia, and arthralgia; alleviation of postoperative pain; relief of the pain associated with arthritic disorders such as rheumatoid arthritis, juvenile arthritis, ankylosing spondylitis, and osteoarthritis; and treatment of

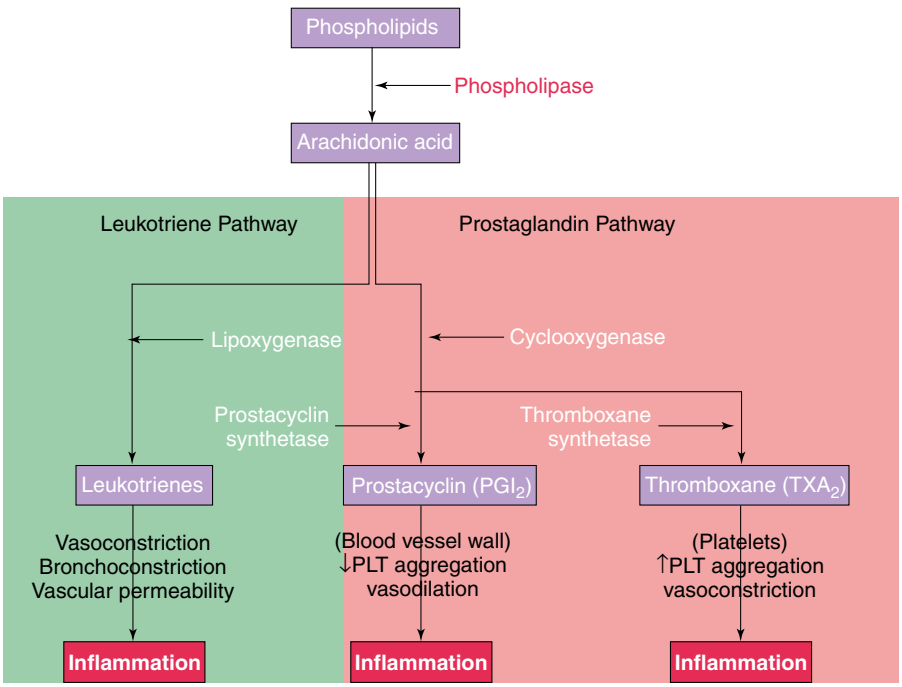

FIGURE 44-1 Arachidonic acid pathway. *PGI2,* Prostaglandin I_2; *PLT,* platelet; *TXA_2,* thromboxane A_2.

BOX 44-1 CHEMICAL CATEGORIES OF NSAIDs

Salicylates
aspirin
diflunisal (Dolobid)
salsalate (Salistab)
choline salicylate (Arthropan)

Acetic Acid Derivatives
diclofenac sodium (Voltaren)
indomethacin (Indocin)
sulindac (Clinoril)
tolmetin (Tolectin)
etodolac (Lodine)
ketorolac (Toradol)
meclofenamate (generic only)
mefenamic acid (Ponstel)

Cyclooxygenase-2 Inhibitors
celecoxib (Celebrex)

Enolic Acid Derivatives
nabumetone (Relafen)
meloxicam (Mobic)
piroxicam (Feldene)

Propionic Acid Derivatives
fenoprofen (Nalfon)
flurbiprofen (Ansaid)
ibuprofen (Motrin, Advil, others)
ketoprofen (Orudis KT)
naproxen (Naprosyn, Aleve)
oxaprozin (Daypro)

NSAID, Nonsteroidal antiinflammatory drug.

BOX 44-2 NSAIDs: FDA-APPROVED INDICATIONS

- Acute gout
- Acute gouty arthritis
- Ankylosing spondylitis
- Bursitis
- Fever
- Juvenile rheumatoid arthritis
- Mild to moderate pain
- Osteoarthritis
- Primary dysmenorrhea
- Rheumatoid arthritis
- Tendinitis
- Various ophthalmic uses

FDA, U.S. Food and Drug Administration; *NSAID,* nonsteroidal antiinflammatory drug.

gout and hyperuricemia (discussed later in the chapter). Aspirin is used for its effect in inhibiting platelet aggregation, which has been shown to have protective qualities against certain cardiovascular events such as myocardial infarction and stroke. Corticosteroid antiinflammatory drugs (e.g., prednisone, dexamethasone) are also used for similar purposes and were discussed in Chapter 33. NSAIDs have a generally more favorable adverse effect profile than the corticosteroid antiinflammatory drugs.

In 1899, acetylsalicylic acid (ASA; aspirin) was marketed and rapidly became the most widely used drug in the world. The success of aspirin established the importance of drugs with antipyretic, analgesic, and antiinflammatory properties—the properties that all NSAIDs share. The widespread use of aspirin also yielded evidence of its potential for causing major adverse effects. Gastrointestinal intolerance, bleeding, and renal impairment became major factors limiting its long-term administration. As a result, efforts were mounted to develop drugs that did not have the adverse effects of aspirin. This led to the discovery of other NSAIDs, which in general are associated with a lower incidence of and less serious adverse effects and are often better tolerated than aspirin in patients with chronic diseases. If aspirin were to be a newly discovered drug today, it would require a prescription.

As a single class, NSAIDs constitute an exceptional variety of drugs, and they are used for an equally wide range of indications. Box 44-1 categorizes these drugs into a number of distinct chemical classes. The NSAIDs have been approved for a variety of indications and are considered the drug of choice for most of the conditions listed in Box 44-2. Almost all NSAIDs are used for the treatment of rheumatoid arthritis (see Chapter 47) and degenerative joint disease (osteoarthritis). Several of these drugs are available in sustained-release formulations. This allows once- or twice-daily dosing, which is known to improve patients' adherence to prescribed drug therapy regimens.

Mechanism of Action and Drug Effects

The NSAIDs work through inhibition of the leukotriene pathway, the prostaglandin pathway, or both. More specifically, NSAIDs relieve pain, headache, and inflammation by blocking the chemical activity of the enzyme called *cyclooxygenase (COX).* It is now recognized that there are at least two types of cyclooxygenase. Cyclooxygenase-1 (COX-1) is the isoform of the enzyme that promotes the synthesis of prostaglandins, which have primarily beneficial effects on various body functions. One example is their role in maintaining an intact gastrointestinal mucosa. In contrast, the cyclooxygenase-2 (COX-2) isoform promotes the synthesis of prostaglandins that are involved in inflammatory processes. In 1998, the newest class of NSAIDs, the COX-2 inhibitors, was approved. These drugs work by specifically inhibiting the COX-2 isoform of cyclooxygenase and theoretically have limited or no effects on COX-1. Previous NSAIDs nonspecifically inhibited both COX-1 and COX-2 activity. This greater enzyme specificity of the COX-2 inhibitors allows for the beneficial antiinflammatory effects while reducing the prevalence of adverse effects associated with the nonspecific NSAIDs, such as gastrointestinal ulceration. The leukotriene pathway is inhibited by some antiinflammatory drugs, but not by salicylates.

All NSAIDs can be ulcerogenic and induce gastrointestinal bleeding due to their activity against tissue COX-1. One notable effect of aspirin is its inhibition of platelet aggregation, also known as its *antiplatelet activity.* Aspirin has the unique property among NSAIDs of being an irreversible inhibitor of COX-1 receptors within the platelets themselves. This in turn results in reduced formation of thromboxane A_2, a substance that normally promotes platelet aggregation. This antiplatelet action has made aspirin, along with thrombolytic drugs (see Chapter 26), a primary drug in the treatment of acute myocardial infarction and many other thromboembolic disorders. Other NSAIDs lack these antiplatelet effects.

Indications

Some of the therapeutic uses of this broad class of drugs are listed in Table 44-1; however, NSAIDs are primarily used for their analgesic, antiinflammatory, and antipyretic effects, and for platelet inhibition. NSAIDs are also widely used for the treatment of rheumatoid arthritis (see Chapter 47) and osteoarthritis, as well as other inflammatory conditions, rheumatic

TABLE 44-1 SUGGESTED NSAIDs FOR PATIENTS WITH VARIOUS MEDICAL CONDITIONS

MEDICAL CONDITION	RECOMMENDED NSAID
Ankylosing spondylitis	indomethacin, diclofenac
Diabetic neuropathy	sulindac
Dysmenorrhea	Fenamates, naproxen, ibuprofen
Gout	indomethacin, naproxen, sulindac
Headaches	aspirin, naproxen, ibuprofen
Hepatotoxicity	tolmetin, naproxen, ibuprofen, piroxicam, fenamates
History of aspirin or NSAID allergy	Avoid if possible; if deemed necessary, consider a nonacetylated salicylate
Hypertension	sulindac, nonacetylated salicylate, ibuprofen, etodolac
Osteoarthritis	diclofenac, oxaprozin, indomethacin
Risk for gastrointestinal toxicity	COX-2 inhibitors (celecoxib), nonacetylated salicylate, enteric-coated aspirin, diclofenac, nabumetone, etodolac, ibuprofen, oxaprozin
Risk for nephrotoxicity	sulindac, nonacetylated salicylate, nabumetone, etodolac, diclofenac, oxaprozin
Warfarin therapy	sulindac, tolmetin, naproxen, ibuprofen, oxaprozin

COX, Cyclooxygenase; *NSAID,* nonsteroidal antiinflammatory drug.

fever, mild to moderate pain, and acute gout. They also have proved beneficial as adjunctive pain relief medications in patients with chronic pain syndromes, such as pain from bone cancer and chronic back pain. For the relief of pain, NSAIDs are sometimes combined with an opioid (see Chapter 10). They tend to have an opioid-sparing effect when given together with opioids, because the drugs attack pain using two different mechanisms. This often allows less opioids to be used. Unlike opioids, NSAIDs show a ceiling effect that limits their effectiveness; that is, any further increase in the dosage beyond a certain level increases the risk for adverse effects without a corresponding increase in the therapeutic effect. In contrast, opioid dosages may be titrated almost indefinitely to increasingly higher levels, especially in terminally ill patients with severe pain.

The appropriate selection of an NSAID is a clinical judgment based on consideration of the patient's history, including any previous medical conditions; the intended use of the drug; the patient's previous experience with NSAIDs; the patient's preference; and the cost.

Contraindications

Contraindications to NSAIDs include known drug allergy and conditions that place the patient at risk for bleeding, such as rhinitis (risk for epistaxis [nosebleed]), vitamin K deficiency, and peptic ulcer disease. Patients with documented aspirin allergy must not receive NSAIDs. Other common contraindications are those that apply to most drugs and include severe renal or hepatic disease. NSAIDs are generally categorized as pregnancy category C drugs for use during the first two trimesters of pregnancy but are categorized as pregnancy category D (not recommended) for use during the third trimester. This is because NSAID use has been associated with both excessive maternal bleeding and neonatal toxicity during the perinatal period. These drugs also are not recommended for nursing mothers, because they are known to be excreted into human milk. Because of the potential of NSAIDs to increase bleeding, patients undergoing elective surgery need to stop taking NSAIDs at least 1 week prior to surgery.

TABLE 44-2 NSAIDs: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Moderate to severe noncardiogenic pulmonary edema
Gastrointestinal	Dyspepsia, heartburn, epigastric distress, nausea, vomiting, anorexia, abdominal pain, gastrointestinal bleeding, mucosal lesions (erosions or ulcerations)
Hematologic	Altered hemostasis through effects on platelet function
Hepatic	Acute reversible hepatotoxicity
Renal	Reduction in creatinine clearance, acute tubular necrosis with renal failure
Other	Skin eruption, sensitivity reactions, tinnitus, hearing loss

NSAID, Nonsteroidal antiinflammatory drug.

Adverse Effects

Although NSAIDs are the most widely used class of drugs, and some are available without prescription, their potential for serious adverse events has been underemphasized. Over 100,000 hospitalizations occur each year due to NSAID use, with over 16,000 deaths reported annually. One of the more common and potentially serious adverse effects of the NSAIDs is their effect on the gastrointestinal tract. Symptoms can range from mild symptoms such as heartburn to the most severe gastrointestinal complication, gastrointestinal bleeding. Most fatalities associated with NSAID use are related to gastrointestinal bleeding. In addition, acute renal failure is quite common with NSAID use, especially if the patient is dehydrated. The potential adverse effects of NSAIDs are listed in Table 44-2. Not all of the adverse effects necessarily apply to all drugs, but many do. In 2006, the U.S. Food and Drug Administration (FDA) began requiring a black box warning on all of the NSAIDs (see Box 44-3).

Many of the adverse effects of NSAIDs are secondary to their inactivation of protective prostaglandins that help maintain the normal integrity of the stomach lining. The drug misoprostol (Cytotec) (see Chapter 50) has proved successful in preventing the gastric ulcers and hence gastrointestinal bleeding that can occur in patients receiving NSAIDs. Misoprostol is a synthetic prostaglandin E_1 analogue that inhibits gastric acid secretion and also has a cytoprotective component, although the mechanism responsible for this action is unclear. This drug also has abortifacient properties, which were discussed in Chapter 34.

Renal function depends partly on prostaglandins. Disruption of prostaglandin function by NSAIDs is sometimes strong enough to precipitate acute or chronic renal failure, depending on the patient's current level of renal function. The use of NSAIDs can compromise existing renal function. Renal toxicity can occur in patients who are dehydrated, those with heart failure or liver dysfunction, and those taking diuretics or angiotensin-converting enzyme inhibitors.

BOX 44-3 FDA REQUIRED WARNINGS ON ALL NSAIDs

The following black box warning must now be included in the packaging for all NSAIDs:

Cardiovascular Risk

- NSAIDs may cause an increased risk of serious cardiovascular thrombotic events, myocardial infarction, and stroke, which can be fatal. This risk may increase with duration of use. Patients with cardiovascular disease or risk factors for cardiovascular disease may be at greater risk.
- NSAIDs are contraindicated for the treatment of perioperative pain in the setting of coronary artery bypass graft surgery.

Gastrointestinal Risk

- NSAIDs cause an increased risk of serious gastrointestinal adverse events, including bleeding, ulceration, and perforation of the stomach or intestines, which can be fatal. These events can occur at any time during use and without warning symptoms. Elderly patients are at greater risk for serious gastrointestinal events.
- See Chapter 4 for more information on black box warnings.

FDA, U.S. Food and Drug Administration; *NSAID,* nonsteroidal antiinflammatory drug.

TABLE 44-3 ACUTE OR CHRONIC SALICYLATE INTOXICATION: SIGNS AND SYMPTOMS

BODY SYSTEM	SIGNS AND SYMPTOMS
Cardiovascular	Increased heart rate
Central nervous	Tinnitus, hearing loss, dimness of vision, headache, dizziness, mental confusion, lassitude, drowsiness
Gastrointestinal	Nausea, vomiting, diarrhea
Metabolic	Sweating, thirst, hyperventilation, hypoglycemia or hyperglycemia

Toxicity and Management of Overdose

Salicylate toxicity, usually from aspirin, is not as common as it was; however, there are both chronic and acute manifestations of salicylate toxicity. Chronic salicylate intoxication is also known as **salicylism** and results from either short-term administration of high dosages or prolonged therapy with high or even lower dosages. The most common signs and symptoms of acute or chronic salicylate intoxication are listed in Table 44-3.

The most common manifestations of chronic salicylate intoxication in adults are tinnitus and hearing loss. Those in children are hyperventilation and central nervous system (CNS) effects such as dizziness, drowsiness, and behavioral changes. Metabolic complications such as metabolic acidosis and respiratory alkalosis often occur to varying degrees in cases of chronic salicylate intoxication. Metabolic acidosis can also occur with acute intoxication, but it is usually less severe than that in patients with chronic intoxication. Hypoglycemia may also arise and can be life-threatening. The treatment of chronic intoxication is based on the presenting symptoms.

The signs and symptoms of acute salicylate toxicity are similar to those of chronic intoxication, but the effects are often more pronounced and occur more quickly. Acute salicylate overdose usually results from the ingestion of a single toxic dose, and its severity can be judged based on the estimated amount ingested (in milligrams per kilogram of body weight), as follows:

- Little or no toxicity: less than 150 mg/kg
- Mild to moderate toxicity: 150 to 300 mg/kg
- Severe toxicity: 300 to 500 mg/kg
- Life-threatening toxicity: over 500 mg/kg

However, doses lower than 150 mg/kg have resulted in fatal toxicity. A serum salicylate concentration measured 6 hours or longer after the ingestion may be used in conjunction with the **Done nomogram** to estimate the severity of intoxication and help guide treatment. The Done nomogram is a graphic plot of serum salicylate level as a function of time since salicylate ingestion. It was first published in a 1960 issue of the journal *Pediatrics* and is still used today for gauging salicylate toxicity. This nomogram is intended for estimating only the severity of acute intoxications and not the severity of chronic salicylate intoxication. Table 44-4 describes, in general terms, the treatment for cases of varying severity. Treatment goals include removing salicylate from the gastrointestinal tract and/or preventing its further absorption; correcting fluid, electrolyte, and acid-base disturbances; and implementing measures to enhance salicylate elimination, including hemodialysis.

TABLE 44-4 ACUTE SALICYLATE INTOXICATION: TREATMENT

SEVERITY	TREATMENT
Mild	1. Dosage reduction or discontinuation of salicylates 2. Symptomatic and supportive therapy
Severe	1. Discontinuation of salicylates 2. Intensive symptomatic and supportive therapy 3. Dialysis if: high salicylate levels, unresponsive acidosis (pH less than 7.1), impaired renal function or renal failure, pulmonary edema, persistent CNS symptoms (e.g., seizures, coma), progressive deterioration despite appropriate therapy

CNS, Central nervous system.

An acute overdose of nonsalicylate NSAIDs (e.g., ibuprofen) causes effects similar to those of salicylate overdose, but they are generally not as extensive or as dangerous. Symptoms include CNS toxicities such as drowsiness, lethargy, mental confusion, paresthesias (abnormal touch sensations), numbness, aggressive behavior, disorientation, and seizures, and gastrointestinal toxicities such as nausea, vomiting, and gastrointestinal bleeding. Intense headache, dizziness, cerebral edema, cardiac arrest, and death have also been known to occur in extreme cases. Treatment consists of the administration of activated charcoal, with supportive and symptomatic treatment initiated thereafter. Unlike in the case of salicylates, hemodialysis appears to be of no value in enhancing the elimination of nonsalicylate NSAIDs.

Interactions

Drug interactions associated with the use of salicylates and other NSAIDs can result in significant complications and morbidity. Some of the more common of these are listed in Table 44-5.

TABLE 44-5 SALICYLATES AND OTHER NSAIDs: DRUG INTERACTIONS

INTERACTING DRUG	MECHANISM	RESULT
Alcohol	Additive effect	Increased gastrointestinal bleeding
Anticoagulants	Platelet inhibition, hypoprothrombinemia	Increased bleeding tendencies
aspirin and other salicylates with other NSAIDs	Reduction of NSAID absorption, additive gastrointestinal toxicities	Increased gastrointestinal toxicity with no therapeutic advantage
Bisphosphonates	Additive GI toxicities	Increased GI bleeding risk
Corticosteroids and other ulcerogenic drugs	Additive toxicities	Increased ulcerogenic effects
cyclosporine	Inhibition of renal prostaglandin synthesis	Increased nephrotoxic effects of cyclosporine, renal failure
Diuretics and ACE inhibitors	Inhibition of prostaglandin synthesis	Reduced hypotensive and diuretic effects
lithium	Increased lithium absorption	Increased lithium concentrations
Protein-bound drugs	Competition for binding	More pronounced drug actions
Uricosurics	Antagonism	Decreased uric acid excretion
Herbals: feverfew, garlic, ginger, gingko	Interference with platelet function	Increased bleeding risk

ACE, Angiotensin-converting enzyme; *GI,* gastrointestinal; *NSAID,* nonsteroidal antiinflammatory drug.

DOSAGES

Most Commonly Used NSAIDs

DRUG (PREGNANCY CATEGORY*)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ aspirin (ASA; many product names) (C/D)	Salicylate	**Adult**	
		PO/PR: 325-650 mg 4-6 times daily (max 4 g/day)	Fever, pain
		PO/PR: 3 g/day divided q4-6h	Arthritis
		PO: 81-325 mg once daily	Thromboprevention
		PO/PR: 90-130 mg/kg/day	Juvenile rheumatoid arthritis
♦ celecoxib (Celebrex) (C/D)	COX-2 inhibitor	**Adult and adolescent older than 15 yr**	
		PO: 100-200 mg/day given in 1 or 2 doses	Arthritis, acute pain, primary dysmenorrhea
		Pediatric	
		Less than 25 kg: 50 mg twice daily	Juvenile rheumatoid arthritis
		More than 25 kg: 100 mg twice daily	
♦ ibuprofen (Motrin, Advil, others) (C/D)	Propionic acid derivative	**Adult**	
		1200-3200 mg/day divided 3-4 times daily	Arthritis, fever, pain, dysmenorrhea
		Pediatric	
		30-40 mg/kg/day divided 3-4 times daily	
♦ indomethacin (Indocin, Indocin SR) (C/D)	Acetic acid derivative	**Adult**	
		PO/PR: 25-50 mg 2-3 times daily (max 200 mg/day)	Arthritis, including acute gouty arthritis, bursitis or tendonitis
		Pediatric	
		PO/PR: 1-2 mg/kg/day divided 2-4 times daily (max 200 mg/day)	
♦ ketorolac (Toradol) (C/D)	Acetic acid derivative	**Adult**†	
		PO‡: 10 mg q4-6h (max 40 mg/day)	Acute painful conditions that would otherwise require opioid-level analgesia
		IV/IM: 15-60 mg q6-12h (max 120 mg/day if younger than 65 yr; max 60 mg/day if 65 yr or older)	
		Maximum treatment 5 days	

ASA, Acetylsalicylic acid; *COX,* cyclooxygenase; *IM,* intramuscular; *IV,* intravenous; *NSAID,* nonsteroidal antiinflammatory drug; *PO,* oral; *PR,* rectal; *SR,* sustained release.

*Pregnancy category C/D = *C,* first trimester; *D,* third trimester.

†Pediatric dosing guidelines are not as well established, but the recommended range for IV, IM, or PO use is 0.4 to 1 mg/kg as a single dose for acute conditions (e.g., sports injury).

‡PO form is recommended only when transitioning from injectable form to oral form of ketorolac.

NSAIDs can also interfere with laboratory test results. Specifically, salicylates can cause what are usually minor and transient elevations in the levels of liver enzymes (ALT, AST), but, unlike with acetaminophen (see Chapter 10), cases of severe hepatotoxicity are rare. Hematocrit, hemoglobin level, and RBC count can drop if any drug-induced gastrointestinal bleeding does occur, and bleeding time may be prolonged. NSAID-induced hyperkalemia or hyponatremia can also occur.

Dosages

For dosage information on selected NSAIDs, see the table on this page.

DRUG PROFILES

SALICYLATES

Aspirin is the most commonly used of all salicylates. Although aspirin is available over the counter, many of the other salicylate drugs do require a prescription. These include diflunisal (Dolobid), choline magnesium trisalicylate (Trilisate), and salsalate (Salsitab). Salicylates are most commonly used in solid oral dosage forms (i.e., tablets, capsules). Other available dosage forms include a topical cream (Aspercreme), rectal suppositories, and oral liquids. Aspirin is also contained in many combination products, including aspirin/acetaminophen/caffeine combinations such as Excedrin and aspirin/antacid combinations (e.g., Bufferin). Aspirin also is available in special dosage forms, such as enteric-coated aspirin (Ecotrin), designed to protect the stomach mucosa by dissolving in the duodenum.

♦ aspirin

Aspirin is known chemically as acetylsalicylic acid (ASA). It is the prototype salicylate and NSAID and is the most widely used drug in the world. A daily aspirin tablet (81 mg or 325 mg) is now routinely recommended as prophylactic therapy for adults who have strong risk factors for developing coronary artery disease or stroke, even if they have no previous history of such an event. The 81-mg strength (which is traditionally thought of as "children's" aspirin) and the 325-mg strength appear to be equally beneficial for the prevention of thrombotic events. For this reason, the lower strength is often chosen for patients who have any elevated risk for bleeding, such as those with previous stroke history or history of peptic ulcer disease and those taking the anticoagulant warfarin (Coumadin). Aspirin is also often used to treat the pain associated with headache, neuralgia, myalgia, and arthralgia, as well as other pain syndromes resulting from inflammation. These include arthritis, pleurisy, and pericarditis. Patients with systemic lupus erythematosus may also benefit from aspirin therapy because of its antirheumatic effects. Aspirin is also used for its antipyretic action.

Aspirin and other salicylates all have one very specific contraindication. This drug class is contraindicated in children with flulike symptoms, because the use of these drugs has been strongly associated with Reye's syndrome. This is an acute and potentially life-threatening condition involving progressive neurologic deficits that can lead to coma and may also involve liver damage. It is believed to be triggered by viral illnesses such as influenza as well as by salicylate therapy itself, in the presence of a viral illness. Survivors of this condition may or may not suffer permanent neurologic damage.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	15-30 min	1-2 hr	5-9 hr	4-6 hr

ACETIC ACID DERIVATIVES

There are several acetic acid derivatives, and they are listed in Table 44-1. Indomethacin and ketorolac are the most commonly used.

♦ indomethacin

Like the other NSAIDs, indomethacin (Indocin) has analgesic, antiinflammatory, antirheumatic, and antipyretic properties. Its therapeutic actions are of particular use in the treatment of rheumatoid arthritis, osteoarthritis, acute bursitis or tendonitis, ankylosing spondylitis, and acute gouty arthritis. The drug is available for both oral and rectal use. An injectable form of the drug is also used intravenously (IV) to promote closure of patent ductus arteriosus, a heart defect that sometimes occurs in premature infants. It is also used for the treatment of preterm labor (see Chapter 34).

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30 min	2 hr	4.5 hr	4-6 hr

♦ ketorolac

Ketorolac (Toradol) is somewhat unique in that, although it does have some antiinflammatory activity, it is used primarily for its powerful analgesic effects. Its analgesic effects are comparable to those of narcotic drugs such as morphine, which can make it a desirable choice for opiate-addicted patients who have acute pain control needs, because ketorolac lacks the addictive properties of the opioids. Ketorolac is indicated for the treatment of moderate to severe acute pain such as that resulting from orthopedic injuries or surgery. Ketorolac can be given orally or by injection, and there is also a dosage form for ophthalmic use (see Chapter 57). It is available only by prescription. It is indicated for short-term use (up to 5 days) to manage moderate to severe acute pain. It is not indicated for treatment of minor pain or chronic pain. The main adverse effects of ketorolac include renal impairment, edema, gastrointestinal pain, dyspepsia, and nausea. It is important to note that the drug can only be used for 5 days, because of its potential adverse effects on the kidney and gastrointestinal tract.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV/IM	0.5 hr	1-2 hr	5-7 hr	4-6 hr

PROPIONIC ACID DERIVATIVES

♦ ibuprofen

Ibuprofen (Motrin, Advil) is the prototype NSAID in the propionic acid category, which also includes fenoprofen, flurbiprofen, ketoprofen, naproxen, and oxaprozin. Ibuprofen is the most commonly used of the propionic acid drugs because of the numerous indications for its use and because of its relatively safe adverse effect profile. It is often used for its analgesic effects in the management of rheumatoid arthritis, osteoarthritis, primary dysmenorrhea, gout, dental pain, and musculoskeletal disorders; in addition, it is used for its antipyretic actions. Naproxen is the second most commonly used NSAID, with a reportedly somewhat better adverse effect profile than

ibuprofen, as well as fewer drug interactions with angiotensin-converting enzyme inhibitors given for hypertension. Both drugs are available for oral use in both over-the-counter and prescription strengths. In 2011, an injectable form of ibuprofen became available.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-60 min (analgesic) 7 days (anti-inflammatory)	1-2 hr	2-4 hr	4-6 hr

CYCLOOXYGENASE-2 INHIBITORS

The COX-2 inhibitors were developed primarily to decrease the gastrointestinal adverse effects characteristic of other NSAIDs because of their COX-2 selectivity. However, they are not totally devoid of gastrointestinal toxicity. Gastritis and upper gastrointestinal bleeding have been reported with their use, although much less frequently than with the older NSAIDs. Originally there were three COX-2 inhibitors; however, because the use of rofecoxib (Vioxx) and valdecoxib (Bextra) was found to be associated with an increased risk for adverse cardiovascular events, including myocardial infarction, stroke, and death, they were removed from the U.S. market.

♦ celecoxib

Celecoxib (Celebrex) was the first COX-2 inhibitor and is the only one remaining on the market. It is indicated for the treatment of osteoarthritis, rheumatoid arthritis, acute pain symptoms, ankylosing spondylitis, and primary dysmenorrhea. It is available only for oral use. There is evidence that celecoxib may pose a risk of cardiovascular events similar to that associated with rofecoxib and valdecoxib. However, there is inconsistency in the literature regarding the true potential for these effects. Celecoxib currently remains on the U.S. market, although its use is now being monitored more closely by the FDA. Other adverse effects associated with celecoxib include headache, sinus irritation, diarrhea, fatigue, dizziness, lower extremity edema, and hypertension. COX-2 inhibitors have little effect on platelet function. Celecoxib is not to be used in patients with known sulfa allergy.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	3 hr	11 hr	4-8 hr

ENOLIC ACID DERIVATIVES

The enolic acid derivatives include piroxicam, meloxicam, and nabumetone. Piroxicam and meloxicam are very potent drugs that are commonly used in the treatment of mild to moderate osteoarthritis, rheumatoid arthritis, and gouty arthritis. Both are available only in oral dosage formulations and have contraindications similar to those of the other NSAIDs.

Nabumetone (Relafen) is better tolerated than some of the others in terms of gastrointestinal adverse effects. It is relatively nonacidic compared with most of the other NSAIDs, which may account for its improved gastrointestinal tolerance. Currently it is indicated only for the treatment of osteoarthritis and rheumatoid arthritis.

ANTIGOUT DRUGS

Gout is caused by the overproduction of uric acid or decreased uric acid excretion, or both. This overproduction and/or decreased excretion can often result in hyperuricemia (too much uric acid in the blood). Persons with gout either overproduce or underexcrete uric acid. When the body contains too much uric acid, deposits of uric acid crystals collect in tissues and joints. This causes an inflammatory response and extreme pain, because these crystals are like small needles that jab and stick into sensitive tissues and joints, which is an end product of purine metabolism. Purines are part of the normal dietary intake and are used to make the essential structural units of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). During purine metabolism, they are converted from hypoxanthine to xanthine and eventually to uric acid. The normal pathway for purine metabolism is depicted in Figure 44-2. This pathway is overactive in patients with gout and is reduced by antigout drug therapy. The goals of gout treatment are to decrease the symptoms of an acute attack and to prevent recurrent attacks.

DRUG PROFILES

Although specific antigout drugs are available, the NSAIDs (described earlier) are considered first-line therapy for most patients with gout. The specific antigout drugs—allopurinol, febuxostat, colchicine, probenecid, and sulfinpyrazone—are targeted at the underlying defect in uric acid metabolism, which causes either overproduction or underexcretion of uric acid (see Figure 44-2). Both of these pathologic processes lead to tissue accumulations of uric acid crystalline deposits (gouty deposits) and symptoms of gout. Not all gouty deposits occur within joints. Gouty arthritis is the condition in which one or more joints are inflamed due to the collection of gouty deposits inside the joint anatomy. This is also called *articular gout,* whereas gout that occurs in tissues outside of the joints is called *abarticular gout.*

♦ allopurinol

The beneficial effect of allopurinol (Zyloprim) in the relief of gout is the inhibition of the enzyme xanthine oxidase, which thereby prevents uric acid production. Allopurinol is indicated for patients whose gout is caused by the excess production of uric acid (hyperuricemia). Oxypurinol, a metabolite of allopurinol, also prevents uric acid production. Oxypurinol is available as an orphan drug for patients with hyperuricemia who are intolerant of allopurinol therapy. Allopurinol is also used to prevent acute tumor lysis syndrome (see Chapter 45).

Allopurinol is contraindicated in patients with a hypersensitivity to it. Significant adverse effects of the drug include agranulocytosis, aplastic anemia, and serious and potentially fatal

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

Reye's Syndrome

Reye's syndrome is associated with the administration of aspirin to children and teenagers and is a potentially life-threatening illness. Encephalopathy and liver damage are two of the serious complications resulting from Reye's syndrome, which usually occurs after a viral infection such as chickenpox or influenza B, during which time aspirin is often given to decrease fever. To reduce the risk for Reye's syndrome, aspirin or medications that contain aspirin must not be given to children or teenagers to treat viral illnesses or fever. Other names for aspirin include acetylsalicylic acid, acetylsalicylate, salicylic acid, and salicylate. Other drugs that can be used instead of aspirin to reduce fever and relieve pain include acetaminophen and ibuprofen. Check the label on any medication that is to be given to a child, because aspirin is contained in many over-the-counter drugs, for example, Alka-Seltzer, some Excedrin products, and Pepto-Bismol.

Signs and Symptoms of Reye's Syndrome

- Altered liver function
- Encephalopathy and fatty degeneration of the viscera, primarily in children and teenagers
- Changes in level of consciousness
- Coma, flaccid paralysis, loss of deep tendon reflexes
- Hypoglycemia
- Seizures
- Vomiting

Medical Management

- Provide supportive treatment in intensive care unit
- Maintain life functions, restore metabolic balance, and control cerebral edema
- Administer intravenous glucose (10% or higher) for treatment of hypoglycemia
- Monitor blood glucose level; insulin may be needed
- Administer vitamin K for clotting problems
- Give fresh frozen plasma if needed for significant bleeding
- Provide prophylactic antiepileptic drugs
- Monitor intracranial pressure
- Initiate cautious fluid administration
- Administer osmotic diuretics with steroids if needed to treat cerebral edema

Nursing Management

- Critical care setting often indicated for care of these patients
- Assess neurologic status, vital signs, and arterial and central venous pressures
- Monitor blood gas concentrations and intracranial pressure as ordered
- Control temperature to prevent elevations and increased O_2 demands
- Elevate the head of the bed
- Monitor intake and output
- Initiate hyperventilation (if patient is intubated and if ordered) to reduce intracranial pressure by lowering CO_2 levels and increasing O_2 levels
- Provide a quiet environment
- Handle gently
- Monitor for seizure activity
- Provide family support during critical phase of the illness
- Provide physical and emotional support for the child and family with recovery
- Ensure appropriate spiritual care
- Educate the public about Reye's syndrome and its life-threatening complications

Data from Mayo Foundation for Medical Education and Research: Reye's syndrome, September 17, 2011. Available at www.mayoclinic.com/health/reyes-syndrome/DS00142. Accessed October 14, 2011.

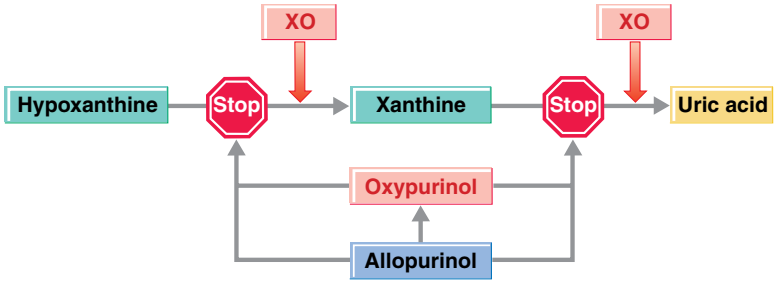

FIGURE 44-2 Uric acid production. *XO*, Xanthine oxidase.

skin conditions such as exfoliative dermatitis, Stevens-Johnson syndrome, and toxic epidermal necrolysis. Azathioprine and mercaptopurine both significantly interact with allopurinol, and, as a result, their dosages may have to be adjusted. Allopurinol is available only for oral use. The usual recommended adult dosage is 200 to 600 mg/day, and the maximum dosage is 800 mg/day. It is categorized as a pregnancy category C drug.

The new drug febuxostat (Uloric) is non-purine selective inhibitor of xanthine oxidase. It is the first new drug approved for the treatment of gout since the 1960s. It is more selective for xanthine oxidase than allopurinol and may pose a greater risk of cardiovascular events than allopurinol. It is not to be given along with theophylline, azathioprine, or mercaptopurine. It is dosed as 40 to 80 mg/day, with a maximum dose of 120 mg/day.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-2 wk	30-120 min	18-30 hr	Unknown

colchicine

Colchicine is the oldest available therapy for acute gout and is considered second-line therapy, after the NSAIDs. Colchicine appears to be effective in the treatment of gout by reducing the inflammatory response to the deposits of urate crystals in joint tissue. Its mechanism of action is not clearly defined, but it is thought to inhibit the metabolism, mobility, and chemotaxis of polymorphonuclear leukocytes. Chemotaxis is the chemical

attraction of leukocytes to the site of inflammation, which worsens an inflammatory response.

Colchicine is a powerful inhibitor of cell mitosis and can cause short-term leukopenia. For this reason, it is generally used for the short-term treatment of acute attacks of gout. However, it may be used for prophylaxis of acute attacks in dosages of 0.6 mg once or twice a day. The more severe adverse effects can include bleeding into the gastrointestinal or urinary tracts, and the drug needs to be stopped if such effects appear. Colchicine is contraindicated in patients with a known hypersensitivity to it and in those with severe renal, gastrointestinal, hepatic, or cardiac disorders, and blood dyscrasias. There is no specific antidote for colchicine poisoning. The drug is available in oral forms only. Until 2008, it was also available in an injectable form, but at that time the FDA asked that it no longer be manufactured in or shipped to the United States, because of the potential for life-threatening adverse effects. In 2010, the FDA required the withdrawal of all "unapproved" colchicine products that had been used for decades. Currently, there is only one FDA-approved colchicine product, Colcrys, which is an oral tablet.

For acute gout, colchicine is given in an initial dose of 0.6 to 1.2 mg, followed by 0.6 mg/hr until pain is relieved, the patient develops severe nausea and diarrhea, or a total of 6 mg has been administered. Some clinicians choose to limit the cumulative dose to 3 mg. When colchicine is used for treatment of acute gout, 3 days must pass before a second course of therapy is initiated. Colchicine dosage must be reduced with renal impairment. It is categorized as a pregnancy category D drug.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	12 hr	0.5-2 hr	12-30 min	12 hr

probenecid

Probenecid (generic) inhibits the reabsorption of uric acid in the kidney and thus increases the excretion of uric acid. Drugs that promote uric acid excretion are known as *uricosurics.* In some patients, gout is due to the underexcretion of uric acid. Probenecid works by binding to the special transporter protein in the proximal convoluted renal tubule that takes uric acid from the urine and places it back into the blood. The probenecid is then reabsorbed back into the bloodstream while the uric acid remains in the urine and is excreted. Besides being used to treat the hyperuricemia associated with gout and gouty arthritis, it also has the ability to delay the renal excretion of penicillin, which increases the serum levels of penicillin and prolongs its effect (see Chapter 38). Probenecid is available as a 500-mg oral tablet. The usual adult dosage is 250 mg twice a day with food, milk, or antacids for 1 week, followed by 500 mg twice daily thereafter. This dosage may be adjusted as needed to maintain desirable serum uric acid levels. Contraindications include peptic ulcer disease and blood dyscrasias. Probenecid is ineffective and is not to be used in patients with renal impairment. It is categorized as a pregnancy category B drug.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	3 hr	3-17 hr	8 hr

NURSING PROCESS

ASSESSMENT

Prior to giving an *antiinflammatory, antigout*, and/or related drugs, it is critical to patient safety and drug effectiveness to assess for drug allergies, contraindications, cautions, and drug interactions associated with each drug in these major groups. Before administering antiinflammatory drugs, perform a thorough head-to-toe physical assessment, measure vital signs, perform a nursing assessment, and take a thorough medication history, noting any prescription, over-the-counter, herbal, and/or alternative drugs that the patient is taking. Analyze results of laboratory tests reflecting hematologic, renal, and hepatic functioning before initiation of therapy as ordered, especially if long-term use is indicated. These tests will most likely include RBC count, hemoglobin level, hematocrit, WBC count, platelet count, BUN level, and liver enzyme levels such as ALP, AST, and LDH. If NSAIDs are used short-term for other conditions (e.g., fever, acute pain), laboratory studies are not usually indicated since these drugs are available over the counter and are self-administered.

With aspirin, NSAIDs, other *antiinflammatory* drugs, and *antigout* drugs, assess and document the duration, onset, location, and type of inflammation and/or pain the patient is experiencing as well as any precipitating, exacerbating, or relieving factors. Note any interference of the symptoms with the patient's ability to perform activities of daily living (ADLs). Inspect all joints with attention to deformities, immobility or limitations in mobility, overlying skin condition, and presence of any heat or swelling over the joint. Age is important to assess because aspirin and many of the other NSAIDs are not to be used in children and teenagers due to the increased risk for Reye's syndrome (see the Patient-Centered Care: Lifespan Considerations for the Pediatric Patient box on p. 714). These drugs are to be used very cautiously in elderly patients. Assessing the odor of aspirin is also important because a vinegary odor is associated with a chemical breakdown of the drug. With aspirin, assess the patient for a history of asthma, wheezing, or other respiratory problems because of the increased incidence of allergic reactions to aspirin in these individuals. With aspirin, identify patients who have been diagnosed with what is called the *aspirin triad,* which includes asthma, nasal polyps, and rhinitis. These conditions are considered to put the patient at risk for reactions to aspirin. Other contraindications, cautions, and drug interactions for aspirin and other NSAIDs have been discussed previously. Remember that salicylic acid or aspirin and other NSAIDs have antiinflammatory, antipyretic, analgesic, and antiplatelet activity but also carry a risk for ulcerogenic and gastrointestinal bleeding adverse effects. NSAIDs carry the risk for acute reversible hepatotoxicity, renal

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

Glucosamine and Chondroitin

Overview

Glucosamine is chemically derived from glucose. Its chemical name is 2-amino-2-deoxyglucose sulfate.

Chondroitin is a protein usually isolated from bovine (cow) cartilage. To date, there are no reports of any type of disease transmission from cows to humans with chondroitin.

Common Uses

These two supplements are often used in combination, and sometimes individually, to treat pain from osteoarthritis. Although they are most commonly taken orally, injectable forms are commercially available (e.g., for administration by naturopathic prescribers).

Adverse Effects

Glucosamine: Usually mild adverse effects that are comparable to those of placebo in clinical studies, including gastrointestinal discomfort, drowsiness, headache, and skin reactions.

Chondroitin: No major ill effects in studies lasting from 2 months to 6 years. Gastrointestinal discomfort is the most common adverse effect but is usually well tolerated.

Potential Drug Interactions

Both supplements: May enhance the anticoagulant effects of warfarin. The patient's international normalized ratio needs to be measured more frequently during glucosamine/chondroitin therapy, and the warfarin dosage adjusted if indicated.

Glucosamine: May cause an increase in insulin resistance, necessitating the need for higher dosages of oral hypoglycemics or insulin.

Contraindications

Both supplements: No specific contraindications listed, but avoidance during pregnancy is recommended due to lack of firm safety data.

failure, hearing loss, and noncardiogenic pulmonary edema, so a review of the patient's history of pre-existing medical conditions is important.

In addition to patient assessment, the use of ketorolac requires assessment of the drug order because it is important to be sure the drug has been ordered for a short term (e.g., no more than 5 days) and for patients experiencing moderate to severe acute pain. Assess the patient for underlying signs of infection before the use of any NSAID or other antiinflammatory drug, because these drugs may mask symptoms. With use of celecoxib, document any cardiovascular disorders or symptoms because use of the drug, as with rofecoxib and valdecoxib, carries a risk of cardiovascular events.

With *antigout* drugs, perform a thorough assessment of hydration status and baseline serum uric acid levels. Closely assess urinary output prior to and during drug therapy to ensure an output of at least 30 to 60 mL/hr. Determine and assess renal function through monitoring of BUN and serum creatinine as well as liver function through monitoring of ALP, AST, ALT, and LDH. If receiving febuxostat (Uloric), assess the patient for a history of cardiovascular disease due to risk of adverse effects linked to the cardiac system. Additionally, drug interactions may occur with theophylline, azathiaprine, or mercaptopurine. If the patient is taking allopurinol, assess the integrity of the skin due to potentially life-threatening skin adverse effects of exfoliative dermatitis, Stevens-Johnson syndrome, and toxic epidermal necrolysis. Assess blood counts because of the potential for aplastic anemia and agranulocytosis. With colchicine, conduct a thorough assessment for a history of gastrointestinal distress; ulcers; or cardiac, renal, or liver disease. When assessing the prescriber's order, remember that there is only one colchicine product available, Colcyrys, because of FDA recall. Also worthy of mentioning for antigout drugs (e.g., allopurinol, Colycrys, probenecid) is that these drugs may be used for either their short-term or long-term effects. Therefore, assess the order and indication for the antigout drug to ensure that the patient is receiving the appropriate treatment. Also assess for all contraindications, cautions, and drug interactions (see earlier discussion).

NURSING DIAGNOSES

1. Acute pain related to the disease process or injury to joints and other disease-affected areas
2. Deficient knowledge related to first-time drug therapy for treatment of a disease process
3. Risk for injury related to the effects of the disease and treatment on mobility and the performance of ADLs

PLANNING

GOALS

1. Patient experiences pain relief or relief of symptoms within the expected time frame.
2. Patient demonstrates increased knowledge about the disease process, medication regimen, and lifestyle changes.
3. Patient remains free from injury related to the disease process and/or drug regimen.

OUTCOME CRITERIA

1. Patient remains pain free or near pain free with adequate drug and nondrug therapy.
   - Patient states that pain and changes in joints and mobility are characteristic of inflammation, injury, or related disease processes and will decrease with effective therapy.
   - Patient identifies factors that aggravate or alleviate pain, such as movement, activity, exercise, and change in the weather or atmosphere.
   - Patient states nonpharmacologic measures to use to promote comfort, increase joint function and mobility, and increase performance of ADLs (e.g., biofeedback, imagery, massage, application of hot or cold packs, physical therapy, relaxation therapy).
2. Patient describes disease process requiring treatment with NSAID or antigout drug therapy.
   - Patient states impact of effective and consistent drug therapy in the prevention of damage to the part of the musculoskeletal system being impacted by disease process of injury, gout, arthritis, and so on.

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

NSAIDs

It is anticipated that by 2030 there will be more than 60 million Americans 65 years of age and older, exceeding 20% of the population. It is also anticipated that the use of over-the-counter NSAIDs will be widespread and increasing in this population and require special attention and education to prevent and/or minimize adverse effects. Understanding the physiologic changes of the elderly patient will help ensure safe and effective use of these medications.

The underlying pharmacokinetic characteristics and physical and biologic changes in elderly patients must be understood. Even if older patients have normal kidney and liver function, they have a reduced rate of drug metabolism and drug elimination compared with younger adults.

Patients 65 years of age and older do not have to be ill for NSAIDs to adversely affect them because of normal age-related physiologic changes. The presence of chronic or multiple illnesses may result in an increased incidence of adverse reactions.

Some changes noted in elderly patients that effect drug treatment include changes in renal elimination, protein binding, body composition, drug distribution, drug clearance, and sensitivity to drugs, as well as an increased incidence of adverse reactions to all types of medications.

Older patients who are at risk for renal insufficiency because of natural physiologic changes may experience changes in fluid balance as well as changes in drug reabsorption, excretion, and filtration processes. This may lead to drug toxicity.

Cardiac output decreases by 25% between 25 and 65 years of age, which results in decreased blood flow to the kidneys and, consequently, reduced glomerular filtration rate. There is also an overall decline in circulating blood volume, which may affect overall pharmacokinetics and lead to decreased drug absorption, distribution, metabolism, and excretion.

Many individuals older than 65 years of age become slow metabolizers of medications, which affects the way NSAIDs are handled by the liver. In addition, the liver decreases in size and weight with advancing age. Liver blood flow is also decreased. Drug metabolism is affected by these changes, resulting in the need to possibly decrease drug dosages and/or monitor very closely for toxicity.

Gastrointestinal functioning is impacted by aging, with a more acidic content of gastric juice and decreased gastric motility. This may lead to slower emptying of the stomach and result in decreased intestinal absorption and drug absorption. Serum levels of drugs, including NSAIDs, may be higher due to these changes, and the overall drug dosage may need to be decreased. It has also been documented that elderly individuals may be at increased risk for developing NSAID-related gastrointestinal problems.

Interventions to help decrease NSAID-related adverse reactions include asking questions, listing all drugs, teaching about all medications, and assessing the patient's gastrointestinal, cardiovascular, and neurologic systems, depending on patient complaints.

NSAID, Nonsteroidal antiinflammatory drug.

Data from Argoff CH: Optimal pain management in older patients, 2010, available at http://www.medscape.com/viewarticle/730074. Accessed July 2, 2011; Durrance S: Older adults and NSAIDs: avoiding adverse reactions, 2004, available at http://www.medscape.com/viewarticle/466796. Accessed July 2, 2011.

- Patient states adverse effects associated with NSAIDs or antigout therapy.
- Patient states symptoms to report to the prescriber immediately such as fever, increase in symptoms, joint pain, jaundice, changes in skin, severe rash, and so on.

3. Patient takes medication regimen as prescribed to prevent further damage and injury to self.
   - Patient contacts prescriber if lack of improvement in injury or disease process.
   - Patient maintains follow-up appointments with prescriber to enhance therapeutic effectiveness and minimize injury.

IMPLEMENTATION

If *aspirin*, an antigout drug is used, the oral dosage forms are given with food, milk, or meals. Advise the patient that sustained-release or enteric-coated tablets are not to be crushed or broken. Monitor serum levels of aspirin if aspirin therapy is used for its antiarthritic effect; however, this indication is very rare. Because of the high risk of adverse effects that may be severe, aspirin is mainly used in lower doses (e.g., 81 mg) for cardioprotective reasons. If used in higher doses, monitor for clinical presentation as well as serum aspirin levels to help distinguish among mild, moderate, and severe toxicity (see pharmacology discussion). If aspirin is used in higher doses, it is important to be aware of signs and symptoms of toxicity such as gastrointestinal bleeding, other bleeding, and abdominal pain. If these occur, report the findings to the prescriber for immediate treatment. If aspirin is used as an antipyretic, the patient's temperature generally begins to decrease within 1 hour. See the Patient Teaching Tips for more information on the safe use of aspirin.

Non-aspirin NSAIDs or other *antiinflammatory drugs* may also come in enteric-coated or sustained-release preparations; stress to the patient that these are not to be crushed or chewed. Oral dosage forms of these drugs—including ketorolac—may be taken with antacids or food to decrease gastrointestinal upset or irritation. Instruct the patient to report to the prescriber immediately any moderate to severe gastrointestinal upset, dyspepsia with nausea, vomiting, abdominal pain, or blood in the stool or vomitus. Advise the patient to avoid other ulcerogenic substances (e.g., alcohol, prednisone, aspirin-containing products, other NSAIDs) to help minimize the risk of gastrointestinal mucosal breakdown. During therapy with NSAIDs, continuously monitor the patient for bowel patterns, stool consistency, and any occurrence of gastrointestinal symptoms and/or dizziness, and document the findings. Monitor laboratory tests during high-dose or long-term treatment, including CBC; BUN levels; platelet counts; and serum bilirubin, ALP, AST, and ALT levels. Emphasize safe ambulation with NSAID use as well as with the use of any other antiinflammatory drugs and/or analgesics. With ketorolac, understand that dosing is not to exceed a 5-day period for either the oral, intramuscular, or IV dosage forms. Administer intramuscular injections slowly into a large muscle mass, and administer IV dosage forms over a period of no less than 15 seconds. Educate the patient to take celecoxib only as ordered and, as with the other NSAIDs, to avoid alcohol, aspirin, salicylates, and over-the-counter drugs containing any of these. Celecoxib may be taken without regard

to meals; however, taking the drug with food and fluids may decrease any gastrointestinal upset. Instruct the patient to report immediately to the prescriber any stomach or abdominal pain, gastrointestinal problems, unusual bleeding, blood in the stool or vomitus, chest pain, edema, and/or palpitations.

The *antigout drugs* are somewhat different from the NSAIDs, with different mechanisms of action and also very different nursing considerations. Colchicine needs to be taken on an empty stomach for more complete absorption but is best tolerated if given with food. Educate the patient with gout on the importance of increasing fluid intake of up to 3 L/day, unless contraindicated. Advise the patient to avoid alcohol and any over-the-counter cold relief products that contain alcohol while this medication is being taken. In addition, instruct the patient with gout that adherence to the complete medical regimen—both pharmacologic and nonpharmacologic—is critical to successful treatment. If allopurinol is prescribed, it is to be given with meals to minimize the occurrence of gastrointestinal symptoms such as nausea, vomiting, and anorexia. If allopurinol is to be administered in conjunction with chemotherapy (in an attempt to decrease hyperuricemia associated with malignancy and cell death from successful treatment), it is recommended that it be given a few days before the antineoplastic therapy. Patients taking allopurinol must also increase fluid intake to 3 L/day. Patients need to avoid hazardous activities if dizziness or drowsiness occurs with the medication. Alcohol and caffeine must also be avoided because these drugs will increase uric acid levels and decrease the level of allopurinol.

CASE STUDY

NSAIDs

A 49-year-old writer has developed severe pain in her right wrist and has been unable to make her publisher's deadlines because of the pain she is having. After magnetic resonance imaging and a physical examination, she is diagnosed with tendinitis and started on diclofenac (Voltaren) extended release, 75 mg twice a day. She is also given a wrist brace and instructed to resume work slowly once she is feeling better.

1. What instructions are important for her at this time?
2. After 1 week of therapy, she calls the office and says, "There has been no change! My wrist still hurts. I need to get better quickly!" What is the nurse's best response?

At her 1-month checkup, the writer is happy that her wrist has stopped hurting and that she has been able to resume her writing part time. She mentions, however, that she has felt very tired recently and has had increased abdominal discomfort. She also tells the nurse that her bowel movements have been darker and asks if that could be an adverse effect of the medicine.

3. Explain what is possibly happening, and what steps will be taken next.

For answers, see http://evolve.elsevier.com/Lilley.

EVALUATION

Aspirin and *NSAIDs* may vary in their potency and antiinflammatory and analgesic effects. Therapeutic responses to NSAIDs include the following: decrease in acute pain; decrease in swelling, pain, stiffness, and tenderness of a joint or muscle area; improved ability to perform ADLs; improved muscle grip and strength; reduction in fever; return to normal laboratory values for CBC and sedimentation rate; and return to a less inflamed state as evidenced by improved sedimentation rates, radiographic examination, computed tomographic scan, or magnetic resonance imaging. Monitoring for the occurrence of adverse effects and toxicity is essential to the safe and effective use of *antiinflammatory drugs* (aspirin, COX-II inhibitors, other NSAIDs) and *antigout drugs* (see Box 44-3 and Tables 44-2 and 44-3).

Therapeutic responses to the *antigout* drug colchicine include decreased pain in the affected joints and increased sense of well-being. Monitor the patient closely for any increased pain, blood in the urine, excessive fatigue and lethargy, or chills or fever, and contact the prescriber immediately should these occur. A therapeutic response to allopurinol, another antigout drug, includes a decrease in pain in the joints, a decrease in uric acid levels, and a decrease in stone formation in the kidneys.

PATIENT TEACHING TIPS

- Instruct the patient that these drugs—if in sustained-release or enteric-coated dosage forms—are not to be crushed or chewed. Instruct the patient to report to the prescriber immediately any ringing in the ears, persistent gastrointestinal or abdominal pain, or easy bruising or bleeding.
- Educate the patient that the full antiinflammatory effect of the drug may not be apparent immediately, depending on the specific drug. For example, onset of full therapeutic antiinflammatory action may take 7 days for ibuprofen or 30 to 60 minutes for its analgesic effects.
- Advise the patient to share a list of all medications with all health care providers/dentists especially if the patient is taking high dosages of aspirin or has been taking aspirin or other NSAIDs for prolonged periods. Aspirin and other NSAIDs are generally discontinued 1 week before any type of surgery, including oral or dental surgery, per the prescriber's or surgeon's orders.
- Always keep aspirin and other drugs out of the reach of children. If a child (or adult) has consumed large or unknown quantities of aspirin or other NSAIDs, contact a poison control center and/or seek emergency medical attention immediately. Children and teenagers must never take aspirin because of the risk of Reye's syndrome (see the Patient-Centered Care: Lifespan Considerations for the Pediatric Patient box on p. 714). Acetaminophen in the recommended dosage range is usually preferred.
- Educate the patient about the adverse effects of aspirin, such as gastrointestinal upset, nausea, vomiting, diarrhea, dizziness, and tinnitus. Table 44-3 lists the signs and symptoms of acute or chronic salicylate intoxication. Instruct the patient to report to the prescriber immediately any black or tarry stools, bleeding around the gums, petechiae (very small red-brown spots), ecchymosis (easy bruising), or purpura (large red spots).

PATIENT TEACHING TIPS—cont'd

- Inform the patient about the most common adverse effects of NSAIDs (see Table 44-2). Advise the patient to take NSAIDs with food, milk, or antacids to help minimize gastrointestinal distress.
- Educate the patient about the many drug interactions with aspirin, other NSAIDs, and antigout drugs.
- Alert the patient to look-alike sound-alike drugs, especially Celebrex (celecoxib), which may be confused with Celexa (citalopram) or Cerebyx (fosphenytoin).

KEY POINTS

- Antiinflammatory drugs include aspirin, NSAIDs, and COX-2 inhibitors.
- NSAIDs are one of the most commonly prescribed categories of drugs.
- The first drug in this category to be synthesized was salicylic acid or aspirin. Aspirin is often identified as and included in discussion of antiinflammatory drugs. NSAIDs have analgesic, antiinflammatory, and antipyretic activity; aspirin also has antiplatelet activity. NSAIDs are often used in the treatment of gout, osteoarthritis, juvenile arthritis, rheumatoid arthritis, dysmenorrhea, and musculoskeletal injuries such as strains and sprains.
- The three main adverse effects of NSAIDs are gastrointestinal intolerance, bleeding (often gastrointestinal bleeding), and renal impairment. Misoprostol (Cytotec) may be given to prevent gastrointestinal intolerance and ulcers resulting from NSAID use. It is classified as a prostaglandin analogue. There are also many contraindications to the use of NSAIDs, such as gastrointestinal tract lesions, peptic ulcers, and bleeding disorders.
- Most oral NSAIDs are better tolerated if taken with food to minimize gastrointestinal upset.
- When NSAIDs are used to decrease joint inflammation in arthritis patients, full therapeutic effects may not be experienced for 1 week or longer.
- Antigout drugs are indicated for either acute or chronic gout or gout prophylaxis. Diarrhea and abdominal pain are common adverse effects. Antigout drugs are often given to patients during cancer chemotherapy that causes cell death to avoid gout-like syndromes and pain.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 When a patient is receiving long-term NSAID therapy, which drug may be given to prevent the serious gastrointestinal adverse effects of NSAIDs?
   - **a** misoprostol (Cytotec)
   - **b** metoprolol (Lopressor)
   - **c** metoclopramide (Reglan)
   - **d** magnesium sulfate

2 The nurse recognizes that manifestations of NSAID toxicity include
   - **a** constipation.
   - **b** nausea and vomiting.
   - **c** tremors.
   - **d** urinary retention.

3 During a teaching session about antigout drugs, the nurse tells the patient that antigout drugs work by which mechanism?
   - **a** Increasing blood oxygen levels
   - **b** Decreasing leukocytes and platelets
   - **c** Increasing protein and rheumatoid factors
   - **d** Decreasing serum uric acid levels

4 When the nurse is teaching about antigout drugs, which statement by the nurse is accurate?
   - **a** "Drink only limited amounts of fluids with the drug."
   - **b** "This drug may cause limited movements of your joints."
   - **c** "There are very few drug interactions with these medications."
   - **d** "Colchicine is best taken on an empty stomach."

5 A mother calls the clinic to ask what medication to give her 5-year-old child for a fever during a bout of chickenpox. The nurse's best response would be:
   - **a** "Your child is 5 years old, so it would be okay to use children's aspirin to treat his fever."
   - **b** "Start with acetaminophen or ibuprofen, but if these do not work, then you can try aspirin."
   - **c** "You can use children's dosages of acetaminophen or ibuprofen, but aspirin is not recommended."
   - **d** "It is best to wait to let the fever break on its own without medication."

6 A 49-year-old patient has been admitted with possible chronic salicylate intoxication after self-treatment for arthritis pain. The nurse will assess for which symptoms of salicylate intoxication?
   - **a** Tinnitus
   - **b** Headache
   - **c** Constipation
   - **d** Nausea
   - **e** Bradycardia

7 An order for a child reads: "Give ibuprofen suspension 30 mg/kg/day, divided into four doses, for pain." The child weighs 33 pounds. How many milligrams will this child receive per dose?

1. a, 2. b, 3. d, 4. d, 5. c, 6. a, b, d, 7. 112.5 mg per dose

For Critical Thinking and Prioritization Questions, see http://evolve.elsevier.com/Lilley.

PART 8

Immune and Biologic Modifiers and Chemotherapeutic Drugs

STUDY SKILLS TIPS

Manage Time • Evaluate Prior Performance • Anticipate the Test • Plan for Distributed Study

MANAGE TIME

The first step in preparing for a chapter or part exam is to plan for the time needed. Let us begin by assuming that the next test you have will cover the chapters in Part 8. First, examine the material to determine just how much there is to cover. Look at the objectives, the key terms, and the number of pages of text in each chapter. This will help you determine just how big a task you face. As you are doing this, also consider how much study time you have been devoting to these chapters in the days before the exam. If you have been doing regular study with frequent review sessions, then the demand on your time in the day or two just before the exam will be less than if you have to do a major "cram" session to try to catch up on study that has been put off. The basic question to answer here is a simple one: "How much time do I need to schedule for exam preparation?" The answer varies with each student. Some will need 6, 8, or more hours of preparation time in the 2 to 3 days before the exam. Others will find that 3, 4, or 5 hours will be adequate. You must assess your own learning and prior success to determine what time is necessary for you, but you must set time aside and use it effectively.

There is one thing that should play a major role in helping you determine how much time you will need to set aside. Evaluate your performance on prior exams. How have you been doing? How much time have you been spending to achieve that level? If you are not achieving according to your capabilities, then you should certainly consider spending more time preparing for the next exam. If you are achieving at a satisfactory level, then plan on devoting about the same amount of time to test preparation as you have devoted before.

The next step in preparing for an exam is to organize the time. Write down what you are going to study and when, as well as how much time you will spend. Consider the following example based on the materials in Chapters 47 and 49:

1. Review Chapter 47 objectives. Monday, 4:00 to 4:30 PM. Note objectives that are unclear for further review.
2. Question and answer review. Monday, 4:30 to 5:15 PM.
3. Self-test, Chapter 47 key terms. Monday, 6:30 to 7:00 PM. Note terms that need further review for mastery.
4. Review Chapter 49 objectives. Monday, 7:00 to 7:30 PM.
5. Question and answer review. Monday, 7:30 to 8:00 PM.
6. Self-test, Chapter 49 key terms. Monday, 8:00 to 8:30 PM.

The advantage to this test preparation model is that you now know where you must focus in the days before the exam.

EVALUATE PRIOR PERFORMANCE

As you begin preparing to review for any exam, take some time to look back at previous exams. Evaluate your performance and use that evaluation to improve on subsequent tests. As you look at prior tests, consider the following factors.

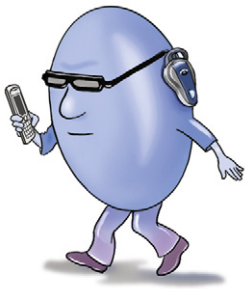
Did I Have Trouble with Questions That Required Mastery of Terminology?

As part of the evaluation of prior tests, also look at questions that demanded mastery of the terms from the chapters. If you missed more than one or two questions of that type, then you know you need to spend more time reviewing terminology.

Did I Miss Concept Questions?

If the question asked you to apply a principle, evaluate a drug response, or in some other way apply knowledge from the course, you are dealing with concepts rather than facts. If you missed a number of concept questions, then you should spend more of your review time studying applications and principles than memorizing facts and terms. Working with a study group may help you to improve your responses to concept questions.

Did I Make Errors Because I Did Not Know the Material?



This question focuses on the quality of your learning. If you miss one or two questions on an exam because you did not learn (or did not remember) the material, it is not a major problem. There will almost always be one or two questions that one does not remember. If you are analyzing past performance and find that there are several questions on which you guessed because you did not recall any information that seemed relevant to the question, it may be necessary to put more time into review. This may involve doing more oral rehearsal so that the material is stored in long-term memory. Whatever the cause, it is essential that you acknowledge to yourself that you have missed questions because you did not know the material. Once you have acknowledged the problem, take steps to correct it.

ANTICIPATE THE TEST

Do not wait until exam time to find out what you should know. As you do your review, try to think like the instructor. Generate questions that you think might be a part of the test. This does not mean you need to try to write multiple-choice stems and choices, but you should be trying to focus your review in a way that will facilitate learning and long-term memory. The process of working with a study group to anticipate test questions and to quiz each other can help move concepts from short-term memory to long-term memory.

Here are some examples of questioning that you might use based on material found in Chapter 47.

1. What are biologic response modifiers?
2. What is the role of biologic response modifiers in the care of patients with cancer?
3. What is the role of the immune system in treating cancer?

These sample questions were drawn from just the first few pages of the chapter. Some questions may focus on literal comprehension and are relatively easy to generate. Being able to answer them is important, but if all of your questions are literal, it may be difficult to answer questions that require application of principles and concepts. For that reason, it is essential that some questions require analysis, synthesis, and/or evaluation of the material. A study group is helpful in creating this more complicated type of question. The process of discussion can generate ideas you may not develop on your own. Answers to these questions require the learner to put together the literal information and relate the terms to the concepts being explained.

PLAN FOR DISTRIBUTED STUDY

One of the major problems that many students encounter when trying to review for a test is waiting too long to begin the review, which forces them into a review pattern of long hours of intensive study all packed into the last day or two before the exam. This is known as "cramming," and although cramming does work to some degree, it is not the most effective way to learn. A better model is to distribute the review over a period of several days with short study sessions of 30 minutes to 1 hour several times each day. Distributing practice in this way allows time for you to think about what you have been learning, and it fosters long-term memory. Studying with a group adds variety to your study time and provides another method of receiving and processing information.

One important consideration is spending more of the review time doing oral rehearsal ("ask and answer" sessions) and not simply rereading material. Oral rehearsal encourages active learning, which enhances your ability to concentrate, improves comprehension and memory, and thus improves test performance. Oral rehearsals work well in study groups, but if you are satisfied with the test results you get by reviewing alone, keep doing what works for you.

CHAPTER

45

Antineoplastic Drugs Part 1: Cancer Overview and Cell Cycle–Specific Drugs

evolve WEBSITE

http://evolve.elsevier.com/Lilley

- Animations
- Answer Key—Textbook Case Studies
- Critical Thinking and Prioritization Questions
- Key Points—Downloadable
- Review Questions for the NCLEX® Examination
- Unfolding Case Studies

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1. Briefly describe the concepts related to carcinogenesis.
2. Define the different types of malignancy.
3. Discuss the purpose and role of the various treatment modalities in the management of cancer.
4. Define *antineoplastic.*
5. Discuss the role of antineoplastic therapy in the treatment of cancer.
6. Contrast the cell cycle of normal cells and malignant cells with regard to growth, function, and response of the cell to chemotherapeutic drugs and other treatment modalities.
7. Compare the characteristics of highly proliferating normal cells (including cells of the hair follicles, gastrointestinal tract, and bone marrow) with the characteristics of highly proliferating cancerous cells.
8. Briefly describe the specific differences between cell cycle–specific and cell cycle–nonspecific antineoplastic drugs (cell cycle–nonspecific drugs and miscellaneous other antineoplastics are discussed in Chapter 46).
9. Identify the drugs that are categorized as cell cycle specific, including mitotic inhibitors, topoisomerase inhibitors, and antineoplastic enzymes.
10. Describe the common adverse effects and toxic reactions associated with the various antineoplastic drugs, including the causes for their occurrence and methods of treatment, such as antidotes for toxicity.
11. Discuss the mechanisms of action, indications, dosages, routes of administration, cautions, contraindications, and drug interactions of cell cycle–specific drugs, including mitotic inhibitors, topoisomerase inhibitors, and antineoplastic enzymes.
12. Apply knowledge about the various antineoplastic drugs to the development of a comprehensive nursing care plan for patients receiving cell cycle–specific drugs, including mitotic inhibitors, topoisomerase inhibitors, and antineoplastic enzymes.

DRUG PROFILES

- ♦ **asparaginase, p. 738**
- **capecitabine, p. 734**
- **cladribine, p. 734**
- ♦ **cytarabine, p. 734**
- ♦ **etoposide, p. 735**
- **fludarabine, p. 734**
- **fluorouracil, p. 734**
- **gemcitabine, p. 734**
- **irinotecan, p. 737**
- ♦ **methotrexate, p. 732**
- ♦ **paclitaxel, p. 736**
- **pegaspargase, p. 738**
- **topotecan, p. 737**
- ♦ **vincristine, p. 736**

♦ *Key drug*

KEY TERMS

Analogue A chemical compound with a structure similar to that of another compound but differing from it with respect to some component. (p. 730)

Anaplasia The absence of the cellular differentiation that is part of the normal cellular growth process (see *differentiation;* adjective: *anaplastic*). (p. 728)

Antineoplastic drugs Drugs used to treat cancer. Also called *cancer drugs, anticancer drugs, cancer chemotherapy,* and *chemotherapy.* (p. 728)

Benign Denoting a neoplasm that is noncancerous and therefore not an immediate threat to life. (p. 724)

Cancer A malignant neoplastic disease, the natural course of which is fatal (see *neoplasm*). (p. 724)

Carcinogen Any cancer-producing substance or organism. (p. 726)

Carcinomas Malignant epithelial neoplasms that tend to invade surrounding tissue and metastasize to distant regions of the body. (p. 724)

Cell cycle–nonspecific Denoting antineoplastic drugs that are cytotoxic in any phase of the cellular growth cycle. (p. 728)

Cell cycle–specific Denoting antineoplastic drugs that are cytotoxic during a specific phase of the cellular growth cycle. (p. 729)

Clone A cell or group of cells that is genetically identical to a given parent cell. (p. 724)

Differentiation An important part of normal cellular growth in which immature cells mature into specialized cells. (p. 724)

Dose-limiting adverse effects Adverse effects that prevent an antineoplastic drug from being given in higher dosages, often restricting the effectiveness of the drug. (p. 729)

Emetic potential The potential of a drug to cause nausea and vomiting. (p. 729)

Extravasation The leakage of any intravenously or intraarterially administered medication into the tissue space surrounding the vein or artery. Such an event can cause serious tissue injury, especially with antineoplastic drugs. (p. 729)

Gene expression How a cell expresses a receptor or gene; the process in which information from a gene is used in the synthesis of a gene product. (p. 726)

Growth fraction The percentage of cells in mitosis at any given time. (p. 728)

Intrathecal A route of drug injection through the theca of the spinal cord and into the subarachnoid space. This route is used to deliver certain chemotherapy medications to kill cancer cells in the central nervous system. (p. 734)

Leukemias Malignant neoplasms of blood-forming tissues characterized by the replacement of normal bone marrow cells with leukemic blasts resulting in abnormal numbers and forms of immature white blood cells in the circulation. (p. 724)

Lymphomas Malignant neoplasms of lymphoid tissue. (p. 724)

Malignant Tending to worsen and cause death; anaplastic, invasive, and metastatic. (p. 724)

Metastasis The process by which a cancer spreads from the original site of growth to a new and remote part of the body (adjective: *metastatic*). (p. 724)

Mitosis The process of cell reproduction occurring in somatic (nonsexual) cells and resulting in the formation of two genetically identical daughter cells containing the diploid (complete) number of chromosomes characteristic of the species. (p. 727)

Mitotic index The number of cells per unit (usually 1000 cells) undergoing mitosis during a given time. (p. 728)

Mutagen A chemical or physical agent that induces or increases genetic mutations by causing changes in deoxyribonucleic acid (DNA). (p. 726)

Mutation A permanent change in DNA that is transmissible to future cellular generations. Mutations can transform normal cells into cancer cells. (p. 724)

Myelosuppression Suppression of bone marrow function, which can result in dangerously reduced numbers of red blood cells, white blood cells, and platelets. (p. 729)

Nadir Lowest point in any fluctuating value over time; for example, the lowest white blood cell count measured after the count has been depressed by chemotherapy. (p. 729)

Neoplasm Any new and abnormal growth, specifically growth that is uncontrolled and progressive; a synonym for *tumor.* A malignant neoplasm or tumor is synonymous with *cancer.* (p. 724)

Nucleic acids Molecules of DNA and ribonucleic acid (RNA) in the nucleus of every cell (hence the name *nucleic acid*). Chromosomes are made up of DNA and encode all of the genes necessary for cellular structure and function. (p. 726)

Oncogenic Cancer producing; often applied to tumor-inducing viruses. (p. 726)

Paraneoplastic syndromes Symptom complexes arising in patients with cancer that cannot be explained by local or distant spread of their tumors. (p. 725)

Primary lesion The original site of growth of a tumor. (p. 724)

Sarcomas Malignant neoplasms of the connective tissues arising in bone, fibrous, fatty, muscular, synovial, vascular, or neural tissue, often first presenting as painless swellings. (p. 724)

Tumor A new growth of tissue characterized by a progressive, uncontrolled proliferation of cells. Tumors can be solid (e.g., brain tumor) or circulating (e.g., leukemia or lymphoma), and benign (noncancerous) or malignant (cancerous). Circulating tumors are more precisely called *hematologic tumors* or *hematologic malignancies.* A tumor is also called a *neoplasm.* (p. 724)

Tumor lysis syndrome A common metabolic complication of chemotherapy for rapidly growing tumors. It is characterized by the presence of excessive cellular waste products and electrolytes, including uric acid, phosphate, and potassium, and by reduced serum calcium levels. (p. 731)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Cancer is a broad term encompassing a group of diseases that are characterized by cellular transformation (e.g., by genetic **mutation**), uncontrolled cellular growth, possible invasion into surrounding tissue, and metastasis to other tissues or organs distant from the original body site. This cellular growth differs from normal cellular growth in that cancerous cells do not possess a growth control mechanism. Lack of cellular **differentiation** or maturation into specialized, productive cells is also a common characteristic of cancer cells. Figure 45-1 illustrates the multiple steps involved in the development of cancer. Cancerous cells will continue to grow and invade adjacent structures. They may break away from the original tumor mass and travel by means of the blood or lymphatic system to establish a new clone of cancer cells and create a metastatic growth elsewhere in the body. A **clone** is a cell or group of cells that is genetically identical to a given parent cell. For the remainder of this and the next chapter, the term *cancer* will generally be used to refer to any type of malignant neoplasm.

Metastasis refers to the spreading of a cancer from the original site of growth **(primary lesion)** to a new and remote part of the body (secondary or metastatic lesion). The terms *malignancy, neoplasm,* and *tumor* are often used as synonyms for *cancer*. A **neoplasm** ("new tissue") is a mass of new cells. It is another term for **tumor.** There are two types of tumors: benign and malignant. A **benign** tumor is of a uniform size and shape and displays no invasiveness (in terms of infiltrating other tissues) or metastatic properties. The terms *nonmalignant* and *benign* suggest that tumors may be harmless, which is true in most cases. However, a benign tumor can be lethal if it grows large enough to mechanically interrupt the normal function of a critical tissue or organ. **Malignant** neoplasms consist of cancer cells that invade (infiltrate) surrounding tissues and metastasize to other tissues and organs. Some of the various characteristics of benign and malignant neoplasms are listed in Table 45-1.

Over 100 types of cancer affect humans. Various tumor types based on tissue categories include sarcomas, carcinomas, lymphomas, leukemias, and tumors of nervous tissue origin. Examples of these common types of malignant tumors are presented in Table 45-2. It is important to know the tissue of origin, because this determines the type of treatment, the likely response to therapy, and the prognosis.

Carcinomas arise from epithelial tissue, which is located throughout the body. This tissue covers or lines all body surfaces, both inside and outside the body. Examples are the skin, the mucosal lining of the entire gastrointestinal (GI) tract, and the lining of the bronchial tree (lungs). The purpose of these epithelial tissues is to protect the body's vital organs.

Sarcomas are malignant tumors that arise primarily from connective tissues, but some sarcomas are tumors of epithelial cell origin. Connective tissue is the most abundant and widely distributed of all tissues and includes bone, cartilage, muscle, and lymphatic and vascular structures. Its purpose is to support and protect other tissues.

Lymphomas are cancers within the lymphatic tissues. **Leukemias** arise from the bone marrow and are cancers of blood and bone marrow. Leukemias differ from carcinomas and sarcomas in that the cancerous cells do not form solid tumors but are interspersed throughout the lymphatic or circulatory system and interfere with the normal functioning of these systems. For

TABLE 45-1 TUMOR CHARACTERISTICS: BENIGN AND MALIGNANT

CHARACTERISTIC	BENIGN	MALIGNANT
Potential to metastasize	No	Yes
Encapsulated	Yes	No
Similar to tissue of origin	Yes	No
Rate of growth	Slow	Unpredictable and unrestrained
Recurrence after surgical removal	Rare	Common

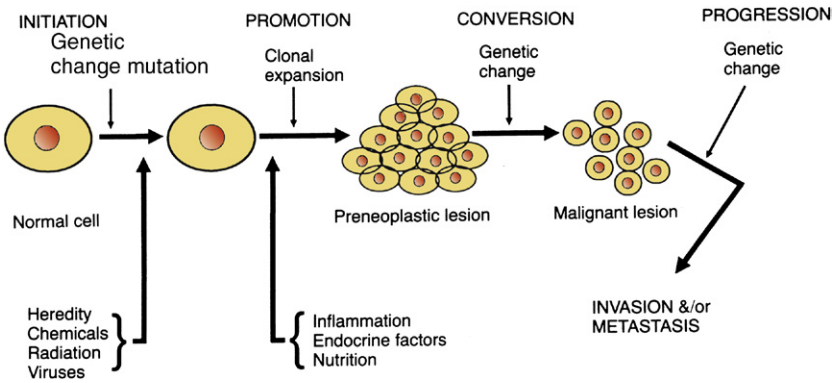


FIGURE 45-1 Schematic model of multistep carcinogenesis. Genetic change refers to events such as the activation of protooncogenes or drug resistance genes or the inactivation of tumor suppressor genes, antimetastasis genes, or apoptosis (normal cell death). Genetic change may be relatively minimal, as with the translocations seen in various leukemias, or it may involve multiple sequential genetic alterations, as exemplified by the development of colon cancer. (From Haskell CM: *Cancer treatment,* ed 5, Philadelphia, 2001, Saunders.)

this reason, they are sometimes referred to as *circulating tumors,* although *hematologic malignancy* is a more precise term. Lymphomas can be quite bulky and are usually classified as solid tumors.

Cancer patients may also experience various groups of symptoms that cannot be directly attributed to the spread of a cancerous tumor. Such symptom complexes are referred to as **paraneoplastic syndromes.** They are estimated to occur in up to 15% of patients with cancer and may even be the first sign of malignancy. *Cachexia* (general ill health and malnutrition) is the most common such symptom complex. Examples of other common paraneoplastic syndromes are given in Table 45-3. These syndromes are believed to result from the effects of biologically or immunologically active substances, such as hormones and antibodies, secreted by the tumor cells. Many patients also exhibit more generalized symptoms, such as anorexia, weight loss, fatigue, and fever.

TABLE 45-2 TUMOR CLASSIFICATION BASED ON SPECIFIC TISSUE OF ORIGIN

TISSUE OF ORIGIN	MALIGNANT TISSUE
Epithelial = Carcinomas	
Glands or ducts	Adenocarcinomas
Respiratory tract	Small and large cell carcinomas
Kidney	Renal cell carcinoma
Skin	Squamous cell, epidermoid, and basal cell carcinoma; melanoma
Connective = Sarcomas	
Fibrous tissue	Fibrosarcoma
Cartilage	Chondrosarcoma
Bone	Osteogenic sarcoma (Ewing's tumor)
Blood vessels	Kaposi's sarcoma
Synovia	Synoviosarcoma
Mesothelium	Mesothelioma
Lymphatic = Lymphomas	
Lymph tissue	Lymphomas (e.g., Hodgkin's, non-Hodgkin's)
Glia	Glioma
Adrenal medulla nerves	Pheochromocytoma
Blood and Bone Marrow	
White blood cells	Leukemia
Bone marrow	Multiple myeloma

TABLE 45-3 PARANEOPLASTIC SYNDROMES ASSOCIATED WITH SOME CANCERS

PARANEOPLASTIC SYNDROME	ASSOCIATED CANCER
Hypercalcemia, sensory neuropathies, SIADH	Lung
Disseminated intravascular coagulation	Leukemia
Cushing's syndrome	Lung, thyroid, testes, adrenal
Addison's syndrome	Adrenal, lymphoma

SIADH, Syndrome of inappropriate secretion of antidiuretic hormone.

ETIOLOGY OF CANCER

The etiology of cancer remains a mystery for the most part, and cancer researchers have made slow progress toward identifying possible causes. Certain etiologic factors have been identified, and some of these factors and the cancers with which they are causally associated are listed in Table 45-4. Causative factors that have been identified include age-related and sex-related characteristics; genetic and ethnic factors; oncogenic viruses; environmental and occupational factors; radiation; and immunologic factors.

Age- and Sex-Related Differences

The probability that a neoplastic disease will develop generally increases with advancing age. A number of rare cancers, such as acute lymphocytic leukemia and Wilms tumor, occur predominantly in pediatric patients.

With the exception of cancers affecting the reproductive system, few cancers exhibit a sex-related difference in incidence. Lung and urinary cancers are more common in men than in women, but this may have more to do with exogenous factors such as smoking patterns and occupational exposure to environmental toxins than to sex-related characteristics. The incidence of colon, rectal, pancreatic, and skin cancers are comparable

TABLE 45-4 CANCER: PROPOSED ETIOLOGIC FACTORS

RISK FACTOR	ASSOCIATED CANCER
Environment	
Radiation (ionizing)	Leukemia, breast, thyroid, lung
Radiation (ultraviolet)	Skin, melanoma
Viruses	Leukemia, lymphoma, nasopharyngeal
Food	
Aflatoxin	Liver
Dietary factors	Colon, breast, endometrial, gallbladder
Lifestyle	
Alcohol	Esophageal, liver, stomach, laryngeal, breast
Tobacco	Lung, oral, esophageal, laryngeal, bladder
Medical Drugs	
Diethylstilbestrol (DES)	Vaginal in offspring, breast, testicular, ovarian
Estrogens	Endometrial, breast
Alkylating drugs	Leukemia, bladder
Occupational	
Asbestos	Lung, mesothelioma
Aniline dye	Bladder
Benzene	Leukemia
Vinyl chloride	Liver
Reproductive History	
Late first pregnancy, early menses	Breast
No children	Ovarian
Multiple sexual partners	Cervical, uterine

in men and women. A number of hematologic cancers have a slight male predominance.

Genetic and Ethnic Factors

Few cancers have been confirmed to have a hereditary basis (some types of breast, colon, and stomach cancer are exceptions). The understanding of tumor biology has helped guide therapy tremendously. Two such advances are determination of hormone receptor status and identification of specific **gene expression** in various types of tumor cells. For example, some tumor cells express themselves on their cell membrane surfaces, either estrogen receptors or progesterone receptors, and some tumor cells express specific genes such as the *HER2/neu* gene. Because these indicators aid in classification of a patient's tumor, they also help in choosing appropriate drug therapy, predicting response to therapy, and anticipating prognosis. Discovery of the *BRCA1* and *BRCA2* genes has allowed identification of women who are at risk of breast cancer because they have a certain alteration in one of these *BRCA* genes. Many women with a family history of breast cancer choose to be tested for the presence of a *BRCA* gene mutation, which has led some women to undergo prophylactic breast removal. Tumors with identifiable gene expression patterns can show a familial pattern of inheritance. For example, Burkitt's lymphoma is more common in young African children and children of African descent. Another example of an ethnic predisposition is the high incidence of nasopharyngeal cancer in persons of Chinese descent. These associations with race are complicated by a well-recognized viral pathogenesis for both diseases.

Oncogenic Viruses

Extensive research has indicated that there are cancer-causing **(oncogenic)** viruses that can affect most mammalian species. Examples include human papillomavirus, the various cat leukemia viruses, the Rous sarcoma virus in chickens, and the Shope papillomavirus in rabbits.

The herpesviruses are common examples of oncogenic viruses. Epstein-Barr virus is a type of herpesvirus. It is most commonly recognized as the cause of infectious mononucleosis (commonly referred to as "mono" or the "kissing disease"). However, it is also associated with the development of Burkitt's lymphoma and nasopharyngeal cancer. Infection with human papillomavirus (often abbreviated as HPV) has been linked to both cervical and anal cancer.

Occupational and Environmental Carcinogens

A **carcinogen** is any substance that can cause cancer. In the nucleus of every cell are found molecules of **nucleic acids,** so named because of their location in the cell nucleus. The two types of nucleic acids are deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). DNA molecules are the master molecules of genetic material within cells and contain the approximately 30,000 genes of the human genome. Genes are transcribed into messenger RNA molecules, which in turn are translated into protein molecules necessary for cellular structure and function. This process is discussed further in the section on alkylating drugs in Chapter 46. A **mutagen** is any substance or physical agent (e.g., radiation) that induces changes in DNA molecules. Mutations often transform normal cells into cancer cells. Thus, mutagenicity is associated with and often (but not always) leads to carcinogenicity. The U.S. Food and Drug Administration (FDA) mandates that carcinogenic studies be performed before any new drug is approved for use. However, no amount of clinical testing can fully reveal all of a drug's possible carcinogenic effects. Carcinogenic effects may not be observed in the laboratory animals on which the drug has been tested but may be reported when the drugs are used in human subjects. Given the relatively small numbers of patients tested in clinical research trials, the carcinogenic potential of a given drug may not be observed until after the drug is marketed for use in the general population. If patterns of carcinogenicity begin to emerge during this period of postmarketing surveillance (or postmarketing studies), the drug may be recalled from the market.

Radiation

Radiation is a well-known and potent carcinogenic agent. There are two basic types of radiation: (1) ionizing, or high-energy, radiation, and (2) nonionizing, or low-energy, radiation. Both types can be carcinogenic. Ionizing radiation is very potent and can penetrate deeply into the body. It is called *ionizing* because it causes the formation of ions within living cells. This type of radiation (e.g., that used in radiographic studies) is also used to treat (irradiate) cancerous tumors (e.g., radium implants). Nonionizing radiation is much less potent and cannot penetrate deeply into the body. Ultraviolet light is an example of this type of radiation and is the cause of skin cancer. In contrast to chemotherapy, radiation therapy is considered to be a locoregional and not a systemic cancer treatment. Adverse effects of radiation therapy (e.g., radiation burns; nausea with GI tract irradiation) tend to be more localized to the site of treatment as well. Scientific specialists known as *radiation oncologists* are involved in the planning of radiation treatments, including calculation of the appropriate dose (dosimetry).

Immunologic Factors

The immune system plays an important role in the body in terms of cancer surveillance and the elimination of neoplastic cells. Neoplastic cells are believed to develop in everyone; however, a healthy person's immune system recognizes them as abnormal and eliminates them by means of cell-mediated immunity (cytotoxic T lymphocytes; see Chapter 47). It has also been shown that the incidence of cancer is much higher in immunocompromised individuals. The relationship between cancer and a suppressed immune system has also been noted in cancer patients being treated with immunosuppressive drugs after organ transplantation. The higher rates of cancers such as skin cancer and lymphoma in transplant patients is a result of this aggressive use of drugs to prevent organ rejection.

Cell Growth Cycle

Normal cells in the body divide (proliferate) in a controlled and organized fashion, and this growth is regulated by various mechanisms. In contrast, cancer cells lack such regulatory mechanisms and divide uncontrollably. Often the growth of

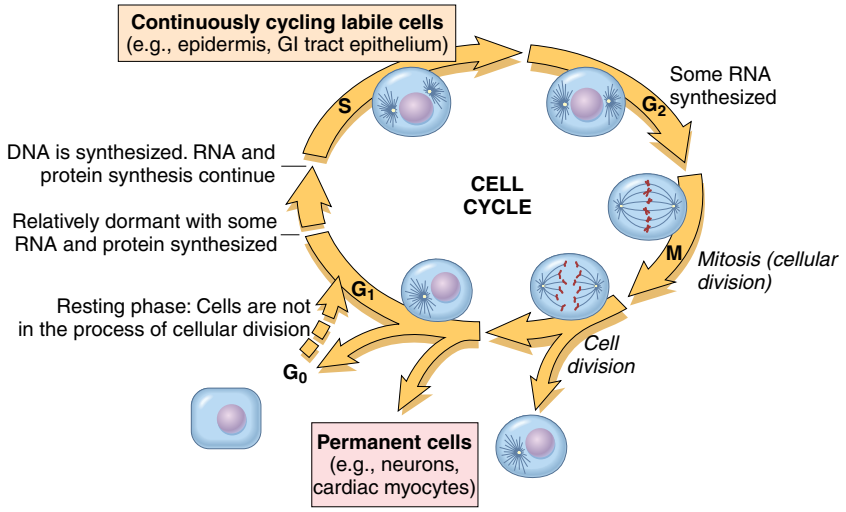

FIGURE 45-2 Cell life cycle and metabolic activity. Generation time is the period from M phase to M phase. Cells not in the cycle but capable of division are in the resting phase (G_0). (From Lewis SL, Dirksen SR, Heitkemper MM, et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 8, St. Louis, 2011, Mosby).

TABLE 45-5 CELL CYCLE PHASES

PHASE	DESCRIPTION
G_0: Resting phase	Most normal human cells exist predominantly in this phase. Cancer cells in this phase are not susceptible to the toxic effects of cell cycle–specific drugs.
G_1: First gap phase or postmitotic phase	Enzymes necessary for DNA synthesis are produced.
S: DNA synthesis phase	DNA synthesis takes place, from DNA strand separation to replication of each strand to create duplicate DNA molecules.
G_2: Second gap phase or premitotic phase	RNA and specialized proteins are made.
M: Mitosis phase	Divided into four subphases: prophase, metaphase, anaphase, and telophase; cell divides (reproduces) into two daughter cells.

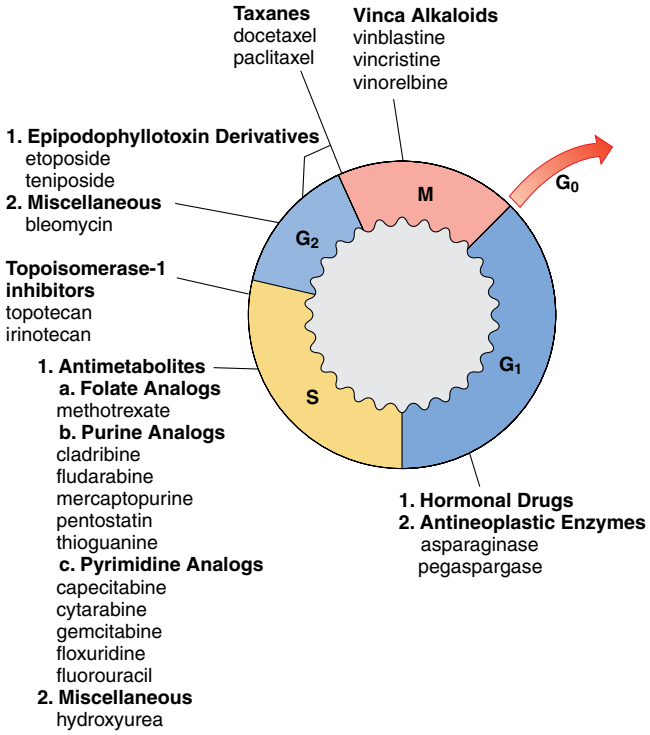

FIGURE 45-3 General phase of the cell cycle in which the various cell cycle–specific chemotherapeutic drugs have their greatest proportionate kill of cancer cells.

cancer cells is more constant or continuous than that of nonmalignant cells. Thus, one important growth index for malignant tumors is the time it takes for the tumor to double in size. This doubling time varies greatly for various types of cancers and is directly related to and important in determining the prognosis. Cancer treatment that cannot destroy every neoplastic cell does not prevent the regrowth of the tumor. The time it takes for regrowth to occur depends on the doubling time of the particular cancer. For instance, Burkitt's lymphoma has an extremely short doubling time. This shorter doubling time is associated with a tumor that, although it may be chemosensitive, is often difficult to cure due to rapid regrowth.

The cell growth characteristics of normal and neoplastic cells are similar. Both types of cells pass through five distinct gap phases: G_0, the resting phase, in which the cell is considered out of the cell cycle; G_1, the first gap phase; S, the synthesis phase; G_2, the second gap phase; and M, the **mitosis** phase (Figure 45-2). During mitosis, one cell divides into two identical daughter cells. Mitosis is further subdivided into four distinct subphases related to the time periods before and during the alignment and separation of the chromosomes (DNA strands): prophase, metaphase, anaphase, and telophase. A complete cell cycle from one mitosis to the next is called the *generation time.* It is different for all tumors, ranging from hours to days. The cell growth cycle and the events that occur in the various phases are summarized in Table 45-5. Figure 45-3 shows where in the general phases of the cell cycle the various cell cycle–specific chemotherapeutic drugs show their greatest activity.

The growth activity in a mass of tumor cells has an important bearing on the killing power of chemotherapeutic drugs. The percentage of cells undergoing mitosis at any given time is called the **growth fraction** of the tumor. The actual number of cells that are in the M phase of the cell cycle is called the **mitotic index.** Chemotherapy is most effective when used in a rapidly dividing or highly proliferative tumor.

Hematopoietic stem cells are cells in the bone marrow that have the capacity for self-renewal and repopulation of the different types of blood and bone marrow cells. In the bone marrow, the hematopoietic stem cell divides asynchronously, regenerating itself while producing a cell that will go through a series of cell divisions to produce mature blood cells. Tumors in the bone marrow that affect a cell close to the stem cell are unable to mature and are considered poorly differentiated. The level of differentiation within a tumor, whether solid or circulating, becomes especially important in the treatment of neoplasms. This is because more highly differentiated tumors generally have a better therapeutic response (tumor shrinkage) to treatments such as chemotherapy and radiation. In contrast, some cancers, such as leukemia, involve proliferation of immature white blood cells (WBCs) known as *blast cells.* Cancers with a larger proportion of such undifferentiated cells are often less responsive to chemotherapy or radiation and therefore are more difficult to treat. Lack of normal cellular differentiation is known as **anaplasia,** and such undifferentiated cells are said to be *anaplastic* cells.

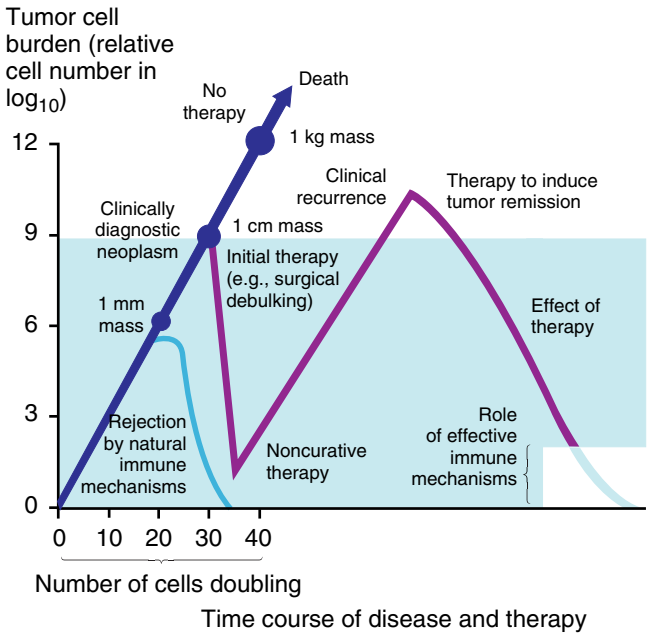

FIGURE 45-4 Relationship between tumor cell burden and phases of cancer treatment. (From McCance KL: *Pathophysiology: The biologic basis for disease in adults and children,* ed 5, St Louis, 2006, Mosby.)

PHARMACOLOGY OVERVIEW

CANCER DRUG NOMENCLATURE

The more technical term for cancer is *malignant neoplasm.* Drugs used to treat cancer are therefore known as **antineoplastic drugs** but are also called *cancer drugs, anticancer drugs,* and, most commonly, *cytotoxic chemotherapy* or just *chemotherapy.* The nomenclature (naming system) of cancer drugs can be somewhat more complex and confusing than that for other drug classes. Cancer treatment is an intensively researched area in health care with many active research protocols. Multiple names are often used for the same drug, depending on its stage of development.

Recall from Chapter 2 that medications have a chemical name, a generic name, and a trade name. This section introduces yet another name for medications, especially cancer drugs: the investigational or protocol name. A drug's chemical name is used by the chemists who first discover and work with the drug. The generic name is frequently first assigned to a chemical compound after a pharmaceutical manufacturer has determined that it is worthy of continued clinical research. It is often at this point that the chemical compound becomes an investigational drug. The trade name is a marketing name used by the manufacturer of a given drug primarily to market the drug. During the time before marketing and while a given medication is undergoing clinical research, it is frequently referred to by its protocol name. The protocol name is often a code name that consists of a combination of letters and numbers separated by one or more dashes. Although investigational drugs for all disease classes usually have some kind of protocol name, protocol names tend to be used more commonly in patient care settings for cancer drugs than for other drug classes. Here are two typical examples that illustrate these concepts:

Other Name	Generic Name	Trade Name
STI-571 (protocol name)	imatinib	Gleevec
5-fluorouracil* (chemical name)	fluorouracil	Adrucil

*The "5" refers to the position of a fluorine atom in the cyclic ring structure of the uracil molecule.

DRUG THERAPY

Cancer is normally treated using one or more of three major medical approaches: surgery, radiation therapy, and chemotherapy. The term *chemotherapy* is a general term that technically can refer to chemical (drug) therapy for any kind of illness. In practice, however, this term usually refers to the pharmacologic treatment of cancer.

Normal cells in the body divide (proliferate) in a controlled and organized fashion, and this growth is regulated by means of various mechanisms. In contrast, cancer cells lack regulatory mechanisms, and they proliferate uncontrollably. Figure 45-4 shows how various combinations of cancer treatment may succeed, or fail, over time.

Cancer chemotherapy drugs can be subdivided into two main groups based on where in the cell cycle they have their effects. Antineoplastic drugs that are cytotoxic (cell killing) in any phase of the cycle are called **cell cycle–nonspecific** drugs.

Those drugs that are cytotoxic during a specific cell cycle phase are called **cell cycle–specific** drugs. These are broad categories that describe the activity of a drug with regard to cell cycle. Individual drugs may have actions that fall into both of these categories. Regardless of the cell cycle characteristics of a drug, it is more effective on rapidly growing tumors. This chapter discusses the cell cycle–specific drugs. Chapter 46 focuses on cell cycle–nonspecific drugs as well as various miscellaneous antineoplastic drugs.

The ultimate goal of any anticancer regimen is to kill every neoplastic cell and produce a cure, but this goal is not achieved in most cases. Fortunately, some patients' immune systems may be able to clear the remaining tumor. Factors that affect the chances of cure and the length of patient survival include the cancer stage at time of diagnosis, the type of cancer and its doubling time, the efficacy of the cancer treatment, the development of drug resistance, and the general health of the patient. When total cure is not possible, the primary goal of therapy is to control the growth of the cancer while maintaining the best quality of life for the patient with the least possible level of discomfort and fewest treatment adverse effects.

It must be emphasized that cancer care and treatment involve many rapidly evolving medical sciences. Cancer is an intensively researched area, with the ultimate goals being to prevent cancer and to prevent premature death. Chemotherapy medications are often dosed as part of complex, specific treatment protocols that are subject to frequent revision by oncology clinicians and researchers. For these reasons, you must recognize that the drug dosing information provided in this chapter is intended only to be representative of current cancer treatment and is not absolute or comprehensive. Furthermore, the indications that are listed for each specific drug are the primary FDA-approved indications that are current at the time of this writing. These, too, may change unpredictably with time as a given drug is determined to be more (or less) effective for treating certain types of cancer. Also, in clinical practice, patients are often treated with one or more antineoplastic medications in "off-label" uses; that is, the drug is not currently approved for those particular uses by the FDA.

No antineoplastic drug is effective against all types of cancer. Most cancer drugs have a low therapeutic index, which means that a fine line exists between therapeutic and toxic levels. Clinical experience has shown that a combination of drugs is usually more effective than single-drug therapy. Because drug-resistant cells often develop, exposure to multiple drugs with multiple mechanisms and sites of action will destroy more subpopulations of cells. The delayed onset of resistance to a particular antineoplastic drug is one benefit of combination drug therapy. To be most effective, however, the drugs used in such a combination regimen would ideally possess the following characteristics:

- Some efficacy even as single drugs in the treatment of the particular type of cancer
- Different mechanisms of action so that the cytotoxic effect is maximized; this includes differences in cell cycle specificity
- No or minimal overlapping toxicities

One major drawback to the use of antineoplastic drugs is that nearly all of them cause adverse effects. These toxicities generally stem from the fact that chemotherapy drugs affect rapidly dividing cells—both harmful cancer cells and healthy, normal cells. Three types of rapidly dividing human cells are the cells of hair follicles, GI tract cells, and bone marrow cells. Because most of today's antineoplastic drugs cannot differentiate between cancer cells and healthy cells, the healthy cells are also destroyed, so hair loss, nausea and vomiting, and bone marrow toxicity are the undesirable consequences. Effects on the GI tract and bone marrow are often **dose-limiting adverse effects;** that is, the patient can no longer tolerate an increase in dosage that may be necessary to adequately treat the cancer and achieve good disease response.

Hair follicle cells are rapidly dividing cells. Cancer drugs that affect these cells often cause the adverse effect known as *alopecia,* or hair loss. Many patients, especially women, choose to wear wigs, hats, or scarves to disguise this adverse effect. Some antineoplastic drugs are more harmful to the epithelial cells of the stomach and intestinal tract, which often leads to diarrhea and mucositis, and may also increase the risk of nausea and vomiting. The likelihood that a given drug will produce vomiting is known as its **emetic potential.** Anticancer drugs cause nausea and vomiting by stimulating the cells of the chemoreceptor trigger zone. Several antiemetic drugs are used to prevent these symptoms and are described in Chapter 52. Box 45-1 lists the relative emetic potential of selected chemotherapy drugs.

Myelosuppression, also known as *bone marrow suppression* or *bone marrow depression,* is another unwanted adverse effect of certain antineoplastics. It commonly results from drug- or radiation-induced destruction of certain rapidly dividing cells in the bone marrow, primarily the cellular precursors of WBCs, red blood cells (RBCs), and platelets. This can also occur due to the disease processes of the cancer itself. Myelosuppression, in turn, leads to leukopenia, anemia, and thrombocytopenia. The cancer patient is often at greater risk for infection because of leukopenia (reduced WBC count) secondary to chemotherapy. Patients often need antibiotics intravenously (IV), either to prevent or to treat bacterial infections. Such patients are referred to as being neutropenic. Drug-induced anemia (reduced RBC count) often leads to hypoxia and fatigue, whereas thrombocytopenia (reduced platelet count) makes the patient more susceptible to bleeding. The lowest level of WBCs in the blood following chemotherapy (or radiation) treatment is called the **nadir.** The time until the nadir is reached in a given patient may become shorter and the recovery time for the bone marrow may become longer with multiple courses of antineoplastic treatment. The nadir normally occurs roughly 10 to 28 days after dosing, depending on the particular cancer drug or combination of drugs that is used to treat the patient. Anticipation of this nadir based on known cancer drug data can be used to guide the timing of prophylactic (preventative) administration of antibiotics and blood stimulants known as *hematopoietic growth factors* (see Chapter 47).

Common indications for various antineoplastic drugs are listed in the Dosages tables. Also provided in various locations in this chapter and in Chapter 46 are tables and boxes (Tables 45-8 and 46-2 and Boxes 46-1 and 46-2) containing drug-specific guidelines for the treatment of **extravasation**—unintended

BOX 45-1 RELATIVE EMETIC POTENTIAL OF SELECTED ANTINEOPLASTIC DRUGS*

Low (Less than 10% to 30%)
asparaginase
bleomycin
busulfan
capecitabine
chlorambucil
cladribine
cytarabine (less than 1000 mg/m^2)
daunorubicin, liposomal
docetaxel
doxorubicin (less than 20 mg/m^2)
doxorubicin, liposomal
estramustine
etoposide
floxuridine
fludarabine
fluorouracil (less than 1000 mg/m^2)
gefitinib
gemcitabine
hydroxyurea
imatinib
melphalan
mercaptopurine
methotrexate (less than 250 mg/m^2)
mitomycin
paclitaxel
pegaspargase
pentostatin
rituximab
teniposide
thioguanine
thiotepa
topotecan
trastuzumab
tretinoin
vinblastine
vincristine
vinorelbine

Moderate (30% to 60%)
altretamine
cyclophosphamide (less than 750 mg/m^2)
dactinomycin
daunorubicin (50 mg/m^2 or less)
doxorubicin (20 to 60 mg/m^2)
epirubicin (less than 90 mg/m^2)
idarubicin
ifosfamide (1500 mg/m^2 or less)
irinotecan
methotrexate (250 to 1000 mg/m^2)
mitoxantrone (15 mg/m^2 or less)
temozolomide

High (60% to More than 90%)
carboplatin
carmustine
cisplatin
cyclophosphamide (750 to more than 1500 mg/m^2)
cytarabine (more than 1000 mg/m^2)
dacarbazine
dactinomycin
daunorubicin (more than 50 mg/m^2)
doxorubicin (more than 60 mg/m^2)
ifosfamide (more than 1500 mg/m^2)
lomustine
mechlorethamine
methotrexate (more than 1000 mg/m^2)
mitoxantrone (more than 15 mg/m^2)
oxaliplatin
procarbazine
streptozocin

*Drugs in this list not covered in this chapter are described in Chapter 46.

leakage of a chemotherapy drug (with vesicant potential) into the surrounding tissues outside of the IV line.

Because of the often severe toxicity of cancer medications, a current major focus of cancer drug research is the development of targeted drug therapy. Targeted drug therapy utilizes drugs that recognize a specific molecule involved in the growth of cancer cells, while mostly sparing healthy cells. One example of such targeted therapy is the newer class of cancer drugs known as *monoclonal antibodies* (see Chapter 47).

Pharmacokinetic data for antineoplastic medications is seldom used to guide dosing. Assay complexity coupled with a poor correlation between blood concentration and toxicity and efficacy limits its value. Only a handful of anticancer drugs benefit from therapeutic drug monitoring. For these reasons, pharmacokinetic data are not included with the drug profiles in this chapter.

In spite of their notorious toxicity, given the often fatal outcome of neoplastic diseases, most cancer drugs are only rarely considered to be absolutely contraindicated. Even if a patient has a known allergic reaction to an antineoplastic medication, the urgency of treating the patient's cancer necessitates administering the medication and treating any allergic symptoms with premedications such as antihistamines, corticosteroids, and acetaminophen. For these reasons, no specific contraindications are listed for any of the drugs in this chapter.

Common relative contraindications for cancer drugs include weakened status of the patient as manifested by indicators such as very low WBC count, ongoing infectious process, severe compromise in nutritional and hydration status, reduced kidney or liver function, or a decline in organ function in any system that may be further affected by the toxic effect of the drug being administered. These are situations in which chemotherapy treatment is commonly delayed until the patient's status improves. In general, most chemotherapy is held when the patient's absolute neutrophil count (ANC) is less than 500 cells/mm^3 (severe neutropenia) (see Chapter 46). Alternatively, dosages are often reduced for frail elderly patients or others with significantly compromised organ system function, depending on the drugs used.

Reduction in fertility is a major concern in postpubertal patients. Cancer also complicates 1 in 1000 pregnancies. All chemotherapy drugs are classified as pregnancy category D. The choice to use chemotherapy in a pregnant woman is based on risk versus benefit. Both radiation and chemotherapy treatments can cause significant permanent fetal harm or death. The greatest risk is during the first trimester. Chemotherapy treatment during the second or third trimester is more likely to improve maternal outcome without significant fetal risk. However, radiation treatment poses great risk to the fetus throughout pregnancy and is reserved for the postpartum period if possible. Prepubertal patients are more resilient, however, and can have normal puberty and fertility.

In the elderly, *frailty* refers to loss of most of the patient's functional reserve and limited ability to tolerate even minimal physiologic stress (e.g., chemotherapy treatment). More robust elderly patients are certainly better candidates for cancer treatment, although frail patients often benefit as well, especially in terms of palliative (noncurative) symptom control.

CELL CYCLE–SPECIFIC ANTINEOPLASTIC DRUGS

Cell cycle–specific drug classes include antimetabolites, mitotic inhibitors, alkaloid topoisomerase II inhibitors, topoisomerase I inhibitors, and antineoplastic enzymes. These drugs are collectively used to treat a variety of solid and/or circulating tumors, although some drugs have much more specific indications than others.

ANTIMETABOLITES

A compound that is structurally similar to a normal cellular metabolite is known as an **analogue** of that metabolite. Analogues may have agonist or antagonist activity relative to the corresponding cellular compounds. An antagonist analogue is also known as an *antimetabolite*.

Mechanism of Action and Drug Effects

Antineoplastic antimetabolites are cell cycle–specific analogues that work by antagonizing the actions of key cellular metabolites. More specifically, antimetabolites inhibit cellular growth by interfering with the synthesis or actions of compounds critical to cellular reproduction: the vitamin folic acid, purines, and pyrimidines. Purines and pyrimidines make up the bases contained in nucleic acid molecules (DNA and RNA). Antimetabolites work via two mechanisms: (1) by falsely substituting for purines, pyrimidines, or folic acid; and (2) by inhibiting critical enzymes involved in the synthesis or function of these compounds. Thus, they ultimately inhibit the synthesis of DNA, RNA, and proteins, all of which are necessary for cell survival. Antimetabolites work primarily in the S phase of the cell cycle, during which DNA synthesis is most active. The available antimetabolites and the metabolites they antagonize are as follows:

Folate antagonists

- methotrexate (MTX)
- pemetrexed
- pralatrexate

Purine antagonists

- cladribine
- fludarabine (F-AMP)
- mercaptopurine (6-MP)
- pentostatin
- thioguanine (6-TG)

Pyrimidine antagonists

- capecitabine
- cytarabine (ara-C)
- floxuridine (FUDR)
- fluorouracil (5-FU)
- gemcitabine

Folic Acid Antagonism

The antimetabolite methotrexate is an analogue of folic acid. It inhibits the action of dihydrofolate reductase, an enzyme responsible for converting folic acid to its active form, folate, which is needed for the synthesis of DNA. The result is that DNA is not produced and the cell dies. In practice, the terms *folic acid* and *folate* are often used interchangeably. Pemetrexed is the name of a newer folate antagonist with a mechanism of action similar to that of methotrexate. Pralatrexate (Folotyn) is the newest dihydrofolate reductase inhibitor, specifically indicated for T-cell lymphoma.

Purine Antagonism

The purine bases present in DNA and RNA are adenine and guanine (see the discussion in Chapter 46), and they are required for the synthesis of the purine nucleotides that are incorporated into the nucleic acid molecules. Mercaptopurine and fludarabine are synthetic analogues of adenine, and thioguanine is a synthetic analogue of guanine. Cladribine is a more general purine antagonist, whereas pentostatin inhibits the action of the critical enzyme adenosine deaminase. Cladribine is unique in that it actually lacks cell cycle specificity relative to other drugs in its class. It is included in this section because of its similar pharmacology and mechanism of action. All of these drugs work by ultimately interrupting the synthesis of both DNA and RNA.

Although allopurinol is chemically similar to purines, it does not disrupt DNA synthesis. Instead, it inhibits xanthine oxidase, which reduces serum and/or urinary levels of uric acid. Rasburicase is an enzyme that degrades uric acid to more soluble end products. Uric acid is a common waste product that often accumulates in the blood following lysis of tumor cells, part of a condition known as **tumor lysis syndrome** (see Adverse Effects).

Pyrimidine Antagonism

The pyrimidine bases, cytosine and thymine, occur in the structure of DNA molecules, and cytosine and uracil are part of the structure of RNA molecules. These bases are essential for DNA and RNA synthesis. Floxuridine and fluorouracil are synthetic analogues of uracil, and cytarabine is a synthetic analogue of cytosine. Capecitabine is actually a prodrug of fluorouracil and is converted to that drug in the liver and other body tissues. Because of its prodrug form, it can be given orally. Gemcitabine inhibits the action of two essential enzymes, DNA polymerase and ribonucleotide reductase. Overall, these drugs act in a way that is very similar to that of the purine antagonists, incorporating themselves into the metabolic pathway for the synthesis of DNA and RNA and thereby interrupting the synthesis of both of these nucleic acids.

Indications

Antimetabolite antineoplastic drugs are used for the treatment of a variety of solid tumors and some hematologic cancers. They may also be used in combination chemotherapy regimens to enhance the overall cytotoxic effect. Methotrexate is also used to treat severe cases of psoriasis (a skin condition) as well as rheumatoid arthritis (see Chapter 47). Because some of these drugs are available in both oral and topical preparations, they are sometimes used for low-dose maintenance and palliative (noncurative) cancer therapy.

Allopurinol and rasburicase are both indicated for the hyperuricemia associated with tumor lysis syndrome and are usually given in anticipation of this condition during various chemotherapy regimens associated with this syndrome. Allopurinol is also used commonly in oral form to treat gout (see Chapter 44). The commonly used drugs and their common specific therapeutic uses are listed in the Dosages table on p. 733.

Adverse Effects

Like most antineoplastic drugs, antimetabolites can cause hair loss, nausea, vomiting, diarrhea, and myelosuppression. The relative emetic potentials for some of these drugs are listed in Box 45-1. In addition, other major types of toxicity including neurologic, cardiovascular, pulmonary, hepatobiliary, GI, genitourinary, dermatologic, ocular, otic, and metabolic toxicity. Common manifestations of these various toxicities are listed in Table 45-6, roughly in order of increasing severity. Note that a single drug may not cause all of the specific symptoms that are listed for each toxicity category, and actual symptoms may vary widely in severity among patients. The most common general symptoms are fever and malaise. Metabolic toxicity also includes tumor lysis syndrome, a common postchemotherapy

TABLE 45-6 COMMON MANIFESTATIONS OF ANTINEOPLASTIC TOXICITY

TYPE OF TOXICITY	COMMON MANIFESTATIONS
Neurologic	Fatigue, weakness, depression, agitation, euphoria, insomnia, sedation, headache, reduced libido, confusion, amnesia, hallucinations (visual and auditory), dizziness, loss of taste or altered taste sensations, dysarthria (joint pain), polyneuropathy (e.g., numbness in extremities), neuritis, paresthesia (abnormal touch sensations), facial paralysis, migraine, tremor, hemiplegia, loss of consciousness, seizures, ataxia, stroke, encephalopathy
Cardiovascular	Hot flushes, edema, thrombophlebitis and bleeding (e.g., near infusion site), chest pain, tachycardia, bradycardia, other dysrhythmias, angina, venous or arterial thrombosis, transient ischemic attacks, heart failure, myocardial ischemia, pericarditis, pericardial effusion, pulmonary embolism, aneurysm, cardiomyopathy, myocardial infarction, stroke, cardiac arrest, sudden cardiac death
Pulmonary-respiratory	Cough, rhinorrhea (runny nose), sore throat, sinusitis, bronchitis, pharyngitis, laryngitis, epistaxis (nosebleed), abnormal breath sounds, asthma, bronchospasm, atelectasis, pleural effusion, hemoptysis, hypoxia, respiratory distress, pneumothorax, diffuse interstitial pneumonitis, fibrosis, hemorrhage, anaphylaxis and generalized allergic reactions
Hepatobiliary	Increased bilirubin and liver enzyme levels, jaundice, cholestasis, acalculic cholecystitis (inflamed gallbladder without stones), hepatitis, sclerosis, fibrosis, fatty liver changes, venoocclusive hepatic disease, cirrhosis, hepatic coma
Gastrointestinal (GI)	Dyspepsia (heartburn), hiccups, gingivitis (inflamed gums), glossitis (inflamed tongue), abdominal pain, nausea, vomiting, diarrhea, constipation, gastroenteritis, stomatitis (painful mouth sores), oral candidiasis (thrush), ulcers, proctalgia (rectal pain), hematemesis, GI hemorrhage, melena (blood in stool), toxic intestinal dilation, ileus (bowel paralysis), ascites, necrotizing enterocolitis
Genitourinary	Oliguria, nocturia, dysuria, proteinuria, crystalluria, hematuria, urinary retention, abnormal renal function test results, hemorrhagic cystitis, renal failure
Dermatologic	Rash, erythema, pruritus, ecchymosis, dryness, edema, photosensitivity, sweating, discoloration (pigmentation changes), freckling, petechiae, purpura, numbness, tingling, hypersensitivity, fissuring, scaling, seborrhea, acne, eczema, psoriasis, skin hypertrophy, subcutaneous nodules, alopecia, nail disorder including onycholysis (loss of nails), dermatitis, cellulitis, excoriation, maceration, ulceration, urticaria, abscesses, benign skin neoplasm, hemorrhage (at injection site), palmar-plantar dysesthesia-paresthesia, toxic epidermal necrolysis, Stevens-Johnson syndrome
Ocular	Eye irritation, increased lacrimation, nystagmus, photophobia, visual changes, conjunctivitis, keratitis, dacryostenosis (narrowing of lacrimal duct)
Otic	Hearing loss
Metabolic	Weight loss or gain, anorexia, dehydration, hypokalemia, hypocalcemia, hypomagnesemia, hypertriglyceridemia, hyperglycemia, syndrome of inappropriate secretion of antidiuretic hormone, hypoadrenalism, protein-losing enteropathy, hyperuricemia, tumor lysis syndrome
Musculoskeletal	Back pain, limb pain, bone pain, myalgia, joint stiffness, arthralgia, muscle weakness, fibromyositis

condition. This syndrome is often associated with induction (initial) chemotherapy for rapidly growing hematologic malignancies. It may include hyperphosphatemia, hyperkalemia, and hypocalcemia. These electrolyte abnormalities are often treated with diuretics such as mannitol, IV calcium supplementation, oral or rectal potassium exchange resin, and oral aluminum hydroxide. Hyperuricemia can lead to nephropathy, and hemodialysis may be required in severe cases of tumor lysis syndrome.

A severe, but usually reversible, form of dermatologic toxicity is known as *palmar-plantar dysesthesia* or paresthesia (also called *hand-foot syndrome*). It can range from mild symptoms such as painless swelling and erythema to painful blistering of the patient's palms and soles. Other severe, but fortunately uncommon, dermatologic syndromes that can similarly affect the skin in more generalized regions include Stevens-Johnson syndrome and toxic epidermal necrolysis.

Interactions

As is true for cancer drugs in general, the administration of one antimetabolite drug with another that causes similar toxicities may result in additive toxicities. Therefore, the respective risks and benefits must be weighed carefully before therapy is initiated with either another antimetabolite or any other drug possessing a similar toxicity profile. Table 45-7 lists some known common examples of drugs that cause interactions with antimetabolites.

Dosages

For dosage information on selected antimetabolite chemotherapeutic drugs, see the table on p. 733. It is important to note that dosages of antineoplastics are highly variable based on type of cancer, prior therapy, and planned co-administration of other agents.

DRUG PROFILES

FOLATE ANTAGONIST

♦ methotrexate

Methotrexate is the prototypical antimetabolite of the folate antagonist group and is currently one of only three antineoplastic folate antagonists used clinically. It has proved useful for the treatment of solid tumors such as breast, head and neck, and lung cancers and for the management of acute lymphocytic leukemia and non-Hodgkin's lymphomas. Methotrexate also has immunosuppressive activity, because it can inhibit lymphocyte multiplication. For this reason, it may be useful in the treatment of rheumatoid arthritis (see Chapter 47). Its combined immunosuppressant and antiinflammatory properties also make it useful for the treatment of psoriasis.

High-dose methotrexate is associated with severe bone marrow suppression and is always given in conjunction with the "rescue" drug leucovorin. Leucovorin is an antidote for folic acid antagonists. The body produces active folic acid via metabolic steps utilizing the enzyme dihydrofolate reductase. Because

TABLE 45-7 SELECTED ANTIMETABOLITES: COMMON DRUG INTERACTIONS

ANTIMETABOLITE	INTERACTING DRUG	OBSERVED AND REPORTED EFFECTS*
capecitabine	warfarin	Altered coagulation test results with potential for fatal bleeding
	phenytoin	Reduced phenytoin clearance and toxicity
	leucovorin	Potentiation of capecitabine with possible toxicity
cladribine	None listed	None listed
cytarabine	digoxin	Reduced absorption likely due to cytarabine-induced damage to intestinal mucosa; elixir form may be better absorbed
	Aminoglycoside antibiotics	Reduced antibiotic efficacy against *Klebsiella pneumoniae* infections
floxuridine	None listed	None listed
fludarabine	cytarabine	Increased antitumor activity of cytarabine
	pentostatin	Potentially fatal pulmonary toxicity; do not use together
fluorouracil	warfarin	Enhanced anticoagulant effects
	leucovorin	Same as for capecitabine
	cimetidine	Increases toxicity of fluorouracil
gemcitabine	None listed	None listed
mercaptopurine (6-MP)	allopurinol	Inhibition of 6-MP metabolism by inhibition of xanthine oxidase enzyme, with possible enhanced 6-MP toxicity; reduce dose to one third to one fourth
	warfarin	6-MP reported to both enhance and inhibit effects of warfarin
	Hepatotoxic drugs	Increased risk of liver toxicity
methotrexate (MTX)	Protein-bound drugs and weak organic acids (e.g., salicylates, sulfonamides, sulfonylureas, phenytoin)	Possible displacement of MTX from protein-binding sites, enhancing its toxicity
	Penicillins, NSAIDs	Possible reduced renal elimination of MTX with potentially fatal hematologic and GI toxicity
	Live virus vaccines	Viral infection (true for any immunosuppressive drug)
	folic acid	Reduced MTX efficacy (theoretical only)
	theophylline	Reduced theophylline clearance
	Hepatotoxic drugs	Increased risk of liver toxicity
pentostatin	fludarabine	Potentially fatal pulmonary toxicity
thioguanine	busulfan	Reports of hepatotoxicity, esophageal varices, and portal hypertension
	Other cytotoxic drugs in general	Reports of hepatotoxicity

GI, Gastrointestinal; *NSAIDs,* nonsteroidal antiinflammatory drugs.
*Not all mechanisms for these drug interactions have been clearly identified. The information in this table is based on reported clinical observations, with mention of known or theorized mechanisms when available.

DOSAGES

Selected Antimetabolites

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE*	INDICATIONS
capecitabine (Xeloda) (D)	Pyrimidine antagonist (analogue)	PO: 1250 mg/m^2 bid for 2 wk, followed by 1-wk rest period; this 3-wk cycle repeatable as ordered	Metastatic colorectal and breast cancer
cladribine (Leustatin) (D)	Purine antagonist (analogue)	IV: 0.09 mg/kg/day by continuous infusion for 7 consecutive days	Hairy cell leukemia
♦ cytarabine (Cytosar-U) (D)	Pyrimidine antagonist (analogue)	IV: 100 mg/m^2/day by continuous infusion for 7 days (other regimens as well)	Leukemias (several varieties), NHL
fludarabine (Fludara) (D)	Purine antagonist (analogue)	IV: 25 mg/m^2/day for 5 consecutive days; repeatable q28d	Various acute and chronic leukemias, NHL
fluorouracil (Adrucil) (D)	Pyrimidine antagonist (analogue)	IV: short infusion: 400 mg/m^2; continuous infusion: 2400 mg/m^2 over 46 hr; dosage varies afterward depending on patient response	Colon, rectal, breast, esophageal, head and neck, cervical, and renal cancer
gemcitabine (Gemzar) (D)	Pyrimidine antagonist (analogue)	IV: 1000 mg/m^2 once weekly or as protocol dictates; cycle may be repeated or modified according to patient tolerance	Pancreatic, non–small cell lung, and bladder cancer
♦ methotrexate (Trexall, tablet form; otherwise generic) (X)	Folate antagonist (analogue)	IV: 30-40 mg/m^2/wk PO: 15-30 mg/day for 5 days, repeated q7d for 3-5 courses	Acute lymphocytic† leukemia; gestational choriocarcinoma; breast, head and neck, and many other cancers

IV, Intravenous; *NHL,* non-Hodgkin's lymphoma; *PO,* oral.
*NOTE: Dosages are highly variable.
†The term *lymphocytic* is synonymous in the literature with the term *lymphoblastic*.

methotrexate inhibits this enzyme, healthy cells die due to lack of folic acid. By giving leucovorin (which is rapidly converted to the active form of folic acid), it provides the body with active folic acid, which prevents death of normal cells. Methotrexate is available in both injectable and oral (tablet) form. A preservative-free injectable formulation is required for **intrathecal** (into the subarachnoid space) administration, used in the treatment of some cancers. Other folate antagonists are pemetrexed and pralatrexate, which have actions similar to that of methotrexate. However, they are used less commonly than methotrexate because they have limited indications: lung cancer and T cell lymphoma, respectively.

PURINE ANTAGONISTS

The currently available purine antagonists are cladribine, fludarabine, mercaptopurine, pentostatin, and thioguanine. Mercaptopurine and thioguanine are administered orally, whereas the other three are available only in injectable form. These drugs are used largely in the treatment of leukemia and lymphoma.

cladribine

Cladribine (Leustatin) is indicated specifically for the treatment of a certain type of leukemia known as *hairy cell leukemia,* so named because of the appearance of its cancerous cells under the microscope.

fludarabine

Fludarabine (Fludara), like cladribine, also has a very specific single indication—in this case, chronic lymphocytic leukemia. It is also commonly used in the treatment of follicular lymphoma and as part of salvage therapy in acute myelogenous leukemia.

PYRIMIDINE ANTAGONISTS

The currently available pyrimidine antagonists are capecitabine, cytarabine, floxuridine, fluorouracil, and gemcitabine. These drugs are used more commonly than the purine antagonists. They are available only in parenteral formulations except for capecitabine, which is currently available only in tablet form. Dosage and other information appear in the Dosages table on p. 733.

capecitabine

Capecitabine (Xeloda) is indicated primarily for the treatment of metastatic breast cancer.

♦ cytarabine

Cytarabine (ara-C) (Cytosar) is used primarily for the treatment of leukemias (acute myelocytic and lymphocytic leukemia and meningeal leukemia) and non-Hodgkin's lymphomas. It is available only in injectable form and may be given IV, subcutaneously, or intrathecally. It is also now available in a special encapsulated liposomal form for intrathecal use only in treating meningeal leukemia. Cytarabine has a unique set of adverse reactions, called "cytarabine syndrome." Cytarabine syndrome is characterized by fever, muscle and bone pain, maculopapular rash, conjunctivitis, and malaise. It usually occurs 6 to 12 hours following cytarabine administration. The syndrome may be treated or prevented by the use of corticosteroids.

fluorouracil

Fluorouracil (5-FU) (Efudex, Adrucil) is used in a variety of treatment regimens, including the palliative treatment of cancers of the colon, rectum, stomach, breast, and pancreas. It also is used in the adjuvant setting in the treatment of breast and colorectal cancer.

gemcitabine

Gemcitabine (Gemzar) is an antineoplastic drug structurally related to cytarabine. Gemcitabine is believed to have antitumor activity superior to that of cytarabine. It is used as first-line therapy for locally advanced or metastatic cancer of the pancreas and for the treatment of non–small cell lung cancer. Gemcitabine is increasingly used to treat other solid tumors, including breast cancer.

MITOTIC INHIBITORS

Mitotic inhibitors include natural products obtained from the periwinkle plant and semisynthetic drugs obtained from the mandrake plant (also known as the "may apple"). The periwinkle plant contains antineoplastic alkaloids. These vinca alkaloids include vinblastine, vincristine, and vinorelbine. Two newer plant-derived drugs are the taxanes. These include paclitaxel, once derived from the bark of the slow-growing Western (Pacific) yew tree, and docetaxel, a semisynthetic taxane produced from the needles of the European yew tree. The current process of isolating the starting material for paclitaxel from the needles has made the drug supply more abundant. Docetaxel is pharmacologically similar to paclitaxel. The newest taxanes are cabazitaxel (Jevtana), which is indicated for prostate cancer, and eribulin (Halaven), which is indicated for breast cancer. Dosage and other information appears in the Dosages table on p. 736.

Mechanism of Action and Drug Effects

Depending on the particular drug, these plant-derived compounds can work in various phases of the cell cycle (late S phase, throughout G_2 phase, and M phase), but they all work shortly before or during mitosis and thus retard cell division. Each different subclass inhibits mitosis in a unique way.

The vinca alkaloids (vincristine, vinblastine, and vinorelbine) bind to the protein tubulin during the metaphase of mitosis (M phase). This prevents the assembly of key structures called *microtubules.* This, in turn, results in the dissolution of other important structures known as *mitotic spindles.* Without these mitotic spindles, cells cannot reproduce properly. This results in inhibition of cell division and cell death.

The taxanes paclitaxel, docetaxel, and cabazitaxel act in the late G_2 phase and M phase of the cell cycle. They work by causing the formation of nonfunctional microtubules, which halts mitosis during metaphase.

Indications

Mitotic inhibitors are used to treat a variety of solid tumors and some hematologic malignancies. They are often used in combination chemotherapy regimens to enhance the overall cytotoxic

TABLE 45-8 MITOTIC INHIBITOR AND ETOPOSIDE EXTRAVASATION: LISTED SPECIFIC ANTIDOTE

DRUG	ANTIDOTE PREPARATION	METHOD
etoposide teniposide vinblastine vincristine	hyaluronidase (Wydase) 150 units/mL: add 1 mL NaCl (150 units/mL)	1. Inject 1-6 mL into the extravasated site with multiple subcut injections. 2. Repeat subcut dosing over the next few hours. 3. Apply warm compresses.* No total dose established.

subcut, Subcutaneous.
*Important: Administration of corticosteroids and topical cooling appear to worsen toxicity.

effect. Selected drugs and some of their specific therapeutic uses are listed in the Dosages table on p. 736.

Adverse Effects

Like many of the antineoplastic drugs, mitotic inhibitor antineoplastic drugs can cause hair loss, nausea and vomiting, and myelosuppression (see Table 45-6). The emetic potential of some of these drugs is given in Box 45-1.

Toxicity and Management of Extravasation

Most of the mitotic inhibitor antineoplastics are administered IV, and extravasation of these drugs is potentially serious. Specific antidotes and additional measures to be taken for the treatment of extravasation of the mitotic inhibitors are given in Table 45-8.

Interactions

A variety of drug interactions are possible with most antineoplastic drugs, some more significant than others. A few basic principles apply to all antineoplastic drug classes. Any drug that reduces the clearance of an anticancer drug also increases the risk of toxicity, whereas a drug that increases the elimination of an anticancer drug reduces its efficacy. The use of multiple antineoplastic drugs can cause severe neutropenia and infection, due to additive bone marrow suppression. Monitor and treat patients accordingly for hematologic toxicity and infections. Observed drug interactions specific for mitotic inhibitors are summarized in Table 45-9.

Dosages

For dosage information on selected mitotic inhibitors and alkaloid topoisomerase II inhibitors, see the table on p. 736.

ALKALOID TOPOISOMERASE II INHIBITORS

Etoposide and teniposide are derivatives of epipodophyllotoxin. They exert their cytotoxic effects by inhibiting the enzyme topoisomerase II, which causes breaks in DNA strands. These drugs work during the late S phase and the G_2 phase of the cell cycle.

TABLE 45-9 SELECTED MITOTIC INHIBITORS AND ETOPOSIDE: COMMON DRUG INTERACTIONS

DRUG	INTERACTING DRUG	OBSERVED AND REPORTED EFFECTS*
etoposide	warfarin	Enhanced anticoagulation
	cyclosporine	Reduced etoposide clearance
docetaxel	CYP3A4 inhibitors (e.g., azole antifungals, ciprofloxacin, clarithromycin, imatinib, verapamil, many others)	Enhanced docetaxel effect (possible toxicity)
	CYP3A4 inducers (e.g., carbamazepine, rifampin, phenytoin)	Reduced docetaxel effect
paclitaxel	doxorubicin	Increased cardiotoxicity
	CYP3A4 inhibitors and inducers	Same as for docetaxel
vincristine	phenytoin	Reduced phenytoin concentrations with consequent enhanced seizure risk
	asparaginase	Reduced vincristine clearance and increased neurotoxicity (give vincristine 12 to 24 hours before asparaginase)
	mitomycin	Increased risk of pulmonary toxicity
	CYP3A4 inhibitors and inducers	Same as for docetaxel

CYP3A4, Cytochrome P-450 liver enzyme 3A4.
*Not all mechanisms for these drug interactions have been clearly identified. The information in this table is based on reported clinical observations, with mention of known or theorized mechanisms when available.

Dosages

For dosage information on selected mitotic inhibitors and alkaloid topoisomerase II inhibitors, see the table on p. 736.

DRUG PROFILES

SELECTED MITOTIC INHIBITORS AND ETOPOSIDE

♦ etoposide

Etoposide (VP-16) (generic) is a topoisomerase II inhibitor. Its structure, mechanism of action, and adverse effect profile are similar to those of teniposide. It is believed to kill cancer cells in the late S phase and the G_2 phase of the cell cycle. It is indicated for the treatment of small cell lung cancer and testicular cancer. It is available in both oral and injectable forms. The oral form is poorly absorbed and has fallen out of favor because it produces significant toxicities without therapeutic benefit. The IV drug is formulated in a hydroalcoholic diluent, which can cause toxicity (hypotension) if administered in too high a concentration. A water-soluble form of the drug (Etopophos) can eliminate these administration issues, but it is very expensive compared with the standard preparation.

DOSAGES

Selected Mitotic Inhibitors and Etoposide

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE*	INDICATIONS
Epipodophyllotoxin Derivative			
♦ etoposide (Toposar, generics) (D)	Topoisomerase II inhibitor	IV: 50-160 mg/m^2/day for 4-5 days, then repeated cycles and dosage based on type of cancer	Testicular and small cell lung cancer
Taxane			
♦ paclitaxel (Taxol, Onxol) (D)	Mitotic inhibitor	IV: 135-250 mg/m^2 q3wk	Ovarian, breast, esophageal, bladder, head and neck, cervical cancer; non–small cell and small cell lung cancer; Kaposi's sarcoma
Vinca Alkaloid			
♦ vincristine (Vincasar PFS, generics) (D)	Mitotic inhibitor	IV: 1.4 mg/m^2 q1wk; usual max dose 2 mg; fatal if given intrathecally	ALL, AML, HL, NHL, rhabdomyosarcoma, neuroblastoma, Wilms tumor, brain tumors, small cell lung cancer, Kaposi's sarcoma

ALL, Acute lymphocytic leukemia; *AML,* acute myelocytic leukemia; *HL,* Hodgkin's lymphoma; *IV,* intravenous; *NHL,* non-Hodgkin's lymphoma.
*NOTE: Dosages may vary widely among treatment protocols.

♦ paclitaxel

Paclitaxel (Taxol) is a natural mitotic inhibitor that was originally isolated from the bark of the Pacific yew tree. The European yew tree is the source for another mitotic inhibitor known as docetaxel (Taxotere). Paclitaxel is currently approved for the treatment of ovarian cancer, breast cancer, non–small cell lung cancer, and Kaposi's sarcoma, among other cancers. Paclitaxel is water-insoluble (hydrophobic), and for this reason it is put into a solution containing oil rather than water. The particular oil used is a type of castor oil called Cremophor EL, the same oil with which cyclosporine is formulated. Many patients tolerate it poorly and show hypersensitivity associated with infusion. For this reason, before patients receive paclitaxel they are premedicated with a steroid (dexamethasone), H_1 receptor antagonist (diphenhydramine), and H_2 receptor antagonist (ranitidine). Paclitaxel is available only in injectable form. There is an albumin-bound form of the drug (Abraxane) that is not associated with severe infusion reactions.

♦ vincristine

Vincristine is an alkaloid isolated from the periwinkle plant that is indicated for the treatment of acute lymphocytic leukemia and other cancers. It is available only in injectable form. It is an M phase–specific drug that inhibits mitotic spindle formation. Vincristine is the most significant neurotoxin of the cytotoxic drug class, but it continues to be used in part because of its relative lack of bone marrow suppression. Special care must be taken not to inadvertently give vincristine via the intrathecal route. Several deaths have been reported due to this error. The World Health Organization and the Institute for Safe Medication Practices suggest that vincristine be diluted in 25 mL of fluid and never dispensed via a syringe to prevent this lethal error from occurring. A special warning is required for all vincristine products dispensed that states "For Intravenous Use Only—Fatal If Given By Other Routes." (See the Safety and Quality Improvement: Preventing Medication Errors box.)

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Vincristine: Right Route Is Essential

For several years, the Institute for Safe Medication Practices has recommended changes in procedures to ensure that vincristine and other vinca alkaloids are not given intrathecally (via the spinal route) or by any other route. Administering these drugs through the spinal route is almost always fatal, and the death is slow and excruciating. Mistakes occur when the drug is drawn up in a syringe for intravenous administration and then is inadvertently given via the intrathecal route. These errors are preventable. The World Health Organization has suggested that pharmacies prepare vincristine in a diluted volume, such as in a 50-mL minibag of normal saline, to deter practitioners from giving the drug intrathecally. Drugs given intrathecally are not normally dispensed in a minibag. The nurse, who may be assisting the health care practitioner with intrathecal procedures, needs to be aware of the potential fatal error that may occur if vincristine is given via the wrong route.

Data from Institute for Safe Medication Practices, *Nurse Advise ERR* 9(11):2, 2011, available at www.ismp.org/newsletters/nursing/Issues/NurseAdviseERR201101.pdf. Accessed October 17, 2011.

TOPOISOMERASE I INHIBITORS

Topoisomerase I inhibitors are a relatively new class of chemotherapy drugs. The two drugs currently available in this class are topotecan and irinotecan. Both are semisynthetic analogues of the compound camptothecin, which was originally isolated in the 1960s from *Camptotheca acuminata,* a Chinese shrub. For this reason, these drugs are also referred to as *camptothecins.*

Mechanism of Action and Drug Effects

The camptothecins inhibit proper DNA function in the S phase by binding to the DNA–topoisomerase I complex. This complex normally allows DNA strands to be temporarily cleaved and then reattached in a critical step known as *religation.* The

binding of the camptothecin drugs to this complex retards this religation process, which results in a DNA strand break.

Indications

The two currently available topoisomerase I inhibitors are used primarily to treat ovarian and colorectal cancer. Topotecan has been shown to be effective even in cases of metastatic ovarian cancer that have failed to respond to platinum-containing regimens (e.g., cisplatin, carboplatin) and paclitaxel. Topotecan is also used to treat small cell lung cancer. Irinotecan is currently approved for the treatment of metastatic colorectal cancer, small cell lung cancer, and cervical cancer.

Adverse Effects

The main adverse effect of topotecan is bone marrow suppression. Topotecan is not given to patients with baseline neutrophil counts of less than 1500 cells/mm^3. Other adverse effects are relatively minor compared with those of the other antineoplastic drug classes. These include mild to moderate nausea, vomiting, and diarrhea; headache; rash; muscle weakness; and cough.

TABLE 45-10 IRINOTECAN: COMMON DRUG INTERACTIONS

INTERACTING DRUG	OBSERVED AND REPORTED EFFECTS*
CYP2B6 inhibitors (e.g., paroxetine, sertraline)	Increased effects and toxicity of irinotecan
CYP3A4 inhibitors (e.g., azole antifungals, ciprofloxacin, clarithromycin, imatinib, isoniazid, verapamil)	Increased effects and toxicity of irinotecan; concurrent use not recommended
CYP2B6 inducers (e.g., carbamazepine, phenytoin, nevirapine)	Reduced effects of irinotecan
CYP3A4 inducers (e.g., aminoglutethimide, rifampin, nevirapine, phenytoin)	Reduced effects of irinotecan
St. John's wort (CYP3A4 inducer)	Reduced effects of irinotecan; stop St. John's wort 2 wk before initiating irinotecan therapy

CYP2B6, Cytochrome P-450 liver enzyme 2B6; *CYP3A4,* cytochrome P-450 liver enzyme 3A4.
*Note that not all mechanisms for these drug interactions have been clearly identified. The information in this table is based on reported clinical observations, with mention of known or theorized mechanisms when available.

Irinotecan causes more severe adverse effects than topotecan. In addition to producing similar hematologic adverse effects, it has been associated with severe diarrhea known as *cholinergic diarrhea.* It is recommended that this condition be treated with atropine unless use of that drug is strongly contraindicated. Delayed diarrhea may occur 2 to 10 days after infusion of irinotecan. This diarrhea can be severe and even life-threatening and must be treated aggressively with loperamide. There is a moderate risk of nausea and vomiting with irinotecan, which requires appropriate supportive care such as IV rehydration and antiemetic drug therapy.

Interactions

Topotecan has a unique drug interaction involving the granulocyte colony-stimulating factor filgrastim (see Chapter 47). Filgrastim is commonly used to enhance WBC recovery after chemotherapy. When topotecan is given along with filgrastim, myelosuppression has actually been shown to be worsened. It is recommended that filgrastim be administered 24 hours after completion of the topotecan infusion. Laxatives and diuretics are not given with irinotecan, because of the potential to worsen the dehydration resulting from the severe diarrhea that this drug can produce. Severe cardiovascular toxicity, including thrombosis, pulmonary embolism, stroke, and acute fatal myocardial infarction, have been reported when irinotecan is given with fluorouracil and leucovorin. The role of irinotecan in this toxicity syndrome is unclear, because fluorouracil is a well-recognized cause of myocardial ischemia, including myocardial infarction and sudden death. Such drug combinations are given with careful monitoring. Several additional recognized drug interactions occur with irinotecan, which are summarized in Table 45-10.

Dosages

For dosage information on selected topoisomerase I inhibitors, see the table below.

DRUG PROFILES

irinotecan

Irinotecan (Camptosar) is often given with both fluorouracil and leucovorin. It is available only in injectable form.

topotecan

After initial therapy with other antineoplastics, cancer cells commonly become resistant to their effects. The use of topotecan (Hycamtin) to treat ovarian cancer and small cell lung

DOSAGES

Selected Topoisomerase I Inhibitors

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE*	INDICATIONS
irinotecan (Camptosar) (D)	Synthetic camptothecin	IV: 125-350 mg/m^2 on various days depending on protocol	Metastatic colorectal cancer, small cell lung cancer, cervical cancer
topotecan (Hycamtin) (D)	Semisynthetic camptothecin	IV: 1.5 mg/m^2 once daily for 5 consecutive days on a repeatable 21-day course	Ovarian and small cell lung cancer

IV, Intravenous.
*NOTE: Dosages are highly variable.

cancer has been studied extensively. As noted earlier, it produces therapeutic responses even in cases in which powerful drugs such as cisplatin and paclitaxel have failed. Topotecan is available only in injectable form.

ANTINEOPLASTIC ENZYMES

Two antineoplastic enzymes are commercially available: asparaginase and pegaspargase. A third, *Erwinia* asparaginase, is available only by special request from the National Cancer Institute for patients who have developed allergic reactions to *Escherichia coli*–based asparaginase. All three drugs are synthesized from cultures of certain bacteria using recombinant DNA technology.

TABLE 45-11 SELECTED ANTINEOPLASTIC ENZYMES: COMMON DRUG INTERACTIONS

ENZYME	INTERACTING DRUG	OBSERVED AND REPORTED EFFECTS*
asparaginase	cyclophosphamide, mercaptopurine, vincristine	Interference with efficacy or clearance of asparaginase
	mercaptopurine, methotrexate, prednisone	Enhanced liver toxicity of asparaginase
	methotrexate	Reduced antineoplastic effect when given concurrently, but possibly enhanced antineoplastic effect when given 9 to 10 days before or shortly after methotrexate
	prednisone	Hyperglycemia (give asparaginase after prednisone)
	vincristine	Neuropathy (give asparaginase after vincristine)
	aspirin, NSAIDs, dipyridamole, heparin, warfarin	Use with caution due to possible coagulation abnormalities

NSAIDs, Nonsteroidal antiinflammatory drugs.
*Note that not all mechanisms for these drug interactions have been clearly identified. The information in this table is based on reported clinical observations, with mention of known or theorized mechanisms when available.

Indications

The antineoplastic enzymes are currently approved exclusively for the treatment of acute lymphocytic leukemia.

Adverse Effects

Of particular note for the antineoplastic enzymes is a fairly unique adverse effect of impaired pancreatic function. This can lead to hyperglycemia and severe or fatal pancreatitis. Other types of adverse effects associated with these drugs are dermatologic, hepatic, genitourinary, neurologic, musculoskeletal, GI, and cardiovascular effects.

Interactions

Commonly reported drug interactions involving the antineoplastic enzymes are summarized in Table 45-11.

Dosages

For dosage information on antineoplastic enzymes, see the table below.

DRUG PROFILES

♦ asparaginase

Asparaginase (Elspar) is used for the treatment of acute lymphocytic leukemia. Its mechanism of action is slightly different from that of traditional antineoplastic drugs in that it is an enzyme that catalyzes the conversion of the amino acid asparagine to aspartic acid and ammonia. Leukemic cells are then unable to synthesize the asparagine required for the synthesis of DNA and proteins needed for cell survival.

The only commercially available asparaginase product in the United States is Elspar. It is derived from the *E. coli* bacterium, and it is common for patients to develop allergic reactions to it. When this happens, one alternative is to switch to a product synthesized from *Erwinia* bacteria. This product is not sold commercially in the United States but is available by special request from the National Cancer Institute. Another treatment alternative is to use the commercially available pegaspargase product described in the following drug profile. All antineoplastic enzymes are available only in injectable form.

pegaspargase

Pegaspargase (Oncaspar) has a mechanism of action, indications, and contraindications similar to those of asparaginase. It is essentially the same enzyme that has been formulated so as to

DOSAGES

Selected Antineoplastic Enzymes

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE*	INDICATIONS
♦ asparaginase (Elspar) (C)	*Escherichia coli*–derived l-asparagine amidohydrolase enzyme	IV/IM: 200 units/kg/day to 40,000 units per dose depending on protocol	Acute lymphocytic leukemia
pegaspargase (Oncaspar) (C)	Pegylated version of asparaginase	IV/IM: 2500 IU/m^2 q14d (smaller pediatric dosages)	Acute lymphocytic leukemia (usually in patients who have developed an allergy to asparaginase)

IM, Intramuscular; *IV,* intravenous.
*NOTE: Dosages are highly variable.

reduce its allergenic potential. This process involves chemical conjugation of the enzyme with units of a relatively inert compound known as monomethoxypolyethylene glycol. Because polyethylene glycol is abbreviated PEG, this process is known as *pegylation*. It is a process that is increasingly used in formulating various drugs, some of which are described in other chapters (e.g., see Chapter 47). These drugs are recognized by the prefix *peg* in their generic names. Pegaspargase is usually prescribed for patients who have developed an allergy to asparaginase—a common occurrence, as mentioned earlier, especially with repeated treatment.

NURSING PROCESS

ASSESSMENT

With antineoplastic therapy, perform the following components of a thorough physical assessment: nursing history; past and present medical history; family history; medication profile with a notation of allergies as well as a listing of all prescription drugs, over-the-counter (OTC) drugs, and herbals; height, weight, and vital signs; and baseline hearing and vision testing (as ordered). Also assess bowel and bladder patterns, neurologic status, heart sounds, heart rhythm, breath sounds, and lung function. Examine the skin and mucosa, giving attention to turgor, hydration, color, and temperature. Note any signs and symptoms of fear and anxiety with attention to complaints of insomnia, irritability, shakiness, restlessness, and/or palpitations. Also complete an assessment of cultural, emotional, spiritual, sexual, and financial influences, concerns, and issues. Assess the patient's ability to perform activities of daily living and the patient's mobility status and gait. Perform a pain assessment using objective methods such as an intensity rating scale (e.g., 0 to 10, where 0 = no pain and 10 = worst pain ever). Note the pattern of pain, focusing on the location, quality, onset, duration, and precipitating or alleviating factors. Document any oral, pharyngeal, esophageal, and/or abdominal pain; painful swallowing; epigastric or gastric pain, especially after eating spicy or acidic foods; achiness in joints or lower extremities; or numbness, tingling, and any burning or sharp pain. Question the patient about past experiences with pain and about any drug, nondrug, or alternative therapies used as well as any previous successes or failures in pain management. Cultural beliefs and background as they relate to pain are important to assess because the individual's culture may affect how pain is perceived, verbalized, and treated (see Chapter 10).

Assess contraindications, cautions, and drug interactions. Document the findings prior to the use of these drugs. Laboratory tests that are usually ordered include levels of electrolytes and minerals, uric acid levels, complete blood count, platelet count, bleeding time, tests of renal and hepatic function, and cardiac enzyme levels (see the Safety: Laboratory Values Related to Drug Therapy box). Assays of tumor markers may also be ordered to establish baseline levels and determine the impact of the disease and subsequent therapeutic effectiveness. For more information about the specific adverse effects associated with the destruction of various populations of normal cells due to chemotherapy, see Box 45-2. Specific areas of assessment related to some of the more common adverse effects of chemotherapy on normal, rapidly dividing cells include the following:

- For *altered nutritional status* and *impaired oral mucosa:* Assess signs and symptoms of altered nutrition with a focus on weight loss, abnormal serum protein-albumin and blood urea nitrogen (BUN) levels (a negative nitrogen status due to low protein levels would be indicated by a decreasing BUN level), weakness, fatigue, lethargy, poor skin turgor, and pale conjunctiva. Assess oral mucosa for any signs and symptoms of *stomatitis,* such as pain or burning in the mouth, difficulty swallowing, taste changes, viscous saliva, dryness, cracking, and/or fissures with or without bleeding of the mucosa.
- For *effects on the GI mucosa:* Assess bowel sounds (hyperactive or hypoactive versus normoactive). Assess for signs and symptoms of *diarrhea,* such as frequent, loose stools (more than three stools per day), urgency, and abdominal cramping. Obtain information about the presence of blood in the stool as well as consistency, color, odor, and amount. Assess for *nausea and vomiting* and determine whether symptoms are acute, delayed, or anticipatory; if vomiting occurs, determine the color, amount, consistency, frequency, and odor, and whether blood is present. The severity of nausea and vomiting may be rated using a scale of 1 to 10 (where 10 is the worst symptoms) or using the terms *mild, moderate,* and *severe.*
- For *alopecia:* Assess the patient's views, concerns, and emotions about potential hair loss. Assess the patient's need to prepare for hair loss, either by leaving the hair as it is and

BOX 45-2 EFFECTS OF ANTINEOPLASTIC DRUGS ON NORMAL CELLS AND RELATED ADVERSE EFFECTS

Antineoplastic drugs are designed to kill rapidly dividing *cancer* cells, but they also kill rapidly dividing *normal* cells. Such normal cells include cells of the oral and gastrointestinal (GI) mucous membranes, hair follicles, reproductive germinal epithelium, and components of bone marrow (e.g., WBCs, RBCs, and platelets). The more common adverse effects of normal cell kill are as follows:

- Killing of normal cells of the GI mucous membranes may result in adverse effects such as *altered nutritional status, stomatitis* with inflammation and/or ulceration of the oral mucosa throughout the GI tract, *altered bowel function, poor appetite, nausea, vomiting* (often intractable and requiring aggressive antiemetic treatment), and *diarrhea.*
- Killing of the normal cells of hair follicles leads to *alopecia* (loss of hair).
- Killing of normal cells in the bone marrow results in dangerously low (life-threatening) blood cell counts. Because of the negative impact on these normal cells, the nurse must carefully assess the patient's WBCs levels (leukocytes, neutrophils, and band neutrophils), RBC counts, hemoglobin level, hematocrit, and platelet counts (see the Safety: Laboratory Values Related to Drug Therapy box). In addition, monitoring of the patient's absolute neutrophil count (ANC) is needed (ANC = % of neutrophils + % bands × WBC). Monitoring ANC values allows the nurse and other health care providers to identify the nadir—the time of the lowest count when the patient is most vulnerable. An ANC of 500 cells/mm^3 or lower indicates high risk for infection.
- Killing of germinal epithelial cells (also rapidly dividing) leads to *sterility* (irreversible) in males, damage to the ovaries with subsequent *amenorrhea* in females, and *teratogenic* effects with possible fetal death in pregnant women.

SAFETY: LABORATORY VALUES RELATED TO DRUG THERAPY

Rationales for Assessment and Monitoring of Blood Cell Counts with Antineoplastics

Antineoplastic drugs kill both normal and abnormal cells that are rapidly dividing, and thus the bone marrow and its rapidly dividing cellular constituents are negatively impacted. Because of this characteristic of chemotherapeutic drugs, RBCs, WBCs, and platelets are suppressed and therefore their levels require frequent monitoring. This box presents information specifically on RBCs and hemoglobin (Hgb) and hematocrit (Hct) levels as well as platelet levels. Chapter 46 presents more information on WBCs with neutrophil counts and nadir levels.

LABORATORY TEST	NORMAL RANGES	RATIONALE FOR ASSESSMENT
RBC count	M: 4.6-6.2 million cells/mm^3 F: 4.2-5.4 million cells/mm^3	Bone marrow suppression from antineoplastics affects RBC values, leading to severe anemia. RBCs carry oxygen—attached to the hemoglobin—from the lungs to the rest of the body. RBCs also help carry carbon dioxide back to the lungs for exhalation. Therefore, if RBC counts are low (e.g., with anemia), the body does not get the oxygen it needs, which leads to lack of energy, fatigue, intolerance of activity, shortness of breath, and hypoxemia. For the cancer patient who may already be experiencing the effects of bone marrow suppression from the disease and then from the treatment, this loss of oxygen saturation will be exacerbated resulting in a lesser ability to get up and about and perform activities of daily living.
Hct	M: 40%-54% F: 37%-47%	Hct measures the amount of space or volume of RBCs in the blood, so if the RBC value is low the Hct is also low. The impact of this low value is discussed above under RBCs.
Hgb level	M: 14-18 g/dL F: 12-16 g/dL	Hgb is the major substance in RBCs. It carries oxygen and is responsible for the red color of the blood cell. With low levels of Hgb, the consequence to the patient is as noted with RBCs.
Platelet count	150,000-140,000 platelets/mm^3	Platelets are the smallest type of blood cell and play a large role in the process of blood clotting. When bleeding occurs, the platelets swell, clump, and form a plug that helps stop the bleeding. Therefore, if platelet levels are lower than 100,000 platelets/mm^3, the patient is at high risk for uncontrolled bleeding and/or hemorrhage. Some guidelines may use a platelet count of 50,000 platelets/mm^3 and above as the criterion. Seek out further information in policies and procedures, or contact the prescriber.

F, Female; *M,* male.

allowing it to fall out on its own; having the hair cut short; or wearing a scarf, hat, bandana, or hair wrap and/or purchasing a wig before the hair is actually lost. Purchasing a wig prior to chemotherapy will allow for a closer match to a patient's pre-chemotherapy hairstyle.

- For *bone marrow suppression:* Assess for signs and symptoms of *anemia* or the decrease in RBCs, hemoglobin level, and hematocrit (e.g., pallor of the skin, oral mucous membranes, and conjunctiva; fatigue; lethargy; loss of interest in activities; shortness of breath; and inability to concentrate). Assess for signs and symptoms of *leukopenia* (decrease in WBCs [see Chapter 46] and/or absolute neutrophil count [ANC; normal range is 1500 cells/mm^3, with severe neutropenia being less than 500 cells/mm^3]), including fever; chills; tachycardia; abnormal breath sounds; productive cough with purulent, green, or rust-colored sputum; change in the color of the urine; lethargy, fatigue; and/or acute confusion. Assess for signs and symptoms of *thrombocytopenia* (decrease in thrombocytes [usually less than 100,000] and platelet clotting factors), including indications of unusual bleeding such as petechiae; purpura; ecchymosis; gingival (gum) bleeding; excessive or prolonged bleeding from puncture sites (e.g., intramuscular or IV administration sites or blood draw sites); unusual joint pain; blood in the stool, urine, or vomitus; and a decrease in blood pressure with elevated pulse rate (see the Safety: Laboratory Values Related to Drug Therapy box in this chapter as well as Chapters 26 and 27; see also Box 45-2). Always assess for the normal ranges of laboratory values.
- For possible *sterility, teratogenesis,* damage to ovaries with *amenorrhea:* In adult male patients, assess baseline reproductive history with attention to sexual functioning, fathering of children, and/or past or current reproductive or sexual problems or concerns. In female adult patients, in addition to the relevant aspects already mentioned, inquire about fertility, menstrual and childbearing history, and age of onset of menses and menopause, if applicable.

With *cell cycle–specific drugs,* document all allergies, cautions, contraindications, and drug interactions. Most *antimetabolite drugs* do not produce severe emesis (i.e., in fewer than 10% of cases). Pentostatin and some of the pyrimidine analogues have emetic potential, so perform an assessment of baseline GI functioning. In addition, the folate antagonists are not as likely to cause emesis but may be associated with GI abnormalities, such as ulcers and stomatitis. Because these drugs are generally administered parenterally (IV), assessing peripheral access areas or central venous sites is critical to prevent risk of damage to surrounding tissue, joints, and tendons. Assess IV sites every hour, as needed, or as per facility protocol for redness, swelling, heat, and pain. One specific assessment consideration associated with the use of the antimetabolite cytarabine is monitoring for the occurrence of *cytarabine syndrome.* This syndrome usually occurs within 6 to 12 hours after drug administration and is characterized by fever, muscle and bone pain, maculopapular rash, conjunctivitis, and malaise. Assessment and quick identification of this syndrome can lead to its prevention and appropriate treatment.

In patients receiving *mitotic inhibitors* (e.g., vinblastine, vincristine) and *alkaloid topoisomerase II inhibitors* (e.g., etoposide), perform baseline hepatic and renal function tests, as ordered. Serum uric acid levels are usually ordered because these levels

rise with increased cell death from cancer and/or its treatment. The increase in uric acid may precipitate or exacerbate gout, which, if diagnosed accurately, may be managed. Other mitotic inhibitors, docetaxel and paclitaxel, are associated with severe neutropenia and a decrease in platelet counts (see the Safety: Laboratory Values Related to Drug Therapy box on p. 740, as well as Chapter 47); therefore, perform blood counts before, during, and after drug therapy. Constantly assess the patient for severe hypersensitivity reactions characterized by dyspnea, severe hypotension, and angioedema and generalized urticaria (during treatments). Drops in blood cell counts may even occur before any clinical evidence is present. Note baseline neurologic functioning as well as the presence of any peripheral neuropathies. Because these drugs have multiple incompatibilities and are irritants (irritating the IV site and vein) or vesicants (causing cell death with extravasation and necrosis with ulcerations), you must become familiar with potential solution and/or drug interactions. Consulting with the prescriber and pharmacist as well as authoritative resources would be appropriate. Documentation must include initial and frequent follow-up assessments of the IV site.

Topoisomerase I inhibitors are associated with hematologic adverse effects; thus, perform baseline WBC counts as ordered. Bone marrow suppression is predictable, noncumulative, reversible, and manageable; therefore, do not give drugs such as topotecan to patients with baseline neutrophil counts of fewer than 1500 cells/mm^3. Irinotecan causes more severe adverse effects than topotecan; assess related systems and note the findings. The potential for irinotecan-related *cholinergic diarrhea* requires continual assessment of the GI tract. Diarrhea may appear 2 to 10 days after the irinotecan infusion, and further medical treatment may be required if severe forms of diarrhea occur. The diarrhea may even be life-threatening. There is only moderate risk of nausea and vomiting with irinotecan, which requires immediate and appropriate assessment and care. Drug interactions to assess for include the concurrent administration of topotecan with filgrastim which results in a worsening of myelosuppression. Do not give laxatives or diuretics with irinotecan due to the potential for severe diarrhea, volume loss, and subsequent dehydration. When given with fluorouracil and leucovorin, severe cardiovascular (toxicity including thrombosis), pulmonary embolism, stroke, and acute fatal myocardial infarction may occur. Perform a cautious and skillful assessment of related systems. See Table 45-10 for more drug interactions.

With the use of *natural enzyme* drugs (e.g., asparaginase, pegaspargase), assess pancreatic function because of the potential for severe or even fatal pancreatitis. Because of this risk of pancreatitis, assess the patient closely for moderate to severe abdominal pain (upper left quadrant), nausea, vomiting, and hyperglycemia. Serum alkaline phosphatase and WBC counts, if elevated, may indicate possible pancreatitis if also supported by clinical presentation. Additionally, assessment and documentation of dermatologic, hepatic, genitourinary, neurologic, musculoskeletal, GI, and cardiovascular systems is important due to impact on these systems.

Genetic considerations are an additional area of importance in the treatment of cancer with antineoplastics, as well as with all drug therapy. Assess individuals for the presence of the following characteristics before chemotherapy is initiated: (1) genetic markers for oral cancers, (2) genetic determinants of testosterone or estrogen metabolism, and (3) genetically linked enzyme system abnormalities such as those involving specific cytochrome P-450 enzymes that metabolically convert nicotine to a carcinogenic substance. These genetic factors are very complex; nevertheless, be aware of the possible influence of genetic differences and be forward thinking on the impact of drug research and genetics. See Chapter 8 for more information on genetics as related to drug therapy and the nursing process.

NURSING DIAGNOSES

1. Diarrhea related to the adverse effects of antineoplastic drugs
2. Acute pain related to the disease process and drug-induced joint pain, stomatitis, GI distress, and other discomforts associated with antineoplastic cell cycle–specific therapy
3. Risk for infection related to drug-induced bone marrow suppression with possible leukopenia and neutropenia

PLANNING

GOALS

1. Patient regains as near normal as possible bowel elimination patterns during antineoplastic therapy.
2. Patient achieves improved comfort levels with improved pain control, and symptom and adverse effect management.
3. Patient remains free from infection.

OUTCOME CRITERIA

1. Patient states measures to minimize diarrhea.
   - Patient states foods and beverages to avoid such as hot, spicy foods and beverages; alcohol; foods high in fiber; gaseous foods such as cruciferous vegetables; and raw seafood.
   - Patient takes antidiarrheal medication, as instructed and if indicated, to avoid dehydration and electrolyte loss.
2. Patient experiences improved pain relief through use of pharmacologic and nonpharmacologic measures to maximize comfort levels associated with chemotherapy-related adverse effects, such as joint pain, stomatitis, and GI distress.
   - Patient requests medication(s) for comfort before pain is uncontrollable and severe.
   - Patient uses a number scale of 0 to 10 for identification of pain level, with 0 being no pain and 10 representing worst pain ever experienced.
   - Patient uses nonpharmacologic measures (such as relaxation, music therapy, pet therapy, biofeedback, massage, therapeutic touch, and diversion) concurrently with drug therapy for increasing comfort levels.
3. Patient states measures to assist in supporting immune system and preventing infection such as frequent handwashing, performance of deep breathing exercises, forcing of fluids, consumption of a well-balanced diet, avoidance of malls and other crowded places, and avoidance of persons with colds, flu, or communicable respiratory illnesses.

- Patient states ways to minimize oral mucosal breakdown and infection, such as frequent mouth care and dental hygiene measures using mild toothpaste, gentle sponge-type toothettes, and non–alcohol-based mouthwash, as well as taking fluids frequently.
- Patient demonstrates the use of various measures to enhance skin integrity, such as keeping skin clean, dry, and lubricated.
- Patient adheres to daily regimen for increasing urinary health, such as forcing fluids and consuming fluids that minimize urinary infections (e.g., cranberry juice).

(Note that the nursing diagnoses, goals, and outcome criteria presented here are appropriate to treatment with many antineoplastic drugs.)

IMPLEMENTATION

Antineoplastic drugs are some of the most toxic medications given to patients because they cause the death of normal cells along with the death of cancer cells. The high potency of these drugs also places the patient at higher risk for toxicity, serious complications, and adverse effects. The possibility of such adverse effects and toxicities requires skillful nursing care based on cautious and thorough assessment and subsequent critical thinking. General considerations in nursing implementation applicable to most antineoplastic drugs as well as some specific aspects of implementation related to cell cycle–specific drugs are discussed in the following paragraphs. Other nursing process information related to cell cycle–nonspecific drugs is presented in Chapter 46.

For antineoplastic therapy in general, nursing considerations related to *reducing fear and anxiety* include establishing a therapeutic relationship beginning with trust and empathy. Approach the patient in a warm, empathic, and supportive manner while projecting confidence in providing nursing care. Provide individualized explanations and teaching about the patient's illness, care, and treatments that are appropriate to the patient's educational level. Collaborate with all members of the health care team. Encourage patients to consider relaxation techniques such as listening to music, performing meditation, or engaging in guided imagery. It may be necessary to call on all potential sources of support, including social services, counseling services, financial assistance services, Meals On Wheels, and religious-spiritual or belief systems with respect to the patient's needs. Appropriate consults may also be necessary with other practitioners such as a licensed clinical social worker, discharge planner, clinical psychiatrist, mental health nurse, nurse practitioner, and oncology nurse specialist, as well as with support groups for the patient, family, and/or significant others.

A variety of interventions that may be indicated for the management of *stomatitis* or excessive oral mucosa dryness and irritation include the following: (1) Instruct the patient to perform oral hygiene before and after eating or as needed to provide cleanliness and comfort. Advise the patient to avoid lemon, glycerin, undiluted peroxide, or alcohol-containing products because they are drying and irritating to the oral mucosa. (2) Recommend using a soft-bristle toothbrush or soft-tipped toothette or swab with solutions of diluted warm saline. (3) If dentures are worn, encourage the patient to remove and clean them frequently and, if stomatitis is severe, to insert only at mealtimes. (4) Advise using OTC saliva substitutes, keeping the lips moist, and using sugarless candy or gum to stimulate saliva flow. (5) Stress that spicy, acidic, or hot foods; alcohol; and tobacco must be avoided because they are irritants. (6) Oral antifungal suspensions (e.g., nystatin) may be ordered if white patches are noted on the oral mucosa; use analgesic solutions (e.g., lidocaine swish and swallow), as ordered, to help manage discomfort. Other regimens may be prescribed, as needed.

Nausea and vomiting occur commonly with antineoplastic drugs. Emetic potential varies depending on the drug and treatment protocol (see earlier discussion and Box 45-1). Educate the patient on measures to enhance comfort during times of nausea and vomiting, including restricting oral intake as ordered; removing noxious odors or sights to avoid stimulating the vomiting center; performing oral hygiene as needed; promoting relaxation through slow, deep breathing; consuming small, frequent meals and eating slowly; and consuming clear liquids and a bland diet. Use of IV fluids may be indicated if nausea and vomiting are severe for hydration purposes. Antiemetics are also a vital part of antineoplastic therapy (see Chapter 52 for more specific drug-related information). Premedication with antiemetics 30 to 60 minutes before administration of the antineoplastic(s) is the preferred treatment protocol to help reduce nausea and vomiting, prevent dehydration and malnutrition, and promote comfort. Combination antiemetic drug therapy may be more effective than single-drug therapy. An antiemetic may be given with the chemotherapeutic regimen and prescription medication for at home use. Ginger ale and ginger-based teas may be helpful.

Diarrhea is also a common adverse effect of antineoplastic therapy. Perform the following nursing interventions: (1) Advise the patient to avoid or limit oral intake of irritating, spicy, and gas-producing foods; caffeine; high-fiber foods; alcohol; very hot or cold foods or beverages; and lactose-containing foods and beverages. (2) Consult appropriate personnel, as ordered, to help the patient and family plan meals and arrange ways to meet the patient's dietary and bowel elimination needs. (3) Administer opioids (e.g., paregoric) or synthetic opioids (e.g., loperamide, diphenoxylate hydrochloride) as prescribed, as antidiarrheals. Adsorbents-protectants and antisecretory drugs may also help reduce GI upset and diarrhea (see Chapter 51).

To address *nutritional concerns,* the following measures may prove beneficial in improving oral intake and nutritional status: (1) Perform a 24-hour recall of food intake, and report the typical week's diet for the patient. (2) Use antiemetic therapy, pain management, mouth care, and hydration, as ordered, to reduce the adverse effects of therapy and improve appetite. (3) To ease taste alterations, advise the patient to consume mild-tasting foods and to use chicken, turkey cheese, or greek yogurt for protein sources as tolerated. (4) Provide plastic rather than metal utensils if the patient complains of a metallic taste. (5) Encourage eating

foods that are easy to swallow, such as custards; gelatins; puddings; milkshakes; eggnog; commercially prepared high-protein, high-calorie supplemental shakes; mashed white or sweet potatoes; blended drinks with crushed ice, fruit, and yogurt; nutritional supplement drinks and snacks; frozen popsicles; and lactose-free ice cream. (6) Instruct the patient to avoid sticky or dry foods. (7) Encourage the consumption of small, frequent meals in an environment that is conducive to eating (e.g., free of odors and excess noise). (8) Appetite stimulants such as megestrol acetate or dronabinol may be helpful. (9) Encourage the patient to practice energy conservation, with frequent rest periods before and after meals.

Alopecia is a common adverse effect of antineoplastics and is very disturbing regardless of age or gender. Warn the patient and family about the possibility of hair loss, and tell them when it will occur (usually 7 to 10 days after treatment begins but dependent upon the specific drug used) and that it is reversible. Inform the patient that new hair growth is often a different color and/or texture from the hair lost. Provide information about the options of acquiring a wig or hairpiece, or wearing scarves or hats, before the actual hair loss. The American Cancer Society may be a resource for items such as wigs, scarves, and hats.

Antineoplastic-induced bone marrow suppression leads to *anemias, leukopenia, neutropenia,* and *thrombocytopenia* (see previous discussion and Safety: Laboratory Values Related to Drug Therapy boxes in this chapter and Chapter 46). Anemias result in fatigue and loss of energy and are common adverse effects of therapy and the disease process. Anemias may require blood transfusions, peripheral blood stem cell treatment, or treatment with prescribed medications such as iron preparations, folic acid, or erythropoietic growth factors (e.g., epoetin or darbepoetin alfa). These injections may be given at home and may be administered at the first sign of a decrease in RBC counts. Conservation of energy and planning of care is very important in minimizing patient fatigue.

Risk of infection from leukopenia or neutropenia and/or immunosuppression is one of the more significant adverse effects that requires close attention. Inform the patient and family and/or caregivers that when WBC counts are low, the patient is at high risk for infection and that defenses remain low until the counts recover. Following Standard Precautions and using good handwashing technique are most important in preventing transmission of infection in the hospital and home settings. Because fever is a principal early sign of infection, take oral or axillary temperature at least every 4 hours during periods in which the patient is at risk. Avoid taking the temperature rectally to minimize tissue trauma, breaks in skin integrity, and thus loss of the first line of defense and increased risk to infection. Encourage the patient to immediately report to the prescriber a temperature elevation of 100.5° F (38.1° C) or higher so that appropriate treatment may be initiated and complications avoided.

If needed, and as ordered, administration of colony-stimulating factors may be beneficial. Filgrastim, pegfilgrastim, and sargramostim are examples of drugs given to accelerate WBC recovery during antineoplastic drug therapy. Use these drugs, as ordered, to minimize neutropenia. These medications act on the bone marrow to enhance neutrophil production and help decrease the incidence, severity, and duration of neutropenia. You must administer these drugs within a certain time frame (see Chapter 47). Encourage patients with *immune suppression* to be aware of environments and persons to avoid, such as individuals who have recently been vaccinated (who may have a subclinical infection) or who have a cold or flu or other symptoms of an infection. Maintaining a "low-microbe" diet by washing fresh fruits and vegetables and making sure foods are well cooked is also recommended. Educate patients on the importance of performing oral care frequently (see discussion of stomatitis) and to turn, cough, and deep breathe to help prevent stasis of respiratory secretions.

Thrombocytopenia is also an adverse effect of antineoplastic therapy and puts the patient at risk for bleeding. Monitor platelet counts, coagulation studies, RBC counts, hemoglobin levels, and hematocrit values, and report any decreases (see the Safety: Laboratory Values Related to Drug Therapy box). Avoid injections if possible, and utilize alternative routes of administration. If injections or venipunctures are absolutely necessary, always use the smallest gauge needle possible and apply gentle, prolonged pressure to the site afterward. Monitor patients undergoing bone marrow aspiration closely after the procedure for bleeding at the aspiration site. Perform blood pressure monitoring as needed. Be efficient and quick and without overinflating the cuff to avoid bruising. Monitor the patient for bleeding from the mouth, gums, and nose. Check for bleeding after teeth brushing and report excessive bleeding to the prescriber.

Inform the patient that antineoplastics may also have a *negative impact on the reproductive tract,* causing destruction of the germinal epithelium of the testes and damage to the ovaries and to a fetus (teratogenesis). Other problems may include sterility; amenorrhea; premature menopausal symptoms of hot flashes, decreased vaginal secretions, mood changes, or irritability; and decreased libido or sexual dysfunction. Counsel male patients about the risk of sterility which may be irreversible. Discuss with male patients the option and topic of sperm banking before chemotherapy, if deemed appropriate. Stress that female patients of childbearing age who are sexually active need to protect themselves against pregnancy because of the risk of embryonic death. Encourage contraceptive measures during chemotherapy and for up to 8 weeks after discontinuation of therapy; however, some antineoplastic drugs require use of contraception for up to 2 years after completion of treatment because of the long-term risk for genetic abnormalities.

With *antimetabolites,* always follow the prescriber's orders regarding premedication with antiemetics and/or antianxiety drugs. Follow orders or protocol for the use of other symptom-control medications, as prescribed. GI adverse effects are common with antimetabolites and usually occur on about the fourth day and require preplanning for special pharmacologic interventions (e.g., antiemetics, antispasmodics, analgesics) and nonpharmacologic measures (dietary changes, oral care). Antibiotic therapy may also be ordered prophylactically. See earlier discussion of nursing considerations associated with stomatitis, loss of appetite, diarrhea, nausea, nutrition,

hydration, vomiting, and anemias. For further discussion of the handling of antimetabolites and other IV antineoplastic drugs, see Box 46-3.

Use extreme caution in handling and administration of cytarabine by the various routes (IV, subcutaneous, or intrathecal). Other major concerns with cytarabine therapy are bone marrow suppression (see earlier discussion) and cytarabine syndrome (see the Assessment section). If high dosages are used, cytarabine may also cause central nervous system, GI, and/or pulmonary toxicity, so closely monitor these systems to ensure patient safety and comfort. For intrathecal administration, the drug may be reconstituted with sodium chloride, or the prescriber may use the patient's spinal fluid. Do not add fluorouracil to any other IV infusions; administer the drug by itself in the appropriate diluent. When an infusion port is not used, do not use IV sites over joints, tendons, or small veins, or in extremities that are edematous. Give IV dosages exactly as ordered, and constantly monitor the IV site, infusion port, and/or infusion solution and equipment. If IV infiltration occurs, follow the protocol for management of infiltration and contact the prescriber. Follow all hospital or infusion protocols without exception because treatment of extravasation is handled differently depending on the specific drug. If extravasation of a vesicant occurs, the drug is usually discontinued immediately; leave the IV cannula in place (for possible use of antidotes through cannula to access affected area), and follow facility protocol. Antidotes and use of other drugs, as well as use of hot or cold packs, is usually outlined in the protocol for managing extravasation (see Box 46-1). If topical forms of the drug are used, inform the patient that it is important to apply the drug exactly as ordered and to the affected area only. Use gloves or a finger cot to apply the topical dosage form.

Gemcitabine another antimetabolite, is dosed based on absolute granulocyte counts and platelet nadirs and is given if the counts exceed 1500×10^6 cells/L and $100{,}000 \times 10^6$ platelets/L, respectively. Keep IV solutions at room temperature to avoid crystallization and use within 24 hours. Give infusions as ordered. Antiemetics and antidiarrheals may be needed. Mercaptopurine comes in oral dosage forms; give as ordered. Finally, the antimetabolite methotrexate has numerous toxicities and adverse effects that may be minimized by appropriate medical treatment. For example, there may be orders for boosting the immune status and blood cell counts before aggressive therapy is initiated. Cytoprotective drugs are used. Continue to monitor creatinine clearance, as ordered, to detect any nephrotoxicity. Nutritional status may be enhanced by the intake of foods high in folic acid, including bran, dried beans, nuts, fruits, asparagus, and other fresh vegetables, if tolerated. Consumption of these foods is yet another measure to help minimize the possibility of methotrexate toxicity. If GI upset and/or stomatitis occur, the patient may need to decrease any sources of irritation (e.g., high-fiber food). Methotrexate is usually given orally or IV. Wear gloves when giving the drug. If any of the solution comes in contact with the skin, wash the area immediately and thoroughly with soap and water. (See Box 46-3 for discussion of concerns in the handling and administration of vesicant drugs.)

For the *mitotic inhibitors,* specifically the taxane family of drugs and docetaxel in particular, premedication protocols are usually specified and include administration of oral corticosteroids (e.g., dexamethasone) beginning several days before day 1 of therapy to help decrease the risk of hypersensitivity. Measure vital signs frequently during the infusion, especially in the first hour of the infusion. Closely monitor the patient for the sudden onset of bronchospasm, flushing of the face, and localized skin reactions; these may indicate a hypersensitivity response requiring immediate treatment. Contact the prescriber immediately. These symptoms may occur within just a few minutes of beginning the infusion. In addition, any dyspnea, abdominal distension, crackles in the lungs, or dependent edema during therapy require immediate attention. Cutaneous reactions may also appear during therapy and include rash on the hands and feet; these also need immediate attention and treatment. With paclitaxel, the patient may also be premedicated with diphenhydramine, corticosteroids, and H_2 antagonist drugs. Take all measures to minimize tissue trauma (e.g., avoidance of intramuscular injections and rectal temperature taking, if possible) to promote comfort and prevent bleeding and infection.

With the *topoisomerase I inhibitors,* irinotecan and topotecan, monitor blood counts closely with every treatment. A drop in blood counts and/or severe diarrhea may cause a temporary postponement of therapy. Treat any extravasation of the solution immediately, and follow protocol. Ensuring that IV sites remain patent is critical to the prevention of tissue damage secondary to extravasation of antineoplastic drugs that are considered to be irritants and/or vesicants. Nausea and vomiting may lead to dehydration and electrolyte disturbances. Advise patients and family members to report these symptoms immediately before negative consequences occur (see previous discussion for specific interventions). IV incompatibilities are numerous for both these drugs and are of constant concern. With topotecan, IV extravasation is usually accompanied by a mild local reaction such as erythema or bruising. If these symptoms are noted, they must be managed immediately to avoid further trauma and/or risk for loss of skin integrity (the first line of defense against infection). Headaches and difficulty breathing may be more common with topotecan; therefore, closely and frequently monitor the patient for these symptoms.

Handle the *enzyme antineoplastics* asparaginase and pegaspargase with extreme caution and care. The patient may receive an intradermal test dose of asparaginase before therapy begins or when a week or longer has passed between doses. With asparaginase and pegaspargase, if the solution comes in contact with the skin, thoroughly wash or rinse the area with copious amounts of water for a minimum of 15 minutes. During therapy, if there are signs and symptoms of oliguria, anuria (renal failure), or pancreatitis, the drug will most likely be discontinued. The intramuscular route of administration is usually preferred because it carries a lower risk of causing clotting abnormalities, GI disorders, and renal and hepatic toxicity. If solutions are cloudy, do not use them. If more than 2 mL is ordered/required for an intramuscular dosing, use two injections. Pancreatitis is problematic with these drugs and can be serious. Pay close attention to symptoms such as severe abdominal pain with

nausea and vomiting. Constantly monitor serum lipase and amylase levels. If any signs or symptoms of pancreatitis occur, the prescriber will usually discontinue the drugs immediately. Use of cytoprotective drugs has been briefly discussed in the Pharmacology section of this chapter, with further discussion provided in Chapter 46.

EVALUATION

Focus evaluation of nursing care on reviewing whether goals and outcomes are being met as well as monitoring for therapeutic responses and adverse and toxic effects of the antineoplastic therapy. Therapeutic responses may manifest as clinical improvement, decrease in tumor size, and decrease in metastatic spread. Evaluation of nursing care, with reference to goals and outcomes, may reveal improvements related to a decrease in adverse effects and a decrease in the impact of cancer on the patient's well-being. There will be increases in comfort, nutrition, hydration, energy levels, ability to carry out activities of daily living, and improved quality of life with therapeutic effectiveness. Revisit goals and outcomes to identify more specific areas to monitor. In addition, certain laboratory studies such as tumor marker levels, levels of carcinoembryonic antigens, RBC and WBC counts, and platelet counts may be performed to aid in determining how well the treatment protocol has worked and to monitor adverse effects of bone marrow suppression. Also, if absolute neutrophil count (ANC) drops below 500 cells/mm^3, the prescriber may discontinue chemotherapy but then reinitiate when the level is above 1000 cells/mm^3 or as facility policy or prescriber dictates. Other blood counts are considered, too. As part of the evaluation, prescribers may also order additional radiographs, computed tomographic scans, magnetic resonance images, tissue analyses, or other studies appropriate to the diagnosis both during and after antineoplastic therapy has been completed, at time intervals related to the anticipated tumor response.

CASE STUDY

Facing Chemotherapy

Mrs. D., a 48-year-old married mother of two teenage daughters, has been diagnosed with breast cancer. She has undergone lumpectomy to remove the tumor and is about to start adjuvant chemotherapy. She states that she has "faced the facts" about her disease and the threat to her life but says, "I know this is silly, but I hate the thought of losing my hair to this disease."

1. What measures can be taken to help Mrs. D. deal with her hair loss?
2. Ten days after the chemotherapy, Mrs. D.'s neutrophil count drops to 2000 cells/mm^3. She has been hospitalized because she has developed a cough, and several of her friends have come in to visit her with a fresh fruit basket. What actions will be taken to protect her from infection?
3. During rounds, the nurse finds Mrs. D. curled up in the bed and sobbing. Mrs. D. says that she feels "so afraid" and is worried about who will care for her family if she dies. What actions will the nurse take at this time?

For answers, see http://evolve.elsevier.com/Lilley.

PATIENT TEACHING TIPS

- Educate patients that GI adverse effects and irritation to the oral and GI mucosa may be decreased by avoiding intake of alcohol, tobacco, spicy and high-fiber foods, citrus fruit juices or foods, and foods that are too hot or cold or have a rough texture.
- Stress that daily mouth care is needed. Instruct the patient to report mouth sores, pain, or white patches to the prescriber immediately. Headache, fatigue, faintness, shortness of breath (possibly indicative of anemia), bleeding, easy bruising (possibly indicative of a drop in platelet count), sore throat, and fever (possibly indicative of infection) also need to be reported immediately to the appropriate prescriber. Fever and/or chills may be the first sign of an oncoming infection.
- Discuss contraception, sperm banking, and other reproductive issues with male patients and women of childbearing age.
- Emphasize to the patient receiving antineoplastic drugs which OTC medications to avoid (e.g., aspirin, ibuprofen, and any combination products containing these OTC drugs).
- Antineoplastics may cause alopecia (hair loss). Before therapy, provide the patient with the opportunity to discuss options for hair and scalp care. These options may include, but are not limited to, having the hair cut short before treatment; selecting, purchasing, or renting a wig or hairpiece comparable to the patient's existing hair in color, texture, length, and style; or having bandanas, scarves, or hats on hand before the hair is actually lost. Although hair loss is temporary, inform patients that it will occur and that hair will appear differently upon growing back. The American Cancer Society may be a resource for wigs and hairpieces.
- The following websites are helpful online resources for the patient and significant others: www.fda.gov, http://www.fda.gov/ForHealthProfesionals/default.htm,www.nih.gov, http://www.healthfinder.gov, www.who.int/en, and http://www.oncolink.org/index.cfm.
- With *cytarabine,* encourage the patient to increase fluid intake to help decrease the risk of dehydration and/or hyperuricemia.
- With *fluorouracil* and *gemcitabine,* encourage frequent oral hygiene and for the patient to report to the prescriber immediately any bleeding, bruising, chest pain, diarrhea, nausea, vomiting, heart palpitations, infection, or changes in vision. Instruct patients to protect themselves from the sun while taking fluorouracil, including avoiding overexposure to sun or ultraviolet light and using protective clothing, sunscreen, and sunglasses.
- With *mercaptopurine,* educate the patient that alcohol must be avoided to help minimize drug toxicity.
- With *methotrexate,* inform the patient to notify the prescriber if nausea and vomiting are problematic or uncontrollable, or if fever, sore throat, muscle aches and pains, or

PATIENT TEACHING TIPS—cont'd

unusual bleeding occurs. Advise the patient to avoid alcohol, salicylates, nonsteroidal antiinflammatory drugs, and exposure to sunlight or ultraviolet light. Instruct both male and female patients to use contraceptive measures for up to 3 months or longer, if appropriate.

- With *taxanes,* specifically paclitaxel, counsel the patient to report to the prescriber immediately any signs or symptoms of neuropathy (e.g., numbness or tingling of the extremities).
- With *etoposide* and *teniposide* as with other antineoplastics, if WBC counts are low, caution the patient to avoid individuals who are ill. Additionally, advise the patient to report to the prescriber immediately any easy bleeding, bruising, difficulty breathing, fever, sore throat, or chills.
- With *asparaginase* and *pegaspargase,* encourage the patient to force fluids and to report any severe nausea or vomiting, bleeding, excessive fatigue, or fever or other signs or symptoms of infection.

KEY POINTS

- Cancers are diseases that are characterized by uncontrolled cellular growth.
- *Malignancy* refers specifically to a neoplasm that is anaplastic, invasive, and metastatic, as opposed to benign.
- Tumors are generally classified by tissue of origin, as follows: epithelial (carcinoma), connective (sarcoma), lymphatic (lymphoma), and leukocytes (leukemia).
- Antineoplastics are drugs that are used to treat malignancies. They may be either cell cycle–specific or cell cycle–nonspecific drugs or may have miscellaneous actions.
- Cell cycle–specific drugs kill cancer cells during specific phases of the cell growth cycle. Cell cycle–nonspecific drugs kill cancer cells during any phase of the cell growth cycle.
- Chemotherapy, or antineoplastic drug therapy, requires very skillful and perceptive nursing care. It is important to act prudently and think critically when making decisions about the nursing care of patients receiving these drugs.
- Cell cycle–specific drug classes include antimetabolites, mitotic inhibitors, alkaloid topoisomerase II inhibitors, topoisomerase I inhibitors, and antineoplastic enzymes.
- Antineoplastic antimetabolites are cell cycle–specific antagonistic analogues that work by inhibiting the actions of key cellular metabolites.
- Two plant-derived antineoplastic drugs are the taxanes paclitaxel, derived from the bark of the slow-growing Western (Pacific) yew tree, and docetaxel, a semisynthetic taxoid produced from the needles of the European yew tree. Docetaxel is pharmacologically similar to paclitaxel.
- The topoisomerase I inhibitors topotecan and irinotecan compose a relatively new class of chemotherapy drugs.
- Antineoplastic enzymes include asparaginase and pegaspargase.
- Several drugs are available that are classified as cytoprotective and help reduce the toxicity of various antineoplastics.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A patient is experiencing stomatitis after a round of chemotherapy. Which intervention by the nurse is correct?
   - **a** Clean the mouth with a soft-bristle toothbrush and warm saline solution.
   - **b** Rinse the mouth with commercial mouthwash twice a day.
   - **c** Use lemon-glycerin swabs to keep the mouth moist.
   - **d** Keep dentures in the mouth between meals.

2 The nurse is caring for a patient who becomes severely nauseated during chemotherapy. Which intervention is most appropriate?
   - **a** Encourage light activity during chemotherapy as a distraction.
   - **b** Provide antiemetic medications 30 to 60 minutes before chemotherapy begins.
   - **c** Provide antiemetic medications only upon the request of the patient.
   - **d** Hold fluids during chemotherapy to avoid vomiting.

3 The nurse monitors a patient who is experiencing thrombocytopenia from severe bone marrow suppression by looking for
   - **a** severe weakness and fatigue.
   - **b** elevated body temperature.
   - **c** decreased skin turgor.
   - **d** excessive bleeding and bruising.

4 A patient receiving chemotherapy is experiencing severe bone marrow suppression. Which nursing diagnosis is most appropriate at this time?
   - **a** Activity intolerance
   - **b** Risk for infection
   - **c** Disturbed body image
   - **d** Impaired physical mobility

NCLEX® EXAMINATION REVIEW QUESTIONS—cont'd

5 If extravasation of an antineoplastic medication occurs, which intervention will the nurse perform first?
- **a** Apply cold compresses to the site while elevating the arm.
- **b** Inject subcutaneous doses of epinephrine around the IV site every 2 hours.
- **c** Stop the infusion immediately while leaving the catheter in place.
- **d** Inject the appropriate antidote through the IV catheter.

6 The nurse is assessing a patient who has experienced severe neutropenia after chemotherapy and will monitor for which possible signs of infection? (Select all that apply.)
- **a** Elevated WBC count
- **b** Fever
- **c** Nausea
- **d** Sore throat
- **e** Chills

7 The order for chemotherapy reads: "Give asparaginase (Elspar) IV 200 units/kg/day." The patient weighs 297 lb. The pharmacy department will prepare the medication for intravenous infusion. How much drug will be given per dose? Is this a safe dose?

1. a, 2. b, 3. d, 4. b, 5. c, 6. b, d, e, 7. 27,000 units; yes

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Review the concepts related to carcinogenesis, the types of malignancies and related terminology, and the different treatment modalities, including the use of cell cycle–nonspecific and miscellaneous antineoplastic drugs.
2 Identify the various drugs that are classified as cell cycle nonspecific or hormonal or are considered to be miscellaneous antineoplastic drugs.
3 Discuss the common adverse effects and toxic effects of the cell cycle–nonspecific and miscellaneous antineoplastic drugs, including the reasons for their occurrence and methods of treatment, such as any antidotes.
4 Describe the mechanisms of action, indications, dosages, routes of administration, cautions, contraindications, and drug interactions of the cell cycle–nonspecific drugs, hormonal drugs, and miscellaneous antineoplastic drugs.
5 Apply knowledge about the cell cycle–nonspecific, hormonal agonist-antagonist, and other miscellaneous antineoplastic drugs and their characteristics in the development of a comprehensive nursing care plan for patients with cancer who are receiving these drugs.
6 Briefly describe extravasation and other major adverse effects associated with the cell cycle–nonspecific and miscellaneous antineoplastics, including discussion of protocols and antidotes.

KEY TERMS

Alkylation A chemical reaction in which an alkyl group is transferred from one molecule to another. In chemotherapy, alkylation leads to damage of the cancer cell deoxyribonucleic acid (DNA) and cell death. (p. 749)

Bifunctional Referring to those alkylating drugs composed of molecules that have two reactive alkyl groups and that are therefore able to alkylate at two sites on the DNA molecule. (p. 750)

Extravasation The leakage of any intravenously or intraarterially administered medication into the tissue space surrounding the vein or artery. Such an event can cause serious tissue injury, especially with antineoplastic drugs. (p. 751)

Mitosis The process of cell reproduction occurring in somatic (nonsexual) cells and resulting in the formation of two genetically identical daughter cells, each containing the diploid (complete) number of chromosomes characteristic of the species. (p. 750)

Polyfunctional Referring to the action of alkylating drugs that can engage in several alkylation reactions with cancer cell DNA molecules per single molecule of drug. (p. 750)

This chapter is a continuation of Chapter 45 and focuses on additional classes of antineoplastic drugs. Chapter 45 describes the various antineoplastic drugs that are effective against cancer cells during specific phases in the cell growth cycle. In contrast, this chapter focuses on drugs that have antineoplastic activity regardless of the phase of the cell cycle. Also discussed in this chapter are drugs that are classified as miscellaneous antineoplastics, either because of their lack of clear cell cycle specificity or their unique or novel (new) mechanisms of action. For a description of the cell growth cycle, see Chapter 45.

PHARMACOLOGY OVERVIEW

CELL CYCLE–NONSPECIFIC ANTINEOPLASTIC DRUGS

There are currently two broad classes of cell cycle–nonspecific cancer drugs: alkylating drugs and cytotoxic antibiotics.

ALKYLATING DRUGS

Records of the use of drugs to treat cancer date back several centuries. However, truly successful systemic cancer chemotherapy treatments are not documented until the 1940s. At this time, the first alkylating drugs were developed from mustard gas agents that were used for chemical warfare before and during World War I. The first drug to be developed was mechlorethamine, which is also known as *nitrogen mustard*. It is the prototypical drug of this class and is still used today for cancer treatment. Since its antineoplastic activity was discovered in the mid-twentieth century, many analogues have been synthesized for use in the treatment of cancer, and they are collectively referred to as nitrogen mustards also.

The alkylating drugs commonly used in clinical practice in the United States today fall into three categories: classic alkylators (the nitrogen mustards); nitrosoureas, which have a different chemical structure than the nitrogen mustards but also work by **alkylation;** and miscellaneous alkylators, which also have a different chemical structure than the nitrogen mustards but are known to work at least partially by alkylation. These drugs are used to treat a wide spectrum of malignancies. The drugs in each category are as follows:

Classic alkylators (nitrogen mustards)
- chlorambucil
- cyclophosphamide
- ifosfamide
- mechlorethamine
- melphalan

Nitrosoureas
- carmustine
- lomustine
- streptozocin

Miscellaneous alkylators
- altretamine
- busulfan
- carboplatin
- cisplatin
- dacarbazine
- oxaliplatin
- procarbazine
- temozolomide
- thiotepa

Mechanism of Action and Drug Effects

The alkylating drugs work by preventing cancer cells from reproducing. Specifically, they alter the chemical structure of the cells' deoxyribonucleic acid (DNA), which is essential to the reproduction of any cell. DNA molecules consist of two adjacent strands, each consisting of alternating sequences of phosphate and sugar molecules (Figure 46-1). These components make up what is called the "backbone" of the DNA strands. These two strands are chemically linked to each other by the third DNA structural element: nitrogen-containing bases (adenine, guanine, thymine, and cytosine, abbreviated A, G, T, and C, respectively). These bases are bound to the sugar molecules of the DNA backbone, and two bases, linked to each other by hydrogen bonds, form the molecular bridges between the two DNA strands that bring them into the double helix structure. A nucleotide, which consists of one molecule each of base, sugar, and phosphate that are bound together, is the structural unit of the molecules of both DNA and ribonucleic

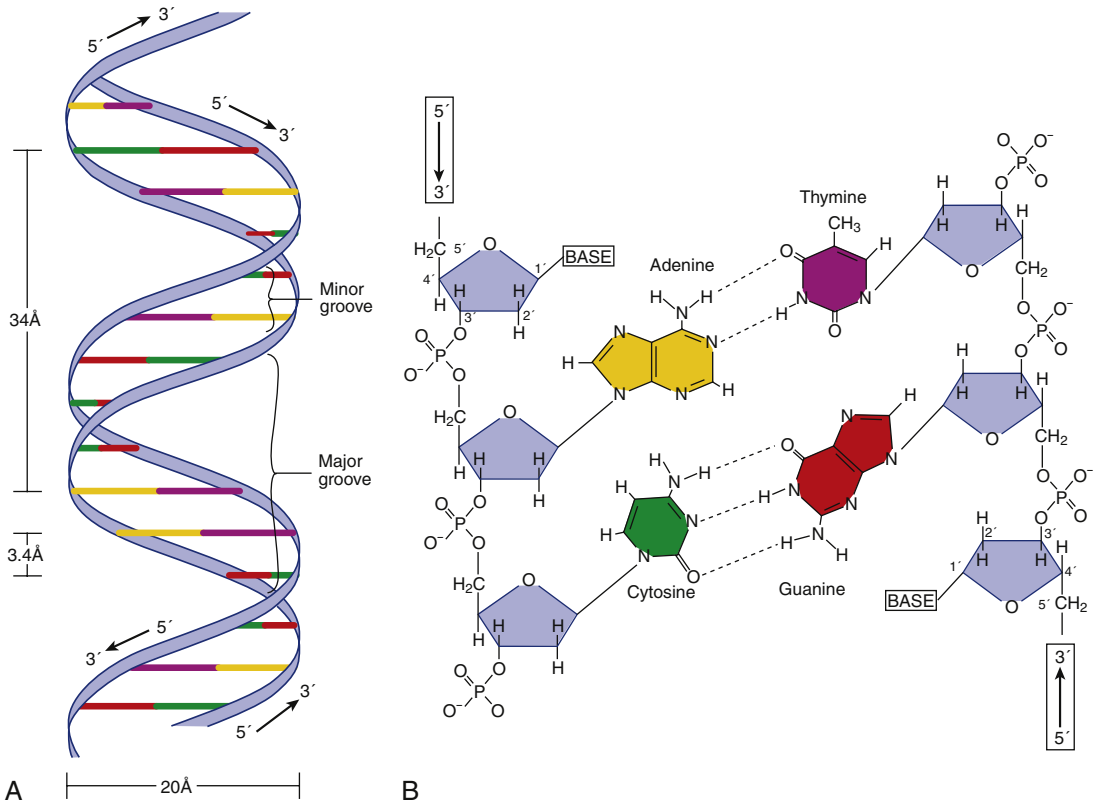

FIGURE 46-1 Deoxyribonucleic acid (DNA) double helix. **A,** Diagrammatic model of the helical structure, showing its dimensions, the major and minor grooves, the periodicity of the bases, and the antiparallel orientation of the backbone chains (represented by ribbons). The base pairs (represented by rods) are perpendicular to the axis and lie stacked one on another. **B,** The chemical structure of the backbone and bases of DNA, showing the sugar-phosphate linkages of the backbone and the hydrogen bonding between the base pairs. There are two hydrogen bonds between adenine and thymine, and three between cytosine and guanine. (From *Dorland's illustrated medical dictionary,* ed 31, Philadelphia, 2007, Saunders.)

acid (RNA), another nucleic acid that is important in cellular reproduction. Messenger RNA (mRNA) molecules are produced by DNA molecules during the complex process of transcription. These mRNA molecules differ from DNA molecules in at least three ways: they are single stranded (instead of double stranded), the thymine base is replaced by another base known as uracil (U), and the sugar molecule is ribose, which has a slightly different structure from that of the deoxyribose molecules of DNA.

During the normal process of reproduction, the double helix uncoils, and its two strands separate. A strand of RNA is then assembled next to each single DNA strand in a process known as *transcription.* RNA strands, in turn, are involved in both protein synthesis (translation) and replication of the original DNA structure before cell division, or **mitosis.** These processes ultimately result in the creation of a new cell with the same DNA sequence, and thus the same characteristics, as its parent cell.

Alkyl groups that are part of the structure of antineoplastic alkylating drugs attach to DNA molecules by forming covalent bonds with the bases described earlier. As a result, abnormal chemical bonds form between the adjacent DNA strands, which leads to the formation of defective nucleic acids that are then unable to perform the normal cellular reproductive functions mentioned previously. This leads to cell death.

Alkylating drugs can be characterized by the number of alkylation reactions in which they can participate. **Bifunctional** alkylating drugs have two reactive alkyl groups that are able to alkylate two sites on the DNA molecule. **Polyfunctional** alkylating drugs can participate in several alkylation reactions. Figure 46-2 shows the location along the DNA double helix where the alkylating drugs work.

Indications

The most commonly used alkylating drugs today are effective against a wide spectrum of malignancies, including both solid and hematologic tumors. Common examples of the various types of cancer that different alkylating drugs are used to treat are listed in the Dosages table on p. 752.

Adverse Effects

Alkylating drugs are capable of causing all of the dose-limiting adverse effects described in Chapter 45. Other adverse effects are described in Table 46-1. The relative emetic potential of the various alkylating drugs is given in Box 45-1. The adverse effects of these drugs are important because of their severity, but they can often be prevented or minimized by prophylactic measures. For instance, nephrotoxicity from cisplatin can often be prevented by adequately hydrating the patient with intravenous fluids.

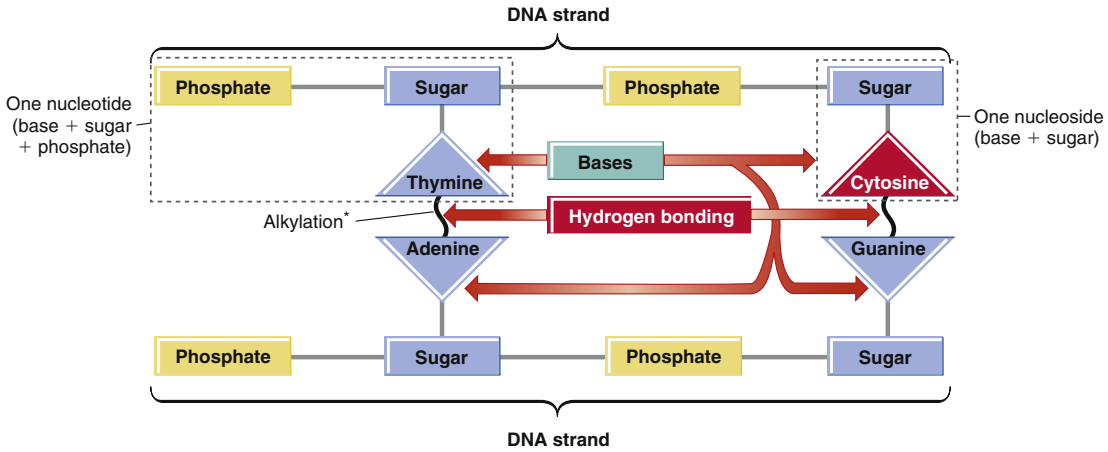

FIGURE 46-2 Organization of deoxyribonucleic acid (DNA) and site of action (*) of alkylating drugs.

TABLE 46-1 COMMONLY USED ALKYLATING DRUGS: SEVERE ADVERSE EFFECTS

DRUG	ADVERSE EFFECTS
busulfan	Pulmonary fibrosis
carboplatin*	Nephrotoxicity, neurotoxicity, bone marrow suppression
cisplatin	Nephrotoxicity, peripheral neuropathy, ototoxicity
cyclophosphamide	Hemorrhagic cystitis

*Carboplatin has less nephrotoxicity and neurotoxicity but more bone marrow suppression than cisplatin.

Drug **extravasation** (Box 46-1) occurs when an intravenous catheter punctures the vein and medication leaks (infiltrates) into the surrounding tissues. With cancer chemotherapeutic drugs, in particular doxorubicin (a cytotoxic antibiotic), extravasation can cause severe tissue damage and necrosis (tissue death). Extravasation antidotes for selected drugs are listed in Table 46-2.

Interactions

Only a few alkylating drugs are capable of causing significant drug interactions. The most important rule for preventing such drug interactions is to avoid administering an alkylating drug with any other drug capable of causing similar toxicities. For example, a major adverse effect of cisplatin is nephrotoxicity. Therefore, if possible, do not administer it with a drug such as an aminoglycoside antibiotic (gentamicin, tobramycin, or amikacin) because of the resulting additive nephrotoxic effects and hence the increased likelihood of renal failure. Mechlorethamine and cyclophosphamide, both of which have significant bone marrow–suppressing effects, are not to be administered with radiation therapy or with other drugs that suppress the bone marrow. In general, you need to work with available pharmacy and oncology staff to proactively anticipate (and avoid, if possible) undesirable drug and treatment interactions.

Dosages

For dosage information on selected alkylating drugs, see the table on p. 752. It is important to note that dosages are highly

BOX 46-1 EXTRAVASATION OF ANTINEOPLASTICS

Extravasation is one of the more devastating complications of antineoplastic therapy and may lead to extensive tissue damage, the need for skin grafting, other problems in the surrounding areas, and even loss of limb. Because many cell cycle–specific and cell cycle–nonspecific drugs are given intravenously, there is a constant danger of extravasation of vesicants and subsequent injury, including permanent damage to nerves, tendons, and muscles. Skillful and perceptive nursing care helps to prevent extravasation or to identify it early if it does occur, which may reduce the severity of tissue damage. There are important reasons for the placement of central venous intravenous catheters rather than peripheral catheters when long-term treatment is anticipated. Infiltration may occur with any intravenous catheter; it is the specific drug and its characteristics, such as irritant (irritating the IV site or vein) or vesicant (causing cell death with extravasation and necrosis with ulcerative properties, that poses the concern. Because peripheral veins are small and offer minimal dilution of the intravenous drug with blood, there is a greater risk of severe and irreversible damage if a substance infiltrates and spreads to surrounding areas. If the drug is a vesicant, extravasation may lead to massive tissue injury, whereas extravasation of an irritant results in significantly less damage. Central venous access is needed for administration of vesicants to avoid the problems associated with extravasation. However, extravasation may occur with central lines and PICC lines due to dislodging of the access catheter, venous thrombosis, and catheter breakage. Blood needs to be aspirated prior to administration to check for patency. Extravasation may be suspected if the following occurs at either a central line site, PICC line site, or peripheral IV site: complaints of burning, stinging pain, or any other acute change of sensation at the site or along the chest wall, neck, or shoulder (central line); or leakage, swelling, or induration at the site. If extravasation of a vesicant is suspected, immediate action must be taken and the antidote, if known, must be given following strict guidelines and procedures. Steps to help manage extravasation of an irritant and/or a vesicant include the following: (1) Stop the infusion immediately and contact the prescriber, leaving the intravenous catheter in place. (2) Next, it is usually recommended to aspirate any residual drug and/or blood from the catheter. (3) Consult institutional policy or guidelines or the pharmacist regarding the use of antidotes, application of hot or cold packs and/or sterile occlusive dressings, and elevation and rest of the affected limb. Document the extravasation incident with attention to all phases of the nursing process related to the problem. Remember to always consult facility protocol and guidelines.

Data from National Cancer Institute website, http://www.nci.nih.gov; United States Pharmacopeial Convention: *USP DI volume 1: drug information for the health care professional,* Greenwood Village, CO, 2005, Micromedex. TABLE 46-2 ALKYLATING DRUG EXTRAVASATION: SPECIFIC ANTIDOTES

DRUG	ANTIDOTE PREPARATION	METHOD
carmustine	Mix equal parts 1 mEq/mL sodium bicarbonate (premixed) with sterile NS (1:1 solution); resulting solution is 0.5 mEq/mL.	1. Inject 2 to 6 mL IV through the existing line along with multiple subcut injections into the extravasated site. 2. Apply cold compresses. 3. Total dose is not to exceed 10 mL of 0.5-mEq/mL solution.
mechlorethamine	Mix 4 mL 10% sodium thiosulfate with 6 mL sterile water for injection.	1. Inject 5 to 6 mL IV through the existing line with multiple subcut injections into the extravasated site. 2. Repeat subcut injections over the next few hours. 3. Apply cold compresses. 4. No total dose has been established.

IV, Intravenous; *NS,* normal saline; *subcut,* subcutaneous.

DOSAGES

Selected Alkylating Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC SUBCLASS	USUAL DOSAGE RANGE*	INDICATIONS
♦ cisplatin (Platinol-AQ) (D)	Platinum coordination complex	IV: 50-100 mg/m^2 q4wk	Metastatic testicular, ovarian, and bladder cancer; brain tumors; esophageal, head, neck, lung, and cervical cancer
♦ cyclophosphamide (Cytoxan) (D)	Classic alkylator	IV: 3-5 mg/kg 2 × wk **(many other regimens as well)**	HL, NHL, leukemia; breast, ovarian, and testicular cancer; retinoblastoma; almost every solid tumor
♦ mechlorethamine (Mustargen) (D)	Classic alkylator	IV: 6 mg/m^2 day 1 and day 28 q4wk	HL, NHL, leukemia, bronchogenic carcinoma, others

HL, Hodgkin's lymphoma; *IV,* intravenous; *NHL,* non-Hodgkin's lymphoma.
*NOTE: Dosages are highly variable.

variable based on type of cancer, previous drugs used, and concurrent drug administration.

DRUG PROFILES

The most widely used alkylating drugs, based on standard treatment protocols, are profiled here. Information for these drugs also appears in the Dosages table on this page.

♦ cisplatin

Cisplatin (Platinol) is an antineoplastic drug that contains platinum in its chemical structure. It is classified as a probable alkylating drug because it is believed to destroy cancer cells in the same way as the classic alkylating drugs—by forming cross-links with DNA and thereby preventing its replication. It is also considered a bifunctional alkylating drug.

Cisplatin is used for the treatment of many solid tumors, such as bladder, lung, testicular, and ovarian tumors. It is available only in injectable form. Medication errors, resulting in deaths, have occurred when cisplatin was confused for carboplatin. The best practice is to use both trade name and generic name when dealing with chemotherapy drugs.

♦ cyclophosphamide

Cyclophosphamide (Cytoxan) is a nitrogen mustard derivative that was discovered during the course of research to improve mechlorethamine. It is a polyfunctional alkylating drug and is a prodrug requiring *in vivo* activation. It is used in the treatment of cancers of the bone and lymph, as well as other solid tumors. Cyclophosphamide is also used in the treatment of leukemias and multiple myeloma, as well as for non-cancer related illnesses such as prophylaxis for rejection of kidney, heart, liver, and bone marrow transplants and severe rheumatoid disorders. It is available in both oral and injectable dosage forms.

♦ mechlorethamine

Mechlorethamine (nitrogen mustard) (Mustargen) is the prototypical alkylating drug. It is a nitrogen analogue of sulfur mustard (mustard gas) that was used for chemical warfare in World War I. Mechlorethamine was the first alkylating antineoplastic drug discovered, and its beneficial effects in the treatment of various cancers were identified after the war. Although its use has declined with the development of newer and better drugs, it continues to be administered in the treatment of Hodgkin's and Non-Hodgkin's lymphoma.

Mechlorethamine is a bifunctional alkylating drug capable of forming cross-links between two DNA nucleotides, which interferes with RNA transcription and prevents cell division and protein synthesis. It is available in parenteral form only, for administration intravenously or by an intracavitary route, such as intrapleurally or intraperitoneally. It can also be used topically for treatment of cutaneous T-cell lymphoma.

CYTOTOXIC ANTIBIOTICS

The cytotoxic antibiotics consist of natural substances produced by the mold *Streptomyces* as well as semisynthetic substances in which chemical changes are made in the natural molecule. Cytotoxic antibiotics have bone marrow suppression

as a common toxicity. The one exception is bleomycin, which instead causes pulmonary toxicity (pulmonary fibrosis and pneumonitis). Other severe toxicities associated with the use of cytotoxic antibiotics are heart failure (daunorubicin) and in rare cases acute left ventricular failure (doxorubicin). The available cytotoxic antibiotics, categorized according to the specific subclass to which they belong, are as follows:

Anthracyclines

- daunorubicin
- doxorubicin
- epirubicin
- idarubicin
- valrubicin

Other cytotoxic antibiotics

- bleomycin (which is actually a cell cycle–specific drug)
- dactinomycin
- mitomycin
- mitoxantrone
- plicamycin

Mechanism of Action and Drug Effects

Cytotoxic antibiotic antineoplastic drugs are cell cycle–nonspecific drugs. They interact with DNA through a process called *intercalation,* in which the drug molecule is inserted between the two strands of a DNA molecule, ultimately blocking DNA synthesis. These drugs inhibit the enzyme topoisomerase II, which leads to DNA strand breaks. Many of these drugs are able to generate free radicals, which also leads to DNA strand breaks and programmed cell death.

Indications

Cytotoxic antibiotics are used to treat a variety of solid tumors and some hematologic malignancies as well. Commonly used examples of these drugs and the malignancies they are used to treat are presented in the Dosages table on p. 754.

Adverse Effects

As with all of the antineoplastic drugs, cytotoxic antibiotics have the undesirable effects of hair loss, nausea and vomiting, and myelosuppression. The emetic potential of the various drugs in this category is given in Box 45-1. Major adverse effects specific to the cytotoxic antibiotics are listed in Table 46-3.

Toxicity and Management of Overdose

Severe cases of cardiomyopathy are associated with large cumulative doses of doxorubicin. Routine monitoring of cardiac ejection fraction with multiple-gated acquisition (MUGA) scans, cumulative dose limitations, and the use of cytoprotective drugs such as dexrazoxane can decrease the incidence of this devastating toxicity. Box 46-2 outlines the management of doxorubicin extravasation.

Interactions

The cytotoxic antibiotics that are used in chemotherapy interact with many drugs. They all tend to produce increased toxicities when used in combination with other chemotherapeutic drugs or with radiation therapy. Some drugs, most notably bleomycin and doxorubicin, have been known to cause serum digoxin levels to increase. Observe patients receiving one of these drugs along with digoxin for signs of digoxin toxicity. Dosage reduction or elimination of digoxin therapy may be indicated (see Chapter 24).

TABLE 46-3 CYTOTOXIC ANTIBIOTICS: SEVERE ADVERSE EFFECTS

DRUG	ADVERSE EFFECTS
bleomycin	Pulmonary fibrosis, pneumonitis
dactinomycin, daunorubicin	Liver toxicity, tissue damage in the event of extravasation, heart failure
doxorubicin, idarubicin	Liver and cardiovascular toxicities
mitomycin	Liver, kidney, and lung toxicities
mitoxantrone	Cardiovascular toxicity
plicamycin	Tissue damage in the event of extravasation

BOX 46-2 TREATMENT OF DOXORUBICIN EXTRAVASATION

1. Cool the site to patient tolerance for 24 hours.
2. Elevate and rest the extremity for 24 to 48 hours, and then have the patient resume normal activity as tolerated.
3. If pain, erythema, or swelling persists beyond 48 hours, discuss with the prescriber the need for surgical intervention or other treatment options.

Data from National Cancer Institute website, http://www.nci.hih.gov; United States Pharmacopeial Convention: *USP DI volume 1: drug information for the health care professional,* Greenwood Village, CO, 2005, Micromedex; Internet resources for additional information: www.cancer.org, www.oncolink.org/index.cfm, w; http://www.hospicenet.org; http://www.acponline.org.

Dosages

For dosage information on selected cytotoxic antibiotics, see the table on p. 754.

DRUG PROFILES

♦ doxorubicin

Doxorubicin (Adriamycin) is used in many combination chemotherapy regimens. The drug is contraindicated in patients with a known hypersensitivity to it, patients with severe myelosuppression, and patients who are at risk for severe cardiotoxicity because they have already received a large cumulative dose of any of the anthracycline antineoplastics. It is available only in injectable form. Doxorubicin is also available in a liposomal drug delivery system (Doxil). In this dosage formulation, the drug is encapsulated in a lipid molecule bilayer called a *liposome.* The advantages of liposomal encapsulation are reduced systemic toxicity and increased duration of action. Liposomal encapsulation extends the biologic half-life of doxorubicin to 50 to 60 hours and increases its affinity for cancer cells. The liposomal dosage formulation is currently indicated for the treatment of ovarian cancer and in combination with bortezomib for the treatment of multiple myeloma.

DOSAGES

Selected Cytotoxic Antibiotics

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC SUBCLASS	USUAL DOSAGE RANGE*	INDICATIONS
Anthracycline Antibiotics			
♦ doxorubicin, conventional (Adriamycin, Rubex) (D)	Anthracycline	IV: 30-75 mg/m2 q7-28d (depending on type of cancer)	Multiple cancers, including breast, bone, and ovarian cancer, and leukemia, neuroblastoma, HL, NHL
♦ doxorubicin, liposomal (Doxil) (D)	Anthracycline	IV: 20-50 mg/m2 q3-4wk for as long as tolerated and tumor is responsive to treatment	AIDS-related Kaposi's sarcoma when other chemotherapy drugs have failed or patient is intolerant of them; recurrent metastatic ovarian cancer
Anthracenedione Antibiotic			
mitoxantrone (Novantrone) (D)	Anthracenedione	IV: 12 mg/m2 q3wk (prostate cancer) **(many other regimens as well)**	Prostate cancer, acute myelocytic leukemia

AIDS, Acquired immunodeficiency syndrome; *HL,* Hodgkin's lymphoma; *IV,* intravenous; *NHL,* non-Hodgkin's lymphoma.
*NOTE: Dosages are highly variable.

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Sound-Alike Drugs: "Rubicins"

The anthracycline chemotherapy drugs have the same sound-alike suffix and are often nicknamed the "rubicins." These drugs include daunorubicin, doxorubicin, epirubicin, idarubicin, and valrubicin. Even though these drugs are in the same class, their use and drug effects are very different. Medication errors have occurred because one "rubicin" has been mistaken for another. It is important to refer to these drugs by both trade and generic names rather than as a "rubicin."

mitoxantrone

Mitoxantrone (Novantrone) is indicated for the treatment of acute nonlymphocytic leukemia and prostate cancer as well as the neurologic disorder multiple sclerosis. It is available only in injectable form.

MISCELLANEOUS ANTINEOPLASTICS

The miscellaneous antineoplastic drugs are those that, because of their unique structure and mechanism of action, cannot be classified into the previously described categories. However, some drugs that are originally classified as miscellaneous drugs are later reclassified as more is learned about their mechanisms of action and other characteristics. Drugs currently in the miscellaneous category include bevacizumab, everolimus, hydroxyurea (which is actually cell-cycle specific), ipilimumab, imatinib, mitotane, ofatumumab, pazopanib, romidepsin, sorafenib, sunitinib, hormonal drugs, and radioactive and related antineoplastic drugs. Selected miscellaneous drugs are profiled in the following sections.

DRUG PROFILES

The various drugs in the miscellaneous category of antineoplastics are used to treat a wide range of neoplasms. Hydroxyurea and imatinib are administered orally. Bevacizumab and mitotane are available only in injectable form.

bevacizumab

Bevacizumab (Avastin) was the first antineoplastic drug in a new category—*angiogenesis inhibitors. Angiogenesis* is the creation of new blood vessels that supply oxygen and other blood nutrients to growing tissues. In the case of malignant tumors, angiogenesis that occurs within the tumor mass promotes continued tumor growth. As a tumor enlarges, its central tissues gradually die off *(necrosis)*. However, its outer portion continues to grow, often to fatal proportions. Thus, inhibiting this process offers a promising new mechanism for antineoplastic drug action. Bevacizumab is a recombinant "humanized" monoclonal immunoglobulin G1 antibody derived from mouse antibodies. The scientific name for any compound derived from mouse tissue is *murine. Humanization* refers to the use of recombinant DNA techniques to make animal-derived antibody proteins more genetically similar to those of humans. It works by binding to and inhibiting the biologic activity of human vascular endothelial growth factor (VEGF). VEGF is an endogenous protein that normally promotes angiogenesis in the body. Bevacizumab is available only in injectable form. The only recognized contraindication is severe drug allergy or allergy to other murine products. It is approved for the treatment of metastatic colon cancer, rectal cancer in combination with 5-flurouracil (see Chapter 45), non–small cell lung cancer, and malignant glioblastoma. Bevacizumab was approved for treatment of breast cancer; however, the FDA revoked the breast cancer indication in 2011.

Adverse reactions include those affecting the cardiovascular system (hypertension or hypotension, deep vein thrombosis), central nervous system (pain, headache, dizziness, asthenia), skin (alopecia, dry skin), metabolism (weight loss, hypokalemia), gastrointestinal (GI) tract (nausea, vomiting, diarrhea, epistaxis, abdominal pain, constipation, GI hemorrhage), kidneys (nephrotoxicity with proteinuria), hematopoeitic system (leukopenia), and respiratory tract (infection). More severe effects can occur in any of these systems but are much less common than those listed. Drug interactions reported to date are limited but include potentiation of the cardiotoxic effects of the anthracycline antibiotics such as doxorubicin.

hydroxyurea

Hydroxyurea (Hydrea, Droxia) is an antimetabolite that interferes with the synthesis of DNA by inhibiting the incorporation of thymidine into DNA. More specifically, it inhibits ribonucleotide reductase, which is involved in conversion of ribonucleotides to deoxyribonucleotides. It works primarily in the S and G_1 phases of the cell cycle, which makes it a cell cycle–specific drug. It is discussed in this chapter because it is included as a miscellaneous drug.

It is used in the treatment of squamous cell carcinoma in concert with radiation to take advantage of its radiosensitizing activity. It is also used in the treatment of various types of leukemia. The drug is available only in oral form. Adverse reactions include edema, drowsiness, headache, rash, hyperuricemia, nausea, vomiting, dysuria, myelosuppression, elevated liver enzyme levels, muscular weakness, peripheral neuropathy, nephrotoxicity, dyspnea, and pulmonary fibrosis. Hydroxyurea interacts with the anti-HIV drugs zidovudine, zalcitabine, and didanosine (see Chapter 40), all of which can have a synergistic effect with hydroxyurea. Concurrent use with fluorouracil increases the risk of neurotoxic symptoms. Because hydroxyurea can reduce the clearance of cytarabine, dosage reduction of cytarabine is recommended when the two are used concurrently.

imatinib

Imatinib (Gleevec) is the standard of care for the treatment of chronic myeloid leukemia (CML). It works by inhibiting the action of a key enzyme (bcr-abl tyrosine kinase) responsible for causing CML. Although its name sounds similar to those of various monoclonal antibody drugs, imatinib is not a monoclonal antibody but rather a targeted therapy. It is available only in oral form. Common adverse reactions include fatigue, headache, rash, fluid retention, GI and hematologic effects, musculoskeletal pain, cough, and dyspnea. Potential drug interactions are numerous and involve other drugs metabolized by the cytochrome P-450 hepatic enzymes. Examples include amiodarone, verapamil, warfarin, azole antifungals, antidepressants, and antibiotics. A pharmacist may be needed to review the patient's medication regimen and adjust dosages or delete medications accordingly, in collaboration with the patient's prescriber.

mitotane

Mitotane (Lysodren) is an adrenal cytotoxic drug that is indicated specifically for the treatment of inoperable adrenal corticoid carcinoma. It is available only in oral form. Adverse reactions include CNS depression, rash, nausea, vomiting, muscle weakness, and headache. Reported drug interactions include enhanced CNS depressive effects when taken concurrently with other CNS depressants (e.g., benzodiazepines). Mitotane may also increase the clearance of both warfarin and phenytoin, reducing their effects. The potassium-sparing diuretic spironolactone may negate the effects of mitotane.

octreotide

Octreotide (Sandostatin) (see Chapter 30) is a unique medication used for the management of a cancer-related condition called *carcinoid crisis* and treatment of the diarrhea caused by vasoactive intestinal peptide–secreting tumors (VIPomas).

HORMONAL ANTINEOPLASTICS

Hormonal drugs are used in the treatment of a variety of neoplasms. The rationale is that sex hormones act to accelerate the growth of some common types of malignant tumors, especially certain types of breast and prostate cancer. Therefore, therapy may involve administration of hormones with opposing effects (i.e., male versus female hormones) or drugs that block the body's sex hormone receptors. These drugs are used most commonly as palliative and adjuvant therapy. For certain types of cancer, they may be used as drugs of first choice. Some of the more commonly used hormonal drugs for female-specific neoplasms such as breast cancer are the aromatase inhibitors anastrazole and aminoglutethimide, the selective estrogen receptor modulators tamoxifen and toremifene, the progestins megestrol and medroxyprogesterone, the androgens fluoxymesterone and testolactone, and the estrogen receptor antagonist fulvestrant. For male-specific neoplasms such as prostate cancer, the following drugs are used: the antiandrogens bicalutamide, flutamide, and nilutamide; and the antineoplastic hormone estramustine. The most common adverse effects of these drugs used to treat female and male cancers are listed in Table 46-4.

RADIOPHARMACEUTICALS AND RELATED ANTINEOPLASTICS

Antineoplastic drugs that are administered by prescribers include porfimer sodium and various radioactive pharmaceuticals

TABLE 46-4 HORMONAL ANTINEOPLASTICS: ADVERSE EFFECTS

CLASS	DRUG	ADVERSE EFFECTS
Aromatase inhibitors	anastrozole, aminoglutethimide	Vasodilation, hypertension, hot flashes, mood disorders, weakness, arthritis
Selective estrogen receptor modulators	tamoxifen, toremifene	Hypertension, peripheral edema, mood disorders, depression, hot flushes, nausea, weakness
Progestins	megestrol, medroxyprogesterone	Hypertension, chest pain, headache, weight gain, hepatotoxicity, dizziness, abdominal pain
Androgens	fluoxymesterone, testolactone	Menstrual irregularities, virilization of female, gynecomastia, hirsutism, acne, anxiety, headache, nausea
Estrogen receptor antagonists	fulvestrant	Vasodilation, pain, headache, hot flushes, nausea, vomiting, pharyngitis
Antiandrogens	bicalutamide, flutamide, nilutamide	Peripheral edema, pain, hot flushes, gynecomastia, anemia, nausea, diarrhea
Gonadotropin-releasing hormone agonists	leuprolide, goserelin	Rash, pain on injection, alopecia, body odor
Antineoplastic hormone	estramustine	Edema, dyspnea, leg cramps, breast tenderness, nausea, anorexia, diarrhea

(radiopharmaceuticals). Porfimer sodium is used to treat esophageal or bronchial tumors that are present on the surface mucosa. The medication is given intravenously, and administration is followed by one or more sessions of laser light therapy to the esophageal or bronchial mucosa for direct tumor lysis and manual débridement. Radiopharmaceuticals are used to treat a variety of cancers or symptoms caused by cancers. Five commonly used radioisotopes are chromic phosphate P 32 (for cancer-induced peritoneal or pleural effusions), samarium SM 153 lexidronam (for bone cancer pain), sodium iodide I 131 (for thyroid cancer and hyperthyroidism), sodium phosphate P 32 (for various leukemias and palliative treatment of bone metastases), and strontium Sr 89 chloride (for bone cancer pain). Two drugs used in the treatment of various forms of non-Hodgkin's lymphoma are iodine I 131 tositumomab (Bexxar) and yttrium Y 90 ibritumomab tiuxetan (yttrium 90–labeled CD20 antibody; Zevalin). These medications are usually administered by nuclear medicine specialists.

NURSING PROCESS

Antineoplastics are some of the most toxic drugs given to patients (see Chapter 45), and because of these toxicities, serious complications and adverse effects may occur. Nursing care must be based on a thorough knowledge of cancer, its treatment, and the subsequent effects of different treatment modalities. This chapter presents information about cell cycle–nonspecific, hormonal, and miscellaneous antineoplastic drugs, whereas Chapter 45 covers cell cycle–specific antineoplastic drugs.

ASSESSMENT

Begin the overall assessment of patients taking any of these drugs with a thorough nursing history, medication profile, and past and present medical history. Measure and record vital signs. Document the presence of conditions that represent cautions or contraindications as well as potential drug interactions. Perform a head-to-toe physical assessment that includes attention to the following: skin turgor with level of moisture and integrity of the skin and oral mucosa; baseline level of neurologic functioning including level of consciousness, alertness, motor and sensory intactness, reflexes, and presence of any abnormal sensations; bowel sounds, bowel patterns, and inquiry into any problems such as diarrhea, constipation, nausea, vomiting, or reflux; urinary patterns and color, amount, and odor of urine; breath sounds as well as respiratory rate, rhythm, and depth; and heart sounds. Laboratory tests that may be ordered include fluid and electrolyte levels (sodium, potassium, chloride, magnesium, calcium), RBC and WBC counts, hemoglobin, hematocrit, renal and hepatic function tests, and serum protein-albumin levels.

For patients receiving *alkylating drugs,* bone marrow suppression (carboplatin), pulmonary fibrosis (busulfan), nephrotoxicity and/or neurotoxicity (more with cisplatin than carboplatin), and hemorrhagic cystitis (cyclophosphamide) may occur; thus, perform an appropriate and thorough nursing assessment (see Assessment in Chapter 45). Assess deep tendon reflexes and baseline hearing level. Document the findings. Assess results of any baseline pulmonary function testing and perform a thorough respiratory assessment. High-dose cyclophosphamide may lead to hemorrhagic cystitis; therefore, document urinary patterns and any abnormal symptoms. Note hydration status before administering cyclophosphamide to avoid hemorrhagic cystitis.

One of the major adverse effects associated with the use of *cytotoxic antibiotics* (e.g., bleomycin) is pulmonary fibrosis. Medical testing (e.g., radiographs, computed tomographic [CT] scans, magnetic resonance imaging [MRI] scans, arterial blood gas levels, and partial pressures of CO_2 and O_2) may be ordered so assess findings. When dactinomycin or daunorubicin are given intravenously, it is generally administered via a central line indwelling catheter device (e.g., Port-A-Cath or MediPort), because if it is given by peripheral intravenous line and extravasation occurs, there is a risk for necrosis with tissue sloughing that may erode through the layers of skin and underlying supportive structures (e.g., muscles, ligaments). See the pharmacology discussion of extravasation as well as Table 46-2 and Box 46-3. In addition, in patients with documented cardiac disease or a history of thoracic irradiation, administer dactinomycin, daunorubicin, and doxorubicin with extreme caution due to cardiovascular toxicity. CT scans and ultrasound studies may be needed before and during treatment to assess cardiac ejection fraction because of the risk of cardiotoxicity, which is often associated with cumulative doses.

With use of *hormonal antineoplastic drugs,* obtain a thorough medical, nursing, and medication history. Many of the drugs included in this category are presented in depth in Chapters 34 and 35, which also discuss aspects of the nursing process related

BOX 46-3 CONCERNS IN THE HANDLING AND ADMINISTRATION OF VESICANT DRUGS

The handling and administration of antineoplastic drugs is of major concern because the nurse mixing and giving the drug may experience negative consequences. The pharmacy department is responsible for mixing these drugs, and preparation must be carried out carefully in an appropriate environment with use of a laminar airflow hood and personal protective equipment (mask, gown, gloves). Many facilities recommend taking special precautions during the care of a patient who is receiving chemotherapy, such as double-flushing the patient's bodily secretions in the commode and using special hampers for the disposal of all items that come into contact with the patient, including used personal protective equipment. Special spill kits are employed to clean up even the smallest chemotherapy spills. These precautions are necessary to protect the health care provider from the cytotoxic effects of these drugs. In addition, proper and up-to-date knowledge about these drugs is important to safe and appropriate nursing care. All nurses giving these drugs must be certified to administer chemotherapy and must remain current in their level of practice and competencies related to this treatment modality. All equipment and containers must be handled appropriately once the infusion is completed. Hands and any exposed areas must be washed to ensure the safety of the health care provider. The Centers for Disease Control and Prevention and the Oncology Nursing Society offer exceptional resources for individuals involved in the care of patients receiving chemotherapy.

to their use. Assessment associated with the use of *estrogen antagonists* such as fulvestrant, tamoxifen, raloxifene, and toremifene citrates often begins with a review of the results of any tumor estrogen receptor assays, CT scans, radiographs, and other diagnostic testing. Perform a neurologic assessment (see previous discussion and Chapters 34 and 45) with attention to baseline complaints of any pain, abnormal sensations, or headaches. Note any menopausal symptoms upon assessment because of the possible adverse effect of vasodilation and hot flashes. In addition, these drugs may cause nausea and vomiting so a thorough GI assessment is beneficial.

With the use of *androgens* (e.g., fluoxymesterone or testosterone), obtain a thorough gynecologic history of the female patient with attention to any menstrual issues or problems because of the adverse effect of menstrual irregularities. It is also important to assess the patient's body image and feelings of self-esteem because of the possible adverse effects of acne, hirsutism, and virilization in female patients as well as gynecomastia in male patients. See Chapter 35 for more information on the side effects of androgens.

Bicalutamide, flutamide, and nilutamide are *antiandrogens* and require thorough assessment of any cardiac diseases due to the potential for peripheral edema. This could exacerbate any pre-existing cardiac disorder. Perform a thorough GI and gynecologic assessment because of the possibility for nausea, diarrhea, and hot flashes. Documentation of the use of a reliable form of birth control is important because of teratogenic effects. Male sperm production may be affected (see Chapter 45), and a decline in sexual functioning and/or desire may occur because of the antiandrogenic effects.

With use of *gonadotropin-releasing hormone agonists,* such as leuprolide and goserelin, assess the patient for allergies to the drugs. Contraceptive history is important because women who are taking these drugs must use a nonhormonal contraceptive. Often the prescriber will order laboratory tests for serum testosterone and prostatic acid phosphatase level for male patients before and during therapy; an increase will be noted during the initial week of therapy, with levels returning to baseline by 4 weeks.

For patients taking *antiadrenal drugs* (e.g., mitotane), in addition to performing a basic assessment, inquire about any GI disturbances because of the common adverse effects of nausea and vomiting. The *miscellaneous antineoplastic drugs* glucocorticoids and mineralocorticoids may be given to prevent adrenal insufficiency and may also play a part in the therapeutic regimen. An understanding of baseline adrenal functioning through examination of laboratory test results is important.

With the *miscellaneous* drug hydroxurea, assessment of liver, renal, neurologic, and pulmonary function with baseline blood cell counts are important due to the adverse reactions associated with this drug. With use of bevacizumab, an *angiogenesis inhibitor,* assess cardiovascular, central nervous system, GI tract, and renal functioning. Assess adverse effects of hypotension or hypertension, headache, pain, dizziness, nausea, vomiting, diarrhea, and nephrotoxicity.

CASE STUDY

Chemotherapy with Alkylating Drugs

W.S. is receiving cisplatin as part of treatment for ovarian cancer. She is receiving her third treatment today and has just arrived at the cancer treatment center for her outpatient infusion. W.S. says that she felt "okay" during the time between the last treatment and today but is not looking forward to today's treatment because of the side effects.

1. While the nurse prepares to start the infusion, what is important for the nurse to assess before beginning the chemotherapy?
2. What will the nurse do before the infusion to help reduce or prevent adverse effects?
3. During the infusion, W.S. mentions that she is hearing a slight "roaring" sound and that she feels a bit dizzy. What will the nurse do next?
4. After stopping the infusion, the nurse spills some of the chemotherapy solution on her arm and the floor. What is the nurse's priority action at this time?

For answers, see http://evolve.elsevier.com/Lilley.

NURSING DIAGNOSES

1. Decreased cardiac output related to the adverse effect of cardiotoxicity associated with cytotoxic antibiotics
2. Diarrhea related to the adverse effects of antineoplastic drugs
3. Imbalanced nutrition, less than body requirements, related to loss of appetite, nausea, and vomiting, as a result of antineoplastic therapy

PLANNING

GOALS

1. Patient's cardiac output remains within normal limits while the patient is taking antineoplastics.
2. Patient experiences minimal problems with alteration in bowel elimination (e.g., diarrhea).
3. Patient maintains adequate and balanced nutritional status while taking antineoplastics.

OUTCOME CRITERIA

1. Patient maintains normal blood pressure and heart rate while being monitored during therapy with cytotoxic antibiotics.
   - Patient demonstrates adequate knowledge of self-monitoring of blood pressure and pulse rate daily.
   - Patient understands the importance of daily weights.
   - Patient, family member, or caregiver adheres to a daily heart-healthy regimen of conserving energy, planning activities, and asking for assistance with care and activities as needed.
   - Patient, family member, or caregiver contacts prescribers immediately with the occurrence of shortness of breath, high or low blood pressure or pulse rate, and chest pain.
2. Patient states measures to prevent or decrease the occurrence of diarrhea during antineoplastic therapy such as avoiding

spicy, irritating foods, gas-producing foods, caffeine, high fiber foods, alcohol and very hot or cold foods and beverages.
- Patient has preventative medication, as prescribed, such as synthetic opioids (e.g., loperamide) or adsorbents-protectants, to be taken to help with excess diarrhea.

3. Patient maintains daily regimen for healthy nutritional patterns such as maintaining adequate fluid intake, maintaining a balanced diet as tolerated, avoiding foods that are irritating to the GI tract, and taking nutritional supplements as prescribed.

IMPLEMENTATION

Before initiating drug therapy with the cell cycle–nonspecific drugs, hormonal antineoplastics and miscellaneous drugs, you must be completely knowledgeable about the drug, its use, and its impact on all rapidly dividing cells, whether normal or malignant (see Chapters 34, 35, and 45 for additional information).

With *alkylating drugs,* always handle these and all other antineoplastics with caution because of their possible carcinogenic, mutagenic, and teratogenic properties (see Box 46-3). The patient receiving alkylating drugs will more than likely experience problems related to bone marrow suppression, such as anemia, leukopenia, and thrombocytopenia (see Chapter 45 for specific interventions). Most nursing interventions are focused on preventing infection, conserving energy, preventing bleeding and injury, and reducing nausea. Other nursing considerations for these drugs include taking vital signs every 1 to 2 hours, or as needed during infusion forcing fluids; monitoring intake and output; following orders for intravenous therapy for hydration; and monitoring any vomiting. Contact the prescriber if vomiting is uncontrolled. Monitor the patient constantly for abnormal peripheral sensations, especially with cisplatin. Report to the prescriber any numbness or tingling of extremities and any ringing or roaring in the ears and/or hearing loss. Encourage the patient experiencing peripheral neuropathies to avoid extremely cold temperatures or the handling of cold objects. Cisplatin is particularly nephrotoxic, so monitor renal function closely throughout therapy. Intravenous hydration is often required at a rate of 100 to 200 mL/hr starting before cisplatin administration with a total of 2000 to 3000 mL/day, depending on the dose of cisplatin and if not contraindicated. Do not use aluminum needles or administration sets with many of these drugs because aluminum can degrade their platinum compounds ensure that the proper infusion equipment is used. Because hemorrhagic cystitis is associated with cyclophosphamide use, make sure the patient's hydration is maintained to minimize this adverse effect. Pulmonary toxicity may occur with some of the alkylating drugs, particularly busulfan; therefore, constantly monitor and be alert to cough, shortness of breath, and abnormal breath sounds. Immediately report these adverse effects to the prescriber. Other drugs in this group may be given by various routes, such as intrapericardial, intratumoral, and intravesical. Be sure you perform appropriate interventions per the manufacturer's guidelines or hospital/facility policy. Reconstitute the parenteral formulations for any of these drugs according to the manufacturer's guidelines and suggestions. Not all diluents are compatible.

One very important component of nursing care with alkylating drugs and their parenteral administration is monitoring the IV site/infusion continually for signs and symptoms of infiltration. Infilltration could lead to extravasation of the medication into the surrounding tissue. To briefly review, IV infiltration is the leakage of fluids or blood from a dislodged catheter or needle cannula from the intima of the vein and into the surrounding tissue. Signs and symptoms of infiltration include inflammation at or near the insertion site with swollen, taut skin with pain, blanching, and coolness of skin around the IV site; slowed or stopped IV infusion; and no backflow of blood into the IV tubing. The reason infiltration is of concern with these drugs is that some of them are irritants and others are vesicants with the potential of severe tissue damage. Therefore, if extravasation occurs with some of these drugs, antidotes are required to try and prevent damage from leakage of the drug into the tissue. Specific antidotes for alkylating drugs are presented in Table 46-2. Always follow hospital/facility policy when treating extravasation of any medication. With IV infusions of antineoplastics, monitoring of the IV site and infusions is usually more frequent, and some guidelines state hourly assessment. It is important to mention that the vast majority of chemotherapeutic drugs are administered via a central line indwelling catheter device (such as Port-A-Cath or MediPort). Check the device and its patency prior to the drug's administration.

Patients receiving *cytotoxic antibiotics* such as bleomycin may require more frequent monitoring of pulmonary function. Baseline chest radiographs may be obtained for comparison with subsequent radiographs if pneumonitis occurs. Monitor results of liver and renal function tests throughout therapy with dactinomycin, daunorubicin, doxorubicin, and mitomycin. Heart sounds, daily weights, blood pressure, pulse rate, and monitoring for signs and symptoms of cardiovascular toxicities (e.g., alterations in vital signs, abnormal heart sounds, dyspnea, chest pain) are especially important with doxorubicin, idarubicin, and mitoxantrone. Additionally, if the patient experiences an increase of 2 pounds or more in 24 hours or 5 pounds or more in 1 week, notify the prescriber, as this may reflect fluid retention related to heart failure. Mitomycin is associated with liver, kidney, and lung toxicities. Close monitoring of these systems during treatment is key to patient safety.

Use of *hormone antagonists* in the treatment of various neoplasms is common, particularly with breast and prostate cancer. Associated nursing interventions and patient education for the use of these hormone antagonists are discussed in depth in Chapters 34 and 35. Corticosteroid therapy and related nursing considerations are presented in Chapter 33.

Hydroxyurea is used sparingly but is a component of some treatment protocols. This drug is given orally. Monitor platelet and leukocyte counts due to the adverse effect of bone marrow suppression. Monitoring must be ongoing during therapy. If platelet count falls below 100,000 platelets/mm^3 or leukocyte count falls below 2000 cells/mm^3, therapy may need to be temporarily halted until counts rise toward the normal values. See earlier discussion and Chapter 45 about nursing considerations associated with anemias, fatigue, weakness, bleeding tendencies, and infection. Additionally, hyperuricemia may precipitate

SAFETY: LABORATORY VALUES RELATED TO DRUG THERAPY

Rationales for Assessment and Monitoring of Blood Cell Counts with Antineoplastics

LABORATORY TEST	NORMAL RANGES	RATIONALE FOR ASSESSMENT
Leukocytes (WBCs)	5000 to 10,000 cells/mm^3	WBCs protect against infection and when an infection develops, the WBCs attack and destroy the causative bacteria, virus, or other organism. In response to the infection, WBCs increase in number dramatically. If WBC levels are decreased from antineoplastic treatment and subsequent bone marrow suppression, and if they decrease to levels less than 2000 cells/mm^3 (leukopenia), there is a high risk for severe infection and immunosuppression.
WBC components:		The major types of WBCs are neutrophils, lymphocytes, monocytes, eosinophils, and basophils. Immature neutrophils are called *band neutrophils* and their number, along with neutrophil counts, provides a picture of the patient's immune system. If neutrophils are decreased to levels of less than 500 cells/mm^3 (neutropenia), then there is risk for severe infection. If band neutrophils are included in the WBC differential count, then an abnormally low value reinforces the risk for severe infection (see Chapter 45).
Neutrophils	47% to 77% or above 1500 cells/mm^3	
Band neutrophils	0% to 3%	
Nadir	See normal range of each blood cell.	*Nadir* refers to the lowest levels of bone marrow cells that are reached. The time to reach this nadir may become shorter and the recovery time longer with successive courses of antineoplastic treatment. A general estimate of the time to nadir is 10 to 28 days. Anticipation of the nadir allows the oncologist and health care team to develop a preventative treatment plan which may include use of biologic response modifiers and antibiotics.

WBCs, White blood cells.

NOTE: Similar information on red blood cell and platelet counts is presented in Chapter 45. Also note that chemotherapy may be discontinued with anemia, leukopenia, neutropenia, and/or thrombocytopenia. Once counts recover (sometimes more quickly with certain drugs), treatment is often reinitiated.

gout-related symptoms (e.g., painful, swollen joints); report these to the prescriber so that the appropriate medication may be ordered. Often a drug such as allopurinol is prescribed to help control the levels of uric acid caused by cell death from the chemotherapy.

In addition to the nursing interventions discussed earlier and in Chapter 45, keep epinephrine, antihistamines, and antiinflammatory drugs available in case of an allergic or anaphylactic reaction. Each antineoplastic drug has its own peculiarities and its own set of cautions, contraindications, nursing implementations, and toxicities. *Cytoprotective drugs* are useful in reducing certain toxicities. For example, use of intravenous amifostine may help to reduce the renal toxicity associated with cisplatin; intravenous or oral allopurinol may be given to reduce hyperuricemia (see Table 45-6 and Box 45-2). Other major concerns related to the care of patients receiving chemotherapy are the oncologic emergencies that arise because of damage occurring to rapidly dividing normal cells as well as rapidly dividing cancerous cells. Some of the complications that are potential emergencies include infections, infusion reactions and allergy, stomatitis with severe ulceration, bleeding, metabolic aberrations, severe diarrhea, renal failure, liver failure, and cardiotoxicity, including dysrhythmia or heart failure (Box 46-4).

BOX 46-4 INDICATIONS OF AN ONCOLOGIC EMERGENCY

- Fever and/or chills with a temperature higher than 100.5° F (38.1° C)
- New sores or white patches in the mouth or throat
- Swollen tongue with or without cracks and bleeding
- Bleeding gums
- Dry, burning, "scratchy," or "swollen" throat
- A cough that is new and persistent
- Changes in bladder function or patterns
- Blood in the urine
- Changes in GI or bowel patterns, including "heartburn" or nausea, vomiting, constipation, or diarrhea lasting longer than 2 or 3 days
- Blood in the stools

NOTE: The patient must contact the prescriber immediately if any of the listed signs or symptoms occurs. If the prescriber is not available, the patient must seek medical treatment at the closest emergency department.

EVALUATION

Focus the evaluation of nursing care upon determining whether goals and outcomes have been met, as well as on monitoring for therapeutic responses and adverse and toxic effects of antineoplastic therapy. Therapeutic responses may manifest as clinical improvement, decrease in tumor size, and decrease in metastatic spread. Evaluation of nursing care with reference to goals and outcomes may reveal improvements related to a decrease in adverse effects; a decrease in the impact of cancer on the patient's well-being; an increase in comfort, nutrition, and hydration; improved energy levels and ability to carry out the activities of daily living; and improved quality of life. The goals and outcomes may be revisited to identify more specific parameters to monitor. In addition, certain laboratory studies such as measurement of tumor markers, levels of carcinoembryonic antigens, red blood cell, white blood cell, and platelet counts may also be used to determine how well the goals and outcomes have been met. As part of the evaluation, prescribers may also order additional radiographs, CT scans, MRIs, tissue analyses, and other studies appropriate to the diagnosis during and after antineoplastic therapy, at time intervals related to anticipated tumor response.

PATIENT TEACHING TIPS

- Advise the patient to avoid aspirin, ibuprofen, and products containing these drugs to help prevent excessive bleeding.
- Be open with discussion about the risk of alopecia (a complete discussion is presented in Chapter 45) as an adverse effect of many of the antineoplastic drugs.
- Encourage forcing of fluids up to 3000 mL/day, if not contraindicated, to prevent dehydration and further weakening and, in the case of cyclophosphamide therapy, to prevent or help manage hemorrhagic cystitis.
- Constipation and diarrhea may be problematic, so educate the patient about ways to help manage these alterations in bowel status that may be due to the antineoplastic or due to narcotics used for pain management. To help avoid constipation, forcing of fluids and consumption of a balanced diet are important; however, the oncologist often orders either a stool softener or a mild noncramping laxative to prevent the problem. Diarrhea is generally treated by dietary restrictions and use of antidiarrheals, as ordered.
- The following are helpful online resources for the patient and significant others: www.fda.gov, www.fda.gov/ForHealthProfessionals/default.htm, www.nih.gov, www.healthfinder.gov, www.who.int/en, and www.oncolink.org/index.cfm.

KEY POINTS

- Antineoplastics are drugs that are used to treat malignancies and are classified as cell cycle–specific drugs, cell cycle–nonspecific drugs, miscellaneous antineoplastics, and hormonal drugs.
- Cell cycle–specific drugs kill cancer cells during specific phases of the cell growth cycle, whereas the cell cycle–nonspecific drugs discussed in this chapter kill cancer cells during any phase of the growth cycle.
- Chemotherapy, or antineoplastic drug therapy, requires very skillful and perceptive care and you must act prudently and make critical decisions about the nursing care of patients receiving these drugs.
- Knowledge is important to ensure patient and health care provider safety and for protection from the adverse effects of antineoplastics.
- Always exercise extreme caution in the handling and administration of cell cycle–nonspecific (as well as cell cycle–specific) drugs.
- Hormonal drugs, both agonists and antagonists, are used to treat a variety of malignancies.
- Extravasation of strong vesicants (e.g., doxorubicin) may lead to severe tissue injury with complications such as permanent damage to muscles, tendons, and ligaments, and possible loss of limb. Constantly monitor the IV site and infusions to prevent this possible complication. Checking the patency of central venous access devices is also important because the majority of chemotherapy drugs are given via this route.
- Oncologic emergencies occur as a consequence of cell death and may be life-threatening. Skillful assessment and immediate intervention may help to decrease the severity of the problem or even reduce the occurrence of such emergencies.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A patient who is receiving chemotherapy with cisplatin (Platinol) has developed pneumonia. The nurse would be concerned about nephrotoxicity if which type of antibiotic was ordered as treatment for the pneumonia at this time?
   - **a** Penicillin
   - **b** Sulfa drug
   - **c** Fluoroquinolone
   - **d** Aminoglycoside

2 During treatment with doxorubicin (Adriamycin), the nurse must monitor closely for which potentially life-threatening adverse effect?
   - **a** Nephrotoxicity
   - **b** Peripheral neuritis
   - **c** Cardiomyopathy
   - **d** Ototoxicity

3 While teaching a patient who is about to receive cyclophosphamide (Cytoxan) chemotherapy, the nurse will instruct the patient to watch for potential adverse effects, such as
   - **a** cholinergic diarrhea.
   - **b** hemorrhagic cystitis.
   - **c** peripheral neuropathy.
   - **d** ototoxicity.

4 When chemotherapy with alkylating drugs is planned, the nurse expects to implement which intervention to prevent nephrotoxicity?
   - **a** Hydrating the patient with intravenous fluids before chemotherapy
   - **b** Limiting fluids before chemotherapy
   - **c** Monitoring drug levels during chemotherapy
   - **d** Assessing creatinine clearance during chemotherapy

5 During therapy with the cytotoxic antibiotic bleomycin, the nurse will assess for a potentially serious adverse effect by monitoring
   - **a** blood urea nitrogen and creatinine levels.
   - **b** cardiac ejection fraction.
   - **c** respiratory function.
   - **d** cranial nerve function.

NCLEX® EXAMINATION REVIEW QUESTIONS

6 While administering bevacizumab (Avastin), what will the nurse assess to look for drug-related toxicities? (Select all that apply.)

a Blood pressure
b Color of the skin and sclera of the eye (for jaundice)
c Blood glucose level
d Urine protein level
e Hearing

7 The nurse is preparing to add a dose of bevacizumab (Avastin) to a patient's intravenous infusion. The dose is 70 mg of bevacizumab in 100 mL of normal saline, and it is to infuse over 90 minutes. The nurse will set the infusion pump to what rate for this dose?

1. d, 2. c, 3. b, 4. a, 5. c, 6. a, d, 7. 67 mL/hour (66.66 rounds to 67)

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Describe the basic anatomy, physiology, and functions of the immune system.
2 Compare the two major classes of biologic response–modifying drugs: hematopoietic drugs and immunomodulating drugs.
3 Discuss the mechanisms of action, indications, dosages, routes of administration, adverse effects, cautions, contraindications, and drug interactions of the different biologic response–modifying drugs.
4 Describe the pathology associated with rheumatoid arthritis.
5 Discuss the mechanisms of action, indications, dosages, routes of administration, adverse effects, cautions, contraindications, and drug interactions of the different antirheumatic drugs.
6 Develop a nursing care plan that includes all phases of the nursing process for patients receiving biologic response–modifying drugs and for those receiving antirheumatic drugs.

DRUG PROFILES

abatacept, p. 778
adalimumab, p. 772
♦ **aldesleukin, p. 775**
alemtuzumab, p. 772
anakinra, p. 775
belimumab, p. 773
bevacizumab, p. 773
certolizumab, p. 773
cetuximab, p. 773
denileukin diftitox, p. 775
etanercept, p. 777
♦ **filgrastim, p. 768**
golimumab, p. 773
ibritumomab tiuxetan, p. 773
infliximab, p. 773
♦ **interferon alfa-2a, interferon alfa-2b, interferon alfa-n3, interferon alfacon-1, peginterferon alfa-2a, and peginterferon alfa-2b, p. 770**
♦ **interferon beta-1a, interferon beta-1b, p. 770**
interferon gamma-1b, p. 770
leflunomide, p. 777
methotrexate, p. 777
natalizumab, p. 773
♦ **oprelvekin, p. 768**
♦ **rituximab, p. 773**
♦ **sargramostim, p. 768**
tocilizumab, p.775
tositumomab and iodine I 131 tositumomab, p. 774
trastuzumab, p. 774

♦ *Key drug*

KEY TERMS

Adjuvant A nonspecific *immunostimulant* that enhances overall immune function, rather than stimulating the function of a specific immune system cell or cytokine through specific chemical reactions. (p. 776)

Antibodies Immunoglobulin molecules (see Chapter 49) that have the ability to bind to and inactivate antigen molecules through formation of an antigen-antibody complex. This process serves to inactivate foreign antigens that enter the body and are capable of causing disease. (p. 765)

Antigen A biologic or chemical substance that is recognized as foreign by the body's immune system. (p. 764)

Arthritis Inflammation of one or more joints. (p. 777)

Autoimmune disorder A disorder that occurs when the body's tissues are attacked by its own immune system. (p. 776)

B lymphocytes (B cells) Leukocytes of the humoral immune system that develop into plasma cells, and then produce the antibodies that bind to and inactivate antigens. B cells are one of the two principal types of lymphocytes; T lymphocytes are the other. (p. 765)

Biologic response–modifying drugs A broad class of drugs that includes hematopoietic drugs and immunomodulating drugs. Often referred to as *biologic response modifiers (BRMs),* they alter the body's response to diseases such as cancer as well as autoimmune, inflammatory, and infectious diseases. Examples are cytokines (e.g., interleukin, interferons), monoclonal antibodies, and vaccines. They are also called *biomodulators* or *immunomodulating drugs.* Biologic response–modifying drugs may be adjuvants, immunostimulants, or immunosuppressants. (p. 764)

Cell-mediated immunity Collective term for all immune responses that are mediated by T lymphocytes (T cells). Also called *cellular immunity.* Cell-mediated immunity acts in collaboration with humoral immunity. (p. 764)

Colony-stimulating factors Cytokines that regulate the growth, differentiation, and function of bone marrow stem cells. (p. 766)

Complement Collective term for about 20 different proteins normally present in plasma that assist other immune system components (e.g., B cells and T cells) in mounting an immune response. (p. 774)

Cytokines The generic term for nonantibody proteins released by specific cell populations (e.g., activated T cells) on contact with antigens. Cytokines act as intercellular mediators of an immune response. (p. 765)

Cytotoxic T cells Differentiated T cells that can recognize and lyse (rupture) target cells that have foreign antigens on their surfaces. These antigens are recognized by the corresponding antigen receptors that are expressed (displayed) on the cytotoxic T-cell surface. Also called *natural killer cells.* (p. 765)

Differentiation The process of cellular development from a simplified into a more specialized cellular structure. In hematopoiesis, it refers to the multistep processes involved in the maturation of blood cells. (p. 766)

Disease-modifying antirheumatic drugs (DMARDs) Medications used in the treatment of rheumatic diseases that have the potential to arrest or slow the actual disease process instead of providing only antiinflammatory and analgesic effects. (p. 777)

Hematopoiesis Collective term for all of the body's processes originating in the bone marrow that result in the formation of various types of blood components (adjective: *hematopoietic*). It includes the three main processes of *differentiation* (see earlier): erythropoiesis (formation of red blood cells, or erythrocytes), leukopoiesis (formation of white blood cells, or leukocytes), and thrombopoiesis (formation of platelets, or thrombocytes). (p. 764)

Humoral immunity Collective term for all immune responses that are mediated by B cells, which ultimately work through the production of antibodies against specific antigens. Humoral immunity acts in collaboration with *cell-mediated immunity*. (p. 764)

Immunoglobulins Complex immune system glycoproteins that bind to and inactivate foreign antigens. The term is synonymous with *immune globulins.* (p. 765)

Immunomodulating drugs Collective term for various subclasses of biologic response–modifying drugs that specifically or nonspecifically enhance or reduce immune responses. The three major types of immunomodulators, based on mechanism of action, are adjuvants, immunostimulants, and immunosuppressants (see Chapter 48). (p. 764)

Immunostimulant A drug that enhances immune response through specific chemical interactions with particular immune system components. An example is interleukin-2. (p. 776)

Immunosuppressant A drug that reduces immune response through specific chemical interactions with particular immune system components. An example is cyclosporine (see Chapter 48). (p. 769)

Interferons One type of cytokine that promotes resistance to viral infection in uninfected cells and can also strengthen the body's immune response to cancer cells. (p. 768)

Leukocytes The collective term for all subtypes of white blood cells. Leukocytes include the granulocytes (neutrophils, eosinophils, and basophils), monocytes, and lymphocytes (B cells and T cells). Some monocytes also develop into tissue macrophages. (p. 766)

Lymphokine-activated killer (LAK) cell *Cytotoxic T cells* that have been activated by interkeukin-2 and therefore have a stronger and more specific response against cancer cells. (p. 774)

Lymphokines Cytokines that are produced by sensitized T lymphocytes on contact with antigen particles. (p. 765)

Memory cells Cells involved in the humoral immune system that remember the exact characteristics of a particular foreign invader or antigen for the purpose of expediting immune response in the event of future exposure to this antigen. (p. 765)

KEY TERMS—cont'd

Monoclonal Denoting a group of identical cells or organisms derived from a single cell. (p. 765)

Plasma cells Cells derived from B cells that are found in the bone marrow, connective tissue, and blood. They produce antibodies. (p. 765)

Rheumatism General term for any of several disorders characterized by inflammation, degeneration, or metabolic derangement of connective tissue structures, especially joints and related structures. (p. 776)

T helper cells Cells that promote and direct the actions of various other cells of the immune system. (p. 765)

T lymphocytes (T cells) Leukocytes of the cell-mediated immune system. Unlike B cells, they are not involved in the production of antibodies but instead occur in various cell subtypes (e.g., T helper cells, T suppressor cells, and cytotoxic T cells). They act through direct cell-to-cell contact or through production of cytokines that guide the functions of other immune system components (e.g., B cells, antibodies). (p. 765)

T suppressor cells Cells that regulate and limit the immune response, balancing the effects of T helper cells. (p. 766)

Tumor antigens Chemical compounds expressed on the surfaces of tumor cells. They signal to the immune system that these cells do not belong in the body, labeling the tumor cells as foreign. (p. 764)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

OVERVIEW OF IMMUNOMODULATORS

Over the last two decades, medical technology has developed a group of drugs whose primary site of action is the immune system. This has resulted in new additions to the class of drugs known as **biologic response–modifying drugs,** or biologic response modifiers(s). These drugs alter the body's response to diseases such as cancer and autoimmune, inflammatory, and infectious diseases. These drugs can enhance or restrict the patient's immune response to disease, can stimulate a patient's hematopoietic (blood-forming) function, and can prevent disease. **Hematopoiesis** is the collective term for all of the blood component–forming processes of the bone marrow. Two broad classes of biologic response–modifying drugs are hematopoietic drugs and **immunomodulating drugs.** Subclasses of immunomodulating drugs include interferons, monoclonal antibodies, interleukin receptor agonists and antagonists, and miscellaneous drugs. Disease-modifying antirheumatic drugs are drugs that are used to treat rheumatoid arthritis, which is discussed later in the chapter.

Immunomodulating drugs therapeutically alter a patient's immune response. In cancer treatment, they make up the fourth type of cancer therapy, along with surgery, chemotherapy, and radiation. The human immune system is most commonly viewed as the body's natural defense against pathogenic bacteria and viruses. However, it also has effective antitumor capabilities. An intact immune system can identify cells as malignant and destroy them. In contrast to chemotherapeutic drugs, a healthy immune system can distinguish between tumor cells and normal body tissues. Normal cells are recognized as "self" and are not damaged, whereas tumor cells are recognized as "foreign" and are destroyed. People develop cancerous cells in their bodies on a regular basis. Normally the immune system is able to eliminate these cells before they multiply to uncontrollable levels. It is only when the natural immune responses fail to keep pace with these initially microscopic cancer cell growths that a person develops a true "cancer" requiring clinical intervention.

In terms of their activity against cancer cells, biologic response–modifying drugs work by one of three mechanisms: (1) enhancement or restoration of the host's immune system defenses against the tumor; (2) direct toxic effect on the tumor cells, which causes them to lyse, or rupture; or (3) adverse modification of the tumor's biology, which makes it harder for the tumor cells to survive and reproduce.

Some immunomodulating drugs are used to treat autoimmune, inflammatory, and infectious diseases. In these instances, the drug functions either to reduce the patient's inappropriate immune response (in the case of inflammatory and autoimmune diseases such as rheumatoid arthritis) or to strengthen the patient's immune response against microorganisms (especially viruses) and cancer cells. To better understand these complex drugs, a review of immune system physiology is beneficial.

IMMUNE SYSTEM

The immune system is an intricate biologic defense network of cells that are capable of distinguishing an unlimited variety of substances as either foreign ("nonself") or a natural part of the host's body ("self"). When a foreign substance such as a bacteria or virus enters the body, the immune system recognizes it as being foreign and mounts an immune response to eliminate or neutralize the invader. Tumors are not truly foreign substances because they arise from cells of normal tissues whose genetic material (deoxyribonucleic acid [DNA] and ribonucleic acid [RNA]) has somehow mutated. Tumor cells express chemical compounds on their surfaces that signal the immune system that these cells are a threat. These chemical markers are called **tumor antigens** or *tumor markers,* and they label the tumor cells as abnormal cells. An **antigen** is any substance that the body's immune system recognizes as foreign. Recognition of antigens varies among individuals, which is why some people are more prone than others to immune-related diseases such as allergies, inflammatory diseases, and cancer.

The two major components of the body's immune system are **humoral immunity,** mediated by B-cell functions (primarily *antibody* production), and **cell-mediated immunity,**

which is mediated by T-cell functions. These two systems work together to recognize and destroy foreign particles and cells in the blood or other body tissues. Communication between these two divisions is vital to the success of the immune system as a whole. Attack against tumor cells by antibodies produced by the **B lymphocytes (B cells)** of the humoral immune system prepares those tumor cells for destruction by the **T lymphocytes (T cells)** of the cell-mediated immune system. This is just one example of the effective way that the two divisions of the immune system communicate with each other for a collaborative immune response.

Humoral Immune System

The functional cells of the humoral immune system are the B lymphocytes. They are also called *B cells* because they originate in the bone marrow. The B cells that are capable of generating a particular antibody normally remain dormant until the corresponding antigen is detected. When an antigen binds to receptors located on the B cells, a biochemical signal is sent to the B lymphocytes. These B cells then mature or *differentiate* into **plasma cells,** which in turn produce antibodies. **Antibodies** are **immunoglobulins** (large glycoprotein molecules; *glyco* = sugar; *protein* = amino acid chain) that bind to specific antigens, forming an *antigen-antibody complex* that inactivates disease-causing antigens.

The immune system in a healthy individual is genetically preprogrammed to be able to mount an antibody response against literally millions of different antigens. This ability results from the individual's lifetime antigen exposure and is further developed through exposure to new antigens and passed down through many generations. Antibodies that a single plasma cell makes are all identical. They are therefore called **monoclonal** antibodies. Since the 1980s, monoclonal antibodies have also been prepared synthetically using recombinant DNA technology, which has resulted in newer drug therapies.

There are five major types of naturally occurring immunoglobulins in the body: immunoglobulins A, D, E, G, and M. These unique types have different structures and functions and are found in various areas of the body. During an immune response, when B lymphocytes differentiate into plasma cells, some of these B cells become **memory cells.** Memory cells "remember" the exact characteristics of a particular foreign invader or antigen, which allows a stronger and faster immune response in the event of reexposure to the same antigen. The cells of the humoral immune system are shown in Figure 47-1.

Cell-Mediated Immune System

The functional cells of the cell-mediated (as opposed to antibody-mediated) immune system are the T lymphocytes. They are also referred to as *T cells* because they mature in the thymus. There are three distinct populations of T cells: cytotoxic T cells, T helper cells, and T suppressor cells (Figure 47-2). They are distinguished by the different functions that they perform. **Cytotoxic T cells** directly kill their targets by causing cell lysis or rupture. **T helper cells** are considered the master controllers of the immune system. They direct the actions of many other immune components, such as lymphokines and cytotoxic T cells. **Cytokines** are nonantibody proteins that serve as chemical mediators of various physiologic functions. **Lymphokines** are a subset of cytokines. They are released by T lymphocytes upon contact with antigens and serve as chemical mediators

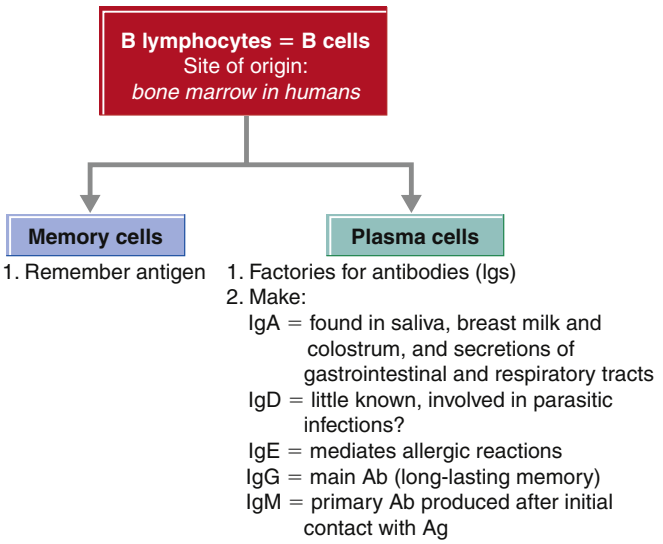

FIGURE 47-1 Cells of the humoral (antibody-mediated) immune system. *Ig,* Immunoglobulin.

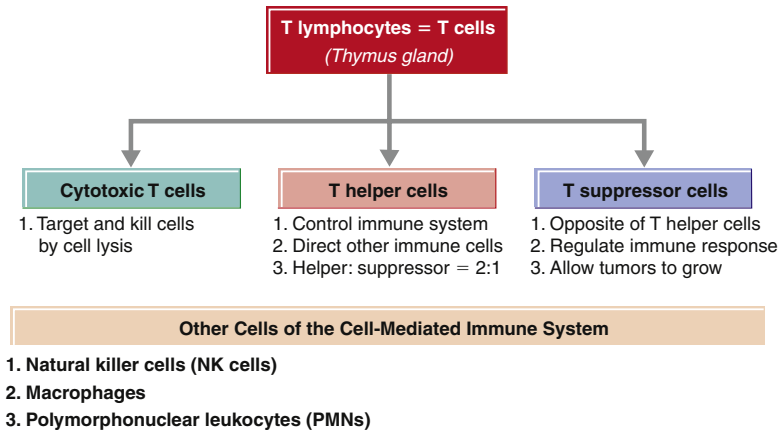

FIGURE 47-2 Cells of the cellular immune system.

of the immune response. **T suppressor cells** have an effect on the immune system that is opposite to that of T helper cells and serve to limit or control the immune response. A healthy immune system has about twice as many T helper cells as T suppressor cells at any given time.

The major cells involved in the destruction of cancer cells are part of the cell-mediated immune system (see Figure 47-2). The cancer-killing cells of the cellular immune system are the macrophages (derived from monocytes), natural killer (NK) cells (another type of lymphocyte), and polymorphonuclear **leukocytes** (not lymphocytes), which are also called *neutrophils.* In contrast, T suppressor cells have an important negative influence on antitumor actions of the immune system. Overactive T suppressor cells may be responsible for clinically significant cancer cases by permitting tumor growth beyond the immune system's control.

PHARMACOLOGY OVERVIEW

Therapy with biologic response–modifying drugs combines the knowledge of several disciplines, including general biology, genetics, immunology, pharmacology, medicine, and nursing. The general therapeutic effects of these drugs are as follows:

- Enhancement of hematopoietic function
- Regulation or enhancement of the immune response, including cytotoxic or cytostatic activity against cancer cells
- Inhibition of metastases, prevention of cell division, or inhibition of cell maturation

Box 47-1 lists the currently available biologic response–modifying drugs used in the treatment of cancer and other illnesses that have varying levels of immune system–related pathophysiology. The drugs are classified according to their biologic effects.

HEMATOPOIETIC DRUGS

Hematopoietic drugs include several medications developed over the past 10 to 15 years. Falling into this category are two erythropoietic drugs (epoetin alfa and darbepoetin alfa), three **colony-stimulating factors** (filgrastim, pegfilgrastim, and sargramostim), and one platelet-promoting drug (oprelvekin). All of these drugs promote the synthesis of various types of major blood components by promoting the growth, **differentiation,** and function of their corresponding precursor cells in the bone marrow.

Mechanism of Action and Drug Effects

Although the hematopoietic drugs are not toxic to cancer cells, they do have beneficial effects in the treatment of cancer. All hematopoietic drugs have the same basic mechanism of action. They decrease the duration of chemotherapy-induced anemia, neutropenia, and thrombocytopenia and enable higher dosages of chemotherapy to be given; decrease bone marrow recovery time after bone marrow transplantation or irradiation; and stimulate other cells in the immune system to destroy or inhibit the growth of cancer cells, as well as virus- or fungus-infected cells.

All of these drugs are produced by recombinant DNA technology, which allows them to be essentially identical to their endogenously produced counterparts. These substances work by binding to receptors on the surfaces of specialized progenitor cells in the bone marrow. Progenitor cells are responsible for the production of three particular cell lines: red blood cells (RBCs), white blood cells (WBCs), and platelets. When a hematopoietic drug binds to a progenitor cell surface, the immature progenitor cell is stimulated to mature, proliferate (reproduce itself), differentiate (transform into its respective type of specialized blood component), and become functionally active. Hematopoietic drugs may enhance certain functions of mature cell lines as well.

Epoetin alfa is a synthetic derivative of the human hormone erythropoietin, which is produced primarily by the kidney. It promotes the synthesis of erythrocytes (RBCs) by stimulating RBC progenitor cells in the bone marrow. Darbepoetin alfa is a longer-acting form of epoetin alfa. These drugs

G-CSF, Granulocyte colony-stimulating factor; *GM-CSF,* granulocyte-macrophage colony-stimulating factor; *IL,* interleukin.
*Also available in combination with the antiviral drug ribavirin.

are discussed in detail in Chapter 54. Filgrastim is a colony-stimulating factor that stimulates progenitor cells for the subset of WBCs (leukocytes) known as *granulocytes* (including basophils, eosinophils, and neutrophils). For this reason, it is also commonly called *granulocyte colony-stimulating factor (G-CSF).* Pegfilgrastim is a longer-acting form of filgrastim. Sargramostim is also a colony-stimulating factor that works by stimulating the bone marrow precursor cells that synthesize both granulocytes and the phagocytic (cell-eating) cells known as *monocytes,* some of which become macrophages. For this reason, it is also called *granulocyte-macrophage colony-stimulating factor (GM-CSF).* Oprelvekin is classified as an *interleukin,* namely, interleukin-11 (IL-11). Other interleukins are discussed later in the chapter. Oprelvekin stimulates the bone marrow cells, specifically megakaryocytes that eventually give rise to platelets.

Indications

Neutrophils are the most important granulocytes for fighting infection. Infections often appear in patients who have experienced destruction of bone marrow cells as a result of chemotherapy. Colony-stimulating factors stimulate neutrophils to grow and mature and thus directly oppose the detrimental bone marrow actions of chemotherapy. Because these drugs reduce the duration of low neutrophil counts, they reduce the incidence and duration of infections. Colony-stimulating factors also enhance the functioning of mature cells of the immune system, such as macrophages and granulocytes. This increases the ability of the body's immune system to kill cancer cells, as well as virus- and fungus-infected cells. Ultimately these properties allow patients to receive higher dosages of chemotherapy. Similar benefits occur with epoetin alfa and oprelvekin with regard to RBC and platelet counts, respectively.

The effect of hematopoietic drugs on the bone marrow cells also reduces the recovery time after bone marrow transplantation and radiation therapy. Dosages of chemotherapy used in bone marrow transplantation are often much higher than those used in conventional chemotherapy. Both the chemotherapy and radiation therapy are toxic to the bone marrow. When one or more colony-stimulating factors are administered as part of the drug therapy for bone marrow transplantation, bone marrow cell counts return to normal in a drastically shortened time. This helps to increase the likelihood of a successful bone marrow transplantation and therefore patient survival. Specific drug indications are listed in the Dosages table on this page.

TABLE 47-1 HEMATOPOIETIC DRUGS: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Edema
Gastrointestinal	Anorexia, nausea, vomiting, diarrhea
Integumentary	Alopecia, rash
Respiratory	Cough, dyspnea, sore throat
Other	Fever, blood dyscrasias, headache, bone pain

Contraindications

Contraindications for all these drugs include drug allergy. Use of filgrastim, sargramostim, and pegfilgrastim is contraindicated in the presence of more than 10% myeloid blasts (immature tumor cells in the bone marrow), because colony-stimulating factors may stimulate malignant growth of these myeloid tumor cells.

Adverse Effects

Adverse effects associated with the use of hematopoietic drugs are mild. The most common are fever, muscle aches, bone pain, and flushing. Table 47-1 lists additional adverse effects.

Interactions

Filgrastim and sargramostim have significant drug interactions when these two drugs are given with myelosuppressive (bone marrow depressant) antineoplastic drugs. Remember that these two drugs are administered to enhance the production of bone marrow cells; therefore, when myelosuppressive antineoplastics are given with them, the drugs directly antagonize each other. Typically filgrastim and sargramostim are not given within 24 hours of administration of myelosuppressive antineoplastics. However, they are given soon after this time to help prevent the WBC nadir from dropping to dangerous levels and also to speed WBC recovery. It is also recommended that these drugs be used with caution or not be given with other medications that can potentiate their myeloproliferative (bone marrow–stimulating) effects. Two examples are lithium and corticosteroids.

Dosages

For dosage information on hematopoietic drugs, see the table on this page.

DOSAGES

Hematopoietic Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ filgrastim (Neupogen) (C)	Colony-stimulating factor	IV/subcut: 5-10 mcg/kg/day	Chemotherapy-induced leukopenia
♦ oprelvekin (IL-11) (Neumega) (C)	Synthetic human interleukin analogue	**Adult only** Subcut: 50 mcg/kg/day for up to 21 days	Chemotherapy-induced thrombocytopenia
♦ sargramostim (Leukine) (C)	Colony-stimulating factor	IV: 250 mcg/m^2/day	Chemotherapy-induced leukopenia

IL, Interleukin; *IV,* intravenous; *subcut,* subcutaneous.

DRUG PROFILES

♦ filgrastim

Filgrastim (Neupogen) is a synthetic analogue of human granulocyte colony-stimulating factor and is commonly referred to as *G-CSF*. Filgrastim promotes the proliferation, differentiation, and activation of the cells that make granulocytes. Granulocytes are the body's primary defense against bacterial and fungal infections. Filgrastim has the same pharmacologic effects as endogenous human G-CSF, which is normally secreted by specialized leukocytes known as *monocytes, macrophages,* and *mature neutrophils*. Filgrastim is indicated to prevent or treat febrile neutropenia in patients receiving myelosuppressive antineoplastics for nonmyeloid (non–bone marrow) malignancies. It must be given *before* a patient develops an infection, but not within 24 hours before or after myelosuppressive chemotherapeutic drugs. Pegfilgrastim (Neulasta) is a long-acting form of filgrastim that reduces the number of injections required. Both drugs are available for injection only. These drugs are usually discontinued when a patient's absolute neutrophil count (ANC) rises above 10,000 cells/mm^3. However, some prescribers will stop it when the ANC is between 1000 and 2000 cells/mm^3.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Subcut or IV	1 hr	2-6 hr	3-5 hr	12-24 hr

♦ sargramostim

Sargramostim (Leukine) is a synthetic analogue of human granulocyte-macrophage colony-stimulating factor and is commonly referred to as *GM-CSF*. There are three major subsets of leukocytes: *granulocytes, monocytes,* and *lymphocytes* (B cells and T cells). Granulocytes are further subdivided into *basophils, eosinophils,* and *neutrophils*. Neutrophils are the most important in fighting infection. Macrophages are tissue-based (as opposed to circulating) cells that are derived from monocytes, which circulate in the blood. Neutrophils, monocytes, and macrophages make up the three main categories of phagocytic (cell-eating) blood cells, and they literally ingest foreign cells and other antigens as part of their immune system function. Sargramostim has the same pharmacologic effects as endogenous human GM-CSF. It stimulates the proliferation, differentiation, and activation of the cells in the bone marrow that eventually become granulocytes, monocytes, and macrophages.

Sargramostim is indicated for promoting bone marrow recovery after autologous (own marrow) or allogenic (donor marrow) bone marrow transplantation in patients with various types of leukemia and lymphoma. This drug is available for injection only.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Subcut or IV	4 hr	2 hr	2 hr	10 days

♦ oprelvekin

Oprelvekin (Neumega) is both a hematopoietic drug and one of the interleukins. However, its function is similar to that of the colony-stimulating factors (filgrastim and sargramostim) in that it enhances synthesis of a specific blood component—in this case, the platelets. Oprelvekin is indicated for the prevention of chemotherapy-induced severe thrombocytopenia and avoidance of the need for platelet transfusions. Its use is contraindicated in cases of known drug allergy. It is available for injection only.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Subcut	5-9 days*	3 hr	7 hr	14 days

*Platelet counts begin to increase.

INTERFERONS

Interferons are proteins that have three basic properties: they are antiviral, antitumor, and immunomodulating. There are three different groups of interferon drugs—the alpha, beta, and gamma interferons—each with its own antigenic and biologic activity. Interferons are most commonly used in the treatment of certain viral infections and certain types of cancer.

Mechanism of Action and Drug Effects

Interferons are recombinantly manufactured substances that are identical to the interferon cytokines that are naturally present in the human body. In the body, interferons are produced by activated T cells and by other cells in response to viral infection. Interferons protect human cells from virus attack by enabling the human cells to produce enzymes that stop viral replication and prevent viruses from penetrating into healthy cells. Interferons prevent cancer cells from dividing and replicating and also increase the activity of other cells in the immune system, such as macrophages, neutrophils, and natural killer cells. Their effect on cancer cells is caused by a combination of direct inhibition of DNA and protein synthesis within cancer cells (antitumor effects) and multiple immunomodulatory effects on the host's immune system. Interferons increase the cytotoxic activity of natural killer cells and the phagocytic ability of macrophages. Interferons also increase the expression of cancer cell antigens on the cell surface, which enables the immune system to recognize cancer cells more easily, specifically marking them for destruction.

Overall, interferons have three different effects on the immune system. They can (1) restore its function if it is impaired, (2) augment (amplify) the immune system's ability to function as the body's defense, and (3) inhibit the immune system from working. This latter function may be especially useful when the immune system has become dysfunctional, causing an *autoimmune* disease. This is believed to be the case in multiple sclerosis. Two interferons (interferon beta-1a and interferon beta-1b) are specifically indicated for treatment of multiple sclerosis. Inhibiting the dysfunctional

immune system prevents further damage to the body from the disease process.

Indications

The beneficial actions of interferons (antiviral, antineoplastic, and immunomodulatory) make them excellent drugs for the treatment of viral infections, various cancers, and some autoimmune disorders. Currently accepted indications for interferons are listed in the Dosages table on this page.

Contraindications

Contraindications to the use of interferons include known drug allergy and may include autoimmune disorders, hepatitis or liver failure, concurrent use of **immunosuppressant** drugs, Kaposi's sarcoma related to acquired immunodeficiency syndrome (AIDS), and severe liver disease.

Adverse Effects

The most common adverse effects can be broadly described as flulike symptoms: fever, chills, headache, malaise, myalgia, and fatigue. The major dose-limiting adverse effect of interferons is fatigue. Patients taking high dosages become so exhausted that they are often confined to bed. Other adverse effects of interferons are listed in Table 47-2.

TABLE 47-2 INTERFERONS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
General	Flulike syndrome, fatigue
Cardiovascular	Tachycardia, cyanosis, ECG changes, orthostatic hypotension
Central nervous	Confusion, somnolence, irritability, seizures, hallucinations
Gastrointestinal	Nausea, diarrhea, vomiting, anorexia, taste alterations, dry mouth
Hematologic	Neutropenia, thrombocytopenia
Renal and hepatic	Increased BUN and creatinine levels, proteinuria, abnormal liver function test

BUN, Blood urea nitrogen; *ECG,* electrocardiogram.

Interactions

Drug interactions are seen with both interferon alfa-2a and interferon alfa-2b when they are used with drugs that are metabolized in the liver via the cytochrome P-450 enzyme system. The combination results in decreased metabolism and increased accumulation of these drugs, which leads to drug toxicity. There is also some evidence that using interferons together with antiviral drugs such as zidovudine enhances the activity of both drugs but may lead to toxic levels of zidovudine. Additive toxic effects to the bone marrow can occur when interferon gamma products are used with other myelosuppressive drugs.

Dosages

For dosage information on interferons, see the table on this page.

DOSAGES

Interferons

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ interferon alfa-2a (Roferon-A) (C)	Immunomodulator, antiviral, antineoplastic	IM/subcut: 3 million units 3 × per week, depending on indication	Chronic hepatitis C, hairy cell leukemia, AIDS-related Kaposi's sarcoma, chronic myelogenous leukemia
♦ interferon alfa-2b (Intron-A) (C)	Immunomodulator, antiviral, antineoplastic	IM/subcut: 1-30 million units 3 × per week*	Hairy cell leukemia, malignant melanoma, follicular lymphoma, condylomata acuminata (venereal-genital warts), AIDS-related Kaposi's sarcoma, chronic hepatitis C, chronic hepatitis B
♦ peginterferon alfa-2a (Pegasys) (C)	Immunomodulator, antiviral	Subcut: 180 mcg weekly for 48 wk	Chronic hepatitis C
♦ peginterferon alfa-2b (PEG-Intron) (C)	Immunomodulator, antiviral	Subcut: 1 mcg/kg/wk for 1 yr†	Chronic hepatitis C
♦ interferon alfa-n3 (Alferon-N) (C)	Immunomodulator, antiviral	Intralesional: 250,000 units (0.05 mL) into the base of each wart 2 × per week for up to 8 wk	Condylomata acuminata
♦ interferon alfacon-1 (Infergen) (C)	Immunomodulator, antiviral	Subcut: 9 mcg 3 times per week for 24 wk	Chronic hepatitis C
♦ interferon beta-1a (Avonex, Rebif) (C)	Immunomodulator	IM (Avonex): 30 mcg 1 time per week Subcut (Rebif): 44 mcg 3 × per week	Multiple sclerosis
interferon gamma-1b (Actimmune) (C)	Immunomodulator	**BSA more than 0.5 m^2** Subcut: 50 mcg/m^2 3 × per week **BSA less than 0.5 m^2** Subcut: 1.5 mcg/kg 3 × per week	Chronic granulomatous disease, osteopetrosis

AIDS, Acquired immunodeficiency syndrome; *BSA,* body surface area; *IM,* intramuscular; *subcut,* subcutaneous.
*May also be given by intravenous infusion for melanoma. Route and dose vary depending on indication.
†Dose is 1.5 mcg/kg/wk if given with ribavirin capsules (see Chapter 40).

DRUG PROFILES

The three major classes of interferon drugs are alfa, beta, and gamma, which are sometimes also written using the lowercase Greek letters α, β, and γ, respectively. The "alfa" designation is synonymous with the Greek letter "alpha," but "alfa" is now more commonly used clinically. The interferons vary in their antigenic makeup, biologic actions, and pharmacologic properties. The best known interferon class is interferon alfa. Interferon products are biologic response–modifying drugs that can be broadly classified as cytokines. Cytokines are immune system proteins that serve two essential functions: they direct the actions and communication between the cell-mediated and humoral divisions of the immune system, and they augment or enhance the immune response. Other cytokines include tumor necrosis factor (TNF), interleukins, and colony-stimulating factors.

INTERFERON ALFA PRODUCTS

♦ **interferon alfa-2a, interferon alfa-2b, interferon alfa-n3, interferon alfacon-1, peginterferon alfa-2a, peginterferon alfa-2b**

The most commonly used interferon products are in the alfa class. They are also referred to as *leukocyte interferons* because they are produced from human leukocytes. Two newer types of interferon alfa include peginterferon alfa-2a and peginterferon alfa-2b. The *peg* refers to the attachment of a polymer chain of the hydrocarbon polyethylene glycol (PEG). This "pegylation" process increases the size of the interferon molecule. This increased size delays drug absorption, increases half-life, and decreases plasma clearance rate, which prolongs the drug's therapeutic effects. In addition, pegylation is believed to reduce the immunogenicity of the interferon and thus delay its recognition and destruction by the immune system. Similarly, pegfilgrastim, mentioned previously in this chapter, is a pegylated form of filgrastim and is also longer-acting. The alfa-2a and alfa-2b interferons share the following indications: chronic hepatitis C, hairy cell leukemia, and AIDS-related Kaposi's sarcoma. Interferon alfa-2a (only) is also indicated for the treatment of chronic myelogenous leukemia. Additional indications unique to interferon alfa-2b are chronic hepatitis B, malignant melanoma (an often fatal form of skin cancer), follicular lymphoma (so named because its malignant cells gather in clumps called *follicles*—not to be confused with hair follicles), and condylomata acuminata (virally induced genital or venereal warts). Peg-interferon alfa-2a and peginterferon alfa-2b are currently indicated only for treatment of chronic hepatitis C.

Interferon alfa-n3 is a polyclonal mixture of all interferon alfa subtypes. It is the product of pooled human leukocytes. Its only current indication is condylomata acuminata. Interferon alfacon-1 is a purely synthetic (i.e., non–naturally occurring) recombinant product that is currently indicated only for treatment of hepatitis C.

Interferons are most commonly given by either intramuscular or subcutaneous injection, but intravenous and intraperitoneal routes have been used as well. It is important to note that some interferons are dosed in millions of units. Although it is unacceptable to use the abbreviation MU for "millions of units," you may see it written as such. It is imperative to double-check the dose, because the prescriber's writing of "MU" may be mistaken for "mg" or "mcg." If there is any question about the dose of any medication, double-check with the prescriber, pharmacist, or other experienced colleague before administering the medication to the patient. Although this is true for all medications, it is a special consideration for interferons and other biologic response–modifying drugs, because of both their potency and their dosage variability.

INTERFERON BETA PRODUCTS

♦ **interferon beta-1a, interferon beta-1b**

Interferon beta-1a and interferon beta-1b are the currently available beta products. They interact with specific cell receptors found on the surfaces of human cells and possess antiviral and immunomodulatory activity. Both are produced by recombinant DNA techniques and are indicated for the treatment of relapsing multiple sclerosis (to slow the progression of physical disability and decrease the frequency of clinical exacerbations). The only contraindication is drug allergy, including allergy to human albumin. Both drugs are available for injection only.

INTERFERON GAMMA PRODUCT

interferon gamma-1b

Interferon gamma-1b (Actimmune) is a synthetic product produced by recombinant DNA technology. It is indicated for the treatment of serious infections associated with chronic granulomatous disease, a genetic immunodeficiency, and osteopetrosis, a genetic bone disease characterized by abnormally dense bone, anemia, and frequent fractures. Interferon gamma-1b is available for injection only.

MONOCLONAL ANTIBODIES

Monoclonal antibodies are quickly becoming standards of therapy in many areas of medicine, including treatment of cancer, rheumatoid arthritis and other inflammatory diseases, multiple sclerosis, and organ transplantation. In cancer treatment they have advantages over traditional antineoplastics in that they can specifically target cancer cells and have minimal effect on healthy cells. This reduces many of the adverse effects traditionally associated with antineoplastic drugs. There are several commercially available monoclonal antibodies used to treat cancer and rheumatoid arthritis. The most commonly used ones are listed in the Dosages table on p. 772. The *mab* suffix in a drug name is usually an abbreviation for "monoclonal antibody." Muromonab is used in kidney transplantation and is discussed in Chapter 48.

Mechanism of Action, Drug Effects, and Indications

Because these drugs are so diverse, specific information for each appears in the individual drug profiles provided later in the chapter.

Contraindications

The only clear contraindication to the use of monoclonal antibodies reported thus far is drug allergy to a specific

product. Their use is usually contraindicated in patients with known active infectious processes due to their immunosuppressive qualities. Although known drug allergy is a contraindication, depending on the urgency of the clinical situation, a given monoclonal antibody may be the only viable treatment option for a seriously ill patient. In such situations, allergic symptoms may be controlled with supportive medications such as diphenhydramine and acetaminophen (for fever control). All of the drugs that are TNF antagonists are contraindicated in patients with active tuberculosis or other infections. Infliximab has been shown to worsen severe cases of heart failure and is dosed at no more than 5 mg/kg and only after considering other treatment options for its indications. Use of alemtuzumab is also contraindicated in patients with active systemic infections and immunodeficiency conditions, including AIDS.

Adverse Effects

Many, if not most, patients receiving these very potent drugs manifest acute symptoms that are comparable to classic allergy or flulike symptoms, such as fever, dyspnea, and chills. The primary objective is to administer the medication and control such symptoms as well as possible. Because the mechanisms of action of these drugs work through augmentation or inhibition of the human immune response, they can have a variety of adverse effects, some mild, some severe, that affect several body systems. Drug-specific adverse effects with the highest reported incidence (10% to 50% or more) are listed in Table 47-3. The risk of such adverse effects must be weighed against the severity of the patient's underlying illness. Many of these adverse effects may also be associated with the patient's disease process (e.g., infections) and even with life in general (e.g., headache, depression). This is especially true for the milder effects. The risk of acquiring an infection is a serious adverse effect of all of the biologic response–modifying agents, because they alter the normal immune response.

Interactions

Drug interactions associated with monoclonal antibodies are relatively few, and no major food interactions are listed. Administration of adalimumab with the anti–rheumatoid arthritis drug anakinra (an interleukin) may increase the risk of serious infections secondary to neutropenia. The clearance of natalizumab may be reduced by concurrent administration of interferon beta-1a (both used for multiple sclerosis). Coadministration of anti-TNF drugs (e.g., etanercept, anakinra) with infliximab may also increase the risk of neutropenia and infections. Etanercept is not to be given concurrently with varicella-zoster immune globulin (VZIG) because of undesirable drug interactions. However, etanercept may be resumed after completion of VZIG therapy. Bevacizumab is associated with increased risk of severe diarrhea and neutropenia when given concurrently with another anti–colorectal cancer drug, irinotecan (see Chapter 45). Paclitaxel (see Chapter 45) has been shown to reduce the clearance of trastuzumab when the two are administered concurrently to treat breast cancer.

Dosages

For dosage information on the monoclonal antibodies, see the table on p. 772.

TABLE 47-3 SELECTED IMMUNOMODULATING DRUGS: COMMON ADVERSE EFFECTS

DRUG	ADVERSE EFFECTS
adalimumab	Localized inflammatory reaction at the injection site, infectious processes such as upper respiratory tract and urinary tract infections, and higher rates of various malignancies
alemtuzumab	Rash, pruritus, nausea, vomiting, diarrhea, dyspnea, cough, muscle spasms, fever, fatigue, skeletal pain, myelosuppression
belimumab	Nausea, diarrhea, depression, insomnia, fever, infection, anaphylaxis
bevacizumab	Deep vein thrombosis, hypertension, diarrhea, abdominal pain, constipation, vomiting, GI hemorrhage, leukopenia, asthenia, headache, dizziness, dry skin, proteinuria, hypokalemia, epistaxis, weight loss
certolizumab	Arthralgia, respiratory tract infection, cardiac dysrhythmia, rash, bowel obstruction
cetuximab	Headache, insomnia, skin rash, conjunctivitis, GI discomfort, anemia, leukopenia, dehydration, edema, weight loss, dyspnea, asthenia, back pain, fever
golimumab	Hypertension, increased liver function tests, infection
ibritumomab tiuxetan	Nausea, myelosuppression, asthenia, infection, chills
infliximab	Headache, rash, GI discomfort, dyspnea, upper and lower respiratory tract infection
natalizumab	Depression, fatigue, headache, GI discomfort, urinary tract infection, lower respiratory tract infection, joint pain. Of even greater concern are case reports of a rare and potentially fatal brain disorder known as progressive multifocal leukoencephalopathy.
rituximab	Fever, chills, headache. Potentially fatal infusion-related events, including severe bronchospasm, dyspnea, hypoxia, pulmonary infiltrates, adult respiratory distress syndrome, hypotension, and angioedema. Tumor lysis syndrome (see Chapter 45) with acute renal failure has also been reported. The drug must be stopped immediately and indicated supportive care provided if such a reaction appears imminent.
tocilizumab	Hypertension, rash, diarrhea, dizziness, anaphylaxis, infection, injection site reaction
tositumomab and iodine I-131 tositumomab	Headache, rash, GI discomfort, muscle pains, dyspnea, pharyngitis, asthenia, fever, chills, infection
trastuzumab	Fever, chills, headache, infection, nausea, vomiting, diarrhea, dizziness, headache, insomnia, rash, GI discomfort, edema, dyspnea, rhinitis, asthenia, back pain, fever, chills, infection

GI, Gastrointestinal.

DOSAGES

Monoclonal Antibodies

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
adalimumab (Humira) (B)	Anti–TNF-alpha monoclonal antibody	**Adult only** Subcut: 40 mg every other week; may advance to 40 mg weekly if indicated	Severe, progressive RA for which other RA therapies have failed
alemtuzumab (Campath) (C)	Anti–glycoprotein CD52	IV: 3-10 mg daily to maximum tolerated dose, then 30 mg 3 × per week (alternate days) for up to 12 wk	B-cell chronic lymphocytic leukemia
belimumab (Benlysta) (C)	B-lymphocyte stimulator-specific inhibitor	IV: 10 mg/kg at 2-week intervals	Systemic lupus erythematosus
certolizumab (Cimzia) (B)	Anti-TNF	Subcut: 400 mg at 2-week intervals × 2, then monthly	RA, Crohn's disease
bevacizumab (Avastin) (C)	Anti–human vascular endothelial growth factor	IV: 5-10 mg/kg every 14 days	Metastatic colorectal cancer
cetuximab (Erbitux) (C)	Anti–human epidermal growth factor	IV: 400 mg/m^2 loading dose, then 250 mg/m^2 weekly	Metastatic colorectal cancer
golimumab (Simponi) (B)	Anti-TNF	Subcut: 50 mcg monthly	RA, ankylosing spondylitis
ibritumomab tiuxetan (Zevalin) (D)	Chelator immunoconjugate	IV: 250 mg/m^2 × 2 doses 7 to 9 days apart	Non-Hodgkin's lymphoma
infliximab (Remicade) (B)	Anti–TNF-alpha	IV: 3-5 mg/kg at 0, 2, and 6 wk, then every 6 wk	Ankylosing spondylitis, Crohn's disease, RA
natalizumab (Tysabri) (C)	Anti–alpha4 integrin subunit	IV: 300 mg every 4 wk	Multiple sclerosis
♦ rituximab (Rituxan) (C)	Anti–CD20 surface antigen	IV: 375 mg/m^2 1 × per week × 4 doses	Non-Hodgkin's lymphoma
tositumomab and iodine I-131 tositumomab (Bexxar) (X)	Radioactive MAB	IV: Complex dosing regimen involving both drug components; follow instructions in package insert as ordered	Non-Hodgkin's lymphoma
trastuzumab (Herceptin) (B)	Anti–HER2 protein MAB	IV: Loading dose, 4 mg/kg IV: Maintenance dose, 2 mg/kg/wk	Breast cancer

IV, Intravenous; *MAB,* monoclonal antibody; *RA,* rheumatoid arthritis; *subcut,* subcutaneous; *TNF,* tumor necrosis factor.

DRUG PROFILES

All of the monoclonal antibodies are synthesized using recombinant DNA technology. Because of the complexities of this technology, these drugs tend to be much more expensive than most other medications, with prices in the hundreds or thousands of dollars per single dose. Many of the monoclonal antibodies are used to treat various forms of cancer. Their advantage is that they offer greater cell-killing specificity aimed at cancer cells instead of all body cells. Nonetheless, these drugs are associated with significant adverse effects and therefore with risk, which must be weighed against the benefit using expert clinical judgment. Severe allergic inflammatory-type infusion reactions can occur, and patients may therefore be premedicated with acetaminophen or diphenhydramine to reduce the occurrence of such reactions. If reactions do occur, they may be treated with diphenhydramine and other drugs such as epinephrine and corticosteroids. Conventional pharmacokinetic data are not listed for the majority of these drugs because they do not follow standard pharmacokinetic models owing to their unique behavior in the body. It is known, however, that they may remain in the affected tissues for many weeks or months. The elimination half-life is given in the following profiles when known.

adalimumab

Adalimumab (Humira) works through its specificity for human tumor necrosis factor (TNF)-alpha. TNF-alpha is a naturally occurring cytokine that is involved in normal inflammatory and immune responses. Adalimumab is indicated for the treatment of severe cases of rheumatoid arthritis that have failed to respond to other medications, including methotrexate. It can be used either alone or concurrently with such medications. In patients with rheumatoid arthritis, elevated levels of TNF are found in the synovial fluid in the spaces of affected joints. In addition to preventing TNF-alpha molecules from binding to TNF cell surface receptors, adalimumab also modulates the inflammatory biologic responses that are induced or regulated by TNF. Use of adalimumab is contraindicated in patients with any active infectious process, whether localized or systemic, acute or chronic.

alemtuzumab

Alemtuzumab (Campath) is approved to treat B cell–mediated chronic lymphocytic leukemia. It is classified as a recombinant humanized antibody that is directed against the CD52 glycoprotein that appears on the surfaces of virtually all B and T lymphocytes. Humanization involves the insertion of human DNA sequences during drug production to make the drug better tolerated by human patients. It is used specifically in patients for whom other first-line chemotherapy treatments, including treatment with alkylating drugs and the antimetabolite fludarabine (see Chapter 45), have failed. Its contraindications are known drug allergy, active systemic

infection, and documented immunodeficiency disease such as HIV-positive status. The half-life of alemtuzumab is 10 hours to 30 days.

belimumab

Belimumab (Benlysta) is the first drug approved for the treatment of systemic lupus erythematosus in the past 40 years. It is a B-lymphocyte stimulator-specific inhibitor. The most common side effects include nausea, diarrhea, insomnia, bronchitis, migraine, and pain in the extremities. The most serious adverse effects include infection (sometimes fatal), anaphylaxis, and depression. It is given via IV infusion.

bevacizumab

Bevacizumab (Avastin) is approved for the treatment of metastatic colon cancer, rectal cancer in combination with 5-flurouracil (see Chapter 45), non–small cell lung cancer, and malignant glioblastoma. It is unique in that it binds to and inhibits vascular endothelial growth factor, a protein that promotes development of new blood vessels in tumors (as well as in normal body tissues). It has no listed contraindications but may complicate surgical wound healing because of its antivascular effects. The half-life of bevacizumab is 11 to 50 days.

certolizumab

Certolizumab (Cimzia) is a tumor necrosis factor (TNF) antagonist. It is indicated for moderately to severe active Crohn's disease that is unresponsive to other therapy and for severe rheumatoid arthritis. The most common adverse effects include headache, nausea, upper respiratory infection, hypertension, and infections. A patient medication guide must be dispensed with each prescription, warning patients of potential serious infections and possible lymphoma.

cetuximab

Cetuximab (Erbitux) is approved for the treatment of metastatic colorectal cancer. It is a recombinant monoclonal antibody made from both human and mouse (murine) genetic material and is designed for concurrent use with the second-line antineoplastic drug irinotecan (see Chapter 45). It binds to *epidermal growth factor* on the surface of tumor cells, where it hinders cell growth through interference with cell metabolism. Cetuximab is used either in combination with irinotecan or alone in patients who are intolerant of the latter drug. It has no listed contraindications but is known to cause severe infusion reactions in up to 3% of patients receiving it. The half-life of cetuximab is 97 to 114 hours.

golimumab

Golimumab (Simponi) is a TNF antagonist approved for the treatment of severe rheumatoid arthritis and ankylosing spondylitis. The most common side effects include hypertension, dizziness, increased liver function tests, and infection. It is not to be given with other TNF antagonists. Patients must be monitored for infection, as with all TNF antagonists. Golimumab is given subcutaneously in a dose of 50 mg once a month. It is given in conjunction with methotrexate for RA.

ibritumomab tiuxetan

Ibritumomab tiuxetan (Zevalin) is approved for treating B-cell non-Hodgkin's lymphoma. This drug is an immunoconjugate, consisting of ibritumomab conjugated with the metal chelator tiuxetan. This drug comes in kits that also include one of two radioactive metal isotopes (radioisotopes). The antibody binds to the CD20 antigen that occurs on the surfaces of both normal and malignant B lymphocytes. Once the complex is bound to the cells, the tiuxetan component binds the radioisotope, which is administered as another part of the anticancer therapy. Radioactive beta emission from the bound radioisotope, a unique feature of this drug, induces free radical formation and cell damage in both the cell containing the drug complex and neighboring cells.

infliximab

Infliximab (Remicade) is one of the earliest monoclonal antibodies, approved in 1998. It works through an anti–TNF-alpha action, similar to adalimumab. It is approved for the treatment of ankylosing spondylitis, Crohn's disease, and rheumatoid arthritis. It has the special contraindication of severe heart failure (class III or IV on the New York Heart Association scale) because it may worsen this condition. It also carries an FDA black box warning reporting cases of fatal tuberculosis and/or fungal infections associated with the use of this drug. It is recommended that patients be tested for latent tuberculosis before it is administered. The half-life of infliximab is 8 to 9 days.

natalizumab

Natalizumab (Tysabri) is approved for the treatment of multiple sclerosis. It is a humanized monoclonal antibody derived from murine myeloma cells. Natalizumab works by binding to the $alpha_4$ subunits of integrins, proteins found on the surfaces of leukocytes (with the exception of neutrophils). These proteins are implicated in the multiple sclerosis disease process, but its exact mechanism of action has not been determined. However, the drug is known to inhibit the leukocyte adhesion that is mediated by these $alpha_4$ protein subunits, and this is also believed to be part of the disease process. Natalizumab has no listed contraindications. The half-life is 11 days. Natalizumab was taken off the market only 1 year after it was originally approved in 2004 due to reports of patients developing multifocal leukoencephalopathy, a rare and serious viral infection of the brain. In 2006, the FDA allowed the marketing of natalizumab to resume under a special distribution program. Only patients who are enrolled in the program are allowed to receive the drug.

♦ rituximab

Rituximab (Rituxan) specifically binds to antigen CD20. This antigen is a protein on the membranes of both normal and malignant B cells found in patients with non-Hodgkin's lymphoma. Antigen CD20 is expressed in more than 90% of B-cell non-Hodgkin's lymphomas. Once rituximab binds to these B cells, a host immune response causes lysis of the cells. Rituximab has become a standard drug for the treatment of patients

with follicular low-grade non-Hodgkin's lymphoma for whom previous therapy has failed. It is recommended that patients be premedicated with acetaminophen and diphenhydramine before each infusion of the drug to reduce its well-known infusion-related adverse effects.

tositumomab and iodine I 131 tositumomab

Tositumomab and iodine (I-131) tositumomab (Bexxar) are approved for the treatment of non-Hodgkin's lymphoma. This drug is a murine monoclonal antibody with a dual radioactive and nonradioactive component. Both components bind to the CD20 antigen, a transmembrane protein that, as noted earlier, is expressed on the cell membranes of more than 90% of B-cell non-Hodgkin's lymphoma cells. Theoretical mechanisms of action include induction of apoptosis (programmed cell death), *complement-dependent* cytotoxicity, or antibody-dependent cytotoxicity mediated by the drug itself. **Complement** is a collective term for about 20 different proteins normally present in plasma that aid other immune system components (e.g., B cells and T cells) in mounting an immune response.

trastuzumab

Trastuzumab (Herceptin) kills tumor cells by mediating antibody-dependent cellular cytotoxicity. It accomplishes this by inhibiting proliferation of human tumor cells that overexpress the HER2 protein. The HER2 protein is overexpressed in 25% to 30% of primary malignant breast tumors and has been established as an adverse prognostic factor for early-stage breast cancer. Because of the relatively selective expression of HER2 on cancer cells, it has been an appealing target for antineoplastic therapy. Trastuzumab has a special FDA black box warning reporting cases of ventricular dysfunction and heart failure associated with this drug. Monitor for signs and symptoms of heart failure and ventricular dysfunction before and during treatment. In addition, fatal hypersensitivity reactions, infusion reactions, and pulmonary events have occurred in association with its use; therefore, careful clinical judgment, risk evaluation, and informed patient consent are called for in its use. The half-life of trastuzumab is 10 to 30 days.

INTERLEUKINS AND RELATED DRUGS

Interleukins are a natural part of the immune system and are classified as *lymphokines.* Lymphokines are soluble proteins that are released from activated lymphocytes such as natural killer cells. There are several known interleukins in the body (IL-2, IL-3, IL-4, IL-5, IL-6, and IL-11), and more are being identified as knowledge of the immune system increases.

The pharmaceutical interleukin receptor agonists currently available are aldesleukin (IL-2), oprelvekin (IL-11), denileukin diftitox, tocilizumab (IL-6), and anakinra. Oprelvekin was mentioned with the hematopoietic drugs earlier in the chapter and is used to help patients produce platelets. It has a dual classification as both an interleukin and hematologic drug. All interleukins are prepared via recombinant technology.

BOX 47-2 INTERLEUKIN-2: DRUG EFFECTS

Modulating Effects
Proliferation of T cells
Synthesis and secretion of cytokines
Increased production of B cells (antibodies)
Proliferation and activation of NK cells
Proliferation and activation of LAK cells

Enhancing Effects
Enhancement of killer T cell activity
Amplification of the effects of cytokines
Enhancement of the cytotoxic actions of NK cells and LAK cells

LAK, Lymphokine-activated killer; *NK,* natural killer.

Mechanism of Action and Drug Effects

Interleukins cause multiple effects in the immune system, one of which is antitumor action. IL-2 is produced by activated T cells in response to macrophage-"processed" antigens and secreted interleukin (IL-1). It was formerly called *T-cell growth factor* because, among other actions, it aids in the growth and differentiation of T lymphocytes. The IL-2 derivative aldesleukin acts indirectly to stimulate or restore immune response. Aldesleukin binds to receptor sites on T cells, which stimulates the T cells to multiply. One type of cell that results from this multiplication is the **lymphokine-activated killer (LAK) cell.** These LAK cells recognize and destroy only cancer cells and ignore normal cells. Aldesleukin is currently the most widely used of the interleukin drugs. A detailed list of its specific immunomodulating effects appears in Box 47-2.

Denileukin diftitox consists of one segment (denileukin) that is patterned after natural human IL-2 and a second segment (diftitox) that is patterned after diphtheria toxin. It is an IL-2 receptor antagonist and binds to cell surface IL-2 receptors that are expressed on both normal and certain malignant cells. It causes cell death upon binding to these receptors through the cytocidal activity of diphtheria toxin, which inhibits intracellular protein synthesis.

Anakinra is a recombinant form of the natural human IL-1 receptor antagonist. It competitively inhibits the binding of IL-1 to its corresponding receptor sites, which are expressed in many different tissues and organs. Tocilizumab is a recombinant form of the natural IL-6 receptor antagonist.

Indications

Aldesleukin was previously indicated only for the treatment of metastatic renal cell carcinoma, a malignancy that originates in the kidney tissues. It is now also approved for the treatment of metastatic melanoma. Denileukin diftitox is currently indicated only as therapy for a skin-based lymphoma known as *cutaneous T-cell lymphoma,* which often metastasizes to other areas of the body. Anakinra and tocilizumab are indicated for symptom control in patients with rheumatoid arthritis for whom other therapy has failed.

Contraindications

Contraindications to the administration of aldesleukin include drug allergy, organ transplantation, and abnormal results on

thallium cardiac stress tests or pulmonary function tests. For denileukin diftitox, the only usual contraindication is drug allergy, as is also the case for anakinra and tocilizumab.

Adverse Effects

Therapy with aldesleukin is commonly complicated by severe toxicity. A syndrome known as *capillary leak syndrome* is responsible for the severe toxicities of aldesleukin. As the name implies, capillary leak syndrome refers to a condition induced by interleukin therapy in which the capillaries lose their ability to retain vital colloids such as albumin, protein, and other essential components of blood. Because the capillaries are "leaky," these substances migrate into the surrounding tissues. This results in massive fluid retention (20 to 30 pounds), which can lead to the life-threatening problems of respiratory distress, heart failure, dysrhythmias, and myocardial infarction. Fortunately, these are all reversible after discontinuation of the interleukin therapy. Close patient monitoring and vigorous supportive care are essential in the patient receiving aldesleukin therapy. Other adverse effects that may be associated with aldesleukin therapy are fever, chills, rash, fatigue, hepatotoxicity, myalgias, headaches, and eosinophilia.

The most common adverse effects associated with denileukin diftitox administration are GI upset, hypoalbuminemia, elevated liver enzyme levels, edema, dyspnea, cough, fever, chills, asthenia, generalized pain, chest pain, infection, and headache. Anakinra has a much milder adverse effect profile that includes local reactions at the injection site, various respiratory tract infections, and headache. Tocilizumab has a high risk of causing anaphylaxis.

Interactions

Aldesleukin, when given with antihypertensives, can produce additive hypotensive effects. Coadministration of corticosteroids with aldesleukin can reduce its antitumor effectiveness and is to be avoided. No particular drug interactions have been reported to date for denileukin diftitox. Anakinra and tocilizumab are not to be used (or used cautiously) with other immune modifiers due to increased risk of serious infections.

Dosages

For dosage information on the interleukin agonists and antagonists, see the table on this page.

DRUG PROFILES

The interleukins are a group of naturally occurring cytokines in the body that originally were believed to be produced by and to act primarily on leukocytes (WBCs). They are now recognized as multifunctional cytokines that are produced by a variety of cells but act at least partly within the lymphatic system.

♦ aldesleukin

Aldesleukin (Proleukin) is a human IL-2 derivative that is manufactured using recombinant DNA technology. It is a cytokine that is produced by lymphocytes and is therefore classified as a lymphokine. Aldesleukin is currently approved only for the treatment of metastatic renal cell carcinoma and metastatic melanoma, despite its activity against other cancers. Off-label uses include HIV infection and AIDS, and non-Hodgkin's lymphoma. Aldesleukin is contraindicated in patients with known drug allergy, abnormal thallium stress test or pulmonary function tests (due to potential drug effects on cardiopulmonary function), and organ transplants (due to the immunostimulating qualities of the drug, which may cause organ rejection). Aldesleukin is available only for injection.

denileukin diftitox

Denileukin diftitox (Ontak) is an IL-2 receptor antagonist that is used to treat cutaneous T-cell lymphoma. Its only current contraindication is known drug allergy. Denileukin is available for injection only.

anakinra

Anakinra (Kineret) is an IL-1 receptor antagonist that is used to help control the symptoms of rheumatoid arthritis. Its only current contraindication is known drug allergy. Anakinra is available for injection only.

tocilizumab

Tocilizumab (Actemra) is an interleukin-6 antagonist approved for the treatment of severe rheumatoid arthritis. It is approved for patients who have not had an adequate response to other agents. It has a significant risk of anaphylaxis, and premedication must be given. A medication guide must be given to all patients receiving tocilizumab. Serious adverse effects include hepatotoxicity, infections, herpes zoster reactivation, and GI perforation. Tocilizumab is not to be given with other biologic response–modifying agents. It is given as an IV infusion.

DOSAGES

Interleukins and Related Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ aldesleukin (IL-2) (Proleukin) (C)	Human recombinant IL-2 analogue	IV: 600,000 IU/kg (0.037 mg/kg) q8h (14 doses)	Metastatic renal cell carcinoma or melanoma
anakinra (Kineret) (B)	IL-1 receptor antagonist	Subcut: 100 mg/day	Rheumatoid arthritis
denileukin diftitox (Ontak) (C)	Recombinant IL-2 and diphtheria toxin protein	IV: 9 or 18 mcg/kg/day for 5 consecutive days every 21 days	Cutaneous T-cell lymphoma
tocilizumab (Actemra)	IL-6 antagonist	IV: 4-8 mg/kg monthly	Rheumatoid arthritis

IL, Interleukin; *IV,* intravenous; *subcut,* subcutaneous.

TABLE 47-4 MISCELLANEOUS IMMUNOMODULATING DRUGS

DRUG (TRADE AND OTHER NAMES)	CLASSIFICATION	INDICATIONS	MECHANISM OF ACTION
abatacept (Orencia)	Selective costimulation modulator	RA	Inhibits T-cell activation
bexarotene (Targretin)	Retinoid receptor agonist	Cutaneous T-cell lymphoma	Exact mechanism is unknown; binds to and activates retinoid X receptor subtypes; this regulates the expression of genes that control cellular differentiation
BCG vaccine (Pacis, TICE BCG, TheraCys)	Live virus vaccine, adjuvant	Localized bladder cancer	Promotes local inflammation and immune response in bladder mucosa
etanercept (Enbrel)	TNF receptor antagonist	RA (including juvenile) and psoriatic arthritis	Blocks effects of TNF, a major inflammatory mediator in RA
leflunomide (Arava)	Antimetabolite	RA	Exerts antiinflammatory effects via inhibition of cellular DNA synthesis
levamisole (Ergamisol)	Immunostimulant, adjuvant	Dukes stage C colon cancer (given with fluorouracil)	Exact mechanism is unknown, but may enhance the therapeutic effects of fluorouracil and have its own immunostimulatory effects
mitoxantrone (Novantrone)	Anthracycline antibiotic (also an antineoplastic drug)	MS (secondary chronic type)	Inhibits cellular DNA synthesis, which reduces neurologic disability in MS (exact mechanism unclear)
pegademase bovine (Adagen)	Immunostimulant	SCID	Modified enzyme that compensates for deficiency of the enzyme adenosine deaminase, which is associated with SCID
thalidomide (Thalomid)	Immunostimulant	Erythremia nodosum*	Exact mechanism is unknown, but may have anti-TNF properties, which counter the disease process
tretinoin (Vesanoid)	Retinoid receptor agonist	Acute promyelocytic leukemia	Induces differentiation and maturation of leukemic cells, reducing proliferation of immature, disease-causing cells

BCG, Bacille Calmette-Guérin; *MS,* multiple sclerosis; *RA,* rheumatoid arthritis; *SCID,* severe combined immunodeficiency disease; *TNF,* tumor necrosis factor.
*An inflammatory reaction in the subcutaneous fat, often following a bacterial infection, or in reaction to drugs such as oral contraceptives or sulfonamides.

MISCELLANEOUS IMMUNOMODULATING DRUGS

In addition to the drugs in the major classes discussed thus far, there are several additional medications that can be broadly classified as miscellaneous immunomodulating drugs. They work by various specific and nonspecific mechanisms. A special term used for **immunostimulant** drugs that work by a nonspecific mechanism is **adjuvant.** These miscellaneous medications, including some that are classified as adjuvants, are listed in Table 47-4.

PATHOPHYSIOLOGY OVERVIEW

RHEUMATOID ARTHRITIS

Rheumatism is a general term for any of several disorders characterized by inflammation, degeneration, or metabolic derangement of connective tissue structures, especially joints and related structures such as muscles, tendons, bursae, fibrous tissue, and ligaments. Rheumatoid arthritis is a chronic **autoimmune disorder** that commonly causes inflammation and tissue damage in joints. It can also cause anemia and diffuse inflammation in the lungs, eyes, and pericardium of the heart, and subcutaneous nodules under the skin (Figure 47-3). It is a painful and oftentimes disabling disease. It is diagnosed primarily based on symptoms and the results of a blood test for rheumatoid factor. Symptoms include pain, stiffness, and reduced range of motion. Treatment encompasses both pharmacologic and nonpharmacologic modalities, including physical and occupational therapy. There is no known cure for rheumatoid arthritis, and the goal of therapy is to alleviate current symptoms and to prevent further damage of the joints. Rheumatoid arthritis affects over 2 million people in the United States and usually appears between the ages of 25 and 50. Women are two

FIGURE 47-3 Areas of the body affected by rheumatoid arthritis. Rheumatoid arthritis is most frequently seen in the shoulders, elbows, wrists, knees, and ankles, and it often affects the joints on both sides of the body equally.

to three times more likely than men to have rheumatoid arthritis. Smokers and those with a family history are also at risk. Osteoarthritis is another type of **arthritis** that tends to be an age-related degeneration of joint tissues resulting in pain and reduced function. This section focuses on rheumatoid arthritis.

Because rheumatoid arthritis is a disease characterized by inflammation, the nonsteroidal antiinflammatory drugs (NSAIDs) are the most commonly used (see Chapter 44). Full dosages of NSAIDs are tried in the early stages of rheumatoid arthritis. Corticosteroids, also potent antiinflammatory drugs (see Chapter 33), are also used to prevent inflammatory symptoms. These drugs, although they are effective in reducing inflammation, do not actually affect the disease itself. **Disease-modifying antirheumatic drugs (DMARDs)** not only provide antiinflammatory and analgesic effects, but they can arrest or slow the disease processes associated with arthritis.

PHARMACOLOGY OVERVIEW

DISEASE-MODIFYING ANTIRHEUMATIC ARTHRITIS DRUGS

DMARDs are drugs that modify the disease of rheumatoid arthritis. They exhibit antiinflammatory, antiarthritic, and immunomodulating effects and work by inhibiting the movement of various cells into an inflamed, damaged area, such as a joint. These cells (neutrophils, monocytes, and macrophages) are responsible for causing many of the deleterious effects of chronic rheumatoid arthritis. By preventing the accumulation of these inflammatory cells in the area of the diseased joint, antiarthritic drugs prevent progression of the disease. DMARDs often have a slow onset of action of several weeks, versus minutes to hours for NSAIDs. For this reason, DMARDs are sometimes also referred to as *slow-acting antirheumatic drugs (SAARDs)*. They were previously thought of as second-line drugs for the treatment of arthritis because they can have much more toxic adverse effects than do the NSAIDs. However, the American College of Rheumatology updated its treatment guidelines in 2008 and now recommends the use of DMARDs as first-line therapy in many patients. The guidelines differentiate the DMARDs into nonbiologic and biologic DMARDs. Nonbiologic DMARDs include methotrexate, leflunomide, hydroxychloroquine, and sulfasalazine. The guidelines recommend starting with methotrexate or leflunomide in most patients. Use of the other drugs, including the biologic DMARDs, is generally reserved for those patients who do not respond to methotrexate or leflunomide. The biologic DMARDs include adalimumab, anakinra, certolizumab, etanercept, golimumab, infliximab, adalimumab, abatacept, rituximab, and tocilizumab. Box 47-3 lists the DMARDs. Etanercept and abatacept are discussed in this section; the others were discussed in the section on monoclonal antibodies.

Mechanism of Action, Indications, and Adverse Effects

The mechanism of action and adverse effects of the different DMARDs vary. The individual drug profiles provide information on mechanism of action and adverse effects. All of these drugs are indicated for the treatment of rheumatoid arthritis, and some have other uses as previously mentioned.

BOX 47-3 DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

- abatacept
- adalimumab
- anakinra
- certolizumab
- etanercept
- golimumab
- infliximab
- leflunomide
- methotrexate
- rituximab
- tocilizumab
- hydroxychloroquine
- sulfasalazine

Contraindications

DMARDs are not used in patients with active bacterial infection, active herpes zoster, active or latent tuberculosis, or acute or chronic hepatitis B or C. Etanercept, infliximab, and adalimumab are not to be used in patients with heart failure, lymphoma, or multiple sclerosis. Methotrexate and leflunomide are to be avoided during pregnancy and lactation.

DRUG PROFILES

methotrexate

Methotrexate is an anticancer drug that is commonly used for treatment of rheumatoid arthritis in much lower dosages than those used for cancer. It is usually started at dosages of 7.5 to 10 mg/wk but can be increased to 25 mg/wk. It is very important to note that the drug is given once per week, not once per day. Serious medication errors, including deaths, have occurred when an order is mistranscribed and the drug is given daily instead of once a week. It is usually given orally for rheumatoid arthritis, but it can also be given by injection. Bone marrow suppression is the main adverse effect of methotrexate. Most patients are advised to take supplemental folic acid to lessen the likelihood of adverse effects. The onset of antirheumatic action is 3 to 6 weeks. The half-life of the drug is 3 to 10 hours.

leflunomide

Leflunomide (Arava) is indicated for the treatment of active rheumatoid arthritis. It modulates or alters the response of the immune system to rheumatoid arthritis. It has antiproliferative, antiinflammatory, and immunosuppressive activity. Most common adverse effects are diarrhea, respiratory tract infection, alopecia, elevated liver enzyme levels, and rash. It is contraindicated in women who are or may become pregnant and is not to be used by nursing mothers or those with a hypersensitivity to it. It is classified as a pregnancy category X drug. Aspirin, other NSAIDs, and/or low-dose corticosteroids may be continued during leflunomide therapy. Leflunomide is available only for oral use. The half-life is 14 to 15 days.

etanercept

Etanercept (Enbrel) is a recombinant DNA–derived TNF-blocking drug. It binds TNF and blocks its interaction with cell surface receptors. It is indicated for the treatment of

rheumatoid arthritis (including juvenile rheumatoid arthritis) and moderate to severe chronic plaque psoriasis. It is contraindicated in patients with a known hypersensitivity to it and in those with sepsis and active infections (including chronic or local infections). Use with caution in patients with preexisting demyelinating central nervous system disorders, heart failure, or significant hematologic abnormalities. Some dosage forms may contain latex, so screen patients for latex allergy. Reactivation of hepatitis and tuberculosis have been reported. Live vaccines should not be given with etanercept. Common adverse effects include headache, injection site reaction, upper respiratory tract infection, dizziness, and weakness. The drug is administered subcutaneously. Drugs with which it interacts include anakinra, which may increase the risk of infection, and cyclophosphamide, which may increase the risk of malignancy. Etanercept is classified as a pregnancy category B drug. It is not known if the drug is excreted in breast milk, and its use is not recommended in lactating women. The onset of action is 1 to 2 weeks, and the half-life is 72 to 132 hours.

abatacept

Abatacept (Orencia) is a selective costimulation modulator; it inhibits T-cell activation. Abatacept is indicated for the treatment of rheumatoid arthritis. It is contraindicated in patients with a known hypersensitivity to it or any of its components. Use with caution in patients with a history of recurrent infections or chronic obstructive pulmonary disease. Bring patients up to date with all current immunizations before starting abatacept therapy. Adverse effects include headache, upper respiratory tract infections, and hypertension. Abatacept may increase the risk of infections associated with live vaccines and may decrease the response to dead and/or live vaccines. Abatacept is not to be given with anakinra or TNF-blocking drugs because of the risk of serious infections, or with the herb echinacea, which has immunostimulant properties. Abatacept is dosed according to body weight and is given at 4-week intervals. It is administered intravenously, and a filter must be used. The half-life is 8 to 25 days.

NURSING PROCESS

ASSESSMENT

For *hematopoietic* drugs, assess the medication order thoroughly as well as the specific indication for each of the drugs prescribed. Once you understand the indication, specific laboratory value(s) may be easily determined for further assessment (e.g., WBC counts with sargramostin and filgrastim, and platelets with use of oprelvekin). After initial assessment and monitoring of baseline blood counts, measure drug response against these values. Additionally, prior to administering these medications, document baseline assessment of the following: vital signs, skin turgor/intactness, bowel sounds/bowel patterns, and breath sounds. Assess also for any complaints of pain and rate accordingly (see discussion in Chapter 10). These areas are all very important to assess when giving hematopoietic drugs because of the adverse effects of edema, nausea, vomiting, diarrhea, rash, cough, dyspnea, sore throat, fever, blood dyscrasias, headache, and bone pain. Assess potential intravenous and subcutaneous sites and, if appropriate, note chemotherapy-induced absolute neutrophil nadir (low point). This is important because timing of the dose is critical in helping to boost blood cell counts. For example, with filgrastim, do *not* give the drug within 24 hours before or after the chemotherapy. With use of filgrastim, assess for any existing joint or bone pain because of the possible adverse effect of mild to severe bone pain with filgrastim. Specific information regarding assessment associated with use of epoetin alfa is found in Chapter 54.

Before administering any of the *biologic response–modifying drugs* (and other drugs included in this chapter), assess your own knowledge about these medications with attention to the drug's action, pharmacokinetic properties, associated cautions, contraindications, drug interactions, adverse effects, and toxicities. Assess the patient for the presence of any conditions that represent contraindications or cautions to their administration as well as possible interacting drugs. Assess for hypersensitivity to the drug, egg proteins, or immunoglobulin G. Furthermore, assess the following systems: (1) respiratory system with attention to rate, rhythm, and depth as well as breath sounds, listening for any adventitious (abnormal) sounds; (2) cardiac system with attention to vital signs, heart sounds, heart rate and rhythm, and oxygen saturation levels, as well as assessment for edema and/or shortness of breath, presence of cyanotic discoloration around the mouth or nail beds, and any chest pain; (3) central nervous system with a focus on baseline mental status, as well as assessment for any seizure-like activity or central nervous system abnormalities; and (4) immune system, noting any history of chronic illnesses, ability to fight off infections, and history of suppressed immunity. Note nutritional status, height, and weight as well as results of any prescribed laboratory tests, such as complete blood count (CBC) and especially hemoglobin and hematocrit levels, serum protein and albumin levels, and immunoglobulin levels (see Nursing Process in Chapters 45 and 46). Also document the presence or absence of underlying diseases, symptoms, and success or failure of medication regimens in the past. Assess the patient's ability to carry out the activities of daily living, emotional and socioeconomic status, educational level, learning needs, desire and ability to learn, past coping strategies, and support systems.

Before *interferons* (e.g., interferon alfa-2a or alfa-2b; interferon gamma-1b) are given, assess the patient's history of drug allergies as well as any history of autoimmune disorders, hepatitis, liver failure, or AIDS. Contraindications include concurrent use of immunosuppressant drugs and Kaposi's sarcoma. Determine baseline WBC and platelets prior to initiation of therapy due to the potential of drug-induced neutropenia and thrombocytopenia. Monitor other serum laboratory values such as blood urea nitrogen, creatinine levels, and ALP and AST levels before and during treatment due to the risk of problems with renal and liver functioning. It is important to document baseline neurologic functioning, bowel status, heart sounds, pulse rate, and blood pressure (including postural readings). Significant drug interactions to assess for include those drugs that are metabolized via the cytochrome P-450 enzyme system

in the liver because of the risk of subsequent drug toxicity. Bone marrow suppression may be exacerbated when the interferon gamma products are given with other bone marrow suppressive drugs.

With the use of *monoclonal antibody drugs* (e.g., alemtuzumab, rituximab, trastuzumab), assess and document history of allergic reactions. Assess for ranges of responses with these medications including mild to severe reactions (see Table 47-3). Assessment of baseline vital signs and any signs of infection are important because of the risk of acquiring an infection when these drugs are given. Contraindications to their use include any active infectious process and HIV. With infliximab (Remicade), there is an FDA black box warning stating that fatal tuberculosis and/or fungal infections have been associated with use of this drug, so any infections process needs to be ruled out prior to its use. Trastuzumab has an FDA black box warning for cases of ventricular dysfunction and heart failure. Fatal hypersensitivity and infusion reactions have occurred with this drug, so prior to administration there must be very careful risk evaluation and subsequent prudent clinical judgment-making by the prescriber and you. Perform close monitoring and supervision before, during, and after the infusion of these drugs. Table 47-3 provides a listing of common adverse effects associated with these drugs requiring further areas and systems to be assessed.

With *interleukins,* assess for drug allergy as well as the contraindications of organ transplantation. Review results of various tests such as thallium cardiac stress tests and pulmonary function tests. Assess vital signs, and document any history of respiratory and/or cardiac disorders due to the severe toxicities of capillary leak syndrome with aldesleukin. As mentioned earlier in the chapter, capillary leak syndrome results in massive fluid retention of 20 to 30 pounds leading to potentially life-threatening problems of respiratory distress and heart failure. These are reversible after discontinuation of the interleukin therapy. Assess liver function studies prior to therapy. Drug interactions of significance include antihypertensives which produce additive hypotensive effects. Corticosteroid use is contraindicated because of a reduction in antitumor effectiveness. Tocilizumab is one interleukin drug that is indicated for severe rheumatoid arthritis and is not to be given with other biologic response modifiers.

With *DMARDs,* perform a close assessment of any past or present medical conditions as well a thorough assessment of allergies. Compile a complete and thorough medication profile, listing prescription drugs, herbals, and over-the-counter drugs. Assess the specific type of DMARD prescribed because there are nonbiologic and biologic DMARDS. Nonbiologic DMARDs include methotrexate, leflunomide, hydroxychoroquine, and sulfasalazine. Biologic DMARDs include several of the monoclonal antibodies already discussed. Assess for contraindications to the use of DMARDs such as active bacterial infections, active herpes, active/latent tuberculosis, and acute or chronic hepatitis B or C. Additional contraindications are presented in the pharmacology discussion. Because bone marrow suppression is one of the main adverse effects (e.g., with methotrexate), assess and monitor baseline blood cell and platelet counts before, during, and after therapy. Another important area for assessment is the medication order by the prescriber, because serious medication errors have occurred when the order for this drug has been transcribed incorrectly and the drug has been given daily instead of in the recommended once-weekly dosing.

Before initiation of therapy with leflunomide, perform a complete assessment of hepatic functioning as well as baseline blood cell counts. Because of the possible adverse effects of diarrhea and respiratory infections, assess respiratory and gastrointestinal functioning. A thorough respiratory assessment includes obtaining a history of past and present respiratory disorders and infections as well as noting breath sounds, presence of sputum, and baseline respiratory rate, rhythm, and depth. Assess bowel patterns and document findings. Etanercept is to be avoided in those with sepsis and active infections, so conduct a thorough assessment of WBC counts and for any signs and symptoms of infection or a history of infection. Because some dosage forms may contain latex, it is critical to also assess for latex allergy. The DMARD abatacept is given based on weight; thus, there is a need for an accurate, predrug therapy weight. Additionally, assess the patient's immunization record because all immunizations must be current prior to beginning therapy with abatacept. Document the findings of a baseline head-to-toe physical assessment, and note any musculoskeletal changes due to the pathology of arthritis and related changes in activities of daily living and other basic activities before drug therapy is initiated as well as throughout the therapeutic regimen.

TEAMWORK AND COLLABORATION: LEGAL AND ETHICAL PRINCIPLES

The Nurse and Patient Care

Never neglect or deceive a patient, even if a conflict arises with your own cultural, racial-ethnic, spiritual, or personal belief systems. Such a dilemma is often encountered in connection with various treatment modalities for cancer patients or patients needing drugs that alter the body's biologic response. You do have the right to refuse to participate in any treatment or aspect of a patient's care that violates personal ethical principles, but it is important to understand that this refusal of care can in *no* way involve desertion or neglect of the patient. In these situations, inform the appropriate supervisory personnel about the conflict, and transfer the patient to the safe care of another qualified professional. As detailed in the American Nurses Association *Code of Ethics for Nurses,* nurses are bound by the profession always to remain ethical in the provision of care to patients. This may include participation in the care of a patient who needs the nurse's care but who may be receiving treatment or care that is not "acceptable" by the nurse's own standards or ethics.

NURSING DIAGNOSES

1. Imbalanced nutrition, less than body requirements, related to the adverse effects of biologic response–modifying drugs
2. Impaired skin integrity (rash) related to the adverse effects of biologic response–modifying drugs
3. Risk for infection related to adverse effect of bone marrow suppression related to DMARDs and immunomodulating drugs

PLANNING

GOALS

1. Patient regains nutritional status to predrug or as near normal as possible.
2. Patient's skin and mucous membranes remain intact.
3. Patient remains free from infection and/or decreases the risk for infection during drug therapy.

OUTCOME CRITERIA

1. Patient describes nutritional needs and daily meal planning reflecting dietary needs, such as consumption of a high-calorie, low-residue, high-protein diet, high-energy foods from protein and complex carbohydrates, and forcing of fluids.
   - Patient performs a 24-hour recall of food intake to report a typical week's menus.
   - Patient understands the importance of consuming small, frequent meals in an environment conducive to eating as well as the use of MyPlate.
   - Patient states measures to minimize gastrointestinal adverse effects, such as eating small, frequent meals and avoiding spicy foods, and uses antiemetics as prescribed.
   - Patient understands the importance of energy consumption with frequent rest periods before and after meals while undergoing treatment.
2. Patient's skin and mucous membranes remain intact and clean with daily bathing, skin care with moisturizing products, and daily oral hygiene with gentle flossing as well as follow-up care with a dental professional.
   - Patient reports breaks in skin, redness, irritation, areas of swelling, drainage, or pain to prescriber.
   - Patient contacts prescriber and/or dental professional with complaints or problems of poor dentition, sores in the mouth, bleeding, and/or swelling of gums.
3. Patient states ways to minimize risk of infection such as proper diet, adequate fluid intake, and identifying early signs and symptoms of infection.
   - Patient understands needed food items (e.g., increase in protein), using MyPlate and advice of a nutritional consult to meet additional nutritional demands in prevention of malnourishment and in boosting nutritional status.
   - Patient knows to take temperature orally or via axillary route every 4 hours during periods of increased risk of infection.
   - Patient states need to report temperature elevations of 100.5° F (38.1° C) to the prescriber for appropriate and immediate treatment.

IMPLEMENTATION

Administer *biologic response–modifying drugs* exactly as prescribed and in keeping with manufacturer guidelines to minimize adverse effects. It is important to acknowledge that acquiring an infection is a serious adverse effect of these drugs and so the risk must always be weighed against the severity of the patient's underlying illness. Measure vital signs with special attention to temperature. Premedication with acetaminophen and diphenhydramine may be deemed necessary when any of the biologic response–modifying drugs are administered to help minimize any allergic type of reaction. With some of the biologic response–modifying drugs, treatment with opioids, antihistamines, and/or anti-inflammatory drugs may be required for the management of bone pain and chills if treatment with acetaminophen or diphenhydramine is not successful. Antiemetics may also be needed for any drug-related nausea or vomiting and may be administered prior to the administration of the biologic response–modifying drug. Antiemetics may need to be dosed around the clock if nausea and vomiting are problematic. Encourage the patient to rest when tired, not to overexert self during therapy, and to contact the prescriber if he or she experiences profound fatigue or loss of appetite. Encourage forcing fluids up to 3000 mL/day (unless contraindicated) to promote excretion of the by-products of cellular breakdown and maintain cellular hydration. Consultation with a dietitian or nutritionist may be helpful for the patient to learn about a nourishing diet to promote health and wellness (e.g., foods high in protein, complex carbohydrates, and necessary minerals, vitamins, and/or herbals). Discuss menu planning and grocery shopping with specific individualized suggestions. Nowadays, many grocery stores support internet food shopping with car pickup at the store on the same day or home delivery at no or minimal cost to the patient. Inform patients of community resources (e.g., Meals On Wheels, respite care organizations) as deemed appropriate and as needed.

With *hematopoietic drugs,* it is important to administer the drug as ordered. Determine and rotate subcutaneous and IV sites, as specified by facility policy. With filgrastim, administer the drug before a patient receiving myelosuppressive chemotherapy develops an infection, but not within 24 hours before or after a myelosuppressive chemotherapy drug is given. Once a patient's absolute neutrophil count (ANC) reaches 10,000 cells/mm^3, discontinue the drug, as ordered and as recommended by the manufacturer. Give filgrastim and use D_5W to dilute the product. With sargramostim, reconstitute the dose with sterile water for injection. Do not use oprelvekin if any discoloration or particulate matter is noted in the vial. Treatment may be ordered to begin within 6 to 24 hours after completion of antineoplastic therapy. Daily subcutaneous dosing for 14 days has been found to produce dose-dependent platelet elevations, with counts increasing within 5 to 9 days of starting injections. Once oprelvekin is discontinued, counts remain increased for about 7 days and return to baseline within 14 days. Subcutaneous sites for oprelvekin administration include the thigh, abdomen, hip, and upper arm. When drugs are given subcutaneously, rotate injection sites. See the Patient Teaching Tips for more information.

When *interferons* are given, be sure to first read the order for correct spelling and be careful not to confuse with any other sound-alike, look-alike drugs. Administer the interferons parenterally by

either the subcutaneous, intravenous, or intramuscular route, depending on the drug. For example, give interferon alfa-2a subcutaneously or intramuscularly. Be sure to rotate sites and use accurate technique (see Chapter 9). With concerns of infection, as with many of the biologic response–modifying drugs, monitor the patient's vital signs with attention to temperature and also for the occurrence of chills and headache. An ECG, before and during treatment, is generally prescribed, so monitor the results and report any chest pain, hypotension, hypertension, or dyspnea. Make sure to always check each brand of medication for the dilution directions as each brand has different directions. Read the package insert prior to giving these drugs. Acetaminophen may be prescribed to help with fever and headache. Encourage forcing of fluids.

With *monoclonals,* serious infections are a major concern. With belimumab, the most serious concern is infection, which may sometimes be fatal. Constantly monitor for infection during therapy. Certolizumab, which is used with severe Crohn's disease and severe rheumatoid arthritis, is also associated with the risk of serious infections and possible lymphoma, all of which need to be explained to the patient. Continue to monitor blood counts during and after therapy with these drugs. Monitor the patient for changes in blood pressure and pulse rate and for chest pain. Contact the prescriber immediately if there are significant changes in baseline parameters. Avoid infliximab in patients with severe heart failure. When giving this drug, it is important monitor the patient for heart sounds, blood pressure, pulse rate, pulse oximetry reading, and ECG. If there are signs and symptoms of infection and/or changes in cardiac status, contact the prescriber immediately.

With the the biologic DMARD methotrexate, a test dose is usually administered to see how the patient react to the medication. Be aware of the FDA black box warning about the cautious administration of this drug in those with renal disease, infection, pulmonary disease, and stomatitis. Be sure that if methotrexate is ordered for rheumatoid arthritis, it is administered weekly as ordered. For more information on methotrexate, see Chapter 45. Give etanercept, yet another drug with black box warnings (see the pharmacology discussion), subcutaneously into the thigh, abdomen, or upper arm, rotating injection sites. Give leflunomide very cautiously while monitoring liver and renal functioning; administer it orally with meals or food to minimize gastrointestinal upset. Monitor daily weights due to possible edema.

CASE STUDY

Hematopoietic Biologic Response Modifiers

P.S., a 38-year-old surveyor, is receiving a second round of chemotherapy as part of treatment for non-Hodgkin's lymphoma. The oncologist is monitoring for signs of bone marrow suppression of the various blood cell components.

1. What symptoms would the nurse expect to see if P.S. had diminished production of platelets? White blood cells? Explain your answers.

One week after this round of chemotherapy, P.S.'s white blood cell count is 0.8 cells/mm^3 (pretherapy value was 6200 cells/mm^3), and his absolute neutrophil count is 450 cells/mm^3 (pretherapy value was 1600 cells/mm^3). The oncologist orders strict neutropenic precautions and filgrastrim (Neupogen), 480 mcg, subcut daily.

2. Explain the purpose of the order for the filgrastim.The nurse will need to assess P.S. for what conditions before beginning the filgrastim?
3. The nurse notices a woman with a baby about to enter P.S.'s room. The baby is fussy, and the woman is wiping the baby's nose after the baby sneezed. What does the nurse need to do at this time?
4. P.S.. asks the nurse, "How long will I need to take these injections? I hate having to have another shot!" What is the answer to his question?

For answers, see http://evolve.elsevier.com/Lilley

EVALUATION

Therapeutic responses to *biologic response–modifying drugs* include a variety of responses, such as a decrease in the growth of the lesion or mass, decreased tumor size, and an easing of symptoms related to the tumor or disease process. Other therapeutic effects are an improvement in WBC and platelet counts and/or a return of blood counts to normal levels, and absence of infection and hemorrhage. Encourage patient journaling which may help provide health care providers with more data from which to evaluate the patient's response during and after therapy. Possible adverse effects for which to evaluate are presented in Tables 47-1 and 47-2. *DMARDs* are expected to have therapeutic results within a documented time frame (often weeks) with the patient experiencing increased ability to move joints, less discomfort, and an overall increased sense of improvement and well-being. Toxicity of these drugs may be manifested by liver, renal, and respiratory dysfunction and, for methotrexate, bone marrow suppression.

PATIENT TEACHING TIPS

- Advise the patient to avoid hazardous tasks because of the central nervous system changes noted with several biologic response–modifying drugs. Fatigue is also a common adverse effect; instruct the patient to report any excessive fatigue.
- Instruct the patient to report to the prescriber immediately any signs of infection, such as sore throat, diarrhea, vomiting, and/or fever of 100.5° F (38.1° C) or higher. Advise the patient also to report excessive fatigue, loss of appetite, edema, or bleeding.
- Pregnancy is discouraged while the patient is taking a biologic response–modifying drug. Educate patients of childbearing age about contraceptive choices and the need to use contraception for up to 2 years after completion of therapy.
- Inform the patient that adverse effects associated with biologic response–modifying drugs usually disappear within 72 to 96 hours after therapy is discontinued.

Continued

PATIENT TEACHING TIPS—cont'd

- Interleukins may be self-administered; therefore, teach the patient self-injection technique and proper disposal of equipment (e.g., needles, syringes). Provide the patient with corresponding written instructions. Encourage the daily keeping of a journal to record the site of injection and an overall rating of how the patient feels.
- Bone pain and flulike symptoms often occur with some of the biologic response–modifying drugs, and the use of non-opioid or, in some cases, opioid analgesics may be required. Some patients may find relief with acetaminophen or ibuprofen.
- With DMARDs, the patient will experience improved joint function and decreased pain. Encourage the patient to report any bleeding, excess fatigue, fever, or respiratory symptoms.

KEY POINTS

- Cancer treatment has traditionally involved surgery, radiation, and chemotherapy. Surgery and radiation are usually local or regional therapies. Chemotherapy is generally systemic, but it often does not completely eliminate all of the cancer cells in the body. Adjuvant therapy is frequently used to destroy undetected distant micrometastases.
- The humoral and cellular immune systems act together to recognize and destroy foreign particles and cells. The humoral immune system is composed of lymphocytes that are known as B cells until they are transformed into plasma cells when they come in contact with an antigen (foreign substance). The plasma cells then manufacture antibodies to that antigen.
- Biologic response–modifying drugs provide another treatment option for patients who have malignancies and/or those who are receiving chemotherapy and have a need to boost blood cell counts. Biologic response–modifying drugs include hematopoietics, interferons, interleukins, monoclonal antibodies, and DMARDs. Use of these drugs may augment, restore, or modify host defenses against the tumor.
- Nursing management associated with the administration of biologic response–modifying drugs focuses on the use of careful aseptic technique and other measures to prevent infection; proper nutrition; oral hygiene; monitoring of blood counts; and management of adverse effects, including joint/bone pain and flulike symptoms.
- Do not administer filgrastim and sargramostim within 24 hours of a myelosuppressive antineoplastic, and follow the timeframe for their use (as prescribed), whether in an inpatient or home setting.
- The recommend therapy with nonbiologic DMARDs usually begins with methotrexate or leflunomide for most patients. Biologic DMARDs are generally reserved for those patients whose disease does not respond to methotrexate or leflunomide. The biologic DMARDs include etanercept, infliximab, adalimumab, abatacept, and rituximab.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is conducting a class on drugs for malignant tumors for a group of new oncology staff members. Which best describes the action of interferons in the management of malignant tumors?
   - **a** Interferons increase the production of specific anticancer enzymes.
   - **b** Interferons have antiviral and antitumor properties and strengthen the immune system.
   - **c** Interferons stimulate the production and activation of T lymphocytes and cytotoxic T cells.
   - **d** Interferons help improve the cell-killing action of T cells because they are retrieved from healthy donors.

2 When planning care for a patient who is receiving interferon therapy, the nurse must keep in mind that the major dose-limiting factor is
   - **a** fatigue.
   - **b** bone marrow suppression.
   - **c** fever.
   - **d** nausea and vomiting.

3 The nurse is administering methotrexate as part of the treatment for rheumatoid arthritis and will monitor for which sign of bone marrow suppression?
   - **a** Edema
   - **b** Tinnitus
   - **c** Increased bleeding tendencies
   - **d** Tingling in the extremities

4 In caring for a patient receiving therapy with a myelosuppressive antineoplastic drug, the nurse notes an order to begin filgrastim after the chemotherapy is completed. Which statement correctly describes when the nurse will begin the filgrastim therapy?
   - **a** It can be started during the chemotherapy.
   - **b** It will begin immediately after the chemotherapy is completed.
   - **c** It will be initiated 24 hours after the chemotherapy is completed.
   - **d** It will not be started until at least 72 hours after the chemotherapy is completed.

NCLEX® EXAMINATION REVIEW QUESTIONS—cont'd

5 The nurse is monitoring a patient who has been receiving aldesleukin (IL-2) (Proleukin) for treatment of malignant melanoma. Which adverse effect, if noted on assessment, is of primary concern?
- **a** Chills
- **b** Fatigue
- **c** Headache
- **d** Fluid retention

6 The nurse is reviewing the medical history of a patient who is about to receive therapy with etanercept (Enbrel). Which conditions, if present, would be a contraindication or caution for therapy with this drug? (Select all that apply.)
- **a** Urinary tract infection
- **b** Psoriasis
- **c** Heart failure
- **d** Glaucoma
- **e** Latex allergy

7 A patient is to receive filgrastim (Neupogen) after therapy with carmustine and radiation therapy for treatment of a brain tumor. The patient weighs 132 pounds. The protocol that the oncologist has written states that the filgrastim will be dosed at 5 mcg/kg. Filgrastim comes in a 300-mcg/mL vial. What dose will the patient receive? How many milliliters will the patient be given?

1. b, 2. a, 3. c, 4. c, 5. d , 6. a, c, e, 7. 300 mcg; 1 mL

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the role of immunosuppressive therapy in organ transplantation and in the treatment of autoimmune diseases.
2 Discuss the mechanisms of action, contraindications, cautions, adverse effects, routes of administration, drug interactions, and toxicity of the most commonly used immunosuppressants.
3 Develop a nursing care plan that includes all phases of the nursing process for patients receiving immunosuppressants after organ transplantation or for the treatment of autoimmune disease.

DRUG PROFILES

♦ *Key drug*

KEY TERMS

Autoimmune diseases A large group of diseases characterized by the alteration of the function of the immune system so that the immune response is directed against normal tissue(s) of the body, which results in pathologic conditions. (p. 785)

Grafts The term used for transplanted tissues or organs. (p. 787)

Immune-mediated diseases A large group of diseases that result when the cells of the immune system react to a variety of situations, such as transplanted organ tissue or drug-altered cells. (p. 785)

Immunosuppressants Drugs that decrease or prevent an immune response. (p. 785)

Immunosuppressive therapy A drug treatment used to suppress the immune system. (p. 785)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY DISEASE OVERVIEW

IMMUNE SYSTEM

The purpose of the *immune system* is to distinguish self from nonself and to protect the body from foreign material (antigens). There are three layers of barriers to protect the body (Figure 48-1). There are two types of immunity: humoral immunity, which is mediated by B lymphocytes, and cellular immunity, which is mediated by T lymphocytes. This chapter focuses on drugs that suppress the T lymphocytes.

The immune system defends the body against invading pathogens, foreign antigens, and its own cells that become cancerous, or neoplastic. Besides performing this beneficial function, it can also attack itself and cause what are known as **autoimmune diseases** or **immune-mediated diseases.** The immune system also participates in hypersensitivity, or anaphylactic, reactions, which can be life-threatening. The rejection of kidney, liver, and heart (whole organ) transplants is directed by the immune system as well.

Drugs that decrease or prevent an immune response, and hence suppress the immune system, are known as **immunosuppressants.** Treatment with such drugs is referred to as **immunosuppressive therapy**. Immunosuppressants are used for many immune-related disorders, including rheumatoid arthritis, systemic lupus erythematosus, Crohn's disease, multiple sclerosis, myasthenia gravis, psoriasis, and others. Examples of these drugs include cyclophosphamide (see Chapter 46), glatiramer acetate, fingolimod, and many immunomodulators, which are discussed in Chapter 47. This chapter focuses on the drugs used in organ transplantation.

Transplantation is one of the most complex areas of modern medicine. Many different types of transplants are routinely done including, but not limited to, kidney, heart, liver, lung, pancreas, small bowel, bone marrow, and cornea transplantation. The primary concern with transplantation is rejection, which could necessitate the transplanted organ to be removed. Rejection occurs from an immune response targeted against the transplanted organ. Immunosuppressants are used to inhibit the immune system and prevent organ rejection. Transplant patients are on immunosuppressant therapy for their lifetime.

PHARMACOLOGY OVERVIEW

IMMUNOSUPPRESSANT DRUGS

Mechanism of Action and Drug Effects

All immunosuppressants have similar mechanisms of action in that they selectively suppress certain T-lymphocyte cell lines. By suppressing the T-lymphocyte cell lines, they prevent their involvement in the immune response. This results in a pharmacologically immunocompromised state similar to that in a cancer patient or in a patient with acquired immunodeficiency syndrome (AIDS). Each drug differs in the exact way in which it suppresses certain cell lines involved in an immune response. The major classes of immunosuppressant drugs used in preventing organ rejection include glucocorticoids, calcineurin inhibitors, antimetabolites, and biologics. Corticosteroids inhibit all stages of T-cell activation and are used for induction, maintenance immunosuppression, and acute rejection. Corticosteroids are discussed in depth in Chapter 33 and are not discussed further in this chapter. Calcineurin inhibitors (e.g., cyclosporine, tacrolimus, sirolimus) inhibit the phosphate required for interleukin 2 production. Siromilus does not inhibit calcineurin but instead inhibits mTOR, which ultimately inhibits interleukin 2 communication. Antimetabolites (e.g., azathioprine, mycophenolate) inhibit cell proliferation. Biologics (e.g., muromonab-CD3, basiliximab, daclizumab) inhibit cytotoxic T killer cell function. Table 48-1 gives the mechanisms of action and indications of the available immunosuppressant drugs.

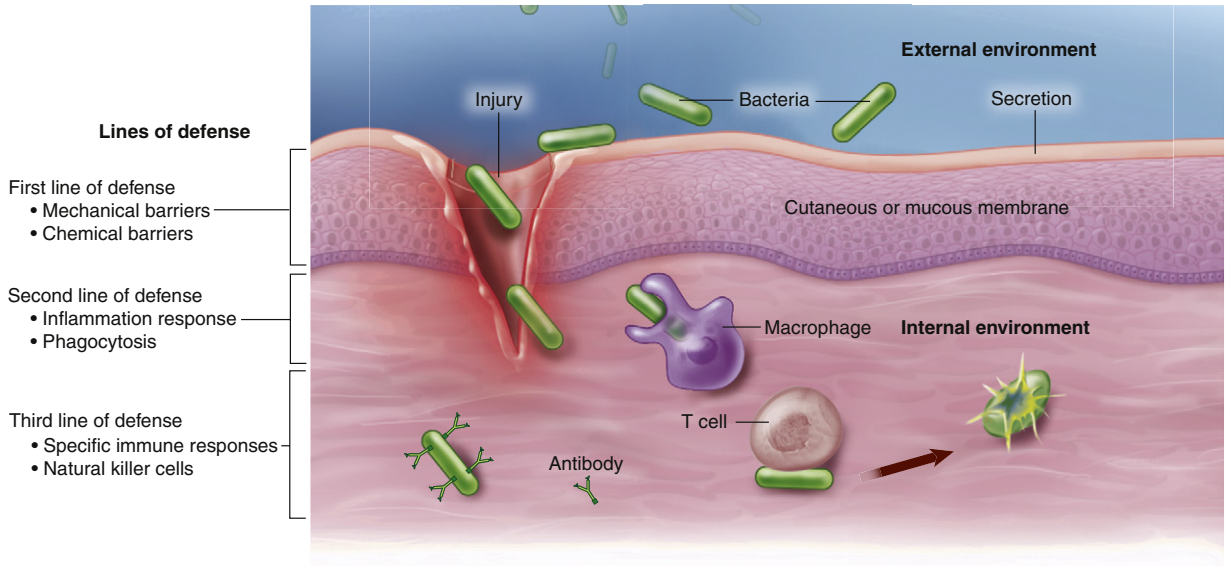

FIGURE 48-1 A simplified depiction of the complicated immune system. (From Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 7, St Louis, 2010, Mosby.)

TABLE 48-1 AVAILABLE IMMUNOSUPPRESSANT DRUGS: MECHANISMS OF ACTION AND INDICATIONS

DRUG NAME, YEAR OF FDA APPROVAL	MECHANISM OF ACTION	INDICATIONS/USES
azathioprine (Imuran), 1980	Blocks metabolism of purines, inhibiting the synthesis of T-cell DNA, RNA, and proteins and thereby blocking immune response	Prevention of organ rejection in kidney transplantation; treatment of rheumatoid arthritis
basiliximab* (Simulect), 1998	Suppresses T-cell activity by blocking the binding of the cytokine mediator IL-2 to a specific receptor	Prevention of organ rejection in kidney transplantation
cyclosporine (Sandimmune, Neoral, Gengraf), 1983	Inhibits activation of T cells by blocking the production and release of the cytokine mediator IL-2	Prevention of organ rejection in kidney, liver, and heart transplantation; treatment of rheumatoid arthritis and psoriasis. Unlabeled uses* include prevention of rejection in pancreas, bone marrow, and heart/lung transplantation.
daclizumab* (Zenapax), 1997	Suppresses T-cell activity by blocking the binding of the cytokine mediator IL-2 to a specific receptor	Prevention of organ rejection in kidney transplantation
fingolimod (Gilenya), 2010	Decreases the amount of lymphocytes available to the central nervous system.	Reduction of relapse frequency in patients with RRMS
glatiramer acetate (Copaxone), 1996	Precise mechanism unknown; believed to somehow modify immune system processes that are associated with MS symptoms	Reduction of relapse frequency in patients with RRMS
muromonab-CD3† (Orthoclone OKT3), 1986	Binds to CD3 glycoprotein on T-cell receptors, which blocks antigen recognition and reverses graft rejection that is already in progress	Treatment of acute organ rejection in kidney, liver, and heart transplantation
mycophenolate mofetil (CellCept), 1995	Prevents proliferation of T cells by inhibiting intracellular purine synthesis	Prevention of organ rejection in kidney, liver, and heart transplantation
sirolimus (Rapamune), 1999	Inhibits T-cell activation by binding to an intracellular protein known as FKBP-12 that subsequently prevents cellular proliferation	Prevention of organ rejection in kidney transplantation
tacrolimus (Prograf), 1994	Inhibits T-cell activation, possibly by binding to an intracellular protein known as FKBP-12	Prevention of organ rejection in liver, kidney, and heart transplantation. Unlabeled uses† include prevention of rejection in bone marrow, pancreas, pancreatic islet cell, and small intestine transplantation; treatment of autoimmune diseases; and severe psoriasis.

FDA, U.S. Food and Drug Administration; *FKBP-12,* FK-binding protein 12; *IL-2,* interleukin-2; *MS,* multiple sclerosis; *RRMS,* relapsing-remitting multiple sclerosis.
*Non–FDA-approved but under investigation.
†Note that "ab" in any drug name usually indicates that it is a monoclonal antibody synthesized using recombinant DNA technology.

Indications

The therapeutic uses of immunosuppressants vary from drug to drug, as noted in Table 48-1. They are primarily indicated for the prevention of organ rejection. Three of the immunosuppressants are indicated for both prevention of rejection and treatment of organ rejection; they include muromonab-CD3, mycophenolate, and tacrolimus. Fingolimod and glatiramer acetate are immunosuppressants that are indicated for reduction of the frequency of relapses (exacerbations) in a type of multiple sclerosis known as *relapsing-remitting multiple sclerosis.*

Contraindications

The main contraindication for all immunosuppressants is known drug allergy. Relative contraindications, depending on the patient's condition, may include renal or hepatic failure, hypertension, and concurrent radiation therapy. Pregnancy is not necessarily a contraindication to the use of these drugs, but immunosuppressants should be given to pregnant women only in clinically urgent situations.

Adverse Effects

Immunosuppressant drugs have many significant adverse effects, which are listed in Table 48-2. By virtue of their actions, immunosuppressants place patients at increased risk of opportunistic infections. Immunosuppressant drugs may also increase the risk of certain types of cancers, especially skin cancers. Other serious adverse effects are limited to the particular drug. For example, cyclosporine and tacrolimus can cause nephrotoxicity, and corticosteroids, cyclosporine, and tacrolimus can cause posttransplant diabetes mellitus. Patients taking immunosuppressant drugs need to avoid live vaccines.

Interactions

Because transplant patients are on immunosuppressant drugs for their lifetime and are often on combination therapy, they are at increased risk for drug interactions. Immunosuppressants have narrow therapeutic windows, and drug interactions can be significant. Drugs that cause increased levels of immunosuppressant drugs can cause toxicity, whereas drugs that reduce

TABLE 48-2 SELECTED IMMUNOSUPPRESSANT DRUGS: COMMON ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Azathioprine	
Hematologic	Leukopenia, thrombocytopenia
Hepatic	Hepatotoxicity
Cyclosporine	
Cardiovascular	Moderate hypertension in as many as 50% of patients
Central nervous	Neurotoxicity, including tremors, in 20% of patients
Hepatic	Hepatotoxicity with cholestasis and hyperbilirubinemia
Renal	Nephrotoxicity is common and dose limiting
Other	Posttransplant diabetes mellitus, gingival hyperplasia, and hirsutism
Muromonab-CD3	
Cardiovascular	Chest pain
Central nervous	Pyrexia (fever), chills, tremors
Gastrointestinal	Vomiting, nausea, diarrhea
Respiratory	Dyspnea, wheezing, pulmonary edema
Other	Flulike symptoms, fluid retention
Tacrolimus	
Central nervous	Agitation, anxiety, confusion, hallucinations, neuropathy
Renal	Albuminuria, dysuria, acute renal failure, renal tubular necrosis
Other	Posttransplant diabetes mellitus
Antibody Immunosuppressants (basiliximab, daclizumab, and muromonab-CD3)	
Multiple body systems	Cytokine release syndrome, which includes such immune-mediated symptoms as fever, dyspnea, tachycardia, sweating, chills, headache, nausea, vomiting, diarrhea, muscle and joint pain, and general malaise

immunosuppressant drug levels may lead to organ rejection. The major drug interactions with immunosuppressant drugs are listed in Table 48-3. Many of the immunosuppressant drugs are metabolized by the cytochrome P-450 enzyme system, thus drug interactions are common and can be significant. Grapefruit can inhibit metabolizing enzymes and thus can increase the activity of cyclosporine, tacrolimus, and sirolimus. Grapefruit juice may increase the bioavailability of cyclosporine by 20% to 200% and should be avoided. Foods that are high in potassium, such as bananas and tomatoes, can increase cyclosporine nephrotoxicity. Meals that have high fat content can increase sirolimus levels.

Because the antibodies basiliximab, daclizumab, and muromonab-CD3 are generally given in a relatively short single course of therapy, they have few recognized drug interactions. However, cases of encephalopathy have occurred in patients in whom the antiinflammatory drug indomethacin (see Chapter 44) was used concurrently with muromonab-CD3.

The potential for interactions between immunosuppressant drugs and herbal preparations also should not be overlooked. For example, the enzyme-inducing properties of St. John's wort have been demonstrated to reduce the therapeutic levels of cyclosporine and cause organ rejection. The immunostimulant properties of cat's claw and echinacea may be similarly undesirable in transplant recipients, because they have effects that are opposite those of the immunosuppressants.

Dosages

For dosage information on selected immunosuppressants, see the table on p. 789. Immunosuppressants must be taken exactly as directed and at the exact times and with the exact foods. Adherence to dosing schedules can be very difficult for patients because they are on multiple medications that must be taken at different times throughout the day. Patients should never stop taking their immunosuppressants without being told to do so by their transplant doctor. Cyclosporine and tacrolimus should not be taken at the same time. Sirolimus should be taken 4 hours after cyclosporine. If a dose is missed, it should be taken as soon as the patient remembers, unless it is close to the time the next dose is due; in this case, the patient must contact the transplant doctor.

DRUG PROFILES

♦ azathioprine

Azathioprine (Imuran) is a chemical analogue of the physiologic purines, such as adenine and guanine. It blocks T-cell proliferation by inhibiting purine synthesis, which in turn prevents synthesis of deoxyribonucleic acid (DNA). Azathioprine is used for prophylaxis of organ rejection concurrently with other immunosuppressant drugs, such as cyclosporine and corticosteroids. It is available in both oral and injectable forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2-4 days*	1-2 hr	5 hr	Unknown

*6 to 8 weeks for rheumatoid arthritis.

basiliximab and daclizumab

Basiliximab (Simulect) and daclizumab (Zenapax) are both monoclonal antibodies that work by inhibiting the binding of the cytokine mediator interleukin-2 (IL-2) to the high-affinity IL-2 receptor. These drugs are used to prevent rejection of transplanted kidneys (grafts) and are generally used as part of a multidrug immunosuppressive regimen that includes cyclosporine and corticosteroids. Both basiliximab and daclizumab have a tendency to cause the allergy-like reaction known as *cytokine release syndrome,* which can be severe and even involve anaphylaxis. Patients are often premedicated with corticosteroids (e.g., intravenous methylprednisolone) in an effort to avoid or alleviate this problem. Both basiliximab and daclizumab are available only in injectable form.

TABLE 48-3 IMMUNOSUPPRESSANT DRUGS: SELECTED DRUG INTERACTIONS

DRUG	MECHANISM	RESULT
Cyclosporine		
clarithromycin, fluconazole, amiodarone, Estrogens, verapamil, allopurinol, Protease inhibitors, HMG-CoA reductase inhibitors	Inhibit metabolism of cyclosporine	Increased levels of cyclosporine and toxicity
phenytoin, phenobarbital, carbamazepine, rifampin, St. John's wort	Induce metabolism of cyclosporine	Decreased levels of cyclosporine and reduced effect
NSAIDs	Inhibit synthesis of renal prostaglandin	Increased nephrotoxic effects of cyclosporine; renal failure
Grapefruit juice	Increases absorption of cyclosporine	Cyclosporine toxicity
Sirolimus		
cyclosporine	Unknown	Increased concentration of sirolimus
fluconazole, ketoconazole, clarithromycin, erythromycin, Protease inhibitors, verapamil, Grapefruit juice	Inhibit metabolism of sirolimus	Increased concentration and effect of sirolimus
rifampin, phenytoin, phenobarbital, carbamazepine, St. John's wort	Induce metabolism of sirolimus	Decreased concentration and effect of sirolimus
Tacrolimus		
amphotericin, gentamicin, tobramycin	Increase nephrotoxicity of tacrolimus	Renal failure
clarithromycin, fluconazole, ketoconazole, voriconazole, Protease inhibitors, verapamil, diltiazem, Grapefruit juice	Inhibit metabolism of tacrolimus	Increased effect of tacrolimus
rifampin, phenytoin, phenobarbital, carbamazepine, St. John's wort	Induce metabolism of tacrolimus	Decreased effect of tacrolimus
Mycophenolate Mofetil		
Antacids, Iron, cholestyramine	Reduce absorption of mycophenolate	Decreased effect of mycophenolate
Oral contraceptives	Mycophenolate decreases progesterone levels	Possible pregnancy
rifampin	Induces metabolism of mycophenolate	Decreased effect of mycophenolate
Azathioprine		
allopurinol	Decreases metabolism of azathioprine	Bone marrow suppression

NSAIDs, Nonsteroidal antiinflammatory drugs.

Pharmacokinetics (basiliximab)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	1 day	3-4 days	7-9 days	Unknown

Pharmacokinetics (daclizumab)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	1 day	3-5 days	20 days	Unknown

♦ cyclosporine

Cyclosporine (Sandimmune) and cyclosporine-modified (Neoral, Gengraf) are immunosuppressant drugs indicated for the prevention of organ rejection. They are classified as calcineurin inhibitors and work by inhibiting the production and release of IL-2. Like azathioprine, they may also be used for the treatment of other immunologic disorders, such as various forms of arthritis, psoriasis, and irritable bowel disease.

Cyclosporine is available in both oral and injectable forms. Neoral and Gengraf are brand names for cyclosporine-modified and were developed to improve absorption over Sandimmune (cyclosporine). Although these three products contain the same active ingredient (cyclosporine), they cannot be used interchangeably. The nurse must double-check the formulation before giving cyclosporine. Neoral, Gengraf, or generic cyclosporine-modified refer to interchangeable products; however, if the patient is prescribed the aforementioned, Sandimmune or generic cyclosporine must not used. If an error occurs in which product is administered, it is extremely important that the prescribing transplant physician be notified. When a change is made from Neoral or Gengraf to Sandimmune, the starting dose should be a 1:1 mg amount, but dosage adjustments may be necessary to compensate for the greater bioavailability of Neoral and Gengraf. It is recommended that cyclosporine blood concentration be monitored in patients changing from

DOSAGES

Selected Immunosuppressant Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
♦ azathioprine (Imuran) (D)	Antimetabolite	**Adult and pediatric** IV/PO: 2-5 mg/kg/day to start, then 1-3 mg/kg/day maintenance	Prevention of rejection of kidney transplants
basiliximab (Simulect) (B)	Monoclonal antibody	**Pediatric 2-15 yr, less than 35 kg** IV: 10 mg within 2 hr of transplant surgery, then 4 days afterward **Adult and pediatric 35 kg or more** Use 20-mg doses in same regimen	Prevention of rejection of kidney and liver transplants
♦ cyclosporine (Sandimmune, Neoral, Gengraf) (C)	Calcineurin inhibitor	**Adult and pediatric** PO: 15 mg/kg as a single dose 4-12 hr preoperatively; continue same dose daily postoperatively for 1-2 wk, then reduce by 5%/wk to a maintenance dose of 5-10 mg/kg/day IV: 5-6 mg/kg as a single dose 4-12 hr preoperatively and continued daily postoperatively until patient can be switched to PO dosing	Prevention of rejection of kidney, liver, and heart transplants
daclizumab (Zenapax) (C)	Monoclonal antibody	**Adult and pediatric** IV: Bolus injection of 1 mg/kg 24 hr preoperatively and for 4 additional postoperative doses, spaced 14 days apart	Prevention of rejection of kidney transplants
glatiramer acetate (Copaxone) (B)	Miscellaneous biologic	**Adult only** Subcut: 20 mg once daily	Treatment of RRMS
♦ muromonab-CD3 (Orthoclone OKT3) (C)	Monoclonal antibody	**Adult and pediatric** IV: 2.5-5 mg/day as a single bolus injection for 10-14 days (pediatric patients often started with 2.5 mg/day)	Treatment of active rejection of kidney transplants; treatment of active rejection of liver, heart, pancreas, and bone marrow transplants that are resistant to conventional treatment
mycophenolate mofetil (CellCept, Myfortic) (C)	Antimetabolite	**Adult** IV/PO: 1 g twice daily (delayed-release formulation) **Pediatric** IV/PO: 600 mg/m^2 twice daily (maximum daily dose: 400 mg or 720 mg twice daily)	Prevention of rejection of kidney, liver, or heart transplants; treatment of rejection of kidney transplants
sirolimus (Rapamune) (C)	mTOR kinase Inhibitor	**Adult and pediatric** IV/PO: 6-mg loading dose on day 1, followed by maintenance dose of 2 mg/day	Prevention of rejection of kidney transplants
tacrolimus (Prograf) (C)	Calcineurin inhibitor	**Adult and pediatric** IV: 0.03-0.05 mg/kg/day as continuous IV infusion; then PO: 0.1-0.2 mg/kg/day divided q12h	Prevention and treatment of rejection of liver, kidney, heart, lung, pancreas, and small bowel transplants

IV, Intravenous; *PO,* oral; *RRMS,* relapsing-remitting multiple sclerosis; *subcut,* subcutaneous.

one product to another. Cyclosporine has a narrow therapeutic range, and for this reason laboratory monitoring of drug levels may be used to ensure therapeutic plasma concentrations and to avoid toxicity.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1-3 hr	3.5 hr	1-2 hr (parent compound) 10-40 hr (metabolites)	Unknown

glatiramer acetate

Glatiramer acetate (Copaxone) is a mixture of random polymers of four different amino acids. This mixture results in a compound that is antigenically similar to myelin basic protein. This is a protein that is found on the myelin sheaths of nerves. The drug is believed to work by blocking T-cell autoimmune activity against this protein, which reduces the frequency of the neuromuscular exacerbations associated with multiple sclerosis. This drug is mixed in the sugar known as mannitol; therefore, it is contraindicated in patients who are allergic to that component. It is available only in injectable form.

A new drug, fingolimod (Gilenya), which actually failed as an antirejection drug, was approved in 2010 for multiple sclerosis. It is the only oral drug for relapsing forms of multiple sclerosis. It has significant adverse effects, including headache, hepatotoxicity, flulike symptoms, back pain, AV block, bradycardia, hypertension, and macular edema. For these reasons, the FDA requires a patient medication guide for all patients dispensed fingolimod.

♦ muromonab-CD3

Muromonab-CD3 (Orthoclone OKT3) is indicated for the reversal and prevention of graft rejection. It is a monoclonal antibody, synthesized using recombinant DNA technology, and it is very similar to the antibodies produced naturally by the body (immunoglobulins G, M, D, A, and E). It specifically targets the binding sites on the T cells that recognize foreign invaders, such as a transplanted organ. It differs from human antibodies in that it comes from mice. Other monoclonal antibodies used for the prevention of organ rejection are basiliximab and daclizumab. Muromonab-CD3, often called OKT3, is contraindicated in patients with hypersensitivity to murine products and in those who are experiencing fluid overload. Muromonab-CD3 can cause cytokine release syndrome, and patients are often pretreated with a corticosteroid as described previously for basiliximab and daclizumab. This drug is available only in injectable form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	Rapid	3 days	18 hr	Unknown

♦ mycophenolate mofetil

Mycophenolate (CellCept) is an antimetabolite and suppresses T cell proliferation. It is indicated for the prevention of organ rejection as well as the treatment of organ rejection. Mycophenolate has a black box warning from the FDA stating that it is associated with an increased risk of congenital malformations and spontaneous abortions when used during pregnancy. It is available in oral and intravenous forms. Common side effects include hypertension (28% to 77% incidence), hypotension, peripheral edema, tachycardia, pain, headache, hyperglycemia, hyperlipidemia, electrolyte disturbances, abdominal pain, leukopenia, thrombocytopenia, cough, and dyspnea.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	4 wk	0.8-1.8 hr	8-16 hr	Unknown

♦ sirolimus and tacrolimus

Sirolimus (Rapamune) is an immunosuppressant drug, similar in structure to tacrolimus (Prograf). Sirolimus is a macrocyclic immunosuppressive, antifungal, and antitumor drug, and tacrolimus is used to prevent rejection and to treat rejection once it occurs. Sirolimus works by inhibiting T-lymphocyte activation in response to antigenic stimulation and inhibits antibody production, which in turn suppresses cytokine-mediated T-cell proliferation. Sirolimus and tacrolimus are structurally related and act through similar mechanisms. Sirolimus is classified as an mTOR kinase inhibitor, whereas tacrolimus is classified as a calcineurin inhibitor. Sirolimus is available only for oral use, whereas tacrolimus is available in both oral and injectable forms. Sirolimus levels are increased when taken with high-fat meals.

Everolimus (Certican) originally was approved for the treatment of advanced renal cell carcinoma and recently has been approved for the prevention of rejection in kidney transplant. It is an analogue of sirolimus.

Pharmacokinetics (sirolimus)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Rapid	1-3 hr	60-80 hr	Unknown

Pharmacokinetics (tacrolimus)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Variable	0.5-4 hr	21-61 hr	Unknown

NURSING PROCESS

ASSESSMENT

Transplantation is indeed a very complex medical and ethical health care issue. With transplants, the primary concern (as previously discussed) is that of rejection and the possibility of subsequent removal of the transplanted organ. Therefore, immunosuppressants are used to inhibit the patient's immune system to help prevent rejection. It also means that patients are on drug therapy for their entire lifetime. Before administering any of the *immunosuppressants,* perform a thorough patient assessment with baseline measurements of vital signs and weight. Obtain a thorough history of past and present medical conditions, and document the following systems assessment information: (1) preexisting diseases that impact the patient's immune status, such as diabetes, hypertension, and cancer; (2) urinary functioning and patterns; (3) presence of jaundice, edema, and/or ascites; (4) history of cardiac disease and/or dysrhythmias, chest pain, or heart failure; (5) level of central nervous system functioning, with attention to any seizure disorders, alteration of motor or sensory function, paresthesias, or changing levels of consciousness; (6) respiratory status and baseline respiratory functioning, breath sounds, presence of asthma, pulmonary diseases, wheezing, cough, activity intolerance, dyspnea, or sputum production; (7) gastrointestinal (GI) functioning and patterns and bowel disease; (8) musculoskeletal intactness, with attention to ability to perform activities of daily living, range of motion, and appearance of joints and any deformities; and (9) presence and location of any inflammatory reactions as well as any pain, redness, and/or drainage. In addition, the following laboratory and diagnostic tests may be ordered: renal function tests with blood urea nitrogen (BUN) and creatinine levels; hepatic function tests with ALP, AST, ALT, and bilirubin levels; and

cardiovascular function with baseline electrocardiogram. See Table 48-2 for information on other systems affected by the *immunosuppressant drugs*. Assess for and document all cautions, contraindications, and drug interactions.

With azathioprine, assess white blood cell and platelet counts, noting any signs and symptoms of infection as well as any bleeding tendencies due to the potential for drug-related leukopenia and thrombocytopenia. Assess liver function prior to administering this drug. A significant drug interaction is with allopurinol. It important to assess for this interaction to avoid the resultant effect of bone marrow suppression. For cyclosporine, specifically assess the functional level of all organs as well as assess for any underlying cardiovascular, central nervous system, hepatic, and/or renal disease because of potential drug-related toxicities involving these systems and the physiologic impact of the organ transplant process on multiple systems. Perform a baseline oral assessment because of the possible adverse effect of drug-induced gingival hyperplasia. Assess and document baseline blood pressures because as many as 50% of patients on this drug suffer from subsequent moderate hypertension. Common drug interactions to assess for include estrogens, protease inhibitors, HMG-CoA reductase inhibitors, clarithromycin, phenytoin, phenobarbital, St. John's wort, NSAIDs, and grapefruit juice (see Table 48-3).

Muromonab-DC3 requires assessment for cardiovascular disorders as well as a history of GI and respiratory disorders. Assess baseline temperature as well as breath sounds and respiratory rate. Fluid retention may also occur, so baseline vital signs and weight are important to note and document.

With tacrolimus, obtain a thorough patient history with attention to medication use, and perform a physical assessment with close attention to renal functioning through monitoring of BUN, serum creatinine, and serum electrolyte levels. When the drug is administered, closely assess the patient for the first 30 minutes with the first dose of the medication. Concern for anaphylactic reaction also continues past this first 30 minutes and first dose. It is important to confirm that resuscitative equipment is accessible and functioning and that appropriate doses of epinephrine and oxygen are also readily available. Drug interactions to assess for are listed in Table 48-3. With basiliximab, daclizumab, and muromonab-CD3 (antibody immunosuppressants), complete a thorough documentation of baseline vital signs and other presenting complaints because of the possible occurrence of cytokine release syndrome with resultant fever, dyspnea, tachycardia, sweating, chills, vomiting, diarrhea, muscle/joint pain, and general malaise.

With the assessment phase, it is also important to be aware of the difference between cyclosporine-modified (Neoral, Gengraf) and cysclopsorine (Sandimmune). Neoral and Gengraf were modified to improve absorption over Sandimmune. If cylcosporine-modified drugs are prescribed, they cannot be interchangeably used with Sandimmune. The nurse must always double-check the medication order against the formulation on hand.

NURSING DIAGNOSES

1. Acute pain (e.g., joint and muscle aches and pain and flulike symptoms) related to adverse effects of immunosuppressant medications
2. Risk for injury related to the physiologic effects of the disease, overall weakness, and the adverse effects of immunosuppressants
3. Risk for infection related to altered immune status caused by chronic disease, treatment with immunosuppressants, and/or the transplantation process

PLANNING

GOALS

1. Patient experiences maximal comfort during drug therapy with immunosuppressants.
2. Patient remains free from injury.
3. Patient remains free from infection during therapy with immunosuppressants.

OUTCOME CRITERIA

1. Patient states measures to help maximize comfort and minimize unpleasant adverse effects of drug therapy, such as taking acetaminophen for fever and joint pain, reporting unusually high blood pressure readings, and engaging in relaxation therapy, massage, diversional activities, hypnosis, imagery, and biofeedback.
2. Patient states measures to decrease injury to self such as reporting to the prescriber the onset of fever, rash, sore throat, fatigue, or breaks in skin (rash, sores) or other unusual problems or symptoms that may develop during therapy.
3. Patient maintains immune system and prevents infection with healthy diet inclusive of an increase in caloric and protein intake, as deemed necessary by nutritional consult, during drug therapy.
   - Patient reports fever, chills, increased malaise, productive cough, lethargy, fatigue, and/or confusion.
   - Patient minimizes contact with large crowds and those individuals with known bacterial or viral infections while on immunosuppressive therapy.

IMPLEMENTATION

Oral *immunosuppressants* need to be taken with food to minimize GI upset. It is also important, because of the immunosuppressed state of patients receiving immunosuppressants, that oral forms of the drugs be used whenever possible to decrease the risk for infection associated with parenteral injections and subsequent injury to the first line of defense (skin). An oral antifungal medication may be ordered to treat the oral candidiasis that may occur as a consequence of the treatment and the disease process; however, significant drug interactions may occur between the immunosuppressant and the antifungal drug so always check for drug interactions. It is also important with the use of any of the immunosuppressants to be sure that supportive treatment equipment and related drugs

CASE STUDY

Cyclosporine

V., a 62-year-old retired orchestra teacher, moved to Florida after her husband died. Over the past few years she has developed renal problems and last year was told that she needed a kidney transplant. After a year of waiting and undergoing hemodialysis, she was told that her niece was a match and was willing to donate a kidney. She has had the transplant, and after 1 week, the transplant seems to be successful so far.

Cyclosporine is one of the immunosuppressants she will be receiving. She was given her first dose of cyclosporine 12 hours before surgery and is now receiving oral doses. The nurse has provided instructions on how to take the oral doses at home.

1. The next day, when another nurse comes in with V.'s morning medications, V. says, "You can't give me the medicine like that. Don't you know how to mix it?" What do you think the nurse did wrong?
2. What important measures will be taken to prevent toxicity?
3. V. tells the nurse that she can't wait to get home and relax by her pool. She is also looking forward to getting her strength back and going shopping with her girlfriends. How will the nurse respond to these statements?
4. After V. gets home, she calls the office to ask about eating grapefruit. "The pill bottle says no grapefruit, but I thought the doctor said I could have a little bit. I have a wonderful grapefruit tree in my backyard, and I love fresh grapefruit juice. What should I do?" What is the nurse's best answer?

For answers, see http://evolve.elsevier.com/Lilley.

are available in case of an anaphylactic or allergic reaction. Be aware of the high risk for such an occurrence, and be constantly prepared. The use of premedication protocols involving various antihistamines and/or antiinflammatory drugs is also common.

Cyclosporine is available in both oral and injectable formulations. As noted previously, Neoral and Gengraf are cyclorpsorine-modified and are not to be used interchangeably with Sandimmune (cyclosporine) which is unmodified. If an error occurs, the prescribing physician must be notified immediately. Do not refrigerate these oral solutions. To safely administer oral liquid dosage forms, use a calibrated liquid measuring device. Oral solutions may be mixed in a glass container with chocolate milk, milk, or orange juice and served at room temperature. Once the solution is mixed, make sure the patient drinks it immediately. Avoid Styrofoam containers or cups because the drug has been found to adhere to the inside wall of such containers. If the prescriber orders a change to be made from Neoral or Gengraf to Sandimmune, there is a dosage adjustment that may be needed (see pharmacology discussion). With intravenous administered cyclosporine, the dose must be diluted as recommended by the manufacturer and given according to standards of care and institutional policy. Cyclosporine is usually diluted with normal saline or 5% dextrose in water and infused using an intravenous infusion pump. Always infuse over the recommended period. Monitor the patient very closely during the infusion, especially during the first 30 minutes, for any allergic reactions manifested by facial flushing, urticaria, wheezing, dyspnea, and rash. Record vital signs frequently and document. It is also important to closely monitor the patient's levels of BUN, LDH, AST, and ALT during therapy, as ordered, to detect possible renal and hepatic impairment. Oral hygiene may be performed frequently to prevent dry mouth and subsequent infections. The prescriber will also order blood tests to confirm therapeutic serum levels of cyclosporine. These serum drug levels must be closely monitored. Intravenously administered muromonab-CD3 is usually infused over 1 minute. When the dose is prepared, withdraw the medication from the ampule through a low protein-binding 0.22-micron filter, detach the filter, and apply a new sterile needle after withdrawing the medication. Follow the premedication protocol to help minimize reactions. Basiliximab and daclizumab are administered parenterally. Follow manufacturer guidelines regarding the type and amount of dilutional solution. Closely monitor the intravenous drip. Using an intravenous infusion pump may help to ensure that the proper dose is administered.

Sirolimus and tacrolimus need to be administered as ordered by either the intravenous or oral route. If intravenous tacrolimus is to be discontinued and maintenance dosing needed, oral tacrolimus is usually ordered to be given 8 to 12 hours after the discontinuation of the intravenous drug. Do not store intravenous solution in polyvinyl chloride containers. It must be administered in an appropriately designed container and tubing. Oral doses of tacrolimus are given on an empty stomach. As with cyclosporine, the oral dosage forms of tacrolimus are not to be put in Styrofoam cups/containers. Inform the patient to avoid the consumption of grapefruit within 2 hours of taking the drug. Both sirolimus and tacrolimus have long half-lives, so toxicity is an added concern because of possible cumulative effects.

Because immunosuppressant therapy is lifelong, it is important for the patient to receive adequate and appropriate emotional, spiritual, social, and financial support. Additionally, there are other specifics of therapy that must be emphasized with patients, family members, and significant others, such as the need to always have a 1-week supply of medication available so that there is never a risk of running out. There also needs to be discussion about the estimated cost of medication to all involved. Drug regimens are expensive and lifelong, and, as such, constant monitoring of drug serum levels is required. Complexity of dosing must be explained clearly and thoroughly.

Ethical dilemmas are also of a complex nature. Organ transplantation raises a number of complex bioethical issues, including definition of death, consents for transplantation, and payment for transplanted organs. Additionally, transplantation tourism and the broader socioeconomic context in which organ harvesting or transplantation may occur are of concern. Organ trafficking is another bioethical issue. More information about the many ethical concerns associated with transplantation is provided by the World Health Organization and the Universal Declaration of Human Rights. Even within developed countries, there is concern that enthusiasm for increasing the supply of organs may adversely and negatively impact the respect for the right to life.

EVALUATION

Continually evaluate and reevaluate patient goals and outcome criteria related to the nursing process and administration of *immunosuppressants.* In addition, evaluate therapeutic responses to immunosuppressants, including acceptance of the transplanted organ or graft and improved symptoms in those with autoimmune disorders. Complete blood count; erythrocyte sedimentation rate; C-reactive protein level; liver, kidney, and cardiac function tests; pulmonary function tests; chest radiography; and analysis of T-lymphocyte surface phenotype are a few of the tests performed to evaluate patients during and after drug therapy. Continually evaluate for drug-specific adverse effects and toxicity (see Table 48-2).

PATIENT TEACHING TIPS

- Educate transplant patients on the need for life-long immunosuppressant therapy with often complex therapeutic regimens.
- Emphasize the importance of avoiding situations that pose an increased risk of exposure to infection, such as being in crowds, malls, or movie theaters.
- Stress the importance of reporting any fever, sore throat, chills, joint pain, or fatigue to the prescriber, as these may indicate infection and require immediate medical attention.
- Educate female patients of childbearing age who are receiving immunosuppressants about the need to use some form of contraception during treatment and for up to 12 weeks after therapy ends.
- Advise patients to take the drug at the same time every day (as with most immunosuppressants) and, if a dose is omitted, to contact the prescriber for further instructions.
- Follow-up appointments are important because of the need to monitor the patient's status through examinations and blood testing.
- Educate patients about the adverse effects of cyclosporine (e.g., headache, tremor), and inform patients to avoid consumption of grapefruit or grapefruit juice because of the potential for an increase in the blood concentration of cyclosporine.
- Inform patients that gelcaps are to be stored in a cool, dry environment and must not be exposed to light. The dosage form must be kept in its original packaging. Also, instruct patients to avoid prolonged exposure to the sun and encourage them to use sunscreen and wear protective clothing when outdoors.
- Inform patients who are to undergo transplant surgery and are receiving cyclosporine about the fact that several days before surgery they may be told to take the cyclosporine with corticosteroids. They may also be given an oral antifungal as prophylaxis for *Candida* infections.
- Encourage patient to inspect the oral cavity frequently for any white patches on the tongue, mucous membranes, and/or oral pharynx. These patches may indicate oral candidiasis.
- Advise patients taking oral forms of cyclosporine to take the medication with meals or mixed with milk to minimize GI upset.
- Inform patients taking azathioprine or muromonab-CD3 that several days before transplant surgery they are to take all of their medication by the oral route if possible and avoid trauma and subcutaneous and intramuscular injections, which increase the risk for infection.
- Provide patients on tacrolimus a list of foods, especially those high in fats and carbohydrates, so that the absorption of the medication will not be negatively impacted. Nutritional counseling would be extremely beneficial in understanding food interactions as well as any concerns related to hyperlipidemia and increased triglycerides associated with many of the immunosuppressive drugs.
- All immunosuppressants taken at home are to be taken exactly as ordered and at the same time every day. Educate patients about the adverse effects of the medication. Instruct them to report problems of particular concern, such as fever, chest pain, dizziness, headache, problems with urination, rash, and respiratory and/or other infections.

KEY POINTS

- Immunosuppressants decrease or prevent the body's immune response.
- Some of the clinical uses for immunosuppressants are suppression of immune-mediated disorders, malignancies, and improvement of short-term and long-term allograft survival.
- Oral antifungals are generally given with immunosuppressant medications to treat the oral candidiasis that occurs as a result of immunosuppression and fungal overgrowth.
- Monitor the results of prescriber-ordered laboratory studies such as hemoglobin level, hematocrit, and red blood cell, white blood cell, and platelet counts. If the values drop below normal ranges, notify the prescriber.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A patient has a new order for glatiramer acetate. The patient has not had an organ transplant. The nurse knows that the patient is receiving this drug for which condition?
- **a** Psoriasis
- **b** Rheumatoid arthritis
- **c** Irritable bowel syndrome
- **d** Relapse-remitting multiple sclerosis

2 While assessing a patient who is to receive muromonab-CD3, the nurse knows that which condition would be a contraindication for this drug?
- **a** Acute myalgia
- **b** Fluid overload
- **c** Polycythemia
- **d** Diabetes mellitus

3 During therapy with azathioprine (Imuran), the nurse must monitor for which common adverse effect?
- **a** Bradycardia
- **b** Diarrhea
- **c** Vomiting
- **d** Thrombocytopenia

4 During a teaching session for a patient receiving an immunosuppressant drug, the nurse will include which statement?
- **a** "It is better to use oral forms of these drugs to prevent the occurrence of thrush."
- **b** "You will remain on antibiotics to prevent infections."
- **c** "It is important to use some form of contraception during treatment and for up to 12 weeks after the end of therapy."
- **d** "Be sure to take your medications with grapefruit juice to increase absorption."

5 During drug therapy with basiliximab, the nurse monitors for signs of cytokine release syndrome, which results in
- **a** fever, dyspnea, and general malaise.
- **b** neurotoxicity and peripheral neuropathy.
- **c** hepatotoxicity with jaundice.
- **d** thrombocytopenia with increased bleeding tendencies.

6 When assessing a patient who is to begin therapy with an immunosuppressant drug, the nurse recognizes that such drugs should be used cautiously in patients with which condition(s)? (Select all that apply.)
- **a** Pregnancy
- **b** Glaucoma
- **c** Anemia
- **d** Myalgia
- **e** Renal dysfunction
- **f** Hepatic dysfunction

7 The order reads: "Give tacrolimus IV 0.03 mg/kg/day as a continuous IV infusion." The patient weighs 110 lb. How many milligrams per day will this dose provide?

1. d, 2. b, 3. d, 4. c, 5. a, 6. a, d, f, 7. 1.5 mg/day

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the importance of immunity as it relates to the various immunizing drugs and their use in patients of all ages.
2 Identify the diseases that are treated or prevented with toxoids or vaccines.
3 Compare the mechanisms of action, indications, cautions, contraindications, adverse effects, toxicity, drug interactions, and routes of administration of various toxoids and vaccines.
4 Develop a nursing care plan that includes all phases of the nursing process related to the administration of immunizing drugs across the life span.
5 Develop a nursing care plan covering aspects of the nursing process related to bioterrorism, with emphasis on the nurse's role.

DRUG PROFILES

- ♦ **diphtheria and tetanus toxoids and acellular pertussis vaccine tetanus (adsorbed), p. 803**
  ***Haemophilus influenzae* type b conjugate vaccine, p. 804**
- ♦ **hepatitis B immunoglobulin, p. 806**
- ♦ **hepatitis B virus vaccine (inactivated), p. 804**
  herpes zoster vaccine, p. 806
  human papillomavirus vaccine, p. 806
- ♦ **immunoglobulin, p. 806**
- ♦ **influenza virus vaccine, p. 804**
- ♦ **measles, mumps, and rubella virus vaccine (live), p. 805**
- ♦ **meningococcal vaccine, p. 805**
- ♦ **pneumococcal vaccine, polyvalent and thirteen valent, p. 805**
- ♦ **poliovirus vaccine (inactivated), p. 805**
  rabies immunoglobulin, p. 807
  rabies virus vaccine, p. 805
  Rh_0(D) immunoglobulin, p. 807
  tetanus immunoglobulin, p. 807
- ♦ **varicella virus vaccine, p. 806**
  varicella-zoster immunoglobulin, p. 807

♦ *Key drug*

KEY TERMS

Active immunization A type of immunization that causes development of a complete and long-lasting immunity to a certain infection through exposure of the body to the associated disease antigen; it can be natural active immunization (i.e., having the disease) or artificial active immunization (i.e., receiving a vaccine or toxoid). (p. 797)

Active immunizing drugs Toxoids or vaccines that are administered to a host to stimulate host production of antibodies. (p. 799)

Antibodies Immunoglobulin molecules that have an antigen-specific amino acid sequence and are synthesized by the humoral immune system (B cells) in response to exposure

KEY TERMS—cont'd

to a specific antigen. Their purpose is to attack and destroy molecules of this antigen. (p. 797)

Antibody titer The amount of an antibody needed to react with and neutralize a given volume or amount of a specific antigen. (p. 799)

Antigens Substances, usually proteins and foreign to a host, that stimulate the production of antibodies and that react specifically with those antibodies. Examples of antigens include bacterial exotoxins and viruses. An allergen (e.g., dust, pollen, mold) is an antigen that can produce an immediate-type hypersensitivity reaction or allergy. (p. 797)

Antiserum A serum that contains antibodies. It is usually obtained from an animal that has been immunized against a specific antigen. (p. 799)

Antitoxin An antiserum against a toxin (or toxoid). It is most often a purified antiserum obtained from animals (usually horses) by injection of a toxin or toxoid so that antibodies to the toxin (i.e., antitoxin) can be collected from the animals and used to provide artificial passive immunity to humans exposed to a given toxin (e.g., tetanus immunoglobulin). (p. 799)

Antivenin An antiserum against a venom (poison produced by an animal) used to treat humans or other animals that have been envenomed (e.g., by snakebite, spider bite, or scorpion sting). (p. 799)

Biologic antimicrobial drugs Substances of biologic origin used to prevent, treat, or cure infectious diseases (e.g., vaccines, toxoids, immunoglobulins). These drugs are often simply referred to as *biologics*. However, *biologics* also refers to drugs of bioterrorism (e.g., anthrax spores, smallpox virus), depending on the context. (p. 797)

Bioterrorism The use of infectious biologic or chemical agents as weapons for human destruction. (p. 807)

Booster shot A repeat dose of an antigen, such as a vaccine or toxoid, which is usually administered in an amount smaller than that used in the original immunization. It is given to maintain the immune response of a previously immunized patient at, or return the response to, a clinically effective level. (p. 799)

Cell-mediated immune system The immune response that is mediated by T cells (as opposed to B cells, which produce antibodies). T cells mount their immune response through activities such as the release of cytokines (chemicals that stimulate other protective immune functions) as well as through direct cytotoxicity (e.g., phagocytosis of an antigen). (p. 799)

Herd immunity Resistance to a disease on the part of an entire community or population because a large proportion of its members are immune to the disease. (p. 800)

Immune response A cascade of biochemical events that occurs in response to entry of an antigen (foreign substance) into the body; key processes of the immune response include phagocytosis ("eating of cells") of foreign microorganisms and synthesis of antibodies that react with specific antigens to inactivate them. Immune response centers around the blood but may also involve the lymphatic system and the *reticuloendothelial system* (see later). (p. 797)

Immunization The induction of immunity by administration of a vaccine or toxoid (active immunization) or antiserum (passive immunization). (p. 797)

Immunizing biologics Toxoids, vaccines, or immunoglobulins that are targeted against specific infectious microorganisms or toxins. (p. 797)

Immunoglobulins Glycoproteins synthesized and used by the humoral immune system (B cells) to attack and kill all substances foreign to the body. The term is synonymous with *immune globulins*. (p. 797)

Passive immunization A type of immunization in which immunity to infection occurs by injecting a person with antiserum or concentrated antibodies that directly give the host the means to fight off an invading microorganism (artificial passive immunization). The host's immune system therefore does not have to manufacture these antibodies. This process also occurs when antibodies pass from mother to infant during breastfeeding or through the placenta during pregnancy (natural passive immunization). (p. 797)

Passive immunizing drugs Drugs containing antibodies or antitoxins that can kill or inactivate pathogens by binding to the associated antigens. These are directly injected into a person (host) and provide that person with the means to fend off infection, bypassing the host's own immune system. (p. 798)

Recombinant Relating to or containing a combination of genetic material from two or more organisms. Such genetic recombination is one of the key methods of biotechnology and is often used to manufacture immunizing drugs and various other medications. (p. 799)

Reticuloendothelial system Specialized cells located in the liver, spleen, lymphatics, and bone marrow that remove miscellaneous particles from the circulation, such as aging antibody molecules. (p. 800)

Toxin Any poison produced by a plant, animal, or microorganism that is highly toxic to other living organisms. (p. 798)

Toxoids Bacterial exotoxins that are modified or inactivated (by chemicals or heat) so that they are no longer toxic but can still bind to host B cells to stimulate the formation of antitoxin; toxoids are often used in the same manner as vaccines to promote artificial active immunity in humans. They are one type of active immunizing drug (e.g., tetanus toxoid). (p. 797)

Vaccines Suspensions of live, attenuated, or killed microorganisms that can promote an artificially induced active immunity against a particular microorganism. They are another type of active immunizing drug (e.g., tetanus vaccine). (p. 798)

Venom A poison that is secreted by an animal (e.g., snake, insect, or spider). (p. 799)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

IMMUNITY AND IMMUNIZATION

Centuries ago it was noticed that people who contracted certain diseases acquired an immune tolerance to the disease so that, when exposed to it again, they did not experience a second bout of illness. This basic observation prompted scientists to investigate ways of artificially producing this tolerance. Along with this came an understanding of how the normal immune system functions, which is important to an understanding of how immunizing drugs work. Briefly, when the body first comes into contact with **antigens** (foreign proteins) from an invading organism, specific information is imprinted into a cellular "memory bank" of the immune system. The body can then effectively fight any future invasion by that same organism by mounting an **immune response.** This cellular memory bank consists of specialized immune cells known as *memory cells.* When an antigen presents itself to a person's humoral immune system (B cells, or B lymphocytes) by binding to B cells, the B cells differentiate into two other types of cells. One type is the memory cells. The second type is plasma cells, which produce large volumes of antibodies against the antigen in question. **Antibodies** are immunoglobulin molecules that have antigen-specific amino acid sequences. **Immunoglobulins,** or immune globulins, are glycoprotein molecules synthesized by the humoral immune system for the purpose of destroying all substances that the body recognizes as foreign. Immunoglobulins can be general or specific. A general immunoglobulin lacks a specific amino acid sequence that allows it to recognize a specific antigen. An immunoglobulin with such a specific amino acid sequence is known as an *antibody.* It is because of this process that people rarely suffer twice from certain diseases such as mumps, chickenpox, and measles. Instead they have a complete and long-lasting immunity to those infections.

In contrast to the humoral immune system, which is the focus of this chapter, the **cell-mediated immune system** is the branch of the immune system that does not synthesize antibodies. Instead, it is driven by T cells (T lymphocytes) and works by the release of cytokines (chemicals that promote other immune system functions, e.g., inflammatory responses, runny nose) and by phagocytosis (engulfing and destruction of the antigens by the T cells). The cell-mediated immune system is discussed in Chapter 47, because it is the target of immunosuppressant drugs. To varying degrees, these two immune system branches work simultaneously or even interdependently. The humoral immune system is also activated and/or driven partly by cytokines from the cell-mediated immune system.

There are two ways of obtaining immunity to certain infections: **active immunization** and **passive immunization.** Each can be an artificial or natural process. In artificial active immunization, the body is clinically exposed to a relatively harmless form of an antigen that does not cause an actual infection. Information about the antigen is then imprinted into the memory of the immune system and the body's defenses are stimulated to resist any subsequent exposure (by producing antibodies). In contrast, natural active immunization occurs when a person acquires immunity by surviving the disease itself and producing antibodies to the disease-causing organism. Artificial passive immunization involves administration of serum or concentrated immunoglobulins. This directly gives the inoculated person the substance needed to fight off the invading microorganism. This type of **immunization** bypasses the host's immune system. Finally, natural passive immunization occurs when antibodies are transferred from the mother to her infant in breast milk or through the bloodstream via the placenta during pregnancy. The major differences between active and passive immunization are summarized in Table 49-1 and are discussed in greater depth in the following sections.

Active Immunization

In general, **biologic antimicrobial drugs** (also referred to simply as *biologics*) are substances such as antitoxins, antisera, toxoids, and vaccines that are used to prevent, treat, or cure infectious diseases. Toxoids and vaccines are known as **immunizing biologics,** and they target a particular infectious microorganism.

Toxoids

Toxoids are substances that contain antigens, most often in the form of bacterial (usually gram-positive bacterial) exotoxins.

TABLE 49-1 ACTIVE VERSUS PASSIVE IMMUNIZATION

CHARACTERISTIC	ACTIVE	PASSIVE
Artificial		
Type of immunizing drug	Toxoid or vaccine	Immunoglobulin or antitoxin
Mechanism of action	Results from an antigen-antibody response similar to that after antigen exposure in the natural disease process	Results from direct administration of exogenous antibodies; antibody concentration will decrease over time, so if reexposure is expected, it is wise to continue passive immunizations.
Use	To prevent development of active disease in the event of exposure to a given antigen in individuals who have at least a partially functioning immune system	To provide temporary protection against disease in individuals who are immunodeficient, those for whom active immunization is contraindicated, and those who have been exposed to or anticipate exposure to the organism or toxin; an antibody response is not stimulated in the host.
Natural		
Mechanism of action	Production of one's own antibodies during actual infection	Transmission of antibodies from mother to infant through placenta or during breastfeeding

These substances have been detoxified or weakened (attenuated) with chemicals or heat, which renders them nontoxic and unable to revert back to a toxic form. Nonetheless, they remain highly antigenic and can stimulate an artificial active immune response (production of antitoxin antibodies) when injected into a host patient. These antibodies can then neutralize the same exotoxin upon any future exposure. Toxoids were first developed in 1923 at the Pasteur Institute by Gaston Ramon and his associates, and modern versions are effective against diseases such as diphtheria and tetanus caused by **toxin**-producing bacteria.

Vaccines

Vaccines are suspensions of live, attenuated (weakened), or killed (inactivated) microorganisms that can stimulate production of antibodies against the particular organism. As with toxoids, these slight alterations in the bacteria and viruses prevent the person injected from contracting the disease. They are still able to promote active immunization against the organism, including an antibody response. People vaccinated with live bacteria or viruses (as well as those who recover from an actual infection) enjoy lifelong immunity against that particular disease. However, only partial immunity is conferred on those vaccinated with killed bacteria or viruses, and for this reason they must be given periodic booster shots to maintain immune system protection against infection with the given organism.

Edward Jenner, an English physician born in 1749, noticed that milkmaids who had contracted cowpox infections were rarely victims of smallpox and was the first to study the relationship of cowpox to smallpox immunity. His observation led to the development of the smallpox vaccine. In 1796, Jenner successfully immunized a young boy against smallpox by vaccinating him with cowpox virus obtained from a cowpox vesicle on an infected cow. With the help of the modern version of this vaccine, smallpox was considered to be eradicated as of 1980. However, following the terrorist attacks in the United States on September 11, 2001, fears arose of a large-scale bioterrorism attack using the smallpox virus. By 2003, these fears had subsided somewhat, and the Centers for Disease Control and Prevention (CDC) released guidelines recommending routine early detection surveillance activities on the part of all public health agencies. These guidelines also included a plan for rapid vaccination of local populations in the event of a suspected smallpox outbreak and listed several high-priority high-risk groups, including direct health care personnel, who need to be vaccinated first if a suspected outbreak occurs.

Today there are more than 20 infectious diseases for which vaccines are available. New vaccines appear periodically but not with the rapidity of other types of drugs, because of the complexities of developing a safe and effective vaccine. Most modern vaccines are produced in a laboratory by genetic engineering methods and contain some extract of the pathogen, or a synthetic extract, rather than the microbe itself. Some vaccines, such as influenza vaccine, may contain actual whole or split virus particles. Most, however, contain a smaller fraction of the organism, such as the bacterial capsular polysaccharides that are used to make pneumococcal vaccine. The attenuating or killing agent is usually a chemical such as formaldehyde or a physical mechanism such as heat. Attenuation may also be accomplished by repeated passage of the microbe through some medium such as a fertile hen egg or a special tissue culture. The search for new and better drugs will never end. Current goals include finding vaccines against human immunodeficiency virus infection/acquired immunodeficiency syndrome (HIV/AIDS) and malaria; the ultimate goal is to develop an effective vaccine against all infectious diseases. The currently available immunizing vaccines are listed in Box 49-1. Note that the drug given to prevent respiratory syncytial virus (RSV) infection is not an immunizing drug per se but is a specialized antiviral drug. It is discussed in Chapter 40. The RSV immunoglobulin is listed in Box 49-1. People who travel to different parts of the world may require specific vaccines. This information can be found on the CDC website at http://wwwnc.cdc.gov/travel/page/vaccinations.htm.

The current childhood immunization schedule published by the CDC is available at http://www.cdc.gov/vaccines. This advisory is published annually as a joint effort of the American Academy of Pediatrics, the CDC's Advisory Committee on Immunization Practices, and the American Academy of Family Physicians. The CDC also posts on its website a catch-up schedule for children who may have missed scheduled immunizations. The CDC's current adult immunization schedule can be found online at http://www.cdc.gov/vaccines/recs/schedules/adult-schedule.htm#print.

Passive Immunization

In passive immunization, the host's immune system is bypassed, and the person is inoculated with serum containing immunoglobulins obtained from other humans or animals. These substances give the person the means to fight off the invading organism. This is known as *artificially acquired passive immunity* and it confers temporary immunity against a particular antigen following exposure to the antigen. It differs from active immunization in that it produces a transitory (short-lived) immune state and the antibodies are already prepared for the host—the host's immune system does not have to synthesize its own antibodies. This allows for more rapid prevention or treatment of disease. Important examples include immunization with tetanus immunoglobulin, hepatitis immunoglobulin, rabies immunoglobulin, and snakebite antivenin.

Passive immunization occurs naturally between a mother and the fetus or the nursing infant when the mother passes maternal antibodies directly, either through the placenta to the fetus or through breast milk to the nursing infant. This is called *naturally acquired passive immunity*.

There are specific populations that can benefit from passive immunization but not from active immunization (see Table 49-1). These are people who have been rendered immunodeficient for one reason or another (e.g., by drugs or disease) and who therefore cannot mount an immune response to a toxoid or vaccine injection because their immune system is suppressed. **Passive immunizing drugs** are also used in people who already have the given disease, especially those with diseases that are rapidly harmful or fatal, such as rabies, tetanus, and hepatitis. Because these diseases can progress rapidly, the body does not have time to mount an adequate immune defense against them before death occurs. The passive immunization of such

BOX 49-1 AVAILABLE IMMUNIZING DRUGS

Passive Immunizing Drugs

Antivenin, pit viper (Crotalidae), polyvalent
Crotalidae polyvalent immune Fab (for pit viper snakebite; e.g., rattlesnake, water moccasin)
Antivenin, *Latrodectus mactans* (black widow spider)
Antivenin, *Micrurus fulvius* (coral snake)
Botulism immunoglobulin
Cytomegalovirus immunoglobulin (human)
Digoxin immune Fab
Hepatitis B immunoglobulin
Immunoglobulin, intramuscular
Immunoglobulin, intravenous
Lymphocyte immunoglobulin, antithymocyte globulin
Rabies immunoglobulin (human)
Respiratory syncytial virus immunoglobulin, intravenous (human)
Rh_0(D) immunoglobulin
Tetanus immunoglobulin
Vaccinia immunoglobulin
Varicella-zoster immunoglobulin (chickenpox/shingles)

Active Immunizing Drugs

BCG (bacille Calmette-Guérin) vaccine (tuberculosis)
Diphtheria and tetanus toxoids (adsorbed)
Diphtheria and tetanus toxoids, and acellular pertussis vaccine (adsorbed)
Diphtheria and tetanus toxoids, acellular pertussis, and *Haemophilus influenzae* type b conjugate vaccines
Diphtheria and tetanus toxoids, acellular pertussis (adsorbed), hepatitis b (recombinant), and inactivated poliovirus vaccine combined
H. Influenzae type b conjugate vaccine
H. Influenzae type b conjugate vaccine with hepatitis b vaccine
Hepatitis a virus vaccine (inactivated)
Hepatitis b virus vaccine (recombinant)
Hepatitis a virus vaccine (inactivated) and hepatitis b virus vaccine (recombinant)
Herpes zoster virus vaccine (live, attenuated)
Human papillomavirus vaccine (attenuated)
Influenza virus vaccine
Japanese encephalitis virus vaccine
Measles virus* vaccine (live, attenuated)
Measles, mumps, and rubella virus vaccine (live)
Meningococcal bacterial vaccine
Mumps virus vaccine (live)
Pneumococcal bacterial vaccine, polyvalent
Pneumococcal thirteen-valent conjugate vaccine
Poliovirus vaccine (inactivated)
Rabies virus vaccine
Rubella virus vaccine (live)
Rubella and mumps virus vaccine (live)
Rubella, measles, and mumps virus vaccine (live)
Smallpox virus vaccine†
Tetanus toxoid (fluid)
Tetanus toxoid (adsorbed)
Typhoid bacterial vaccine
Varicella virus vaccine
Yellow fever virus vaccine

*Also known as *rubeola* virus.
†Not currently on the U.S. market but according to the Centers for Disease Control and Prevention website may be reintroduced because of current bioterrorism threats.

individuals confers a temporary protection that is usually sufficient to keep the invading organisms from killing them, even though it does not stimulate an antibody response.

The passive immunizing drugs are divided into three groups: antitoxins, immunoglobulins, and snake and spider antivenins. An **antitoxin** is a purified **antiserum** that is usually obtained from horses inoculated with the toxin. An immunoglobulin is a concentrated preparation containing predominantly immunoglobulin G and is harvested from a large pool of blood donors. An **antivenin,** often referred to as *antivenom,* is an antiserum containing antibodies against a **venom,** which is a poison secreted by an animal such as a reptile, insect, or other arthropod (e.g., spider). Most antivenins are obtained from animals (usually horses) that have been injected with the particular venom; however, the newer ones are produced by **recombinant** technology. The serum contains immunoglobulins that can neutralize the toxic effects of the venom.

PHARMACOLOGY OVERVIEW

IMMUNIZING DRUGS

Mechanism of Action and Drug Effects

Active immunizing drugs consist of vaccines and toxoids that may be given either orally or intramuscularly and work by stimulating the humoral immune system. This system synthesizes substances called *immunoglobulins,* of which there are five distinct types, designated as M, G, A, E, and D. These immunoglobulins attack and kill the foreign substances that invade the body. In this case, these foreign substances are called *antigens,* and the immunoglobulins are called *antibodies.*

Vaccines contain substances that trigger the formation of these antibodies against specific pathogens. They may contain the actual live or attenuated pathogen or a killed pathogen. The **antibody titer** is a measure of how many antibodies to a given antigen are present in the blood and is used to assess whether enough antibodies are present to protect the body effectively against the particular pathogen. Sometimes the antibody levels decline over time. When this happens, another dose of the vaccine is given to restore the antibody titers to a level that can protect the person against the infection. This repeat dose is referred to as a **booster shot.** Toxoids are altered forms of bacterial toxins that stimulate the production of antibodies in the same way as vaccines.

Because both toxoids and vaccines rely on the immunized host to mount an immune response, the host's immune system must be intact. Therefore, patients who are immunocompromised (i.e., who cannot mount an immune response) may not benefit from receiving vaccines or toxoids. Instead, their clinical situations may warrant giving them passive immunizing drugs such as immunoglobulins.

Passive immunizing drugs are the actual antibodies (immunoglobulins) that can kill or inactivate the pathogen. The process is called *passive* because the person's immune system does not participate in the synthesis of antibodies; instead, the antibodies are provided by the immunizing drug. Immunity acquired in this way generally lasts for a much shorter time than that produced by active immunization. Passive immunization lasts only until the injected immunoglobulins are removed from the person's immune system by the **reticuloendothelial system.** The reticuloendothelial system is composed of specialized cells in the liver, spleen, lymphatics, and bone marrow.

Indications

Vaccines and toxoids are active immunizing drugs that have been developed for the prevention of many illnesses caused by bacteria and their toxins, as well as those caused by various viruses. Antivenins, antitoxins, and immunoglobulins are passive immunizing drugs. Such drugs can inactivate spider and snake venom, bacterial toxins (exotoxins), and potentially lethal viruses. Box 49-1 lists the currently available immunizing drugs. The successful immunization of 95% or more of a population confers protection on the entire population. This is called **herd immunity.**

Antivenins, also known as *antisera,* are used to prevent or minimize the effects of poisoning by the venoms of crotalids (rattlesnakes, copperheads, cottonmouths, water moccasins), black widow spiders, and coral snakes, some of which can be lethal. Most healthy adults do not die from the bites of spiders or snakes if they receive prompt and appropriate treatment (i.e., administration of the appropriate antivenin). However, very young children and older persons with health problems are particularly susceptible to the effects of the venom of some of these animals. In either situation, an antivenin is needed to neutralize the venom.

Contraindications

Contraindications to the administration of immunizing drugs include allergy to the immunization itself or allergy to any of its components, such as eggs or yeast. In the case of a potentially fatal illness such as rabies, the drug may still need to be given and any allergic reaction controlled with other medications. Administration of some immunizing drugs is best deferred until after recovery from a febrile illness or temporary immunocompromised state (e.g., following cancer chemotherapy), if possible. However, this is often a matter of clinical judgment, and the individual patient's condition and risk factors for serious illness may be arguments for or against administration of a given immunizing drug at a given time.

Adverse Effects

The undesirable effects of the various immunizing drugs can range from mild and transient to serious and even life-threatening and are listed in Table 49-2. The overwhelming majority of adverse effects are minor. Minor reactions can be treated with acetaminophen and rest. More severe reactions, such as fever higher than 103° F (39.4° C), can be treated with acetaminophen and sponge baths. Serum sickness sometimes occurs after repeated injections of equine (horse)–derived immunizing drugs. The signs and symptoms consist of edema of the face, tongue, and throat; rash; urticaria; arthritis; adenopathy; fever; flushing; itching; cough; dyspnea; cyanosis; vomiting; and cardiovascular collapse. Serum sickness is best treated with analgesics, antihistamines, epinephrine, and/or corticosteroids. In these cases, hospitalization may be required.

TABLE 49-2 IMMUNIZING DRUGS: MINOR AND SEVERE ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Minor Effects	
Central nervous	Fever, adenopathy
Integumentary	Minor rash, soreness at injection site, urticaria, arthritis
Severe Effects	
Central nervous	Fever higher than 103° F (39.4° C), encephalitis, convulsions, peripheral neuropathy, anaphylactic reaction, shock, unconsciousness
Integumentary	Rash
Respiratory	Dyspnea
Other	Cyanosis

Any serious or unusual reactions to immunizing drugs need to be reported to the Vaccine Adverse Event Reporting System (VAERS). This is a national vaccine safety surveillance program that is cosponsored by the Food and Drug Administration (FDA) and the CDC. A report can be submitted via the toll-free telephone number 800-822-7967. Alternatively, a reporting form can be printed from the website of either the FDA (http://www.fda.gov) or the CDC (http://www.cdc.gov). These websites have extensive information describing this reporting system and the data collected by it. Such data are used to improve the quality of immunizing drugs and can even be grounds for an FDA recall of biologic drugs whose adverse effects exceed acceptable safety thresholds.

In the early 1980s, in response to vaccine-related injuries, many parents became reluctant to immunize their children against common, and even potentially fatal, childhood illnesses. Increasing numbers of legal actions were also brought by parents of injured children. In 1986, the U.S. Congress passed the Childhood Vaccine Injury Act, which in turn established the National Vaccine Injury Compensation Program (VICP). The purpose was to create a no-fault alternative to the civil tort system, which had driven many vaccine manufacturers out of the field. Serious adverse events following vaccination are very uncommon. The Vaccine Injury Table published by the Health Resources and Services Administration itemizes serious adverse events reported for vaccines that are covered under the VICP, as well as the expected time frame for such events to occur. The first symptom must appear within the listed time frame (Table 49-3) for it to be presumed to be caused by the vaccine. For more information, the reader is referred to www.hrsa.gov/vaccinecompensation/index.html.

TABLE 49-3 U.S. DEPARTMENT OF HEALTH AND HUMAN SERVICES VACCINE INJURY TABLE

VACCINE	ADVERSE EVENT	TIME INTERVAL
Tetanus toxoid–containing vaccines (e.g., DTaP, Tdap, DTP-Hib, DT, Td, TT)	Anaphylaxis or anaphylactic shock	0-4 hr
	Brachial neuritis	2-28 days
	Any acute complication or sequela (including death) of above events	NA
Pertussis antigen–containing vaccines (e.g., DTaP, Tdap, DTP, P, DTP-Hib)	Anaphylaxis or anaphylactic shock	0-4 hr
	Encephalopathy (or encephalitis)	0-72 hr
	Any acute complication or sequela (including death) of above events	NA
Measles, mumps, and rubella virus–containing vaccines in any combination (e.g., MMR, MR, M, R)	Anaphylaxis or anaphylactic shock	0-4 hr
	Encephalopathy (or encephalitis)	5-15 days
	Any acute complication or sequela (including death) of above events	NA
Rubella virus–containing vaccines (e.g., MMR, MR, R)	Chronic arthritis	7-42 days
	Any acute complication or sequela (including death) of above event	NA
Measles virus–containing vaccines (e.g., MMR, MR, M)	Thrombocytopenic purpura	7-30 days
	Vaccine-strain measles viral infection in an immunodeficient recipient	0-6 mo
	Any acute complication or sequela (including death) of above events	NA
Polio live virus–containing vaccines (OPV)	Paralytic polio	
	In a nonimmunodeficient recipient	0-30 days
	In an immunodeficient recipient	0-6 mo
	In a vaccine-associated community case	NA
	Vaccine-strain polio viral infection	
	In a nonimmunodeficient recipient	0-30 days
	In an immunodeficient recipient	0-6 mo
	In a vaccine-associated community case	NA
	Any acute complication or sequela (including death) of above events	NA
Polio inactivated virus–containing vaccines (e.g., IPV)	Anaphylaxis or anaphylactic shock	0-4 hr
	Any acute complication or sequela (including death) of above event	NA
Hepatitis B antigen–containing vaccines	Anaphylaxis or anaphylactic shock	0-4 hr
	Any acute complication or sequela (including death) of above event	NA
Haemophilus influenzae type b polysaccharide conjugate vaccines	No condition specified for compensation	NA
Varicella vaccine	No condition specified for compensation	NA
Rotavirus vaccine	No condition specified for compensation	NA
Vaccines containing live, oral, rhesus-based rotavirus	Intussusception	0-30 days
	Any acute complication or sequela (including death) of above event	NA
Pneumococcal conjugate vaccines	No condition specified for compensation	NA
Any new vaccine recommended by the Centers for Disease Control and Prevention for routine administration to children, after publication by the Secretary of DHHS of a notice of coverage*	No condition specified for compensation	NA

DHHS, Department of Health and Human Services; *DT,* diphtheria and tetanus vaccine; *DTaP,* diphtheria, tetanus, and acellular pertussis vaccine; *DTP,* diphtheria, tetanus, and pertussis vaccine; *Hib, Haemophilus influenzae* type b conjugate vaccine; *IPV,* inactivated poliovirus; *M,* measles vaccine; *MMR,* measles, mumps, and rubella vaccine; *MR,* measles and rubella vaccine; *NA,* not applicable; *OPV,* oral polio vaccine; *P,* pertussis vaccine; *R,* rubella vaccine; *Td,* tetanus and diphtheria toxoids; *Tdap,* tetanus and diphtheria toxoids and acellular pertussis vaccine; *TT,* tetanus toxoid.
*Refer to the "News & Updates" link on the National Vaccine Injury Compensation Program website (www.hrsa.gov/vaccinecompensation) for more information.

For many years, there was controversy in the national news pertaining to the link between immunizations and autism in children. It was thought that thimerosal (a mercury-containing preservative used in vaccines) may have been a causative link, so since 2001 thimerosal has no longer been used in the preparation of vaccines. In 2011, the medical community declared that the original study suggesting a link to autism was fraudulent. It is suggested that the original author falsified the medical histories of the patients in his study and that he was "hoping to create a vaccine scare." Although there is absolutely no scientific data to support a link between autism and vaccines, many parents are still reluctant to vaccinate their children.

Interactions

Drug interactions are not generally a problem with the majority of immunizing drugs, because they are normally given in a single dose or a relatively small number of doses. One drug class of note that can potentially reduce the efficacy of immunizing drugs is immunosuppressive drugs, including corticosteroids (see Chapter 33), transplant antirejection drugs (see Chapter 48), and cancer chemotherapy drugs (see Chapters 45 and 46). All of these drugs can, to varying degrees, hinder the generation of the active immunity that would normally occur following vaccine or toxoid administration. The bacille Calmette-Guérin vaccine

for tuberculosis (used mostly outside the United States in developing countries) can cause false-positive results on the tuberculin skin test (see Chapter 41).

Some vaccines are not to be given close in time to one other. For example, the meningococcal vaccine, whole-cell pertussis vaccine, and typhoid vaccine together have undesirably large bacterial endotoxin content and should not be administered simultaneously. The effectiveness of measles, mumps, and rubella vaccines may be reduced by concurrent interferon therapy (see Chapter 47). Influenza vaccine may also theoretically lose efficacy if given while antiviral influenza drugs are being taken (see Chapter 40). Recommendations are to give the influenza vaccine at least 48 hours after stopping such antiviral drug therapy. In general, immunizations requiring intramuscular injection are given with particular caution (and with appropriate monitoring) to patients receiving anticoagulant drugs such as warfarin (see Chapter 26). Review the package insert for any immunizing drugs given to obtain the latest information and identify other specific drug interactions that may occur. Hepatitis B

DOSAGES

Selected Immunizing Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE*	INDICATIONS/USES
Active Immunizing Drugs			
diphtheria, tetanus, and acellular pertussis vaccine (DTaP) (Daptacel)	Mixed toxoid/vaccine	**Pediatric only** IM: Series of three 0.5-mL injections; age of first injection 6 wk-7 yr; give second and third doses at 4-8 wk intervals	Prophylaxis against diphtheria, tetanus, and pertussis
Haemophilus influenzae type b conjugate vaccine (HibTITER) (C)	Bacterial capsular antigenic extract vaccine	**Pediatric** *Infant 2-6 mo* Give three IM injections (0.5 mL each) about 2 mo apart *Previously unvaccinated child 7-11 mo* Give two IM injections about 2 mo apart *Previously unvaccinated child 12-14 mo* Give only one IM injection	*H. influenzae* type b prophylaxis
♦ hepatitis B virus vaccine, inactivated (Recombivax HB) (C)	Viral surface antigen vaccine	**Pediatric to age 10 yr** IM: 5 mcg (0.5 mL) at birth, and then again at 1 mo and 6 mo **Adult** IM: Three 10-mcg (1-mL) doses: day 0, 1 mo, and 6 mo	Hepatitis B virus prophylaxis
♦ influenza virus vaccine (Fluzone, FluShield, Fluvirin) (C)	Viral surface antigen vaccine	**Pediatric 6 mo-9 yr** IM: Single yearly dose (two doses of 0.25 mL at least 1 mo apart if receiving influenza vaccine for first time) **Adult** IM: Single yearly dose (0.5 mL)	Influenza prophylaxis
♦ measles, mumps, and rubella virus vaccine, live (M-M-R II) (C)	Live, attenuated viral vaccine	**Adult and pediatric older than 12 mo** Subcut: 0.5-mL single dose; booster recommended for children entering middle or high school	Prophylaxis against measles, mumps, and rubella
♦ meningococcal vaccine (Menactra, Menveo) (B)	Inactivated	**Menactra: Adult and pediatric 9 mo-55 yr:** 0.5 mL IM **Menveo: Adult and pediatric 11-55 yr:** 0.5 mL IM	Prophylaxis against meningococcal disease
♦ pneumococcal vaccine, polyvalent (Pneumovax 23) (C)	Bacterial capsular antigenic extract vaccine	**Adult and pediatric 2 yr and older** Subcut: 0.5 mL × 1	*Streptococcus pneumoniae* prophylaxis
♦ poliovirus vaccine, inactivated (IPOL) (C)	Inactivated viral vaccine	**Pediatric (infant)** Subcut: Three 0.5-mL doses: 4-8 wk, 2-4 mo, and 6-12 mo **Adult** Subcut: Two 0.5-mL doses 1-2 mo apart, and then a third dose 6-12 mo later	Polio prophylaxis
rabies virus vaccine (Imovax, RabAvert) (C)	Inactivated viral vaccine	**Adult and pediatric** *Postexposure prophylaxis* IM: 1 mL on days 3, 7, and 14 (with one dose of rabies immunoglobulin [see later] within 8 days of first vaccine dose) *Preexposure prophylaxis for those at high risk for rabies exposure (e.g., veterinarians)* IM/ID: 1 mL IM or 0.1 mL ID on days 0, 7, and once between days 21 and 28, for a total of three doses; then q2-5yr, depending on antibody titers	Rabies prophylaxis

DOSAGES—cont'd

Selected Immunizing Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE*	INDICATIONS/USES
tetanus and diphtheria toxoids, adsorbed (Tdap) (Adacel)	Mixed toxoid	**Adult and pediatric** IM: Doses vary based on age; once initial series has been completed, give 0.5-mL booster shot every 10 years	Prophylaxis against diphtheria, tetanus, and pertussis
♦ varicella virus vaccine (Varivax) (C)	Live, attenuated viral vaccine	**Adult and pediatric older than 12 yr** Subcut: Two 0.5-mL doses given 4-8 wk apart **Pediatric 1-12 yr** Subcut: One 0.5-mL dose	Prophylaxis against varicella virus (causes chickenpox and shingles)
Passive Immunizing Drugs			
♦ hepatitis B immunoglobulin (BayHep B, Nabi-HB) (C)	Pooled human immunoglobulin	**Infant (of mother known to be hepatitis B positive)** IM: 0.5 mL within 12 hr after birth **Adult** IM: 0.06 mg/kg after exposure and 30 days later	Passive hepatitis B prophylaxis
♦ immunoglobulin intravenous (Gammar-P IV, Panglobulin NF, others) (C)	Pooled human immunoglobulin	Dosages vary widely; refer to manufacturer's current dosage information for specific indications	Therapy for many disorders, including primary immune deficiency syndrome, pediatric AIDS, idiopathic thrombocytopenic purpura, B-cell lymphocytic leukemia
rabies immunoglobulin (Imogam, Rabies-HT, BayRab) (C)	Pooled human immunoglobulin	**Adult and pediatric** Single dose of 20 IU/kg; infiltrate as much of dose as possible into bite wound area, and give remainder IM in gluteal region; do not give into same site as rabies vaccine	Rabies prophylaxis
Rh_0(D) immunoglobulin (RhoGAM, MICRhoGAM) (C)	Immunosuppressant globulin	**Adult female** IM (full dose): Inject total contents of a single vial within 72 hr after delivery IM (microdose): Inject full contents of a single vial after spontaneous or elective abortion of pregnancy of 12 wk gestation or less	Postpartum antibody suppression to prevent hemolytic disease of future newborns
tetanus immunoglobulin (BayTet) (C)	Pooled human immunoglobulin	**Adult and pediatric** IM: 250 units as a single dose IM: 3000-6000 units as a single dose	Postexposure tetanus prophylaxis Tetanus treatment

AIDS, Acquired immunodeficiency syndrome; *ID,* intradermal; *IM,* intramuscular; *subcut,* subcutaneous.
*NOTE: Dosages given are only for brands listed. Dosing amounts and regimens may vary for different brands. Always follow manufacturer's current dosing directions.

immunoglobulin interacts with live vaccines; defer administration of such vaccines until 3 months after the dose of immunoglobulin is given.

Dosages

For dosage information on selected immunizing drugs, see the table on p. 802.

DRUG PROFILES

Some of the more commonly used vaccines, toxoids, and immunoglobulins are described in the following sections. The immunizing drugs currently available commercially in the United States, including several combination vaccines for prevention of more than one disease, are listed in Box 49-1. Combination vaccines obviously reduce the number of injections that the patient receives, and thus their use is desirable when possible, especially in children.

ACTIVE IMMUNIZING DRUGS

diphtheria and tetanus toxoids and acellular pertussis vaccine (adsorbed)

The active immunizing drugs include diphtheria and tetanus toxoids and the acellular pertussis vaccine (adsorbed) (Tripedia, Daptacel, Infanrix). *Adsorption* refers to the laboratory techniques used to make most vaccines and toxoids. The biologic materials (i.e., virus or toxin particles) are adsorbed (separated out of solution and dried) onto carrier media such as alum, from which they are later removed for packaging into final dosage forms. Diphtheria, tetanus, and pertussis are very different disorders, but an injection that combines all three vaccines (DTP; also commonly called DPT) was routinely given to children since the 1940s. The vaccine combination called *diphtheria and tetanus toxoids with acellular pertussis vaccine (adsorbed) (DTaP [Daptacel])* was approved for the full childhood immunization series and has replaced DPT. Tdap (Adacel, Boostrix) is also a combination vaccine used for teenagers

and adults. DTaP (Daptacel) and Tdap use a different form of the pertussis component, known as *acellular pertussis.* Acellular pertussis consists of only a single weakened toxoid, whereas previous pertussis vaccines contained multiple toxoids; this may reduce the number of adverse effects seen from DTP. Pertussis, also known as *whooping cough,* is highly contagious and is spread through contact with respiratory secretions. Its incidence has increased in several states. Currently DTaP is the preferred preparation for primary and booster immunization against these diseases in children from 6 weeks to 6 years of age, unless use of the pertussis component is contraindicated. Tdap (Adacel) is the recommended vaccine for adolescents and adults. See the Safety and Quality Improvement: Preventing Medication Errors box on p. 808.

Tetanus, diphtheria, and pertussis are prevalent in the populations of many developing countries throughout the world. Full immunization against these diseases with Tdap or DTaP is recommended for travelers to these areas and as well as for their inhabitants. A combination product containing only tetanus and diphtheria toxoids (Td) used to be administered to persons 7 years of age and older who require a primary or booster immunization against tetanus for routine wound management. Booster doses were required approximately every 10 years. However, with the recent increase in pertussis cases, Tdap or DTaP are recommended in place of Td. If persons had received Td in the past, it is recommended that they receive another immunization containing pertussis with Tdap or DTaP.

These toxoids (DTP, DTaP, Tdap, and Td) are available only as parenteral preparations, given as deep intramuscular injections. Their use is contraindicated in persons who have had a prior systemic hypersensitivity reaction or a neurologic reaction to one of the ingredients. Some manufacturers state that use is contraindicated in cases of concurrent acute or active infections but not in cases of minor illness. Although there have been very few studies, if any, documenting the safety of their use in pregnant women, it is generally considered safe to give diphtheria, tetanus, and pertussis toxoids after the first trimester.

Haemophilus Influenzae type b conjugate vaccine

Haemophilus influenzae type b (Hib) (HibTITER, ActHIB, Liquid PedvaxHIB) vaccine is a noninfectious, bacteria-derived vaccine. It is made by extracting *H. influenzae* particles that are antigenic and then chemically attaching these particles to a protein carrier medium for use in injections. The vaccine is given by injection to adults and children considered at high risk for acquiring *H. influenzae* infection. Conditions that may predispose an individual to Hib infection are septicemia, pneumonia, cellulitis, arthritis, osteomyelitis, pericarditis, sickle cell anemia, an immunodeficiency syndrome, and Hodgkin's disease. Before this vaccine was developed, infections caused by Hib were the leading cause of bacterial meningitis in children 3 months to 5 years of age. This form of bacterial meningitis has a mortality rate of 5% to 10%. Of those who survive, 20% to 45% suffer serious morbidity in the form of neurologic deficits. All Hib vaccine products are parenteral formulations that are administered intramuscularly.

♦ hepatitis B virus vaccine (inactivated)

Hepatitis B virus vaccine (inactivated) (Recombivax HB, Engerix-B) is a noninfectious viral vaccine containing hepatitis B surface antigen (HBsAg). It is made from viral particles and yeast using recombinant DNA technology. In this technique, DNA from two or more organisms is combined. Yeast cells then produce this viral antigenic substance in mass quantities. The substance is then attached to a carrier medium (alum) and made into a vaccine injection preparation. This antigenic HBsAg is used to promote active immunity to hepatitis B infection in persons considered at high risk for potential exposure to the hepatitis B virus or HBsAg-positive materials (e.g., blood, plasma, serum). Health care workers, for example, are persons considered at high risk, and many hospitals require this vaccination upon employment. It is recommended that all children receive this vaccine, and it is usually started shortly after birth. It is also recommended that adults with diabetes mellitus receive hepatitis B vaccination.

Use of the vaccine is contraindicated in persons who are hypersensitive to yeast. Pregnancy is not considered a contraindication to use. The vaccine is administered by intramuscular injection and is given as a series of three injections. There are three main formulations designed for three different populations: a pediatric formulation for neonates, infants, children, and adolescents; an adult formulation for persons older than 20 years of age; and a dialysis formulation for predialysis and dialysis patients and for other immunocompromised individuals.

♦ influenza virus vaccine

The influenza virus vaccine (Fluzone, Fluvirin, FluMist) is the vaccine used to prevent influenza. It needs to be given each year before the influenza season begins. Such inoculation is the single most important influenza control measure. FluMist is given intranasally, whereas the others are given intramuscularly.

Each year a new influenza vaccine is developed by virology researchers. It usually contains three different influenza virus strains. These strains are chosen from among the hundreds of influenza virus strains in the environment based on the latest epidemiologic data indicating which influenza viruses will most likely circulate in North America in the upcoming winter. The latest influenza vaccine in the United States also included activity against the H1N1 strain. The vaccine is made from highly purified, egg-grown viruses that have been rendered noninfectious (inactivated).

Influenza is characterized by abrupt onset of fever, myalgia, sore throat, and nonproductive cough. Severe malaise may last several days. More severe illness can occur in certain populations. Older individuals, children, and adults with underlying serious health problems (e.g., HIV infection, asthma, cardiopulmonary disease, cancer, diabetes) are at increased risk for complications from influenza infection. Health care personnel are also considered a high-risk group. Increased mortality results not only from influenza but also from other chronic diseases that can be exacerbated by influenza. More than 90% of the deaths attributed to pneumonia and influenza occur among persons 65 years of age or older. Another fairly unusual but important risk group is children and teenagers who are receiving long-term aspirin therapy (e.g., for juvenile arthritis) and who therefore might be at risk for developing Reye's syndrome after influenza (see Chapter 44).

The effectiveness of influenza vaccine varies. Factors that may alter its effectiveness are the age and immunocompetence

of the vaccine recipient and the degree of similarity between the virus strains included in the vaccine and those that actually predominate during a given influenza season. Healthy persons younger than 65 years of age have a 70% chance of avoiding illness caused by influenza virus when there is a good match between the vaccine and the circulating viruses.

Older persons, especially those residing in nursing homes, can avoid severe illness, secondary complications, and death by taking the influenza vaccine. In elderly persons, the vaccine can prevent hospitalization and pneumonia up to 50% to 60% of the time and death up to 80% of the time. Achieving a high rate of vaccination among nursing home residents can reduce the spread of infection in a facility, thus preventing disease through herd immunity. The CDC now recommends that all people older than 6 months of age receive the influenza vaccine.

♦ measles, mumps, and rubella virus vaccine (live)

The measles, mumps, and rubella vaccine (M-M-R II) is a virus preparation consisting of live measles, mumps, and rubella viruses that are weakened (attenuated). The vaccine promotes active immunity to these diseases by inducing the production of virus-specific immunoglobulin G and immunoglobulin M antibodies. The antibody response to initial vaccination resembles that caused by primary natural infection.

Administration of the measles vaccine or any of the combination products that includes the measles virus is contraindicated in persons with a history of anaphylactic or anaphylactoid reaction, or some other immediate reaction to egg ingestion. Use of these products is also contraindicated in persons who have had an anaphylactic reaction to topically or systemically administered neomycin, because this antibiotic is used as a preservative in some of the vaccine preparations. These vaccines are not to be administered to pregnant women, and pregnancy needs to be avoided for 3 months after measles virus vaccination and 30 days after vaccination with a rubella-containing (measles-rubella or measles-mumps-rubella [MMR]) measles virus vaccine. This precaution is based on the theoretic risk that the live virus vaccine may cause a fetal infection.

♦ meningococcal vaccine

There are two meningococcal vaccines, Menactra and Menveo. They are indicated for active immunization to prevent invasive meningococcal disease caused by *Neisseria meningitidis*. Menactra is approved for patients 9 months to 55 years of age, and Menveo is approved for persons 11 to 55 years of age. The powder must be diluted with the included liquid conjugate component. Side effects include a 41% incidence of pain at injection site and a 30% incidence of headache. Other side effects include myalgia, malaise, and nausea. Caution must be used to prevent sound-alike errors with Menactra and Menomune. The most current recommendations indicate at a two-dose series be given for adults with asplenia or those who are immunocompromised. All other patients receive a one-time dose.

♦ pneumococcal vaccine, polyvalent and thirteen valent

Two forms of vaccine against pneumococcal pneumonia are available that also protect against any illness caused by *Streptococcus pneumoniae. Pneumococcus* is the common name for the bacterium *S. pneumoniae,* the causative organism of this common bacterial infection. The polyvalent type of vaccine (Pneumovax 23) is used primarily in adults. (The term *polyvalent* refers to the fact that the vaccine is designed to be effective against the 23 strains of pneumococcus most commonly implicated in adult cases of pneumonia.) This vaccine also may sometimes be recommended for pediatric patients at higher risk for pneumonia as a result of serious chronic illnesses, especially those who are immunocompromised. However, the thirteen-valent vaccine is the pneumococcal vaccine that is routinely recommended for children. Its official full name is *thirteen-valent conjugate vaccine (PVC13,* or *Prevnar 13).* The name *thirteen-valent* refers to the fact that the vaccine is designed to immunize against the top thirteen pneumococcal strains found in pediatric pneumonia cases. In 2008, the CDC recommended that all smokers 19 to 64 years of age receive the pneumococcal vaccine. Contraindications to the use of either vaccine include known drug allergy to components of the vaccine itself, as well as the presence of current significant febrile illness or immunosuppressed state as a result of drug therapy (e.g., cancer chemotherapy). The vaccine may sometimes still be given in such cases, if it is felt that withholding the vaccine poses an even greater risk to the patient.

♦ poliovirus vaccine (inactivated)

The use of live oral polio vaccine (OPV) is no longer routine in the United States, due to case reports of vaccine-acquired polio. Since 1979, the only indigenous cases of poliomyelitis reported in the United States (44 cases) have been associated with use of the live OPV. Injected doses of inactivated polio vaccine (brand name, IPOL) are instead recommended for routine use. The use of OPV is reserved for the following groups: populations that are the target of mass vaccination campaigns to control outbreaks of paralytic polio, unvaccinated children who will be traveling in fewer than 4 weeks to areas in which polio is endemic, and children of parents who object to the recommended number of IPV injections.

rabies virus vaccine

Although vaccination against the rabies virus is not normally a routine immunization, situations requiring it occur periodically in many practice settings. Rabies virus vaccine (Imovax, RabAvert) is produced using laboratory techniques involving infected human cell cultures and selected antimicrobial drugs. Rabies is a virus that can infect a variety of mammals, including skunks, foxes, raccoons, bats, dogs, and cats. The virus is usually transferred to humans by an animal bite and almost universally causes fatal brain tissue destruction if the patient is not treated with rabies vaccine and immunoglobulin (discussed later). Current recommendations call for a total of five intramuscular injections on days 0, 3, 7, 14, and 28 following an animal bite that raises concern for rabies transmission. This includes a bite by any animal whose rabies immunization status is unknown or which escapes and cannot be observed for signs of rabies. This type of treatment is known as *postexposure prophylaxis. Preexposure prophylaxis* is recommended for persons at high risk for exposure to the rabies virus (e.g., veterinarians). The preexposure course consists of only three injections on day 0, day 7, and

sometime between days 21 and 28. Periodic booster shots are also recommended for such individuals approximately every 2 to 5 years, or based on the levels of the patient's rabies virus antibody titers. Patients who have been previously immunized who have a new bite may need only two booster shots on days 0 and 3. Contraindications to the administration of rabies vaccine include a history of allergic reaction to the vaccine itself or to the drugs neomycin, gentamicin, or amphotericin B. However, given the life-threatening nature of rabies infection, treatment may still be required, with supportive therapy (e.g., epinephrine, diphenhydramine, corticosteroids) provided to minimize allergic reactions. Patients with any kind of febrile illness need to delay occupational preexposure prophylaxis treatment until the illness has subsided.

human papillomavirus vaccine

Human papillomavirus virus (HPV) is a common cause of genital warts and cervical cancer. Genital HPV is a common virus that is transmitted through genital contact, most often during sex. Most sexually active people will get HPV at some time in their lives, although most will never even know it. It is most common in people in their late teens and early twenties. Every year, about 12,000 women are diagnosed with cervical cancer, and almost 4000 women die from this disease in the United States. The papillomavirus vaccines (Gardasil, Cervarix) are the first and only vaccines known to prevent cancer. Cervarix is a bivalent vaccine, whereas Gardasil is a quadrivalent vaccine. The most current recommendations are that either vaccine is recommended for all girls 11 and 12 years of age and for women 13 to 26 years of age who have not yet been vaccinated. In 2012, the CDC began recommending the HPV vaccine for all boys ages 11 and 12, and for males through age 21, who have not already received all three doses. The vaccine is also recommended for gay and bisexual men (or any man who has sex with men), and men with compromised immune systems (including those with HIV) through age 26 if they did not get fully vaccinated when they were younger.

HPV vaccine protects against four types of HPV: two types known to cause 70% of reported cervical cancers and two types known to cause 90% of genital warts. The vaccine is given in three injections—the first dose, and then two more doses 2 months and 6 months later. It is contraindicated in patients who show hypersensitivity to yeast or to their first injection of the vaccine. The HPV vaccine is not recommended for pregnant patients, because appropriate studies have not been completed. Pain on injection is common.

herpes zoster vaccine

Zoster vaccine (Zostavax) is a newly released vaccine (first available in 2008) for the prevention of herpes zoster. Herpes zoster, also known as *shingles,* is an extremely painful condition caused by the varicella-zoster virus that also causes chickenpox. The vaccine is recommended for patients 50 years of age or older to prevent reactivation of the zoster virus that causes shingles. It is a one-time vaccine. The vaccine does not prevent postherpetic neuralgia. It can be given to patients who have already had shingles. Herpes zoster virus vaccine is a live attenuated vaccine. Its use is contraindicated in patients with hypersensitivity to neomycin, gelatin, or any component of the vaccine. It is also contraindicated in immunosuppressed patients or those receiving immunosuppressant therapies, as well as in pregnant women. Because it is a live vaccine, there is a risk of transmission of the virus from the person who is vaccinated to other people. The vaccine is not to be used for the prevention of chickenpox and is not given to children. The drug must be stored in the freezer.

♦ varicella virus vaccine

The live attenuated varicella virus vaccine (Varivax) is used to prevent varicella (chickenpox). Varicella primarily occurs in children younger than 8 years of age or in individuals with compromised immune systems such as elderly or HIV-infected patients. It is estimated that only 10% of children older than 12 years of age are still susceptible to varicella. Only 2% of adults develop varicella-zoster virus infections. However, 50% of the deaths associated with varicella are in adults. Half of these are in immunocompromised patients.

The virus in varicella vaccine is attenuated by the passage of virus particles through human and embryonic guinea pig cell cultures. Varicella vaccine must be stored in a freezer. It is not to be given to immunodeficient patients or to patients who have received high doses of systemic steroids in the previous month. It is also recommended that salicylates be avoided for 6 weeks after administration of varicella vaccine because of the possibility of Reye's syndrome (see Chapter 44). The varicella vaccine is given at 12 months of age, and then a second dose given at 4 to 6 years of age. All patients need to receive a second dose.

PASSIVE IMMUNIZING DRUGS

The currently available antivenins, antitoxins, and immunoglobulins that compose the passive immunizing drugs are listed in Box 49-1. Those that are more commonly used are described in the following profiles.

♦ hepatitis B immunoglobulin

Hepatitis B immunoglobulin (BayHep B, Nabi-HB) is used to provide passive immunity against hepatitis B infection in the postexposure prophylaxis and treatment of persons exposed to hepatitis B virus or HBsAg-positive materials (e.g., blood, plasma, serum). It is prepared from the plasma of human donors with high titers of antibodies to HBsAg. All donors are tested for HIV antibodies to prevent HIV transmission.

Because of the possible devastating consequences of hepatitis B infection, pregnancy is not considered a contraindication to the use of hepatitis B immunoglobulin when there is a clear need for it.

♦ immunoglobulin

Immunoglobulin (BayGam, Octagam) is available in both intramuscular and intravenous dosage forms. It provides passive immunity by increasing antibody titer and antigen-antibody reaction potential. Immunoglobulins are given to help prevent certain infectious diseases in susceptible persons or to ameliorate the diseases in those already infected. Immunoglobulins are pooled from the blood of at least 1000 human

BOX 49-2 CURRENT FDA-APPROVED INDICATIONS FOR IMMUNOGLOBULINS*

Pediatric HIV infection	Kawasaki disease
B-cell chronic lymphocytic leukemia	Immunoglobulin deficiencies
Bone marrow transplantation	Measles
Hepatitis A	Primary immunodeficiency diseases
Idiopathic thrombocytopenic purpura	Rubella
	Varicella

FDA, Food and Drug Administration; *HIV,* human immunodeficiency virus.
*Approved routes of administration are intramuscular and intravenous.

donors. This plasma is prepared by cold alcohol fractionation and usually washed with a detergent to destroy any harmful viruses, such as hepatitis virus or HIV. There are many FDA-approved and non–FDA-approved uses for immunoglobulins; the approved uses are listed in Box 49-2. In recent years, there has been a shortage of immunoglobulin products. The supply of these drugs is dependent on donors. Because of fluctuations in supply and the unfavorable risk/benefit ratio of using products derived from human donors, product insurers have restricted reimbursement to force practitioners to administer the drugs for FDA-approved indications only. "Off-label" or non–FDA-approved uses have been severely curtailed because of such restrictions as well as because of product shortages.

$Rh_0(D)$ immunoglobulin

$Rh_0(D)$ immunoglobulin (RhoGAM, WinRho) is used to suppress the active antibody response and the formation of anti-$Rh_0(D)$ antibodies in an $Rh_0(D)$-negative person exposed to Rh-positive blood. Because an $Rh_0(D)$-negative person reacts to Rh-positive blood as if it were a foreign, "nonself" substance, an immune response develops against it and an antigen-antibody reaction occurs. This reaction can be fatal. The administration of this immunoglobulin helps to prevent the reaction. The most common use of this product is in cases of maternal-fetal Rh incompatibility (postpartum). Only the mother is normally dosed. The objective is to prevent a harmful maternal immune response to a fetus during a future pregnancy if an Rh-negative mother becomes pregnant with an Rh-positive child.

$Rh_0(D)$ immunoglobulin is prepared from the plasma or serum of adults with a high titer of anti-$Rh_0(D)$ antibody to the red blood cell antigen $Rh_0(D)$. Administration of this immunoglobulin is contraindicated in persons who have been previously immunized with this drug and in $Rh_0(D)$-positive/Du-positive patients. It is normally given postpartum but is classified as a pregnancy category C drug.

rabies immunoglobulin

Rabies immunoglobulin (BayRab, Imogam Rabies-HT) is a passive immunizing drug that is administered concurrently with rabies virus vaccine following suspected exposure to the rabies virus. In humans, this usually occurs after an animal bite. Rabies immunoglobulin is derived from human cells that are harvested from persons who have been immunized with rabies vaccine. The only contraindication to its use is drug allergy, although an allergic patient may still need to be dosed rather than face infection with the almost universally fatal rabies virus. The decision to dose a patient in such a case is based on the probability of rabies infection given the particular circumstances surrounding the animal bite.

tetanus immunoglobulin

Tetanus immunoglobulin (BayTet) is a passive immunizing drug effective against tetanus. It contains tetanus antitoxin antibodies that neutralize the bacterial exotoxin produced by *Clostridium tetani,* the bacterium that causes tetanus. Tetanus immunoglobulin is prepared from the plasma of adults who are hyperimmunized with the tetanus toxoid and is given as prophylaxis to persons with tetanus-prone wounds. It may also be used to treat active tetanus.

varicella-zoster immunoglobulin

Varicella-zoster immunoglobulin (VZIG; available only in generic form from the American Red Cross) can be used to modify or prevent chickenpox in susceptible individuals who have had recent significant exposure to the disease. VZIG is best administered within 96 hours of exposure. Candidates for therapy with VZIG are those at high risk of serious disease or complications if they become infected with the varicella-zoster virus. Two examples are newborn children, including premature infants with significant exposure, and immunocompromised adults. If the infection manifests in a pregnant woman within 5 days of delivery, a dose of VZIG is recommended for the infant. It may also be beneficial to both mother and infant when given to the mother during pregnancy, preferably as soon as possible after diagnosis of infection. Healthy adults, including pregnant women, are evaluated on a case-by-case basis. The duration of protection against infection provided by VZIG is at least 3 weeks. VZIG is prepared from the plasma of normal blood donors with high antibody titers to varicella-zoster virus.

BIOLOGIC AND CHEMICAL TERRORISM

Because of the terrible tragedy that occurred on September 11, 2001, there is heightened concern regarding the potential use of infectious or otherwise toxic agents as weapons against human populations. A terrorist attack involving the use of pathogenic microorganisms or other biologic agents is referred to as **bioterrorism,** whereas an attack in which harmful chemical agents are used is called *chemical terrorism.* In June 2002, President George W. Bush signed into law the Public Health Security and Bioterrorism Preparedness and Response Act (the Bioterrorism Act). This legislation marked the official beginning of the President's Countering Bioterrorism Initiative, which attempts to address this issue proactively as a matter of public health. The Center for Biologics Evaluation and Research (CBER), a branch of the FDA, is an important participant in this public health initiative. Recent CBER activities include the funding of rapid development by private industry of new vaccines for the prevention of anthrax and smallpox as well as vaccinia immunoglobulin to prepare for possible bioterrorist attack using these infectious organisms. Although smallpox vaccine is no longer routinely administered in the United States, supplies are maintained by the CDC in

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Tdap and DTaP

The Institute for Safe Medication Practices has reported several errors that involve incorrect use of two vaccines that are used to immunize patients against diphtheria, tetanus, and pertussis (whooping cough). Adacel (Tdap) and Daptacel (DTaP) have similar official names but are used in different situations and for different patients.

DTaP, sold under the trade names Daptacel, Tripedia, and Infanrix, contains toxoids of diphtheria and tetanus as well as the acellular pertussis vaccine. This vaccine is for active immunization of pediatric patients 6 weeks to 6 years of age.

Tdap, sold under the trade names Boostrix and Adacel, contains tetanus toxoid, reduced diphtheria toxoid, and acelluar pertussis vaccine. It is used as a booster vaccine for older children, adolescents, and adults.

The lettering gives a clue as to the contents and strengths of the various vaccines contained in each formulation. In the DTaP vaccine, the uppercase letters correspond with higher amounts of antigens of the diphtheria and pertussis components, as compared to the Tdap (where the *d* and *p* are in lowercase letters). The DTaP, with its larger amount of antigens, is indicated for initial immunizations.

If an adult received the DTaP instead of the Tdap immunization, a higher amount of the antigens is delivered and the patient usually suffers nothing more than a sore arm at the injection site. However, an infant or child who receives Tdap instead of DTaP receives a lower amount of antigen and may not be sufficiently immunized against diphtheria and pertussis.

The similar names and commonly used abbreviations are the main cause of the confusion between the two vaccines. As a result of these medication mix-ups, the manufacturers have taken steps to provide the medications with labels that are clearly marked with the vaccines' purpose. Recommendations include encouraging prescribers to order the vaccines by brand names, not by the vaccine abbreviations. In addition, ensure that parents and caregivers are aware of which vaccine is needed through the use of written information sheets.

Data from ISMP: DTaP-Tdap mix-ups now affecting hundreds of patients, *ISMP Medication Safety Alert,* July 2010, available at www.ismp.org/Newsletters/acutecare/articles/20100701.asp. Accessed October 30, 2011.

the event of a smallpox bioterrorist attack. The Department of Defense currently owns all lots of anthrax vaccine produced in the United States. Although the CDC does not currently recommend public inoculation with the anthrax vaccine, it is administered prophylactically to military personnel considered to be at higher risk of anthrax exposure because of the location and nature of their assigned duties. The Environmental Health Laboratory of the CDC's Division of Laboratory Sciences oversees planned responses to chemical terrorist attacks. One of its newest developments is the Rapid Toxic Screen. This laboratory test is able to analyze the blood and/or urine of multiple patients to detect 150 chemicals that could potentially be used in a terrorist attack to confirm exposure and direct treatment decisions. Tables 49-4 and 49-5 provide examples of microorganisms and chemical agents, respectively, believed potentially likely to be used in a terrorist attack. The chemical agents listed all have a history of prior military use. Because a small-scale attack with anthrax has already occurred in the United States, this disease is also discussed in more detail in the following section.

ANTHRAX

In October 2001, the month following the September 11 terrorist attacks, six U.S. Postal Service workers were infected with anthrax via contaminated mail. Two of them did not survive. Anthrax is a bacterial infectious disease caused by spores of the bacterium *Bacillus anthracis.* In humans, infection can occur via three routes of exposure: skin (20% mortality), gastrointestinal tract (25% to 75% mortality), and inhalation (80% or higher mortality). Antibiotics such as the fluoroquinolone ciprofloxacin are used to treat more severe cases (i.e., the inhalational form). Milder cases (i.e., cutaneous and gastrointestinal forms) are often treated with the tetracycline antibiotic doxycycline.

TABLE 49-4 ILLNESSES CAUSED BY CDC CATEGORY "A" POSSIBLE BIOTERRORISM AGENTS*

NAME OF ILLNESS	CAUSATIVE ORGANISM	CLINICAL PRESENTATION	PREVENTION/TREATMENT
Anthrax	Bacterium: *Bacillus anthracis*	Inhalational form most severe and can lead to potentially fatal bacteremia	Vaccine available; treatable with antibiotics such as ciprofloxacin and dicloxacillin
Smallpox	Virus: vaccinia	Flulike symptoms followed by total-body disfiguring rash	Vaccine available and may be effective for up to 3 days after exposure; antiviral drug cidofovir possibly effective
Botulism	Bacterium: *Clostridium botulinum*	Visual changes; dry mouth; muscle weakness; progressive downward paralysis, including paralysis of diaphragm	Vaccine available only for highly exposed persons; antitoxin effective if given early in disease; immunoglobulin also now available; antibiotics of no benefit
Tularemia	Bacterium: *Francisella tularensis*	Severe, potentially life-threatening respiratory illness	Vaccine still under review by FDA; treatable with antibiotics such as tetracycline and ciprofloxacin
Viral hemorrhagic fever	Viruses: several viral causes, including Ebola, Marburg, and Lassa viruses, yellow fever virus, Argentine hemorrhagic fever virus	Bleeding from body orifices and in internal organs in severe cases; possible renal failure and coma	No vaccines except for yellow fever virus and Argentine hemorrhagic fever virus; no current treatment other than supportive care; prevention focuses on rodent control
Plague	Bacterium: *Yersinia pestis*	Can occur in lungs (pneumonic plague), skin (bubonic plague—most common), or blood (septicemic plague); death possible from respiratory failure and shock	No vaccine currently available in U.S.; antibiotics best if given within 24 hr and include gentamicin and tetracycline

CDC, Centers for Disease Control and Prevention; *FDA,* Food and Drug Administration.
*Classified as "high-priority" biologic diseases by the CDC.
Data from U.S. Centers for Disease Control and Prevention: Emergency preparedness and response, available at www.bt.cdc.gov/bioterrorism/. Accessed March 20, 2012.

The vaccine is produced from an attenuated strain of *B. anthracis.* It has a calculated efficacy level of 92.5% for protection against anthrax infection. Anthrax vaccination is recommended for selected military personnel and others considered being at higher than average risk for exposure to the bacterium. Included are veterinarians and others who handle potentially infected animals as well as workers who process imported animal hair, which is used to manufacture various commercial products.

NURSING PROCESS

ASSESSMENT

Before administering a toxoid or vaccine, gather complete information about the patient's health history, including a list of medications taken (prescription, over-the-counter, and herbal), reactions to drugs, present and past health status, previous allergy test results, use of any immunosuppressants, presence of autoimmune or immunosuppressive diseases or infections, pregnancy and lactation status, and any unusual reaction to any substance. When pediatric patients are to receive a vaccine or toxoid, assess and follow the prescribed immunization schedule and dose. The Department of Health and Human Services, specifically the CDC, provides the latest recommendations for adult and pediatric immunizations in the United States. These recommendations along with cautions and contraindications are easily accessible on the Internet at www.cdc.gov and are available for referral to gain updated information prior to giving vaccines.

Because *passive immunizing drugs* may precipitate serum sickness, carefully assess patients who have chronic illnesses, are debilitated, or are elderly. This includes measuring vital signs, completing a physical assessment, and obtaining a medication history, as well as examining the results of any laboratory testing ordered by the prescriber. Document the patient's general health status with attention overall well-being and any illness. See the pharmacology discussion on passive vaccines as well as Box 49-1 and Table 49-1 for further information.

For the various *active immunizing drugs,* the pharmacology section and Tables 49-1, 49-2, and 49-3, as well as the Dosages table, provides more specific insight and information including contraindications, cautions, and drug interactions. It is also important to note that use of these drugs in the following patient groups must be considered carefully: pregnant patients; those with active infections (especially those caused by the same pathogen or organism producing the same toxin); patients with severe febrile illnesses excluding minor illnesses such as a cold, mild infection, ear infection, or low-grade fever; and patients with a history of reactions or serious adverse effects to the drug. In addition, research has shown that patients who are already immunosuppressed (e.g., those with AIDS, elderly patients, those with chronic diseases or cancer, neonates) are at increased risk for serious adverse effects to toxoids or vaccines; therefore, use these drugs cautiously or not at all in such patients. Many adults assume that the vaccines they received as children will protect them for a lifetime. This is usually the case. Some adults, however, were never vaccinated as children, or newer vaccines were not available at the time they were vaccinated. In addition, immunity may fade over time, and as an individual ages, he or she may become more susceptible to serious diseases caused by common infections, such as *Pneumococcus* infections.

Tetanus, diphtheria, and pertussis vaccines are to be used in patients 6 weeks to 6 years of age and are contraindicated in those with previous vaccine reactions. In addition, the use of these toxoids is contraindicated in patients with any type of neurologic reactions to the vaccine. Pertussis, or whooping cough, is very contagious, spread through respiratory secretions, and can certainly become a widespread problem. Assess age of the patient because DTaP is the preferred preparation in children from 6 weeks to 6 years of age unless the pertussis component is contraindicated. In adolescents and adults, Tdap is indicated.

The *H. influenzae* type b vaccine is administered to adults and children considered at high risk for acquiring *H. influenzae* infection, such as individuals with septicemia, pneumonia, cellulitis, arthritis, osteomyelitis, pericarditis, sickle cell anemia,

TABLE 49-5 POSSIBLE CHEMICAL TERRORISM AGENTS

AGENT (CLASSIFICATION)	EFFECTS	TREATMENT
Sarin (nerve gas)	Headache, runny nose, difficulty breathing, seizures	Remove from area; provide supportive care (e.g., mechanical ventilation). Specific antidote drugs include atropine, pralidoxime, and pyridostigmine. FDA approved special pediatric atropine dosage forms in 2003.
Mustard (blistering agent)	Skin burns, pulmonary edema, ocular damage	Rinse copiously with water; remove contaminated clothing; provide airway support as needed. FDA approved special skin lotion in 2003.
Cyanide (blood agent)	Seizures, gastrointestinal hemorrhage, respiratory arrest	Remove from area; provide airway support. Specific antidote drug therapy includes the chemicals amyl nitrite (by inhalation) and sodium nitrite and sodium thiosulfate (both by injection).
Chlorine (choking agent)	Eye and respiratory irritation; pulmonary edema	Remove from area; remove contaminated clothing; provide airway support.
Radioactive elements	DNA mutations, tissue fibrosis, vascular insufficiency, bone marrow toxicity, organ failure, pneumonitis, enteritis	Several chelating drugs are used to facilitate bodily excretion of various radioactive elements. For example, in 2004, FDA approved two new drugs (pentetate calcium trisodium and pentetate zinc trisodium) for internal decontamination of various radioactive elements (plutonium, americium, curium).
Ricin (by-product of processing of castor beans for production of castor oil)	Respiratory failure, seizures, fever, cough, diarrhea	Remove from area; remove and dispose of contaminated clothing; provide supportive care as needed (e.g., mechanical ventilation, intravenous hydration).

FDA, Food and Drug Administration.

an immunodeficiency syndrome, or Hodgkin's disease. It is important to note that each year a new influenza vaccine is developed (see the pharmacology discussion). The latest one developed in the United States included activity against the H1N1 strain of influenza. Assess whether the patient belongs in a high-risk group for exposure, such as health care personnel. Assessment of age and medical history is important with these vaccines because individuals 65 years of age and older or those with chronic diseases are at risk for increased mortality from the influenza. The influenza virus vaccine is contraindicated in those with a known hypersensitivity to it. *Hepatitis B virus vaccines* are indicated for those at high risk for exposure to the hepatitis B virus or HBsAg-positive materials (e.g., blood, plasma, serum), such as health care workers. This vaccine is contraindicated in those allergic to yeast. Assess the need of the patient receiving the vaccine because there are different formulations for pediatric patients, adults older than 20 years of age, and individuals receiving dialysis or other immunocompromised patients.

The *MMR vaccine* is contraindicated in pregnant women, in persons with a history of anaphylactic reaction or other immediate reaction to egg ingestion, and in those with an anaphylactic reaction to topically or systemically administered neomycin. With the *meningococcal vaccine,* gather data about any history of allergies as well as age because Menactra is indicated for patients who are 9 months to 55 years of age, and Menveo is indicated for those who are 11 to 55 years of age. The *pneumococcal vaccine* is contraindicated in those with known allergy to the drug or its components or in those patients with significant febrile illness or immunosuppressed state as a result of drug therapy (e.g., chemotherapy).

Do not give the *papillomavirus vaccine* (Gardasil, Cervarix) to patients with allergies to yeast or patients who have a documented allergic reaction to the first injection of the vaccine. This vaccine is also contraindicated in pregnancy. The *zoster vaccine* (Zostavax) is for the prevention of herpes zoster. Assessment of age is an important factor in the administration of this vaccine. It is recommended for patients 50 years of age and older to prevent shingles and is not to be given to those patients with allergic reactions to neomycin, gelatin, or any component of the vaccine. Assessment of immune status is also important because it is not to be given to those who are pregnant, immunosuppressed, or receiving immunosuppressant therapies. The *varicella vaccine virus,* Varivax, is used to prevent chickenpox, which occurs mainly in those younger than 8 years of age or in those who are immunocompromised. Assess the patient's medical and medication history because it should not be given to individuals who have received high doses of systemic steroids in the previous month. Advise the patient to avoid salicylates for 6 weeks after its administration because of the risk of Reye's syndrome (see Chapter 44). Age of the patient is important because it is given at 12 months of age and then again at 4 to 6 years of age.

Bioterrorism and *chemical terrorism* are unfortunately a reality in today's society. Your role as a nurse may range from contributing significantly during emergency drills to preparation for a biologic terrorist attack after a warning has been issued or performing triage and carrying out the nursing process during such an attack. It may also include assessing individuals, groups, and communities and providing related education to help people understand the benefits of being informed, making plans, and maintaining a state of preparedness at all times as much as it is possible. Cultural background, level of knowledge and education, age, motor skills, cognitive abilities, awareness of extended family members and their level of preparedness, and ability to manage stress and to think during a crisis are just a few of the areas worthy of assessment. Regardless of the situation, maintain a calm, reassuring, compassionate, caring, and empathic manner during the assessment phase and all other phases of the nursing process. Avoid excessively anxiety-provoking comments or actions. Just discussing the topic of terrorism or bioterrorism can evoke fear and other emotions in individuals. Conduct questioning and assessment in a way that is calming and provides a sense of control.

NURSING DIAGNOSES

1. Acute pain related to local and/or systemic effects of the injection of a toxoid, vaccine, or passive immunizing drug
2. Deficient knowledge related to the use of toxoids, vaccines, or passive immunizing drugs
3. Anxiety related to suspected risk of bioterrorism

PLANNING

GOALS

1. Patient experiences minimal pain associated with the injection of toxoid, vaccine, or immunizing drug.
2. Patient demonstrates adequate and updated knowledge regarding the use of toxoids, vaccines, or immunizing drugs.
3. Patient experiences minimal anxiety associated with the daily stress of suspected risk of bioterrorism.

OUTCOME CRITERIA

1. Patient uses measures to increase comfort associated with injection such as the application of warm packs to the site of injection, as indicated and as ordered by the prescriber, to help relieve localized discomfort or alleviate any localized reactions.
   - Patient uses additional comfort measures such as eating small meals, controlling the environmental temperature, decreasing stimuli, increasing opportunity for rest, and using analgesics and antiinflammatory drugs as prescribed or recommended.
2. Patient states rationale and benefits versus risks of the use of toxoids, vaccines, or immunizing drugs.
   - Patient describes symptoms to report to the prescriber immediately if they occur, such as fever higher than 101° F (38.3° C), infection, wheezing, increasing weakness, or any other unusual reaction.
3. Patient minimizes anxiety by becoming more informed and staying informed about the true risk/possibility of bioterrorism.

- Patient describes full understanding of specific actions for self-protection, including reading reliable sources, staying abreast of local and national news, and even keeping special kits in the home containing items useful in a disaster, such as hurricane preparedness kits and, even more importantly, Homeland Security bioterrorism kits.

IMPLEMENTATION

When any *immunizing drug* is administered, always check and then recheck the specific protocols and schedules of administration to ensure patient safety and accuracy. Provide individuals receiving any immunizing drug with the proper instructions and updated written materials about the medication, technique and route of administration, adverse effects, and potential complications. Educate the patient receiving the vaccine that he or she will not "get" the disease in question from receiving the attenuated or dead virus. It is also important to follow the manufacturer's recommendations concerning storage and administration of the drug, routes and site of administration, dosage, precautions pertaining to the drug's use, and contraindications to its use. Always provide the patient with a written record of immunization with the date of administration and reminder of when a booster is needed. Encourage and teach parents of young children how to maintain an accurate journal of the child's immunization status, including dates of immunization and any reactions if they occur. Prior to giving the vaccine, always inquire again about any previous reaction. Administer all immunizing drugs, as prescribed, using the route specified. The midlateral muscle of the thigh is the preferred site for infants. The deltoid muscle is preferred for older children and adults. If the patient experiences discomfort at the injection site, apply warm compresses to the site or administer an analgesic, antipyretic, or antiinflammatory medication as ordered. Have epinephrine 1:1000 readily available at the time of injection due to the risk of hypersensitivity reactions. Additionally, if fever (101° F or 38.3° C or higher), convulsions with or without fever, altered consciousness, neurologic symptoms, collapse, or somnolence occur, report them immediately to the prescriber, monitor the patient, and initiate emergency treatment as needed.

With regard to the possibility of *bioterrorism,* keep patients well informed and be aware of the need to minimize anxiety at all times. See the Patient Teaching Tips for more information.

CASE STUDY

Varicella Vaccination

Mrs. T. has taken her daughter, 12-month-old Jamie, for a well-baby checkup. Jamie has been healthy overall and is due for the varicella virus vaccination. The nurse reviews the vaccination process with Mrs. T. and gives her information about what to expect after the vaccination.

1. Mrs. T. looks at the information sheet and then asks, "This is just one shot, right? After this, she'll be immune to chickenpox. What a relief that will be!" What is the nurse's best response?
2. The nurse reviews the information with Mrs. T. and tells her that a slight fever may develop. She asks Mrs. T. what she has at home to give to Jamie if a fever or discomfort at the injection site develops. Mrs. T. replies, "Oh, I have children's aspirin." What instructions will the nurse give regarding this?
3. The next morning, the skin around Jamie's injection site is slightly swollen, red, and warm to the touch. Mrs. T. calls the office to "make sure everything is all right." What further assessment questions will the nurse ask Mrs. T.?
4. Mrs. T.'s grandmother, who is 65 years of age, is visiting and tells Mrs. T., "Oh, I had that same vaccine 2 months ago! I don't ever want to get shingles." Is she correct? Did she receive the same vaccine that Jamie did?

For answers, see http://evolve.elsevier.com/Lilley.

EVALUATION

The therapeutic response in patients receiving *immunizing drugs* is the prevention or amelioration of the specific disease being targeted. Adverse reactions for which to monitor in patients receiving immunizing drugs are specific to the drug, but there may be a localized reaction including swelling, redness, discomfort, and heat at the site of injection or a more serious reaction that must be reported immediately to the prescriber (e.g., high fever, lymphadenopathy, rash, itching, joint pain, severe flulike symptoms, decreased level of consciousness, and/or shortness of breath). For a complete list of expected reactions or adverse effects, including minor and severe, see Table 49-2. As immunizing drugs improve and newer ones are developed, it is hoped that fewer adverse effects will occur and fewer adverse drug events and complications will be seen. For biologic and chemical terrorism, constantly monitor for individuals, groups, or situations that may require intervention from other health care or governmental officials.

PATIENT TEACHING TIPS

- A localized reaction to the injection sometimes occurs when toxoids and vaccines are administered. Inform the patient that the discomfort can be relieved by placing warm compresses on the injection site, resting, and taking acetaminophen and/or diphenhydramine, as directed by the prescriber. Instructions for the care of infants or children experiencing such reactions are generally given by the child's prescriber when the immunizing drug is administered.
- Advise the patient or parent/caregiver to notify the prescriber if high or prolonged fever, rash, itching, or shortness of breath occur after the vaccination.
- Stress that the patient or parent/caregiver always keep a double record (two copies stored in separate places) of all of the medications being taken, especially all vaccinations received.
- A vaccine adverse event reporting system is available through the FDA by calling 800-822-7967.

KEY POINTS

- A foreign substance in the body is termed an *antigen;* the body creates a substance called an *antibody* specifically to bind to it.
- B lymphocytes (B cells), when stimulated by the binding of an antigen molecule, begin to differentiate into memory cells and plasma cells.
- Memory cells remember what that particular antigen looks like in case the body is exposed to the same antigen again in the future. Plasma cells manufacture the antibodies and will mass-produce clones of the antibodies upon reexposure to a particular antigen.
- The two types of immunity are active and passive immunity. Different types of drugs are used to induce each, and these drugs are indicated for different populations, as follows:
  - Active immunization involves administration of a toxoid or a vaccine that exposes the body to a relatively harmless form of the antigen (foreign invader) to imprint cellular memory and stimulate the body's defenses to fight any subsequent exposure. It provides long-lasting or permanent immunity. The recipient must have an active, functioning immune system to benefit.
  - Passive immunization involves the administration of immunoglobulins, antitoxins, or antivenins. Serum or concentrated immunoglobulins are obtained from humans or animals and, after screening and testing, are injected into the patient, directly giving the individual the ability to fight off an invading microorganism or inactivate a toxin. Passive immunization provides temporary protection and does not stimulate an antibody response in the host. It is used in patients who are immunocompromised or who have been exposed to, or anticipate exposure to, an organism or toxin.
- Patients who are not to receive immunizing drugs include those with active infections, febrile illnesses, or history of a previous reaction to the drug. Use of these drugs in pregnant women is usually contraindicated.
- Patients who are immunocompromised are at greater risk of experiencing serious adverse effects from immunizing drugs.
- Encourage parents to keep updated records of their children's and their own immunizations with any toxoids or vaccines.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 When assessing a patient who will be receiving a measles vaccine, the nurse will consider which condition to be a possible contraindication?
   - **a** Anemia
   - **b** Pregnancy
   - **c** Ear infection
   - **d** Common cold

2 When giving a vaccination to an infant, the nurse should tell the mother to expect which adverse effect?
   - **a** Fever over 101° F (38.3° C)
   - **b** Rash
   - **c** Soreness at the injection site
   - **d** Chills

3 In the emergency department, several patients have possibly been exposed to anthrax. The nurse will prepare to administer prophylactic doses of
   - **a** ciprofloxacin.
   - **b** cidofovir.
   - **c** immunoglobulin.
   - **d** antitoxin.

4 During a routine checkup, a 72-year-old patient is advised to receive an influenza vaccine injection. He questions this, saying, "I had one last year. Why do I need another one?" What is an appropriate response from the nurse?
   - **a** "The effectiveness of the vaccine wears off after 6 months."
   - **b** "Each year a new vaccine is developed based on the flu strains that are likely to be in circulation."
   - **c** "When you reach 65 years of age, you need boosters on an annual basis."
   - **d** "Taking the flu vaccine each year allows you to build your immunity to a higher level each time."

5 A 28-year-old is in the urgent care center after stepping on a rusty tent nail. The nurse evaluates the patient's immunity status and notes that the patient thinks she had her last tetanus booster about 10 years ago, just before starting college. Which immunization would be most appropriate at this time?
   - **a** Immunoglobulin intravenous (Gammar-P IV)
   - **b** DTaP (Daptacel) (diphtheria, tetanus, and acellular pertussis)
   - **c** Tdap (Adacel) (diphtheria, tetanus, and acellular pertussis)
   - **d** No immunizations are necessary at this time.

6 The nurse is providing teaching after an adult receives a booster immunization. Which adverse reactions should be reported immediately to the health care provider? (Select all that apply.)
   - **a** Swelling and redness at the injection site
   - **b** Fever of 100° F (37.8° C)
   - **c** Joint pain
   - **d** Heat over the injection site
   - **e** Rash over the arms, back, and chest
   - **f** Shortness of breath

7 The order for an adult who needs passive hepatitis B prophylaxis reads: "Give hepatitis B immunoglobulin (Bay-Hep B), 0.06 mg/kg IM now, and then again in 30 days." The patient weighs 176 pounds. How many milligrams will this patient receive per dose?

1. b, 2. c, 3. a, 4. b, 5. c, 6. c, e, f, 7. 4.8 mg per dose

For Critical Thinking and Prioritization Questions, see http://evolve.elsevier.com/Lilley.

PART 9

Drugs Affecting the Gastrointestinal System and Nutrition

STUDY SKILLS TIPS

Active Questioning • What Are the Right Questions? • Kinds of Questions • Questioning Application

ACTIVE QUESTIONING

There is one technique for study that cannot be overemphasized: active questioning. In the PURR study model, it is critical to be able to generate questions in the Plan, Rehearsal, and Review steps. The questions you generate when applying the PURR method are essential in helping you maintain concentration as you study, improving your comprehension as you read assigned material, and developing your long-term memory. Active questioning is a strategy that you must practice continuously. It is a strategy that develops with practice.

WHAT ARE THE RIGHT QUESTIONS?

Some questions generated during the Plan step will be useful and will focus on exactly the right issues for maximum learning. On the other hand, sometimes the questions generated by looking at the chapter outline or accented material in the body of the text will be inappropriate. These questions seem logical and important when you are working with the limited amount of information available in the Plan step, but as you read the chapter you will find that they miss the mark. Do not worry about whether each question you ask is perfectly focused. As you read, rehearse, and review the material, you can and should revise questions based on your growing understanding of the material. The important point is to ask many questions to help you maintain active involvement in the learning process and anticipate questions that will appear on exams. The more questions you ask, the more effective you will become, both as an active questioner and as an active learner.

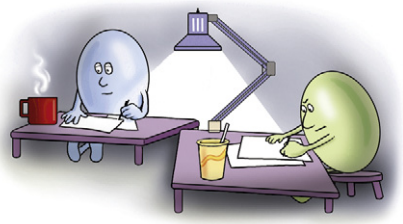
KINDS OF QUESTIONS

First, you must realize that there is more than one kind of question to be asked. Over the years, many questioning hierarchies have been proposed by educators and scholars. The different kinds of questions identified vary from three or four to as many as seven or eight. The following is a simple approach that focuses on two types of questions.

Literal Questions

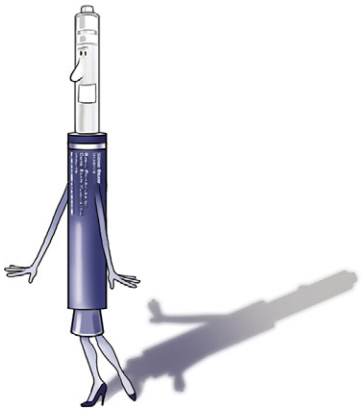
Literal questions are those that are answered directly and specifically by the text. When you were reading a story in elementary school and the teacher asked, "What did Sally do when she lost her movie money?" you were able to answer easily because the question asked for specific information that was stated clearly and directly in the story. If you were reading an American history text and found a topic heading for "The First President," an obvious question would be, "Who was the first president?" The answer is one that would be stated clearly and directly in the body of this topic. These are examples of literal questions. A literal question usually has a single correct response. The answer is stated directly in the text, and every reader will find that same information.

Interpretive Questions



Interpretive questions are more challenging questions that require the reader to interpret, synthesize, evaluate, and analyze the material. Interpretive questions require knowing the literal information in addition to understanding the reading material well enough to be able to select several different pieces or bits of data and put them together to formulate a response that demonstrates your understanding. In the American history example about the first president, an interpretive question might be, "Why was George Washington considered to be such an exemplary model as the first president of the new nation?" This question requires not only that you know the literal facts about Washington, but also that you be able to evaluate and judge those facts to reach a conclusion that could be supported by the literal information. Even though a question is interpretive, it is possible that there is only one correct response. However, it is equally possible that there is more than one correct response to an interpretive question. The literal information can be evaluated in a number of different ways in responding to the question, and the answers derived by different readers will vary. This is why it is a good choice to work with a study group when reviewing for interpretive questions. A study group can develop a variety of responses that result in a more comprehensive understanding of the course material. This depth of learning is what is necessary to pass not only your course test but also the NCLEX Examination, as well as to become a competent nurse. Both literal and interpretive questions are essential in the learning process.

QUESTIONING APPLICATION



Italicization is used to gain the reader's attention and to indicate that the italicized material is especially noteworthy. Accented material should always be considered as a potential source of questions. Again, the questioning can begin with simple, literal questions, but it is essential that interpretive questions also be asked. Your questions should require that you read for broader general understanding and not just focus on "the facts."

Critical Thinking and Prioritization Questions are available on the Evolve website for your textbook. Even though you may answer these questions as they are stated, you should consider generating additional questions of your own. The first question for Chapter 53 is, "The nurse is about to administer calcium supplemental therapy to a patient with a history of cardiac disease. What is the most important assessment that is needed before the nurse gives the drug?" In answering this question, some additional questions will help you focus your learning. What is calcium supplemental therapy? How does calcium affect cardiac patients? Why? Is calcium supplemental therapy inappropriate for all cardiac patients? If not, what are the circumstances that might rule out supplemental calcium? Of what signs and symptoms should the caregiver be aware if calcium supplemental therapy is being administered to a cardiac patient?

The more active you become as a questioner, the easier it will become to ask the kinds of questions that are necessary for your own learning.

CHAPTER

50

Acid-Controlling Drugs

evolve WEBSITE

http://evolve.elsevier.com/Lilley

- Animations
- Answer Key—Textbook Case Studies
- Critical Thinking and Prioritization Questions
- Key Points—Downloadable
- Review Questions for the NCLEX® Examination
- Unfolding Case Studies

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the physiologic influence of various pathologies, such as peptic ulcer disease, gastritis, spastic colon, gastroesophageal reflux disease, and hyperacidic states, on the health of patients and their gastrointestinal tracts.
2 Describe the mechanisms of action, indications, cautions, contraindications, drug interactions, adverse effects, dosages, and routes of administration for the following classes of acid-controlling drugs: antacids, histamine 2 (H_2)–blocking drugs (H_2 receptor antagonists), proton pump inhibitors, and acid suppressants.
3 Develop a nursing care plan that includes all phases of the nursing process for patients receiving acid-controlling drugs.

DRUG PROFILES

antacids, general, p. 819
♦ **cimetidine, p. 821**
♦ **famotidine, p. 822**
lansoprazole, p. 823
misoprostol, p. 824
omeprazole, p. 823
pantoprazole, p. 823
ranitidine, p. 822
simethicone, p. 824
♦ **sucralfate, p. 823**

♦ *Key drug*

KEY TERMS

Antacids Basic compounds composed of different combinations of acid-neutralizing ionic salts. (p. 818)

Chief cells Cells in the stomach that secrete the gastric enzyme pepsinogen (a precursor to pepsin). (p. 816)

Gastric glands Secretory glands in the stomach containing the following cell types: parietal, chief, mucous, endocrine, and enterochromaffin. (p. 816)

Gastric hyperacidity The overproduction of stomach acid. (p. 816)

Hydrochloric acid (HCl) An acid secreted by the *parietal cells* in the lining of the stomach that maintains the environment of the stomach at a pH of 1 to 4. (p. 816)

Mucous cells Cells whose function in the stomach is to secrete mucus that serves as a protective mucous coat against the digestive properties of HCl. Also called *surface epithelial cells.* (p. 816)

Parietal cells Cells in the stomach that produce and secrete HCl. These cells are the primary site of action for many of the drugs used to treat acid-related disorders. (p. 816)

Pepsin An enzyme in the stomach that breaks down proteins. (p. 816)

One of the conditions of the stomach requiring drug therapy is hyperacidity, or excessive acid production. Left untreated, hyperacidity can lead to serious conditions such as acid reflux, ulcer disease, esophageal damage, and even esophageal cancer. Overproduction of stomach acid is also referred to as **gastric hyperacidity.**

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

ACID-RELATED PATHOPHYSIOLOGY

The stomach secretes several substances with various physiologic functions, including the following:

- Hydrochloric acid, an acid that aids digestion and also serves as a barrier to infection
- Bicarbonate, a base that is a natural mechanism to prevent hyperacidity
- Pepsinogen, an enzymatic precursor to pepsin, an enzyme that digests dietary proteins
- Intrinsic factor, a glycoprotein that facilitates gastric absorption of vitamin B_{12}
- Mucus, which protects the stomach lining from both hydrochloric acid and digestive enzymes
- Prostaglandins, which have a variety of antiinflammatory and protective functions (see Chapter 44)

The stomach, although one structure, can be divided into three functional areas. Each area is associated with specific glands. These glands are composed of different cells, and these cells secrete different substances. Figure 50-1 shows the three functional areas of the stomach and the distribution of the associated types of stomach glands.

The three primary types of glands in the stomach are the cardiac, pyloric, and gastric glands. These glands are named for their positions in the stomach. The cardiac glands are located around the cardiac sphincter (also known as the *gastroesophageal sphincter*); the gastric glands are in the fundus, also known as the *greater part of the body of the stomach;* and the pyloric glands are in the pyloric region and in the transitional area between the pyloric and the fundic zones.

The **gastric glands** are highly specialized secretory glands composed of several different types of cells: parietal, chief, mucous, endocrine, and enterochromaffin. Each cell secretes a specific substance. The three most important cell types are parietal cells, chief cells, and mucous cells. These cells are depicted in Figure 50-1.

Parietal cells produce and secrete **hydrochloric acid (HCl).** They are the primary site of action for many of the drugs used to treat acid-related disorders. **Chief cells** secrete *pepsinogen.* Pepsinogen is a *proenzyme* (enzyme precursor) that becomes **pepsin** when activated by exposure to acid. Pepsin breaks down proteins and is therefore referred to as a *proteolytic* enzyme. **Mucous cells** are mucus-secreting cells that are also called *surface epithelial cells.* The secreted mucus serves as a protective coating against the digestive action of hydrochloric acid and digestive enzymes.

These three cell types play an important role in the digestive process. When the balance of these cells and their secretions is impaired, acid-related diseases can occur. The most harmful of these involve hypersecretion of acid and include peptic ulcer disease and esophageal cancer. However, the most common condition is mild to moderate hyperacidity. Many lay terms (e.g., indigestion, sour stomach, heartburn, acid stomach) have been used to describe this condition of overproduction of hydrochloric acid by the parietal cells. Hyperacidity is often associated with gastroesophageal reflux disease (GERD). This is the tendency of excessive and acidic stomach contents to back up, or reflux, into the lower (and even upper) esophagus. Over time, this condition can lead to more serious disorders such as erosive esophagitis and Barrett esophagus, a precancerous condition. Therefore, to prevent serious disorders from occurring and to promote patient comfort, GERD is aggressively treated with one or more of the medications described in this section.

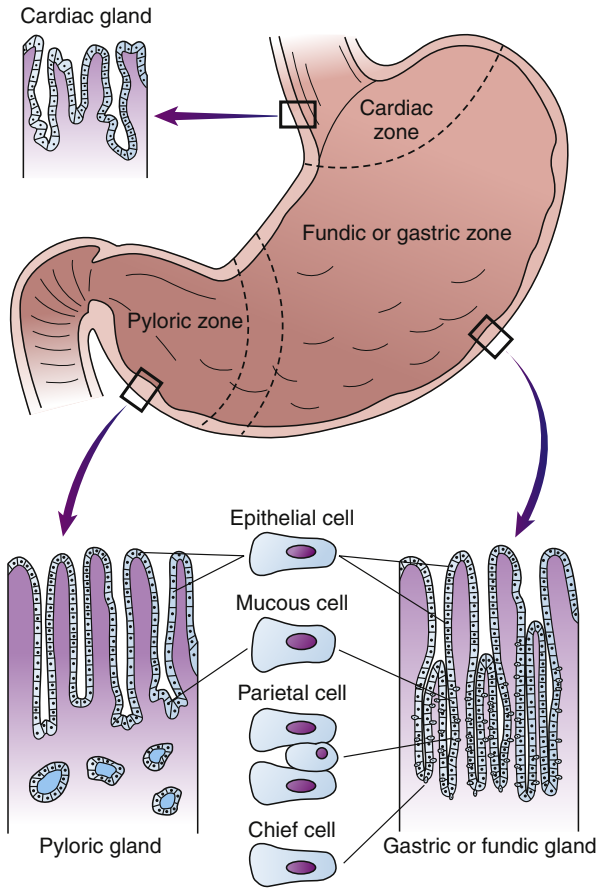


FIGURE 50-1 The three zones of the stomach and the associated glands.

Hydrochloric acid is secreted by the parietal cells in the lining of the stomach and maintains the environment of the stomach at a pH of 1 to 4. This acidity aids in the proper digestion of food and also serves as one of the body's defenses against microbial infection via the gastrointestinal (GI) tract. Several substances stimulate hydrochloric acid secretion by the parietal cells, such as food, caffeine, chocolate, and alcohol. In moderation, any of these is usually not problematic. However, excessive consumption of large, fatty meals or alcohol, as well as emotional stress, may result in hyperproduction of hydrochloric acid and lead to hypersecretory disorders such as peptic ulcer disease.

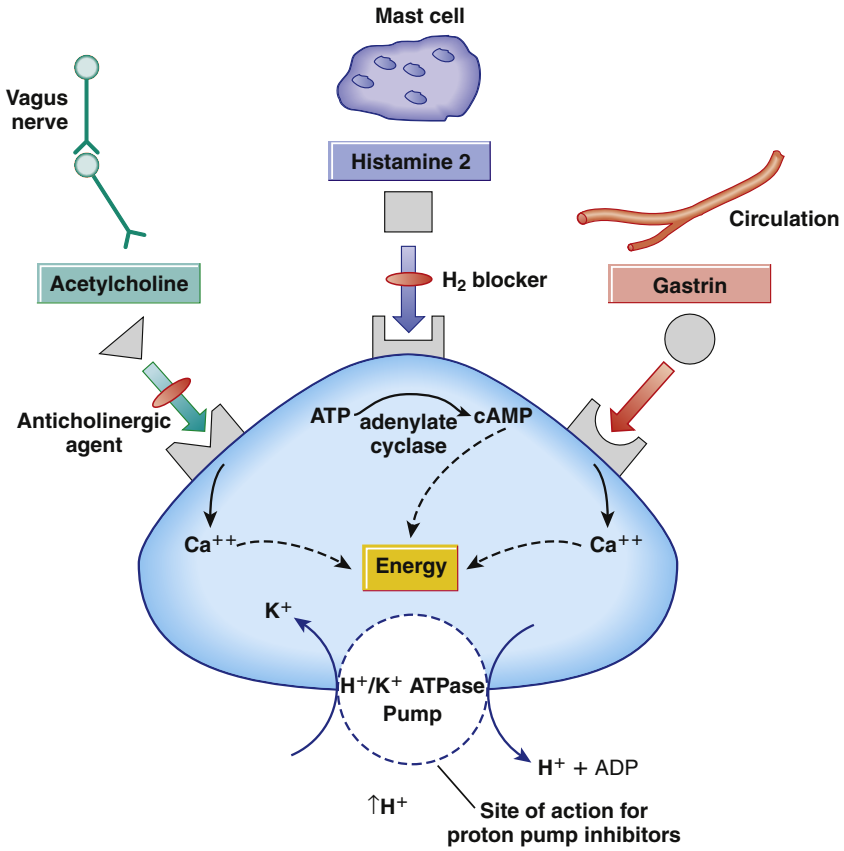

FIGURE 50-2 Parietal cell stimulation and secretion. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *ATPase,* adenosine triphosphatase; *cAMP,* cyclic adenosine monophosphate.

The parietal cell is the primary target for many of the most effective drugs for the treatment of acid-related disorders. A closer look at how the parietal cell receives signals to produce and secrete hydrochloric acid will enhance the understanding of the mechanism of action of many of the drugs used to treat acid-related disorders.

The wall of the parietal cell contains three types of receptors: acetylcholine (ACh), histamine, and gastrin. When any one of these is occupied by its corresponding chemical stimulant (ACh, histamine, or gastrin, which can all be considered *first messengers*), the parietal cell will produce and secrete hydrochloric acid. Figure 50-2 shows the parietal cell with its three receptors. Once these receptors have become occupied, a *second messenger* is sent inside the cell. In the case of histamine receptors, occupation results in the production of adenylate cyclase. Adenylate cyclase converts adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP), which provides energy for the proton pump. The proton pump—or, more precisely, the hydrogen–potassium–adenosine triphosphatase (ATPase) pump—is a pump for the transport of hydrogen ions and is located in the parietal cells. The pump requires energy to work. If energy is present, the proton pump will be activated, and the pump will be able to transport hydrogen ions needed for the production of hydrochloric acid.

In the case of both ACh and gastrin receptors, the second messenger that drives the proton pump is not cAMP but is instead calcium ions. Anticholinergic drugs (see Chapter 21) such as atropine block ACh receptors, which also results in decreased hydrogen ion secretion from the parietal cells. However, these drugs are no longer used for this purpose and have been superseded by other drug classes discussed in this chapter. There is currently no drug to block the binding of the hormone gastrin to its corresponding receptor on the parietal cell surface.

Peptic ulcer disease is a general term for gastric or duodenal ulcers that involve digestion of the GI mucosa by the enzyme pepsin. Pepsin normally breaks down only food proteins and is the activated form of pepsinogen. Pepsinogen is produced by the chief cells of the stomach in response to hydrochloric acid released from the parietal cells. The sight, smell, and taste of food and its presence in the stomach are the primary stimulus for the release of hydrochloric acid from the parietal cells. Because the process of ulceration is driven by the proteolytic (protein breakdown) actions of pepsin together with the caustic effects of hydrochloric acid, peptic ulcer disease and related problems are also referred to by the more general term *acid-peptic disorders.*

In 1983, a gram-negative spiral bacterium, *Campylobacter pylori,* was isolated from several patients with gastritis. Over the next few years this bacterium was studied further, and it became implicated in the pathophysiology of peptic ulcer disease. The official name of the bacterium was changed to *Helicobacter pylori* because it was felt to have more characteristics of the *Helicobacter* genus. The prevalence of *H. pylori* as measured by serum antibody tests is approximately 40% to 60%

for patients older than 60 years of age but only 10% for those younger than 30 years of age. The bacterium is found in the GI tracts of roughly 90% of patients with duodenal ulcers and 70% of those with gastric ulcers. This bacterium is also found in many patients who do not have peptic ulcer disease, and its presence is not associated with acute, perforating ulcers. These latter observations suggest that more than one factor is involved in ulceration. The American College of Gastroenterologists published treatment guidelines in 2007 for *H. pylori* infections. First-line therapy includes a 10- to 14-day course of a proton pump inhibitor (discussed later in the chapter) and the antibiotics clarithromycin and either amoxicillin or metronidazole (see Chapters 38 and 39) or a combination of a proton pump inhibitor, bismuth subsalicylate (see Chapter 51), and the antibiotics tetracycline and metronidazole (see Chapters 38 and 39). Many different combinations are used, but all incorporate the aforementioned key drugs.

Stress-related mucosal damage is an important issue for critically ill patients. Stress ulcer prophylaxis (or therapy to prevent severe GI damage) is undertaken in almost every critically ill patient in an intensive care unit (ICU) and for many patients on general medical surgical units. GI lesions are a common finding in ICU patients, especially within the first 24 hours after admission. The etiology and pathophysiology of stress-related mucosal damage is multifactorial and is not fully understood. Factors include decreased blood flow, mucosal ischemia, hypoperfusion, and reperfusion injury. Procedures performed commonly in critically ill patients, such as passing nasogastric (NG) tubes, placing patients on ventilators, and others, predispose patients to bleeding of the GI tract. Coagulopathy, a history of peptic ulcer or GI bleed, sepsis, use of steroids, ICU stay of longer than 1 week, and occult bleeding are considered to indicate high risk of GI lesions. Guidelines suggest that all such patients receive either a histamine receptor–blocking drug or a proton pump inhibitor, both of which are discussed in detail in this chapter.

PHARMACOLOGY OVERVIEW

ANTACIDS

Antacids are basic compounds used to neutralize stomach acid. Most commonly they are nonprescription salts of aluminum, magnesium, calcium, and/or sodium. They have been used for centuries in the treatment of patients with acid-related disorders. The ancient Greeks used crushed coral (calcium carbonate) in the first century AD to treat patients with dyspepsia. Antacids were the principal antiulcer treatment, along with anticholinergic drugs, until the introduction of the *histamine 2 (H_2) receptor antagonists* in the late 1970s. The use of anticholinergic drugs has fallen out of favor; however, the antacids, especially the over-the-counter (OTC) formulations, are still used extensively. They are available in a variety of dosage forms, some including more than one antacid salt. In addition, many antacid preparations also contain the *antiflatulent* (antigas) drug simethicone (see the section on miscellaneous acid-controlling drugs), which reduces gas and bloating.

Many aluminum- and calcium-based formulations also include magnesium, which not only contributes to the acid-neutralizing capacity but also counteracts the constipating effects of aluminum and calcium. There are multiple salts of calcium, with calcium carbonate being used most often. However, calcium antacids may lead to the development of kidney stones and increased gastric acid secretion, so they are not used as frequently as other antacids. Antacids containing magnesium must be avoided in patients with renal failure. Sodium bicarbonate is a highly soluble antacid form with a quick onset but short duration of action.

Mechanism of Action and Drug Effects

Antacids work primarily by neutralizing gastric acidity. They do not prevent the overproduction of acid but instead help to neutralize acid secretions. It is also believed that antacids promote gastric mucosal defensive mechanisms, especially at lower dosages. They do this by stimulating the secretion of mucus, prostaglandins, and bicarbonate from the cells inside the gastric glands. Mucus serves as a protective barrier against the destructive actions of hydrochloric acid. Bicarbonate helps buffer the acidity of hydrochloric acid. Prostaglandins prevent histamine from binding to its corresponding parietal cell receptors, which inhibits the production of adenylate cyclase. Without adenylate cyclase, no cAMP can be formed and no second messenger is available to activate the proton pump (see Figure 50-2).

The primary drug effect of antacids is the reduction of the symptoms associated with various acid-related disorders, such as pain and reflux ("heartburn"). A dose of antacid that raises the gastric pH from 1.3 to 1.6 (only 0.3 point) reduces gastric acidity by 50%, whereas acidity is reduced by 90% if the pH is raised an entire point (e.g., 1.3 to 2.3). Antacid-associated pain reduction is thought to be a result of base-mediated inhibition of the protein-digesting ability of pepsin, increase in the resistance of the stomach lining to irritation, and increase in the tone of the cardiac sphincter, which reduces reflux from the stomach.

Indications

Antacids are indicated for the acute relief of symptoms associated with peptic ulcer, gastritis, gastric hyperacidity, and heartburn.

Contraindications

The only usual contraindication to antacid use is known allergy to a specific drug product. Other contraindications may include severe renal failure or electrolyte disturbances (because of the potential toxic accumulation of electrolytes in the antacids themselves) and GI obstruction (antacids may stimulate GI motility when it is undesirable because of the presence of an obstructive process requiring surgical intervention).

Adverse Effects

The adverse effects of the antacids are limited. The magnesium preparations, especially milk of magnesia, can cause diarrhea. Both the aluminum- and calcium-containing formulations can result in constipation. Calcium products can also cause kidney

BOX 50-1 NURSING CONCERNS FOR PATIENTS TAKING ANTACIDS

Aluminum, used to reduce gastric acid, binds to phosphate and may lead to hypercalcemia. Early hypercalcemia is characterized by constipation, headache, increased thirst, dry mouth, decreased appetite, irritability, and a metallic taste in the mouth. Later signs and symptoms of hypercalcemia include confusion, drowsiness, increase in blood pressure, irregular heart rate, nausea, vomiting, and increased urination. Use of aluminum-based antacids may also produce hypophosphatemia, which is characterized by loss of appetite, malaise, muscle weakness, and/or bone pain. The use of calcium-containing antacids (e.g., calcium carbonate) may lead to *milk-alkali syndrome,* which is associated with headache, anorexia, nausea, vomiting, and unusual tiredness. Use of sodium bicarbonate may lead to metabolic alkalosis if the drug is abused or used over the long term. Alkalosis is manifested by irritability, muscle twitching, numbness and tingling, cyanosis, slow and shallow respirations, headache, thirst, and nausea. Acid rebound occurs with the discontinuation of antacids that have high acid-neutralizing capacity and with overuse or misuse of antacid therapy. If acid neutralization is sudden and high, the result is an immediate elevation in pH to alkalinity and just as rapid a decline in pH to a more acidic state in the gut.

stones. Excessive use of any antacid can theoretically result in systemic alkalosis. This is more common with sodium bicarbonate. Another adverse effect that is more common with the calcium-containing products is rebound hyperacidity, or acid rebound, in which the patient experiences hyperacidity when antacid use is discontinued. Long-term self-medication with antacids may mask symptoms of serious underlying disease such as bleeding ulcer or malignancy. Patients with ongoing symptoms need to undergo regular medical evaluations, because additional medications or other interventions may be needed. Box 50-1 lists several specific nursing concerns for patients taking antacids.

Interactions

Antacids are capable of causing several interactions when administered with other drugs (see Table 50-1). There are four basic mechanisms by which antacids cause interactions:

- *Adsorption* of other drugs to antacids, which reduces the ability of the other drug to be absorbed into the body
- *Chelation,* which is the chemical inactivation of other drugs that produces insoluble complexes
- *Increased stomach pH,* which increases the absorption of basic drugs and decreases the absorption of acidic drugs
- *Increased urinary pH,* which increases the excretion of acidic drugs and decreases the excretion of basic drugs

Most drugs are either weak acids or weak bases. Therefore, pH conditions in both the GI and urinary tracts will affect the extent to which drug molecules are absorbed. Common examples of drugs whose effects may be chemically enhanced by the presence of antacids (due to pH effects) are benzodiazepines, sulfonylureas (effects may also be reduced, depending on the drugs involved), sympathomimetics, and valproic acid. More commonly, the presence of antacids reduces the efficacy of interacting drugs by interfering with their GI absorption. Such drugs include allopurinol, tetracycline, thyroid hormones, captopril, corticosteroids, digoxin, histamine antagonists, phenytoin, isoniazid, ketoconazole, methotrexate, nitrofurantoin, phenothiazines, salicylates, and quinolone antibiotics. Advise patients to dose any interacting drugs at least 1 to 2 hours before or after antacids are taken. Significant patient harm may ensue when the quinolone antibiotics (ciprofloxacin, levofloxacin, moxifloxacin) are given with antacids. These antibiotics are administered orally to treat serious infections. Antacids can reduce their absorption by more than 50%. Thus, antacids must be given either 2 hours before or 2 hours after the dose of a quinolone antibiotic.

TABLE 50-1 ANTACIDS: DRUG INTERACTIONS

INTERACTING DRUG	MECHANISM	RESULT
Benzodiazepines Sulfonylureas Sympathomimetics valproic acid	pH effects	Increased activity of interacting drugs
allopurinol tetracycline Thyroid hormones captopril Corticosteroids digoxin Histamine antagonists phenytoin isoniazid ketoconazole methotrexate nitrofurantoin Phenothiazines Salicylates Quinolone antibiotics	Decreased GI absorption	Reduced effects of interacting drugs

Dosages

For dosage information on selected antacid drugs, see the table on p. 820.

DRUG PROFILES

antacids, general

Some of the available magnesium, aluminum, calcium, and sodium salts that are used in many of the antacid formulations are listed in Box 50-2. There are far too many individual antacid products on the market to mention all formulations. Briefly, OTC antacid formulations are available as capsules, chewable tablets, effervescent granules and tablets, powders, suspensions, and plain tablets. This allows patients a variety of options for self-medication. Pharmacokinetic parameters are not normally listed for antacids, but these drugs are generally excreted quickly through the GI tract and/or the electrolyte homeostatic mechanisms of the kidneys. Antacids are considered safe for use during pregnancy if prolonged administration and high dosages are avoided. It is recommended that pregnant women consult their health care providers before taking an antacid. Aluminum- and sodium-based antacids are often recommended for patients with renal compromise because they are more easily excreted than

DOSAGES

Selected Antacid Drugs*

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
aluminum hydroxide (Amphojel) (A)	Aluminum-containing antacid	**Adult** PO: 600-1500 mg 3-6 times per day	Hyperacidity
aluminum hydroxide and magnesium hydroxide (Maalox, Mylanta) (A)	Combination antacid	**Adult** 400-2400 mg 3-6 times per day	Hyperacidity
calcium carbonate (Tums) (A)	Calcium-containing antacid	**Adult** PO: 0.5-1.5 g prn	Hyperacidity
magnesium hydroxide (milk of magnesia) (A)	Magnesium-containing antacid	**Adult** PO: 0.65-1.3 g prn, up to 4 times per day	Hyperacidity (more commonly used as a laxative)

PO, Oral.
*Many more antacid products are available on the market than appear in this table. Dosages given are approximate dosages of active ingredients; there may be variations among different products and different dosage forms of the same product.

BOX 50-2 ANTACIDS

Antacids: Salt Content

MAGNESIUM SALTS	ALUMINUM SALTS	CALCIUM SALTS	SODIUM SALTS
Carbonate	Carbonate	Carbonate	Bicarbonate
Hydroxide	Hydroxide		Citrate

Trisilicate			

Commonly Available Antacid Products

Magnesium-Containing Antacids

Carbonate salt: Gaviscon Liquid, Gaviscon Extra Strength Relief Formula Tablets
Hydroxide salt: milk of magnesia
Oxide salt: Mag-Ox (included for information only; used primarily as a magnesium supplement)
Trisilicate salt: Gaviscon Tablets

Aluminum-Containing Antacids

Carbonate salt: Basaljel
Hydroxide salt: AlternaGEL, Amphojel
Combination products: Gaviscon, Maalox, Mylanta, Di-Gel

Calcium-Containing Antacids

Carbonate salt: Tums, Maalox Antacid Caplets, Extra Strength Alkets Antacid

Sodium-Containing Antacids

Bicarbonate salt: Alka-Seltzer
Citrate salt: Citra pH

antacids in other categories. Calcium-containing antacids are currently advertised as an extra source of calcium. Calcium carbonate neutralization will produce gas and possibly belching. For this reason, it may be combined with an antiflatulent drug such as simethicone (see the section on Miscellaneous Acid-Controlling Drugs). Magnesium-containing antacids commonly have a laxative effect, and frequent administration of these antacids alone often cannot be tolerated. Both calcium- and magnesium-based antacids are more likely to accumulate to toxic levels in patients with renal disease and are often avoided in this patient group.

H_2 RECEPTOR ANTAGONISTS

H_2 receptor antagonists, commonly abbreviated as H2RAs and also called *H_2 receptor blockers,* are the prototypical acid-secretion antagonists. These drugs reduce but do not completely abolish acid secretion. They have become the most popular drugs for the treatment of many acid-related disorders, including peptic ulcer disease. This can be attributed to their efficacy, patient acceptance, and excellent safety profile. These drugs include cimetidine, ranitidine, famotidine, and nizatidine. There is little difference among the four available H_2 receptor antagonists from the standpoint of efficacy. All are available OTC.

Mechanism of Action and Drug Effects

H_2 receptor antagonists competitively block the H_2 receptor of acid-producing parietal cells. This makes the parietal cell less responsive not only to histamine but also to the stimulation of ACh and gastrin. This is shown in Figure 50-2. Up to 90% inhibition of vagal- and gastrin-stimulated acid secretion occurs when histamine is blocked. However, complete inhibition has not been shown. The effect of these drugs is reduced hydrogen ion secretion from the parietal cells, which results in an increase in the pH of the stomach and relief of many of the symptoms associated with hyperacidity-related conditions.

Indications

H_2 receptor antagonists have several therapeutic uses, including treatment of GERD, peptic ulcer disease, and erosive esophagitis; adjunct therapy in the control of upper GI tract bleeding; and treatment of pathologic gastric hypersecretory conditions such as Zollinger-Ellison syndrome. The latter is one form of hyperchlorhydria, or excessive gastric acidity. H_2 receptor antagonists are commonly used for stress ulcer prophylaxis in critically ill patients.

Contraindications

The only usual contraindication to the use of H_2 receptor antagonists is a known drug allergy. Liver and/or kidney dysfunction are relative contraindications that may warrant dosage adjustment.

TABLE 50-2 H_2 RECEPTOR ANTAGONISTS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Hypotension (monitor for this effect with intravenous administration)
Central nervous	Headache, lethargy, confusion, depression, hallucinations, slurred speech, agitation
Endocrine	Increased prolactin secretion, gynecomastia (with cimetidine)
Gastrointestinal	Diarrhea, nausea, abdominal cramps
Genitourinary	Impotence; increased blood urea nitrogen, creatinine levels
Hepatobiliary	Elevated liver enzyme levels, jaundice
Hematologic	Agranulocytosis, thrombocytopenia, neutropenia, aplastic anemia
Integumentary	Urticaria, rash, alopecia, sweating, flushing, exfoliative dermatitis

Adverse Effects

The H_2 receptor antagonists have a remarkably low incidence of adverse effects (less than 3% of cases). The four available H_2 receptor antagonists are similar in many respects but have some differences in adverse effect profiles. Table 50-2 lists the adverse effects associated with these drugs. Central nervous system adverse effects occur in less than 1% of patients taking these drugs but are sometimes seen in elderly patients. These adverse effects include confusion and disorientation. Be alert for mental status changes when giving these drugs, especially if they are new to the patient. Cimetidine may induce impotence and gynecomastia. This is the result of cimetidine's inhibition of estradiol metabolism and displacement of dihydrotestosterone from peripheral androgen-binding sites. All four H_2 receptor antagonists may increase the secretion of prolactin from the anterior pituitary gland. Thrombocytopenia has been reported with ranitidine and famotidine.

Interactions

Cimetidine carries a higher risk of drug interactions than the other three drugs, especially in elderly patients. These interactions may be of clinical importance. Cimetidine binds enzymes of the hepatic cytochrome P-450 microsomal oxidase system. This is a group of enzymes in the liver that metabolize many different drugs. By inhibiting the metabolism of drugs metabolized via this pathway, cimetidine may raise the blood concentrations of certain drugs. Ranitidine has only 10% to 20% of the binding action of cimetidine on the P-450 system, and nizatidine and famotidine have essentially no effect. This interaction has little clinical significance for most drugs; however, significant interactions are more likely to arise with medications having a narrow therapeutic range, such as theophylline, warfarin, lidocaine, and phenytoin. All H_2 receptor antagonists may inhibit the absorption of certain drugs, such as ketoconazole, that require an acidic GI environment for gastric absorption. Smoking has also been shown to decrease the effectiveness of H_2 antagonists. For optimal results, H_2 receptor antagonists are taken 1 to 2 hours before antacids.

DOSAGES

Selected H_2 Receptor Antagonists

DRUG (PREGNANCY CATEGORY)	USUAL DOSAGE RANGE	INDICATIONS
♦ cimetidine (Tagamet, Tagamet HB) (B)	**Adult**	
	PO: 200 mg bid	Dyspepsia, heartburn
	PO: 300 mg qid or 400 mg bid and at bedtime or 800 mg at bedtime	Ulcers
	PO: 1600 mg/day divided in 2 to 4 doses	GERD
	PO/IM/IV: 300 mg tid and at bedtime; do not exceed 2400 mg/day	Pathologic hypersecretion
♦ famotidine (Pepcid, Pepcid AC) (B)	**Adult**	
	PO: 10 mg daily-bid	Dyspepsia, heartburn
	PO: 40 mg daily at bedtime or 20 mg bid	Ulcers
	PO: 20-160 mg q6h	Pathologic hypersecretion
	IV: 20 mg q12h	
	PO: 20 mg bid	GERD
ranitidine (Zantac) (B)	**Adult**	
	PO: 75 mg bid	Dyspepsia, heartburn
	PO: 150 mg daily-bid or 300 mg at bedtime	Ulcers
	PO: 150 mg bid	
	PO: 150 mg qid	Erosive esophagitis

GERD, Gastroesophageal reflux disease; *IM,* intramuscular; *IV,* intravenous; *PO,* oral.

Dosages

For dosage information on the H_2 antagonists, see the table above.

DRUG PROFILES

H_2 receptor antagonists are the prototypical acid-secretion antagonists. These drugs reduce acid secretion. They are among the most commonly used drugs in the world, due to their efficacy, OTC availability, and overall excellent safety profile. However, this drug class has been partially replaced by proton pump inhibitors (see the next section).

♦ cimetidine

In 1977, cimetidine (Tagamet) became the first drug in this class to be released on the market. It is the prototypical H_2 receptor antagonist and was the first major prescription drug to go OTC. Because of its potential to cause drug interactions, its use has been largely replaced by ranitidine and famotidine. Cimetidine is still used to treat certain allergic reactions.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	15-60 min	1-2 hr	2 hr	4-5 hr

ranitidine

Ranitidine (Zantac) was the second H_2 receptor antagonist introduced. It does not carry the concerns over drug interactions that cimetidine has and has become the most widely used H_2 receptor antagonist. It is available in oral and intravenous forms. Dosing is different for the different forms: oral ranitidine is dosed as 150 mg twice a day or 300 mg at bedtime, whereas the intravenous form is dosed at 50 mg every 8 hours.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	2-4 hr	2-3 hr	4-12 hr
IV	Immediate	Less than 15 min	2-3 hr	4-12 hr

♦ famotidine

Famotidine (Pepcid) was the last H_2 receptor antagonist introduced and, like ranitidine, has no drug interaction concerns. It is available in oral and injectable forms. The dosing is the same for both forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1.4 hr	3 hr	2.6-4 hr	9-12 hr
IV	Immediate	Less than 15 min	2.6-4 hr	9-12 hr

PROTON PUMP INHIBITORS

The newest drugs introduced for the treatment of acid-related disorders are the proton pump inhibitors (PPIs). These include lansoprazole (Prevacid), omeprazole (Prilosec), rabeprazole (AcipHex), pantoprazole (Protonix), and esomeprazole (Nexium). These drugs are even more powerful than the H_2 receptor antagonists. The PPIs bind directly to the hydrogen-potassium-ATPase pump mechanism and irreversibly inhibit the action of this enzyme, which results in a total blockage of hydrogen ion secretion from the parietal cells.

Mechanism of Action and Drug Effects

The action of the hydrogen-potassium-ATPase pump is the final step in the acid-secretory process of the parietal cell (see Figure 50-2). If chemical energy is present to run the pump, the pump will transport hydrogen ions out of the parietal cell, which increases the acid content of the surrounding gastric lumen and lowers the pH. Because hydrogen ions are protons (positively charged atoms), this ion pump is also called the *proton pump*. PPIs bind irreversibly to the proton pump. This inhibition prevents the movement of hydrogen ions out of the parietal cell into the stomach and thereby blocks all gastric acid secretion. The PPIs stop more than 90% of acid secretion over 24 hours, which makes most patients temporarily achlorhydric (without acid). However, food absorption is not affected. For acid secretion to return to normal after a PPI has been stopped, the parietal cell must synthesize new hydrogen-potassium-ATPase. Although there are other proton pumps in the body, hydrogen-potassium-ATPase is structurally and mechanically distinct from other hydrogen-transporting enzymes and appears to exist only in the parietal cells. Thus, the action of PPIs is limited to its effects on gastric acid secretion.

Indications

PPIs are currently indicated as first-line therapy for erosive esophagitis, symptomatic GERD that is poorly responsive to other medical treatment such as therapy with H_2 receptor antagonists, short-term treatment of active duodenal ulcers and active benign gastric ulcers, gastric hypersecretory conditions (e.g., Zollinger-Ellison syndrome), nonsteroidal antiinflammatory drug (NSAID)–induced ulcers, and for stress ulcer prophylaxis. Long-term therapeutic uses include maintenance of healing of erosive esophagitis and pathologic hypersecretory conditions, including both GERD and Zollinger-Ellison syndrome. All of the PPIs can be used in combination with antibiotics to treat patients with *H. pylori* infections. The PPIs can be given orally or through an NG or percutaneous enterogastric tube. For example, esomeprazole capsules may be opened, the granules dissolved in 50 mL of water, and the solution given through the tube. Similar tubal administration is also listed by the manufacturer for lansoprazole capsules and omeprazole powder for oral suspension. Consult the drug packaging for drug-specific instructions. Be aware of the particle size of the drug once it is in solution and the tube size being used. For example, pantoprazole granules are to be used with NG tubes that are larger than 16-French, and it may clog the tube if used with small tubes. Several of the PPIs are now also available for intravenous use.

Contraindications

The only usual contraindication to use of the PPIs is known drug allergy.

Adverse Effects

PPIs are generally well tolerated. The frequency of adverse effects has been similar to that for placebo or H_2 receptor antagonists. There was some early concern that long-term use of PPIs might promote malignant gastric tumors. This has not proved to be the case, however, and this initial concern has subsided. There are some concerns that these drugs may be overprescribed and may predispose patients to GI tract infections because of the reduction of the normal acid-mediated antimicrobial protection. New concerns have arisen over the potential for long-term users of PPIs to develop osteoporosis. This is thought to be due to the inhibition of stomach acid, and it is speculated that PPIs speed up bone mineral loss. The Food and Drug Administration issued a warning in 2010 regarding long-term use of high-dose PPIs, which has been associated with *Clostridium difficile* infections; risk of wrist, hip, and spine fractures; and pneumonia. In 2011, depletion of magnesium was added to the warning.

Interactions

Few drug interactions occur with the PPIs; however, they may increase serum levels of diazepam and phenytoin. There may be an increased chance of bleeding in patients who are taking both

a PPI and warfarin. Other possible interactions include interference with the absorption of ketoconazole, ampicillin, iron salts, and digoxin. When given with clopidogrel, there is some concern of an increased risk of death if the patient has acute coronary syndrome; however, recent studies have not substantiated this concern. Sucralfate may delay the absorption of PPIs. Food may decrease absorption of the PPIs, and it is recommended that they be taken on an empty stomach.

Dosages

For dosage information on selected PPIs, see the table on this page.

DRUG PROFILES

omeprazole

Omeprazole (Prilosec) was the first drug in this breakthrough class of antisecretory drugs. Omeprazole and rabeprazole are not available in injectable form. Other PPIs include lansoprazole (Prevacid), esomeprazole (Nexium), and pantoprazole (Protonix). Orally administered PPIs (and H_2 receptor antagonists) often work best when taken 30 to 60 minutes before meals. Omeprazole was the first PPI to become available generically.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2 hr	5 days	0.5-1 hr	1-5 days

lansoprazole

Lansoprazole (Prevacid) is available in a delayed-release capsule, granules for oral suspension, and orally disintegrating tablets (Prevacid SoluTab). The capsules can be opened and mixed (not crushed) with apple juice for administration via NG tube, or the SoluTab can be dissolved in water. Lansoprazole is also available as Prevpac, a combination product for the treatment of *H. Pylori* infection.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1.7 hr	4 wk	1-2 hr	24 hr

pantoprazole

Pantoprazole (Protonix) was the first PPI available for intravenous use. It was also the first drug to be used as a continuous infusion for the treatment of GI bleeding. It is available as an oral tablet and as delayed-release granules for NG administration. However, the granules are large, and the NG tube must be at least size 16-French or the granules may clog the tube.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	2.5 hr	2-2.5 hr	1 hr	7 days
IV	End of infusion	End of infusion	1 hr	7 days

DOSAGES

Selected Proton Pump Inhibitors

DRUG (PREGNANCY CATEGORY)	USUAL DOSAGE RANGE	INDICATIONS
lansoprazole (Prevacid) (B)	**Adult** PO: 30 mg daily	GERD, ulcer, erosive esophagitis
omeprazole (Prilosec) (C)	**Adult** PO: 20 mg/day for 4-8 wk PO: 60 mg PO once daily initially, then titrated and given in single or multiple daily doses, with dosage titration up to a maximum of 120 mg PO tid	Esophagitis, duodenal ulcer Hypersecretory conditions
pantoprazole (Protonix) (B)	**Adult** PO/IV: 20-80 mg/day depending on indication	GERD, ulcer, stress ulcer prophylaxis

GERD, Gastroesophageal reflux disease; *IV,* intravenous; *PO,* oral.

MISCELLANEOUS ACID-CONTROLLING DRUGS

There are a few other acid-controlling drugs that are unique in terms of their mechanisms and other features. These include sucralfate, misoprostol, and simethicone. They are profiled individually in the following paragraphs. Other drugs are bismuth subsalicylate (Pepto-Bismol; see Chapter 51) and metoclopramide (see Chapter 52).

DRUG PROFILES

♦ sucralfate

Sucralfate (Carafate) is a drug used as a mucosal protectant in the treatment of active stress ulcerations and in long-term therapy for peptic ulcer disease. Sucralfate acts locally, not systemically, binding directly to the surface of an ulcer. Sucralfate has as its basic structure a sugar, sucrose. Once sucralfate comes into contact with the acid of the stomach, it begins to dissociate into aluminum hydroxide (an antacid) and sulfate anions. The aluminum salt stimulates secretion of both mucus and bicarbonate base. The sulfated sucrose molecules of sucralfate are attracted to and bind to positively charge tissue proteins at the bases of ulcers and erosions, forming a protective barrier that can be thought of as a liquid bandage. By binding to the exposed proteins of ulcers and erosions, sucralfate also limits the access of pepsin. Pepsin is an enzyme that normally breaks down proteins in food but can have the same effect on GI epithelial tissue, either causing ulcers or making them worse. Sucralfate also binds and concentrates epidermal growth factor, present in the gastric tissues, which promotes ulcer healing. In addition, the drug stimulates the gastric secretion of prostaglandin molecules, which serve a mucoprotective function. Despite its many beneficial actions, sucralfate has fallen out of common use because its effects are transient and multiple daily dosing (up to four times daily) is therefore needed. It is indicated for stress ulcers, esophageal erosions, and peptic ulcer disease. The only usual contraindication to sucralfate use is known drug

allergy. Adverse effects are uncommon but include nausea, constipation, and dry mouth. Only minimal systemic absorption occurs, and the drug is virtually inert. Sucralfate does not display typical pharmacokinetic parameters, and, as such, no pharmacokinetic table is listed. Drug interactions mainly involve physical interference with the absorption of other drugs. This can be alleviated by taking other drugs at least 2 hours ahead of sucralfate. Sucralfate is also best given 1 hour before meals and at bedtime. It is classified as a pregnancy category B drug that is normally dosed at 1 g orally four times daily.

misoprostol

Misoprostol (Cytotec), a prostaglandin E analogue, has been shown to effectively reduce the incidence of gastric ulcers in patients taking NSAIDs (see Chapter 44). Prostaglandins have a wide variety of biologic activities. They are thought to inhibit gastric acid secretion. They are also believed to protect the gastric mucosa from injury (cytoprotective function), possibly by enhancing the local production of mucus or bicarbonate, by promoting local cell regeneration, and by helping to maintain mucosal blood flow. Use of misoprostol is contraindicated in patients with known drug allergy and in pregnant women (see later in the chapter). Adverse effects include headache, GI distress, and vaginal bleeding. There are no major drug interactions, although antacids may reduce drug absorption.

Although some studies show that synthetic analogues of prostaglandins promote the healing of duodenal ulcers, the drugs must be used in dosages that usually produce disturbing adverse effects, such as abdominal cramps and diarrhea. Thus, they are not believed to be as effective as H_2 receptor antagonists and PPIs for this indication. Misoprostol is also used for its abortifacient properties as discussed in Chapter 34. For this reason, it is classified a pregnancy category X drug. The usual dosage is 200 mcg four times daily with meals for the duration of NSAID therapy in patients at high risk for ulceration.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30 min	12 min	20-40 min	1-2 days

simethicone

Simethicone (Mylicon) is used to reduce the discomforts of gastric or intestinal gas (flatulence) and aid in its release via the mouth or rectum. It is therefore classified as an antiflatulent drug. Gas commonly appears in the GI tract as a consequence of the swallowing of air as well as normal digestive processes. Gas in the upper GI tract is composed of swallowed air and thus consists largely of nitrogen. It is usually expelled from the body by belching. The composition of flatus, however, is determined largely by the dietary intake of carbohydrates and the metabolic activity of the bacteria in the intestines.

Some foods, including legumes (beans) and cruciferous vegetables (e.g., cauliflower, broccoli), are well known for their gas-producing ability. Gas can also result from disorders such as diverticulitis, dyspepsia (heartburn), peptic ulcers, and spastic or irritable colon; gaseous distention can also occur postoperatively. Simethicone works by altering the elasticity of mucus-coated gas bubbles, which causes them to break into smaller ones. This reduces gas pain and facilitates the expulsion of gas via the mouth or rectum. Simethicone has no listed adverse effects, drug interactions, or pharmacokinetic parameters. It is available only for oral use. The usual simethicone dosage is 1 to 2 tablets four to six times daily as needed. A variety of different simethicone products are available for OTC use.

NURSING PROCESS

ASSESSMENT

Before an *acid-controlling drug* is given, perform a thorough patient assessment with attention to past and present medical history with special focus on GI tract–related disorders and signs and symptoms of ulcer disease and GERD. Assess current bowel patterns, any change in bowel patterns or GI tract functioning, and GI tract–related pain. Document the findings. Assess results of baseline serum chemistry laboratory tests, as ordered, with specific attention to hepatic function (e.g., serum ALP, ALT, AST levels) and renal function (serum creatinine and BUN levels). Assess for contraindications, cautions, and drug interactions. The knowledge that acid-controlling drugs have many interactions must spark your close attention to all medications the patient is taking. This underscores the importance of obtaining a medication history that includes information about prescription drugs, OTCs, and herbals. Other components of assessment include performing a physical examination and taking a thorough cardiac history with close attention to a history of heart failure, hypertension, other cardiac diseases, the presence of edema, fluid and electrolyte imbalances and/or or renal disease. One reason it is important to assess for these conditions is that the high sodium content of various antacids may lead to exacerbation of cardiac problems, renal dysfunction, and fluid-electrolyte problems.

When *antacids* containing aluminum and/or magnesium are used, identify all other medications the patient is taking. It is important to note that combination products containing both magnesium and aluminum may have fewer adverse effects than either type of antacid by itself. For example, aluminum-containing antacids are associated with constipation, whereas magnesium-containing antacids may lead to diarrhea. The net effect of a combination of these antacids is a balancing out of both adverse effects and fewer problems with altered bowel patterns. Calcium-based antacids may also be used, especially as a source of calcium; however, they carry the risks of rebound hyperacidity, milk-alkali syndrome, and changes in systemic pH, especially if the patient has abnormal renal functioning (see Box 50-1). Sodium bicarbonate is generally not recommended as an antacid because of the high risk for systemic electrolyte disturbances and alkalosis. The sodium content of sodium bicarbonate is also high, which is very problematic for patients who have hypertension, heart failure, or renal insufficiency.

For patients using *H_2 receptor antagonist drugs,* assess renal and liver function as well as level of consciousness because

of possible drug-related adverse effects. Elderly patients are known to react to these drugs with more disorientation and confusion. Do not administer drugs such as cimetidine and famotidine simultaneously with antacids. These drugs may be spaced 1 hour apart if both drugs need to be given. In patients taking nizatidine or ranitidine, assess baseline blood chemistry results with attention to levels of BUN, creatinine, bilirubin, ALP, AST, and ALT to document renal and hepatic functioning before treatment is initiated.

For *PPIs* (e.g., lansoprazole, omeprazole, and pantoprazole), assess swallowing capacity because of the size of some of the oral capsules. Assess of the patient's medical history with an emphasis on any history of GI tract infections due to decreased acid-mediated antimicrobial protection. Since there are documented concerns about the use of PPIs and the development of osteoporosis, thoroughly assess patients for any history of this disorder. Drug interactions have been discussed previously in the pharmacology section, but important to mention are the interactions with diazepam, phenytoin, warfarin, ampicillin, and iron salts. Always check the patient's medication list before these or any other types of medication are given.

Other GI related drugs include sucralfate and simethicone. The use of simethicone (an antiflatulent) and sucralfate (an ulcer adherent) requires assessment of the patient's bowel patterns and bowel sounds. Assess for abdominal distention and rigidity, which may indicate a medical emergency. Treatment of peptic ulcer disease has become focused on the use of antibiotics (to attack the *H. pylori* bacteria) with frequent dosing of other drugs. Inquire also about the presence of any unusual signs and symptoms related to the GI tract.

NURSING DIAGNOSES

1. Constipation related to the adverse effects of aluminum-containing antacids and other drugs used to treat hyperacidity
2. Diarrhea related to the adverse effects of magnesium-containing antacids and other drugs used to treat hyperacidity
3. Deficient knowledge related to lack of information about antacids, H_2 receptor antagonists, or PPIs, including their use and potential adverse effects

PLANNING

GOALS

1. Patient experiences minimal to no constipation while using antacids and/or other acid-controlling drugs.
2. Patient experiences minimal to no diarrhea during antacid and/or acid-controlling medication regimen.
3. Patient demonstrates adequate knowledge about use of antacid and/or acid-controlling medications and expected adverse effects.

OUTCOME CRITERIA

1. Patient states measures to help prevent and minimize adverse effect of constipation, such as taking the antacid only as directed and taking combination aluminum/magnesium products.
2. Patient states measures to help prevent and minimize the adverse effect of diarrhea such as avoiding magnesium-only antacids, especially milk of magnesia, and taking combination aluminum/magnesium products.
3. Patient states the purpose of taking antacids, H_2 receptor antagonists, and PPIs for management of gastric hyperacidity.
   - Patient describes the various adverse effects associated with antacids such as diarrhea, constipation, and acid rebound.
   - Patient describes the expected adverse effects associated with other acid-controlling drugs such as constipation, diarrhea, headache, and confusion, and seeks advice from the prescriber if adverse effects worsen or are not relieved after several days.

CASE STUDY

Proton Pump Inhibitors

A 50-year-old attorney has self-treated for heartburn for years by drinking large amounts of antacids. She finally made an appointment with her family practice physician, who referred her to a gastroenterologist. Her family practice physician instructed her to stop taking the antacids.

1. Why did the physician ask her to stop taking the antacids?

In a few weeks, the attorney had an endoscopy, and it was discovered that she had gastroesophageal reflux disease (GERD) and gastritis secondary to stress-induced hyperacidity. The physician has prescribed the proton pump inhibitor (PPI) omeprazole (Prilosec) 20 mg once a day.

2. What other conditions will the gastroenterologist test for during this diagnostic stage?
3. What is the rationale for the use of PPIs to treat GERD?
4. What patient teaching is important regarding the PPI?

For answers, see http://evolve.elsevier.com/Lilley.

IMPLEMENTATION

When giving *acid-controlling drugs,* instruct the patient to thoroughly chew the chewable tablets and to thoroughly shake liquid forms before they are taken. *Antacids* need to be given with at least 8 oz of water to enhance absorption of the antacid in the stomach, except for newer forms that are rapidly dissolving drugs. If constipation or diarrhea occurs with single-component drugs, a combination aluminum- and magnesium-based product may be preferred. Educate the patient about the adverse effects of aluminum-only or magnesium-only products. It is also recommended that antacids be given as ordered but not within 1 to 2 hours of other medications because of the effect of antacids on the absorption of oral medications. You may safely implement this dosing schedule without interrupting the safe dosing of other medications. The dosing will differ if

the prescriber has ordered the drug to be given with antacids. With quinolone antibiotics, there may be serious harm if given with antacids because of a 50% reduction in antibiotic absorption. Serious infections may then go unsuccessfully treated due to altered absorption. Antacid overuse or misuse or the rapid discontinuation of antacids with high acid-neutralizing capacity may lead to acid rebound. Therefore, antacids are only to be used as prescribed and/or as directed.

Because so many *H_2 receptor antagonists* and other acid-controlling drugs are now available OTC, instruct the patient about proper use (see the Patient Teaching Tips for more information). For example, cimetidine is to be taken with meals, and antacids, if also used, need to be taken 1 to 2 hours after the cimetidine. Intravenous dosing and related mixing and infusing for intravenous cimetidine are similar to those described later for intravenous famotidine. Famotidine may be given orally in tablet or suspension form and without regard to meals or food. Rapid-release forms of famotidine dissolve quickly under the patient's tongue and can be taken without water. Give ranitidine as ordered, and, if administered with antacids, give 1 to 2 hours before the antacid. Dilute intravenous forms of famotidine or ranitidine with appropriate solutions and infuse over the documented time frame. With intravenous H_2 receptor antagonists, hypotension may occur with rapid infusion, so careful monitoring is critical to patient safety. Refer to appropriate sources for information on other specific drugs and their intravenous administration. For all H_2 receptor antagonists, monitor blood pressure readings as needed during intravenous infusion because of the risk of hypotension. Continue to monitor the patient for GI tract bleeding with the diagnosis of ulcers or GI irritation. Report any blood in the stools or the occurrence of black, tarry stools or hematemesis. Listen to bowel sounds and examine the abdomen to monitor for possible complications.

With *PPIs,* give lansoprazole oral dosage forms as ordered. If the patient has difficulty swallowing these capsules, a capsule may be opened and the granules sprinkled over at least a tablespoon of applesauce, which then must be swallowed immediately. Administer omeprazole before meals, and educate the patient that the capsule must be taken whole and not crushed, opened, or chewed. Omeprazole may also be given with antacids, if ordered. Always double-check the names and dosages of these drugs to ensure that they are not confused with similarly named drugs. Pantoprazole may be given orally without crushing or splitting of the tablet form. Give intravenous dosage forms exactly as ordered using the correct dilutional fluids. Infuse over the recommended time period.

Other GI related drugs, such as simethicone, may also be added to the oral medication protocol with PPIs. Simethicone is usually well tolerated. It is to be taken after meals and at bedtime. Instruct patients to thoroughly chew the tablets or to shake suspensions well before use. Sucralfate is usually given 1 hour before meals and at bedtime. Tablets may be crushed or dissolved in water, if needed. Antacids are to be avoided for 30 minutes before or after administration of sucralfate. Misoprostol is to be given with food and is usually ordered to be taken with meals and at bedtime. Suggestions for drug-related patient education are presented in the Patient Teaching Tips.

EVALUATION

Therapeutic response to the administration of *antacids, H_2 receptor antagonists, PPIs,* and *other GI-related drugs* includes the relief of symptoms associated with peptic ulcer, gastritis, esophagitis, gastric hyperacidity, or hiatal hernia (i.e., decrease in epigastric pain, fullness, and abdominal swelling). Adverse effects for which to monitor include all of those listed for each of the drug categories and range from constipation or diarrhea to nausea, vomiting, abdominal pain, and hypotension. Milk-alkali syndrome, acid rebound, hypercalcemia, and metabolic alkalosis are known complications associated with the various antacids; evaluate the patient for these adverse effects and take measures to prevent or resolve them.

PATIENT TEACHING TIPS

- Medications are not to be taken, unless prescribed, within 1 to 2 hours of taking an antacid because of their impact on the absorption of many medications in the stomach.
- Advise the patient to contact the prescriber immediately if he or she experiences severe or prolonged constipation and/or diarrhea; increase in abdominal pain; abdominal distension; nausea; vomiting; hematemesis; or black, tarry stools (a sign of possible GI tract bleeding).
- If the patient is taking enteric-coated medications, tell the patient that the use of antacids may promote premature dissolution of the enteric coating. Enteric coatings are used to diminish the stomach upset caused by irritating medications, and if the coating is destroyed early in the stomach, gastric upset may occur.
- Encourage the patient to take H_2 receptor antagonists exactly as prescribed. Inform the patient that smoking decreases the drug's effectiveness. Advise that patient that H_2 receptor antagonists are not to be taken within 1 hour of antacids.
- Advise the patient to take omeprazole and other PPIs before meals. Inform the patient that if lansoprazole is being used, the granules may be sprinkled from the capsule into a tablespoon of applesauce if needed.
- Instruct the patient to follow the manufacturer's directions when taking simethicone. Chewable forms must always be chewed thoroughly; liquid preparations need to be shaken thoroughly before administration. Encourage patients experiencing flatulence to avoid problematic foods (e.g., spicy, gas-producing foods) and carbonated beverages.

PATIENT TEACHING TIPS—cont'd

- Sucralfate must be taken on an empty stomach, and antacids are to be avoided or, if indicated, taken 2 hours before or 1 hour after sucralfate administration.
- For a patient taking the drug regimen for the treatment of *H. pylori* infection–peptic ulcer disease, it is important to emphasize the need to take each drug, including the antibiotics, exactly as prescribed and without fail to guarantee successful treatment. If treatment protocols are not followed appropriately, the condition may likely recur.

KEY POINTS

- The stomach secretes many substances (hydrochloric acid, pepsinogen, mucus, bicarbonate, intrinsic factor, and prostaglandins).
- The parietal cell is responsible for the production of acid.
- In acid-related disorders, there is an impairment of the balance among the substances secreted by the stomach.
- H_2 receptor antagonists are H_2 blockers that bind to and block histamine receptors located on parietal cells. This blockade renders these cells less responsive to stimuli and thus decreases their acid secretion. Up to 90% inhibition of acid secretion can be achieved with the H_2 receptor antagonists.
- PPIs block the final step in the acid production pathway, the hydrogen-potassium-ATPase pump and they block all acid secretion.
- Sucralfate is used for the treatment of peptic ulcer disease and stress-related ulcers. It binds to tissue proteins in the eroded area and prevents exposure of the ulcerated area to stomach acid.
- Misoprostol is a synthetic prostaglandin analogue that inhibits gastric acid secretion and is used to prevent NSAID-related ulcers.
- Cautious use of antacids is recommended in patients who have heart failure, hypertension, or other cardiac diseases or who require sodium restriction, especially if the antacid is high in sodium.
- Many drug interactions occur with the acid-controlling drugs due to alteration of oral dosage forms, and so other medications are to be avoided within 1 to 2 hours of taking an antacid. Antacids are sometimes to be avoided when other acid-controlling drugs are taken.
- Magnesium-aluminum combination antacids are used to prevent the adverse effects of constipation and diarrhea. Some of the more serious concerns with antacids include acid rebound, hypercalcemia, milk-alkali syndrome, and metabolic alkalosis.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A 30-year-old man is taking simethicone for excessive flatus associated with diverticulitis. During a patient teaching session, the nurse explains the mechanism of action of simethicone by saying:
   - **a** "It neutralizes gastric pH, thereby preventing gas."
   - **b** "It buffers the effects of pepsin on the gastric wall."
   - **c** "It decreases gastric acid secretion and thereby minimizes flatus."
   - **d** "It causes mucus-coated gas bubbles to break into smaller ones."

2 When evaluating the medication list of a patient who will be starting therapy with an H_2 receptor antagonist, the nurse is aware that which drug may interact with it?
   - **a** codeine
   - **b** penicillin
   - **c** ketoconazole
   - **d** acetaminophen

3 When administering sucralfate, which action by the nurse is most correct?
   - **a** Giving the drug with meals
   - **b** Giving the drug on an empty stomach
   - **c** Instructing the patient to restrict fluids
   - **d** Waiting 30 minutes before administering other drugs

4 A patient with a history of renal problems is asking for advice about which antacid he should use. The nurse will make which recommendation?
   - **a** "Patients with renal problems cannot use antacids."
   - **b** "Aluminum-based antacids are the best choice for you."
   - **c** "Calcium-based antacids are the best choice for you."
   - **d** "Magnesium-based antacids are the best choice for you."

5 A patient who is taking oral tetracycline complains of heartburn and requests an antacid. Which action by the nurse is correct?
   - **a** Give the tetracycline, but delay the antacid for 1 to 2 hours.
   - **b** Give the antacid, but delay the tetracycline for at least 4 hours.
   - **c** Administer both medications together.
   - **d** Explain that the antacid cannot be given while the patient is taking the tetracycline.

NCLEX® EXAMINATION REVIEW QUESTIONS—cont'd

6 When the nurse is administering a proton pump inhibitor (PPI), which actions by the nurse are correct? (Select all that apply.)
- **a** Giving the PPI on an empty stomach
- **b** Giving the PPI with meals
- **c** Making sure the patient does not crush or chew the capsules
- **d** Instructing the patient to open the capsule and chew the contents for best absorption
- **e** Administering the PPI only when the patient complains of heartburn

7 The order reads: "Give cimetidine (Tagamet) 300 mg in 100 mL normal saline IVPB tid and at bedtime. Infuse over 30 minutes." The infusion pump can only be programmed to deliver over 60 minutes (mL per hour). The nurse will set the pump to deliver how many mL/hour for each IVPB dose?

1. d, 2. c, 3. b, 4. b, 5. a, 6. a, c, 7. 200 mL/hour

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the anatomy and physiology of the gastrointestinal tract, including the process of peristalsis.
2 Identify the various factors affecting bowel elimination and/or bowel patterns.
3 List the various groups of drugs used to treat alterations in bowel elimination, specifically diarrhea, constipation, and irritable bowel syndrome (IBS).
4 Discuss the mechanisms of action, indications, cautions, contraindications, drug interactions, dosages, routes of administration, and adverse effects of the various antidiarrheals, probiotics, laxatives, and IBS drugs.
5 Develop a nursing care plan that includes all phases of the nursing process for patients taking antidiarrheals, probiotics, laxatives, and IBS drugs.

KEY TERMS

Antidiarrheal drugs Drugs that counter or combat diarrhea. (p. 830)
Constipation A condition of abnormally infrequent and difficult passage of feces through the lower gastrointestinal tract. (p. 833)
Diarrhea The abnormally frequent passage of loose stools. (p. 830)
Irritable bowel syndrome (IBS) A recurring condition of the intestinal tract characterized by bloating, flatulence, and often periods of diarrhea that alternate with periods of constipation. (p. 838)
Laxatives Drugs that promote bowel evacuation, such as by increasing the bulk of the feces, softening the stool, or lubricating the intestinal wall. (p. 833)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Diarrhea and the diseases associated with it account for 5 to 8 million deaths per year in infants and small children and are among the leading causes of death and morbidity in underdeveloped nations. The key symptoms of gastrointestinal (GI) disease are abdominal pain, nausea and/or vomiting, and diarrhea. **Diarrhea** is defined as the passage of stools with abnormally increased frequency, fluidity, and weight, or increased stool water excretion. Acute diarrhea refers to diarrhea of sudden onset in a previously healthy individual. It lasts from 3 days to 2 weeks and is self-limiting, resolving without sequelae. Chronic diarrhea lasts for longer than 3 to 4 weeks and is associated with recurrent passage of diarrheal stools, possible fever, nausea, vomiting, weight reduction, and chronic weakness.

The probable cause of diarrhea needs to be taken into consideration when designing a drug regimen to treat it. Causes of acute diarrhea include drugs, bacteria, viruses, nutritional factors, and protozoa. Causes of chronic diarrhea include tumors, acquired immunodeficiency syndrome (AIDS), diabetes mellitus, hyperthyroidism, Addison's disease, and irritable bowel syndrome (IBS). Treatment is aimed at stopping the stool frequency, alleviating the abdominal cramps, replenishing fluids and electrolytes, and preventing weight loss and nutritional deficits from malabsorption. Often, replacement of fluids is the only treatment needed. Patients with diarrhea associated with a bacterial or parasitic infection must not use antidiarrheal drugs, because this will cause the organism to stay in the body longer and will prolong recovery.

PHARMACOLOGY OVERVIEW

ANTIDIARRHEALS

Drugs used to treat diarrhea are called **antidiarrheal drugs.** Based on the specific mechanism of action, they are divided into different groups: adsorbents, antimotility drugs (anticholinergics and opiates), and probiotics (also known as *intestinal flora modifiers* and *bacterial replacement drugs*). The specific classes and the drugs in each are listed in Table 51-1. Antidiarrheal and laxative drugs do not have the classic pharmacokinetics of other drugs, and thus pharmacokinetics tables such as those presented throughout the book are not included in this chapter.

TABLE 51-1 ANTIDIARRHEALS: DRUG CATEGORIES AND SELECTED DRUGS

CATEGORY	ANTIDIARRHEAL DRUGS
Adsorbents	Activated charcoal, aluminum hydroxide, bismuth subsalicylate, cholestyramine, polycarbophil
Anticholinergics	Atropine, hyoscyamine
Opiates	Opium tincture, paregoric, codeine, diphenoxylate, loperamide
Probiotics and intestinal flora modifiers	*Lactobacillus acidophilus, Lactobacillus GG, Saccharomyces boulardii*

Mechanism of Action and Drug Effects

Antidiarrheal drugs have varying mechanisms of action. Adsorbents act by coating the walls of the GI tract. They bind the causative bacteria or toxin to their adsorbent surface for elimination from the body through the stool. Adsorption is similar to absorption but differs in that it involves the chemical binding of substances (e.g., ions, bacterial toxins) onto the surface of an adsorbent. In contrast, absorption refers to the penetration of a substance into the interior structure of the absorbant or the uptake of a substance across a surface (e.g., the absorption of dietary nutrients into the intestinal villi). The adsorbent bismuth subsalicylate is a form of aspirin, or acetylsalicylic acid, and therefore it also has many of the same drug effects as aspirin (see Chapter 44). Activated charcoal not only is helpful in coating the walls of the GI tract and adsorbing bacteria but also is useful in cases of overdose because of its drug-binding properties. The antilipemic drugs colestipol and cholestyramine (see Chapter 27) are anion exchange resins that are sometimes prescribed as antidiarrheal adsorbents and lipid-lowering drugs. Besides binding to diarrhea-causing toxins, they have the additional benefit of decreasing cholesterol levels.

Anticholinergic drugs work to slow peristalsis by reducing the rhythmic contractions and smooth muscle tone of the GI tract; they also have a drying effect and reduce gastric secretions. They are used in combination with adsorbents and opiates (see later in the chapter). Anticholinergics are discussed in detail in Chapter 21.

Probiotics are products obtained from bacterial cultures, most commonly *Lactobacillus* organisms, which make up the majority of the body's normal bacterial flora. These organisms are commonly destroyed by antibiotics. Probiotics work by replenishing these bacteria, which helps to restore the balance of normal flora and suppress the growth of diarrhea-causing bacteria.

The primary action of *opiates* (see Chapter 10) in diarrhea treatment is to reduce bowel motility. A secondary effect that makes opiates beneficial in the treatment of diarrhea is reduction of the pain associated with diarrhea by relief of rectal spasms. Because they decrease the transit time of food through the GI tract, they permit longer contact of the intestinal contents with the absorptive surface of the bowel, which increases the absorption of water, electrolytes, and other nutrients from the bowel and reduces stool frequency and net volume.

Indications

Antidiarrheal drugs are indicated for the treatment of diarrhea of various types and levels of severity. Adsorbents are more likely to be used in milder cases, whereas anticholinergics and opiates tend to be used in more severe cases. Probiotics are often helpful in patients with antibiotic-induced diarrhea.

Contraindications

Contraindications to the use of antidiarrheals include known drug allergy and any major acute GI condition, such as intestinal obstruction or colitis, unless the drug is ordered by the patient's prescriber after careful consideration of the specific case.

Adverse Effects

The adverse effects of the antidiarrheals are specific to each drug family. Most of these potential effects are minor and are not life threatening. The major adverse effects of specific drugs in each drug class are listed in Table 51-2. Probiotics do not have any listed adverse effects.

Interactions

Many drugs are absorbed from the intestines into the bloodstream, where they are delivered to their respective sites of action. A number of the antidiarrheals have the potential to alter this normal process, by either increasing or decreasing the absorption of these other drugs.

The adsorbents can decrease the effectiveness of many drugs, primarily by decreasing the absorption of certain drugs. Examples include digoxin, quinidine, and hypoglycemic drugs. The oral anticoagulant warfarin (see Chapter 26) is more likely to cause increased bleeding times or bruising when coadministered with adsorbents. This is thought to be because the adsorbents bind to vitamin K, which is needed to make certain clotting factors. Vitamin K is synthesized by the normal bacterial flora in the bowel. The toxic effects of methotrexate are more likely to occur when it is given with adsorbents.

The therapeutic effects of the anticholinergic antidiarrheals can be decreased by coadministration with antacids. Amantadine, tricyclic antidepressants, monoamine oxidase inhibitors, opiates, and antihistamines, when given with anticholinergics, can result in increased anticholinergic effects. The opiate antidiarrheals have additive central nervous system (CNS) depressant effects if they are given with CNS depressants, alcohol, opioids, sedative-hypnotics, antipsychotics, or skeletal muscle relaxants.

Bismuth subsalicylate can lead to increased bleeding times and bruising when administered with warfarin as well as aspirin and other nonsteroidal antiinflammatory drugs. It can also cause confusion in the elderly. Cholestyramine, when administered with glipizide, can result in decreased hypoglycemic effects. Cholestyramine also decreases the absorption of any drug that is given within 2 hours of it. It is important not to give any drug within 2 hours before or 2 hours after cholestyramine.

Dosages

For dosage information on the antidiarrheal drugs, see the table on p. 832.

TABLE 51-2 SELECTED ANTIDIARRHEALS: ADVERSE EFFECTS

DRUG	ADVERSE EFFECTS
bismuth subsalicylate	Increased bleeding time, constipation, dark stools, confusion, tinnitus, metallic taste, blue gums
atropine, hyoscyamine	Urinary retention, impotence, headache, dizziness, anxiety, drowsiness, bradycardia, hypotension, dry skin, flushing, blurred vision
codeine, diphenoxylate	Drowsiness, dizziness, lethargy, nausea, vomiting, constipation, hypotension, urinary retention, flushing, respiratory depression

DRUG PROFILES

Drug therapy for diarrhea depends on the specific cause of the diarrhea (if known). All antidiarrheals are orally administered drugs available as suspensions, tablets, or capsules. Some antidiarrheals are over-the-counter (OTC) medications, whereas others require a prescription.

ADSORBENTS

bismuth subsalicylate

Even though it is available OTC, it should be used with caution in children and teenagers who have or are recovering from chickenpox or influenza because of the risk of Reye's syndrome (see the Patient-Centered Care: Lifespan Considerations for the Pediatric Patient box). It can also cause all of the adverse effects that are associated with an aspirin-based product (see Chapter 44). Two alarming but harmless adverse effects are temporary darkening of the tongue and the stool. Bismuth subsalicylate is available OTC for oral use.

ANTICHOLINERGICS

The anticholinergics atropine and hyoscyamine are used either alone or in combination with other antidiarrheals because they slow GI tract motility. These drugs are referred to as *belladonna alkaloids* and are discussed in Chapter 21. Their safety margin is not as wide as that of many of the other antidiarrheals, because they can cause serious adverse effects if used inappropriately. For this reason, they are available only by prescription.

belladonna alkaloid combinations

Belladonna alkaloids can be used to treat many GI disorders, including diarrhea; however, their use is limited. Donnatal is the most commonly used drug in this class. Use of the belladonna alkaloid preparations is contraindicated in patients who have shown a hypersensitivity to anticholinergics and in patients with narrow-angle glaucoma, GI obstruction, myasthenia gravis, paralytic ileus, and toxic megacolon. Donnatal tablets contain a combination of four different alkaloids: atropine, hyoscyamine, phenobarbital, and scopolamine. Available dosage forms of this combination include elixir, tablets, and extended-release tablets. Donnatal Extentabs contain increased amounts of the aforementioned ingredients. Belladonna alkaloid preparations are classified as pregnancy category C to X drugs, depending on the ingredients of the specific product.

OPIATES

There are five opiate-related antidiarrheal drugs: codeine, diphenoxylate with atropine, loperamide, paregoric, and tincture of opium. The only opiate-related antidiarrheal that is available as an OTC medication is loperamide; all others are prescription-only drugs because of the risks of respiratory depression and dependency associated with opiate use. Numerous medication errors and deaths have been reported with paregoric and tincture of opium. For those reasons, their use is very limited.

♦ diphenoxylate with atropine

Diphenoxylate (Lomotil, Lonox) is a synthetic opiate agonist that is structurally related to meperidine. It acts on smooth

DOSAGES

Selected Antidiarrheal Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS/ INDICATION	USUAL DOSAGE RANGE	ONSET OF ACTION
belladonna alkaloids/phenobarbital combinations (Donnatal Elixir, Donnatal capsules and tablets, Donnatal Extentabs) (C to X)	Fixed-combination anticholinergic/diarrhea	**Adult** PO: Donnatal Elixir, 5-10 mL tid-qid Donnatal capsules and tablets, 1-2 caps or tabs tid-qid PO: Donnatal Extentabs, 1 tab q8-12h	1-2 hr
bismuth subsalicylate (Pepto-Bismol) (D)	Antimicrobial, antidiarrheal/diarrhea	Doses repeated q30-60 min, not to exceed 8 per day; all doses PO **Pediatric 3-5 yr*** 5 mL or ⅓ tab **Pediatric 6-12 yr*** 10 mL or ⅔ tab **Adult** 30 mL or 2 tab	0.5-2 hr
♦ diphenoxylate with atropine (Lomotil) (C)	Opioid with anticholinergic/diarrhea	**Pediatric 2-12 yr** 0.3-0.4 mg/kg/day in 4 divided doses; use oral solution in children. **Adult** Initially 5 mg (2 tabs) 3-4 × per day, then reduce to 2.5 mg (1 tab) 3-4 × per day as needed. (max of 8 tabs/day)	40-60 min
Lactobacillus acidophilus (Bacid, Lactinex) (A)	Probiotic/dietary supplementation,† diarrhea, need for bacterial replacement	**Adult** PO (Bacid): 2 caps bid-qid PO (Lactinex): 1 packet granules with liquid or food tid-qid; 4 tabs tid-qid with liquid or food	Unknown
♦ loperamide (Imodium A-D) (B)	Opiate antidiarrheal/diarrhea	**Pediatric 2-5 yr** PO: 1 mg tid (liquid only) **Pediatric 6-8 yr (21.8-26.8 kg)** PO: 2 mg after the first unformed stool, followed by 1 mg PO after each subsequent unformed stool; not to exceed 4 mg/day for 2 days **Pediatric 9-12 yr (27.3-43.2 kg)** PO: 2 mg after the first unformed stool, followed by 1 mg PO after each subsequent unformed stool; not to exceed 6 mg/day for 2 days **Adult** PO: 4 mg followed by 2 mg after each BM (not to exceed 16 mg/day)	1-3 hr

BM, Bowel movement; *PO,* oral.
*Used with caution in children and teenagers who have or are recovering from chickenpox or influenza because of the risk of Reye's syndrome.
†Often used to treat uncomplicated diarrhea, although this is an off-label (non–U.S. Food and Drug Administration approved) use.

muscle of the intestinal tract, inhibiting GI motility and excessive GI propulsion. It has little or no analgesic activity; however, because it is an opioid, abuse and physical dependence may occur. Diphenoxylate is combined with subtherapeutic quantities of atropine to discourage its use as a recreational opiate drug. The amount of atropine present in the combination is too small to interfere with the conjugated diphenoxylate. When taken in large dosages, however, the combination results in extreme anticholinergic effects (e.g., dry mouth, abdominal pain, tachycardia, blurred vision).

Use of the combination of diphenoxylate and atropine is contraindicated in patients experiencing diarrhea associated with pseudomembranous colitis or toxigenic bacteria. It is available only for oral use.

♦ loperamide

Loperamide (Imodium A-D) is a synthetic antidiarrheal that is similar to diphenoxylate. It inhibits both peristalsis in the intestinal wall and intestinal secretion, thereby decreasing the number of stools and their water content. Although the drug exhibits many characteristics of the opiate class, physical dependence on loperamide has not been reported. Because of its safety profile, it is the only opiate antidiarrheal drug that is available as an OTC medication. Loperamide use is contraindicated in patients with severe ulcerative colitis, pseudomembranous colitis, and acute diarrhea associated with *Escherichia coli.*

PROBIOTICS

Probiotics suppress the growth of diarrhea-causing bacteria and reestablish the flora that normally resides in the intestine. Most commonly, they are bacterial cultures of *Lactobacillus* organisms. Probiotics are often referred to as *intestinal flora modifiers*. Their mechanism of action is not completely understood, but the general benefits are suppression of growth or invasion by pathogenic bacteria, improvement of intestinal barrier function, modulation of the immune system, and modulation of pain perception.

Lactobacillus

Lactobacillus acidophilus (Bacid) and *Lactobacillus GG* (Culturelle) are acid-producing bacteria prepared in a concentrated,

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

Antidiarrheal Preparations

- If diarrhea is accompanied by fever, malaise, or abdominal pain, contact the prescriber immediately because of the possibility of excessive fluid and electrolyte loss. Dehydration and electrolyte loss occur very rapidly in the pediatric patient because of the patient's size and sensitivity to loss of fluid volume and electrolytes through the stool.
- Always contact the prescriber or pharmacist for the proper dosage of antidiarrheals if the child is 6 years of age or younger or if there is any doubt as to proper dosing. Never hesitate to contact the prescriber with any concern or question regarding any medication recommended for the pediatric patient.
- Bismuth subsalicylate is a salicylate by chemical structure; therefore, it is to be used very cautiously in children and teenagers who have been or are recovering from chickenpox or influenza because of the risk for Reye's syndrome (see Chapter 44).
- Immediately report to the prescriber any abdominal distention, firm abdomen, painful abdomen, or worsening of or lack of improvement in diarrhea 24 to 48 hours after medication administration. Measurement of the amount of diarrhea by the number of soiled diapers or number of stools per day provides important information.
- Antidiarrheal preparations are always to be used very cautiously in the pediatric patient. If symptoms persist or dehydration occurs (e.g., no tears and decreased urine output in the child), contact the prescriber.
- If the patient is sluggish, lethargic, or confused or the diarrhea is bloody, contact the prescriber immediately or go to the closest emergency facility.
- Always assess the pediatric patient, including adolescents, for the presence of an eating disorder such as bulimia or anorexia due to the associated use/abuse of laxatives in these conditions.

dried culture for oral administration. They are normal inhabitants of the GI tract where, through the fermentation of carbohydrates (which produces lactic acid), they create an unfavorable environment for the overgrowth of harmful fungi and bacteria. *L. acidophilus* has been used for more than 75 years for the treatment of uncomplicated diarrhea, particularly that caused by antibiotic therapy that destroys normal intestinal flora. Another commonly used probiotic is *Saccharomyces boulardii* (Florastor).

LAXATIVES

Laxatives are used for the treatment of **constipation,** which is defined as the abnormally infrequent and difficult passage of feces through the lower GI tract. Constipation is a symptom, not a disease; it is a disorder of movement through the colon and/or rectum that can be caused by a variety of diseases or drugs. Some of the more common causes of constipation are listed in Table 51-3.

The GI tract is responsible for the digestive process, which involves (1) ingestion of dietary intake, (2) digestion of dietary intake into basic nutrients, (3) absorption of basic nutrients, and (4) storage and removal of fecal material via defecation (Figure 51-1).

Ingestion → digestion → absorption → storage & removal

TABLE 51-3 CAUSES OF CONSTIPATION

CAUSE	EXAMPLES
Adverse drug effects	Analgesics, anticholinergics, iron supplements, aluminum antacids, calcium antacids, opiates, calcium channel blockers
Lifestyle	Poor bowel movement habits: voluntary refusal to defecate resulting in constipation Diet: poor fluid intake and/or low-residue (low-fiber) diet or excessive consumption of dairy products Physical inactivity: lack of proper exercise, especially in elderly individuals Psychological factors: anxiety, stress, hypochondria
Metabolic and endocrine disorders	Diabetes mellitus, hypothyroidism, pregnancy, hypercalcemia, hypokalemia
Neurogenic disorders	Autonomic neuropathy, intestinal pseudo-obstruction, multiple sclerosis, spinal cord lesions, Parkinson's disease, stroke

The usual time span between ingestion and defecation is 24 to 36 hours. The last segment of the GI tract, the large intestine (colon), is responsible for (1) forming the stool by removing excess water from the fecal material, (2) temporarily storing the stool until defecation, and (3) extracting essential vitamins from the intestinal bacteria (especially vitamin K). The colon is 120 to 150 cm long and is separated from the small intestine by the ileocecal valve. The colon extends into the rectum, which terminates at the anus. The rectum is the temporary storage site for the stool, which is composed of water and unabsorbed and indigestible material. Evacuation of the rectal contents is accomplished by bowel movements.

A bowel movement (defecation) is a reflex act that involves both smooth and skeletal muscles. The entry of feces into the rectum stimulates mass peristaltic movement that results in a bowel movement. However, voluntary initiation or inhibition of defecation is also possible via skeletal muscle pathways.

Treatment of constipation is individualized, with consideration of the patient's age, concerns, and expectations; duration and severity of constipation; and potential contributing factors. Treatment can be either surgical (in extreme cases) or nonsurgical. Nonsurgical treatments can be separated into three broad approaches: dietary (e.g., fiber supplementation), behavioral (e.g., increased physical activity), and pharmacologic. The focus in this chapter is on pharmacologic treatment.

Laxatives are among the most misused OTC medications. Long-term and often inappropriate use of laxatives may result in laxative dependence, produce damage to the bowel, or lead to previously nonexistent intestinal problems. With the exception of the bulk-forming type, laxatives are not to be used for long periods. Based on their mechanisms of action, laxatives are divided into five major groups: bulk-forming, emollient, hyperosmotic, saline, and stimulant laxatives. Table 51-4 lists the currently available laxative drugs categorized by drug family. The onset of action of laxatives is the most important pharmacokinetic feature of these drugs and is listed in the Dosages table on p. 836.

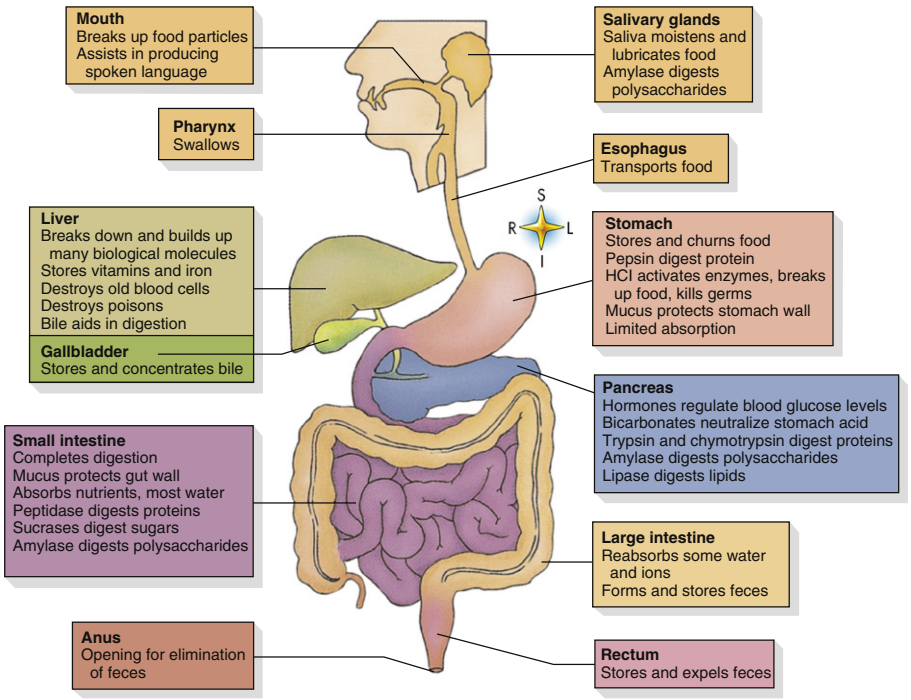

FIGURE 51-1 The digestive system. (From Patton KT, Thibodeau GA: *Mosby's handbook of anatomy and physiology,* St Louis, 2000, Mosby.)

TABLE 51-4 LAXATIVES: DRUG CATEGORIES AND SELECTED DRUGS

CATEGORY	LAXATIVE DRUGS
Bulk-forming	psyllium, methylcellulose
Emollient	docusate salts, mineral oil
Hyperosmotic	polyethylene glycol, lactulose, sorbitol, glycerin
Saline	magnesium hydroxide, magnesium sulfate, magnesium citrate
Stimulant	senna, bisacodyl

Mechanism of Action and Drug Effects

All laxatives promote bowel movements, but each class of laxative has a different mechanism of action. Laxatives may act by (1) affecting fecal consistency, (2) increasing fecal movement through the colon, and/or (3) facilitating defecation through the rectum. Bulk-forming laxatives act in a manner similar to that of the fiber naturally contained in the diet. They absorb water into the intestine, which increases bulk and distends the bowel to initiate reflex bowel activity, thus promoting a bowel movement.

Emollient laxatives are also referred to as *stool softeners* (docusate salts) and *lubricant laxatives* (mineral oil). Fecal softeners work by lowering the surface tension of GI fluids, so that more water and fat are absorbed into the stool and the intestines. The lubricant type of emollient laxatives works by lubricating the fecal material and the intestinal wall and preventing absorption of water from the intestines. Instead of being absorbed, this water in the bowel softens and expands the stool. This promotes bowel distention and reflex peristaltic actions, which ultimately lead to defecation.

Hyperosmotic laxatives work by increasing fecal water content, which results in distention, increased peristalsis, and evacuation. Their site of action is limited to the large intestine. Saline laxatives increase osmotic pressure in the small intestine by inhibiting water absorption and increasing both water and electrolyte (salt) secretions from the bowel wall into the bowel lumen. This results in a watery stool. The increased distention promotes peristalsis and evacuation. Rectal enemas of sodium phosphate, a saline laxative, produce defecation 2 to 5 minutes after administration.

As the name implies, stimulant laxatives stimulate the nerves that innervate the intestines, which results in increased peristalsis. They also increase fluid in the colon, which increases bulk and softens the stool. Table 51-5 summarizes the specific drug effects of the different classes of laxatives.

In 2008, a new class of drugs was approved for the treatment of very specific types of constipation related to opioid use and bowel resection surgery. These peripherally acting opioid antagonists include methylnaltrexone (Relistor) and alvimopan (Entereg). These drugs block the entrance of an opioid drug into the bowel cells, thus allowing bowels to function normally, even with continued opioid use. Methylnaltrexone is approved only for terminally ill (hospice) patients who have opioid-induced constipation. It is available as an injection only and is given once a day. Alvimopan is indicated to accelerate GI recovery time following partial large or small bowel resection surgery. Patients must be hospitalized and registered to receive Alvimopan.

TABLE 51-5 LAXATIVES: DRUG EFFECTS

DRUG EFFECT	BULK	EMOLLIENT	HYPEROSMOTIC	SALINE	STIMULANT
Increases peristalsis	Yes	Yes	Yes	Yes	Yes
Causes increased secretion of water and electrolytes in small bowel	Yes	Yes	No	Yes	Yes
Inhibits absorption of water in small bowel	Yes	Yes	No	Yes	Yes
Increases wall permeability in small bowel	No	Yes	No	No	Yes
Acts only in large bowel	No	No	Yes	No	No
Increases water in fecal mass	Yes	Yes	Yes	Yes	Yes
Softens fecal mass	Yes	Yes	Yes	Yes	Yes

TABLE 51-6 LAXATIVES: INDICATIONS

CATEGORY	INDICATION
Bulk-forming	Acute and chronic constipation, irritable bowel syndrome, diverticulosis
Emollient	Acute and chronic constipation, fecal impaction, anorectal conditions requiring facilitation of bowel movements
Hyperosmotic	Chronic constipation, bowel preparation for diagnostic and surgical procedures
Saline	Constipation, bowel preparation for diagnostic and surgical procedures
Stimulant	Acute constipation, bowel preparation for diagnostic and surgical procedures

TABLE 51-7 LAXATIVES: ADVERSE EFFECTS

CATEGORY	ADVERSE EFFECTS
Bulk-forming	Impaction above strictures, fluid disturbances, electrolyte imbalances, gas formation, esophageal blockage, allergic reaction
Emollient	Skin rashes, decreased absorption of vitamins, lipid pneumonia, electrolyte imbalances
Hyperosmotic	Abdominal bloating, rectal irritation, electrolyte imbalances
Saline	Magnesium toxicity (with renal insufficiency), electrolyte imbalances, cramping, diarrhea, increased thirst
Stimulant	Nutrient malabsorption, skin rashes, gastric irritation, electrolyte imbalances, discolored urine, rectal irritation

Indications

The following are some of the more common uses of laxatives:

- Facilitation of bowel movements in patients with inactive colon or anorectal disorders
- Reduction of ammonia absorption in hepatic encephalopathy (lactulose only)
- Treatment of drug-induced constipation
- Treatment of constipation associated with pregnancy and/or postobstetric period
- Treatment of constipation caused by reduced physical activity or poor dietary habits
- Removal of toxic substances from the body
- Facilitation of defecation in megacolon
- Preparation for colonic diagnostic procedures or surgery

See Table 51-6 for specific therapeutic indications for each laxative drug class.

Contraindications

All categories of laxatives share the same general contraindications and precautions, including avoidance in cases of drug allergy and the need for cautious use in the presence of the following: acute surgical abdomen; appendicitis symptoms such as abdominal pain, nausea, and vomiting; fecal impaction (mineral oil enemas excepted); intestinal obstruction; and undiagnosed abdominal pain.

Adverse Effects

The adverse effects of the various drugs are specific to the laxative group. Most of the adverse effects from laxatives are confined to the intestine; however, the overuse and misuse of laxatives lead to many unwanted effects that are not expected or designed to occur with appropriate use. The major adverse effects of the laxative drugs are listed in Table 51-7.

Interactions

Laxatives alter intestinal function; therefore, they can interact with other drugs, because many drugs are absorbed in the intestines. Bulk-forming laxatives can decrease the absorption of antibiotics, digoxin, salicylates, tetracyclines, and warfarin. Mineral oil can decrease the absorption of fat-soluble vitamins (A, D, E, and K). Hyperosmotic laxatives can cause increased CNS depression if they are given with barbiturates, general anesthetics, opioids, or antipsychotics. Oral antibiotics can decrease the effects of lactulose. Stimulant laxatives decrease the absorption of antibiotics, digoxin, nitrofurantoin, salicylates, tetracyclines, and oral anticoagulants.

Dosages

For dosage information on selected laxatives, see the table on p. 836.

DRUG PROFILES

Laxatives are used for the treatment of constipation. Such treatment must involve an understanding of the whole patient. Many drugs in the five major groups of laxatives are available as OTC medications, whereas others require a prescription for use. The following profiles describe the prototypical drugs in each of the laxative groups.

BULK-FORMING LAXATIVES

Bulk-forming laxatives are composed of water-retaining (hydrophilic) natural and synthetic cellulose derivatives. Psyllium is an example of a natural bulk-forming laxative, and methylcellulose is an example of a synthetic cellulose derivative. Bulk-forming drugs increase water absorption, which results in greater total volume (bulk) of the intestinal contents. Bulk-forming laxatives tend to produce normal, formed stools. Their action is limited to the GI tract, so there are few, if any, systemic effects. However, they need to be taken with liberal amounts of water to prevent esophageal obstruction and/or fecal impaction. The bulk-forming laxatives are all obtainable OTC, are among the safest laxatives available, and are the only ones that are recommended for long-term use.

methylcellulose

Methylcellulose (Citrucel) is a synthetic bulk-forming laxative that attracts water into the intestine and absorbs excess water into the stool, stimulating the intestines and increasing peristalsis. Specific contraindications include GI obstruction and hepatitis. Methylcellulose is an oral drug available in powdered form that provides approximately 2 g of fiber per heaping tablespoon.

DOSAGES

Selected Laxatives

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	ONSET OF ACTION
bisacodyl (Dulcolax) (C)	Stimulant laxative	**Pediatric younger than 2 yr** 5-mg suppository **Pediatric older than 2 yr** 10-mg suppository **Pediatric older than 6 yr** PO: 0.3 mg/kg **Adult** 5-15 mg oral or 10 mg-suppository	Oral: 6-12 hr Rectal: 15-60 minutes
♦ docusate sodium (Colace, others) and docusate calcium (Surfak, others) (C)	Fecal softener, emollient laxative	**Pediatric 2-11 yr*** PO: 33-120 mg/day divided daily-tid **Pediatric 12 yr and older, and adult*** PO: 50-300 mg/day divided daily-qid	1-3 days
♦ glycerin (Sani-Supp, Colace, Fleet Babylax) (C)	Hyperosmotic laxative	**Adult and pediatric** Rectal only: Insert one adult, child, or infant suppository PR daily-bid prn; attempt to retain 15-30 min; suppository does not have to melt to induce BM	16-36 min
♦ lactulose (Enulose, others) (B)	Disaccharide, hyperosmotic laxative	**Pediatric, infant**† PO: 2.5-10 mL/day divided bid-qid **Child and adolescent**† PO: 40-90 mL/day divided bid-qid **Adult**† PO: 30-45 mL tid-qid	24 hr
magnesium citrate (generic only), magnesium sulfate (Epsom salts by various manufacturers) (B)	Saline laxative	***Citrate, PO*** **Pediatric younger than 6 yr** 0.5mL/kg (max 200 mL); may repeat q4-6h until stools clear **Pediatric 6-11 yr** 100-150 mL × 1 dose **Adult** 120-300 mL × 1 dose	0.5-3 hr
methylcellulose (Citrucel, others) (B)	Bulk-forming laxative	**Pediatric 6-11 yr** ½ dose of that for pediatric 12 yr and older, and adult **Pediatric 12 yr and older, and adult** PO: 1 heaping tbsp in 8 oz cold water daily-tid	12-24 hr
mineral oil (Kondremul Plain, Fleet Mineral Oil Enema) (B)	Emollient laxative	***PO*** **Pediatric 6-11 yr** 5-15 mL oil or 10-25 mL Kondremul Plain emulsion **Pediatric 12 yr and older, and adult** 15-45 mL oil or 30-75 mL Kondremul Plain emulsion taken at bedtime ***Rectal enema*** **Pediatric 2-11 yr** PR: 59 mL × 1 **Pediatric 12 yr and older, and adult** PR: 118 mL × 1	6-8 hr

DOSAGES—cont'd

Selected Laxatives

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	ONSET OF ACTION
polyethylene glycol (Colyte, GoLYTELY, Half-Lytely, MiraLax) (C)	Hyperosmotic laxative	**Adult only** PO: 4 L solution, usually ending before procedure; patient needs to fast at least 4 hr before drinking solution MiraLax: 17 g once daily	1 hr
♦ psyllium (Metamucil, Fiberall, others) (B)	Bulk-forming laxative	**Pediatric 6-11 yr** PO: ½ rounded tsp in water or juice daily-tid **Pediatric 12 yr and older, and adult** PO: 1 rounded tsp in 8 oz water or juice daily-tid	12-24 hr
♦ senna (Senokot, others) (C)	Stimulant-irritant laxative	**Pediatric 2-5 yr**‡ PO (liquid): 2.5 mL (max: ½ tsp bid) **Pediatric 6-11 yr**‡ PO (tabs): 1 tab daily (max: 2 tabs bid) PO (liquid): 7.5-10 mL daily (max: 5 mL bid) **Pediatric 12 yr and older, and adult**‡ PO (tabs): Start with 2 tabs daily (max: 4 tabs bid) PO (liquid): 15 mL daily (max: 30 mL bid)	6-24 hr

BM, Bowel movement; *PO,* oral; *PR,* per rectum.
*Docusate sodium is available in both capsule and liquid forms. Docusate calcium is available in capsule form only.
†Rectal route is sometimes used to reverse certain types of coma.
‡Many dosage forms; consult product labeling if in doubt. Most common dosage forms are 8.6-mg sennosides in tablet form and 8.8 mg/5 mL of sennosides in liquid form.

♦ psyllium

Psyllium (Metamucil) is a natural bulk-forming laxative obtained from the dried seed of the *Plantago psyllium* plant. It has many of the characteristics of methylcellulose. Psyllium is contraindicated in patients with intestinal obstruction or fecal impaction. Its use is also contraindicated in patients experiencing abdominal pain and/or nausea and vomiting. Psyllium is available for oral use in wafer and powder form.

EMOLLIENT LAXATIVES

Emollient laxatives either directly lubricate the stool and the intestines, as with mineral oil, or act as fecal softeners. By lubricating the fecal material and the intestinal walls, lubricant emollient laxatives prevent water from moving out of the intestines, which softens and expands the stool. Stool softeners (docusate salts) work by lowering the surface tension of fluids, which allows more water and fat to be absorbed into the stool and the intestines.

♦ docusate salts

Docusate salts (calcium and sodium) (Colace) are stool-softening emollient laxatives that facilitate the passage of water and lipids (fats) into the fecal mass, which softens the stool. These drugs are used to treat constipation, soften fecal impactions, and facilitate bowel movements in patients with hemorrhoids and other painful anorectal conditions. They do not cause patients to defecate; they simply soften the stool to ease its passage. In addition to the docusate salt formulations, combination products are also available. Docusate use is contraindicated in patients with intestinal obstruction, fecal impaction, or nausea and vomiting.

mineral oil

Mineral oil eases the passage of stool by lubricating the intestines and preventing water from escaping the stool. Mineral oil is the only lubricant laxative in the emollient category. It is a mixture of liquid hydrocarbons derived from petroleum and is most commonly used to treat constipation associated with hard stools or fecal impaction.

Mineral oil use is contraindicated in patients with intestinal obstruction, abdominal pain, or nausea and vomiting. Mineral oil drugs are available as enemas and in products for oral use. There are also combination products that contain mineral oil, such as Haley's M-O, which includes both mineral oil and milk of magnesia (magnesium hydroxide).

HYPEROSMOTIC LAXATIVES

The hyperosmotic laxatives glycerin, lactulose, sorbitol, and polyethylene glycol (PEG) relieve constipation by increasing the water content of the feces, which results in distention, peristalsis, and evacuation. They are most commonly used to treat constipation and to evacuate the bowels before diagnostic and surgical procedures.

♦ glycerin

Glycerin promotes bowel movement by increasing osmotic pressure in the intestine, which draws fluid into the colon. Because it is a very mild laxative, it is often used in children. Glycerin has properties similar to those of sorbitol, another hyperosmotic laxative. Glycerin use is contraindicated in patients who have shown a hypersensitivity reaction to it. It is available as a rectal solution and as both adult and pediatric suppositories.

♦ lactulose

Lactulose is a synthetic derivative of the natural sugar lactose, which is not digested in the stomach or absorbed in the small bowel. Instead it passes unchanged into the large intestine, where it is metabolized. Colonic bacteria digest lactulose to produce lactic acid, formic acid, and acetic acid, which creates a hyperosmotic environment that draws water into the colon and produces a laxative effect. This drug-induced acidic environment also reduces blood ammonia levels by converting ammonia to ammonium. Ammonium is a water-soluble cation that is trapped in the intestines and cannot be reabsorbed into the systemic circulation. This effect has proved helpful in reducing serum ammonia levels in patients with hepatic encephalopathy. Lactulose use is contraindicated in patients on a low-galactose diet. It is available as a solution for either oral or rectal use.

polyethylene glycol 3350

PEG-3350 is most commonly given before diagnostic or surgical bowel procedures, because it is a very potent laxative that induces total cleansing of the bowel. The 3350 designation refers to the osmolality of the drug. It is usually available in a powdered dosage form that contains mixtures of electrolytes that also help stimulate bowel evacuation (e.g., Colyte, GoLYTELY, MoviPrep, Half-Lytely). The powder is usually reconstituted in a large volume of fluid (1 gal) that is then gradually drunk by the patient on the afternoon of the day before the procedure. Use of PEG is contraindicated in patients with GI obstruction, gastric retention, bowel perforation, toxic colitis, toxic megacolon, or ileus.

An oral solution of PEG-3350 and electrolytes is available for GI lavage. Diarrhea usually occurs within 30 to 60 minutes after ingestion; complete evacuation and cleansing of the bowel is accomplished within 4 hours. MiraLax is a PEG-3350 product that is available OTC and can be used daily for constipation in much smaller amounts than those used for total bowel cleansing.

SALINE LAXATIVES

Saline laxatives consist of various magnesium or sodium salts. They increase osmotic pressure and draw water into the colon, producing a watery stool, usually within 3 to 6 hours of ingestion. The currently available saline laxatives are listed in Box 51-1. Oral sodium phosphate–containing products used for bowel evacuation, such as Fleet Phospho-Soda, were taken off the market in 2008 because of concerns about acute phosphate nephropathy.

magnesium salts

The magnesium saline laxatives, magnesium citrate (Citroma), and magnesium hydroxide (Phillips Milk of Magnesia) are unpleasant-tasting OTC laxative preparations. They are to be used with caution in patients with renal insufficiency, because they can be absorbed enough to cause hypermagnesemia. They are most commonly used to evacuate the bowel rapidly in preparation for endoscopic examination and to help remove unabsorbed poisons from the GI tract.

Use of magnesium salts is contraindicated in patients with renal disease, abdominal pain, nausea and vomiting, obstruction, acute surgical abdomen, or rectal bleeding. Magnesium hydroxide, more commonly referred to as *milk of magnesia,* is available in oral liquid and tablet form. It is also found in a variety of combination products, such as Haley's M-O (see mineral oil profile). Other magnesium products are listed in the discussion of saline laxatives earlier in the chapter. Note that magnesium *oxide* is used as a supplement, not as a laxative (see Chapter 53).

BOX 51-1 SALINE LAXATIVES

Magnesium Laxatives

Sulfate
Epsom salts

Hydroxide
Milk of magnesia

Citrate
Citrate of magnesia

Sodium Laxatives
Fleet Enema

STIMULANT LAXATIVES

Stimulant laxatives induce intestinal peristalsis. In the past, several different stimulant laxatives were available; however, the U.S. Food and Drug Administration has required that all except bisacodyl (Dulcolax) and senna (Senokot) be removed from the market. Their site of action is the entire GI tract. The action of the stimulant laxatives is proportional to the dose. The stimulant class is the most likely of all laxative classes to cause dependence.

bisacodyl

Bisacodyl (Dulcolax) is the most commonly used stimulant laxative. It is available as an oral tablet and rectal suppository. It is used for constipation or for whole bowel evacuation prior to endoscopic examination. It is available OTC.

♦ senna

Senna (Senokot) is a commonly used OTC stimulant laxative. Senna is obtained from the dried leaves of the *Cassia acutifolia* plant. It may be used for relief of acute constipation or bowel preparation for surgery or examination. Because of its stimulating action on the GI tract, it may cause abdominal pain. It can produce complete bowel evacuation in 6 to 12 hours. Senna is available in a variety of dosages as tablets, syrup, and granules. One product, Senokot-S, includes both senna and the stool softener docusate sodium.

DRUGS FOR IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is a condition of chronic intestinal discomfort characterized by cramps, diarrhea, and/or constipation. Patients usually cope with the symptoms by avoiding irritating foods and/or taking OTC laxatives and antidiarrheal drugs. Women are affected more often than men. In 2009, the American College of Gastroenterology Task Force on Irritable Bowel Syndrome released a position statement on the treatment of IBS. Their conclusions are as follows: psyllium is moderately effective in IBS; the antidiarrheal loperamide is not more effective than placebo at reducing pain or bloating, but it is an effective agent for the treatment of diarrhea,

reducing stool frequency, and improving stool consistency; the 5-hydroxytryptamine 3 (5-HT_3) receptor antagonist alosetron is more effective than placebo; alosetron is most favorable in women with severe IBS and diarrhea who have not responded to conventional therapies; the 5-hydroxytryptamine 4 (5-HT_4) receptor agonist tegaserod and the chloride channel activator lubiprostone are more effective than placebo; and tricyclic antidepressants and selective serotonin reuptake inhibitors are more effective than placebo at relieving IBS symptoms, and appear to reduce abdominal pain.

Tegaserod (Zelnorm) is a serotonin 5-HT_4 receptor agonist and is approved for treatment of IBS with constipation and chronic idiopathic constipation in women younger than 55 years of age for whom no alternative therapy exists. Tegaserod was approved in 2002, taken off the market in 2007, and then reintroduced under restricted availability in 2008. Tegaserod has been associated with serious adverse events including angina, heart attacks, and stroke. Patients must be registered with the manufacturer. It is categorized as a pregnancy category B drug and is dosed at 6 mg twice a day for 4 to 6 weeks.

Lubiprostone (Amitiza) is a chloride channel activator that is indicated for the treatment of chronic idiopathic constipation and IBS with constipation in women 18 years of age and older. It is dosed at 24 mcg twice a day for idiopathic constipation and 8 mcg twice a day for IBS. The most common adverse effects are nausea, diarrhea, and abdominal pain. It is classified as a pregnancy category C drug. Lubiprostone is contraindicated in patients with known or suspected bowel obstruction.

Alosetron (Lotronex) is a selective serotonin 5-HT_3 receptor antagonist that is indicated for the treatment of severe, chronic, diarrhea-predominant IBS in women who have failed conventional therapy. It is dosed at 0.5 mg twice daily for 4 weeks and may be increased to 1 mg twice a day. If response is inadequate after 4 weeks, the drug is to be discontinued. It must be discontinued immediately if constipation or signs of ischemic colitis occur. Only physicians who have enrolled in the manufacturer-sponsored prescribing program can prescribe alosetron.

NURSING PROCESS

ASSESSMENT

Before giving *antidiarrheal* preparations, obtain a thorough history and perform an assessment of bowel patterns, general state of health, any recent illness, and any dietary changes. In the abdominal assessment, include auscultation of bowel sounds in all four quadrants *after* inspection of the entire abdomen but *before* percussion and palpation. Performing auscultation and inspection before percussion prevents any possible stimulation of peristalsis or bowel sounds that would not occur otherwise. When the frequency of bowel sounds ranges from 6 to 32 per minute, it is important to describe exactly what is heard and the amount of activity in each of the four quadrants. Terms such as *high-pitched, low-pitched, gurgling,* or *tinkling* may be used to describe the character of the sounds, whereas activity may be described as *hypoactive* (less than 6 sounds per minute), *normoactive* (between 6 and 32 sounds per minute), or *hyperactive* (more than the normal range). Perform a thorough abdominal assessment for any patient with GI complaints, including altered bowel status. Note the presence of tenderness, rigidity, changes in contour, bulges, and obvious peristaltic waves across the abdomen. Assess frequency, consistency, amount, color, and odor (if present) of stools, and document the findings. In addition, it is critical to patient safety and health to be sure that the possibility of *Clostridium difficile* infection or other infectious diarrhea is ruled out. Assess for and document any contraindications, cautions, and drug interactions for all drugs. Report complaints of abdominal pain, bloody stools, confirmation of hypoactive to no bowel sounds, and/or fever to the prescriber immediately. When administering diphenoxylate with atropine, be wary of overuse because large amounts may result in dry mouth, abdominal pain, tachycardia, and blurred vision. Elderly patients are more susceptible to fluid and electrolyte depletion associated with diarrhea; therefore, closely assess hydration status and age.

Laxative use requires further assessment in addition to the abdominal assessment and bowel pattern history described earlier. For example, focus questions on changes in bowel patterns, long-term use of laxatives (because patients may become laxative dependent), and dietary and fluid intake. Assess vital signs, daily weights, intake and output, and fluid and electrolyte levels, and note the presence of any weakness because of the possibility of hypotension and volume or electrolyte depletion (with long-term laxative use). Another important area to assess is that of laxative abuse in the elderly as well as in pediatric and adolescent patients. Specifically, in the pediatric or adolescent patients, assess for eating disorders with concurrent use of laxatives.

The type of laxative and the related mechanism of action dictate specific assessments because of differences in how strongly the patient reacts to the various laxative drugs. The bulk-forming laxatives are often used to treat chronic constipation and have few adverse effects, but a basic abdominal and bowel pattern assessment and related history taking are still needed. Always assess and document contraindications, cautions, and drug interactions. Use docusate salts or emollient laxatives cautiously in the elderly.

With hyperosmotic laxatives (e.g., polytheylene glycol, lactulose, sorbitol, glycerin), assess baseline fluid and electrolyte levels to identify any deficits prior to use. All of the previously mentioned assessment measures regarding abdominal examination and bowel patterns are also appropriate for these drugs, with the additional assessment for the presence of abdominal pain, the degree of peristalsis, and any history of recent abdominal surgery, nausea, vomiting, or weight loss. Elderly patients react more adversely to this class of laxatives, so use in this group is to be avoided.

Saline laxatives (e.g., magnesium hydroxide, magnesium sulfate, and magnesium citrate) are to be used with caution in elderly patients because of possible dehydration and electrolyte loss. They may also cause magnesium toxicity in those with compromised renal status. Renal function studies are important to assess in those at risk. Senna and bisacodyl are examples of stimulant laxatives. They may also cause electrolyte imbalances, so baseline electrolyte levels are important to assess and monitor.

Patients taking *drugs for IBS* need additional assessment of liver functioning as well as assessment for any underlying cardiac disease. The availability of tegaserod is restricted, and patients are registered with the manufacturer because of the risk of severe adverse effects (e.g., angina, heart attack, and stroke). Therefore, thoroughly assess the patient's medical and medication history as well as complete a thorough head-to-toe physical assessment. Do not use lubiprostone in patients with a known or suspected bowel obstruction.

CASE STUDY

Long-Term Laxative Use

Mrs. M. is a 66-year-old retired schoolteacher. She enjoys good health and exercises three times a week with a senior citizen group in a supervised arthritis swim class at the local recreation center. She arrives at the family practice office with complaints of "constipation" and says that for the past 3 months she has had only one bowel movement every 3 days instead of one every day. In the assessment of this patient, the nurse discovers that Mrs. M. has been taking a stimulant laxative up to twice a day and is also now feeling "weak." Mrs. M. also says that she is experiencing "a lot of tummy cramping."

1. What are at least five questions the nurse should ask Mrs. M.? Provide reasons for each question.
2. What types of problems are generally related to long-term use of laxatives? Explain your answer.
3. What are some nonpharmacologic ways to help prevent constipation?
4. What over-the-counter drug is the best choice to help prevent constipation? Explain your answer.

For answers, see http://evolve.elsevier.com/Lilley.

NURSING DIAGNOSES

1. Constipation related to improper and/or inadequate diet
2. Diarrhea related to GI irritation from food, bacteria or viruses, or pathology
3. Deficient fluid volume related to loss of fluids and electrolytes caused by frequent, loose stools

PLANNING

GOALS

1. Patient experiences minimal constipation.
2. Patient experiences minimal diarrhea.
3. Patient remains free from fluid and electrolyte disturbances related to changes in bowel patterns and lack of proper management of bowel alterations.

OUTCOME CRITERIA

1. Patient states measures to manage/prevent constipation such as forcing fluids; increasing intake of bulk and fiber (unless contraindicated); and increasing physical activity.
   - Patient takes recommended bulk-forming laxatives, stool softeners, as well as other approved laxatives, as prescribed and follows directions closely.
2. Patient states measures to manage and prevent diarrhea such as increasing bulk; avoiding spicy, irritating foods and beverages; and avoiding caffeine.
   - Patient takes recommended antidiarrheal preparation as prescribed and instructed, with close attention to following directions on the medication.
3. Patient reports to the prescriber any signs and symptoms of fluid and electrolyte loss, such as weakness, lethargy, decreased urinary output, and dizziness.
   - Patient implements measures to prevent fluid and electrolyte loss such as nonpharmacologic and pharmacologic therapies (see above).

IMPLEMENTATION

With *antidiarrheals,* educate the patient that the drugs must be taken *exactly* as directions indicate, with strict adherence to the recommended dose, frequency, and duration of treatment. Encourage the patient to be aware of fluid intake and any dietary changes that would impact his or her health status or possibly exacerbate present symptoms. Instruct the patients to be aware of the factors precipitating the diarrhea and, if symptoms persist, to contact his or her health care provider. Document any changes in bowel patterns, weight, fluid volume, intake and output as well as in the mucous membranes during and after treatment—whether for constipation or diarrhea. Inform the patient that bismuth subsalicylate must be taken as directed and that this medication will turn the stool black or gray. If tablets are used, they must be chewed thoroughly before swallowing and with at least 6 oz of fluid. Bismuth subsalicylate is a salicylate-based product and is not to be taken with other salicylates to avoid the risk of toxicity. Encourage parents to check with their children's health care provider before giving bismuth subsalicylate to a child or teenager with a viral infection, such as chickenpox or influenza, because of the risk for Reye's syndrome (see the Patient-Centered Care: Lifespan Considerations for the Pediatric Patient box).

Diphenoxylate hydrochloride and loperamide may be given without regard to food intake but must be given with adequate fluid. Additionally, advise the patient to follow the specific directions (e.g., the specific number of tablets recommended by the manufacturer after the first loose stool and the total number of tablets to be taken within a 24-hour period). Maximum amounts are not to be exceeded, and if diarrhea continues or other symptoms occur (e.g., fever, abdominal pain, bloody stools), instruct the patient to contact the prescriber immediately. See the Patient Teaching Tips for more information.

Probiotics may be recommended for a variety of altered bowel elimination patterns, whether diarrhea or constipation. Probiotics are available in foods and dietary supplements and in capsules, tablets, and powder dosage forms. Most of the probiotics are derived from *Lactobacillus* or *Bifidobacterium* bacteria. It is important to educate the patient about probiotics and to emphasize their healthy benefits when administered in the proper amounts. Tell the patient to take probiotics exactly as directed. Foods that contain probiotics include yogurt, fermented milk, miso, empeh, and some juices and soy beverages.

Bulk-forming *laxatives* such as methylcellulose must be administered, as specified by package insert or as ordered. Methylcellulose is to be taken with at least 8 oz or 1 full glass of liquid after the powder form has been thoroughly stirred into it. The fluid must be taken immediately because of a congealing effect that continues to harden with time. To avoid choking or swelling of the product in the throat or esophagus, the patient must swallow or receive the drug immediately upon stirring. The medication must never be taken or administered in its dry form. See the Patient Teaching Tips for more information.

Docusate is available in a variety of oral dosage forms (e.g., capsules, tablets, syrups, elixir), and it is recommended to take it with at least 6 oz of water or other fluid. An additional 6 to 8 glasses of water a day is also suggested to help with stool softening. Bisacodyl, if ordered, is best taken on an empty stomach for faster action, and whole tablets should not be chewed or crushed. Advise the patient not to take milk, antacids, or juices with the dose or within 1 hour of taking the medication. Rectal suppositories, if too soft, may be placed in a medicine cup with ice to harden the suppository before insertion. Once the wrapper is removed, apply a water-soluble lubricant to the suppository prior to insertion into the rectum. Use a gloved hand or finger cot for insertion. Encourage the patient to try and keep the suppository in place by lying still on the left side for at least 15 to 30 minutes to allow the drug to dissolve for maximal effectiveness. Lactulose may be taken with juice, milk, or water to increase palatability. It is important to note that the normal color of the oral solution is pale yellow. Administer rectal dosage forms as a retention enema with dilution as ordered, and instruct the patient to retain for 30 to 60 minutes. For proper insertion of a retention enema, lubricate the tip of the apparatus well, and insert it carefully with the nozzle pointed toward the umbilicus of the patient, with the patient lying on the left side. Release the fluid gradually, and discontinue administration if the patient experiences severe abdominal pain. If long-term use of the drug is indicated, monitoring serum electrolyte levels is needed.

Magnesium-based laxatives are generally used only in certain situations because they are very potent. Force fluids, and follow other instructions per the prescriber's order or the package instructions. Refrigeration may help increase the palatability of the oral solution. Emphasize the importance that this type of drug is to be taken exactly as prescribed for constipation, with consumption of plenty of fluids and careful attention to adverse effects. Instruct the patient to mix the PEG-electrolyte solution with water or flavored sports drink as directed and to shake well before drinking. Chilled solutions are tolerated better. Rapid drinking of each dose is recommended.

IBS drugs should be given as ordered and usually on an empty stomach before meals. Tegaserod, only available under restricted guidelines, must also be taken exactly as prescribed and only for up to 4 to 6 weeks. With this drug, monitoring for the serious cardio-cerebrovascular adverse effects is so important to patient safety. Continual observation of complaints of chest pain, lightheadedness, and dizziness as well as frequent monitoring of vital signs and neurologic checks (e.g., LOC, reflexes, pupils for reactivity and size, speech) are all very important. Lubiprostone must also be given as prescribed and is usually ordered for twice-daily dosing. Alosetron (Lotronex) is generally given twice daily. Be sure the patient receives the FDA-approved medication guide with each dispensing of alosetron. Encourage the patient to keep a daily journal to help the prescriber in identifying the effectiveness of therapy.

EVALUATION

Therapeutic responses to any of these medications include an improvement in the GI-related signs and symptoms reported by the patient (e.g., decrease in diarrhea or constipation), return to normal bowel patterns with normal bowel sounds, and absence of abnormal findings on assessment of the abdomen and bowel patterns. Adverse effects for which to monitor patients vary according to drug. Use goals and outcome criteria as a means to evaluate the nursing care plan related to each problem, whether it is constipation, diarrhea, or both.

PATIENT TEACHING TIPS

- Instruct the patient that antidiarrheals are to be taken exactly as prescribed, giving close attention to indicated dosages with warnings of overuse!
- Counsel the patient to take antidiarrheal drugs with caution when performing tasks that require mental alertness or motor skills until it is clear how the drug actually affects him or her. Advise the patient to immediately report to the prescriber any abdominal distention or firm/hard abdomen, abdominal pain, worsening (or no improvement) of symptoms, rectal bleeding, unrelieved constipation or diarrhea, fever, nausea, vomiting or other GI-related signs and symptoms, dizziness, muscle weakness, and muscle cramping.
- Encourage frequent mouth care, fluid intake, or use of sugarless gum or candy to help with the adverse effect of dry mouth.
- Bismuth subsalicylate may turn the stool tarry black, so warn the patient that this may happen. Patients must avoid other drugs containing salicylates while taking bismuth. Always check for cautions and contraindications of this drug, especially for pediatric patients.
- Increasing the intake of fluids, preferably water, as well foods high in fiber and whole grain, green leafy vegetables, and fruits may help to minimize constipation. Exercise is also beneficial.
- Educate the patient that what are normal bowel patterns for one person may not be normal for another.
- Keep all antidiarrheals and laxatives out of the reach of children.
- For patients taking powder forms of methylcellulose, emphasize the need to have the powder thoroughly mixed with at

PATIENT TEACHING TIPS—cont'd

least 6 oz of liquid, which is stirred and drunk immediately to avoid esophageal or throat obstruction.
- Probiotics come in various dosages, under different product names, and OTC. Advise the patient to take them exactly as instructed and to be aware that side effects are generally not of concern. Cultured yogurt and cultured milk products provide probiotics.
- Inform the patient taking senna to avoid other medications within 1 hour of taking it and that it often takes 6 to 12 hours for the laxative effect to occur.

KEY POINTS

- Diarrhea is a leading cause of morbidity and mortality in underdeveloped countries.
- Drugs used to treat diarrhea include adsorbents, anticholinergics, opiates, and probiotics.
- Most acute diarrhea is self-limiting, subsiding in 3 days to 2 weeks.
- Fluid and electrolyte replacement is vital while a patient is experiencing diarrhea.
- Encourage patients to check and recheck dosage instructions before taking medication and to note any drug-food and drug-drug interactions.
- Anticholinergics work by decreasing GI peristalsis through their parasympathetic blocking effects. Adverse effects include urinary retention, headache, confusion, dry skin, rash, and blurred vision.
- Adsorbents work by coating the walls of the GI tract. They remain in the intestine and bind the causative bacteria or toxin to the adsorbent surface, so that it can be eliminated from the body through the stool. They may increase bleeding and cause constipation, dark stools, and black tongue.
- Probiotics are also used to manage diarrhea and consist of bacterial cultures of *Lactobacillus.* They reestablish normal intestinal flora destroyed by infection or antibiotics and suppress the growth of diarrhea-causing bacteria.
- Opiates are also used as antidiarrheals and help to decrease bowel motility and thus permit longer contact of intestinal contents with the absorptive surface of the bowel. Opiates also help to reduce the pain associated with rectal spasms.
- Laxatives, especially osmotic medications, may cause fluid and electrolyte loss.
- Alert patients to the abuse potential of laxatives and the problems associated with their misuse as well as laxative dependency issues.
- Stool softeners and bulk-forming drugs are often preferred to other drug classes in the treatment of constipation because they are not as problematic with regard to fluid and electrolyte loss.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 A patient is being prepared for a colonoscopy. The nurse expects which laxative to be used as preparation for this procedure?
- **a** methylcellulose
- **b** docusate sodium
- **c** PEG-3350
- **d** glycerin

2 The nurse is administering oral methylcellulose (Citrucel) and keeps in mind that a major potential concern with this drug is
- **a** dehydration.
- **b** tarry stools.
- **c** renal calculi.
- **d** esophageal obstruction.

3 A 45-year-old woman has been diagnosed with irritable bowel syndrome (IBS) and will be taking lubiprostone (Amitiza). The nurse assesses for conditions that may be contraindications to this drug, such as
- **a** constipation.
- **b** bowel obstruction.
- **c** renal calculi.
- **d** anemia.

4 When the nurse teaches a patient about taking bisacodyl tablets, which instruction is correct?
- **a** "Take this medication on an empty stomach."
- **b** "Chew the tablet for quicker onset of action."
- **c** "Take this medication with juice or milk."
- **d** "Take this medication with an antacid if it upsets your stomach."

5 A patient has been receiving long-term antibiotic therapy as part of treatment for an infected leg wound. He tells the nurse that he has had "spells of diarrhea" for the last week. Which medication is most appropriate for him at this time?
- **a** bismuth subsalicylate
- **b** *L. acidophilus*
- **c** diphenoxylate with atropine
- **d** codeine

NCLEX® EXAMINATION REVIEW QUESTIONS—cont'd

6 A parent calls to ask about giving a medication for diarrhea to his child, 12 years of age, who is recovering from the flu. The nurse expects the prescriber to recommend which medication?
- **a** bismuth subsalicylate (Pepto-Bismol)
- **b** *Lactobacillus GG* (Culturelle)
- **c** belladonna alkaloid/phenobarbital combination (Donnatal Elixir)
- **d** loperamide (Imodium A-D)

7 A patient has been instructed to use an over-the-counter (OTC) form of the bulk-forming laxative methylcellulose (Citrucel) to prevent constipation. The nurse will advise the patient of potential adverse effects, including *(Select all that apply)*
- **a** fluid and electrolyte disturbances.
- **b** decreased absorption of vitamins.
- **c** gas formation.
- **d** darkened stools.
- **e** discolored urine.

1. c, 2. d, 3. b, 4. a, 5. b, 6. d, 7. a, c

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the pathophysiology of nausea and vomiting, including specific precipitating factors and/or diseases.
2 Identify the various antiemetic and antinausea drugs and their drug classification groupings.
3 Describe the mechanisms of action, indications for use, contraindications, cautions, and drug interactions of the various categories of antiemetic and antinausea drugs.
4 Develop a nursing care plan that includes all phases of the nursing process for patients taking antiemetic and antinausea drugs.

DRUG PROFILES

aprepitant, p. 851
dronabinol, p. 850
♦ **meclizine, p. 849**
♦ **metoclopramide, p. 850**
♦ **ondansetron, p. 850**
phosphorated carbohydrate solution, p. 851
♦ **prochlorperazine, p. 849**
promethazine, p. 849
scopolamine, p. 849

♦ *Key drug*

KEY TERMS

Antiemetic drugs Drugs given to relieve nausea and vomiting. (p. 846)
Chemoreceptor trigger zone (CTZ) The area of the brain that is involved in the sensation of nausea and the action of vomiting. (p. 845)
Emesis The forcible emptying or expulsion of gastric and, occasionally, intestinal contents through the mouth; also called *vomiting*. (p. 845)
Nausea Sensation often leading to the urge to vomit. (p. 845)
Vomiting center The area of the brain that is involved in stimulating the physiologic events that lead to nausea and vomiting. (p. 845)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

NAUSEA AND VOMITING

Nausea and vomiting are two gastrointestinal (GI) disorders that can be extremely unpleasant but also can lead to more serious complications if not treated promptly. **Nausea** is an unpleasant feeling that often precedes vomiting. If it does not subside spontaneously or is not relieved by medication, it can lead to vomiting. Vomiting, which is also called **emesis,** is the forcible emptying or expulsion of gastric and, occasionally, intestinal contents through the mouth. A variety of stimuli can induce nausea and vomiting, including foul odors or tastes, unpleasant sights, irritation of the stomach or intestines, and certain drugs (ipecac or antineoplastic drugs).

The **vomiting center** is an area in the brain that is responsible for initiating the physiologic events that lead to nausea and vomiting. Neurotransmitter signals are sent to the vomiting center from the **chemoreceptor trigger zone (CTZ),** another area in the brain involved in the induction of nausea and vomiting. These signals alert those areas of the brain to the existence of nauseating substances (noxious stimuli) that need to be expelled from the body. Once the CTZ and vomiting center are stimulated, they initiate the events that trigger the vomiting reflex. The neurotransmitters involved in this process and their respective receptors are listed in Table 52-1. The various pathways and the areas of the body that send the signals to the vomiting center are illustrated in Figure 52-1. Two specific types of nausea and vomiting, chemotherapy-induced and postoperative, produce much more intense symptoms and are treated much more aggressively than general nausea and vomiting.

TABLE 52-1 NEUROTRANSMITTERS INVOLVED IN NAUSEA AND VOMITING

NEUROTRANSMITTER (RECEPTOR)	SITE IN THE VOMITING PATHWAY
Acetylcholine (ACh)	VC in brain; vestibular and labyrinthine pathways in inner ear
Dopamine (D_2)	GI tract and CTZ in brain
Histamine (H_1)	VC in brain; vestibular and labyrinthine pathways in inner ear
Prostaglandins	GI tract
Serotonin (5-HT_3)	GI tract; CTZ and VC in brain

CTZ, Chemoreceptor trigger zone; *ACh,* acetylcholine receptor; D_2, dopamine 2 receptor; *GI,* gastrointestinal; H_1, histamine 1 receptor; *5-HT_3,* 5-hydroxytriptamine 3 receptor; *VC,* vomiting center.

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

Syrup of Ipecac and Poisoning

- Since November 2003, the American Academy of Pediatrics (AAP) has strongly advised *against* the use of syrup of ipecac as an emetic when children swallow a poisonous substance. In a statement published in the November 2003 issue of *Pediatrics,* the AAP recommended that syrup of ipecac no longer be used as a home treatment for poisoning. Syrup of ipecac is still not recommended for use at this time. See http://www.healthychildren.org for more information.
- If a child has been exposed to a toxic substance, the caregiver must call the national poison control hotline at 800-222-1222. Calls are routed to the local poison control center or take to the nearest emergency department.
- Steps to follow to prevent accidental poisoning, as identified by the AAP, include the following: (1) Keep potential poisons out of sight and out of reach. (2) Always check to make sure containers are securely closed and the cabinets where they are stored are securely shut and locked after poisonous substances are used. (3) Never transfer a substance from its original to an alternate container. (4) Safely dispose of all unused and unneeded medications. (5) *Never* refer to medicines as "candy."
- The AAP specifies that the following steps be implemented for the treatment of poisoning in young children: (1) If the poison has been ingested, *first* call the national poison control hotline at 800-222-1222. (2) If the poison has touched the skin or eyes, run tap water over the skin or eyes for 15 to 20 minutes. (3) If the poison has been inhaled, remove the child from the hazardous environment. (4) In *all* cases of poisoning, *if the victim is conscious and alert, call the local poison control center. If the victim has collapsed or stopped breathing, call 911* for emergency transport to a hospital.
- There remains no indication for use of syrup of ipecac in any setting including health care settings.

Modified from American Academy of Pediatrics: Poison treatment in the home, *Pediatrics* 112:1061-1064, 2003; Tips for poison prevention and treatment, available at http://www.healthychildren.org.

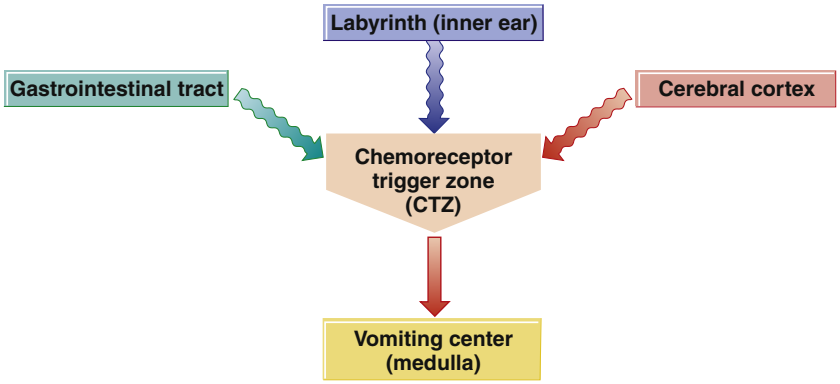

FIGURE 52-1 Various pathways and areas in the body sending signals to the vomiting center.

PHARMACOLOGY OVERVIEW

ANTIEMETIC DRUGS

Drugs used to relieve nausea and vomiting are called **antiemetic drugs.** All antiemetic drugs work at some site in the vomiting pathways. There are six categories of such drugs with varying mechanisms of action. When drugs from different categories are combined, the antiemetic effectiveness is increased because more than one pathway becomes blocked. Some of the more commonly used antiemetics in the various categories are listed in Table 52-2. The sites at which antiemetics work in the vomiting pathway are shown in Figure 52-2.

TABLE 52-2 ANTIEMETIC DRUGS: COMMON DRUG CATEGORIES AND INDICATIONS

CATEGORY	ANTIEMETIC DRUGS	INDICATIONS
Anticholinergics (acetylcholine blockers)	scopolamine	Motion sickness, secretion reduction before surgery, nausea and vomiting
Antihistamines (H_1 receptor blockers)	dimenhydrinate, diphenhydramine, meclizine	Motion sickness, nonproductive cough, sedation, rhinitis, allergy symptoms, nausea and vomiting
Antidopaminergics	prochlorperazine, promethazine, droperidol	Psychotic disorders (mania, schizophrenia, anxiety), intractable hiccups, nausea and vomiting
Prokinetics	metoclopramide	Delayed gastric emptying, gastroesophageal reflux, nausea and vomiting
Serotonin blockers	dolasetron, granisetron, ondansetron, palonosetron	Nausea and vomiting associated with chemotherapy, postoperative nausea and vomiting
Tetrahydrocannabinoids	dronabinol	Nausea and vomiting associated with chemotherapy, anorexia associated with weight loss in patients with AIDS and cancer

Mechanism of Action and Drug Effects

Drugs used to prevent or treat nausea and vomiting have many different mechanisms of action. Most work by blocking one of the vomiting pathways, as shown in Figure 52-2. In doing so, they block the neurologic stimulus that induces vomiting. The mechanisms of action of the drugs in the six antiemetic drug categories are summarized in Table 52-3.

Anticholinergic drugs (see Chapter 21) have several uses. As antiemetics, they act by binding to and blocking acetylcholine (ACh) receptors in the vestibular nuclei, which are located deep

TABLE 52-3 ANTIEMETIC DRUGS: MECHANISMS OF ACTION

CATEGORY	MECHANISM OF ACTION
Anticholinergics	Block ACh receptors in the vestibular nuclei and reticular formation
Antihistamines	Block H_1 receptors, thereby preventing ACh from binding to receptors in the vestibular nuclei
Antidopaminergics	Block dopamine in the CTZ and may also block ACh
Prokinetics	Block dopamine in the CTZ or stimulate ACh receptors in the GI tract
Serotonin blockers	Block serotonin receptors in the GI tract, CTZ, and VC
Tetrahydrocannabinoids	Have inhibitory effects on the reticular formation, thalamus, and cerebral cortex

ACh, Acetylcholine; *CTZ,* chemoreceptor trigger zone; *GI,* gastrointestinal; *VC,* vomiting center.

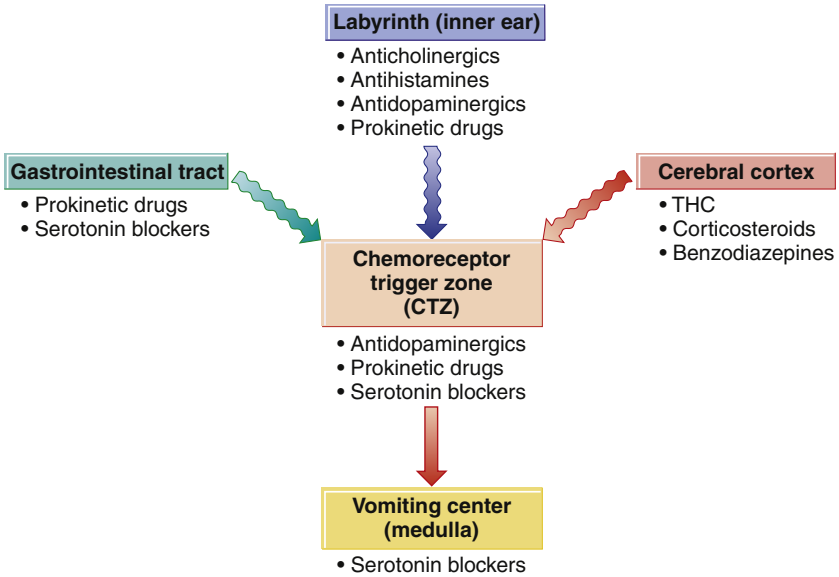

FIGURE 52-2 Sites of action of selected antinausea drugs. *THC,* Tetrahydrocannabinol.

within the brain. When ACh is prevented from binding to these receptors, nausea-inducing signals originating in this area cannot be transmitted to the chemoreceptor trigger zone (CTZ). Anticholinergics also block receptors located in the reticular formation so that nausea-inducing signals originating in this area cannot be transmitted to the vomiting center. Anticholinergics also tend to dry GI secretions and reduce smooth muscle spasms, both of which effects are often helpful in reducing acute GI symptoms, including nausea and vomiting.

Antihistamines (histamine 1 [H_1] receptor blockers) act by inhibiting vestibular stimulation in a manner that is very similar to that of the anticholinergics. Although they bind primarily to H_1 receptors, they also have potent anticholinergic activity, including antisecretory and antispasmodic effects. Thus, the antihistamines (see Chapter 36) prevent cholinergic stimulation in both the vestibular and reticular systems. Nausea and vomiting occur when these systems are stimulated. Note that these drugs are not to be confused with histamine 2 [H_2] receptor blockers used for gastric acid control (see Chapter 50).

Antidopaminergic drugs, although they are traditionally used for their antipsychotic effects (see Chapter 16), also prevent nausea and vomiting by blocking dopamine receptors in the CTZ. Many of the antidopaminergics also have anticholinergic actions similar to those of anticholinergic drugs. In addition, antidopaminergic drugs calm the central nervous system (CNS).

Prokinetic drugs, in particular metoclopramide, act as antiemetics by blocking dopamine receptors in the CTZ, which desensitizes the CTZ to impulses it receives from the GI tract. Their primary action, however, is to stimulate peristalsis in the GI tract. This enhances the emptying of stomach contents into the duodenum, as well as intestinal movements.

Serotonin blockers work by blocking serotonin receptors located in the GI tract, CTZ, and vomiting center. There are many subtypes of serotonin receptors, and they are located throughout the body (CNS, smooth muscle, platelets, and GI tract). The receptor subtype involved in the mediation of nausea and vomiting is the 5-hydroxytryptamine 3 (5-HT_3) receptor. These receptors are the site of action of the serotonin blockers such as ondansetron, granisetron, dolasetron, and palonosetron.

Tetrahydrocannabinol (THC), in a drug class by itself, is the major psychoactive substance in marijuana. Nonintoxicating doses in the form of the drug dronabinol are occasionally used as an antiemetic because of the drug's inhibitory effects on the reticular formation, thalamus, and cerebral cortex. These effects cause an alteration in mood and in the body's perception of its surroundings, which may be beneficial in relieving nausea and vomiting. Although this particular category of antiemetics is less commonly prescribed, there are occasionally patients who respond well to THC. Examples are patients being treated for cancer or acquired immunodeficiency syndrome (AIDS) who experience nausea and vomiting. In such patients, dronabinol may also stimulate the appetite, and nutritional wasting syndromes are common in both diseases. The drug also demonstrates some benefit in controlling the symptoms of glaucoma. There is a large, but highly controversial, political movement with participation of many cancer, AIDS, and glaucoma patients in favor of legalization of the marijuana plant for these uses.

Indications

The therapeutic uses of the antiemetic drugs vary depending on the drug category. There are several indications for the drugs in each class. These are listed in Table 52-2.

Contraindications

The primary contraindication for all antiemetics is known drug allergy. Other contraindications for various specific drugs are mentioned in the drug profiles.

Adverse Effects

Most of the adverse effects of the antiemetics stem from their nonselective blockade of various receptors. Some of the more common adverse effects associated with the various categories of antinausea drugs are listed in Table 52-4.

TABLE 52-4 ANTINAUSEA DRUGS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Anticholinergics	
Central nervous	Dizziness, drowsiness, disorientation
Cardiovascular	Tachycardia
Ears, eyes, nose, throat	Blurred vision, dilated pupils, dry mouth
Genitourinary	Difficult urination, constipation
Integumentary	Rash, erythema
Antihistamines	
Central nervous	Dizziness, drowsiness, confusion
Ears, eyes, nose, throat	Blurred vision, dilated pupils, dry mouth
Genitourinary	Urinary retention
Antidopaminergics	
Cardiovascular	Orthostatic hypotension, tachycardia
Central nervous	Extrapyramidal symptoms, tardive dyskinesia, headache
Ears, eyes, nose, throat	Blurred vision, dry eyes
Genitourinary	Urinary retention
Gastrointestinal	Dry mouth, nausea and vomiting, anorexia, constipation
Prokinetics	
Cardiovascular	Hypotension, supraventricular tachycardia
Central nervous	Sedation, fatigue, restlessness, headache, dystonia
Gastrointestinal	Dry mouth, nausea and vomiting, diarrhea
Serotonin Blockers	
Central nervous	Headache
Gastrointestinal	Diarrhea
Other	Rash, bronchospasm, prolonged QT interval
Tetrahydrocannabinoids	
Central nervous	Drowsiness, dizziness, anxiety, confusion, euphoria
Ears, eyes, nose, throat	Visual disturbances
Gastrointestinal	Dry mouth

Interactions

The drug interactions associated with the antiemetic drugs are specific to the individual drug categories. Anticholinergics have additive drying effects when given with antihistamines and antidepressants. Increased CNS depressant effects are seen when antihistamine antiemetics are administered with barbiturates, opioids, hypnotics, tricyclic antidepressants, or alcohol. Increased CNS depression also occurs when alcohol or other CNS depressants are given together with antidopaminergic drugs. Combining metoclopramide with alcohol can result in additive CNS depression. Anticholinergics and analgesics can block the motility effects of metoclopramide. Serotonin blockers and THC have no significant drug interactions.

Dosages

For dosage information on selected antiemetic drugs, see the table on this page.

DRUG PROFILES

Antiemetics are used to treat nausea and vomiting in a variety of clinical situations, including chemotherapy-induced and postoperative nausea and vomiting, both of which can be especially difficult to treat. The ultimate goals of antiemetic therapy are minimizing or preventing fluid and electrolyte disturbances and minimizing deterioration of the patient's nutritional status. Most of the antiemetics act by blocking receptors in the CNS, but some work directly in the GI tract. There are six major classes of antiemetic drugs, although there are other drugs that may also be used to treat nausea and vomiting, including corticosteroids such as dexamethasone (see Chapter 33) and anxiolytics such as lorazepam (see Chapter 16). Lorazepam is often used in the treatment and prevention of chemotherapy-induced nausea and vomiting. In addition to an antiemetic effect, it also helps to blunt the memory of the nausea and vomiting experience (especially with cancer chemotherapy). Dexamethasone,

DOSAGES

Selected Antiemetic and Antinausea Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
Anticholinergics			
scopolamine (Transderm-Scōp) (C)	Anticholinergic, belladonna alkaloid	Apply 1 patch to hairless area behind ear every 3 days (starting at least 4 hr before travel)	Motion sickness prophylaxis
Antihistamines			
♦ meclizine (Antivert, Bonine) (B)	Anticholinergic, antihistamine	**Adult** PO: 25-50 mg 1 hr before travel and repeated daily during travel	Motion sickness prophylaxis
		PO: 25-100 mg/day, divided 1-4 times daily	Treatment of vertigo
Antidopaminergics			
♦ prochlorperazine (Compazine) (C)	Phenothiazine	**Pediatric*** Doses vary based on weight and age **Adult** PO: 5-10 mg 3-4 times daily IM: 5-10 mg q3-4h (max 40 mg/day) PR: 25 mg twice daily IV: 5-10 mg q6h	Antiemetic
promethazine (Phenergan) (C)	Phenothiazine	**Pediatric older than 2 yr** IV, IM, PO, PR: 0.25-0.5 mg/kg/dose 4-6 times daily **Adult** IV, IM, PO, PR: 12.5-25 mg q4-6h	Antiemetic
Prokinetics			
♦ metoclopramide (Reglan) (B)	Dopamine antagonist	**Adult** IV: 1-2 mg/kg (30 min before chemotherapy; repeat q2h × 2 doses, then q3h × 3 doses)	Chemotherapy antiemetic
		IM: 10-20 mg × 1 dose near end of surgery; repeat q4-6h as needed	Prevention of postoperative nausea and vomiting
Serotonin Blockers			
♦ ondansetron (Zofran) (B)	Antiserotonergic	**Pediatric*** Doses vary based on age and weight **Adult** PO: 8 mg tid **Adult** IV: 24-32 mg once daily	Chemotherapy antiemetic

DOSAGES

Selected Antiemetic and Antinausea Drugs—cont'd

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
		Pediatric: 1 mo-12 yr Less than 40 kg: 0.1 mg/kg More than 40 kg: 4 mg as single dose **Adult** 4 mg as single dose 30 min before surgery ends	Prevention and treatment of postoperative nausea
Tetrahydrocannabinoids			
dronabinol (Marinol) (C)	Marijuana-derived antiemetic	**Adult** PO: Initially, 5 mg/m^2 1-3 hr before chemotherapy, then q2-4h after chemotherapy up to 6 times daily for 3 days; this dose may, if needed, be increased in 2.5-mg/m^2 increments to a max dose of 15 mg/m^2	Chemotherapy antiemetic
		PO: 2.5 mg twice daily before lunch and before or after dinner to a maximum dose of 20 mg/day in divided doses. Adverse effects increase greatly in doses above 20 mg/day.	Appetite stimulation in HIV/AIDS and cancer patients

AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus (infection); *IM,* intramuscular; *IV,* intravenous; *PO,* oral; *PR,* per rectum.
*There are optional dosage regimens for chemotherapy-induced nausea and vomiting; the reader is referred to a drug information handbook.

lorazepam, and dronabinol are beneficial in preventing nausea and vomiting caused by chemotherapy, especially when used in combination with the serotonin blockers.

ANTICHOLINERGIC

scopolamine

Scopolamine (Transderm-Scōp, Scopace) is the primary anticholinergic drug used as an antiemetic. It has potent effects on the vestibular nuclei, which are located in the area of the brain that controls balance. Scopolamine works by blocking the binding of ACh to the cholinergic receptors in this region and thereby correcting an imbalance between the two neurotransmitters ACh and norepinephrine. These effects make scopolamine one of the most commonly used drugs for the treatment and prevention of the nausea and vomiting associated with motion sickness. Scopolamine is also used to treat postoperative nausea and vomiting. Use of the drug is contraindicated in patients with glaucoma. Scopolamine is available in oral, injectable, transdermal, and even ocular forms (see Chapter 57). The most commonly used formulation for nausea is the 72-hour transdermal patch, which releases a total of 1 mg of the drug.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Transdermal	1-2 hr	6-8 hr	8-9.5 hr	72 hr

ANTIHISTAMINES

Antihistamine antiemetics are some of the most commonly used and safest antiemetics. Some of the popular antihistamines are meclizine (Antivert), dimenhydrinate (Dramamine), and diphenhydramine (Benadryl). Many of the antihistamines are available over the counter. Hydroxyzine (Vistaril) is used for antiemetic purposes and is available in oral and intramuscular formulations. Hydroxyzine must never be given by the intravenous route (see the Safety and Quality Improvement: Preventing Medication Errors Box on p. xxx).

♦ meclizine

Meclizine (Antivert) is commonly used to treat the dizziness, vertigo, and nausea and vomiting associated with motion sickness. Contraindications include shock and lactation. It is available for oral use only.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 hr	Variable	6 hr	8-24 hr

ANTIDOPAMINERGICS

Prochlorperazine (Compazine) and promethazine (Phenergan) are the most commonly used antiemetics in the antidopaminergic class. These drugs have antidopaminergic as well as antihistaminergic and anticholinergic properties. Droperidol was one of the most commonly used drugs to treat and prevent postoperative nausea and vomiting for several decades until the U.S. Food and Drug Administration (FDA) called for a black box warning and required continuous electrocardiographic monitoring with its use. These restrictions were in response to concerns over QT widening and possible ventricular dysrhythmias. Some institutions still use droperidol, whereas others have banned its use.

♦ prochlorperazine

Prochlorperazine (Compazine), especially in the injectable form, is used frequently in the hospital setting. The drug is contraindicated in patients with hypersensitivity to phenothiazines, those in a coma, and those who have seizures, encephalopathy, or bone marrow suppression. It is available for both injection and oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IM	30-40 min	2-4 hr	6-8 hr	3-4 hr

promethazine

Promethazine (Phenergan) is commonly used in hospitalized patients as an antiemetic. The preferred route is oral or intramuscular. The intravenous route is not the preferred route but is commonly used. However, extreme care must be taken to avoid accidental intraarterial injection. If promethazine is inadvertently given intraarterially instead of intravenously, severe tissue damage, often requiring amputation, can occur. Promethazine is best diluted in at least 10 mL of fluid (the more dilute the better) and given in a running intravenous line at the port furthest from the patient's vein or through a large-bore vein (not hand or wrist vein). Therapy must be discontinued immediately if burning or pain occurs with administration. Promethazine is contraindicated in children younger than 2 years of age. Sedation is the most common adverse effect and actually may be beneficial. The drug is also available as a rectal suppository. It is not to be given subcutaneously. For more information, see the Safety and Quality Improvement: Preventing Medication Errors Box on p. 851.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IM	20 min	4.4 hr	9-16 hr	2-6 hr

PROKINETIC

Prokinetic drugs promote the movement of substances through the GI tract and increase GI motility. The only prokinetic drug that is also used to prevent nausea and vomiting is metoclopramide.

♦ metoclopramide

Metoclopramide (Reglan) is available only by prescription because it can cause some severe adverse effects if not used correctly. Metoclopramide is used for the treatment of delayed gastric emptying and gastroesophageal reflux and also as an antiemetic. Its use is contraindicated in patients with seizure disorder, pheochromocytoma, breast cancer, or GI obstruction and also in patients with a hypersensitivity to it or to procaine or procainamide. Metoclopramide is available in both oral and parenteral formulations. Extrapyramidal adverse effects can occur with its use, especially in young adults. In 2009, the FDA posted a public health advisory regarding the potential of developing tardive dyskinesia with long-term use of metoclopramide.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	20-60 min	1-2.5 hr	2.5-6 hr	3-4 hr

SEROTONIN BLOCKERS

The serotonin blockers are also called *5-HT3 receptor blockers* because they block the 5-HT_3 receptors in the GI tract, the CTZ, and the vomiting center. (The chemical name for serotonin is 5-hydroxytryptamine, or 5-HT.) Drugs in this class have very specific actions, and as a result they have very few adverse effects. No significant drug interactions are known to occur. These drugs are indicated for the prevention of nausea and vomiting associated with cancer chemotherapy and also for the prevention of postoperative or radiation-induced nausea and vomiting. Currently there are four drugs in this category: dolasetron (Anzemet), granisetron (Kytril), ondansetron (Zofran), and palonosetron (Aloxi). This class of drugs revolutionized the treatment of nausea and vomiting, especially in cancer patients and postoperative patients. When used to prevent postoperative nausea and vomiting, a dose is usually given approximately 30 minutes before the end of the surgical procedure. When used to prevent or treat nausea and vomiting associated with cancer treatment, the drug is given in the first 24 to 48 hours of chemotherapy. All drugs in this class are classified as pregnancy category B drugs. In 2010, the FDA issued a warning regarding dolasetron and the risk of cardiac dysrhythmias. In 2011, the FDA added the same warning for ondansetron. The FDA no longer recommends dolasetron to be used for chemotherapy-induced nausea and vomiting.

♦ ondansetron

Ondansetron (Zofran) is the prototypical drug in this class. Approved in 1992, it represented a major breakthrough in treating chemotherapy-induced nausea and vomiting and, later, postoperative nausea and vomiting. It is also used for the treatment of hyperemesis gravidarum (nausea and vomiting associated with pregnancy). Its only listed contraindication is known drug allergy. It is available in both oral and injectable forms and as orally disintegrating tablets. Doses up to 8 mg can be given by intravenous push over 2 to 5 minutes. Ondansetron was the first of the class to become available as a generic formulation, which significantly increased its use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	15-30 min	1-1.5 hr	3.5-5 hr	6-12 hr

TETRAHYDROCANNABINOID

dronabinol

Dronabinol (Marinol) is the only commercially available tetrahydrocannabinoid. It is a synthetic derivative of THC, the major active substance in marijuana. Dronabinol was approved by the FDA in 1985 for the treatment of nausea and vomiting associated

with cancer chemotherapy. It is generally used as a second-line drug after treatment with other antiemetics has failed. It is also used to stimulate appetite and weight gain in patients with AIDS and chemotherapy patients. Its only listed contraindication is known drug allergy. It is available for oral use only.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-60 min	1-3 hr	19-36 hr	4-6 hr

MISCELLANEOUS ANTINAUSEA DRUGS

phosphorated carbohydrate solution

Phosphorated carbohydrate solution (Emetrol) is a mint-flavored, pleasant-tasting oral solution used to relieve nausea. It works by direct local action on the walls of the GI tract, where it reduces cramping caused by excessive smooth muscle contraction. It can be used to control mild cases of nausea and vomiting. It does not have a pregnancy category rating, but one of its listed unlabeled (non–FDA-approved) uses is for treatment of morning sickness during pregnancy. Phosphorated carbohydrate solution is not sufficient for treatment of more severe nausea symptoms such as those associated with cancer chemotherapy. Its only contraindication is known drug allergy. It is available for oral use only.

aprepitant

Aprepitant (Emend) is the first in a new class of antiemetic drugs and was approved in 2003. It is an antagonist of substance P–neurokinin 1 receptors in the brain. In contrast to other antiemetics, this drug has little affinity for 5-HT_3 (serotonin) and dopamine receptors. Studies show that aprepitant augments the antiemetic actions of both ondansetron and the corticosteroid dexamethasone. This drug is specifically indicated for the prevention of nausea and vomiting associated with highly emetogenic cancer chemotherapy regimens, including high-dose cisplatin, as well as postoperative nausea and vomiting. Common adverse effects include dizziness, headache, insomnia, and GI discomfort, but these are generally no more common than with other standard antiemetic regimens. Aprepitant may induce the metabolism of warfarin, and international normalized ratio (INR) needs to be checked before each cycle of aprepitant. The drug may reduce the effectiveness of oral contraceptives. Because aprepitant is a major inhibitor of the cytochrome P-450 enzyme system, caution must be used in giving it together with drugs that are primarily metabolized by cytochrome P-450 enzyme 3A4, including azole antifungals, clarithromycin, diltiazem, nicardipine, protease inhibitors, and verapamil. It may increase the bioavailability of corticosteroids, including dexamethasone and methylprednisolone, and dosages of these drugs may need to be adjusted by 25% to 50%. Aprepitant is classified as a pregnancy category B drug.

NURSING PROCESS

ASSESSMENT

Before any antinausea or antiemetic drug is administered, obtain a complete nursing history and perform a thorough physical assessment with attention to the following: history of the symptoms of nausea and vomiting; medical history and current medical status; medication history and drugs currently taken including over-the-counter drugs, herbals, prescription drugs, and social drugs (e.g., cigarettes, alcohol); and any alternative therapies used. Identify any factors precipitating nausea or vomiting; note any weight loss; measure baseline vital signs; assess intake and output; examine the skin and mucous membranes, noting turgor and color; and assess and document capillary refill (normal is less than 5 seconds). If laboratory tests are ordered (e.g., serum sodium, potassium, and chloride levels; hemoglobin level and hematocrit; red and white blood cell counts; urinalysis), assess and document the findings to establish baseline levels. Assess for any contraindications or cautions to the use of these drugs and for drug interactions, as well as any allergies.

Only give the *anticholinergic drug* scopolamine after careful assessment of the patient's health history and medication history. One very important concern to emphasize with scopolamine, which is commonly administered in patch form to prevent motion sickness, is the contraindication to its use in patients with narrow-angle glaucoma. If the patient has a history of this disorder, use another antiemetic or antinausea drug. The same concern regarding use in patients with narrow-angle glaucoma applies to *antihistamines* (e.g., meclizine); in addition, use antihistamines cautiously in pediatric patients, who may have severe paradoxical reactions. Elderly patients may develop agitation, mental confusion, hypotension, and even psychotic-type reactions in response to these drugs. Other medications need to be considered for patients if these reactions occur.

Antidopaminergic drugs, such as promethazine, are to be used only after cautious assessment for signs and symptoms of dehydration and electrolyte imbalance by evaluating skin turgor and examining the tongue for the presence of longitudinal furrows. Monitor vital signs, especially blood pressure and pulse rate, due to adverse effects of orthostatic hypotension and

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Right Route Is Essential

Two commonly used antiemetic drugs may have serious consequences for the patient if they are given via the wrong route.

Hydroxyzine (Vistaril) is an antihistamine-class antiemetic that is only to be given either by oral or intramuscular routes. However, when so many other antiemetics are given by the intravenous route, it may be easy to make the mistake of giving hydroxyzine intravenously. It is important to note that intravenous, intraarterial, or subcutaneous administration of hydroxyzine may result in significant tissue damage, thrombosis, and gangrene.

Promethazine (Phenergan) is another commonly used antiemetic. The oral and intramuscular routes are the preferred routes of administration; the intravenous route, while commonly used, is not the preferred route. If this drug is given intraarterially, severe tissue damage, possibly leading to amputation, may occur.

These are just two examples that illustrate the importance of the "right route" with drug administration.

tachycardia. CNS concerns to assess for include any abnormal movements at baseline functioning because these drugs can lead to adverse effects of extrapyramidal symptoms. Contraindications, cautions, and drug interactions for these drugs have been discussed earlier. Double-checking the name and mechanism of action is also important *prochlorperazine* may be confused with *promethazine*) to prevent sound-alike medication errors.

The *prokinetic drug* metoclopramide is often reserved for the treatment of nausea and vomiting associated with antineoplastic drug therapy or radiation therapy and for the treatment of GI motility disturbances. The action of this drug is decreased when it is taken with anticholinergics or opiates; therefore, assess for this interaction. Remember the FDA public health advisory regarding untoward reactions with long-term use (see the pharmacology section).

Only give the *serotonin blocker* granisetron after assessment of baseline vital signs and age (its safety in those younger than 2 years of age has not been established). Ondansetron use requires assessment for the signs and symptoms of dehydration and electrolyte disturbances. Assess skin turgor and examine mucous membranes for dryness and/or longitudinal furrows in the tongue.

With the *tetrahydrocannabinoid* dronabinol, assess patients for signs and symptoms of dehydration, with attention to low urine output, dry mucous membranes, poor skin turgor, and lethargy. Perform a thorough assessment of hydration status because treatment of volume and electrolyte imbalances may be required in addition to treatment with antinausea or antiemetic drugs. Assess motor and cognitive abilities.

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

***Ginger* (Zingiber officinale)**

Overview
Found naturally in the Asian tropics; now cultivated in other continents, including part of the United States; plant parts utilized are the rhizome and root; active ingredients include gingerols and gingerdione

Common Uses
Used as an antioxidant; also used for relief of such varied symptoms as sore throat, migraine headache, and nausea and vomiting (including that induced by cancer chemotherapy, morning sickness, and motion sickness); many other varied uses

Adverse Effects
Skin reactions, anorexia, nausea, vomiting

Potential Drug Interactions
Can increase absorption of all oral medications; may theoretically increase bleeding risk with anticoagulants (e.g., warfarin [Coumadin]) or antiplatelet drugs (e.g., clopidogrel [Plavix])

Contraindications
Contraindicated in cases of known product allergy; may worsen cholelithiasis (gallstones); anecdotal evidence of abortifacient properties—some clinicians recommend not using during pregnancy

NURSING DIAGNOSES

1. Nausea related to disease pathology and adverse effects of specific groups of medications
2. Impaired physical mobility related to adverse effects (e.g., sedation, lethargy, confusion) of antiemetics
3. Risk for injury (falls) related to the adverse effects of antiemetic medications (e.g., sedation and dizziness)
4. Risk for deficient fluid volume related to nausea and vomiting and limited oral intake

PLANNING

GOALS

1. Patient remains free from nausea and vomiting with use of pharmacologic and nonpharmacologic therapies.
2. Patient regains mobility status and/or remains with stable mobility during drug therapy.
3. Patient remains free from injury during drug therapy with antiemetic.
4. Patient maintains/regains fluid volume balance while undergoing treatment.

OUTCOME CRITERIA

1. Patient states specific rationales for reducing nausea and vomiting through use of antiemetic drug therapy as well as specific nondrug measures.
   - Patient states action of specific antiemetic drug, specific dosage, and best time to take the drug, and identifies related adverse effects such as sedation, dizziness, and dry mouth.
   - Patient states specific measures to decrease nausea and vomiting, such as avoiding irritating, spicy foods and beverages, and possibly avoiding fluids and food until nausea and vomiting subsides (but prior to becoming dehydrated).
   - Patient states signs and symptoms of dehydration to report to the prescriber if they occur, such as dry mouth, decrease in urinary output, decreased to no intake of fluids, lethargy, weakness, and dizziness.
2. Patient increases physical mobility and activity, with assistance if needed, by 10 to 15 minutes per day with cautious movements, changing of positions, rising, walking, and performing activities of daily living.
3. Patient states measures to implement to prevent injury, such as obtaining assistance while ill, rising slowly, changing positions slowly, taking medications as ordered, and initiating fluid intake once nausea and/or vomiting subside.
4. Patient states measures to implement to prevent further fluid volume deficits, such as consumption of oral fluids (e.g., clear liquids) or chilled gelatin along with medications.

IMPLEMENTATION

Undiluted forms of diphenhydramine, an *antihistamine,* must be cautiously administered intravenously at the recommended rate of 25 mg/min as ordered. Administer intramuscular forms

CASE STUDY

Nausea and Chemotherapy

Mr. S., a 68-year-old retired bus driver, has begun outpatient chemotherapy after a recent diagnosis of lung cancer. He has recovered well from a right lung lobectomy, the incisions are well healed, and he is now physically and emotionally ready for a 3-month regimen of chemotherapy. The premedication orders call for a variety of drugs, including granisetron (Kytril). Mr. S. has a prescription for oral ondansetron (Zofran) for use at home.

1. What is the mechanism of action of granisetron that makes it effective in the management of chemotherapy-induced nausea and vomiting?
2. What important patient teaching points should you emphasize to Mr. S. about the ondansetron?
3. After 2 weeks of therapy, the oncologist discontinues the ondansetron because Mr. S. complains that it does nothing to help the nausea and vomiting. Mr. S. receives a prescription for dronabinol but expresses concern, exclaiming, "There's marijuana in that pill!" What would you explain to Mr. S.?

For answers, see http://evolve.elsevier.com/Lilley.

into large muscles (e.g., ventral gluteal), and rotate sites if repeated injections are necessary. Promethazine may be given orally without regard to meals, and suppository forms are available, if needed. Keep suppository dosage forms in their foil covering until use and, once the wrap is removed, you may moisten them with water or water-soluble lubricating gel before being inserted well into the rectum. Place the patient on the left side for suppository insertion and keep the patient there for several minutes (see Chapter 9). Tell the patient to hold in the suppository for as long as possible to increase its absorption. Measure vital signs and monitor the patient for extrapyramidal symptoms throughout therapy. Encourage the patient to avoid other CNS depressants and alcohol as well as limit caffeine when this drug is used. Instruct the patient to avoid driving and other activities that require mental alertness or motor coordination.

Frequently monitor blood pressure in patients taking meclizine, especially if they are elderly. Be aware of the concern sedation poses for patient safety and emphasize the need for cautious movement at all times. Dry mouth, another adverse effect, produced by any of these medications may be alleviated by using sugarless gum or hard candy. Metoclopramide given orally is best taken 30 minutes before meals and at bedtime. Infuse intravenous dosage forms over the recommended time period. In addition, keep solutions for parenteral dosing for only 48 hours, and protect them from light. Do not give metoclopramide in combination with any other medications, such as phenothiazines, that would lead to exacerbation of extrapyramidal reactions. The occurrence of extrapyramidal reactions needs to be reported to the prescriber immediately. The development of tardive dyskinesia, an involuntary neurologic movement, has been associated with the long-term use of metoclopramide. The FDA issued a public health advisory on the topic in 2009. Monitor for and educate patients about this potential problem.

The scopolamine transdermal patch is applied behind the ear as directed. The area behind the ear needs to be cleansed and dried before the patch is applied. If the patch becomes dislodged, the residual drug must be washed off and a fresh patch put in place. Remind the patient to avoid tasks requiring mental clarity or motor skills while taking the medication. Granisetron may be given intravenously or orally. Infuse intravenous doses over the recommended time period, and dilute as appropriate. A transient taste disorder may occur, especially if the drug is taken with antineoplastic medications, but will diminish with continued therapy. Encourage the use of various relaxation techniques as complementary therapies. Ondansetron may be given orally, intramuscularly, or intravenously. Inject intramuscular doses into a large muscle mass. Intravenous push is usually given over 2 to 5 minutes and infusions over 15 minutes as ordered and as per manufacturer guidelines. Oral forms are well tolerated regardless of the relation of dosing to meals. Encourage the patient to avoid alcohol and other CNS depressants during this therapy and to avoid any activities requiring mental alertness or motor skill. *Antiemetics* are usually given 30 to 60 minutes before chemotherapy (depending on the specific drug). Ondansetron is usually given 30 minutes before chemotrherapy. Dronabinol is to be administered 1 to 3 hours before antineoplastic therapy and may be taken at home before the scheduled treatment appointment. Relief of nausea and vomiting usually occurs within approximately 15 minutes of oral drug administration. Aprepitant is often used in combination with other medications to prevent nausea and vomiting associated with chemotherapy and is given, as ordered, for postoperative nausea and vomiting. The prescriber's orders may indicate other drugs to be administered as well as the timing of the dosage. Oral dosage forms are to be given as ordered.

EVALUATION

The therapeutic effects of *antiemetic* and *antinausea drugs* include a decrease in or elimination of nausea and vomiting, and avoidance or elimination of complications such as fluid and electrolyte imbalances and weight loss. Monitor the patient for adverse effects such as GI upset, drowsiness, lethargy, weakness, extrapyramidal reactions, and orthostatic hypotension during antiemetic therapy. Laboratory testing (e.g., electrolyte levels, blood urea nitrogen level, urinalysis with specific gravity) may be ordered for evaluation purposes. Defined goals and outcomes may also be used to evaluate therapeutic effectiveness.

PATIENT TEACHING TIPS

- Warn the patient using an antiemetic or antinausea drug about the adverse effect of drowsiness, and instruct the patient to use caution while performing hazardous tasks or driving (while taking these drugs). Caution the patient about taking antiemetic or antinausea drugs with alcohol and other CNS depressants because of the possible toxicity and exacerbation of CNS depression.
- Educate the patient about the possible adverse effects of ondansetron, including headache, which may be relieved by taking a simple analgesic (e.g., acetaminophen).
- Remind the patient taking dronabinol to change positions slowly to prevent syncope or dizziness resulting from the hypotensive effects of the drug. Advise the patient to be cautious when engaging in activities that require mental alertness while taking this medication.
- Rotate the application sites for transdermal scopolamine patches, and apply the patches to nonirritated areas behind the ear; wash the hands thoroughly before and after application.

KEY POINTS

- Antiemetics help to control vomiting, or emesis, and are also useful in relieving or preventing nausea. Antiemetics are used to prevent motion sickness, reduce secretions before surgery, treat delayed gastric emptying, and prevent postoperative nausea and vomiting. Most of these drugs can cause drowsiness.
- Anticholinergics work by blocking ACh receptors in the vestibular nuclei and reticular formation. This blockade prevents areas in the brain from being activated by nauseous stimuli.
- Antihistamines work by blocking H_1 receptors, which produces the same effect as the anticholinergics. Antidopaminergic antiemetics block dopamine receptors in the CTZ and may also block ACh receptors. Prokinetic drugs also block dopamine receptors in the CTZ.
- The serotonin-blocking drugs (granisetron and ondansetron) may be highly effective antiemetics. They are most commonly used for the prevention of chemotherapy-induced nausea and vomiting.
- Antiemetics are often given 30 to 60 minutes before a chemotherapy drug is administered (time may vary depending on the specific drug) and may also be given during the chemotherapeutic treatment.
- Dronabinol therapy is used to prevent chemotherapy-induced nausea and vomiting and is associated with postural hypotension.
- Caution patients taking antiemetic or antinausea drugs that drowsiness and hypotension may occur and to avoid driving and using heavy machinery while taking these medications.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is providing patient teaching regarding scopolamine transdermal patches (Transderm-Scōp) to a patient who is planning an ocean cruise. Which instruction is most appropriate?
   - **a** "Apply the patch the day before traveling."
   - **b** "Apply the patch at least 4 hours before traveling."
   - **c** "Apply the patch to the shoulder area."
   - **d** "Apply the patch to the temple just above the ear."

2 A middle-aged woman is experiencing severe vertigo. The nurse expects this patient will receive which drug, which is considered the most appropriate drug treatment for vertigo?
   - **a** meclizine (Antivert)
   - **b** prochlorperazine (Compazine)
   - **c** metoclopramide (Reglan)
   - **d** dronabinol (Marinol)

3 A 33-year-old patient is in the outpatient cancer center for his first round of chemotherapy. The nurse knows that which schedule is the most appropriate timing for the intravenous antiemetic drug?
   - **a** Four hours before the chemotherapy begins
   - **b** Thirty minutes before the chemotherapy begins
   - **c** At the same time as the chemotherapy drugs
   - **d** At the first sign of nausea

4 When reviewing the various types of antinausea medications, the nurse recognizes that prokinetic drugs are also used for
   - **a** motion sickness.
   - **b** vertigo.
   - **c** delayed gastric emptying.
   - **d** GI obstruction.

5 A patient who has been receiving chemotherapy tells the nurse that he has been searching the Internet for antinausea remedies and that he found a reference to a product called Emetrol (phosphorated carbohydrate solution). He wants to know if this drug would help him. What is the nurse's best answer?
   - **a** "This may be a good remedy for you. Let's talk to your physician."
   - **b** "This drug is used only after other drugs have not worked."
   - **c** "This drug is used only to treat severe nausea and vomiting caused by chemotherapy."
   - **d** "This drug may not help the more severe nausea symptoms associated with chemotherapy."

NCLEX® EXAMINATION REVIEW QUESTIONS—cont'd

6 The nurse is preparing to administer dronabinol (Marinol) to a patient. Which statements about dronabinol therapy are true? (Select all that apply.)

- **a** It is approved for nausea and vomiting related to cancer chemotherapy.
- **b** It is approved for use with hyperemesis gravidarum (nausea and vomiting associated with pregnancy).
- **c** It is approved to help stimulate the appetite in patients with nutritional wasting due to cancer or AIDS.
- **d** It may cause extrapyramidal symptoms.
- **e** It may cause drowsiness or euphoria.

7 The order reads: "Give promethazine (Phenergan) 12.5 mg IM q4h prn nausea/vomiting." The medication is available in 25-mg/mL vials. How many milliliters will the nurse draw up for this dose?

1. b, 2. a, 3. b, 4. c, 5. d, 6. a, c, e, 7. 0.5 mL

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the importance of the various vitamins and minerals to the normal functioning of the human body.
2 Briefly describe the various acute and chronic disease states and conditions that may lead to various imbalances in vitamin and mineral levels.
3 Discuss the pathologies that result from vitamin and mineral imbalances.
4 Describe the treatment of these vitamin and mineral imbalances.
5 Identify mechanisms of action, indications, cautions, contraindications, drug interactions, dosages, recommended daily allowances, and routes of administration of each of the vitamins and minerals.
6 Develop a nursing care plan related to the use of vitamins and minerals that includes all phases of the nursing process.

DRUG PROFILES

ascorbic acid (vitamin C), p. 869
calcifediol (vitamin D), p. 862
calcitriol (vitamin D), p. 862
calcium, p. 871
cyanocobalamin (vitamin B_{12}), p. 868
dihydrotachysterol (vitamin D), p. 862
ergocalciferol (vitamin D), p. 862
magnesium, p. 872
niacin (vitamin B_3), p. 866
phosphorus, p. 873
pyridoxine (vitamin B_6), p. 867
riboflavin (vitamin B_2), p. 866
thiamine (vitamin B_1), p. 865
vitamin A, p. 861
vitamin E, p. 863
vitamin K_1, p. 864

KEY TERMS

Beriberi A disease of the peripheral nerves caused by a dietary deficiency of thiamine (vitamin B_1). Symptoms include fatigue, diarrhea, weight loss, edema, heart failure, and disturbed nerve function. (p. 865)

Coenzyme A nonprotein substance that combines with a protein molecule to form an active enzyme. (p. 857)

Enzymes Specialized proteins that catalyze biochemical reactions. (p. 857)

Fat-soluble vitamins Vitamins that can be dissolved (i.e., are soluble) in fat. (p. 857)

Minerals Inorganic substances that are ingested and attach to enzymes or other organic molecules. (p. 857)

KEY TERMS—cont'd

Pellagra A disease resulting from a deficiency of niacin or a metabolic defect that interferes with the conversion of tryptophan to niacin (vitamin B_3). (p. 865)

Rhodopsin The purple pigment in the rods of the retina, formed by a protein, opsin, and a derivative of retinol (vitamin A). (p. 859)

Rickets A condition caused by a deficiency of vitamin D. (p. 862)

Scurvy A condition resulting from a deficiency of ascorbic acid (vitamin C). (p. 869)

Tocopherols Biologically active chemicals that make up vitamin E compounds. (p. 863)

Vitamins Organic compounds essential in small quantities for normal physiologic and metabolic functioning of the body. (p. 857)

Water-soluble vitamins Vitamins that can be dissolved (i.e., are soluble) in water. (p. 857)

ANATOMY, PHYSIOLOGY AND PATHOPHYSIOLOGY OVERVIEW

For the body to grow and maintain itself, it needs the essential building blocks provided by carbohydrates, fats, and proteins. Vitamins and minerals are needed to efficiently utilize these nutrients. **Vitamins** are organic molecules needed in small quantities for normal metabolism and other biochemical functions, such as growth or repair of tissue. Equally important are **minerals**, inorganic elements found naturally in the earth. **Enzymes** are proteins secreted by cells; they act as catalysts to induce chemical changes in other substances. A **coenzyme** is a substance that enhances or is necessary for the action of enzymes. Many enzymes are useless without the appropriate vitamins and/or minerals that cause them to function properly. Both vitamins and minerals act primarily as coenzymes, binding to enzymes (or other organic molecules) to activate anabolic (tissue-building) processes in the body. For example, coenzyme A is an important carrier molecule associated with the citric acid cycle, one of the body's major energy-producing metabolic reactions. However, it requires pantothenic acid (vitamin B_5) to complete its function in the citric acid cycle.

Vitamins and minerals are essential in our lives, whether or not we are conscientious in our food choices. Under most circumstances, daily requirements of vitamins and minerals are met by ingestion of fluids and balanced meals. Ingesting food maintains adequate stores of essential vitamins and minerals, serves to preserve intestinal structure, provides chemicals for hormones and enzymes, and prevents harmful overgrowth of bacteria.

Various illnesses can cause acute or chronic deficiencies of vitamins, minerals, electrolytes, and fluids. These conditions require replacement or supplementation of these nutrients. Common examples include extensive burn injuries and acquired immunodeficiency syndrome (AIDS). Excessive loss of vitamins and minerals may also be the result of poor dietary intake, an inability to swallow after cancer chemotherapy or radiation, or mental disorders such as anorexia nervosa. Poor dietary absorption can also be caused by various gastrointestinal (GI) malabsorption syndromes. In addition, drug and alcohol abuse are frequently associated with inadequate nutritional intake that warrants vitamin and mineral supplementation. Deficiencies in dietary protein, fat, and carbohydrates are also common. These nutrients are discussed in Chapter 55. Because of some of their distinct properties and functions in the body related to blood formation, iron and the vitamin folic acid (vitamin B_9) are discussed separately in Chapter 54.

PHARMACOLOGY OVERVIEW

The human body requires vitamins in specific minimum amounts on a daily basis, and these can be obtained from both plant and animal food sources. In some cases, the body synthesizes some of its own vitamin supply. Supplemental amounts of vitamin B complex and vitamin K are synthesized by normal bacterial flora in the GI tract. Vitamin D can be synthesized by the skin when the skin is exposed to sunlight.

An inadequate diet will cause various nutrition-related vitamin deficiencies. In 1941, the Food and Nutrition Board of the National Academy of Sciences published its first list of recommended daily allowances (RDAs) of essential nutrients. A newer published standard is the list of dietary reference intakes (DRIs). Whereas the RDAs represented minimum nutrient requirements, the DRIs are designed to represent optimal nutrient amounts for good health. The United States requires that detailed nutritional information be listed on any packaged food product. The values that appear on the labels are the percentage daily values and indicate what percentage of the DRI for a specific nutrient is met by a single serving of the food product. Information regarding DRIs is available from the following sources:

1. Federal Food and Nutrition Information Center: http://fnic.nal.usda.gov/nal_display/index.php?info_center=4&tax_level=1
2. Institute of Medicine: Dietary Reference Intakes (DRIs): recommended intakes for individuals available at www.iom.edu/

Vitamins are classified as either fat-soluble or water-soluble. **Water-soluble vitamins** can be dissolved in water and are easily excreted in the urine. **Fat-soluble vitamins** are dissolvable in fat and tend to be stored longer in the liver and fatty tissues. Because water-soluble vitamins (B-complex group and vitamin C) cannot be stored in the body in large amounts, daily intake is required to prevent the development of deficiencies. Conversely, fat-soluble vitamins (vitamins A, D, E, and K) do not

TABLE 53-1 FAT-SOLUBLE AND WATER-SOLUBLE VITAMINS

FAT-SOLUBLE		WATER-SOLUBLE	
DESIGNATION	**NAME**	**DESIGNATION**	**NAME**
vitamin A	retinol	vitamin B_1	thiamine
vitamin D	D_3, cholecalciferol; D_2, ergocalciferol, dihydrotachysterol	vitamin B_2	riboflavin
vitamin E	tocopherols	vitamin B_3	niacin
vitamin K	K_1, phytonadione	vitamin B_5	pantothenic acid
	K_2, menaquinone	vitamin B_6	pyridoxine
		vitamin B_9	folic acid
		vitamin B_{12}	cyanocobalamin
		vitamin B_7	biotin
		vitamin C	ascorbic acid

need to be taken daily unless one is deficient, because substantial amounts are stored in the liver and fatty tissues. Deficiencies of these vitamins occur only after prolonged deprivation from an adequate supply or from disorders that prevent their absorption. Table 53-1 lists the fat-soluble and water-soluble vitamins.

One controversial topic related to vitamins is that of nutrient "megadosing," as a strategy both for health promotion and maintenance and for treatment of various illnesses. Some cancer patients elect to use supplemental megadosing of specific nutrients in hopes of strengthening their body's response to more conventional cancer treatments. The American Dietetic Association defines megadosing as "doses of a nutrient that are 10 or more times the recommended amount." A related term was coined in 1968 by the Nobel Prize–winning chemist Linus Pauling. He defined *orthomolecular medicine* to be "the preventive or therapeutic use of high-dose vitamins to treat disease." The best-known claim of Dr. Pauling was that megadoses of vitamin C (at more than 100 times the U.S. RDA) could prevent or cure the common cold and cancer. Many studies since have not substantiated this claim. However, there are some situations in which nutrient megadosing are known to be helpful, including the following:

- When concurrent long-term drug therapy depletes vitamin stores or otherwise interferes with the function of a vitamin. A common clinical example is the use of vitamin B_6 (pyridoxine) supplementation in patients receiving the drug isoniazid for treatment of tuberculosis (see Chapter 41).
- In GI malabsorption syndromes such as those seen in patients with severe colitis and cystic fibrosis (all major nutrient classes, including protein, fat, carbohydrates, vitamins, and minerals).
- For the treatment of pernicious anemia, which results from cyanocobalamin (vitamin B_{12}) deficiency. The GI tract uses a fairly complex mechanism to drive cyanocobalamin absorption. Specifically, a glycoprotein known as *intrinsic factor* is secreted by the parietal cells of the gastric glands (see Chapter 50). Intrinsic factor facilitates absorption of cyanocobalamin in the intestine. When this process is compromised (e.g., by disease), administration of megadoses of cyanocobalamin can bypass this absorption mechanism by allowing a small amount of the vitamin to diffuse on its own through the intestinal mucosa.
- When the vitamin acts as a drug when megadosed. The most common example is niacin (vitamin B_3, also called *nicotinic acid*). At dosages of up to 20 mg daily, it functions as a vitamin, but at dosages 50 to 100 times higher, it reduces blood levels of both triglycerides and low-density lipoprotein cholesterol (see Chapter 27).

In contrast with the aforementioned examples, there are some situations in which nutrient megadosing is known to be harmful. For example, any excess of one or more nutrients can result in deficiencies of other nutrients due to their chemical competition for sites of absorption in the intestinal mucosa. This is likely to be the case with megadosing of minerals, such as calcium, copper, iron, and zinc, and is less likely to result from vitamin megadosing. Vitamin megadosing can lead to toxic accumulations known as *hypervitaminosis,* especially with the fat-soluble vitamins A, D, and K. Vitamin E appears safer, however, even at doses 10 to 20 times the recommended DRI. Hypervitaminosis is less likely to occur with the water-soluble vitamins (B complex and C) because they are readily excreted through the urinary system. Nevertheless, it is known that megadosing with vitamin B_6 (pyridoxine) at 50 to 100 times the DRI can cause nerve damage.

Persons with an illness may be less tolerant of nutrient megadosing, although megadosing regimens are often prescribed for them. For example, megadosing may be more of a strain for a GI tract that is already weakened by illness. Megadosing can even interfere with chemotherapy drugs as well as radiation treatments, because these therapies work to destroy cancer cells through oxidation processes. Nutritional supplementation with antioxidants may impede such treatment mechanisms. Patients need to tell their health care providers any unusual nutritional regimens that they plan to try, especially if they have a serious illness.

FAT-SOLUBLE VITAMINS

Fat-soluble vitamins are not readily excreted in the urine and are stored in the body. Thus, daily ingestion of these vitamins is not necessary to maintain good health and, in fact, is more likely to result in hypervitaminosis.

The fat-soluble vitamins are A, D, E, and K. As a group, they share the following characteristics:

- They are present in both plant and animal foods.
- They are stored primarily in the liver.

- They exhibit slow metabolism or breakdown.
- They are excreted via the feces.
- They can reach toxic levels *(hypervitaminosis)* if excessive amounts are consumed.

VITAMIN A

Vitamin A (retinol) is derived from animal fats such as those found in dairy products, eggs, meat, liver, and fish liver oils. Vitamin A is also derived from carotenes, which are found in plants (e.g., green and yellow vegetables, yellow fruits). Therefore, vitamin A is an exogenous substance for humans because it must be obtained from either plant or animal foods. There are more than 600 naturally occurring carotenoid compounds in plant-based foods. Of these, 40 to 50 occur commonly in the human diet. Beta carotene is the most prevalent of these, followed by alpha carotene and cryptoxanthin. These are known as *provitamin A carotenoids,* because they are all metabolized to various forms of vitamin A in the body. Table 53-2 lists the food sources for several nutrients.

Mechanism of Action and Drug Effects

Vitamin A is essential for night vision and for normal vision, because it is part of one of the major retinal pigments called **rhodopsin.** Beta carotene is metabolized in the body to retinal (retinaldehyde), and some of this retinal is reduced to the alcohol compound known as *retinol.* The remainder of the retinal may be oxidized to the carboxylic acid compound retinoic acid. Unlike retinal, retinoic acid has no direct role in vision, but it is essential for normal cell growth and differentiation and for the development of the physical shapes of the body's many parts—a process known as *morphogenesis.* It is also involved in the growth and development of bones and teeth and in other body processes, including reproduction, maintenance of the integrity of mucosal and epithelial surfaces, and cholesterol and steroid synthesis.

Indications

Supplements of vitamin A may be used to satisfy normal body requirements or an increased demand, such as in infants and pregnant and nursing women. A normal diet usually provides adequate amounts of vitamin A, but in cases of excessive need or inadequate dietary intake, vitamin A supplementation is indicated. Symptoms of vitamin A deficiency include night blindness, xerophthalmia, keratomalacia (softening of the cornea), hyperkeratosis of both the stratum corneum (outermost layer) of the skin and the sclera (outermost layer of eyeball), retarded infant growth, generalized weakness, and increased susceptibility of mucous membranes to infection. Vitamin A–related compounds, such as isotretinoin, are also used to treat various skin conditions, including acne, psoriasis, and keratosis follicularis.

Contraindications

Contraindications to vitamin A supplementation include known allergy to the individual vitamin product; known current state of hypervitaminosis; and excessive supplementation beyond recommended guidelines, especially during pregnancy or in oral malabsorption syndromes.

TABLE 53-2 FOOD SOURCES FOR SELECTED NUTRIENTS

VITAMINS/ MINERALS	FOOD SOURCES
vitamin A	Liver; fish; dairy products; egg yolks; dark green, leafy, yellow-orange vegetables and fruits
vitamin D	Dairy products, fortified cereals and fortified orange juice, liver, fish liver oils, saltwater fish, butter, eggs
vitamin E	Fish, egg yolks, meats, vegetable oils, nuts, fruits, wheat germ, grains, fortified cereals
vitamin K	Cheese, spinach, broccoli, brussels sprouts, kale, cabbage, turnip greens, soybean oils
vitamin B_1 (thiamine)	Yeast, liver, enriched whole-grain products, beans
vitamin B_2 (riboflavin)	Meats, liver, dairy products, eggs, legumes, nuts, enriched whole-grain products, green leafy vegetables, yeast
vitamin B_3 (niacin)	Liver, turkey, tuna, peanuts, beans, yeast, enriched whole-grain breads and cereals, wheat germ
vitamin B_6 (pyridoxine)	Organ meats, meats, poultry, fish, eggs, peanuts, whole grain products, vegetables, nuts, wheat germ, bananas, fortified cereals
vitamin B_{12} (cyanocobalamin)	Liver, kidney, shellfish, poultry, fish, eggs, milk, blue cheese, fortified cereals
vitamin C (ascorbic acid)	Broccoli, green peppers, spinach, Brussels sprouts, citrus fruits, tomatoes, potatoes, strawberries, cabbage, liver
calcium	Dairy products, fortified cereals and calcium-fortified orange juice, sardines, salmon
magnesium	Meats, seafood, milk, cheese, yogurt, green leafy vegetables, bran cereal, nuts
phosphorus	Milk, yogurt, cheese, peas, meat, fish, eggs
zinc	Red meats, liver, oysters, certain seafood, milk products, eggs, beans, nuts, whole grains, fortified cereals

Adapted from USDA: Dietary guidelines for Americans, 2010, available at http://www.health.gov/dietaryguidelines/dga2010/DietaryGuidelines2010.pdf, accessed March, 2012.

Adverse Effects

There are very few acute adverse effects associated with normal vitamin A ingestion. Only after long-term excessive ingestion of vitamin A do symptoms appear. Adverse effects are usually noticed in bones, mucous membranes, the liver, and the skin. Table 53-3 lists some of the symptoms of long-term excessive ingestion of vitamin A.

Toxicity and Management of Overdose

The major toxic effects of vitamin A result from ingestion of excessive amounts, which occurs most commonly in children. A few hours after administration of an excess dose of vitamin A, irritability, drowsiness, vertigo, delirium, coma, vomiting, and/or diarrhea may occur. In infants, excessive amounts of vitamin A can cause an increase in cranial pressure, resulting in symptoms such as bulging fontanelles, headache, papilledema, exophthalmos (bulging eyeballs), and visual disturbances. Papilledema is the presence of edematous fluid, often including blood, in the optic disc. This is the portion of the eye in the

TABLE 53-3 VITAMIN A: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Central nervous	Headache, increased intracranial pressure, lethargy, malaise
Gastrointestinal	Nausea, vomiting, anorexia, abdominal pain, jaundice
Integumentary	Dry skin, pruritus, increased pigmentation, night sweats
Metabolic	Hypomenorrhea, hypercalcemia
Musculoskeletal	Arthralgia, retarded growth

back of the retina, where nerve fibers converge to form the optic nerve. Over several weeks, a generalized peeling of the skin and erythema (skin reddening) may occur. These symptoms seem to disappear a few days after discontinuation of the drug, which is the only treatment necessary in situations of overdose.

Interactions

Vitamin A is absorbed less when used together with lubricant laxatives and cholestyramine. In addition, the concurrent use of isotretinoin and vitamin A supplementation can result in additive effects and possible toxicity.

Dosages

For dosage information on vitamin A, see the table below.

DOSAGES

Selected Vitamins

DRUG	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
Vitamin D–Active Compounds			
calcifediol (hydroxyvitamin D_3) (Calderol)	Fat-soluble	**Adult and pediatric 2-10 yr** PO: 50 mcg once daily	Hypocalcemia in hemodialysis patients
calcitriol (dihydroxyvitamin D_3) (Rocaltrol, Calcijex)	Fat-soluble	**Adult and pediatric 6 yr and older** PO/IV: 0.5-2 mcg/day	Hypoparathyroidism; hypocalcemia in patients receiving regular hemodialysis
dihydrotachysterol (DHT, Hytakerol)	Fat-soluble (a form of vitamin D)	**Adult and pediatric 12 yr and older** PO: 0.75-2.5 mg/day × 4 days, then 0.2-1 mg/day	Hypoparathyroidism
ergocalciferol (vitamin D_2) (Drisdol, Calciferol)	Fat-soluble	**Pediatric/Adult*** PO: 300-12,500 mcg/day (equals 12,000-500,000 units/day)	Rickets, hypoparathyroidism, renal failure
Vitamin B–Active Compounds			
vitamin B_1 (thiamine) (Thiamilate)	Water-soluble, B-complex group	**Adult** 100 mg/day until normal dietary intake is established 5-30 mg/day × 30 days	Alcohol-induced deficiency Beriberi
vitamin B_2 (riboflavin) (Lactoflavin)	Water-soluble, B-complex group	**Adult** PO: 5-30 mg/day **Pediatric** 3-10 mg/day	Deficiency
vitamin B_3 (niacin, nicotinic acid) (Nicotinex)	Water-soluble, B-complex group	**Adult** PO: 1-6 g/day	Hyperlipidemia
		Adult PO: Up to 500 mg/day **Pediatric** IV: Up to 300 mg/day	Pellagra (deficiency)
vitamin B_6 (pyridoxine) (Aminoxin, Vitelle)	Water-soluble, B-complex group	**Adult** PO/IV: 2.5-10 mg/day **Pediatric** PO/IV: 5-25 mg/day × 3 wk, then give multivitamin product	Deficiency
		Adult PO/IV: 100-200 mg/day **Pediatric** 10-50 mg/day	Drug-induced neuritis (e.g., isoniazid for tuberculosis)
vitamin B_{12} (cyanocobalamin) (Nascobal)	Water-soluble, B-complex group	**Adult and pediatric** IM/subcut: 100 mcg/mo **Adult and pediatric** PO: 50-100 mcg/day **Adult only** Intranasal gel: 500 mcg/wk	Deficiency; anemia

DOSAGES—cont'd

Selected Vitamins

DRUG	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
Vitamins A, C, E, and K			
vitamin A (Aquasol A, others)	Fat-soluble	**Adult and pediatric older than 8 yr** PO: 100,000 units/day × 3 days, then 50,000 units/day for 14 days	Deficiency
vitamin C (ascorbic acid) (Vita-C, Dull-C, others)	Water-soluble	**Adult and pediatric** PO/IV/IM/subcut: 100-250 mg 1-2 times daily	Deficiency; scurvy
vitamin E (d-alpha tocopherol) (Aquavit E, others)	Fat-soluble	**Adult** PO: 60-75 units/day **Pediatric** 1 unit/kg/day	Nutritional supplementation
vitamin K (phytonadione) (Mephyton, AquaMEPHYTON)	Fat-soluble	**Adult** PO: 2.5-10 mg/day IM/IV: 1-10 mg single dose **Infant and pediatric** PO: 2.5-5 mg/day IM/IV: 1-2 mg single dose	Warfarin-induced hypoprothrombinemia Deficiency; hemorrhagic disease of newborn infant

IM, Intramuscular; *IV,* intravenous; *PO,* oral; *subcut,* subcutaneous; *mo,* month.
*Dosages are individualized. Higher doses may be required based on response to therapy.

DRUG PROFILE

There are three forms of vitamin A: retinol, retinyl palmitate, and retinyl acetate. Medications containing vitamin A may require a prescription, but many over-the-counter (OTC) products, such as vitamin A–containing multivitamins, are also available. All vitamin A products are classified as pregnancy category A.

vitamin A

Vitamin A (Aquasol A), also known as *retinol, retinyl palmitate,* and *retinyl acetate,* is available in a variety of oral forms as well as an injectable form. Doses for vitamin A are expressed as *retinol activity equivalents (RAEs).* One RAE is approximately equal to the following:

- 1 mcg of retinol (either dietary or supplemental)
- 2 mcg of supplemental beta carotene
- 12 mcg of dietary beta carotene
- 24 mcg of dietary carotenoids

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	N/A	4 hr	50-100 days	Unknown

VITAMIN D

Vitamin D, also called the *sunshine vitamin,* is responsible for the proper utilization of calcium and phosphorus in the body. The two most important members of the vitamin D family are vitamin D_2 (ergocalciferol) and vitamin D_3 (cholecalciferol). They have different sites of origin but similar functions in the body. Ergocalciferol (vitamin D_2) is plant derived and is therefore obtained through dietary sources. The natural form of vitamin D produced in the skin by ultraviolet irradiation (sun) is chemically known as *7-dehydrocholesterol.* It is more commonly referred to as *cholecalciferol* (vitamin D_3). This endogenous synthesis of vitamin D_3 usually produces sufficient amounts to meet daily requirements. Vitamin D is obtained through both endogenous synthesis and consumption of vitamin D_2–containing foods such as fish oils, salmon, sardines, and herring; fortified milk, bread, and cereals; and animal livers, tuna fish, eggs, and butter. Normal serum levels are 12 to 50 ng/mL.

Mechanism of Action and Drug Effects

The basic function of vitamin D is to regulate the absorption and subsequent utilization of calcium and phosphorus. It is also necessary for the normal calcification of bone. Vitamin D in coordination with parathyroid hormone and calcitonin regulates serum calcium levels by increasing calcium absorption from the small intestine and extracting calcium from the bone. Ergocalciferol and cholecalciferol are inactive and require transformation into active metabolites for biologic activity. Both vitamin D_2 and vitamin D_3 are biotransformed in the liver by the actions of parathyroid hormone. The resulting compound, calcifediol, is then transported to the kidney, where it is converted to calcitriol, which is believed to be the most physiologically active form of vitamin D. Calcitriol promotes the intestinal absorption of calcium and phosphorus and the deposition of calcium and phosphorus into the structure of teeth and bones.

The drug effects of vitamin D are very similar to those of vitamin A and essentially all vitamin and mineral compounds. It is used as a supplement to satisfy normal daily requirements or an increased demand, as in infants and pregnant and nursing women.

Indications

Vitamin D can be used either to supplement dietary intake or to treat a deficiency of vitamin D. In the case of supplementation, it is given as a prophylactic measure to prevent deficiency-related problems, and it is recommended for breastfed infants. Vitamin D may also be used to treat and correct the result of a long-term deficiency that leads to such conditions as infantile rickets, tetany (involuntary sustained muscular contractions), and osteomalacia (softening of the bones). **Rickets** is specifically a vitamin D deficiency state. Symptoms include soft, pliable bones, which causes deformities such as bowlegs and knock knees; nodular enlargement on the ends and sides of the bones; muscle pain; enlarged skull; chest deformities; spinal curvature; enlargement of the liver and spleen; profuse sweating; and general tenderness of the body when touched. Vitamin D can also help promote the absorption of phosphorus and calcium. For this reason, its use is important in preventing osteoporosis. Because of the role of vitamin D in the regulation of calcium and phosphorus, it may be used to correct deficiencies of these two elements. Other uses include dietary supplementation and treatment of osteodystrophy, hypocalcemia, hypoparathyroidism, pseudohypoparathyroidism, and hypophosphatemia. Many patients have low vitamin D levels, and it is common to see doses of 1000 to 2000 units daily prescribed.

Contraindications

Contraindications to vitamin D products include known allergy to the product, hypercalcemia, renal dysfunction, kidney stones, and hyperphosphatemia.

Adverse Effects

Very few acute adverse effects are associated with normal vitamin D ingestion. Only after long-term excessive ingestion of vitamin D do symptoms appear. Such effects are usually noticed in the GI tract or the central nervous system (CNS) and are listed in Table 53-4.

Toxicity and Management of Overdose

The major toxic effects from ingesting excessive amounts of vitamin D occur most commonly in children. Discontinuation of vitamin D and reduced calcium intake reverse the toxic state. The amount of vitamin D considered to be toxic varies considerably among individuals but is generally thought to be 1.25 to 2.5 mg of ergocalciferol daily in adults and 25 mcg daily in infants and children.

The toxic effects of vitamin D are those associated with hypertension, such as weakness, fatigue, headache, anorexia, dry mouth, metallic taste, nausea, vomiting, abdominal cramps, ataxia, and bone pain. If not recognized and treated, these symptoms can progress to impairment of renal function and osteoporosis.

Interactions

Reduced absorption of vitamin D occurs with the concurrent use of lubricant laxatives and cholestyramine.

Dosages

For dosage information on vitamin D, see the table on p. 860.

TABLE 53-4 VITAMIN D: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Hypertension, dysrhythmias
Central nervous	Fatigue, weakness, drowsiness, headache
Gastrointestinal	Nausea, vomiting, anorexia, cramps, metallic taste, dry mouth, constipation
Genitourinary	Polyuria, albuminuria, increased blood urea nitrogen level
Musculoskeletal	Decreased bone growth, bone and muscle pain

DRUG PROFILES

There are four forms of vitamin D: calcifediol, calcitriol, dihydrotachysterol, and ergocalciferol. Vitamin D is available in OTC medications, such as multivitamin products, or by prescription. Although various pharmaceutical manufacturers may list their individual vitamin D products as pregnancy category C, these products are generally considered to be category A or B as long as the patient is not dosed at higher levels than recommended.

calcifediol

Calcifediol (Calderol) is the 25-hydroxylated form of cholecalciferol (vitamin D_3). It is a vitamin D analogue used primarily for the management of hypocalcemia in patients with chronic renal failure who are undergoing hemodialysis. Calcifediol is also used for signs of hyperparathyroid disease. It is available only for oral use.

calcitriol

Calcitriol (Rocaltrol) is the 1,25-dihydroxylated form of cholecalciferol (vitamin D_3). It is a vitamin D analogue used for the management of hypocalcemia in patients with chronic renal failure who are undergoing hemodialysis. Calcitriol is also used in the treatment of hypoparathyroidism and pseudohypoparathyroidism, vitamin D–dependent rickets, hypophosphatemia, and hypocalcemia in premature infants. It is available in both oral and injectable forms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Less than 3 hr	3-6 hr	3-6 hr	3-5 days

dihydrotachysterol

Dihydrotachysterol (Hytakerol) is a vitamin D analogue that is administered orally once daily for the treatment of any of the previously mentioned conditions. Intramuscular use is indicated for patients with GI, liver, or biliary disease associated with malabsorption of vitamin D analogues. It is available orally and parenterally.

ergocalciferol

Ergocalciferol (Drisdol) is vitamin D_2. It is indicated for use in patients with GI, liver, or biliary disease associated with malabsorption of vitamin D analogues. It is available orally and parenterally.

Pharmacokinetics (ergocalciferol, vitamin D_2)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30 days	Unknown	19 days	Months to years

VITAMIN E

Four biologically active chemicals called **tocopherols** (alpha, beta, gamma, and delta) make up the vitamin E compounds. Alpha tocopherol is the most biologically active natural form of vitamin E and can come from plant and animal sources.

Mechanism of Action and Drug Effects

Vitamin E is a powerful biologic antioxidant and an essential component of the diet. Its exact nutritional function has not been fully demonstrated. The only recognized significant deficiency syndrome for vitamin E occurs in premature infants. In this situation, vitamin E deficiency may result in irritability, edema, thrombosis, and hemolytic anemia.

The drug effects of vitamin E are not as well defined as those of the other fat-soluble vitamins. It is believed to protect polyunsaturated fatty acids, a component of cellular membranes. It has also been shown to hinder the deterioration of substances such as vitamin A and ascorbic acid (vitamin C), two substances that are highly oxygen sensitive and readily oxidized; thus it acts as an antioxidant.

Indications

Vitamin E is most commonly used as a dietary supplement to augment current daily intake or to treat a deficiency. Premature infants are those at greatest risk for complications from vitamin E deficiency. Vitamin E has received much attention as an antioxidant. Preventing the oxidation of various substances prevents the formation of toxic chemicals within the body, some of which are believed to cause cancer. There is a popular but unproved theory that vitamin E has beneficial effects for patients with cancer, heart disease, premenstrual syndrome, and sexual dysfunction. However, the American Heart Association no longer recommends the use of high-dose vitamin E to prevent heart disease. In fact, recent studies have shown no benefit and possible harm.

Contraindications

Contraindications for vitamin E include known allergy to a specific vitamin E product. There are currently no approved injectable forms of this vitamin.

Adverse Effects

Very few acute adverse effects are associated with normal vitamin E ingestion, because it is relatively nontoxic. Adverse effects are usually noticed in the GI tract or CNS and are listed in Table 53-5.

Dosages

For the dosage information on vitamin E, see the table on p. 860.

TABLE 53-5 VITAMIN E: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Central nervous	Fatigue, headache, blurred vision
Gastrointestinal	Nausea, diarrhea, flatulence
Genitourinary	Increased blood urea nitrogen level
Musculoskeletal	Weakness

DRUG PROFILE

Vitamin E is available as an OTC medication. It has four forms: alpha, beta, gamma, and delta tocopherol. It is available in many multivitamin preparations and is also available by prescription. Vitamin E products are usually contraindicated only in cases of known drug allergy.

vitamin E

Vitamin E (Aquasol E) activity is generally expressed in U.S. Pharmacopeia (USP) or international units. It is available for oral and topical use.

VITAMIN K

Vitamin K is the last of the four fat-soluble vitamins (A, D, E, and K). There are three types of vitamin K: phytonadione (vitamin K_1), menaquinone (vitamin K_2), and menadione (vitamin K_3). The body does not store large amounts of vitamin K; however, vitamin K_2 is synthesized by the intestinal flora, which provides an endogenous supply.

Vitamin K is essential for the synthesis of blood coagulation factors, which takes place in the liver. Vitamin K–dependent blood coagulation factors are factors II, VII, IX, and X. Other names for these clotting factors are as follows: factor II (prothrombin); factor VII (proconvertin); factor IX (Christmas factor); and factor X (Stuart-Prower factor). Normal serum levels are 0.1 to 2.2 ng/mL.

Mechanism of Action and Drug Effects

Vitamin K activity is essential for effective blood clotting because, as noted earlier, it facilitates the hepatic biosynthesis of factors II, VII, IX and X. Vitamin K deficiency results in coagulation disorders caused by hypoprothrombinemia. Coagulation defects affecting these clotting factors can be corrected with administration of vitamin K. Vitamin K deficiency is rare because intestinal flora are normally able to synthesize sufficient amounts. If a deficiency develops, it can be corrected with vitamin K supplementation.

Indications

Vitamin K is indicated for dietary supplementation and for treatment of deficiency states. Although rare, deficiency states can develop with inadequate dietary intake or inhibition of the intestinal flora resulting from the administration of broad-spectrum antibiotics. Deficiency states can also be seen in newborns because of malabsorption attributable to inadequate amounts of bile. For this reason, infants born in hospitals are

TABLE 53-6 VITAMIN K: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Central nervous	Headache, brain damage (large doses)
Gastrointestinal	Nausea, decreased liver enzyme levels
Hematologic	Hemolytic anemia, hemoglobinuria, hyperbilirubinemia
Integumentary	Rash, urticaria

often given a prophylactic intramuscular dose of vitamin K on arrival to the nursery. Vitamin K deficiency can also result from the administration and pharmacologic action of the oral anticoagulant warfarin (see Chapter 26). Warfarin's anticoagulant effects occur by inhibiting vitamin K–dependent clotting factors II, VII, IX, and X in the liver. Administration of vitamin K overrides the mechanism by which the anticoagulant inhibits production of vitamin K–dependent clotting factors. Thus vitamin K can be used to reverse the effects of warfarin. It is important to note that when vitamin K is used in this manner, the patient becomes unresponsive to warfarin for approximately 1 week after vitamin K administration.

Contraindications

The only usual contraindication to treatment with vitamin K is known drug allergy.

Adverse Effects

Vitamin K is relatively nontoxic and thus causes very few adverse effects. Severe reactions limited to hypersensitivity or anaphylaxis have occurred rarely during or immediately after intravenous administration. Adverse effects are usually related to injection-site reactions and hypersensitivity. See Table 53-6 for a list of such major effects by body system.

Toxicity and Management of Overdose

Toxicity is primarily limited to use in the newborn. Hemolysis of red blood cells (RBCs) can occur, especially in infants with low levels of glucose-6-phosphate dehydrogenase. In severe cases, replacement with blood products may be indicated.

Dosages

For the dosage information on vitamin K, see the table on p. 860.

DRUG PROFILE

The most commonly used form of vitamin K is phytonadione (vitamin K_1). Both phytonadione and menadione (vitamin K_3) are available by prescription only in oral and parenteral forms. Menadione is classified as a pregnancy category X drug, whereas phytonadione is a category C drug. Both are contraindicated in patients with a known hypersensitivity to them. Their use is also contraindicated in patients who are in the last few weeks of pregnancy and in patients with severe hepatic disease. Vitamin K must be used with caution in patients taking warfarin.

BOX 53-1 WATER-SOLUBLE VITAMINS: ALTERNATE NAMES

DESIGNATION	ALTERNATE NAME
vitamin B complex	
vitamin B_1	thiamine
vitamin B_2	riboflavin
vitamin B_3	niacin
vitamin B_5	pantothenic acid
vitamin B_6	pyridoxine
vitamin B_9	folic acid
vitamin B_{12}	cyanocobalamin
vitamin C	ascorbic acid

vitamin K_1

Vitamin K_1 (phytonadione) (AquaMEPHYTON) is available in both oral and injectable forms. Because of its potential to cause anaphylaxis (due to the formulation), for intravenous use it is usually diluted and given over 30 to 60 minutes. Vitamin K is given IV or subcutaneously and not intramuscularly when used to reverse warfarin effects.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	6-12 hr	24-48 hr	1.2 hr	24 hr
IV	1-2 hr	12-14 hr	1.2 hr	24 hr

WATER-SOLUBLE VITAMINS

The water-soluble vitamins include the vitamin B complex and vitamin C (ascorbic acid). They are present in a variety of plant and animal food sources. The vitamin B complex is a group of 10 vitamins that are often found together in food, although they are chemically dissimilar and have different metabolic functions. Because the B vitamins were originally isolated from the same sources, they were grouped together as B-complex vitamins. Vitamin C (ascorbic acid), the other principal water-soluble vitamin, is concentrated in citrus fruits and is not classified as part of the B complex. The numeric subscripts associated with various B vitamins reflect the order in which they were discovered. In clinical practice, some B vitamins are more often referred to by their common name, whereas others are more often referred to by their numeric designation. For example, "vitamin B_{12}" is used more often in clinical practice than the corresponding common name "cyanocobalamin." However, "folic acid" is rarely referred to as "vitamin B_9." The most commonly used B-complex vitamins, as well as vitamin C, are listed in Box 53-1. Folic acid (vitamin B_9) has a special role in hematopoiesis and therefore is described further in Chapter 54.

Water-soluble vitamins are a chemically diverse group sharing only the characteristic of being dissolvable in water. Like fat-soluble vitamins, they act primarily as coenzymes or oxidation-reduction agents in important metabolic pathways. Unlike fat-soluble vitamins, water-soluble vitamins are not stored in the body in appreciable amounts. Their water-soluble properties promote urinary

excretion and reduce their half-life in the body. Therefore, dietary intake must be adequate and regular or else deficiency states will develop. The body excretes what it does not need, which makes toxic reactions to water-soluble vitamins very rare.

VITAMIN B_1

A deficiency of vitamin B_1 (thiamine) results in the classic disease **beriberi** or Wernicke's encephalopathy (cerebral beriberi). Common findings in beriberi include brain lesions, polyneuropathy of peripheral nerves, serous effusions (abnormal collections of fluids in body tissues), and cardiac anatomic changes. Vitamin deficiency can result from poor diet, extended fever, hyperthyroidism, liver disease, alcoholism, malabsorption, and pregnancy and breastfeeding. Normal serum levels are 66 to 200 nmol/L.

Mechanism of Action and Drug Effects

Vitamin B_1 (thiamine) is an essential precursor for the formation of thiamine pyrophosphate. When thiamine combines with adenosine triphosphate (ATP), the result is thiamine pyrophosphate coenzyme. This is required for the citric acid cycle (Krebs cycle), a major part of carbohydrate metabolism, as well as several other metabolic pathways. In addition, thiamine plays a key role in the integrity of the peripheral nervous system, cardiovascular system, and GI tract.

Indications

The essential role of thiamine in many metabolic pathways makes it useful in treating a variety of metabolic disorders. These include subacute necrotizing encephalomyelopathy, maple syrup urine disease, and lactic acidosis associated with pyruvate carboxylase enzyme deficiency and hyper-beta-alaninemia. Some of the deficiency states treated by thiamine are beriberi, Wernicke's encephalopathy, peripheral neuritis associated with **pellagra** (niacin deficiency), and neuritis of pregnancy. Thiamine is used as a dietary supplement to prevent or treat deficiency in cases of malabsorption such as that induced by alcoholism, cirrhosis, or GI disease. Other situations in which thiamine may have therapeutic value are the management of poor appetite, ulcerative colitis, chronic diarrhea, and cerebellar syndrome or ataxia (impaired muscular coordination). It is also used as an oral insect repellent.

Contraindications

The only usual contraindication to any of the B-complex vitamins is known allergy to a specific vitamin product.

Adverse Effects

Adverse effects are rare but include hypersensitivity reactions, nausea, restlessness, pulmonary edema, pruritus, urticaria, weakness, sweating, angioedema, cyanosis, and cardiovascular collapse. Administration by intramuscular injection can produce local tenderness, and intravenous injections can produce anaphylaxis.

Interactions

Thiamine is incompatible with alkaline- and sulfite-containing solutions.

Dosages

For the dosage information on vitamin B_1, see the table on p. 860.

DRUG PROFILE

thiamine

Thiamine is contraindicated only in individuals with a known hypersensitivity to it. Thiamine is available for both oral use and injection. It is classified as a pregnancy category A drug.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	1-2 hr	1.2 hr	24 hr

VITAMIN B_2

A deficiency of vitamin B_2 (riboflavin) results in cutaneous, oral, and corneal changes that include cheilosis (chapped or fissured lips), seborrheic dermatitis, and keratitis.

Mechanism of Action and Drug Effects

Riboflavin serves several important functions in the body. Riboflavin is converted into two coenzymes (flavin mononucleotide and flavin adenine dinucleotide) that are essential for tissue respiration. Riboflavin also plays an important part in carbohydrate catabolism. Another B vitamin, vitamin B_6 (pyridoxine), requires riboflavin for activation. Riboflavin is also needed to convert tryptophan into niacin and to maintain erythrocyte integrity. Deficiency is rare and does not usually occur in healthy people.

Indications

Riboflavin is primarily used as a dietary supplement and for treatment of deficiency states. Patients who may experience riboflavin deficiency include those with long-standing infections, liver disease, alcoholism, or malignancy, and those taking probenecid. Riboflavin supplementation may also be beneficial in the treatment of microcytic anemia; acne; migraine headache; congenital methemoglobinemia (presence in the blood of an abnormal, nonfunctional hemoglobin pigment); muscle cramps; and Gopalan's syndrome, a symptom of suspected riboflavin (and possibly pantothenic acid [vitamin B_5]) deficiency that involves a sensation of tingling in the extremities (for this reason, it is also called *burning feet syndrome*).

Contraindications

The only usual contraindication to riboflavin is known allergy to a given vitamin product.

Adverse Effects

Riboflavin is a very safe and effective vitamin; to date, no adverse effects or toxic effects have been reported. In large dosages, riboflavin will discolor urine to a yellow-orange.

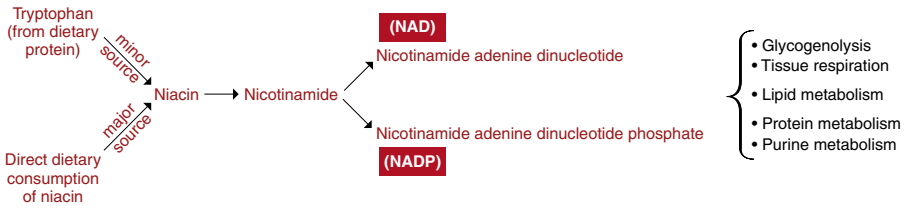

FIGURE 53-1 Niacin, once in the body, is converted to nicotinamide adenosine dinucleotide (NAD) and nicotinamide adenosine dinucleotide (NADP), which are coenzymes needed for many metabolic processes.

Dosages

For dosage information on riboflavin, see the table on p. 860.

DRUG PROFILE

riboflavin

Riboflavin (vitamin B_2) is needed for normal respiratory functions. It is a safe, nontoxic water-soluble vitamin with almost no adverse effects. Riboflavin is available only for oral use. It is classified as a pregnancy category A drug.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	Unknown	66-84 min	24 hr

VITAMIN B_3

The body is able to produce a small amount of vitamin B_3 (niacin) from dietary tryptophan, an essential amino acid occurring in dietary proteins and some commercially available nutritional supplements. A dietary deficiency of niacin (vitamin B_3) will produce the classic symptoms known as *pellagra*. Symptoms of pellagra include various psychotic disorders; neurasthenic syndrome; crusting, erythema, and desquamation of the skin; scaly dermatitis; inflammation of the oral, vaginal, and urethral mucosa, including glossitis (inflamed tongue); and diarrhea or bloody diarrhea.

Mechanism of Action and Drug Effects

The metabolic actions of niacin (vitamin B_3) are not due to niacin in the ingested form but rather to its metabolic product, nicotinamide. Nicotinamide is required for numerous metabolic reactions, including those involved in carbohydrate, protein, purine, and lipid metabolism, as well as tissue respiration (Figure 53-1). A key example involves two compounds, nicotinamide adenosine dinucleotide (NAD) and nicotinamide adenosine dinucleotide phosphate (NADP), both of which are necessary for the carbohydrate pathway known as *glycogenolysis* (the breakdown of stored glycogen into usable glucose). The parent compound, niacin itself, also has a pharmacologic role as an antilipemic drug (see Chapter 27). The doses of niacin required for its antilipemic effect are substantially higher than those required for the nutritional and metabolic effects.

TABLE 53-7 NIACIN (VITAMIN B_3): ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Postural hypotension, dysrhythmias
Central nervous	Headache, dizziness, anxiety
Gastrointestinal	Nausea, vomiting, diarrhea, peptic ulcer
Genitourinary	Hyperuricemia
Hepatic	Abnormal liver function test results, hepatitis
Integumentary	Flushing, dry skin, rash, pruritus, keratosis
Metabolic	Decreased glucose tolerance

Indications

Niacin is indicated for the prevention and treatment of pellagra, a condition caused by a deficiency of vitamin B_3 that is most commonly the result of malabsorption. It is also used for management of certain types of hyperlipidemia (see Chapter 27). Niacin also has a beneficial effect in peripheral vascular disease.

Contraindications

Niacin, unlike certain other B-complex vitamins, has additional contraindications besides drug allergy. These include liver disease, severe hypotension, arterial hemorrhage, and active peptic ulcer disease.

Adverse Effects

The most frequent adverse effects associated with the use of niacin are flushing, pruritus, and GI distress. These usually subside with continued use and are most frequently seen when larger doses of niacin are used in the treatment of hyperlipidemia. Table 53-7 lists adverse effects by body system.

Dosages

For dosage information on niacin, see the table on p. 860.

DRUG PROFILE

niacin

Niacin is used to treat pellagra, hyperlipidemias, and peripheral vascular disease. Its use must be monitored closely in patients who have a history of coronary artery disease, gallbladder disease, jaundice, liver disease, or arterial bleeding. Niacin is available only for oral use. It is classified as a pregnancy category A drug.

Pharmacokinetics (niacin, vitamin B_3)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	30-60 min	45 min	45 min	Variable

VITAMIN B_6

Vitamin B_6 (pyridoxine) is composed of three compounds: pyridoxine, pyridoxal, and pyridoxamine. Deficiency of vitamin B_6 can lead to a type of anemia known as *sideroblastic anemia,* neurologic disturbances, seborrheic dermatitis, cheilosis, and xanthurenic aciduria (formation of xanthine crystals or "stones" in urine). It may also result in convulsions, especially in neonates and infants; hypochromic microcytic anemia; and glossitis (inflamed tongue) and stomatitis (inflamed oral mucosa). Pyridoxine deficiency also affects the peripheral nerves, skin, and mucous membranes. Inadequate intake or poor absorption of pyridoxine causes the development of these conditions. Vitamin B_6 deficiency may occur as a result of uremia, alcoholism, cirrhosis, hyperthyroidism, malabsorption syndromes, and heart failure. It may also be induced by various drugs, such as isoniazid and hydralazine.

Mechanism of Action and Drug Effects

Pyridoxine, pyridoxal, and pyridoxamine are all converted in erythrocytes to the active coenzyme forms of vitamin B_6: pyridoxal phosphate and pyridoxamine phosphate. These compounds are necessary for many metabolic functions, such as protein, carbohydrate, and lipid utilization in the body. They also play an important part in the conversion of the amino acid tryptophan to niacin (vitamin B_3) and the neurotransmitter serotonin. They are also essential in the synthesis of gamma-aminobutyric acid, an inhibitory neurotransmitter in the CNS. They are important in the synthesis of heme and the maintenance of the hematopoietic system. In addition, these substances are necessary for the integrity of the peripheral nerves, skin, and mucous membranes.

Indications

Pyridoxine is used to prevent and treat vitamin B_6 deficiency. This includes deficiency that can result from therapy with certain medications, including isoniazid (for tuberculosis) and hydralazine (for hypertension). Although vitamin B_6 deficiency is rare, it can occur in conditions of inadequate intake or poor absorption of pyridoxine. Seizures that are unresponsive to usual therapy, morning sickness during pregnancy, and various metabolic disorders may respond to pyridoxine therapy.

Contraindications

The only usual contraindication to pyridoxine use is known drug allergy.

Adverse Effects

Adverse effects with pyridoxine use are rare and usually do not occur at normal dosages; high dosages and long-term use may produce the adverse effects listed in Table 53-8. Toxic effects are a result of very large dosages sustained for several months. Neurotoxicity is the most likely result, but this will subside upon discontinuation of the pyridoxine.

TABLE 53-8 PYRIDOXINE (VITAMIN B_6): ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Central nervous	Paresthesias, flushing, warmth, headache, lethargy
Integumentary	Pain at injection site

Interactions

Pyridoxine will reduce the activity of levodopa; therefore, vitamin formulations containing B_6 must be avoided in patients taking levodopa alone. However, the overwhelming majority of patients with Parkinson's disease take a combination of levodopa and carbidopa, and this interaction does not occur with combination therapy.

Dosages

For dosage information on vitamin B_6, see the table on p. 860.

DRUG PROFILE

pyridoxine

Pyridoxine is a water-soluble B-complex vitamin composed of three components: pyridoxine, pyridoxal, and pyridoxamine. It has several vital roles in the body but is primarily responsible for the integrity of peripheral nerves, skin, mucous membranes, and the hematopoietic system. Pyridoxine is available only for oral use. It is classified as a pregnancy category A drug.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	30-60 min	15-20 days	Unknown

VITAMIN B_{12}

Vitamin B_{12} (cyanocobalamin) is a water-soluble B-complex vitamin that contains cobalt (hence, its name; and *cyano-* means "blue"). It is synthesized by microorganisms and is present in the body as two different coenzymes: adenosylcobalamin and methylcobalamin. Cyanocobalamin is a required coenzyme for many metabolic pathways, including fat and carbohydrate metabolism and protein synthesis. It is also required for growth, cell replication, hematopoiesis, and nucleoprotein and myelin synthesis (Figure 53-2).

Vitamin B_{12} deficiency results in GI lesions, neurologic changes that can result in degenerative CNS lesions, and megaloblastic anemia. The major cause of cyanocobalamin deficiency is malabsorption. Other possible but less likely causes are poor diet, chronic alcoholism, and chronic hemorrhage. Normal serum levels are 200 to 900 pg/mL.

Mechanism of Action and Drug Effects

Humans must have an exogenous source of cyanocobalamin, because it is required for nucleoprotein and myelin synthesis,

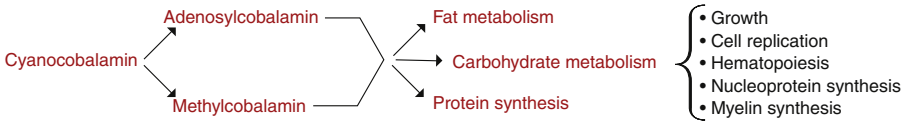

FIGURE 53-2 Cyanocobalamin is a required coenzyme for many body processes.

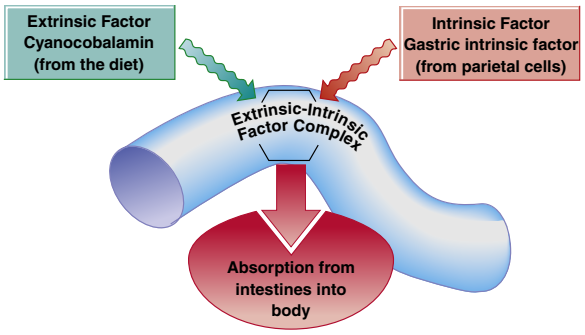

FIGURE 53-3 Oral absorption of cyanocobalamin requires the presence of intrinsic factor, which is secreted by gastric parietal cells.

TABLE 53-9 CYANOCOBALAMIN (VITAMIN B_{12}): ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Heart failure, vascular thrombosis, pulmonary edema
Central nervous	Flushing, optic nerve atrophy
Gastrointestinal	Diarrhea
Integumentary	Pruritus, rash, pain at injection site
Metabolic	Hypokalemia

cell reproduction, normal growth, and the maintenance of normal erythropoiesis. The cells that have the greatest requirement for vitamin B_{12} are those that divide rapidly, such as epithelial cells, bone marrow, and myeloid cells.

Reduced sulfhydryl (–5H) groups are required to metabolize fats and carbohydrates and to synthesize protein. Cyanocobalamin is involved in maintaining sulfhydryl groups in the reduced form. Cyanocobalamin deficiency can lead to neurologic damage that begins with an inability to produce myelin and is followed by gradual degeneration of the axon and nerve head.

Cyanocobalamin activity is identical to the activity of the anti–pernicious anemia factor present in liver extract called *extrinsic factor* or *Castle factor*. The oral absorption of cyanocobalamin (extrinsic factor) requires the presence of intrinsic factor, which is a glycoprotein secreted by gastric parietal cells. A complex is formed between the two factors, which is then absorbed by the intestines. This is depicted in Figure 53-3.

Indications

Cyanocobalamin is used to treat deficiency states that develop because of an insufficient intake of the vitamin. It is also included in multivitamin formulations that are used as dietary supplements. Deficiency states are most often the result of malabsorption or poor dietary intake, including consumption of a strict vegetarian diet, because the primary source of cyanocobalamin is foods of animal origin.

The most common manifestation of untreated cyanocobalamin deficiency is pernicious anemia. The use of vitamin B_{12} to treat pernicious anemia and other megaloblastic anemias results in the rapid conversion of a megaloblastic bone marrow to a normoblastic bone marrow. The preferred route of administration of vitamin B_{12} in treating megaloblastic anemias is deep intramuscular injection. If not treated, deficiency states can lead to megaloblastic anemia and irreversible neurologic damage. Cyanocobalamin is also useful in the treatment of pernicious anemia caused by an endogenous lack of intrinsic factor.

Contraindications

The only usual contraindication to cyanocobalamin (vitamin B_{12}) is known drug product allergy. This may include sensitivity to the chemical element cobalt, which is part of the structure of cyanocobalamin. Another contraindication is hereditary optic nerve atrophy (Leber's disease).

Adverse Effects

Vitamin B_{12} is nontoxic, and large doses must be ingested to produce adverse effects, which include itching, transitory diarrhea, and fever. Other adverse effects are listed by body system in Table 53-9.

Interactions

Concurrent use with anticonvulsants, aminoglycoside antibiotics, or long-acting potassium preparations decreases the oral absorption of vitamin B_{12}.

Dosages

For dosage information on vitamin B_{12}, see the table on p. 860.

DRUG PROFILE

cyanocobalamin

Cyanocobalamin is a water-soluble B-complex vitamin required for maintenance of body fat and carbohydrate metabolism and protein synthesis. It is also needed for growth, cell replication, blood cell production, and the integrity of normal nerve function. Cyanocobalamin (vitamin B_{12}) is available both as OTC preparations and by prescription. Most of the OTC cyanocobalamin-containing products are oral multivitamin preparations, whereas many of the cyanocobalamin-only products contain large doses for parenteral injection and are available by prescription only. Other available dosage forms are an intranasal gel and a sublingual tablet. It is classified as a pregnancy category A drug.

Pharmacokinetics (cyanocobalamin, vitamin B_{12})

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	8-12 hr	6 days	Unknown

VITAMIN C

Vitamin C (ascorbic acid) can be used in many therapeutic situations. Prolonged ascorbic acid deficiency results in the nutritional disease **scurvy,** which is characterized by weakness, edema, gingivitis and bleeding gums, loss of teeth, anemia, subcutaneous hemorrhage, bone lesions, delayed healing of soft tissues and bones, and hardening of leg muscles. Scurvy has been recognized for several centuries, especially among sailors. In 1795, the British navy ordered the consumption of limes to prevent the disease.

Mechanism of Action and Drug Effects

Vitamin C is reversibly oxidized to dehydroascorbic acid and acts in oxidation-reduction reactions. It is required for several important metabolic activities, including collagen synthesis and the maintenance of connective tissue; tissue repair; maintenance of bone, teeth, and capillaries; and folic acid metabolism (specifically, the conversion of folic acid into its active metabolite). It is also essential for erythropoiesis. Vitamin C enhances the absorption of iron and is required for the synthesis of lipids, proteins, and steroids. It has also been shown to aid in cellular respiration and resistance to infections.

Indications

Vitamin C is used to treat diseases associated with vitamin C deficiency and as a dietary supplement. It is most beneficial in patients who have larger daily requirements because of pregnancy, lactation, hyperthyroidism, fever, stress, infection, trauma, burns, smoking, and the use of certain drugs (e.g., estrogens, oral contraceptives, barbiturates, tetracyclines, and salicylates). Because vitamin C is an acid, it can also be used as a urinary acidifier. The benefits of other uses of vitamin C are undocumented. For example, taking vitamin C to prevent or treat the common cold is common practice. However, most large controlled studies have shown that ascorbic acid has little or no value as a prophylactic for the common cold.

Contraindications

The only usual contraindication for vitamin C use is known allergy to a specific vitamin product.

Adverse Effects

Vitamin C is usually nontoxic unless excessive dosages are consumed. Megadoses can produce nausea, vomiting, headache, and abdominal cramps and will acidify the urine, which can result in the formation of cystine, oxalate, and urate renal stones. Furthermore, individuals who discontinue taking excessive daily doses of ascorbic acid can experience scurvy-like symptoms.

Interactions

Ascorbic acid has the potential to interact with many classes of drugs. However, clinical experience concerning many interactions is inconclusive. Coadministration with acid-labile drugs such as penicillin G or erythromycin must be avoided. Large doses of vitamin C can acidify the urine and may enhance the excretion of basic drugs and delay the excretion of acidic drugs.

Dosages

For dosage information on vitamin C, see the table on p. 860.

DRUG PROFILE

ascorbic acid

Ascorbic acid is a water-soluble vitamin required for the prevention and treatment of scurvy. It is also required for erythropoiesis and the synthesis of lipids, protein, and steroids. It is available both in OTC preparations such as multivitamin products and by prescription. Ascorbic acid is available in many oral dosage forms as well as an injectable form. It is classified as a pregnancy category A drug.

MINERALS

Minerals are essential nutrients that are classified as inorganic compounds. They act as building blocks for many body structures and thus are necessary for a variety of physiologic functions. They are also needed for intracellular and extracellular body fluid electrolytes. Iron is essential for the production of hemoglobin, which is required for transport of oxygen throughout the body (see Chapter 54). Minerals are necessary for muscle contraction and nerve transmission, and are required components of essential enzymes.

Mineral compounds are composed of various metallic and nonmetallic elements that are chemically combined with ionic bonds. When these compounds are dissolved in water, they separate (dissociate) into positively charged metallic cations and electrolytes or negatively charged nonmetallic anions (Figure 53-4). Ingestion of minerals provides essential elements necessary for vital bodily functions. Elements that are required in larger amounts are called *macrominerals;* those required in smaller amounts are called *microminerals* or *trace elements.* Table 53-10 classifies these nutrient elements as either *macrominerals* or *microminerals* and as *metal* or *nonmetal.*

CALCIUM

Calcium is the most abundant mineral element in the human body, accounting for approximately 2% of the total body weight. The highest concentration of calcium is in bones and teeth. The efficient absorption of calcium requires adequate amounts of vitamin D.

Calcium deficiency results in hypocalcemia and can affect many bodily functions. Causes of calcium deficiency include inadequate calcium intake and/or insufficient vitamin D to facilitate absorption; hypoparathyroidism; and malabsorption syndrome, especially in older individuals. Calcium deficiency–related disorders include infantile rickets, adult osteomalacia, muscle cramps, osteoporosis (especially in postmenopausal

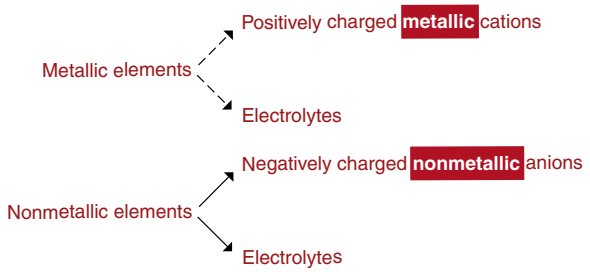

FIGURE 53-4 When mineral compounds are dissolved in water, they separate into positively charged metallic cations or negatively charged nonmetallic anions.

TABLE 53-10 MINERAL ELEMENTS

ELEMENT	SYMBOL	TYPE	IONIC/ELECTROLYTE FORM
Macrominerals			
calcium*	Ca	Metal	Ca^{2+} calcium cation
chlorine	Cl	Nonmetal	Cl^- chloride anion
magnesium*	Mg	Metal	Mg^{2+} magnesium cation
phosphorous*	P	Nonmetal	PO_4^{3-} phosphate anion
potassium	K	Metal	K^+ potassium cation
sodium	Na	Metal	Na^+ sodium cation
sulfur	S	Nonmetal	SO_4^{2-} sulfate anion
Microminerals			
chromium	Cr	Metal	Cr^{3+} chromium cation
cobalt	Co	Metal	Co^{2+} cobalt cation
copper	Cu	Metal	Cu^{2+} copper cation
fluorine	F	Nonmetal	F^+ fluoride anion
iodine*	I	Nonmetal	I^+ iodide anion
iron*	Fe	Metal	Fe^{2+} ferrous cation
manganese	Mn	Metal	Mn^{2+} manganese cation
molybdenum	Mo	Metal	Mo^{6+} molybdenum cation
selenium*	Se	Metal	Se^{2-} selenium cation
zinc*	Zn	Metal	Zn^{2+} zinc cation

*Mineral elements that have a current recommended daily allowance (RDA).

females), hypoparathyroidism, and renal dysfunction. Table 53-11 lists the possible causes of calcium deficiency and the resulting disorders. Normal serum levels are 9 to 10.5 mg/dL.

Mechanism of Action and Drug Effects

Calcium participates in a variety of essential physiologic functions and is a building block for body structures. Specifically, calcium is involved in the proper development and maintenance of teeth and skeletal bones. It is an important catalyst in many of the coagulation pathways in the blood. Calcium acts as a cofactor in clotting reactions involving the intrinsic and extrinsic pathways of thromboplastin. It is also a cofactor in the conversion of prothrombin to thrombin by thromboplastin and the conversion of fibrinogen to fibrin. Calcium is essential for the normal maintenance and function of the nervous, muscular, and skeletal systems and for cell membrane and capillary permeability. It is an important catalyst in many enzymatic reactions, including transmission of nerve impulses; contraction of cardiac, smooth, and skeletal muscles; renal function; respiration; and, as noted earlier, blood coagulation. Calcium also plays a regulatory role in the release and storage of neurotransmitters and hormones, in white blood cell (WBC) and hormone activity, in the uptake and binding of amino acids, and in intestinal absorption of cyanocobalamin (vitamin B_{12}) and gastrin secretion.

TABLE 53-11 CALCIUM DEFICIENCY: CAUSES AND DISORDERS

CAUSE	DISORDER
Inadequate intake	Infantile rickets
Insufficient vitamin D	Adult osteomalacia
Hypoparathyroidism	Muscle cramps
Malabsorption syndrome	Osteoporosis

Indications

Calcium salts are used for the treatment or prevention of calcium depletion in patients for whom dietary measures are inadequate. Calcium requirements are also high for growing children and for women who are pregnant or breastfeeding. Many conditions may be associated with calcium deficiency, including the following:

- Achlorhydria
- Alkalosis
- Chronic diarrhea
- Hyperphosphatemia
- Hypoparathyroidism
- Menopause
- Pancreatitis
- Pregnancy and lactation
- Premenstrual syndrome
- Renal failure
- Sprue
- Steatorrhea
- Vitamin D deficiency

Calcium is also used to treat various manifestations of established deficiency states, including adult osteomalacia, hypoparathyroidism, infantile rickets or tetany, muscle cramps, osteoporosis, and renal insufficiency. In addition, calcium is used as a dietary supplement for women during pregnancy and lactation.

More than 12 different selected calcium salts are available for treatment or nutritional supplementation. Each calcium salt contains a different amount of elemental calcium per gram of calcium salt. Table 53-12 lists the available salts and their associated calcium content.

Contraindications

Contraindications for administration of exogenous calcium include hypercalcemia, ventricular fibrillation of the heart, and known allergy to a specific calcium drug product.

TABLE 53-12 CALCIUM SALTS: CALCIUM CONTENT

CALCIUM SALT	ELEMENTAL CALCIUM CONTENT (PER GRAM)
phosphate tribasic	400 mg (20 mEq)
carbonate*	400 mg (20 mEq)
phosphate dibasic anhydrous	290 mg (14.5 mEq)
chloride	270 mg (13.5 mEq)
acetate	253 mg (12.7 mEq)
phosphate dibasic dihydrate	230 mg (11.5 mEq)
citrate*	211 mg (10.6 mEq)
glycerophosphate	191 mg (9.6 mEq)
lactate	130 mg (6.5 mEq)
gluconate*	90 mg (4.5 mEq)
gluceptate	82 mg (4.1 mEq)
glubionate	64 mg (3.2 mEq)

*Most commonly used forms for the prevention of osteoporosis.

Adverse Effects

Although adverse effects and toxicity are rare, hypercalcemia can occur. Symptoms include anorexia, nausea, vomiting, and constipation. In addition, when calcium salts are administered by intramuscular or subcutaneous injection, mild to severe local reactions, including burning, necrosis and sloughing of tissue, cellulitis, and soft tissue calcification, may occur. Venous irritation may occur with intravenous administration. Other adverse effects associated with both oral and parenteral use of calcium salts are listed in Table 53-13.

Toxicity and Management of Overdose

Long-term excessive calcium intake can result in severe hypercalcemia, which can cause cardiac irregularities, delirium, and coma. Management of acute hypercalcemia may require hemodialysis, whereas milder cases will respond to discontinuation of calcium intake.

Interactions

Calcium salts will chelate (bind with) tetracyclines and quinolones to produce an insoluble complex. If hypercalcemia is present in patients taking digoxin, serious cardiac dysrhythmias can occur.

Dosages

For dosage information on calcium and other selected minerals, see the table below.

TABLE 53-13 CALCIUM SALTS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Hemorrhage, rebound hypertension
Gastrointestinal	Constipation, nausea, vomiting, flatulence
Genitourinary	Renal dysfunction, renal stones, renal failure
Metabolic	Hypercalcemia, metabolic alkalosis

DRUG PROFILE

calcium

Calcium salts are primarily used in the treatment or prevention of calcium depletion in patients in whom dietary measures are inadequate. Many calcium salts are available, all with a different content of elemental calcium per gram of salt. Calcium is available in both oral and parenteral forms. Numerous calcium preparations are available that have different names and provide different doses. Consult manufacturer instructions for recommended dosages. The pharmacokinetics of calcium is highly variable and depends on individual patient physiology and the characteristics of the specific drug product used. Medication errors and confusion are common with calcium products, because the amount of the salt is not the same as the amount of elemental calcium. For example, calcium carbonate 1250 mg is equal to 500 mg of elemental calcium. Depending on the institution, the drug may be profiled as 1250 mg, but the tablet is labeled as 500 mg. Additional confusion occurs with the injectable forms, calcium chloride and calcium gluconate. Calcium chloride provides about three times as much elemental calcium as calcium gluconate, but they are both ordered as 1 g or 1 ampule. Calcium chloride can cause severe problems if it infiltrates from the intravenous line. For that reason, it is recommended that it be diluted or given through a central line if it is given by intravenous push. Adding to the confusion is calcium acetate (PhosLo), which is used not for calcium replacement but to bind phosphate in renal patients. Calcium products are classified as pregnancy category C drugs.

MAGNESIUM

Magnesium is one of the principal cations present in the intracellular fluid. It is an essential part of many enzyme systems associated with energy metabolism. Magnesium deficiency (hypomagnesemia) is usually caused by (1) malabsorption, especially in the presence of high calcium intake;

DOSAGES

Selected Minerals

DRUG	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
calcium carbonate (Tums, others)	Mineral salt	PO: 500 mg 2-4 times daily	Antacid, nutritional-calcium supplementation, hyperphosphatemia associated with chronic renal failure
magnesium oxide (Max-Ox 400, others)	Mineral salt	PO: 400 mg 1-2 times daily	Magnesium supplementation, hypomagnesemia

PO, Oral.

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

All Calcium Forms Are Not the Same!

When calcium is given, it is essential to use the correct form. Calcium chloride has many uses, including treatment of cardiac arrest and hypocalcemic tetany. Both calcium carbonate (Os-Cal, Tums, Caltrate) and calcium citrate (Citracal) are used as antacids and are also used to treat or prevent calcium deficiency and to treat hyperphosphatemia. However, calcium acetate (PhosLo) is not used for calcium replacement. It is used only to control hyperphosphatemia in patients with end-stage renal disease. Be cautious when giving calcium—the different forms are not interchangeable.

(2) alcoholism; (3) long-term intravenous feeding; (4) diuretic use; and (5) metabolic disorders, including hyperthyroidism and diabetic ketoacidosis. Symptoms associated with hypomagnesemia include cardiovascular disturbances, neuromuscular impairment, and mental disturbances. Dietary intake from vegetables and other foods will usually prevent magnesium deficiency. However, magnesium is required in greater amounts in individuals with diets high in protein-rich foods, calcium, and phosphorus. Normal serum levels are 1.7 to 2.2 mg/dL.

Mechanism of Action and Drug Effects

The precise mechanism for the effects of magnesium has not been fully determined. Magnesium is a known cofactor for many enzyme systems. It is required for muscle contraction and nerve function. Magnesium produces an anticonvulsant effect by inhibiting neuromuscular transmission in selected convulsive states.

Indications

Magnesium is used for treatment of magnesium deficiency and as a nutritional supplement in total parenteral nutrition and multivitamin preparations. It is used as an anticonvulsant in magnesium deficiency–induced seizure states; to manage complications of pregnancy, including preeclampsia and eclampsia; as a tocolytic drug for inhibition of uterine contractions in premature labor; for treatment of pediatric acute nephropathy; for management of various cardiac dysrhythmias; and for short-term treatment of constipation.

Contraindications

Contraindications to magnesium administration include known drug product allergy, heart block, renal failure, adrenal gland failure (Addison's disease), and hepatitis.

Adverse Effects

Adverse effects of magnesium are due to hypermagnesemia, which results in tendon reflex loss, difficult bowel movements, CNS depression, respiratory distress and heart block, and hypothermia.

Toxicity and Management of Overdose

Toxic effects are extensions of symptoms caused by hypermagnesemia, a major cause of which is the long-term use of magnesium products (especially antacids in patients with renal dysfunction). Severe hypermagnesemia is treated with intravenous calcium and possibly the diuretic furosemide.

Interactions

The use of magnesium with neuromuscular blocking drugs and CNS depressants produces additive effects.

DRUG PROFILE

magnesium

Magnesium is a mineral that has a variety of dosage forms and uses. It is an essential part of many enzyme systems. When it is absent or diminished in the body, cardiovascular, neuromuscular, and mental disturbances can occur. Magnesium sulfate is the most common form of magnesium used as a mineral replacement. It is available in both oral and injectable forms. It is classified as a pregnancy category B drug.

PHOSPHORUS

Phosphorus is widely distributed in foods, and thus a dietary deficiency is rare. Deficiency states are primarily due to malabsorption, extensive diarrhea or vomiting, hyperthyroidism, hepatic disease, and long-term use of aluminum or calcium antacids. Normal serum levels are 2.8 to 4.2 mg/dL.

Mechanism of Action and Drug Effects

Phosphorus in the form of the phosphate group and/or anion (PO_4^{3-}) is a required precursor for the synthesis of essential body chemicals and an important building block for body structures. Phosphorus is required as a structural unit for the synthesis of nucleic acid and the adenosine phosphate compounds (adenosine monophosphate [AMP], adenosine diphosphate [ADP], and adenosine triphosphate [ATP]) responsible for cellular energy transfer. It is also necessary for the development and maintenance of the skeletal system and teeth. The skeletal bones contain up to 85% of the phosphorus content of the body. In addition, phosphorus is required for the proper utilization of many B-complex vitamins, and it is an essential component of physiologic buffering systems.

Indications

Phosphorus is used for treatment of deficiency states and as a dietary supplement in many multivitamin formulations.

Contraindications

Contraindications to phosphorous or phosphate administration include hyperphosphatemia and hypocalcemia.

Adverse Effects

Adverse effects are usually associated with the use of phosphorus replacement products. These effects include diarrhea, nausea, vomiting, and other GI disturbances. Other adverse effects include confusion, weakness, and breathing difficulties.

Toxicity and Management of Overdose

Toxic reactions to phosphorus are extremely rare and usually occur only after ingestion of the pure element.

Interactions

Antacids can reduce the oral absorption of phosphorus.

DRUG PROFILE

phosphorus

Phosphorus is a mineral that is essential to our well-being. It is needed to make energy in the form of ADP and ATP for all bodily processes. Phosphorus is present in a large number of drug formulations and appears as a phosphate salt (PO_4). Phosphorus is to be used with caution in patients with renal impairment. It is available in both oral and parenteral formulations.

ZINC

The metallic element zinc is often taken orally in the form of the sulfate salt as a mineral supplement. Normally a dietary trace element, zinc plays a crucial role in the enzymatic metabolic reactions involving both proteins and carbohydrates. This makes it especially important for normal tissue growth and repair. It therefore also has a major role in wound healing.

NURSING PROCESS

ASSESSMENT

Before administering *vitamins,* assess the patient for nutritional disorders by reviewing the results of various laboratory tests, such as hemoglobin, hematocrit, WBC and RBC counts, serum albumin, and total protein levels. Assess the patient's dietary intake, dietary patterns, menu planning, grocery shopping/food practices and habits, and cultural influences before giving any supplemental therapy. For vitamin A deficiencies, perform a baseline vision assessment, including night vision, and conduct a thorough examination of the skin and mucous membranes, and document the findings. Assess for contraindications to vitamin A such as known allergy as well as a current state of excessive supplementation and/or hypervitaminosis. Additionally, assess for drug interactions with laxatives and cholestyramine leading to possible decreased absorption of the vitamin. Baseline assessment and documentation of level of consciousness, GI functioning and complaints, vision, condition of the skin, and musculoskeletal status is also important due to the adverse effects and signs and symptoms of toxicity associated with overdosage of vitamin A (see the pharmacology discussion and Table 53-3).

For patients who are deficient in *vitamin D,* perform a baseline assessment of skeletal formation with attention to any deformities. Serum vitamin D (12 to 50 ng/mL) and calcium levels are usually ordered as baseline and then during therapy. It is also important to assess for known contraindications such as renal dysfunction and hypercalcemia or hyperphosphatemia. Assess for drug interactions with laxatives and cholestyramine leading to possible decreased absorption of the vitamin. Before *vitamin E* is administered, assess patients for hypoprothrombinemia because this condition may occur secondary to vitamin E deficiency. Document any baseline bleeding or hematologic problems and conduct a thorough skin assessment with attention to skin integrity, presence of any edema, muscle weakness, easy bruising, and/or bleeding.

The last of the fat-soluble vitamins, *vitamin K,* is associated with clotting function; therefore, prior to its use, measure and document the patient's prothrombin time, international normalized ratio, and platelet counts. Assess the skin for bruises, petechiae, and erythema. Examine the gums for gingival bleeding. Assess urine and stool for the presence of blood. Also assess vital signs with attention to blood pressure and pulse rate. If intravenous dosage forms are prescribed, baseline assessment must include vital signs because of the risk of anaphylactic reactions. This is particularly important with vitamin K_1 (phytonadione or AquaMEPHYTON) because of an associated higher risk of anaphylaxis. Assessment of liver function is also important. It is critical to patient safety to remember that the fat-soluble vitamins are all stored in the body tissue when excessive quantities are consumed and may become toxic if taken in large dosages. Assess and document baseline values of vitamin K; normal ranges are 0.1 to 2.2 ng/mL.

Vitamin B_1 (thiamine) hypersensitivity may cause skin rash and wheezing; therefore, document the presence of any allergic reactions to vitamin B compounds. Also document baseline assessment of vital signs. Because it is rare for a deficiency of only one B-complex vitamin to occur, rule out deficiencies of all the B vitamins before treatment begins. Vitamin B_1 (thiamine) levels range from 66 to 200 nmol/L, and vitamin B_{12} (cyanocolbalamin) levels range from 200 to 900 pg/mL. Urinary thiamine levels may also be ordered (in adults, urinary thiamine levels of less than 27 mcg/dL indicate deficiency). Vitamin B_1 deficiency may result in Wernicke's encephalopathy (see the pharmacology discussion); thus, there is a need for a thorough mental status assessment. Thoroughly assess the medication order for accuracy and for route of administration. Drug interactions include alkaline and sulfite-containing solutions, so be sure to assess for drugs being administered at the same time. *Vitamin B_2* (riboflavin) has no major toxic effects or drug interactions, but assessing for any known allergy to any vitamin product is important. *Vitamin B_3* (niacin) has several important indications. Assess for contraindications such as liver disease, severe hypotension, and active peptic ulcer disease. With *vitamin B_6* (pyridoxine), perform a thorough neurologic assessment due to associated neurotoxicity with large dosages. Levodopa is a significant drug interaction to assess for with pyridoxine because the vitamin reduces the action of levodopa. *Vitamin B_{12}* (cyanocobalamin) requires thorough assessment of the medication order. Note the route of administration because the preferred route is deep IM injection. Drug interactions to assess for include anticonvulsants, aminoglycoside antibiotics, and long-acting potassium supplements because they decrease the oral absorption of vitamin B_{12}.

Vitamin C (ascorbic acid) is usually well tolerated; however, assess the patient for any history of nutritional deficits or problems with dietary intake as well as any allergies to a specific vitamin product. Assess for drug interactions that include acid-labile drugs such as penicillin G or erythromycin. Additionally, it is important to note that large doses of vitamin C may

increase the excretion of many basic (opposite of acidic) drugs and delay the excretion of acidic drugs.

With the minerals *calcium* and *magnesium,* include allergies, nutritional status, use of medications, medical history, contraindications, cautions, and drug interactions in the baseline assessment. Laboratory studies that may be prescribed include serum calcium (9 to 10.5 mg/dL), magnesium (1.7 to 2.2 mg/dL), hemoglobin, hematocrit, and RBC and WBC counts. Calcium interacts with many medications, as described previously, so a thorough assessment of the patient's medication history is important to patient safety. The specific interaction of calcium is that of chelation or binding with the drug and, in this case, it is with tetracycline and quinolone antibiotics. The chelation then forms an insoluble complex rendering the antibiotic inactive. Another significant interaction occurs when a patient is hypercalcemic and takes digitalis with the result of serious cardiac dysrhythmias. If there is a history of cardiac disease, a baseline electrocardiogram (ECG) recording may be ordered prior to calcium therapy. Because of the various calcium preparations with different names and doses, always thoroughly assess the medication order and be certain that the right product is being given. Also note that the injectable forms of calcium (i.e., calcium chloride, calcium gluconate) may be easily confused, so be cautious. Assess patency of the IV site, if intravenous dosage forms are ordered, because infiltrates may lead to severe irritation of the vein and surrounding tissue.

Magnesium is also associated with several drug interactions. Review for potential interactions before drug therapy is initiated, such as with CNS depressants and neuromuscular blocking drugs. Assess the patient's renal, cardiac, and hepatic functioning. Important to document prior to giving magnesium is neurologic functioning and grading of deep tendon reflexes. Hyporeflexia may indicate toxicity. It is also important to assess the prescriber's order for completeness and reason for use so that it is fully understood why the drug is being given (e.g., replacement, antacid, or laxative purposes). In addition, thoroughly assess any order for the use of calcium, magnesium, and/or zinc within total parenteral nutritional infusions.

NURSING DIAGNOSES

1. Impaired physical mobility related to poorly developed muscles from vitamin D and/or vitamin E deficiency and/or from fatigue related to poor nutrition and vitamin B deficiency
2. Impaired tissue integrity related to vitamin C deficiency and subsequent decreased healing
3. Risk for injury related to possible night blindness or altered vision due to vitamin A deficiency

PLANNING

GOALS

1. Patient regains or maintains normal or near-normal physical mobility and musculoskeletal functioning.
2. Patient maintains intact skin and tissue integrity.
3. Patient remains free from injury.

CASE STUDY

Vitamin Supplements

S.C., 49 years of age, was found unconscious in a vacant house and was brought to the emergency department. He had an elevated blood alcohol level and eventually manifested delirium tremens. Now, a week later, he is in stable condition on a medical-surgical unit. He is weak and malnourished, and he cannot remember how he got to the hospital. The nurse is reviewing his medication list and notes that several vitamin supplements are ordered.

1. Based on S.C.'s history, what vitamin deficiencies are possible?
2. Which vitamin supplement is especially used to treat complications associated with alcoholism? Explain your answer.
3. S.C. is receiving large doses of several vitamins, and the nurse is concerned about vitamin toxicities. Which type of vitamin, water-soluble or fat-soluble, carries the risk of toxicities? Explain your answer.
4. Because of S.C.'s long-term malnourished state, the physician is concerned about the condition of his bones and starts S.C. on phosphorus and calcium supplementation, along with vitamin D. Explain the rationale behind the addition of vitamin D.

For answers, see http://evolve.elsevier.com/Lilley.

OUTCOME CRITERIA

1. Patient increases mobility daily with performance of ADLs and usual exercise regimen or as prescribed.
   - Patient states measures to increase energy, stamina, and strength such as increase in dietary consumption of well-balanced diet and fluids with vitamin or mineral supplementation.
2. Patient states measures to minimize injury and maximize intactness of skin and mucous membranes, such as performing frequent mouth care, keeping skin clean and dry and applying moisturizers as needed, as well as drinking at least 6 to 8 glasses of water per day.
3. Patient states measures to prevent injury such as minimizing obstacles in the home setting, removing area or throw rugs, and adding night lights.
   - Patient states measures to replace vitamin A deficiencies through replacement therapy and dietary intake such as increased intake of liver, fish, dairy products, egg yolks, and yellow-orange vegetables/fruits.

IMPLEMENTATION

Before administering *vitamin A* or any vitamin or supplement, document the patient's dietary intake for the preceding 24 hours. Document any signs and symptoms of hypervitaminosis or hypercarotenemia (excess vitamin A).; *Vitamin D* is available in OTC products (e.g., multivitamins) or by prescription but attention to the product prescribed is important to patient safety. Oral dosage forms are available with IM dosage forms for those with GI, liver, biliary and/or malabsorptive syndromes. During therapy, advise the patient to report any palpitations, unresolved nausea, vomiting, constipation, or muscle pain. Instruct the patient to take *vitamin* B_1 (thiamine) as directed. *Vitamin* B_2 (riboflavin) is not associated

with any adverse or toxic effects but it is important to note that in large doses it may turn the urine yellowish-orange. Tell patients to take *vitamin B_3* (niacin) with milk or food to decrease GI upset. Niacin is often used for hyperlipidemia (see Chapter 27) and in much larger doses. *Vitamin B_6* (pyridoxine) is more commonly used to treat drug-induced B_6 deficiencies. Two examples of this are with the antituberculin drug isoniazid (INH) and antihypertensive drug hydralazine. *Vitamin B_{12}* (cyanocobalamin) is administered orally with meals to increase its absorption. Intranasal gel and sublingual tablets are other dosage forms available. If given for megaloblastic anemia, deep IM injection is the preferred route of administration. Give *vitamin C* (ascorbic acid) orally, and if oral effervescent forms are used, instruct the patient to dissolve it in at least 6 oz of water or juice. If vitamin C is administered for acidification of urine, it is important to frequently monitor the patient's urinary pH.

Various oral *calcium* products are available and, because of the differences in the amount of elemental calcium they provide (e.g., calcium carbonate 1250 mg is equal to only 500 mg of elemental calcium), medication errors may occur and confusion may arise about the various dosages available OTC. A list of the various calcium salts available is found in Table 53-12. Instruct the patient to take oral dosage forms of calcium 1 to 3 hours after meals. Injectable dosage forms of calcium may also be confusing. Follow the medication order carefully and check policy and standards regarding infusions (see previous discussion in the pharmacology section and the Safety and Quality Improvement: Preventing Medication Errors box on p. 875). Because of problems with venous irritation, give intravenous calcium via an intravenous infusion pump and with proper dilution. Giving intravenous calcium too rapidly may precipitate severe hypercalcemia with subsequent cardiac irregularities, delirium, and coma. Administer intravenous calcium slowly, as ordered, and within the manufacturer guidelines (e.g., usually less than 1 mL/min). Patients need to remain recumbent for 15 minutes after the infusion to prevent further problems. Should extravasation of the intravenous calcium solution occur, discontinue the infusion immediately but leave the intravenous catheter in place for antidote administration. The prescriber may then order an injection of 1% procaine and/or other antidotes or fluids to reduce vasospasm at the site and dilute the irritating effects of calcium on surrounding tissue. However, follow all facility policies and procedural guidelines and/or manufacturer insert information as is deemed appropriate. In addition, include the appearance of the intravenous site (e.g., erythema, swelling, and any drainage) in the documentation.

Administer *magnesium* according to manufacturer guidelines and as ordered. Always give intravenous magnesium sulfate very cautiously; use an infusion pump, and follow manufacturer guidelines for dosage and dilutional concentration. During intravenous magnesium infusion, monitor the patient's ECG and vital signs, and rate patellar or knee-jerk reflexes. Impaired reflexes are used as an indication of drug-related CNS depressant effects. CNS depression may quickly lead to respiratory and/or cardiac depression; thus perform frequent monitoring. Document IV calcium infusion and record each set of vital sign measurements with ratings of reflexes. If there is a decrease in the strength of reflexes and/or a decrease in respirations to less than 12 breaths/min, contact the prescriber immediately, stop the infusion, and monitor the patient. Other signs that require immediate attention are confusion, irregular heart rhythm, cramping, unusual fatigue, lightheadedness, and dizziness. Calcium gluconate must be readily accessible for use as an antidote to magnesium toxicity. Administer oral dosage forms of magnesium as ordered and in the exact dosage prescribed. See the Patient Teaching Tips for more information related to the use of vitamins, minerals, and trace elements.

EVALUATION

In the patient's evaluation, always review whether goals and outcome criteria have been met. Monitor for therapeutic responses and adverse effects of each vitamin or mineral. Therapeutic responses to *vitamin A* include restoration of normal vision and intact skin; adverse effects include lethargy, headache, nausea, and vomiting (see Table 53-3). Therapeutic responses to *vitamin D* include improved bone growth and formation and an intact skeleton with decreased or no pain compared with baseline musculoskeletal deformity, weakness, and discomfort; adverse effects include hypertension, dysrhythmias, fatigue, weakness, headache, and decreased bone growth (see Table 53-4). Therapeutic responses to *vitamin E* include improved muscle strength, improved skin integrity, and alpha tocopherol levels within normal limits; adverse effects are listed in Table 53-5. Therapeutic responses to *vitamin K* include return to normal clotting; adverse effects include headache, nausea, and hemolytic anemia (see Table 53-6). Therapeutic responses to *vitamin B_1* (thiamine) include improved mental status and less confusion. Therapeutic responses include improved skin integrity, normal vision, improved mental status, and normal RBC count, hemoglobin level, and hematocrit. Adverse effects from vitamin B are rare, but *vitamin B_3* (niacin) is associated with postural hypotension, dysrhythmias, headache, and nausea (see Table 53-7 for complete listing). *Vitamin B_6* (pyridoxine) adverse effects include flushing, paresthesias, lethargy, and headache. *Vitamin B_{12}* (cyanocobalamin) has adverse effects of heart failure, flushing, diarrhea, itching, and hypokalemia. Therapeutic responses to *vitamin C* include improvements in capillary intactness, integrity of the skin and mucous membranes, healing, energy level, and mental state. Therapeutic responses to *calcium* include improved deficiency states. Adverse effects are listed in Table 53-13. Therapeutic effects of *magnesium* include bolstering of many enzymatic functions in the body with other uses as an anticonvulsant, treatment of preeclampsia and eclampsia, and management of various dysrhythmias. Adverse effects include loss of deep tendon reflexes, CNS depression, constipation, respiratory distress, and heart block.

PATIENT TEACHING TIPS

- Educate the patient about the best dietary sources of both water- and fat-soluble vitamins (vitamins A, B, C, D, E, and K), as well as about the best sources of elements and minerals. See Table 53-2 for the nutrient content of various food items.
- Monitor any patient taking vitamins or minerals closely for therapeutic and adverse effects. Encourage the patient to monitor his or her own progress in how well he or she feels and to note any improvement in the related condition or health status. Encourage intake of fluids with all vitamin and mineral therapy.
- Inform patients who have had a gastrectomy or ileal resection and those with pernicious anemia of the necessity for vitamin B_{12} injections.
- Educate the patient taking up to 600 mg/day of vitamin C that there may be a slight increase in daily urination and that diarrhea is associated with intake of more than 1 g/day.
- Stress that patients taking calcium and/or magnesium (see Table 53-10) must take the medication as prescribed and with adequate amounts of fluids.
- Educate the patient about calcium therapy and about food items and drugs that will chelate (or bind) with calcium. For example, calcium binds with tetracycline antibiotics and decreases or negates the effect of the antibiotic.

KEY POINTS

- OTC use of vitamins and minerals may lead to serious problems and adverse effects and requires careful consideration prior to self-medication. A prescriber may be consulted prior to use if there are any questions or concerns.
- Incorporate the nutritional status of the patient into the nursing care plan to provide comprehensive care during vitamin or mineral therapy.
- Provide information about dietary needs and the body's need for vitamins and minerals as part of the patient's health promotion.
- Focus patient education related to vitamin and mineral replacement on dietary sources of the specific nutrient, drug and food interactions, and adverse effects. Instruct the patient on when it is necessary to contact the prescriber.
- Vitamins and minerals can be dangerous to the patient if given without concern or caution for the patient's overall condition and underlying disease processes.
- Never assume that because the drug is a vitamin or a mineral it does not have adverse reactions or toxicity.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 When giving calcium intravenously, the nurse needs to administer it slowly, keeping in mind that rapid intravenous administration of calcium may cause which problem?
- **a** Ototoxicity
- **b** Renal damage
- **c** Tetany
- **d** Cardiac dysrhythmias

2 The nurse will assess which laboratory test results before administration of vitamin K?
- **a** Prothrombin time and international normalized ratio
- **b** Red blood cell and white blood cell counts
- **c** Phosphorous and calcium levels
- **d** Total protein and albumin levels

3 A patient has GI malabsorption due to severe intestinal damage from a gastrointestinal infection. The nurse will need to assess for signs of a deficiency of which vitamin?
- **a** Vitamin A (retinol)
- **b** Vitamin B_{12} (cyanocobalamin)
- **c** Vitamin B_6 (pyridoxine)
- **d** Vitamin E (tocopherols)

4 The nurse is providing wound care for a patient with a stage IV pressure ulcer and expects that the patient will receive which supplement to assist in wound healing?
- **a** Vitamin K
- **b** Vitamin B_1
- **c** Zinc
- **d** Calcium

5 While caring for a newly admitted patient who has a long history of alcoholism, the nurse anticipates that part of the patient's medication regimen will include which vitamin?
- **a** Vitamin B_1 (thiamine)
- **b** Vitamin B_6 (pyridoxine)
- **c** Vitamin C (ascorbic acid)
- **d** Vitamin A (retinol)

6 When administering vitamin and mineral supplements, the nurse implements which appropriate interventions? (Select all that apply.)
- **a** Not administering oral calcium tablets along with oral tetracyclines
- **b** Administering intravenous calcium via a rapid intravenous push infusion
- **c** Monitoring the heart rhythm (ECG) of a patient receiving an intravenous magnesium infusion
- **d** Giving oral niacin with milk or food to decrease gastrointestinal upset
- **e** Monitoring for the formation of renal stones in patients taking large doses of vitamin C

7 The order reads: "Give vitamin K (AquaMEPHYTON) 0.5 mg IM within 1 hour of birth." The medication is available in a vial that contains 1 mg/0.5 mL. How many milliliters will the nurse draw up for the injection?

1. d, 2. a, 3. b, 4. c, 5. a, 6. a, c, d, e, 7. 0.25 mL

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the importance of iron, vitamin B_{12}, and folic acid in the formation of blood cells.
2 Describe the various types of anemia-related drug treatments.
3 Discuss the mechanisms of action, cautions, contraindications, drug interactions, uses, dosages, and special administration techniques of the various drugs used to treat anemia, as well as measures to enhance the effectiveness and decrease the adverse effects of these drugs.
4 Develop a nursing care plan that includes all phases of the nursing process for patients taking drugs used to treat anemia.

DRUG PROFILES

♦ **epoetin alfa, p. 880**
ferric gluconate, p. 883
ferrous fumarate, p. 882
♦ **ferrous sulfate, p. 882**
♦ **folic acid, p. 884**
iron dextran, p. 883
iron sucrose, p. 883

♦ *Key drug*

KEY TERMS

Erythrocytes Another name for red blood cells (RBCs). (p. 878)
Erythropoiesis The process of erythrocyte production. (p. 878)
Globin The protein part of the *hemoglobin* molecule (see later); the four different structural globin chains most often found in adults are the $alpha_1$, $alpha_2$, $beta_1$, and $beta_2$ chains. (p. 878)
Hematopoiesis The normal formation and development of all blood cell types in the bone marrow. (p. 878)
Heme Part of the *hemoglobin* molecule; a nonprotein, iron-containing pigment. (p. 878)
Hemoglobin A complex protein-iron compound in the blood that carries oxygen to the cells from the lungs and carbon dioxide away from the cells to the lungs. (p. 878)
Hemolytic anemias Anemias resulting from excessive destruction of erythrocytes. (p. 879)
Hypochromic Pertaining to less than normal color. The term usually describes an RBC with decreased hemoglobin content and helps further characterize anemias associated with reduced synthesis of hemoglobin. (p. 878)

KEY TERMS—cont'd

Microcytic Pertaining to or characterized by smaller than normal cells. (p. 878)

Pernicious anemia A type of megaloblastic anemia usually seen in older adults and caused by impaired intestinal absorption of vitamin B_{12} (cyanocobalamin) due to lack of availability of intrinsic factor. (p. 879)

Reticulocytes An immature erythrocyte characterized by a meshlike pattern of threads and particles at the former site of the nucleus. (p. 878)

Spherocytes Small, globular, completely hemoglobinated erythrocytes without the usual central concavity or pallor. (p. 879)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

ERYTHROPOIESIS

The formation of new blood cells is one of the primary functions of bones. This process is known as **hematopoiesis,** and it includes the production of **erythrocytes** (red blood cells, or RBCs), as well as leukocytes (white blood cells) and thrombocytes (platelets). This process takes place in the myeloid tissue or bone marrow. This specialized tissue is located primarily in the ends, or *epiphyses,* of certain long bones and also in the flat bones of the skull, pelvis, sternum, scapulae, and ribs.

Erythropoiesis, the process of erythrocyte formation, is the focus of this chapter. This involves the maturation of a nucleated RBC precursor into a hemoglobin-filled, nucleus-free erythrocyte. This process is driven by the hormone erythropoietin, which is produced by the kidneys. Erythropoietin is also produced commercially and is used to treat anemia in certain specific circumstances and is discussed in detail later in the chapter.

When RBCs are manufactured in the bone marrow by myeloid tissue, they are released into the circulation as immature RBCs called **reticulocytes.** Once in the circulation, reticulocytes undergo a 24- to 36-hour maturation process to become mature, fully functional RBCs. After this, they have a lifespan of about 120 days.

More than one third of an RBC is composed of hemoglobin. **Hemoglobin** (abbreviated *Hgb*) is composed of two parts: heme and globin. **Heme** is a red pigment. Each heme group contains one atom of iron. **Globin** is a protein chain. The four different structural globin chains most often found in adults are the $alpha_1$, $alpha_2$, $beta_1$, and $beta_2$ chains. Together, four heme groups, each linked to one protein chain of globin, make up one hemoglobin molecule (Figure 54-1).

TYPES OF ANEMIA

Anemias are classified into four main types based on the underlying causes (Figure 54-2). Anemia of chronic disease is another common type of anemia. Anemias can be caused by maturation defects, or they can be secondary to excessive RBC destruction. Two types of maturation defects lead to anemias, categorized by the location of the defect within the cell: cytoplasmic maturation defects occur in the cell cytoplasm, and nuclear maturation defects occur in the cell nucleus. Factors responsible for excessive RBC destruction can be either intrinsic or extrinsic.

Figure 54-3 summarizes the types of anemias arising from cytoplasmic maturation defects. Major examples include iron-deficiency anemia and genetic disorders such as thalassemia, which result in defective globin synthesis. For each of these anemias, the RBCs appear **hypochromic** (lighter red than normal) and **microcytic** (smaller than normal) on blood smear. Cytoplasmic maturation anemias occur as a result of reduced or abnormal hemoglobin synthesis. Because hemoglobin is synthesized from both iron and globin, a deficiency in either one can lead to a hemoglobin deficiency. Some common

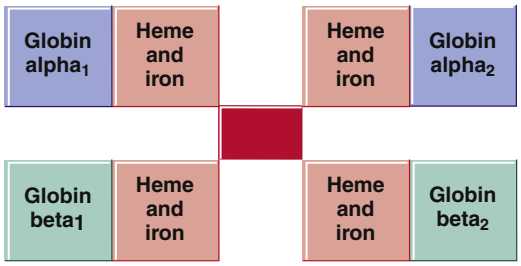

FIGURE 54-1 Schematic structure of a hemoglobin molecule.

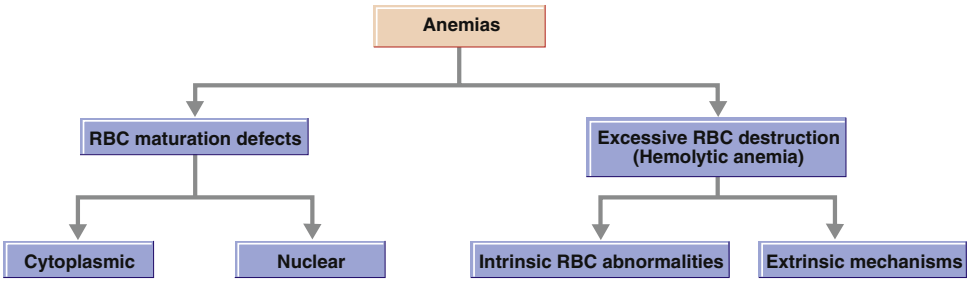

FIGURE 54-2 Underlying causes of anemia are red blood cell (RBC) maturation defects and factors secondary to excessive RBC destruction.

causes of iron-deficiency anemia are blood loss, surgery, childbirth, gastrointestinal bleeding (which can be caused by NSAID ingestion; see Chapter 44), menstrual blood loss, and hemorrhoids.

Figure 54-4 summarizes the types of anemias arising from nuclear maturation defects. These occur because of defects in deoxyribonucleic acid (DNA) or protein synthesis. Both DNA and protein synthesis require vitamin B_{12} and folic acid (B_9) to be present in normal amounts for their proper production. If either of these two vitamins is absent or deficient, anemias secondary to nuclear maturation defects may develop. In such anemias, RBCs actually appear to be *normochromic* (normal in color) but are commonly *macrocytic* (larger than normal) on blood smear. One example is **pernicious anemia.** This type of anemia results from deficiency of vitamin B_{12}, which is used in the formation of new RBCs. The usual underlying cause is the failure of the stomach lining to produce intrinsic factor. Intrinsic factor is a gastric glycoprotein that allows vitamin B_{12} to be absorbed in the intestine (see Chapter 53). Another example is the anemia caused by folic acid deficiency. Both pernicious anemia and folic acid deficiency anemia are also known as types of *megaloblastic* anemia, because they are both characterized by large, immature RBCs. Megaloblastic anemias not caused from a lack of intrinsic factor are usually related to poor dietary intake and are most commonly seen in infancy, childhood, and pregnancy.

Figure 54-5 summarizes the types of anemias arising from excessive RBC destruction, or **hemolytic anemias.** These can occur because of abnormalities within the RBCs themselves (intrinsic factors) or as a result of factors outside of (extrinsic to) the RBCs. In both cases, the erythrocytes appear on blood smear as **spherocytes.** RBC abnormalities caused by intrinsic factors are usually the result of a genetic defect. Examples include sickle cell anemia, hereditary spherocytosis, glucose-6-phosphate dehydrogenase (G6PD) deficiency, and paroxysmal nocturnal hemoglobinuria. Examples of extrinsic mechanisms for excessive RBC destruction include drug-induced antibodies that target and destroy RBCs, septic shock that produces disseminated intravascular coagulation, and mechanical forces such as those created by intraaortic balloon pumps, ventricular assist devices, and continuous veno-venous hemodialysis (CVVHD), commonly used in intensive care units.

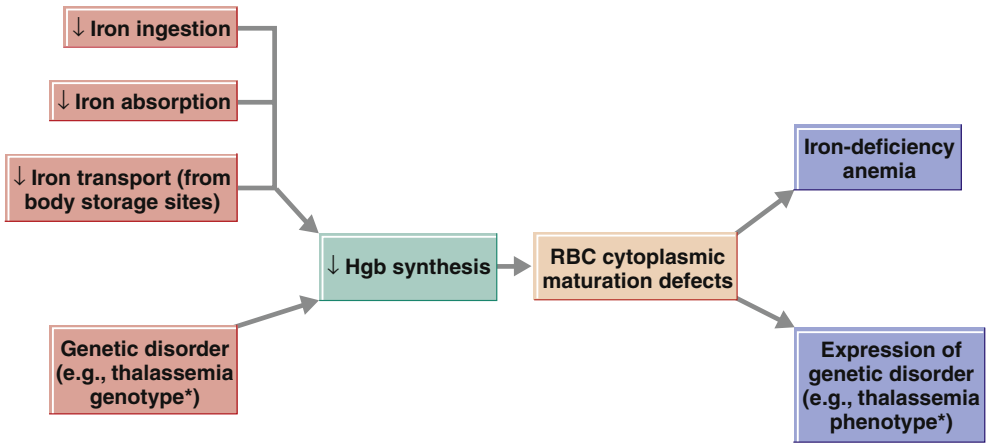

FIGURE 54-3 Schematic showing common causes and results of red blood cell (RBC) cytoplasmic maturation defects. ↓, Decreased.

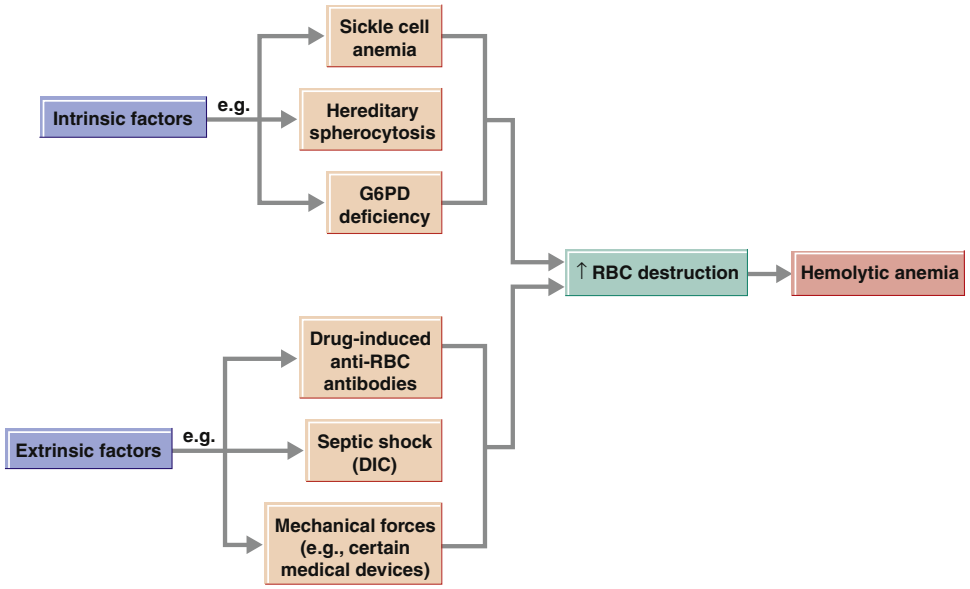

FIGURE 54-5 Increased red blood cell (RBC) destruction occurs as a result of intrinsic and extrinsic factors. ↑, Increased; *DIC,* disseminated intravascular coagulation; *G6PD,* glucose-6-phosphate dehydrogenase.

PHARMACOLOGY OVERVIEW

ERYTHROPOIESIS STIMULATING AGENTS

♦ epoetin alfa

Epoetin alfa (Epogen) is a biosynthetic form of the natural hormone erythropoietin, which is normally secreted by the kidneys in response to a decrease in RBCs. It promotes the synthesis of erythrocytes (RBCs) by stimulating RBC progenitor cells in the bone marrow. Epoetin alfa is used to treat anemia that is associated with end-stage renal disease, chemotherapy-induced anemia, and for anemia associated with zidovudine therapy (see Chapter 40). Epoetin causes the progenitor cells in the bone marrow to manufacture large numbers of immature RBCs and to greatly speed up their maturation. This medication is ineffective without adequate body iron stores and bone marrow function. Most patients receiving epoetin alfa need to also receive an oral iron preparation. A longer-acting form of epoetin called *darbepoetin (Aranesp)* is available that reduces the required number of injections, although one cost study found that there is no significant difference in overall cost between the two. Both drugs are available for injection only and can be given intravenously or subcutaneously. When the drugs are given by the subcutaneous route, the onset of action is slower, and lower dosages can be used.

Contraindications for erythropoiesis-stimulating agents (ESAs) include known drug allergy. Use of epoetin and darbepoetin is contraindicated in cases of uncontrolled hypertension and when hemoglobin levels are above 10 g/dL for cancer patients and 12 g/dL for renal patients. Use in patients with head or neck cancers or patients at risk for thrombosis is controversial as these medications increase tumor growth and risk for thrombosis. The most frequent adverse effects include hypertension, fever, headache, pruritus, rash, nausea, vomiting, arthralgia, and injection site reaction.

In 2010, the U.S. Food and Drug Administration (FDA) issued a public health advisory regarding the overzealous use of epoetin. It was found that when hemoglobin levels are above 12 g/dL and the drug is continued, patients experienced serious adverse events, including heart attack, stroke, and death. Based on these findings, the FDA now requires that any patient receiving epoetin for chemotherapy-induced anemia must be registered in a risk mitigation program called ESA Apprise Oncology. Only physicians and hospitals that are registered in this program may dispense epoetin for cancer patients. The FDA has not yet required the same for its use in chronic kidney disease; however, it is not to be given to renal patients unless their hemoglobin level is less than 12 g/dL. More information can be found at www.esa-apprise.com/ESAAppriseUI/ESAAppriseUI/default.jsp. Abuse of erythropoietin by athletes hoping to increase oxygen-carrying capacity and improve performance places the athlete at risk for diseases caused by increased blood viscosity (stroke, myocardial infarction).

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Subcut or IV	7-10 days	5-24 hr	4-13 hr	Variable

IRON

Iron is a mineral that is essential for the proper function of all biologic systems in the body. It is stored in many sites throughout the body (liver, spleen, and bone marrow). Deficiency of this mineral is the principal nutritional deficiency resulting in anemia. Individuals who require the highest amount of iron are

TABLE 54-1 FERROUS SALTS: IRON CONTENT

FERROUS SALT*	IRON CONTENT	NUMBER OF TABLETS TAKEN PER DAY (ADULTS)
Ferrous fumarate	33% iron or 330 mg/g	6-8 of 100-mg tablets or 2-3 of 325-mg tablets
Ferric gluconate	12% iron or 120 mg/g	3-4
Ferrous sulfate	20% iron or 200 mg/g	3-4
Ferrous sulfate (desiccated or dried)	30% iron or 300 mg/g	3-4

*Some patients may tolerate different formulations better; however, the number of tablets that must be consumed may decrease patient adherence.

women (especially pregnant women) and children, and they are the groups most likely to develop iron-deficiency anemia. For women, this is partly due to ongoing menstrual blood losses. Most vitamin supplements for men contain little or no iron, because men are much less likely to develop iron-deficiency anemia. Nonetheless, dietary iron is usually sufficient for both men and women in developed countries.

Dietary sources of iron include meats and certain vegetables and grains. These forms of iron must be broken down by gastric juices before the iron can be absorbed. Other foods such as orange juice, veal, fish, and ascorbic acid may help with iron absorption. Conversely, eggs, corn, beans, and many cereal products containing chemicals known as *phytates* may impair iron absorption. Beans and eggs are common dietary sources of iron. Oral iron preparations are available as ferrous salts. See Table 54-1 for a list of the currently available oral iron salts and their respective iron content. When a patient cannot tolerate oral iron, intravenous iron may be administered. There are four injectable iron products available: iron dextran (INFeD), iron sucrose (Venofer), ferric gluconate (Ferrlecit, Nulecit), and ferumoxytol (Feraheme).

Mechanism of Action and Drug Effects

Iron is an oxygen carrier in both hemoglobin and *myoglobin* (oxygen-carrying molecule in muscle tissue) and is critical for tissue respiration. Iron is also a required component of a number of enzyme systems in the body and is necessary for energy transfer in the *cytochrome oxidase* and *xanthine oxidase* enzyme systems. Administration of iron corrects iron-deficiency symptoms such as anemia, dysphagia, dystrophy of the nails and skin, and fissuring of the angles of the lips, and also maintains the bodily functions described earlier.

Indications

Supplemental iron contained in multivitamins plus iron or iron supplements alone are indicated for the prevention or treatment of iron-deficiency anemia. In all cases, an underlying cause needs to be identified. After identification of the cause, treatment is aimed at attempting to correct the cause (e.g., chronic blood loss, such as from a peptic or duodenal ulcer, cancerous colon lesion, or Crohn's disease) rather than simply alleviating the symptoms. Iron supplementation is also used in erythropoietin therapy because it is essential for the production of RBCs.

TABLE 54-2 IRON PREPARATIONS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Gastrointestinal	Nausea, constipation, epigastric pain, black and tarry stools, vomiting, diarrhea
Integumentary	Temporarily discolored tooth enamel and eyes, pain on injection

Contraindications

Contraindications to the use of iron products include known drug allergy, *hemochromatosis* (iron overload), hemolytic anemia, and any other anemia not associated with iron deficiency.

Adverse Effects

The most common adverse effects associated with oral iron preparations are nausea, vomiting, diarrhea, constipation, stomach cramps, and stomach pain. Excess iron intake can lead to accumulation and iron toxicity. See Table 54-2 for a more complete listing of the undesirable effects associated with iron preparations. Elderly patients tend to respond to lower doses of iron supplementation, and lower doses tend to decrease the rate of adverse effects.

Toxicity and Management of Overdose

Iron overdose is the most common cause of pediatric poisoning deaths reported to U.S. poison control centers. Many iron supplements are enteric coated and resemble candy. Toxicity from iron ingestion results from a combination of the corrosive effects on the gastrointestinal mucosa and the metabolic and hemodynamic effects caused by the presence of excessive elemental iron.

Treatment is based on symptomatic and supportive measures, including suction and maintenance of the airway, correction of acidosis, and control of shock and dehydration with intravenous fluids or blood, oxygen, and vasopressors. Abdominal radiographs may be helpful, because iron preparations are radiopaque and may be visualized on x-ray film. Serum iron concentrations may be helpful in establishing the amount ingested. A serum iron concentration of more than 300 mcg/dL places the patient at serious risk for toxicity. The GI tract is decontaminated via whole bowel irrigation. In patients with severe symptoms of iron intoxication, such as coma, shock, or seizures, chelation therapy with deferoxamine is initiated. In 2011, the FDA approved deferiprone, which can also be used in iron overload.

Interactions

The absorption of iron can be enhanced when it is given with ascorbic acid and decreased when it is given with antacids and calcium. Iron preparations can decrease the absorption of certain antibiotics, including tetracyclines and quinolones.

DOSAGES

Selected Anemia Drugs

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
♦ epoetin alfa (Epogen, Procrit) (C)	Human recombinant hormone (erythropoietin) analogue	IV/subcut: 2000-40,000 units 1-3 times per week, depending on weight and indication	Chemotherapy-induced anemia; anemia associated with chronic renal failure
ferric gluconate (Ferrlecit) (B)	Parenteral iron salt	**Pediatric* older than 6 yr** 1.5 mg/kg/dose for 8 doses **Adult** 125 mg/dose for 8 doses	Iron deficiency associated with hemodialysis
ferrous fumarate (Feostat) (A)	Oral iron salt	**Pediatric*** 4-6 mg/kg/day 3 mg/kg/day 1-2 mg/kg/day **Adult*** 100-200 mg given 1-3 times daily	 Severe iron-deficiency anemia Mild to moderate iron-deficiency anemia Prophylaxis Prophylaxis
♦ ferrous sulfate (A)	Oral iron salt	**Pediatric*** 4-6 mg/kg/day in 3 divided doses **Adult*** 300 mg 2 × daily, up to 300 mg 4 × daily	 Iron deficiency
♦ folic acid (A)	Water-soluble B-complex vitamin	**Pediatric†** PO/IV/IM/subcut: 0.1-0.4 mg/day **Adult†** PO/IV/IM/subcut: Up to 1 mg/day	Folate deficiency; tropical sprue; nutritional supplementation; pregnancy-related supplementation
iron dextran (INFeD, Dexferrum) (C)	Parenteral iron salt	**Pediatric†** IM/IV: 5-10 kg: 25 mg/day (0.5 mL/day); greater than 10 kg: 50 mg/day (1 mL/day) **Adult†** IM/IV: 100 mg/day (2 mL/day)	Iron deficiency when oral iron therapy is unsatisfactory
iron sucrose (Venofer) (B)	Parenteral iron salt	IV: 100 mg 1-3 times weekly to a cumulative dose of 1000 mg; may give up to 500 mg as single dose on days 1 and 14	Iron deficiency in patients with chronic renal failure

IM, Intramuscular; *IV,* intravenous; *PO,* oral; *subcut,* subcutaneous.
*Doses are expressed in terms of elemental iron, not the salt itself.
†Expressed in milligrams of elemental iron. Dosages are calculated for each patient's weight according to manufacturer's label. Doses are approximate.

Dosages

For dosage information on iron preparations, see the table on this page.

DRUG PROFILES

Iron preparations are available by prescription and as over-the-counter (OTC) medications. They are contraindicated in patients with ulcerative colitis and regional enteritis, conditions of excessive body iron stores (e.g., hemosiderosis, hemochromatosis), peptic ulcer disease, hemolytic anemia, cirrhosis, gastritis, and esophagitis. Goals of therapy include maintenance of normal hemoglobin and hematocrit levels, and improved energy level.

ferrous fumarate

The ferrous fumarate iron salts (Femiron) contain the largest amount of iron per gram of salt consumed. Ferrous sulfate and ferric gluconate are two other forms of iron that are commonly used. Ferrous fumarate is 33% elemental iron; therefore, a 325-mg tablet of ferrous fumarate provides 107 mg of elemental iron. Ferrous fumarate is available only for oral use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	3-10 days	Unknown	6 hr	Variable

♦ ferrous sulfate

Ferrous sulfate is the most frequently used form of oral iron. Ferrous sulfate ($FeSO_4$) is dosed as 300 mg two to three times a day for most adult patients. Confusion arises with ferrous sulfate, because the dose is 300 mg, but many commercially available products are 324 mg. The two doses are used interchangeably. To add to the confusion, each 324-mg tablet contains 65 mg of elemental iron. The adult dose of elemental iron is 50 to 100 mg given two to three times daily. Pediatric dosing is based on elemental iron.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	1 wk	2 hr	6 hr	Variable

iron dextran

Iron dextran (INFeD, Dexferrum) is a colloidal solution of iron (as ferric hydroxide) and dextran. It is intended for intravenous or intramuscular use for treatment of iron deficiency. Anaphylactic reactions to iron dextran, including major orthostatic hypotension and fatal anaphylaxis, have been reported in 0.3% of patients. Because of this, a test dose of 25 mg of iron dextran is administered before injection of the full dose. Although anaphylactic reactions usually occur within a few moments after the test dose, it is recommended that a period of at least 1 hour elapse before the remaining portion of the initial dose is given. Because of the potential of iron dextran to cause anaphylaxis, its use has been replaced by use of the newer products, ferric gluconate and iron sucrose. Iron dextran is available only for injection.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IM	Unknown	24-48 hr	5-20 hr	3 wk

ferric gluconate

Ferric gluconate (Ferrlecit) is an injectable iron product that is indicated for repletion of total body iron content in patients with iron-deficiency anemia who are undergoing hemodialysis. The risk of anaphylaxis is much less than with iron dextran, and a test dose is not required. Doses higher than 125 mg are associated with increased adverse events, including abdominal pain, dyspnea, cramps, and itching.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	End of infusion	7 min	1 hr	4 days

iron sucrose

Iron sucrose (Venofer) is another injectable iron product indicated for the treatment of iron-deficiency anemia in patients with chronic renal disease. It is also used for patients without kidney disease. Its risk of precipitating anaphylaxis is much less than that of iron dextran, and a test dose is not required. Hypotension is the most common adverse effect and appears to be related to infusion rate. Large doses of iron sucrose are infused over 2.5 to 3.5 hours. Low-weight elderly patients appear to be at greatest risk of hypotension. The newest injectable iron product is ferumoxytol (Feraheme). It offers the advantage of being given undiluted as IV push in 1 minute.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	End of infusion	Unknown	6 hr	Unknown

FOLIC ACID

Folic acid is a water-soluble B-complex vitamin. It is also referred to as *folate,* the name of its anionic form. The human body requires oral intake of folic acid. Dietary sources of folic acid include dried beans, peas, oranges, and green vegetables. Several conditions can lead to folic acid deficiency. However, because folic acid is absorbed in the upper duodenum, malabsorption syndromes are the most common cause of deficiency.

Mechanism of Action and Drug Effects

Folic acid is converted in the body to *tetrahydrofolic acid,* which is used for erythropoiesis and for synthesis of nucleic acids (DNA and ribonucleic acid [RNA]). Dietary ingestion of folate is required for the production of DNA and RNA. It is also essential for normal erythropoiesis. Folic acid is not active in the ingested form. It must first be converted to tetrahydrofolic acid, which is a cofactor for reactions in the biosynthesis of nucleic acids.

Indications

Folic acid is primarily used to prevent and treat folic acid deficiency. Anemias caused by folic acid deficiency can be treated by exogenous supplementation of folic acid. There is also much evidence to support the use of folic acid in the prevention of neural tube defects such as spina bifida, anencephaly, and encephalocele. It is recommended that administration begin at least 1 month before pregnancy and continue through early pregnancy to reduce the risk for fetal neural tube defects. Folic acid is also indicated for the treatment of tropical sprue, a malabsorption syndrome.

Contraindications

Contraindications to the use of folic acid include known allergy to a specific drug product and any anemia not related to folic acid deficiency (e.g., pernicious anemia). Folic acid is not to be used to treat anemias until the underlying cause and type of anemia have been determined. For example, administering folic acid to a patient with pernicious anemia may correct the hematologic changes of anemia (making the CBC normal), while deceptively masking neurologic and other symptoms of pernicious anemia that result from B_{12} deficiency.

Adverse Effects

Adverse effects associated with folic acid use are rare. Allergic reaction or yellow discoloration of urine may occur.

Interactions

No significant drug interactions occur with folic acid. However, oral contraceptives (see Chapter 34), corticosteroids (see Chapter 33), sulfonamides (see Chapter 38), and dihydrofolate reductase inhibitors (including the antineoplastic drug methotrexate [see Chapter 45] and the antibiotic trimethoprim [see Chapter 38]) can all cause signs of folic acid deficiency, but are not affected by folic acid administration.

Dosages

For dosage information on folic acid, see the table on p. 882.

DRUG PROFILE

♦ folic acid

Folic acid is a water-soluble B-complex vitamin that is used primarily in the treatment and prevention of folic acid deficiency and anemias caused by folic acid deficiency. Folic acid is available as an OTC medication in multivitamin preparations and by prescription as a single drug. It is contraindicated in patients with anemias other than megaloblastic or macrocytic anemia. The conditions representing contraindications include vitamin B_{12} deficiency anemia and uncorrected pernicious anemia. Folic acid is available for both oral and injectable use.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
PO	Unknown	60-90 min	Unknown	Unknown

OTHER ANEMIA DRUGS

Cyanocobalamin (vitamin B_{12}), which is discussed in Chapter 53, is used to treat pernicious anemia and other megaloblastic anemias. It can be given orally or intranasally to treat vitamin B_{12} deficiency but is usually given by deep intramuscular injection to treat pernicious anemia. Once remission of the anemia is seen, cyanocobalamin can be dosed once a month.

NURSING PROCESS

ASSESSMENT

Before any drug is given to treat an anemia, assess the patient's past and present medical history; compile a medication profile, including all prescription, OTC, and herbal medications the patient is taking; and also assess for drug allergies. It is important to assess for and document any signs and symptoms of anemia, such as fatigue, changes in nails and skin, and fissuring/cracking of the angles of the lip. It is also necessary to assess the patient for contraindications, cautions, and drug interactions prior to beginning treatment with any of these medications. *Erythropoiesis-stimulating agents* (epoetin alfa and darbepoetin) are used to treat anemia associated with end-stage renal disease and/or chemotherapy-induced anemia. Assessment of adequate body iron stores and bone marrow function is needed prior to administration of the drug. Document baseline vital signs because blood pressure may elevate as hematocrit rises; medical intervention may be needed. Assess for allergies to these drugs as well as for other contraindications, such as uncontrolled hypertension and hemoglobin levels of greater than 10g/dL for cancer patients and greater than 12g/dL for renal patients. Discussion of the 2010 FDA requirements and use of epoetin in those with chemotherapy-induced anemia is further clarified in the pharmacology section.

With *iron products,* significant contraindications include hemochromatosis, hemolytic anemia, and any other anemia that is not iron-deficiency related. Drug interactions affecting the absorption of iron preparations include ascorbic acid (increased absorption), antacids (decreased absorption), as well as decreased absorption of other drugs such as tetracyclines and quinolones. Some laboratory studies that may be ordered before, during, and after therapy include RBC count, hemoglobin level, hematocrit, reticulocyte count, bilirubin level, and baseline levels of folate and/or B-complex vitamins. Perform a nutritional assessment with a focus on the amount of iron in the patient's diet. A 24-hour recall of all food intake with serving sizes may prove to be beneficial. A nutritional and dietary consult may also be ordered. In addition, asking questions about the patient's energy levels, ability to carry out activities of daily living, overall immunity to illnesses, and state of health may also provide valuable information.

TEAMWORK AND COLLABORATION: PHARMACOKINETIC BRIDGE TO NURSING PRACTICE

Iron preparations provide a perfect example of how pharmacokinetic properties can impact drug dosing and efficacy. Oral iron is available in a variety of salt forms, such as ferrous fumarate, ferrous sulfate, and ferric gluconate. Although very similar in mechanism of action, the specific salt form is associated with different pharmacokinetics and offers varying amounts of elemental iron. The ferrous fumarate iron salts contain some of the largest amount of iron per gram of salt consumed. For example, each 100 mg of ferrous fumarate provides 33 mg of elemental iron, whereas each 324-mg tablet of ferrous sulfate contains 65 mg of elemental iron. Even though the pharmacokinetics of the different oral iron salts are similar, the amount of elemental iron varies significantly per 100 mg. Because of these varying amounts of elemental iron, the iron salts must not be exchanged for one another and must be given with caution to avoid medication errors. Other similar pharmacokinetic properties of oral iron products, such as absorption and excretion, must be understood because unabsorbed iron—though harmless—turns the stool black and may possibly mask melena (blood in the stools). It is recommended to take oral iron with juice (orange juice is preferred) or water but not with milk or antacids because of subsequent decreased drug absorption.

NURSING DIAGNOSES

1. Activity intolerance related to fatigue and lethargy associated with anemias
2. Imbalanced nutrition, less than body requirements, related to the disease process
3. Constipation related to adverse effects of iron products

PLANNING

GOALS

1. Patient maintains/regains normal level of activity, as ordered.
2. Patient attains adequate nutrition status through use of nonpharmacologic and/or pharmacologic measures.
3. Patient remains free from or experiences minimal constipation as an adverse effect of iron products.

CASE STUDY

Hematopoietic Biologic Response Modifiers

J.T., a 37-year-old homemaker, is receiving a second round of chemotherapy as part of treatment for ovarian cancer. Chemotherapeutic drugs may lead to the adverse effect of bone marrow suppression of various blood cell components.

Two weeks after this round of chemotherapy, J.T.'s hemoglobin level is 7.9 g/dL (pretherapy value was 11 g/dL), and the hematocrit is 28.5% (pretherapy value was 34%). The following orders are received: epoetin alfa (Epogen) 150 units/kg subcutaneously three times a week; ferrous sulfate, 300 mg by mouth daily.

1. What is the purpose of the order for ferrous sulfate?
2. The nurse will assess for what conditions before beginning the epoetin therapy?
3. The nurse needs to monitor J.T. closely. What assessment findings would be of the most concern during this therapy?
4. After 5 weeks, J.T.'s hemoglobin level is 11.4 g/dL and her hematocrit is 33%. The next dose of epoetin is due today. What action will the nurse take?

For answers, see http://evolve.elsevier.com/Lilley.

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

Iron Products

- Instructions on how to take oral forms of iron are crucial to safe administration. Implement all types of teaching strategies to reinforce all verbal and/or written instructions. Make sure education is individualized and geared to patients with alterations in sensory perception. Caution patients not to make changes in their medication regimen, such as doubling doses or discontinuing a drug, without the prescriber's order.
- Provide elderly patients and their spouses and/or caregivers with instructions about food sources that are high in iron and how to include these foods in their menu planning. Instruct patients to steam vegetables and not to overcook them through excessive boiling. Advise patients that to preserve the content of vitamins and minerals, including iron, it is important to avoid overcooking or boiling vegetables.
- Remind elderly patients that gastrointestinal upset may occur with many drugs, including vitamins and iron. Iron products are to be taken with food or a snack to help decrease GI upset.
- Always educate elderly patients, as well as their spouses, other family members or significant others, and/or caregivers, about appropriate community resources (e.g., Meals on Wheels, senior citizen community centers, public recreation centers). A list of these community resources is often made available through a city web page, social services department, and other outlets.

OUTCOME CRITERIA

1. Patient is able to tolerate a gradual increase in activity as ordered (e.g., performing activities of daily living, walking 10 minutes a day with increases as tolerated) while on drug therapy for anemia.
   - Patient reports improved energy levels and less shortness of breath and/or activity intolerance during drug therapy.
2. Patient improves dietary intake as recommended with use of MyPlate (www.choosemyplate.gov/index.html) with recommended amounts of fruits/vegetables, grains/starches, and meat/proteins.
   - Patient increases daily intake of iron such as green leafy vegetables, eggs, and beans.
3. Patient implements measures to minimize constipation, such as dietary intake of increased roughage, fiber, fruits, and vegetables and increase in fluids.
   - Patient reports unresolved constipation to prescriber once above measures have been implemented.
   - Patient takes medication, as prescribed, for management of constipation such as bulk-forming laxatives.

IMPLEMENTATION

With *erythropoiesis-stimulating agents,* do not administer with any other product and do not shake the vial. During treatment, always monitor blood pressure and give vitamin B_{12} supplements orally as prescribed. Instruct the patient to dilute oral liquid dosage forms of *iron products* per manufacturer instructions and to sip through a plastic straw to avoid discoloration of tooth enamel. Other oral forms of iron need to be given with plenty of fluids but not with antacids or milk, and preferably not with meals, because of the risk for decreased absorption of the drug. However, most individuals find that they do need to take oral iron products with meals or food because of the commonly encountered adverse effect of gastrointestinal upset. If antacids or milk products are used, schedule them at least 1 to 2 hours before or after the oral dosage of iron. Iron products are generally packaged in a light-resistant, airtight container. Instruct patients to remain in an upright or sitting position for up to 30 minutes after taking oral dosage forms of iron, ferrous products, and related drugs to help minimize esophageal irritation or corrosion. Warn patients that the use of iron products will turn the stools from brown to a black, tarry color. Patients taking epoetin alfa may also be taking oral iron preparations (see the pharmacology discussion for specific information on FDA restrictions). See the Patient Teaching Tips for more information.

If a patient cannot tolerate oral iron, intravenous iron (e.g., iron dextran, iron sucrose, or ferric gluconate) may be prescribed. A test dose of iron dextran may be ordered, with the remaining dose given an hour later if no adverse reaction occurs. Intramuscularly administered iron must be given deep in a large muscle mass using the Z-track method (see Chapter 9). Intravenous iron dextran must be given after the intravenous line is flushed with 10 mL of normal saline and administered with the recommended amount of diluent and at the recommended drip rate. Keep epinephrine and resuscitative equipment available in case of anaphylactic reaction (to iron or any drug that has an increased risk of causing anaphylaxis). In addition, it may be necessary for the patient to remain recumbent for 30 minutes after the intravenous injection to prevent drug-induced orthostatic hypotension. Encourage the patient to move slowly and purposefully during this time.

EVALUATION

Focus the evaluation of therapeutic responses to drugs used for anemia on ensuring that goals and outcome criteria have been met as well as monitoring for therapeutic and adverse effects. Therapeutic responses to *erythropoiesis-stimulating agents* may take 2 to 6 weeks, so monitor for increased energy, appetite, and sense of well-being. Adverse effects of *erythropoiesis stimulating agents* may include heart attack, stroke and possible death if used in patients with Hgb > 12g/dl. Therapeutic responses to *iron products* include improved nutritional status, increased weight, increased activity tolerance and well-being, and absence of fatigue. Adverse effects of *iron products* include nausea, constipation, epigastric pain, black and tarry stools, and vomiting. Signs of toxicity include nausea, diarrhea, hematemesis, pallor, cyanosis, shock, and coma.

PATIENT TEACHING TIPS

- Epoetin alfa (Epogen) is indicated for anemias associated with end-stage renal disease and chemotherapy and requires very careful use. Always check for route of administration with the subcutaneous route having a slower onset of action as compared to the intravenous route.
- Educate the patient about taking oral iron supplements with the erythropoeisis-stimulating agents. These supplements are often needed to ensure adequate body iron stores, which are needed for the drug therapy to be effective.
- Encourage the patient to take iron products cautiously and to be aware of the potential for poisoning if these drugs are taken in greater than the recommended amounts. Oral iron products need to be taken in their original dosage form and without alteration; for example, without crushing.
- It is recommended that oral dosage forms of iron be taken with at least 4 to 6 oz of water or other fluid to help minimize gastrointestinal upset and increase absorption.
- Oral dosage forms of iron are not interchangeable, and prescription forms of these products may be very different from one another. Each product contains different forms of the iron salt and also comes in different dose amounts. (One exception is that the 300-mg and 324-mg dosage forms of ferrous sulfate are used interchangeably.)
- Instruct the patient to remain upright for up to 30 minutes after taking an oral iron product to prevent esophageal irritation or corrosion. Remind the patient that iron products may turn the stools a black, tarry color.
- Encourage the patient to maintain a diet high in iron including foods such as meat; dark green, leafy vegetables; dried beans; dried fruits; and eggs.

KEY POINTS

- Erythropoiesis-stimulating agents are ineffective without adequate body iron stores.
- Iron and folic acid are very important in the treatment of many disorders and diseases (e.g., malignancies) to achieve RBC and hemoglobin formation that is as adequate as possible and to help prevent nutritional deficits that can affect all body systems, especially the immune system.
- Blood-forming drugs are often used in the treatment of pernicious anemia, malabsorption syndromes, hemolytic anemias, hemorrhage, and renal and liver diseases.
- Instruct patients to take iron products exactly as ordered. Parenteral dosage forms may cause anaphylaxis and orthostatic hypotension.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 When administering oral iron tablets, the nurse should keep in mind that the most appropriate substance, other than water, to give with these tablets is
   - **a** pudding.
   - **b** an antacid.
   - **c** milk.
   - **d** orange juice.

2 The nurse is teaching a patient about oral iron supplements. Which statement is correct?
   - **a** "You need to take this medication on an empty stomach or else it won't be absorbed."
   - **b** "It is better absorbed on an empty stomach, but if that causes your stomach to be upset, you can take it with food."
   - **c** "Take this medication with a sip of water, and then lie down to avoid problems with low blood pressure."
   - **d** "If you have trouble swallowing the tablet, you may crush it."

NCLEX® EXAMINATION REVIEW QUESTIONS

3 The nurse is administering an intravenous dose of iron dextran. For which potential adverse effect is it most important for the nurse to monitor at this time?
- **a** Anaphylaxis
- **b** Gastrointestinal distress
- **c** Black, tarry stools
- **d** Bradycardia

4 The nurse is assessing a patient who is to receive folic acid supplements. It is important to rule out which condition before giving the folic acid?
- **a** Malabsorption syndromes
- **b** Pernicious anemia
- **c** Tropical sprue
- **d** Pregnancy

5 A patient with renal failure has severe anemia, and there is an order for darbepoetin (Aranesp). As the nurse assesses the patient, which condition listed will the nurse consider a contraindication to use of this medication?
- **a** Uncontrolled hypertension
- **b** Diabetes mellitus
- **c** Hypothyroidism
- **d** Angina

6 When iron sucrose is administered, which nursing interventions are correct? (Select all that apply.)
- **a** Administer a test dose before giving the full dose.
- **b** Give via deep intramuscular injection into a large muscle mass using the Z-track method.
- **c** Administer large doses over 2.5 to 3.5 hours, intravenously.
- **d** Monitor the patient for hypertension.
- **e** Monitor the patient for hypotension.

7 The order reads: "Give epoetin alfa (Epogen), 3500 units subcut, three times a week." The medication is available in a vial that contains 4000 units/mL. How many milliliters will the nurse draw up for the ordered dose? Round to hundredths.

1. d, 2. b, 3. a, 4. b, 5. a, 6. c, e, 7. 0.88 mL (rounded from 0.875)

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Describe the various pathophysiologic processes and/or disease states that may lead to nutritional deficiencies and require nutritional supplemental support.
2 Discuss the various enteral and parenteral nutritional supplements used to treat the various deficiencies, including specific ingredients.
3 Describe the nurse's role in the process of initiating and maintaining continuous or intermittent enteral feedings, total parenteral nutrition, and other forms of nutritional supplementation.
4 Compare the various enteral feeding tubes, including specific uses, and detail the special needs of patients requiring this nutritional support.
5 Discuss the mechanisms of action, cautions, contraindications, routes of administration, drug interactions, adverse effects, and complications associated with enteral and parenteral nutritional supplementation.
6 Develop a nursing care plan that includes all phases of the nursing process for patients receiving enteral and parenteral supplemental feedings.
7 Discuss the various laboratory values related to nutritional deficits or altered nutritional status and their impact on monitoring the therapeutic effects of the therapy.

DRUG PROFILES

amino acids, p. 894
carbohydrate formulation, p. 892
carbohydrates, p. 894
fat formulation, p. 892
lipid emulsions, p. 895
protein formulation, p. 892

KEY TERMS

Anabolism Metabolism characterized by the conversion of simple substances into the more complex compounds; tissue building. (p. 889)

Casein The principal protein of milk and the basis for curd and cheese. (p. 892)

Catabolism A complex metabolic process in which energy is liberated for use in work, energy storage, or heat production by the destruction of complex substances to form simple compounds. (p. 894)

Dumping syndrome A complex reaction to the rapid entry of concentrated nutrients into the jejunum of the small intestine. The patient may experience nausea, weakness, sweating, palpitations, syncope, sensations of warmth, and diarrhea. Most commonly occurs with eating following partial gastrectomy or with enteral feedings that are administered too rapidly into the stomach or jejunum via a feeding tube. (p. 891)

Enteral nutrition The provision of food or nutrients via the gastrointestinal tract, either naturally by eating or through a feeding tube in patients who are unable to eat. (p. 889)

Essential amino acids Those amino acids that cannot be manufactured by the body. (p. 894)

Essential fatty acid deficiency A condition that develops if fatty acids that the body cannot produce are not present in dietary or nutritional supplements. (p. 894)

Hyperalimentation An older term for parenteral nutrition; its use is now discouraged because it may be misinterpreted to mean overfeeding; now referred to as *total parenteral nutrition (TPN)*. (p. 892)

Malnutrition Any disorder of undernutrition. (p. 889)

Multivitamin infusion (MVI) A concentrated solution that contains several water- and fat-soluble vitamins and is used as part of an intravenous (parenteral) nutrition source. (p. 895)

Nonessential amino acids Those amino acids that the body can produce without extracting them from dietary intake. (p. 894)

Nutrients Substances that provide nourishment and affect the nutritive and metabolic processes of the body. (p. 889)

Nutritional supplements Oral, enteral, or intravenous nutritional preparations used to provide optimal nutrients to meet the body's nutritional needs. (p. 889)

Nutritional support The provision of nutrients orally, enterally, or parenterally for therapeutic reasons. (p. 889)

Parenteral nutrition The administration of nutrients by a route other than through the alimentary canal, such as intravenously. (p. 889)

Semiessential amino acids Those amino acids that can be produced by the body but not in sufficient amounts in infants and children. (p. 894)

Total parenteral nutrition (TPN) The intravenous administration of the total nutrient requirements of the patient with gastrointestinal dysfunction, accomplished via peripheral or central venous catheter. (p. 892)

Whey The thin serum of milk remaining after the casein and fat have been removed. It contains proteins, lactose, water-soluble vitamins, and minerals. (p. 892)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

Nutrients are dietary products that undergo chemical changes when ingested (and metabolized) that cause tissue to be enhanced and energy to be liberated. Nutrients are required for cell growth and division; enzyme activity; protein, carbohydrate, and fat synthesis; muscle contraction; secretion of hormones (e.g., vasopressin, gastrin); wound repair; immune competence; gut integrity; and numerous other essential cellular functions. Providing for these nutritional needs is known as **nutritional support.** Adequate nutritional support is needed to prevent the breakdown of tissue proteins for use as an energy supply to sustain essential organ systems, which is what occurs during starvation. Malnutrition can decrease organ size and impair the function of organ systems (e.g., cardiac, respiratory, gastrointestinal, hepatic, renal). Nutritional supplements are a means of providing adequate nutritional support to meet the body's nutritional needs.

Malnutrition is a condition in which the body's essential need for nutrients is not met by nutrient intake. The purpose of nutritional support is the successful prevention, recognition, and management of malnutrition. **Nutritional supplements** are dietary products used to provide nutritional support. Nutritional supplement products can be administered to patients in a variety of ways. They vary in the amount and chemical complexity of the carbohydrates, proteins, fats, electrolytes, vitamins, and minerals that compose them, as well as in their osmolality. These nutrients may be given in a digested form, a partially digested form, or an undigested form. Nutritional supplements can also be tailored for specific disease states.

Patients' nutrient requirements vary according to age, gender, size or weight, physical activity, preexisting medical conditions, nutritional status, and current medical or surgical treatment. Nutritional supplements are classified according to the method of administration as either enteral or parenteral. **Enteral nutrition** is the provision of food or nutrients via the gastrointestinal tract. Nutritional supplements may also be administered parenterally. **Parenteral nutrition** is the intravenous administration of nutrients. Its purpose is to promote **anabolism** (tissue building), nitrogen balance, and maintenance or improvement of body weight. It is used when the oral or enteral feeding routes cannot be used (e.g., in postoperative patients or patients who are cachectic from advanced cancer or acquired immunodeficiency syndrome [AIDS]). The selection of either enteral nutrition or parenteral nutrition and the

specific nutritional composition of the product used depend on the specific patient and the clinical situation. Enteral nutrition is used when the patient has a functioning gastrointestinal tract.

Nutritional support → enteral nutrition → gastrointestinal tract
Nutritional support → parenteral nutrition → circulation

PHARMACOLOGY OVERVIEW

ENTERAL NUTRITION

Enteral nutrition is the provision of food or nutrients through the gastrointestinal tract. The most common and least invasive route of administration is oral consumption. A feeding tube is used in the other five enteral routes (Figure 55-1). The six routes of enteral nutrition delivery are listed in Table 55-1.

Patients who may benefit from feeding tube delivery of nutritional supplements include those with abnormal esophageal or stomach peristalsis, altered anatomy secondary to surgery, depressed consciousness, or impaired digestive capacity. The enteral route is considered to be the superior route of administration of nutritional supplements.

Approximately 100 different enteral supplement formulations are available. The enteral supplements have been divided into groups according to the basic characteristics of the individual formulations. The enteral formulation groups are elemental, polymeric, modular, altered amino acid, and impaired glucose tolerance. These are described in Box 55-1.

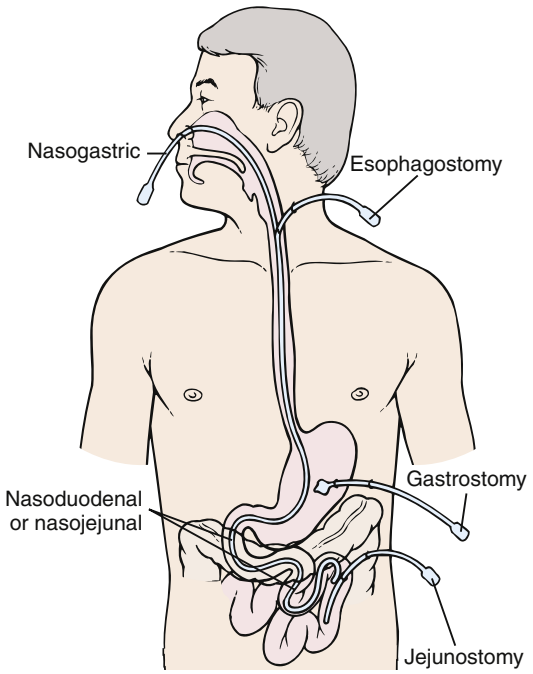

FIGURE 55-1 Tube feeding routes. (From Lewis SM et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 8, St Louis, 2011, Mosby.)

TABLE 55-1 ROUTES OF ENTERAL NUTRITION DELIVERY

ROUTE	DESCRIPTION
Esophagostomy	Feeding tube surgically inserted into the esophagus
Gastrostomy	Feeding tube surgically inserted directly into the stomach
Jejunostomy	Feeding tube surgically inserted into the jejunum
Nasoduodenal	Feeding tube placed from the nose to the duodenum
Nasojejunal	Feeding tube placed from the nose to the jejunum
Nasogastric	Feeding tube placed from the nose to the stomach
Oral	Nutritional supplements delivered by mouth

BOX 55-1 ENTERAL FORMULATIONS

Elemental Formulations

Peptamen
Vital HN
Vivonex Plus
Vivonex TEN

Contents: dipeptides, tripeptides, or crystalline amino acids; glucose oligosaccharides; and vegetable oil or medium-chain triglycerides (MCTs)
Comments: minimal digestion; minimal residue
Indications: malabsorption, partial bowel obstruction, irritable bowel disease, radiation enteritis, bowel fistula, short bowel syndrome

Polymeric Formulations

Complete
Ensure
Ensure Plus
Isocal
Osmolite
Portagen
Jevity
Sustacal

Contents: complex nutrients (proteins, carbohydrates, and fat)
Indications: preferred over elemental formulations for patients with fully functional gastrointestinal tracts and few specialized nutrient requirements

Modular Formulations

Carbohydrate
Moducal
Polycose

Fat
MCT Oil
Microlipid

Protein
Casec
ProMod
Propac
Stresstein

Contents: single-nutrient formulas (protein, carbohydrate, or fat)
Indications: can be added to a monomeric or polymeric formulation to provide a more individualized nutrient formulation

Altered Amino Acid Formulations

Amin-Aid
Hepatic-Aid
Travasorb Renal
Traum-Aid HBC

Contents: varying amounts of specific amino acids
Indications: for use in patients with diseases associated with altered metabolic capacities

Formulation for Impaired Glucose Tolerance

Glucerna

Contents: protein, carbohydrate, fat, sodium, potassium
Indications: for use in patients with impaired glucose tolerance (e.g., diabetic patients)

Mechanism of Action and Drug Effects

The enteral formula groups provide the basic building blocks for anabolism. Different combinations and amounts of these nutrients are used based on the individual patient's anabolic needs. Enteral nutrition supplies complete dietary needs through the gastrointestinal tract by the normal oral route or by feeding tube.

Indications

Enteral nutrition can be used to supplement an oral diet that is currently insufficient for a patient's nutrient needs or used alone to meet all of the patient's nutrient needs. Box 55-2 lists the main types of enteral nutritional supplements and their indications.

Contraindications

The usual contraindication to nutritional supplements of any kind is known allergy to a specific product or genetic disease that renders a patient unable to metabolize certain types of nutrients.

Adverse Effects

The most common adverse effect of nutritional supplements is gastrointestinal intolerance, manifesting as diarrhea. Infant nutritional formulations are most commonly associated with allergies and digestive intolerance. The other nutritional supplements are commonly associated with osmotic diarrhea. Rapid feeding or bolus doses can result in **dumping syndrome,** which produces intestinal disturbances. In addition, tube feeding places the patient at significant risk for aspiration pneumonia. This is especially true in patients in whom mental status, gag reflexes, and general mobility are compromised.

Interactions

Various nutrients can interact with drugs to produce significant food-drug interactions. With some exceptions, food usually delays the absorption of drugs when administered simultaneously. High gastric acid content or prolonged emptying time can result in decreased effects of certain antibiotics (cephalosporins, erythromycin, and penicillins). An increased absorption rate resulting in increased therapeutic effects can be seen when corticosteroids or vitamins A and D are given with nutritional supplements. The antibiotic effects of tetracyclines and quinolones are decreased when they are given with nutritional supplements as a result of chemical inactivation. These drugs must be given at least 2 hours before or after tube feedings.

Tube feedings can also reduce the absorption of phenytoin, which may result in seizures. It is recommended that tube feedings be held for at least 2 hours before and after the administration of phenytoin. This can be problematic, because the patient may not receive adequate nutrition due to withholding of feedings. This issue is somewhat controversial, and some suggest that the interaction is more theoretical than actual. Thus, some institutions have decided to ignore this possible interaction and to monitor phenytoin levels and patient status, rather than holding the tube feedings, whereas others continue to hold the tube feedings. Often the patient requires intravenous phenytoin when continuous tube feedings are necessary.

Dosages

Because nutrient requirements vary greatly, dosages are individualized according to patient needs.

BOX 55-2 ENTERAL NUTRITIONAL SUPPLEMENTS: INDICATIONS

Complete Nutritional Formulations (i.e., for General Nutritional Deficiencies)
- Inability to consume or digest normal foods
- Accelerated catabolic status
- Undernourishment because of disease

Incomplete Nutritional Formulations (i.e., for Specific Nutritional Deficiencies)
- Genetic metabolic enzyme deficiency
- Hepatic or renal impairment

Infant Nutritional Formulations
- Sole nutritional intake for premature and full-term infants
- Supplemental nutritional intake for older infants receiving solid foods
- Supplemental nutritional intake for breast-fed infants

DRUG PROFILES

Enteral nutrition can be provided by a variety of supplements. Individual patient characteristics determine the appropriate enteral supplement. The four most commonly used enteral formulations are elemental, polymeric, modular, and altered amino acid.

ELEMENTAL FORMULATIONS

Elemental formulations are enteral supplements that contain dipeptides, tripeptides, or crystalline amino acids. Minimal digestion is required with elemental formulations. These supplements are indicated for patients with pancreatitis, partial bowel obstruction, irritable bowel disease, radiation enteritis, bowel fistulas, and short bowel syndrome. They are contraindicated in patients who have had hypersensitivity reactions to them. Elemental formulation supplements are available without a prescription and have no pregnancy category.

POLYMERIC FORMULATIONS

Polymeric formulations are enteral supplements that contain complex nutrients derived from proteins, carbohydrates, and fat. The polymeric formulations are some of the most commonly used enteral formulations because they most closely resemble normal dietary intake. They are preferred over elemental formulations in patients who have fully functional gastrointestinal tracts and have no specialized nutrient needs. Polymeric formulations are less hyperosmolar than elemental formulations and therefore cause fewer gastrointestinal problems. They are contraindicated in patients who have had hypersensitivity reactions to them. They are available without a prescription and have no pregnancy category classification.

The most commonly used enteral supplement in the polymeric formulation category of enteral nutrition products is Ensure. It is lactose free and is also available in a higher-calorie formula called Ensure Plus. Other polymeric formulations are listed in Box 55-1. These drugs contain complex nutrients such as **casein** and soy protein for protein, corn syrup, and maltodextrins for carbohydrates, and vegetable oil or milk fat for fat. They are available in liquid formulations only.

MODULAR FORMULATIONS

carbohydrate formulation

Moducal and Polycose are examples of commonly used enteral supplements in the carbohydrate modular formulation category. Both are carbohydrate supplements that supply carbohydrates only. They are intended to be used in addition to monomeric or polymeric formulations to provide a more individual specialized nutrient mix. They are available in liquid formulations only. These products are obtainable without a prescription, have no pregnancy category classification, and are contraindicated only in patients who have had hypersensitivity reactions to them.

fat formulation

Microlipid and MCT Oil are the formulations available in the fat category. Microlipid is a fat supplement supplying only fats. It is a concentrated source of calories and contains 4.5 kcal/mL. These drugs are given to help individualize nutrient formulations. They may be used in patients with malabsorption and other gastrointestinal disorders and in patients with pancreatitis. They are available in liquid formulations only. These products are obtainable without a prescription, have no pregnancy category classification, and are contraindicated only in patients who have had hypersensitivity reactions to them.

protein formulation

Casec, ProMod, and Propac are examples of protein modular formulations. They are used to increase patients' protein intake and provide additional proteins. They are derived from a variety of sources such as **whey,** casein, egg whites, and amino acids. All of the available products are dried powders that must be reconstituted with water. They may sometimes be reconstituted by placing them in enteral feedings that are already in liquid form. They are indicated for patients with increased protein needs. They are contraindicated in patients who have had hypersensitivity reactions to them. Protein formulation supplements are available without a prescription and have no pregnancy category classification.

ALTERED AMINO ACID FORMULATIONS

Amin-Aid is one of the many amino acid formulation nutritional supplements available. Many of the nutritional supplements in this category are also listed as modular formulations because they can be used as both single-nutrient formulas and as nutritional formulations for patients with genetic errors of metabolism. Specialized amino acid formulations are used most commonly in patients who have metabolic disorders such as phenylketonuria, homocystinuria, and maple syrup urine disease. They are also used to supply nutritional support to patients with illnesses such as renal impairment, eclampsia, heart failure, or liver failure.

TABLE 55-2 PERIPHERAL AND CENTRAL PARENTERAL NUTRITION: CHARACTERISTICS

CHARACTERISTIC	PERIPHERAL	CENTRAL
Goal of nutritional therapy (total versus supplemental)	Supplemental (total if moderate to low needs)	Total
Length of therapy	Short (fewer than 14 days)	Long (7 days or longer)
Osmolarity	Hyperosmolar (600-900 mOsm/L)	Hyperosmolar (600-900 mOsm/L)
Fluid tolerance	Must be high	Can be fluid restricted
Dextrose	Less than 10%*	10%-35%
Amino acids	Less than 3%	More than 3%-7%
Fats	10%-20%	10%-20%
Calories per day	Less than 2000 kcal/day	More than 2000 kcal/day

*Many institutions use a maximum of 12.5% dextrose.

PARENTERAL NUTRITION

Parenteral nutritional supplementation (intravenous administration) is the preferred method for patients who are unable to tolerate and/or maintain adequate enteral or oral intake. Instead of administration of partially digested nutrients into the gastrointestinal tract (as in enteral nutrition), vitamins, minerals, amino acids, dextrose, and lipids are administered intravenously directly into the circulatory system. This effectively bypasses the entire gastrointestinal system, which eliminates the need for absorption, metabolism, and excretion. Parenteral nutrition is also called **total parenteral nutrition (TPN)** or **hyperalimentation.**

TPN can supply all of the calories, carbohydrates, amino acids, fats, trace elements, vitamins, and minerals needed for growth, weight gain, wound healing, convalescence, immunocompetence, and other health-sustaining functions.

TPN can be administered through either a peripheral vein or a central vein. Each route of delivery of TPN has specific requirements and limitations. It is generally accepted that TPN is used only when oral or enteral support is impossible or when the gastrointestinal absorptive or functional capacity is not sufficient to meet the nutritional needs of the patient. Some of the factors that must be considered in deciding whether to use peripheral or central TPN for a given patient are listed in Table 55-2.

PERIPHERAL TOTAL PARENTERAL NUTRITION

Peripheral TPN (PPN) is one route of administration of TPN. A peripheral vein is used to deliver nutrients to the patient's circulatory system. PPN is usually a temporary method of administration. The long-term administration of nutritional supplements via a peripheral vein may lead to phlebitis. It is

considered a temporary measure to provide adequate nutrients in patients who have mild deficits or who are restricted from oral intake and have slightly elevated metabolic rates.

PPN is valuable in patients who do not have large nutritional needs, can tolerate moderately large fluid loads, and need nutritional supplements only temporarily. PPN may be used alone or in combination with oral nutritional supplements to provide the necessary fat, carbohydrate, and protein needed by the patient to maintain health.

Mechanism of Action and Drug Effects

PPN provides the basic nutrient building blocks for anabolism. Different combinations and amounts of these nutrients are used based on the individual patient's anabolic needs.

Indications

PPN is used to administer nutrients to patients who need more nutrients than their current oral intake can supply or to provide complete daily nutrition. It is meant only as a temporary means (less than 2 weeks) of delivering TPN.

Circumstances under which patients may benefit from the delivery of PPN are as follows:

- The patient must undergo a procedure that restricts oral feedings.
- The patient has anorexia caused by radiation or cancer chemotherapy.
- The patient has a gastrointestinal illness that prevents oral food ingestion.
- The patient has just undergone surgery of any type.
- The patient's nutritional deficits are minimal, but oral nutrition will not be started for longer than 5 days

Contraindications

As mentioned previously for the enteral nutritional products, the only usual contraindication to nutritional supplementation of any kind is known drug allergy to a specific product or a genetic disease that renders a patient unable to assimilate certain types of nutrients.

Adverse Effects

The most devastating adverse effect of PPN is phlebitis, which is vein irritation or inflammation of a vein. If phlebitis is severe and is not treated appropriately, it can lead to the loss of a limb, although this is rare. Another potential adverse effect is fluid overload. PPN is limited to solutions with a lower dextrose concentration, generally less than 10%, to avoid sclerosing of the vein. Thus, large volumes are needed to meet a patient's daily nutritional requirements. Some patients, such as those with renal failure or heart failure, cannot tolerate large fluid volumes. In these patients, fluid restrictions may make it impossible to provide adequate calories through PPN.

CENTRAL TOTAL PARENTERAL NUTRITION

In central TPN, a large central vein is used to deliver nutrients directly into the patient's circulation. Usually, the subclavian or internal jugular vein is used. Central TPN is generally indicated for patients who require nutritional supplements for a prolonged period, usually longer than 7 to 10 days. It can also be used in the home care setting. There are a variety of indications for central TPN. The disadvantages of central TPN are the risks associated with venous catheter insertion and the use and maintenance of the central vein. There is a greater potential for infection, more serious catheter-induced trauma and related events, metabolic alterations, and other technical or mechanical problems than with peripheral parenteral nutrition (PPN).

Mechanism of Action and Drug Effects

Central TPN is used to supply nutrients to patients who cannot ingest nutrients by mouth and cannot meet required daily nutritional needs by the enteral or peripheral parenteral routes. Like PPN, central TPN supplies the basic building blocks for anabolism. It provides the necessary fat, carbohydrate, and protein that the patient needs to maintain health.

Indications

TPN delivers total dietary nutrients to patients who require nutritional supplementation. Patients who may benefit from the delivery of TPN include the following:

- Patients who have large nutritional requirements (metabolic stress or hypermetabolism)
- Patients who need nutritional support for prolonged periods (longer than 7 to 10 days)
- Patients who are unable to tolerate large fluid loads

Contraindications

TPN is contraindicated in patients with allergy to any of its components. Rarely, a patient who is allergic to eggs may have cross-sensitivity to lipid formulations. TPN is used only when the gastrointestinal tract cannot be used (e.g., in postoperative patients or those who are otherwise unable to eat or digest and absorb nutrients).

Adverse Effects

The most common adverse effects of central TPN are those associated with the use of the central vein for delivery of the TPN. The risks associated with insertion of the infusion line, as well as the use and maintenance of the central vein for administration of TPN, can create some complications. There is a greater potential for infection, serious catheter-induced trauma and related events, and other technical or mechanical problems than with PPN. Larger and more concentrated volumes of nutritional supplements are being delivered with central TPN, and therefore there is a greater chance for metabolic complications such as hyperglycemia.

Dosages

Dosage requirements vary from patient to patient. Age, gender, weight, and numerous other factors must be considered for proper administration of TPN. Guidelines for amino acids appear in Table 55-3.

TABLE 55-3 AMINO ACIDS: RECOMMENDED DAILY DOSAGE GUIDELINES

HEALTHY		MALNOURISHED OR TRAUMA/BURN
ADULT	INFANT/CHILD	ADULT
0.9 g/kg	1.5-3 g/kg	Up to 2 g/kg

BOX 55-3 AMINO ACIDS: CLASSIFICATION

Essential
- Isoleucine
- Leucine
- Lysine
- Methionine
- Phenylalanine
- Threonine
- Tryptophan
- Valine

Semiessential
- Arginine
- Histidine

Nonessential
- Alanine
- Asparagine
- Aspartic acid
- Cysteine
- Glutamine
- Glutamic acid
- Glycine
- Proline
- Serine
- Tyrosine

DRUG PROFILES

The individual components of peripheral and central TPN are the same. The difference lies in the concentrations and amounts of the components delivered per volume of nutritional supplement. The basic components of peripheral or central TPN are amino acids, carbohydrates, lipids, trace elements, vitamins, fluids, and electrolytes. Most of the electrolyte components are discussed in Chapter 29.

AMINO ACIDS

Amino acids have many roles in the maintenance of normal nutritional status. The primary role is protein synthesis, or anabolism. Provision of adequate amino acids in nutritional supplements reduces the breakdown of proteins (catabolism) and also helps to promote normal growth and wound healing.

Amino acids are commonly classified as essential or nonessential according to whether they can or cannot be produced by the body. **Nonessential amino acids** are those that the body produces and therefore need not be present in dietary intake. The body is able to manufacture, from nutritional nitrogen sources, all but eight of the available amino acids. **Essential amino acids** are those amino acids that cannot be produced by the body. Therefore, they must be included in daily dietary intake. Amino acids are used as building blocks for the protein that is needed for normal growth and development. Two amino acids, histidine and arginine, are not manufactured by the body in large enough quantities during rapid growth periods such as infancy or childhood. Thus, they are referred to as **semiessential amino acids.** Box 55-3 lists the amino acids according to their categories.

amino acids

Amino acid crystalline solutions (Aminosyn 3%, 5%, and 10%, and FreAmine III 8.5% and 10%) can be used in either peripheral or central TPN. Amino acids are a source of both protein and calories. They provide 4 kcal/g. The two currently available brands of amino acid solutions differ only in their respective concentrations. The dosage of these solutions varies depending on the patient's weight and requirements. These drugs have no restrictions regarding pregnancy and have no contraindications to use.

CARBOHYDRATES

In nutritional support, carbohydrates are usually supplied to patients through dextrose. Dextrose is normally the greatest source of calories and provides 3.4 kcal/g. However, protein (amino acids) and lipids are also used as calorie sources (Figure 55-2). The concentration of dextrose in TPN is an important consideration. In PPN, dextrose concentrations are kept below 10% to decrease the possibility of phlebitis. In central TPN, dextrose concentrations can range from 10% to 50%, but they are commonly 25% to 35%. Because dextrose is a sugar, supplemental insulin may be given simultaneously in nutritional supplements. Use of a balanced nutritional supplement that contains dextrose and lipids as caloric sources decreases the need for large amounts of insulin.

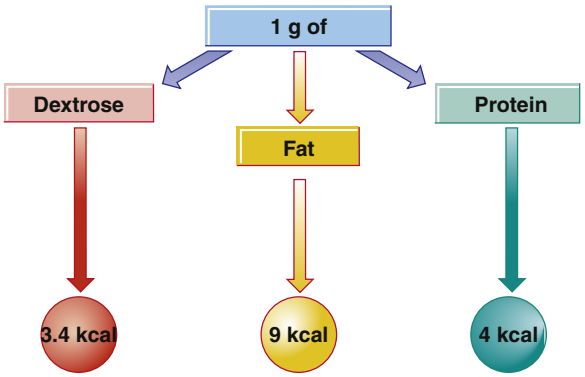

FIGURE 55-2 One gram of dextrose, fat, or protein will provide varying amounts of energy as calories.

FAT

The average North American diet contains 40% fat. This means that of the total calories supplied, 40% to 50% of the calories are obtained through fat grams. The ideal diet contains no more than 30% fat. Intravenous fat emulsions serve two functions: they supply essential fatty acids, and they are a source of energy or calories. As with the amino acids, certain fatty acids are essential because the body cannot produce them. Linoleic acid cannot be synthesized by the body. It is needed to produce linolenic and arachidonic acid. If these fatty acids are not present in dietary or nutritional supplements, an **essential fatty acid deficiency** may develop. Clinical signs of essential fatty acid deficiency are hair loss, scaly dermatitis, growth retardation, reduced wound healing, decreased platelet levels, and fatty liver (Figure 55-3).

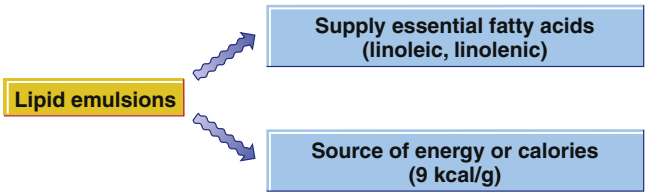

FIGURE 55-3 Lipid emulsions supply essential fatty acids and energy.

lipid emulsions

The currently marketed lipid emulsions, Intralipid and Liposyn, are available as 10%, 20%, or 30% emulsions. They differ in fat origin. Liposyn is made from safflower oil, and Intralipid is made from soybean oil.

Lipid emulsions normally deliver 20% to 30% of the total daily calories and must not exceed 60% of daily caloric intake. Fat emulsions are most beneficial when combined with dextrose solutions. The use of fat to meet caloric needs prevents potentially harmful conditions—such as hyperglycemia, hyperinsulinemia, and hyperosmolarity—that can occur when a patient's entire caloric needs are being met solely by dextrose.

TRACE ELEMENTS

Trace elements are available in individual solutions and in many different combinations. The following are considered trace elements:

- Chromium
- Copper
- Iodine
- Manganese
- Molybdenum
- Selenium
- Zinc

Specific dosages and frequencies depend on the individual patient's requirements. Vitamins and other minerals may also be added accordingly. A common multivitamin combination is **multivitamin infusion (MVI).**

NURSING PROCESS

ASSESSMENT

Perform a thorough nutritional assessment with attention to dietary history, weekly and daily food intake, weight, and height before initiating any *nutritional supplements*. Conduct a thorough nursing history and survey of all systems, including questions about any unusual symptoms, possible nutritional concerns, nausea, vomiting, loss of appetite, and weight gain or loss. Focus other questions on past and present medical and health history; history of any difficulties with nutrition, gastrointestinal absorption, or food intolerance; stressors; and a complete medication profile, including a listing of all prescription drugs, over-the-counter drugs, herbals, and supplements. Consultation with a registered dietitian is crucial to identify the nutrients that are missing in a particular patient's diet. Total body metabolic rate, body mass index, muscle mass, and other variables linked to nutritional status will most likely be assessed and are data that a nutritional consult may provide. Laboratory findings that may need to be assessed include the following: total protein level, albumin level, blood urea nitrogen (BUN) level, red blood cell (RBC) count, white blood cell (WBC) count, vitamin B_{12} level, hemoglobin level, and hematocrit. Other laboratory studies may include cholesterol level, electrolyte levels, total lymphocyte count, serum transferrin level, iron level, urine creatinine clearance, lipid profile, and urinalysis. All of these objective and subjective data will help the prescriber, nutritionist/dietitian, and other members of the health care team to select the appropriate nutritional supplements for the patient.

Before administering an *enteral nutrition* supplement that is an elemental formulation, determine if the patient has a history of allergic reaction to any of the contents of the solution. Assess for contraindications, cautions, and drug interactions, and document the findings. Of most concern is assessing the patient's cardiac and renal status and ensuring that the ingredients and the amount of solution are not too taxing on these systems. In addition, because these solutions are given orally, either by mouth or via tube feedings (see Chapter 9), it is most important to assess ability to swallow, gag reflex, and bowel sounds, and to note any nausea or vomiting. Remember that protein-based formulations are to be avoided in patients with allergies to egg whites and whey.

With *parenteral nutrition,* assess for allergies to any of the ordered components of the intravenous solution, and pay attention to age and metabolic needs. There are usually multiple combinations of products available; thus, it is important to assess the patient carefully for allergies to essential proteins, amino acids, carbohydrates, trace elements, minerals, vitamins, lipids, high concentrations of dextrose, and any other ingredients. Assess your knowledge base about parenteral nutrition and the need for infusions through a central line, peripherally inserted central line, or peripherally inserted midline catheter. Some of the complications of parenteral nutrition include pneumothorax, infection, air emboli or emboli related to protein or lipid aggregation (associated with central catheter intravenous lines), septicemia related to the nutrient-rich solutions with invasive intravenous route of administration, and metabolic imbalances due to the solution ingredients and vomiting (seen with lipid administration in the parenteral nutrition). Also perform a complete baseline assessment and continuously monitor the following: (1) central line site, including patency, intactness, and appearance, (2) WBC and RBC counts as well as other laboratory values and parameters (listed earlier), (3) vital signs, (4) serum glucose levels, and (5) cardiac rhythm with electrocardiogram readings (as prescribed).

NURSING DIAGNOSES

1. Nutrition, less than body requirements, related to inability to take in sufficient nutrients
2. Diarrhea related to a decreased tolerance to enteral feedings and their ingredients
3. Risk for infection (sepsis) related to parenteral infusions and use of central venous access line

CASE STUDY

Total Parenteral Nutrition

Mrs C., a 28-year-old florist, has been unable to eat due to severe vomiting related to her pregnancy. She is at 13 weeks' gestation and has been admitted to the hospital because of dehydration and inability to eat due to her severe nausea and vomiting. The decision has been made to give her total parenteral nutrition (TPN) for at least 1 week. After 1 week of therapy, her obstetrician will then decide whether to continue or stop the infusion, based on her response. She will be receiving the TPN infusion via a peripheral intravenous catheter with infusion bags that will be changed every 24 hours.

1. Mrs. C. is anxious about this infusion and asks the nurse, "Why is that bag so large? What is in the bag?" How will the nurse answer these questions?
2. The nurse explains to Mrs. C. that her blood glucose levels will need to be monitored while she is receiving the TPN. Mrs. C. begins to cry, saying, "This morning sickness is bad enough, but now I have diabetes too? How can that be?" What is the nurse's best response?
3. The nurse will monitor for what potential complication that can occur with peripherally administered TPN?
4. Before beginning the infusion, the nurse checks the ingredients of the TPN bag. The nurse notices that one of the contents is listed as 20% dextrose. Will the nurse add this bag to the patient's infusion? Explain your answer.

For answers, see http://evolve.elsevier.com/Lilley.

PLANNING

GOALS

1. Patient regains normal nutritional status through adequate dietary intake and supplemental feedings or nutrients.
2. Patient remains free from diarrhea as related to enteral supplementation.
3. Patient remains free from infection during parenteral nutritional supplementation.

OUTCOME CRITERIA

1. Patient's nutritional status improves with enteral/parenteral nutritional supplement as prescribed, as evidenced by proportional weight gain, adequate fluid volume status with improved skin turgor, improved urinary output to at least 30 mL/hr, and laboratory values such as total protein, albumin, iron, Hct, and Hgb that return to normal.
2. Patient identifies measures to decrease diarrhea while receiving enteral feedings, such as use of prescribed drugs to decrease motility and/or use of over-the-counter drugs or herbal products, as ordered.
3. Patient states measures to minimize risk for infection at total parenteral nutrition site (peripheral or central), such as checking the site frequently for redness, swelling, drainage, or abnormal warmth, fever, or chills, and reporting these to the prescriber or home health care nurse immediately.

IMPLEMENTATION

A prescriber's order must be complete and dated before *enteral* or *parenteral* (peripheral or central) *nutrition supplementation* is begun. In general, monitoring the status of the patient during and after *enteral feedings* is crucial to safe and prudent nursing care. With nasogastric tube feeding solutions, check for proper placement (and detect gastric residuals so as to avoid aspiration and other complications. Checking for placement ensures that the tube is within the stomach and has not passed through the larynx, into the trachea and down into the bronchi of the lungs. Aspirating fluid from the tube with a syringe with testing of the pH to determine the acidity of the fluid aspirate is one method of placement checking. With a pH of 5.5 or lower, the tube is in the correct position. If these are not possible, a chest radiograph must be used. Measure gastric residual volumes and document before each feeding as well as before administration of each medication. When checking gastric residual volumes, stop the tube feeding and then aspirate stomach contents using a syringe connected to the particular tube. If the volume aspirated is more than the volume delivered over the previous 2 hours (of continuous feeding), return the aspirate, hold the feeding, and contact the prescriber while keeping the head of the patient's bed elevated. For intermittent bolus feedings, if the residual amount is more than 50% of the volume previously infused, it is the standard of care to return the aspirate, withhold the feeding, and contact the prescriber. A reduction in the tube feeding volume will probably then be ordered. Always check hospital/facility policy or protocol before use of enteral feedings, while also checking and managing residuals.

Newer tubes for nasogastric and other enteral feeding have smaller diameters and are thinner (5 French to 10 French) and more pliable for better patient tolerance. However, the smaller-diameter tubes make checking for gastric aspiration more difficult. To prevent clogging of the feeding tube, it is often helpful to flush the tube with 30 mL of cranberry juice or other designated solution (per institutional policy) followed by 10 mL of water. The juice may help break up the formula residue and unclog certain types of feeding tubes; the water helps to keep the tube clean and free of residue. Percutaneous enteral gastrostomy (PEG) tubes are also commonly used in many situations but do require surgical insertion by a gastroenterologist and are often procedurally done under moderate sedation. Their care includes performing dressing changes during the initial period and then checking for residuals. Placement need not be checked, but if it appears that the tube has come out of the opening and is longer than previously noted, stop the infusion and contact the prescriber.

Follow prescriber-ordered enteral feeding infusion rates and concentrations carefully. Usually the initial rate is 50 mL/hr at one-half strength, but this may be increased per patient tolerance to a rate ordered by the physician or appropriate health care provider. More rapid feeding increases the risk for hyperglycemia, dumping syndrome and diarrhea. Infusion rates of enteral feedings may be adjusted by the prescriber as per the patient's tolerance (of the feeding). Keep tube feeding formulas at room temperature and never administer cold or warm. If all the necessary steps to decrease or prevent diarrhea have been taken and have failed, antidiarrheal medications may be needed. Lactose-free solutions are available and are recommended for patients who are lactose intolerant. Patients who

have lactose intolerance may experience cramping, diarrhea, abdominal bloating, and flatulence with the ingestion of milk-based enteral feedings.

Assess *parenteral nutrition infusions* every hour or per the facility's policies and procedures. Document the status of the entire infusion system and equipment as well as the condition of the patient. It is the standard of care to examine the patient first and then check the insertion site, tubing, infusion pump, and solution. To prevent infection, change the parenteral nutrition tubing every time a new bag is added to the infusion, or as per facility policy. It is also recommended that tubing changes occur daily with the beginning of each new infusion. A 1.2-micron filter is used to trap bacteria, including *Pseudomonas* species. Record the patient's temperature every 4 hours, or as prescribed, during the infusion, and report any increase in temperature over 100° F (37.8° C) to the prescriber immediately. Check the patient frequently for signs and symptoms of hyperglycemia such as polydipsia (excessive thirst), polyuria (excessive urination), polyphagia (excessive hunger), headache, dehydration, nausea, vomiting, and weakness. Never accelerate these infusion rates to increase plasma volume because the rapid increase in the amount of dextrose solution may precipitate hyperglycemia and other related complications. Insulin replacement may be needed with the increase in dextrose; therefore, measure serum glucose levels by glucometer so that hyperglycemia may be immediately recognized and treated.

Hypoglycemia is manifested by cold, clammy skin; dizziness; tachycardia; and tingling of the extremities. Hypoglycemia associated with parenteral nutrition may be prevented by gradual reduction of the intravenous feeding rate to allow the pancreas time to adapt to the changing blood glucose levels. If parenteral nutrition is discontinued abruptly, rebound hypoglycemia may occur. This can be prevented by providing infusions of 5% to 10% glucose in situations in which parenteral nutrition must be discontinued immediately. Fluid overload may also occur with parenteral nutrition, manifested by weak pulse, hypertension, tachycardia, confusion, decreased urine output, and pitting edema. This may be prevented by maintaining infusion rates as ordered. If signs of fluid overload occur, slow the infusion rate, measure vital signs, contact the prescriber, and remain with the patient until the patient's condition has stabilized. Include auscultation of breath and heart sounds in the patient assessment, especially if additional therapies are administered that may precipitate fluid overload. Measurement of intake and output is usually indicated when parenteral nutrition is administered (and with enteral supplementation as well). See the Patient Teaching Tips for more information on the use of nutritional supplements.

EVALUATION

Therapeutic responses to *nutritional supplementation* include improved well-being, energy, strength, and performance of activities of daily living; an increase in weight; and laboratory test results that reflect an improved nutritional status. Specific laboratory values may include some of the following: albumin level, total protein level, hematocrit level, hemoglobin level, RBC and WBC counts, BUN level, electrolyte levels, blood glucose and insulin levels, and iron values. Perform ongoing evaluation for adverse effects associated with all *enteral* and/or *parenteral nutrition* infusions during and after therapy, and complete nutritional reevaluation periodically so that the patient's nutritional needs are met. This may require frequent prescriber appointments or monitoring by a home health care nurse. Always refer to goals and outcome criteria to evaluate the effectiveness of therapy.

PATIENT TEACHING TIPS

- Because patients are often discharged with the need for various types of tube feedings, provide the patient, family, and/or caregiver with education, instructions, and demonstrations about the daily care of the tube, preparation of tube feedings, and related procedures. Present the education in a way that reflects the learning needs of the patient and/or those involved in the patient's care.
- Instruct the patient, family, and/or caregiver about the need for correct placement of the tube, which should be checked before each tube feeding if a nasogastric tube is used. Incorrect placement of a nasogastric tube would be manifested by coughing, choking, difficulty in speaking, cyanosis, and subsequent respiratory distress. The head of the bed must remain elevated during infusions; this is more critical with nasogastric tube feedings than with gastrostomy tube feedings.
- Provide contact names and phone numbers for the prescriber, home health care nurse, and other resources to the patient, family, and/or caregiver so that therapy can be monitored and problems and complications averted as related to the feeding. A fever, difficulty breathing, sounds of lung congestion, high residual amounts, resistance to the flow of the feeding solution, and resistance in checking for residual are all causes for concern. Appropriate interventions must be implemented, including seeking emergency medical care if needed.
- Patients who are homebound and are receiving parenteral nutrition will need individualized education as well as support from home health care or related health care services. Practice is critical to acquisition of skill by the patient, family, and/or caregiver and must be an integral part of patient education. Before the patient is discharged, explain and demonstrate all procedures for storage, cleansing and care of the site, dressing changes, irrigation of the catheter, pump function and care, and changing of the bag, filters, and tubing, with a return demonstration by the patient. Advise the patient that parenteral nutrition in the home setting requires home health care services by a registered nurse to help prevent the complications of infection at the site, sepsis, fever, and pneumonia.
- Educate the patient about the need to check serum glucose levels at home as ordered by the prescriber if parenteral

PATIENT TEACHING TIPS—cont'd

nutrition or other infused solutions high in dextrose are administered. Thoroughly explain the operation of a glucometer, with specific steps for its use included in a demonstration to the patient, family, and/or caregiver. In addition, include and reinforce instructions in self-administration of insulin, if needed.

- Instruct the patient to report to the prescriber immediately any signs and symptoms of potential complications of parenteral nutrition, including fever, cough, chest pains, dyspnea, and chills, (all of which are indicative of adverse reactions to lipid infusions). Restlessness, nervousness, fainting, and tachycardia are associated with hypoglycemia and must also be reported, as must the occurrence of polyuria, polydipsia, polyphagia, nausea, vomiting, dehydration, headache, and/or weakness (indicating hyperglycemia).

KEY POINTS

- A thorough nutritional assessment and possible consultation with a registered dietitian or nutritionist are essential for adequate intervention for the malnourished patient.
- Various enteral feeding formulations with different nutritional content are available, including some that are lactose free.
- Enteral feedings may result in complications such as hyperglycemia, dumping syndrome, and aspiration of the nutritional supplement.
- Parenteral nutrition supplementation (intravenously administered) is total parenteral nutrition (TPN) or hyperalimentation. PN or TPN may be administered through a central vein or through a peripheral vein (PPN).
- TPN is administered through a central venous catheter because of the hyperosmolarity of the substances used and the need for dilution provided by a larger-diameter vein to prevent damage to the vein. Parenteral nutrition given through a peripherally inserted central catheter (PPN) line is another option but uses a solution with a lower concentration of dextrose and other ingredients.
- Parenteral feedings may result in air embolism, fever, infection, fluid volume overload, hyperglycemia, or hypoglycemia. If they are discontinued abruptly, rebound hypoglycemia may result.
- Cautious and skillful nursing care may prevent or decrease the occurrence of complications associated with enteral or parenteral nutritional supplementation.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is assessing an enteral feeding that is infusing via a nasogastric feeding tube. Which statement about this tube is accurate?
   - **a** It is surgically inserted into the stomach.
   - **b** It is inserted through the nose into the jejunum.
   - **c** It is surgically inserted directly into the jejunum.
   - **d** It is inserted through the nose into the stomach.

2 When administering total parenteral nutrition (TPN), the nurse is aware that one purpose of intravenous fat (lipid) emulsions is to provide which nutrient?
   - **a** Calories
   - **b** Amino acids
   - **c** Minerals
   - **d** Immunoglobulins

3 The nurse is monitoring a patient who is receiving a total parenteral nutrition (TPN) infusion and notes that the patient has cold clammy skin, shows tachycardia, and is complaining of feeling dizzy. What is the immediate action of the nurse?
   - **a** Stop the TPN infusion.
   - **b** Check the patient's blood glucose level.
   - **c** Order a stat (immediate) electrocardiogram.
   - **d** Obtain an order for blood cultures.

4 A patient has new orders for administration of peripheral parenteral nutrition (PPN). The nurse knows that PPN is most appropriate in which situation?
   - **a** Therapy is expected to last longer than 2 weeks.
   - **b** Therapy is expected to last fewer than 14 days.
   - **c** A dextrose concentration of 20% is needed.
   - **d** Nutritional needs are 3000 kcal/day.

5 During the night shift, a patient's total parenteral nutrition (TPN) infusion runs out, the pharmacy is closed, and a new TPN bag will not be available for about 6 hours. The nurse's most appropriate action at this time would be to
   - **a** hang a bottle of lipid solution.
   - **b** hang a bag of normal saline.
   - **c** hang a bag of 10% dextrose.
   - **d** call the prescriber for stat TPN orders.

6 The nurse is assessing a patient who is receiving an enteral tube feeding. Which are possible adverse effects associated with enteral feedings? (Select all that apply.)
   - **a** Hypoglycemia
   - **b** Air embolism
   - **c** Aspiration
   - **d** Diarrhea
   - **e** Infection

7 A patient is receiving a tube feeding via a percutaneous enteral gastrostomy (PEG) tube of Glucerna at 50 mL/hr. The orders also read to check the residual and flush the tubing every 4 hours with 30 mL of water. Calculate the total intake of fluid at the end of a 12-hour shift.

1. d, 2. a, 3. b, 4. b, 5. c, 6. c, d, 7. 690 mL

PART 10

Dermatologic, Ophthalmic, and Otic Drugs

STUDY SKILLS TIPS

Time Management • PURR • Repeat the Steps

TIME MANAGEMENT

As you plan your study time for Part 10, it should be very clear that Chapter 57 will take significantly more time to complete than the other chapters. Do not let the length of the chapter overwhelm you. Apply the principles of time management to this chapter and you will succeed. The most important aspect of time management to apply to this chapter is the use of clear goal statements and action plan steps to help you achieve the goals.

Goal Statements

Remember the criteria for goal statements. First, they must be realistic; the statements must be things you know you can accomplish. Second, they must be specific to the task. "I will study the chapter" is not a very specific goal. Specify what you expect to accomplish. "I will master the 31 key terms" is a more specific goal statement. Third, there must be a time limit. How long will you spend in achieving this goal? Set a time limit for completion of each learning activity, specifying the quantity of time to be spent in that activity. Finally, goal statements must be measurable. In the example about studying the key terms, including the number of terms contained in Chapter 57 helps clarify the goal.

Action Planning

The second segment of time management is the use of action planning. An action plan is a series of smaller, specific activities that you will accomplish to meet your goal statements. Your goal is to master the 31 terms. What will you do to meet that goal?

Action Steps Example

1. I will spend 1 hour from 3:00 to 4:00 PM on Monday making vocabulary drill cards for the key terms found in Chapter 57.
2. I will spend 15 minutes in rehearsal and review of these cards every day until the exam on this chapter is over.
3. Each time I cannot define and explain a term, I will put an *X* on the card to identify it as a term needing more review.

4. I will spend 1 hour the night before the exam doing a comprehensive review of the terms in Chapter 57, with special emphasis on those cards that have one or more *X* marks.

Action steps help ensure that you are spending your study time actively focusing on what you need to learn.

PURR

Prepare Example

Chapter 57, Objective 3 reads, "Discuss the mechanisms of action, indications, dosage forms with application techniques, adverse effects, cautions, contraindications, and drug interactions of the various ophthalmic drugs."

Question 1: What does *ophthalmic* mean? (literal question [LQ])

Question 2: What are ophthalmic drugs? (LQ)

Question 3: What is the mechanism of action of ophthalmic drugs? (LQ)

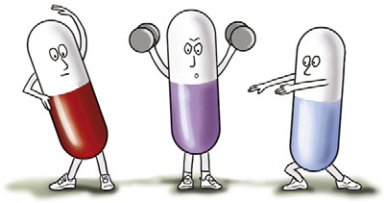
Question 4: Is there more than one mechanism of action? (LQ)

Question 5: If there is more than one mechanism of action, how are the mechanisms similar and how are they different? (interpretive question)

These questions are only suggestions for generated questions based on the chapter objectives. Many more questions can be asked about Objective 3. These questions are an essential part of the study process. Questions help make you an active reader and an active learner. The more questions you generate, the easier it will be to understand the chapter.

Outline Example

1. *Looking through the chapter, decide how much material is appropriate.* The section that begins with Antiglaucoma Drugs is probably too much material. Based on the chapter headings, this section could be broken down into six blocks of material. Block 1 would cover the material under the heading Cholinergic Drugs (Miotics). Block 2 would be the material under the heading Sympathomimetics (Mydriatics). The next four blocks would be Beta-Adrenergic Blockers, Carbonic Anhydrase Inhibitors, Osmotic Diuretics, and Prostaglandin Agonists.
2. *Apply the Prepare step to each block.* Beginning with Cholinergic Drugs (Miotics), generate some questions to guide your reading. Remember that it is important to ask both questions that will focus on literal information and questions that will help you interpret, evaluate, and analyze when you read.
3. *Read the material.* As soon as you have completed the self-questioning on the first block of material, read the material in the chapter. It is important that the reading be done immediately. Read for understanding, and as you read remember the questions you generated. This approach will help your concentration and comprehension.
4. *Take a short break.* Once you have completed the reading of this section of the chapter, give your mind a chance to reflect and consolidate the learning. Limit the time you allow for a break and use the time for something pleasurable. Give yourself 5 or 10 minutes to read the newspaper, get a snack, or just take a short walk.
5. *Rehearse.* Before going on to the next section of the chapter it is important to spend a few minutes in rehearsal. Using the questions from step 2, go back over the material you read and try to respond to those questions. When you find yourself unable to answer a question, put a mark in the text beside the heading that caused the difficulty and move on. The mark will serve as a reminder for future review. At this point, the objective is not complete mastery of the material. The objective is to see what you have learned so that you can move smoothly into the next section. Breaking a chapter into blocks is useful, but it is imperative that the links between sections be made as you study.
6. *Review.* After you have completed two or three major sections of the chapter, it is time to review. Start at the beginning of the chapter. Ask your questions. Try to answer them. If you cannot formulate a clear answer, then some rereading is necessary. Also, pay attention to the marks made during the rehearsal step. Those marks indicate areas that you have already identified as needing review. When rereading, remember that the object is to read only as much of the material as needed to be able to respond to self-generated questions. There simply is not enough time to read the entire chapter a second or third time.



REPEAT THE STEPS

Prepare, read for understanding, take a short break, and then rehearse the material you've just read. It may seem that this process takes an excessive amount of time and involves a lot of repetition, but in the long run this process will produce better learning. The time spent in Prepare, Understand, and Rehearse will reduce the time needed to review. Frequent review as you move through the chapter will make the final review at exam time proceed more quickly and enable you to achieve mastery of the material.

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the normal anatomy, physiology, and functions of the skin.
2 Describe the different disorders, infections, and other conditions commonly affecting the skin.
3 Identify the various dermatologic drugs used to treat these disorders, infections, and other conditions, and describe the various classifications of these drugs.
4 Discuss the mechanisms of action, indications, contraindications, cautions, other drug interactions, application techniques, and adverse effects of the various topical dermatologic drugs.
5 Develop a nursing care plan that includes all phases of the nursing process for patients using topical dermatologic drugs.

DRUG PROFILES

KEY TERMS

Acne vulgaris A chronic inflammatory disease of the *pilosebaceous* glands of the skin, involving lesions such as *papules* and *pustules* ("pimples" or "comedones"); referred to in this chapter as *acne.* (p. 905)

Actinic keratosis A slowly developing, localized thickening of the outer layers of the skin resulting from long-term, prolonged exposure to the sun; also called *solar keratosis.* (p. 911)

Atopic dermatitis A chronic skin inflammation seen in patients with hereditary susceptibility. (p. 903)

Basal cell carcinoma The most common form of skin cancer; it arises from epidermal cells known as *basal cells* and is rarely metastatic. (p. 903)

KEY TERMS—cont'd

Carbuncles Necrotizing infections of skin and subcutaneous tissue caused by multiple furuncles (boils). They are usually caused by the bacterium *Staphylococcus aureus*. (p. 904)

Cellulitis An acute, diffuse, spreading infection involving the skin, subcutaneous tissue, and sometimes muscle as well. It is usually caused by infection of a wound with *Streptococcus* or *Staphylococcus* species. (p. 904)

Dermatitis Any inflammation of the skin. (p. 903)

Dermatophytes Any of the common groups of fungi that infect skin, hair, and nails. These fungi are most commonly from the genera *Microsporum, Epidermophyton,* and *Trichophyton.* (p. 906)

Dermatosis The general term for any abnormal skin condition. (p. 903)

Dermis The layer of the skin just below the epidermis, consisting of papillary and reticular layers and containing blood and lymphatic vessels, nerves and nerve endings, glands, and hair follicles. (p. 902)

Eczema A pruritic, papulovesicular dermatitis occurring as a reaction to many endogenous and exogenous agents, and characterized by erythema, edema, and an inflammatory infiltrate of the dermis accompanied by oozing, crusting, and scaling. (p. 903)

Epidermis The superficial, avascular layers of the skin, made up of an outer dead, cornified portion and a deeper living, cellular portion. (p. 902)

Folliculitis Inflammation of a follicle, usually a hair follicle. A follicle is defined as any sac or pouchlike cavity. (p. 904)

Furuncles Painful skin nodules caused by *Staphylococcus* organisms that enter the skin through the hair follicles; also called a *boil.* (p. 904)

Impetigo A pus-generating, contagious superficial skin infection, usually caused by *Staphylococci* or *Streptococci.* It generally occurs on the face and is most commonly seen in children; may be recognized by honey-colored crusts. (p. 904)

Papules Small, circumscribed, superficial, solid elevations of the skin that are usually pink and less than 0.5 to 1 cm in diameter. (p. 904)

Pediculosis An infestation with lice of the family Pediculidae. (p. 910)

Pruritus An unpleasant cutaneous sensation that provokes the desire to rub or scratch the skin to obtain relief. (p. 907)

Psoriasis A common, chronic squamous cell dermatosis with polygenic (multigene) inheritance and a fluctuating pattern of recurrence and remission. (p. 903)

Pustules Visible collections of pus within or beneath the epidermis. (p. 904)

Scabies A contagious disease caused by *Sarcoptes scabiei,* the itch mite, characterized by intense itching of the skin and injury to the skin (excoriation) resulting from scratching. (p. 910)

Tinea A fungal skin disease caused by a dermatophyte and characterized by itching, scaling, and, sometimes, painful lesions. *Tinea* is a general term for an infection with any of various dermatophytes that occur at several sites; also called *ringworm*. (p. 906)

Topical antimicrobials Substances applied to any surface that either kill microorganisms or inhibit their growth or replication. (p. 904)

Vesicles Small sacs containing liquid; also called *cysts.* (p. 904)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

The skin is the largest organ of the body. It covers the body and serves several functions, including protection, sensation, temperature regulation, excretion, absorption, and metabolism. It acts as a protective barrier for the internal organs. Without skin, harmful external agents such as microorganisms and chemicals would gain access to and damage or destroy many of our delicate internal organs. Part of this protection includes the skin's ability to maintain a surface pH of 4.5 to 5.5. This weakly acidic environment discourages the growth of microorganisms that thrive at a more alkaline pH. The skin also has the ability to sense changes in temperature (heat or cold), pressure, or pain—information that is then transmitted along nerve endings. The temperature of the environment changes continually; despite this, the body maintains an almost constant internal temperature due in large part to the skin, which plays a major role in the regulation of body temperature. Heat loss and conservation are regulated in coordination with the blood vessels that supply blood to the skin and by means of perspiration. The skin is also able to excrete fluid and electrolytes through sweat glands. In addition, it stores fat, synthesizes vitamin D, and provides a site for drug absorption.

The skin is made up of two layers: the **dermis** and the **epidermis** (Figure 56-1). The outer skin layer, or epidermis, is itself composed of four layers. From the outermost to innermost, these are the stratum corneum, stratum lucidum, stratum granulosum, and stratum germinativum. The respective functions of these layers are described in Table 56-1.

None of these layers has a direct blood supply of its own. Instead, nourishment is provided through diffusion from the dermis below. The dermis lies between the epidermis and subcutaneous fat and differs from the epidermis in many ways. It is approximately 40 times thicker than the epidermis. Traversing the dermis is a rich supply of blood vessels, nerves, lymphatic tissue, elastic tissue, and connective tissue, which provide extra support and nourishment to the skin. Also contained in the dermis are the exocrine glands—the eccrine, apocrine, and sebaceous glands—and the hair follicles. The functions of the various types of exocrine glands are explained in Table 56-2.

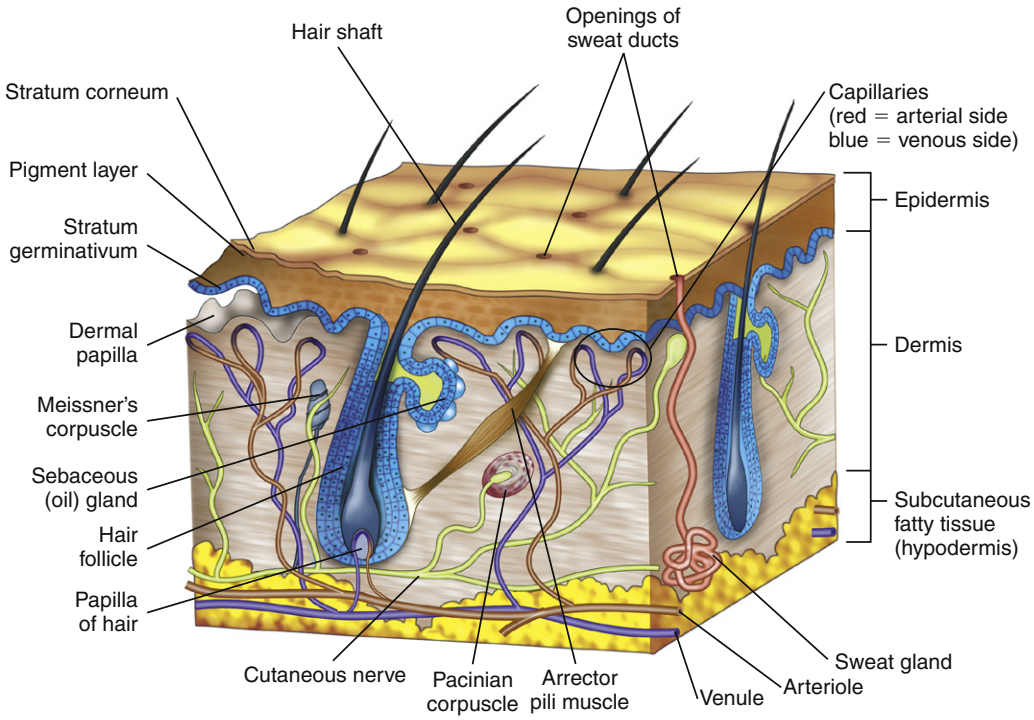

FIGURE 56-1 Microscopic view of the skin. The epidermis, shown in longitudinal section, is raised at one corner to reveal the ridges in the dermis. (Modified from Thibodeau GA, Patton KT: *Anatomy and physiology,* ed 5, St Louis, 2003, Mosby.)

TABLE 56-1 EPIDERMAL LAYERS

LAYER	DESCRIPTION
Stratum corneum ("horny layer," so named because keratin is the same protein that makes up the horns of animals)	Outermost layer consisting of dead skin cells that are made of a converted water-repellant protein known as *keratin;* it is the protective layer for the entire body. After it is desquamated or shed, it is replaced by new cells from below.
Stratum lucidum ("clear layer")	Layer where keratin is formed; it is translucent and contains flat cells.
Stratum granulosum ("granular layer")	Cells die in this layer; granulated cells are located here, which gives this layer the appearance for which it is named.
Stratum germinativum ("germinative layer")	New skin cells are made in this layer; it contains melanocytes, which produce melanin, the skin color pigment.

TABLE 56-2 EXOCRINE GLANDS OF THE SKIN

GLAND	FUNCTION
Sebaceous	Large lipid-containing cells that produce oil or film that covers the epidermis, protects and lubricates the skin, and is water repellent and antiseptic
Eccrine	Sweat glands that are located throughout the skin surface; help regulate body temperature and prevent skin dryness
Apocrine	Mainly in axilla, genital organs, and breast areas; emit an odor; believed to be scent or sex glands

Below the dermis is a layer of loose connective tissue called the *hypodermis.* It helps make the skin flexible. It is also here that the subcutaneous fat tissue is located, which provides thermal insulation and cushioning or padding. It is also the source of nutrition for the skin.

Reactions or disorders of the skin are common and numerous. A **dermatosis** is any abnormal skin condition. Dermatoses include a variety of types of **dermatitis** (skin inflammation). Among these are conditions such as **atopic dermatitis, eczema,** and **psoriasis.** In addition, there are also a variety of skin cancers, including **basal cell carcinoma,** squamous cell carcinoma, and melanoma.

PHARMACOLOGY OVERVIEW

Drugs that are administered directly to a skin site are called *topical dermatologic drugs.* These drugs are available in a variety of formulations that are suitable for specific indications. Each formulation has certain characteristics that make it beneficial for certain uses. For example, ointments have an oil base that makes them stickier than creams and better for smaller areas, whereas creams have a water base that makes them better for larger surfaces. Gels tend to enhance penetration of the active ingredient. Lotions are similar to creams but are lighter. More information on the formulations, their characteristics, and examples are provided in Table 56-3. Note that the focus of this chapter is topically administered medications. Because so many

TABLE 56-3 DERMATOLOGIC FORMULATIONS: CHARACTERISTICS AND EXAMPLES

FORMULATION	CHARACTERISTICS	EXAMPLES
Aerosol foam	Can cover large area; useful for drug delivery into a body cavity (e.g., vagina, rectum) or hair areas	ProctoFoam, Epifoam, contraceptive foams
Aerosol spray	Spreads thin liquid or powder film; covers large areas; useful when skin is tender to touch (e.g., burns)	Solarcaine, Desenex, Kenalog
Bar	Similar to a bar of soap; useful as a wash with water	PanOxyl (benzoyl peroxide)
Cleanser	Nongreasy; used as an astringent (oil remover) and/or wash with water	ZoDerm
Cream	Contains water and can be removed with water; not greasy or occlusive; usually white semisolid; good for moist areas	Hydrocortisone cream (Cortaid), Benadryl cream
Gel/jelly	Contains water and possibly alcohol; easily removed and good lubricator; usually clear, semisolid substance; useful when lubricant properties are desirable	K-Y Jelly, Saligel, Surgilube
Lotion	Contains water, alcohol, and solvents; may be a suspension, emulsion, or solution; good for large or hairy areas	Calamine lotion, Lubriderm lotion, Kwell lotion
Oil	Contains very little if any water; occlusive, liquid; not removable with water	Lubriderm bath oil
Ointment	Contains no water; not removable with water; occlusive, greasy, and semisolid; desirable for dry lesions because of occlusiveness	Vaseline (petrolatum), zinc oxide ointment, A & D ointment
Paste	Similar properties to those of ointments; contains more powder than ointments; excellent protectant properties	Zinc oxide paste (Balmex)
Pledget (pad)	Moistened pad that is applied to or wiped over affected area	EryPads (erythromycin)
Powder	Slight lubricating properties; may be shaken on affected area; promotes drying of area where applied	Tinactin powder, Desenex powder
Shampoo	Soapy liquid for washing hair and/or skin	Nizoral (ketoconazole)
Solution	Nongreasy liquid; dries quickly	Erythromycin topical solution (Eryderm)
Stick	Spreads thin chalky or viscous liquid film; often better for smaller areas	Benadryl Itch Relief
Tape	Most occlusive formulation; consistent topical drug delivery; useful when small, straight areas require drug application	Cordran tape

topical drugs are available, the scope of this chapter is limited to some of the more commonly used medications. Systemically administered drugs (transdermal) are also used to treat several skin disorders (see Part 7) and are cross-referenced throughout this chapter.

There are many therapeutic categories of dermatologic drugs. Some of the most common ones are the following:

- Antibacterial drugs
- Antifungal drugs
- Antiinflammatory drugs
- Antineoplastic drugs
- Antipruritic drugs (for itching)
- Antiviral drugs
- Burn drugs
- Débriding drugs (promote wound healing)
- Emollients (skin softeners)
- Keratolytics (cause softening and peeling of the stratum corneum)
- Local anesthetics
- Sunscreens
- Topical vasodilators

ANTIMICROBIALS

Topical antimicrobials are antibacterial, antifungal, and antiviral drugs that, as the name implies, are applied topically. Although topical antimicrobials have many of the same properties as the systemic forms, there are differences in terms of their absorption, distribution, toxicities, and adverse effects.

GENERAL ANTIBACTERIAL DRUGS

Common skin disorders caused by various bacteria are **folliculitis, impetigo, furuncles, carbuncles, papules, pustules, vesicles,** and **cellulitis.** The bacteria responsible are most commonly *Streptococcus pyogenes* and *Staphylococcus aureus.* Dermatologic antibacterial drugs are used to treat or prevent these skin infections. The most commonly used drugs are bacitracin, polymyxin, and neomycin. Unfortunately, due to the high incidence of infection with methicillin-resistant *S. aureus* (MRSA), mupirocin is now also commonly used.

DRUG PROFILES

♦ bacitracin

Bacitracin is a polypeptide antibiotic that is applied topically for the treatment or prevention of local skin infections caused by susceptible aerobic and anaerobic gram-positive organisms such as staphylococci, streptococci, anaerobic cocci, corynebacteria, and clostridia. It works by inhibiting bacterial cell wall synthesis, which leads to cell death. It can be either bactericidal or bacteriostatic, depending on the causative organism. Its antimicrobial spectrum is broadened in several available combination drug products. Most of these also contain neomycin and/or polymyxin B (see later in the chapter).

Adverse reactions are usually minimal; however, reactions ranging from skin rash to allergic anaphylactoid reactions have occurred. If itching, burning, inflammation, or other signs of sensitivity occur, discontinue bacitracin. This drug is available in ointment form and is usually applied to the affected area one

to three times daily. It is also available in systemic and ophthalmic (see Chapter 57) formulations.

neomycin and polymyxin B

Neomycin and polymyxin B are two additional broad-spectrum antibiotics that are available as the nonprescription product known as Neosporin. Neosporin cream is a combination of these two drugs alone, whereas Neosporin ointment also contains bacitracin. Several brand name and generic combinations of these three topical antibiotics are available, and all are commonly used as topical antiseptics for minor skin wounds. Although neomycin/polymyxin B is still a very popular over-the-counter (OTC) product, there is evidence that use of the drug can increase the likelihood of future allergic reactions of the skin.

mupirocin

Mupirocin (Bactroban) is an antibacterial product available only by prescription. It is used on the skin for treatment of staphylococcal and streptococcal impetigo. It is used topically and intranasally to treat nasal colonization with MRSA. The drug is applied topically three times daily and intranasally twice daily to treat MRSA colonization. Adverse reactions are usually limited to local burning, itching, or minor pain.

♦ silver sulfadiazine

Silver sulfadiazine (Silvadene) has proved both effective and safe in the prevention and treatment of infections in burns. A major concern for burn victims is infection at the burn site. However, because increased systemic absorption of a drug can occur in compromised skin areas, topical burn drugs must not be too potent or toxic to avoid causing dangerous systemic effects. This is especially true when larger burned areas must be treated, because the drug may be applied over a large surface area of skin and therefore may be absorbed in greater quantities. On the other hand, the blood supply to burned areas is often drastically reduced, so that systemically administered antibiotics either cannot reach the site or do so only in quantities too low to be effective. Therefore, the only way of applying these drugs to ensure that they reach the burn site is to do so topically.

Silver sulfadiazine is a synthetic antimicrobial drug produced when silver nitrate reacts with the chemical sulfadiazine. It appears to act on the cell membrane and cell wall of susceptible bacteria and is used as an adjunct in the prevention and treatment of infection in second- and third-degree burns and less frequently in cellulitic or eczematous extremities. The adverse effects of silver sulfadiazine are similar to those of other topical drugs and include pain, burning, and itching. This drug should not be used in patients who are allergic to sulfonamide drugs. It is available only as a 1% cream and is applied topically to cleansed and débrided burned areas once or twice daily using a sterile-gloved hand.

ANTIACNE DRUGS

Acne vulgaris is the most common skin infection. Its precise cause is unknown and somewhat controversial. Likely causative factors include heredity, stress, drug reactions, hormones, and bacterial infections. Common bacterial causes include *Staphylococcus* species (spp.) and *Propionibacterium acnes*. Some of the most commonly used antiacne drugs are benzoyl peroxide, clindamycin, erythromycin, tetracycline, isotretinoin, and the vitamin A acid known as *retinoic acid*. Many other drugs are also used in the treatment and prevention of acne, including systemic formulations of the antibiotics minocycline, doxycycline, and tetracycline (see Chapter 38). Some practitioners also prescribe oral contraceptives (see Chapter 34) for female acne patients, because in some controlled studies estrogen has been shown to have beneficial effects against acne, especially hormone-driven acne.

DRUG PROFILES

♦ benzoyl peroxide

The microorganism that most commonly causes acne, *P. acnes*, is an anaerobic bacterium; that is, it needs an environment that is poor in oxygen to grow. Benzoyl peroxide is effective in combating such infection because it slowly and continuously liberates active oxygen in the skin, resulting in antibacterial, antiseptic, drying, and keratolytic actions. These actions create an environment that is unfavorable for the continued growth of the *P. acnes* bacteria, and they soon die. Drugs such as benzoyl peroxide that soften scales and loosen the outer horny layer of the skin are referred to as *keratolytics*.

Benzoyl peroxide generally produces signs of improvement within 4 to 6 weeks. Adverse effects tend to be related to dose (including overuse) and include peeling skin, red skin, or a sensation of warmth. Blistering or swelling of the skin is generally considered an allergic reaction to the product and is an indication to stop treatment. Overuse of this drug and also of tretinoin is common in teenage patients who are attempting to cure their acne quickly. The result can be painful, reddened skin, which usually resolves on return to use of these medications as prescribed.

Benzoyl peroxide is available in multiple topical dosage forms, including a cleansing bar, liquid, lotion, mask, cream, gel, and cleanser. It is also available in various combination drug products. It is usually applied topically one to four times daily, depending on the dosage form and prescriber's instructions. Benzoyl peroxide is classified as a pregnancy category C drug.

clindamycin

Clindamycin (Cleocin T) is a topical form of the systemic antibiotic described in Chapter 39. Adverse reactions are usually limited to minor local skin reactions, including burning, itching, dryness, oiliness, and peeling. The drug is available in gel, lotion, suspension, pledgettes, and foam. Clindamycin is usually applied once or twice daily. It is classified as a pregnancy category B drug.

♦ isotretinoin

Isotretinoin (Amnesteem, Claravis, Sotret) is an oral product indicated for the treatment of severe recalcitrant cystic acne. Isotretinoin inhibits sebaceous gland activity and has antikeratinizing (anti–skin hardening) and antiinflammatory effects.

Isotretinoin is one of relatively few medications that are classified as pregnancy category X drugs. This means that it is a proven human *teratogen,* or a chemical that is known to induce birth defects. It is imperative that female patients of childbearing age be counseled and agree not to become pregnant during use of the drug. For these reasons, in 2005, the U.S. Food and Drug Administration (FDA) approved stringent guidelines regarding the prescription and use of this medication. It is now officially required that at least two reliable contraceptive methods be used by sexually active women during therapy with isotretinoin and for 1 month after completion of therapy. A risk management program of unprecedented size and scope has been designed and approved by the FDA especially for this drug. It is known as *iPLEDGE* and was fully implemented as of March 1, 2006. As a result, federal law now requires that any health care provider who prescribes this drug be a registered and active member of this program, and patients must also be qualified and registered. Further information is available at the iPLEDGE call center at 866-495-0654 or online at https://www.ipledgeprogram.com/default.aspx. In addition, there have been case reports of suicide and suicide attempts in patients receiving this medication. It has not been determined if the drug increases the risk for suicide or if psychosocial sequelae from severe acne are to blame for increased suicide risk. Educate patients to report any signs of depression immediately to their prescribers. Follow-up treatment may be needed, and simply stopping the drug may be insufficient. The company that produced the brand name Accutane has withdrawn it from the market. Despite these rather strong concerns, this drug does prove to be very helpful in treating severe acne cases. Isotretinoin is available only for oral use.

tretinoin

Tretinoin (retinoic acid, vitamin A acid) (Renova, Retin-A) is a derivative of vitamin A that is used to treat acne and ameliorate the dermatologic changes (e.g., fine wrinkling, mottled hyperpigmentation, roughness) associated with photodamage (sun damage). The drug appears to act as an irritant to the skin, in particular to the follicular epithelium. Specifically, it stimulates the turnover of epidermal cells, which results in skin peeling. While this is occurring, the free fatty acid levels of the skin are reduced, and horny cells of the outer epidermis cannot then adhere to one another. Without fatty acids and horny cells, acne and its comedo, or pimple, cannot exist.

Topically administered tretinoin has been shown to enhance the repair of skin damaged by ultraviolet (UV) radiation, or sunlight. It does this by increasing the formation of fibroblasts and collagen, both of which are needed to rebuild skin. The drug also may reduce collagen degradation by inhibiting the enzyme collagenase that breaks down collagen.

Tretinoin's main adverse effects are local inflammatory reactions, which are reversible when therapy is discontinued. Common adverse effects are excessively red and edematous blisters, crusted skin, and temporary alterations in skin pigmentation. Tretinoin is available in many topical formulations, including creams, gels, and a liquid. Because of its potential to cause severe irritation and peeling, it may initially be applied once every 2 or 3 days, and treatment often starts with a lower-strength product.

Retin-A Micro has been approved for the treatment of acne vulgaris. This particular acne product contains tretinoin formulated inside a synthetic polymer called a *Microsponge system.* This system is made of round microscopic particles of synthetic polymer. These microspheres act as reservoirs for tretinoin, allowing the skin to absorb small amounts of the drug over time. Retin-A Micro is currently available only in gel form. All topical forms of tretinoin are classified as pregnancy category C drugs. They are not to be confused with the oral capsule form of tretinoin that is used to treat leukemia and is classified as a pregnancy category D drug. Another antiacne retinoid is adapalene, a topical solution.

ANTIFUNGAL DRUGS

A few fungi produce keratinolytic enzymes, which allow them to live on the skin. Topical fungal infections are primarily caused by *Candida* spp. (candidiasis), **dermatophytes,** and *Malassezia furfur* (tinea versicolor). These fungi are found in moist, warm environments, especially in dark areas such as the feet or groin.

Candidal infections are most commonly caused by *Candida albicans,* a yeastlike opportunistic fungus present in the normal flora of the mouth, vagina, and intestinal tract. Two significant factors that commonly predispose a person to a candidal infection are broad-spectrum antibiotic therapy, which promotes an overgrowth of nonsusceptible organisms in the natural body flora, and immunodeficiency disorders. Because these infections favor warm, moist areas of the skin and mucous membranes, they most commonly occur orally (e.g., thrush in infants), vaginally, and cutaneously in sites such as beneath the breasts and in diapered areas. They may also cause nail infections.

Dermatophytes are a group of three closely related genera consisting of *Epidermophyton* spp., *Microsporum* spp., and *Trichophyton* spp. that use the keratin found on the skin to feed their growth. They produce superficial mycotic (fungal) infections of keratinized tissue (hair, skin, and nails). Infections caused by dermatophytes are called **tinea,** or *ringworm,* infections. The name *ringworm* comes from the fact that the infection sometimes assumes a circular pattern at the site of infection. Tinea infections are further identified by the body location where they occur: tinea pedis (foot), tinea cruris (groin), tinea corporis (body), and tinea capitis (scalp). Tinea infections of the foot are also known as *athlete's foot* and those of the groin as *jock itch.*

Fungi usually invade the stratum corneum, which is the dead layer of desquamated (shed) cells. Inflammation occurs when the fungi invade this layer; sensitivity (e.g., itching) occurs when they penetrate the epidermis and dermis.

Many of the fungi that cause topical infections are very difficult to eradicate. The organisms are very slow growing, and antifungal therapy may be required for periods ranging from several weeks to as long as 1 year. However, many topical antifungal drugs are available for the treatment of both dermatophytic infections and those caused by yeast and yeastlike fungi. Some of these drugs, their dosage forms, and their uses are

TABLE 56-4 TOPICAL ANTIFUNGAL DRUGS

DRUG	TRADE NAME	DOSAGE FORM	INDICATIONS	LEGAL STATUS
butenafine	Mentax, Lotrimin Ultra	1% cream	Tinea pedis	Rx
butoconazole	Femstat 3	2% vaginal cream	Candidiasis	OTC
ciclopiroxolamine	Loprox	0.77% cream and lotion, 8% solution (for nails)	Candidiasis, dermatophytoses, tinea versicolor	Rx
clotrimazole	Gyne-Lotrimin 3	2% vaginal cream, 100- and 200-mg vaginal tabs	Candidiasis	OTC
	Lotrimin	2% cream, 1% lotion and solution	Candidiasis, tinea versicolor	Rx
	Lotrimin AF	1% cream, lotion, and solution	Dermatophytoses	OTC
	Mycelex	1% cream and solution	Dermatophytoses	Rx
	Mycelex	10-mg troches	Oropharyngeal candidiasis	Rx
	Mycelex-7	1% vaginal cream, 100-mg vaginal tabs	Candidiasis	OTC
ketoconazole	Nizoral	2% cream and shampoo	Candidiasis, dermatophytoses, tinea versicolor	Rx
miconazole	Micatin	2% cream, powder, and spray	Dermatophytoses	OTC
	Monistat-Derm	2% cream	Candidiasis, dermatophytoses, tinea versicolor	Rx
nystatin	Nilstat, Mycostatin	Cream, ointment, powder	Candidiasis	Rx
terbinafine	Lamisil	1% cream and spray	Dermatophytoses	OTC
tolnaftate	Tinactin	1% cream, solution, gel, powder, and spray	Dermatophytoses	OTC
undecylenic acid	Cruex, Desenex	Powder, cream, solution, soap	Dermatophytoses	OTC

OTC, Available over the counter without prescription; *Rx,* currently available by prescription only.

listed in Table 56-4. Systemically administered antifungal drugs are sometimes used to treat skin conditions as well. These drugs are discussed in Chapter 42.

The most commonly reported adverse effects of topical antifungals are local irritation, **pruritus,** a burning sensation, and scaling. Ciclopirox and clotrimazole are classified as pregnancy category B drugs, and econazole, ketoconazole, and miconazole are classified as pregnancy category C drugs. Hypersensitivity is the one contraindication to the use of any of these drugs.

DRUG PROFILES

♦ clotrimazole

Clotrimazole (Lotrimin, Mycelex-G) is available both OTC and by prescription. It is available as a lozenge for the treatment of oropharyngeal candidiasis, commonly known as *thrush.* It is also available as a cream, lotion, or solution for the treatment of dermatophytoses (e.g., athlete's foot), superficial mycoses, and cutaneous candidiasis. Similar topical preparations are available for intravaginal administration in the treatment of vulvovaginal candidiasis, commonly called a *yeast infection,* and vaginal trichomoniasis. Clotrimazole is available in many topical formulations: a powder; a 10-mg oral topical lozenge; a 1% cream, lotion, and solution; 1% and 2% vaginal creams; and 100- and 500-mg vaginal tablets. Different dosages and dosage forms are used for the treatment of different fungal infections. Clotrimazole is classified as a pregnancy category B drug.

miconazole

Miconazole (Monistat) is a topical antifungal drug that is available in several OTC and prescription products. It inhibits the growth of several fungi, including dermatophytes and yeast, as well as gram-positive bacteria, and is commonly used to treat dermatophytoses, superficial mycoses, cutaneous candidiasis, and vulvovaginal candidiasis. It is present in many OTC remedies for athlete's foot, jock itch, and yeast infections.

For the treatment of athlete's foot, jock itch, ringworm, and other susceptible fungal infections, miconazole is applied sparingly to the cleansed, dry, infected area twice daily in the morning and evening. For the treatment of yeast infections, one 200-mg suppository is inserted in the vagina once daily at bedtime for 3 consecutive days or 100 mg (one suppository or 5 g of the 2% cream) is administered intravaginally once daily at bedtime for 7 days. The most common adverse effects of topically administered miconazole are vulvovaginal burning and itching, pelvic cramps and rash, urticaria, stinging, and contact dermatitis. Miconazole is available in a variety of topical formulations: as a 2% aerosol spray and powder, a 2% powder, a 2% cream, a 2% vaginal cream, and a 100- and 200-mg vaginal suppository. It is also available as a 1200-mg vaginal suppository for one-time dosing. It is classified as a pregnancy category C drug.

ANTIVIRAL DRUGS

Topical antivirals are now used less frequently than before, because systemic antiviral drug therapy has generally been shown to be superior for controlling such viral skin conditions. Nevertheless, two antiviral ointments are described here. As is the case with systemic drug therapy, these products are best used early in a viral skin lesion outbreak. Topical antivirals are more likely to be used for acute outbreaks, whereas systemic drugs are used for acute outbreaks as well as ongoing prophylaxis against outbreaks. Viral infections are very difficult to treat because they live in the body's own healthy cells and use their cell mechanisms to reproduce. The same holds true for topical viral infections. Infections caused by herpes simplex virus

types 1 and 2 and human papillomavirus (which causes anogenital warts) are particularly serious and are becoming more common.

The only topical antiviral drugs currently available to treat such viral infections are acyclovir (Zovirax) and penciclovir (Denavir). They work by comparable mechanisms as described for similar antiviral drugs in Chapter 40. Acyclovir and penciclovir are available as topical ointments (5% and 1%, respectively). Acyclovir is applied every 3 hours, or six times daily, for 1 week. Penciclovir is applied every 2 hours while awake for 4 days. A finger cot or rubber glove is to be worn for the application of the ointment to prevent the spread of infection. The most common adverse effects are stinging, itching, and rash. Acyclovir is classified as a pregnancy category C drug and penciclovir as a pregnancy category B drug.

ANESTHETIC, ANTIPRURITIC, AND ANTIPSORIATIC DRUGS

TOPICAL ANESTHETICS

Topical anesthetics are drugs that are used to numb the skin. They accomplish this by inhibiting the conduction of nerve impulses from sensory nerves, thereby reducing or eliminating the pain or pruritus associated with insect bites, sunburn, and allergic reactions to plants such as poison ivy, as well as many other uncomfortable skin disorders. They are also used to numb the skin before a painful injection (e.g., insertion of an intravenous line in a pediatric patient). Topical anesthetics are available as ointments, creams, sprays, liquids, and jellies, and are discussed in Chapter 11. A lidocaine/prilocaine combination drug (EMLA) and lidocaine alone (Ela-max) are topical anesthetic drugs that are used frequently, especially in pediatric patients. EMLA is applied 1 hour before the procedure, whereas Ela-max is effective within 30 minutes.

TOPICAL ANTIPRURITICS AND ANTIINFLAMMATORIES

Topical antipruritic (anti-itching) drugs contain antihistamines or corticosteroids. Many exert a combined anesthetic and antipruritic action when applied topically. The antihistamines and their therapeutic effects are covered in Chapter 36. New recommendations for the use of topical antihistamines state that these drugs are not to be used to treat the following conditions because of systemic absorption and subsequent toxicity: chickenpox, widespread poison ivy lesions, and other lesions involving large body surface areas.

The most commonly used topical antiinflammatory drugs are the corticosteroids (see Chapter 33). They are generally indicated for the relief of inflammatory and pruritic dermatoses. When topically administered corticosteroids are used, many of the undesirable systemic adverse effects associated with the use of the systemically administered corticosteroids are avoided. The beneficial drug effects of topically administered corticosteroids are their antiinflammatory, antipruritic, and vasoconstrictive actions.

TABLE 56-5 COMMONLY USED TOPICAL CORTICOSTEROIDS (IN ORDER OF DECREASING POTENCY)

RANGE OF POTENCY*	CORTICOSTEROID
1. Higher potency	Betamethasone dipropionate (cream and ointment), clobetasol propionate, halobetasol propionate, diflorasone diacetate
2. Moderate potency	Amcinonide, betamethasone dipropionate (cream), betamethasone benzoate, betamethasone valerate (0.1% cream, ointment, and lotion), desoximetasone (0.05% cream), desoximetasone, fluocinolone, halcinonide, fluocinolone (cream and ointment), flurandrenolide, mometasone, triamcinolone acetonide (0.5% cream and ointment)
3. Lower potency	Alclometasone, desonide, fluocinolone (0.01% solution), triamcinolone (0.1% cream, lotion), hydrocortisone, dexamethasone

*Skin penetration and thus potency is enhanced by the vehicle (dosage form) containing the steroid. In decreasing order of effectiveness are ointments, gels, creams, and lotions.

The many different available dosage forms of the various corticosteroids vary in their relative potency, and this often guides their selection for treating various conditions. For instance, corticosteroids that are fluorinated (which increases the potency) are used for the treatment of dermatologic disorders such as psoriasis. The vehicle in which the corticosteroid is contained also may alter its vasoconstrictor properties and therapeutic efficacy. Ointments are generally the most penetrating, followed next by gels, creams, and lotions. Propylene glycol also enhances the penetration of the corticosteroid and its vasoconstrictor effects. Most corticosteroids are available in many topical formulations, which provide a variety of options. The currently available topical corticosteroids, along with their respective potencies, are listed in Table 56-5.

Adverse effects of these drugs include skin reactions such as acne eruptions, allergic contact dermatitis, burning sensations, dryness, itching, skin fragility, hypopigmentation, purpura, hirsutism (usually facial), folliculitis, round and swollen face, and alopecia (usually of the scalp). Another adverse effect is the opportunistic overgrowth of bacteria, fungi, or viruses as a result of the immunosuppressive effects of this class of drugs. *Tachyphylaxis* (weakening of drug effect over time) may also occur with these drugs, especially with long-term use or overuse. The usual adult dosage of these drugs is one or two applications daily as a thin layer over the affected area. Less potent topical corticosteroids are used in children, following the same dosing schedule. Corticosteroids are classified as pregnancy category C drugs and are contraindicated in patients with a known hypersensitivity to them. Because many of these products are available orally as well as topically, the potential exists for both to be administered simultaneously. This is not recommended and is potentially harmful. The combined use of topical and oral preparations of the same drug can lead to toxicity.

ANTIPSORIATIC DRUGS

Psoriasis is a common skin condition in which areas of the skin become thick, reddened, and covered with silvery scales. Psoriasis is actually a result of a disordered immune system, although it is generally referred to as a skin condition. It is believed to involve *polygenic* (multigene) inheritance. Psoriasis has fluctuating patterns of recurrence and remission. Flare-ups can be triggered by changes in climate, infection, stress, excessive alcohol intake, or dry skin. Although there are many subtypes, the most classic one is known as *plaque psoriasis* and typically manifests as large, dry, erythematous scaling patches of the skin that are often white or silver on top. Commonly affected skin areas include nails, scalp, genitals, and lower back. Treatment usually begins with a topical corticosteroid for mild to moderate cases. When this therapy is not successful, topical antipsoriatic drugs are used. In addition to these topical drugs, there are also newer systemically administered antipsoriatic drugs. A thorough discussion of these drugs is beyond the scope of this chapter on topical medications, but those given by injection include etanercept (Enbrel), which is given subcutaneously, and alefacept (Amevive), which is given intramuscularly. Another drug, efalizumab (Raptiva), was withdrawn from the U.S. market in 2009. Etanercept is discussed in more detail in Chapter 47 on biologic response modifiers. In addition, the antineoplastic drug methotrexate (see Chapter 45) is also used for its antipsoriatic properties. The newest injectable drug, ustekinumab (Stelara), is an interleukin 12 inhibitor and is indicated for plaque psoriasis. It is given subcutaneously. Patients must receive an FDA-approved patient medication guide when receiving ustekinumab. The most serious side effect is increased risk of infection.

DRUG PROFILES

tazarotene

Tazarotene is a receptor-selective retinoid. It is thought to normalize epidermal differentiation, reducing the influx of inflammatory cells into the skin. Synthetic retinoids are vitamin A analogues and are thought to play a role in skin cell differentiation and proliferation. Tazarotene is available in gel form and is approved for the treatment of stable plaque psoriasis and mild to moderately severe facial acne. Like isotretinoin, tazarotene is classified as a pregnancy category X drug, and a negative pregnancy test 2 weeks before starting therapy is required for female patients.

tar-containing products

Drug products containing coal tar derivatives were among the first medications used to treat psoriasis and are still used today for this purpose. Tar derivatives are known to have antiseptic, antibacterial, and antiseborrheic properties, and they work to soften and loosen scaly or crusty areas of the skin. *Seborrhea* is excessive secretion of *sebum,* a normal skin secretion containing fat and epithelial cell debris. Tar-containing products are available in a variety of shampoo forms (for scalp psoriasis), as well as solution, oil, ointment, cream, lotion, gel, and even soap forms for bathing. These products typically contain 1% to 10% coal tar. Adverse reactions usually include minor skin burning, photosensitivity, and other irritations. These products may be applied from one to four times daily or once or twice weekly as prescribed.

anthralin

Anthralin (Anthra-Derm) is a unique drug that is thought to work by inhibition of deoxyribonucleic acid (DNA) synthesis and mitosis within the epidermis to reduce psoriatic lesions. It is available in ointment and cream form and is usually applied once daily. Adverse reactions are generally limited to minor skin irritation. Anthralin is classified as a pregnancy category C drug.

calcipotriene

Calcipotriene (Dovonex) is a synthetic vitamin D_3 analogue that works by binding to vitamin D_3 receptors in skin cells known as *keratinocytes,* the abnormal growth of which contributes to psoriatic lesions. Calcipotriene helps to regulate the growth and reproduction of keratinocytes. The most common adverse reaction is minor skin irritation. However, more serious reactions can occur in some cases, including worsening of psoriasis, dermatitis, skin atrophy, and folliculitis. Calcipotriene is usually applied twice daily. It is classified as a pregnancy category C drug. Taclonex is a combination product containing calcipotriene and betamethasone, a topical steroid.

MISCELLANEOUS DERMATOLOGIC DRUGS

There are many other topically applied drugs. Those discussed in this section are the topical ectoparasiticides (scabicides and pediculicides), hair growth drugs, sunscreens, antineoplastics, and immunomodulating drugs. Many of these drugs are available both OTC and by prescription. Aloe vera herbal preparations (see the Safety: Herbal Therapies and Dietary Supplements box) are also available OTC.

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

***Aloe* (Aloe vera L.)**

Overview
The dried juice of the leaves of the aloe plant contains anthranoids, which give aloe a laxative effect when taken orally. The topical application of the plant juice has been known for years to help aid in wound healing.

Common Uses
Wound healing, constipation

Adverse Effects
Diarrhea, nephritis, abdominal pain, dermatitis when used topically

Potential Drug Interactions
Digoxin, antidysrhythmics, diuretics, corticosteroids

Contraindications
Contraindicated in patients who are menstruating or have renal disease; can increase menstrual blood flow and also cause acute renal failure

DRUG PROFILES

ECTOPARASITICIDAL DRUGS

Ectoparasites are insects that live on the outer surface of the body, and the drugs that are used to kill them are called *ectoparasiticidal drugs.* Lice are transmitted from person to person by close contact with infested individuals, clothing, combs, or towels. A parasitic infestation on the skin with lice is called **pediculosis,** and such infestations go by one of the following three names, depending on the location of the infestation:

- Pediculosis pubis—pubic louse or "crabs"; infestation by *Phthirus pubis*
- Pediculosis corporis—body louse; infestation by *Pediculus humanus corporis*
- Pediculosis capitis—head louse; infestation by *Pediculus humanus capitis*

Common findings in infested persons include itching; eggs of the lice attached to hair shafts (called *nits*); lice on the skin or clothes; and, in the case of pubic lice, sky blue macules (discolored skin patches) on the inner thighs or lower abdomen. Pediculoses are treated with a class of drugs called pediculicides. A second common parasitic skin infection known as **scabies** is that caused by the itch mite *Sarcoptes scabiei.* Scabies is transmitted from person to person by close contact, such as by sleeping next to an infested person. The scabies mite causes irritation and itching by boring into the horny layers of skin located in cracks and folds. Itching seems to occur most commonly in the evening. The drugs used to treat these infestations are called *scabicides.*

Treatment of these parasitic infestations begins with identification of the source of infestation to prevent re-infestation. Next, the clothing and personal articles of the infested person must be decontaminated. This is best accomplished by washing them in hot, soapy water or by dry cleaning them. All close contacts of the person also need to be treated to prevent re-infestation.

In addition to lindane (see profile), malathion (Ovide) and crotamiton (Eurax) are also ectoparasiticidal drugs. The newest drugs approved for lice treatment are benzyl alcohol 5% (Ulesfia), which works by suffocating the lice, and spinosad (Natroba). Natroba is indicated for children 4 years of age and older and offers the benefit of not requiring nit combing as do the other treatments.

♦ lindane

Lindane (Kwell) is a chlorinated hydrocarbon originally developed as an agricultural insecticide. It is both a scabicide and a pediculicide because it is effective in treating both scabies and pediculosis. High resistance rates to lindane and malathion have limited its use. It is available in two topical formulations: a 1% lotion and a 1% shampoo.

For the treatment of pubic or body lice, the cream or lotion is applied in a sufficient quantity to cover the skin and hair of the infested and surrounding areas. It is left on for 12 hours and then thoroughly washed off. A second application is seldom needed. Head lice can be treated with lindane shampoo, which is worked into the hair and left on for 4 minutes. The hair is then rinsed and dried, after which the nits (eggs) are combed from the hair shafts. The treatment for scabies is similar. It involves the application of lindane over the entire body, from the neck down. It is left on for 8 to 12 hours and then washed off. A similar second application 1 week later is often recommended. The OTC products are applied in similar fashion, although details may vary among individual products. Adverse effects of lindane are an eczematous skin rash and central nervous system toxicity. The latter is more common in young children and in cases of overuse. For many years, lindane was the most widely used pediculicide, but it has been superseded to some degree by permethrin. This is because of case reports of neurotoxicity, including dizziness, seizures, and deaths, caused by lindane. Most of the adverse events occurred due to product misuse (e.g., ingestion) or overuse. Children are at higher risk of neurotoxicity because their skin surface area is larger in relation to body weight. Lindane is still recommended as second-line therapy for lice and scabies after failure of one of the OTC preparations. However, the FDA has recommended that it be sold in smaller containers (1 to 2 oz) with definitive patient instructions on proper use.

HAIR GROWTH DRUGS

minoxidil

Minoxidil (Rogaine) is a vasodilating drug that is administered systemically to control hypertension (see Chapter 22). Topically it has the same vasodilating effect, but when used in this way it is applied to the scalp to stimulate hair growth. The vasodilation it causes is one possible explanation for how it promotes hair growth. It may also act at the level of the hair follicle, possibly stimulating hair follicle growth directly.

Minoxidil can be used by both men and women who experience baldness or hair thinning. Treatment involves administering the drug to the affected areas (those with balding and anticipated balding) twice daily, usually morning and evening. It generally takes 4 months before results are seen. Systemic absorption of topically applied minoxidil may occur with possible adverse effects, including tachycardia, fluid retention, and weight gain. Local effects may include skin irritation, and the drug is not to be applied to skin that is already irritated, nor used concurrently with other topical medications applied to the same site. Minoxidil is classified as a pregnancy category C drug. Note that the beneficial effects of this drug can be reduced by heat, including the use of a blow dryer.

The systemically administered drug finasteride (Proscar, 5 mg) is used to treat benign prostatic hyperplasia, as discussed in Chapter 35. A lower-strength version known as Propecia (1 mg) is also used to treat male pattern alopecia. Finasteride is classified as a pregnancy category X drug, and women are not to handle this drug without gloves or crush this drug, thereby making it airborne.

SUNSCREENS

Sunscreens are topical products used to protect the skin from damage caused by the UV radiation of sunlight. There are currently nearly 160 specific sunscreen products on the market. None requires a prescription for use. Each is composed of typically three to five various chemical ingredients that work

together to provide UV protection and, usually, a moisturizing effect as well. Common examples of these ingredients are titanium dioxide, octyl methoxycinnamate, homosalate, and parabens. Sunscreens are given a sun protection factor (SPF) rating, which is a number ranging from 2 to 50 (and even higher in some newer products) in order of increasing potency of UV protection. In 2011, the FDA stated that only those with SPF of 15 or greater may state they reduce the risk of skin cancer and early skin aging. Most sunscreens come in lotion, cream, or gel form. A smaller number of lip balms are also available. It is important for sunscreens to have both UVA and UVB protection. Sunscreen is not to be used on infants.

ANTINEOPLASTIC DRUGS

Skin cancer is the most common form of cancer. There are two types of nonmelanoma skin cancer: basal cell carcinoma and squamous cell carcinoma. Basal cell carcinoma is the most common and is rarely fatal, but it can be highly disfiguring. Squamous cell carcinoma, on the other hand, can be fatal, with 2500 deaths reported annually. The most aggressive skin cancer is melanoma and accounts for only 3% of all skin cancers but is responsible for 75% of deaths associated with skin cancer. The most common cause of skin cancer is exposure to the sun and tanning beds. Early detection and prevention (with the use of sunscreen) are of the utmost importance.

fluorouracil

Various premalignant skin lesions and basal cell carcinomas may be treated with the topically applied antineoplastic drug fluorouracil (Efudex). As noted in Chapter 45, this drug is an antimetabolite that acts by interfering with key cellular metabolic reactions, destroying rapidly growing cells, such as premalignant and malignant cells. It is also used topically in the treatment of solar or **actinic keratosis** and superficial basal cell carcinomas of the skin—often in addition to local surgical excision. More aggressive skin cancers *(squamous cell carcinoma and malignant melanoma)* are not treated with fluorouracil but are usually treated with more aggressive interventions, such as surgery, radiation therapy, and/or systemic chemotherapy (see Chapters 45 and 46).

The adverse effects associated with the topical use of this antineoplastic drug are generally limited to local inflammatory reactions such as dermatitis, stomatitis, and photosensitivity. More serious effects include swelling, scaling, pain, pruritus, burning, soreness, tenderness, suppuration, scarring, and hyperpigmentation.

Fluorouracil is available in both cream and solution form. It can be applied with a nonmetallic applicator, clean fingertips, or gloved fingers. If the fingers are used, they need to be washed thoroughly immediately after application. Either a 1% or 2% fluorouracil solution is used for the treatment of multiple actinic keratoses of the head and neck. The solution is applied twice daily to the lesions. Superficial basal cell carcinoma may be treated with 5% fluorouracil, administered twice daily for at least 2 to 6 weeks. Another topical drug also used for the treatment of actinic keratoses and basal cell carcinomas is the immunomodulator imiquimod, discussed in the following section.

IMMUNOMODULATORS

♦ pimecrolimus

Pimecrolimus (Elidel) is available in a cream form for use in treating atopic dermatitis. Atopic dermatitis is caused by a hereditary susceptibility to pruritus and is often associated with allergic rhinitis, hay fever, and asthma. This drug works through a mechanism similar to that of the anti–transplant-rejection drug tacrolimus (Prograf), which was discussed in Chapter 48. A topical form of tacrolimus (Protopic) is also used and has similar actions and indications. Adverse reactions to both drugs are usually limited to minor skin irritations.

imiquimod

Imiquimod (Aldara) is an immunomodulating drug that has demonstrated efficacy in treating actinic keratosis, superficial basal cell carcinoma, and anogenital warts. Its exact mechanism of action is unknown, but it is believed somehow to enhance the body's immune response to these conditions. It is applied two to five times per week, as prescribed, depending on the condition being treated. Adverse reactions include mild skin reactions such as burning, induration (hardness), irritation, pain, and bleeding, which can occur both locally (at the site of medication administration) and at skin areas remote from the site of administration. More severe adverse skin reactions include edema, erosion or ulceration, scaling, scabbing, exudation, and vesicle formation. Systemic reactions, likely related to systemic immunomodulating effects, include cough, upper respiratory tract infection, musculoskeletal reactions (e.g., back pain), and lymphadenopathy. This drug is available only in cream form.

WOUND CARE DRUGS

Although superficial skin wounds usually require minimal interventions, deeper skin wounds often require more definitive care for optimal healing. Such care includes addressing the systemic issues (e.g., body nutritional status) that are critical to tissue repair. Vitamin C (ascorbic acid) and zinc have been shown to improve wound healing when they are given orally. Topical wound care medications are one of the fundamental steps of wound care, referred to in the literature as *preparation of the wound bed.* Wound *débridement* is removal of nonviable tissue and elimination of bacteria by suitable cleansing or surgical intervention. Until 2009, drugs containing papain or papain/urea were commonly used as topical débriding drugs. However, the FDA no longer allows these drugs to be manufactured, because they never received FDA approval. Table 56-6 provides information regarding selected currently available wound care medications.

SKIN PREPARATION DRUGS

The skin must be disinfected before any invasive procedure. Isopropyl alcohol (70%) is most commonly used to prepare the skin before minor procedures such as drawing blood or giving injections. Isopropyl alcohol has been shown to lower the bacterial count for 20 to 40 minutes after application. Other drugs that are used to prepare the skin include povidone-iodine (Betadine), chlorhexidine (Hibiclens), and benzalkonium chloride (Zephiran). Benzalkonium chloride is a surface-active

TABLE 56-6 SELECTED WOUND CARE PRODUCTS

PRODUCT NAME	ADVANTAGES	DISADVANTAGES	CONTRAINDICATIONS
acetic acid (vinegar)	Low cost	Cytotoxic	Allergy
sodium hypochlorite (Dakin's bleach solution, ¼%, ½%, 1%)	Aids débridement; reduces microbial count	Partly toxic and irritating to healing tissue	Clean, noninfected wounds
cadexomer iodine (Iodosorb, others)	Slow release; safe for viable cells; absorbs exudates; promotes wound healing	Partly toxic to fibroblast cells; stains tissue	Iodine allergy
collagenase (Santyl)	Good for patients taking anticoagulants or in whom surgery is contraindicated; selectively removes necrotic tissue; does not harm normal tissue; Okay for infected wounds	Requires prescriber's order; not for use with other common wound products such as silver sulfadiazine (Silvadene) or Dakin's solution; expensive	Clean wounds with granulation tissue and signs of healing but with limited areas of necrosis; product allergy
biafine topical emulsion	Can be used for "tunneling" wounds as well as full-thickness wounds and radiation dermatitis	Must not be applied within 4 hr of radiation therapy	Bleeding wounds, skin rashes related to food or drug allergies

TABLE 56-7 SKIN PREPARATION DRUGS

DRUG	EFFECTIVE AGAINST	ADVERSE EFFECTS
isopropyl alcohol	Bacteria, fungi, virus	Excessive dryness of skin
chlorhexidine (Hibiclens)	Bacteria, fungi	Central nervous system toxicity in neonates and burn patients
povidone-iodine (Betadine)	Bacteria, fungi, virus	Staining of skin, irritation and pain at wound sites; retards or reverses the granulation process
benzalkonium chloride (Zephiran)	Bacteria, fungi	Chemical burns if left in contact with skin for too long

drug that works by denaturing the microorganism or essentially destroying its protein. Chlorhexidine acts by disrupting bacterial membranes and inhibiting cell wall synthesis. It is used primarily as a surgical scrub or hand-washing agent by health care professionals. Povidone-iodine is an antiseptic that kills bacteria, fungi, and viruses. It is used for the prevention or treatment of topical infections associated with surgery, burns, and minor cuts and scrapes, and for relief of minor vaginal infections. It is the most widely used antiseptic, but patients should be screened for iodine or shellfish allergies before using it. It is available in many different dosage forms. See Table 56-7 for more information on selected skin preparation drugs.

NURSING PROCESS

ASSESSMENT

Before administering any *dermatologic preparation,* assess the patient for any allergies (including allergies to all drug ingredients), contraindications, cautions, and drug interaction. Topical antibacterials are associated with a wide range of reactions because of the generalized sensitivity of patients to antibiotics, even when in a different dosage form; therefore, if a patient is allergic to a systemic antibacterial, he or she will also be allergic to topical dosage forms. Assess the results of any culture and sensitivity testing that was ordered before giving the antibacterial to ensure appropriate identification of effective drugs. Before administering any type of topical medication (e.g., antimicrobial, corticosteroid, antiacne drug), always consider the concentration of the medication, length of exposure to the skin, condition of the skin, size of the affected area, and hydration of the skin. All of these factors have a significant influence on the action of the medication. Additionally, assess the medication order for not only the correct drug but also the prescribed route. Inspect the skin or affected area thoroughly under an adequate light source. Palpate the area with a gloved hand. In dark-skinned patients, an erythematous area may not be visible but may be palpated as an area of warmth. Accompany physical assessment of the skin with an assessment and documentation of surrounding structures, including lymph nodes.

Assess the patient's overall health status and hygiene practices, including whether the patient has experienced any trauma and whether there is any history of immunosuppression. Remember that the skin of very young and elderly patients is more fragile and permeable to certain topical dermatologic preparations. These characteristics also lead to a higher risk for systemic absorption from the skin. It is also important to note other possible situations that may result in a drug effect that is less than therapeutic, such as the use of topical drugs over an area that is full of pus or debris. The use of herbal products, such as topical aloe vera, also requires thorough assessment and notation of any allergies, contraindications, cautions, and drug interactions (see the Safety: Herbal Therapies and Dietary Supplements box on p. 909).

NURSING DIAGNOSES

1. Impaired skin integrity related to specific diseases, reactions, conditions, or breaks in the skin barrier
2. Deficient knowledge related to lack of experience with and exposure to use of topical drugs

CASE STUDY

Medications for Wound Care

A.T., 16 years of age, was clearing brush with his father when he cut his hand. His mother washed the wound and told him to apply ointment. A.T. checked the family medicine cabinet and applied clotrimazole (Lotrimin) ointment, the only ointment in the cabinet.

Two days later, the wound is not better and is very painful. A.T.'s mother takes him to the clinic to have the wound checked. The physician assistant (PA) finds that the laceration wound is deep but does not have any drainage. The wound is irrigated with normal saline, bacitracin is applied, and the wound is closed with adhesive strips and then covered with a loose gauze dressing. The nurse gives A.T. instructions on how to care for the wound and tells him that this wound care is to be done twice a day for 1 week. In addition, the PA suggests that A.T. take vitamin C and zinc supplements for the next month and instructs A.T. not to use the clotrimazole ointment on the wound.

1. Why did the PA apply bacitracin instead of clotrimazole? Explain your answer.
2. What is the purpose of the vitamin C and zinc supplements?
3. The next day, A.T. discovers a rash that covers both his arms and legs. The rash is very itchy, and the skin is red with small bumps. He knows that there was poison ivy in the brush and wants something to stop the itching. What will be suggested?
4. The next evening, as he takes off the dressing to clean his wound, A.T. finds that the area is swollen and more inflamed, with tiny red bumps around the wound. There is no drainage. What do you think has happened, and what will be done?

For answers, see http://evolve.elsevier.com/Lilley.

3. Noncompliance related to lack of experience taking or applying medication and maintaining frequent dosing

PLANNING

GOALS

1. Patient's skin remains intact and healed in appearance, and skin integrity is maintained.
2. Patient demonstrates adequate knowledge about the use of the medication.
3. Patient remains compliant as related to the drug regimen.

OUTCOME CRITERIA

1. Patient's skin improves daily as stated by the patient, with less redness, drainage, discomfort, itching, and/or rash.
2. Patient states the rationale for treatment, adverse effects of the specific dermatologic preparation, and symptoms associated with the dermatologic therapy that are to be reported to the prescriber.
   - Patient demonstrates how to apply the medication in keeping with the prescriber's orders, with specific attention to the requirements for emollient, lotion, solution, spray, cream, and ointment dosage forms.
3. Patient experiences improvement in the condition of affected area(s) with continued compliance to the medication regimen.
   - Patient applies or self-administers the medication regimen with frequent dosing, as prescribed or directed.

IMPLEMENTATION

Generally speaking, before any *topical medication* is applied, cleanse the affected area of any debris, drainage, and/or residual medication, taking care to follow any specific directions such as removing water- or alcohol-based topical preparations with soap and water. Always begin (and end) by performing hand hygiene and maintain Standard Precautions (see Box 9-1). Store all dosage forms of medication as recommended. Wear gloves, not only to prevent contamination from secretions but also to prevent absorption of the medication through the skin. Applying topical drug using a gloved hand, tongue depressor, or cotton-tipped applicator is recommended. Shake or mix lotions and solutions thoroughly before use, and apply evenly (see Chapter 9). Wash hands before and after application of the medication. Apply any dressings as ordered, paying special attention to directions concerning occlusive, wet, or wet-to-dry dressing changes. It is important to note, however, that most topical dermatologic drugs do not require use of a dressing once the medication is applied. The medication order may also state that any type of dressing or coverage of the affected area is to be avoided. When medications are used for wound care, there is usually a step-by-step protocol for application of a cleansing agent, possible débridement drug, and rinsing solution, as well as final application of an antibacterial, antifungal, burn, antiseptic, or other solution that may have been ordered. Provide comprehensive patient education regarding wound care and/or use of topical dermatologic drugs to ensure effective and safe treatment. If home health care is needed after discharge, arrangements need to be in place before the patient returns home. Document information about the site of drug application, including drainage (color and amount), swelling, temperature, odor, color, and pain or other sensations, as well as the type of treatment rendered and the response, with each treatment or application, and record a comparative before-and-after assessment.

Follow the manufacturer's guidelines regarding the use of any of the dermatologic preparations because each medication has a different type of base solution. Specific application procedures may be required for different dosage forms. It is also important to follow any instructions or orders regarding other treatments to the affected area, such as the use of an occlusive or wet dressing (see earlier in the chapter). Medicated areas may also need to be protected from exposure to air or sunlight. Strict adherence to the proper method of application and dosage of any dermatologic preparation is important to its effectiveness. Doubling up of a missed dose is not recommended. After the medication administration process is complete, dispose of all contaminated dressings, gloves, or equipment properly. Maintain safety, comfort, and privacy of the patient at all times. See the Patient Teaching Tips for more information. Also see

Table 56-6 for information about specific drugs for wound care and their advantages and disadvantages.

EVALUATION

Begin the evaluation by monitoring to ensure that goals and outcome criteria are being met. Therapeutic responses to the various *dermatologic preparations* include improved condition of the skin and healing of lesions or wounds; a decrease in the size of lesions with eventual resolution; and a decrease in swelling, redness, weeping, itching, and burning of the area. Notify the prescriber if a therapeutic response is not observed within an appropriate time (anywhere from 48 to 72 hours or longer, depending on the drug, disorder or skin problem, and acute or chronic nature of the condition) or if signs and symptoms worsen or new ones appear. Adverse effects for which to evaluate include increased severity of symptoms—for example, increased redness, swelling, pain, and drainage; fever; or any other unusual problems at the affected area. Adverse effects may range from slight irritation of the site where the topical drug has been applied to an allergic reaction to toxic systemic effects.

PATIENT TEACHING TIPS

- Advise the patient to keep the skin clean and dry or clean and moist as prescribed. Provide instructions to the patient and caregivers about maintaining adequate general hygiene, cleanliness, adequate hydration, and proper nutrition during drug therapy.
- Ensure that the patient has a full understanding on how to prepare the skin for application of the medication and any other instructions.
- Apply dressings to the affected area as directed, if indicated or ordered. Perform dressing application after medication use, and properly dispose of contaminated dressings or equipment. Emphasize the need for thorough hand washing before and after application of medication with a gloved hand, cotton-tipped applicator, or tongue depressor. Demonstrate to all individuals involved in the care of the patient. Always emphasize the importance of compliance with the drug regimen.
- Encourage the patient to notify the prescriber if any unusual or adverse reactions occur or if the original condition worsens or fails to improve within a designated period of time.
- Counsel all female patients of childbearing age regarding the birth defect hazards associated with exposure to certain dermatologic drugs. All sexually active women must use contraception during treatment with any teratogenic medication and for at least 1 month after its discontinuation.
- Educate the patient about ways to prevent exposure to the sun through the use of sunscreen and protective clothing, and avoidance of overexposure. Tanning beds create risk for skin cancer as well, so share with the patient appropriate and accurate information regarding their use and risk. Sunscreen must also be used with tanning beds.
- Vitamin D deficiency may be an issue for some sunscreen users and those who live at higher latitudes or are not exposed to sunlight. As adequate oral intake is difficult to achieve without supplementation, many people with minimal exposure to sunlight do not activate vitamin D and are deficient.
- Assess all skin moles or lesions, and monitor for any unusual changes in color, size, texture, and/or shape.
- Adverse effects of lindane (for lice) include skin rash and, rarely, central nervous system toxicity. Lindane's use has been surpassed to some degree by perethrin because of case reports of neurotoxicity, including dizziness, seizures, and deaths. Make sure parents or caregivers understand all instructions regarding this drug's use, application, and cautions/concerns.

KEY POINTS

- Dermatologic drugs are used to treat topical infections.
- Common skin disorders caused by bacteria are folliculitis, impetigo, furuncles, carbuncles, and cellulitis.
- The bacterium most commonly responsible for acne is *P. acnes.*
- The fungi that are responsible for causing topical fungal infections are *Candida,* dermatophytes, and *M. furfur.*
- The most common topical fungal infections are *Candida* infections; for example, yeast infections.
- One of the most common topical viral infections is infection with herpes simplex virus types 1 and 2.
- Topical anesthetics are used therapeutically to numb the skin. Indications for topical anesthetics include insect bites, sunburn, poison ivy, and prevention of pain from injections.
- Corticosteroids are some of the most widely used topical drugs and are indicated for relief of topical inflammatory and pruritic disorders.
- Beneficial effects of corticosteroids include antiinflammatory, antipruritic, and vasoconstrictor actions. Some of the negative effects of potent corticosteroid use or prolonged use of weaker corticosteroids include dermal atrophy and adrenal insufficiency.
- Adverse and toxic reactions to dermatologic drugs can and do occur; therefore, administer these drugs cautiously, and follow the prescriber's orders and manufacturer's guidelines. This is critical to ensure safe and effective treatment.
- Patient education about the medication, its administration, and its effectiveness are important to ensure compliance with the treatment regimen.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The nurse is assessing the skin of a teenage patient who has been using a benzoyl peroxide product for 2 weeks as part of treatment for acne. Which assessment findings indicate that the patient is having an allergic reaction and will need to stop treatment?
- **a** Reddened skin over the treatment area
- **b** Blistering skin over the treatment area
- **c** Peeling skin over the treatment area
- **d** Sensation of warmth when the product is applied

2 When considering the variety of OTC topical corticosteroid products, the nurse is aware that which type of preparation is generally most penetrating and effective?
- **a** Gel
- **b** Lotion
- **c** Spray
- **d** Ointment

3 The nurse is monitoring for an allergic reaction to topical bacitracin, which would be evident by presence of
- **a** petechia.
- **b** thickened skin.
- **c** itching and burning.
- **d** purulent drainage.

4 When the nurse is teaching a patient about the mechanism of action of tretinoin, which statement by the nurse is correct?
- **a** "This medication acts by killing the bacteria that cause acne."
- **b** "This medication actually causes skin peeling."
- **c** "This medication acts by protecting your skin from UV sunlight."
- **d** "This medication has antiinflammatory actions."

5 When the nurse is providing wound care with Dakin's solution for a patient who has a stage III pressure ulcer, the patient exclaims, "I smell bleach! Why are you putting bleach on me?" The nurse's best explanation is:
- **a** "This is a very dilute solution and acts to reduce the bacteria in the wound so that it can heal."
- **b** "This solution is used instead of medication to promote wound healing."
- **c** "This solution is used to dissolve the dead tissue in your wound."
- **d** "Don't worry; we would never use bleach on a patient!"

6 The nurse is instructing a parent on the use of lindane (Kwell) shampoo for treatment of a child's head lice. Which statement by the parent indicates a need for further education?
- **a** "I will wash his hair, then rinse out the shampoo immediately."
- **b** "I will leave the shampoo on his hair for 4 minutes before rinsing."
- **c** "After shampooing, I will rinse and dry his hair."
- **d** "When the hair is dry, I will comb the hair to remove the nits."

7 The nurse is performing wound care on a burned area using silver sulfadiazine cream in a patient with an arm wound. Which actions by the nurse are correct? (Select all that apply.)
- **a** Applying the cream over the previous layer to avoid disturbing the wound bed
- **b** Gently cleansing the wound to remove the previous layer of cream and wound debris
- **c** Using clean gloves to apply the ointment
- **d** Using sterile gloves to apply the ointment
- **e** Always covering the wound with a dressing after applying the cream
- **f** Washing hands before and after the procedure

1. b, 2. d, 3. c, 4. b, 5. a, 6. a, 7. b, d, f

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Discuss the anatomy and physiology of the structures of the eye and the impact of glaucoma and other disorders and disease processes on these structures.
2 List the various classifications of ophthalmic drugs, with examples of specific drugs in each class.
3 Discuss the mechanisms of action, indications, dosage forms with application techniques, adverse effects, cautions, contraindications, and drug interactions of the various ophthalmic drugs.
4 Develop a nursing care plan that includes all phases of the nursing process for patients receiving ophthalmic drugs.

KEY TERMS

Accommodation The adjustment of the lens of the eye for variations in distance. (p. 919)
Angle-closure glaucoma Glaucoma that occurs as a result of a narrowed anatomic angle between the lens and cornea. Also called *closed-angle glaucoma, narrow-angle glaucoma, congestive glaucoma,* and *pupillary closure glaucoma.* (p. 920)
Anterior chamber The bubble-like portion of the front of the eye between the iris and the cornea. (p. 919)
Aqueous humor The clear, watery fluid circulating in the *anterior* and *posterior chambers* of the eye. (p. 919)
Canal of Schlemm A tiny circular vein at the angle of the anterior chamber of the eye through which the aqueous humor is drained and ultimately funneled into the bloodstream. Also called *Schlemm canal.* (p. 919)
Cataract An abnormal progressive condition of the lens of the eye, characterized by loss of transparency with resultant blurred vision. (p. 919)
Ciliary muscle The circular muscle between the anterior and posterior chambers of the eye behind the iris. It is connected to the suspensory ligaments that control the curvature of the lens. (p. 919)
Cones Photoreceptive (light-receiving) cells in the retina of the eye that enable a person to perceive colors and play a large role in central (straight-ahead) vision. (p. 920)
Cornea The convex, transparent anterior part of the eye. (p. 919)
Cycloplegia Paralysis of the ciliary muscles, which prevents the accommodation of the lens for variations in distance. (p. 919)
Cycloplegics Drugs that paralyze the ciliary muscles of the eye. (p. 919)
Dilator muscle A muscle that constricts the iris of the eye but dilates the pupil. Also called *dilator pupillae.* (p. 919)
Glaucoma An abnormal condition of elevated pressure within an eye because of obstruction of the outflow of aqueous humor. (p. 920)
Intraocular pressure The pressure of the fluids of the eye against the tunics (retina, choroid, and sclera). (p. 919)
Iris The round, muscular portion of the eye that gives the eye its color and serves as an aperture controlling the amount of light passing through the pupil. (p. 919)
Lacrimal ducts Small tubes that drain tears from the lacrimal glands into the nasal cavity. (p. 919)
Lacrimal glands Glands located at the medial corners of the eyelids that produce tears. (p. 919)
Lens The transparent, curved structure of the eye that is located directly behind the iris and the pupil and is attached to the ciliary body by ligaments. (p. 919)
Lysozyme An enzyme with antiseptic actions that destroys some foreign organisms. It is normally present in tears, saliva, sweat, and breast milk. (p. 919)
Miotics Drugs that constrict the pupil. (p. 919)
Mydriatics Drugs that dilate the pupil. (p. 919)
Open-angle glaucoma A type of glaucoma that is often bilateral, develops slowly, is genetically determined, and does not involve a narrowing of the angle between the iris and the cornea. (Also called *chronic glaucoma, wide-angle glaucoma,* and *simple glaucoma.*) (p. 920)
Optic nerve A major nerve that connects the posterior end of each eye to the brain, to which it transmits visual signals. (p. 920)
Pupil A circular opening in the iris of the eye, located slightly to the nasal side of the center of the iris. The pupil lies behind the anterior chamber of the eye and the cornea and in front of the lens. (p. 919)
Retina The innermost layer of the eye, containing both rods and cones that receive visual stimuli and transmit them to the optic nerve. (p. 920)
Rods The photoreceptive elements arranged perpendicularly to the surface of the retina. Rods are especially sensitive to low-intensity light and are responsible for black-and-white and peripheral ("off-to-the-side") vision. (p. 920)
Sphincter pupillae A muscle that expands the iris while constricting or narrowing the diameter of the pupil. (p. 919)
Tears Watery saline or alkaline fluid secreted by the lacrimal glands to moisten the conjunctiva (see Figure 57-1). (p. 919)
Uvea The fibrous tunic beneath the sclera that includes the iris, the ciliary body, and the choroid of the eye (see Figure 57-1). Also called *tunica vasculosa bulbi* or *uveal tract.* (p. 919)
Vitreous body A transparent, semigelatinous substance contained in a thin membrane filling the cavity behind the lens. Also called the *corpus vitreum.* (p. 919)
Vitreous humor The fluid component of the vitreous body. (p. 919)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

The eye is the organ responsible for the sense of sight. The structures of the eye are illustrated in Figure 57-1. Each eyeball is nearly spherical and approximately 1 inch in diameter. Each eye is recessed into a small frontal skull cavity known as an *orbit.* The exposed anterior (front) portion of the eye is covered by three layers: the protective external layer (cornea and sclera), a vascular middle layer known as the *uvea* (includes the choroid, iris, and ciliary body), and the internal layer, known as the *retina.* All of these layers are protected by the eyelid, which serves as an external protective tissue.

Each eye is held in place and moved by six muscles that are controlled by cranial nerves. These muscles include the rectus and oblique muscles. There are four types of rectus

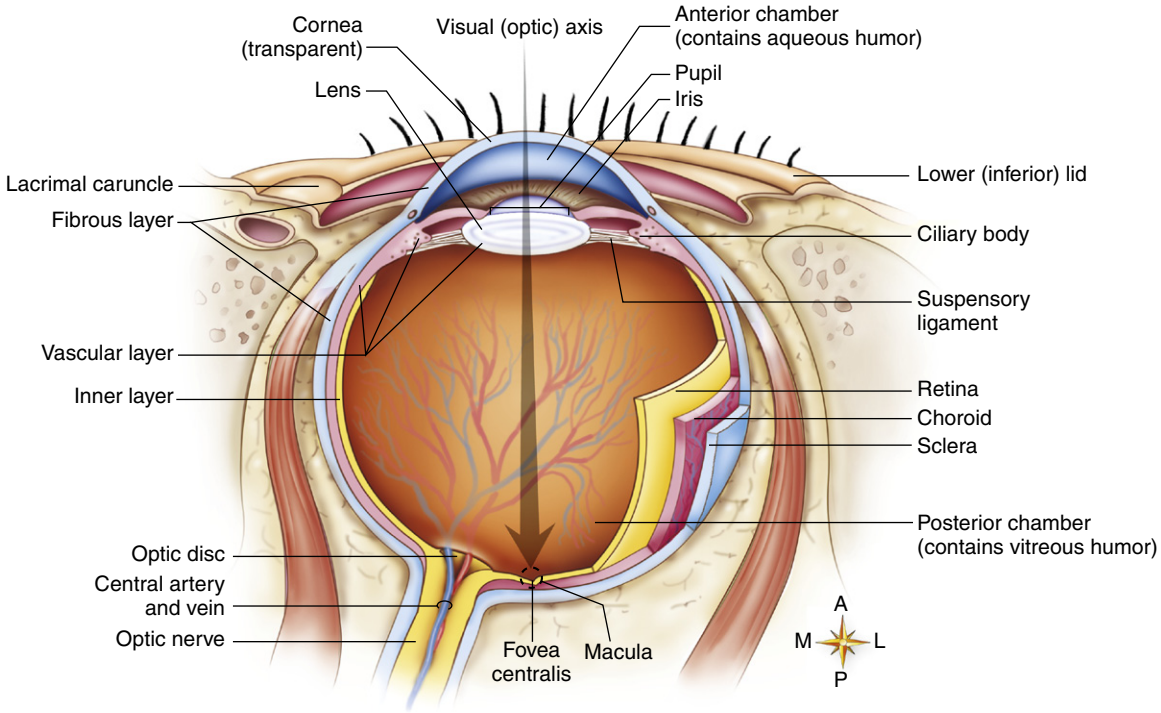

FIGURE 57-1 Horizontal section through the left eyeball, looking from the top down. (Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 7, St Louis, 2010, Mosby.)

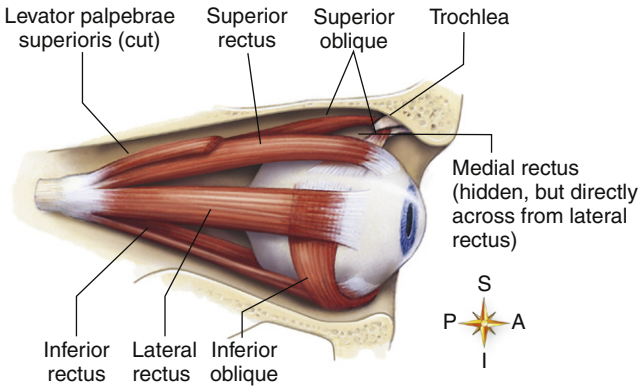

FIGURE 57-2 Extrinsic muscles of the right eye, lateral view. (Modified from Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 7, St Louis, 2010, Mosby.)

muscles: *inferior, superior, medial,* and *lateral.* There are two types of oblique muscles: *inferior* and *superior.* These muscles are shown in Figure 57-2. (The medial rectus muscle is hidden from view in this figure but is directly across from the lateral rectus muscle.) The levator palpebrae superioris muscle opens the eyelid (see later in the chapter). This muscle rests on top of the superior rectus muscle. There are several other important structures that are either part of or adjacent to the eye. The structures and the purpose of each are as follows:

- *Eyebrow:* Rows of short hair above (superior to) the upper eyelids. The eyebrow protects the eye from direct light, falling dust or other small particles, and perspiration coming from the forehead.
- *Eyelid:* The layer of muscle and skin lined interiorly by the conjunctiva. The conjunctiva also covers the outer anterior surface of the eye, which includes the cornea. The eyelid is moveable and can open or close. It protects the eye when closed and allows vision when open. The eyelid is raised by contraction of the levator palpebrae superioris muscle and is lowered by relaxation of this muscle (see Figure 57-2).
- *Cornea:* The convex (outward-projecting; opposite of concave), transparent, anterior portion of the eye. It can be thought of as a window that sits in front of the lens and allows the passage of light.
- *Eyelashes:* Two or three rows of hairs that are located on the edge (margin) of the eyelids. They help prevent small particles from falling into the eye when it is open.
- *Palpebral fissure:* The space between the upper and lower eyelids when the eyelids are open but relaxed.
- *Sclera:* A tough, white coat of fibrous tissue that surrounds the entire eyeball except for the cornea. It helps maintain the shape of the eye. Commonly called the *white* of the eye, the sclera is nonvascular and allows light to pass through it to the lens.
- *Choroid:* One of the middle-layer structures of the eyeball that contains blood vessels that supply the eye; it also absorbs light.
- *Ciliary body:* The structure that supports the ciliary muscles that control the curvature of the lens via attached suspensory ligaments.
- *Conjunctiva:* The mucous membrane that lines the eyelids and also covers the exposed anterior surface of the eyeball.
- *Iris:* The colored (pigmented) muscular apparatus behind the cornea.

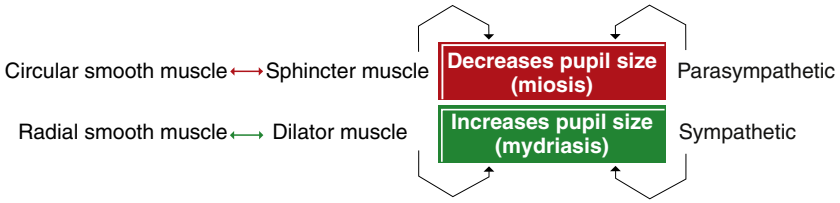

FIGURE 57-3 Different nervous systems control pupil size.

- *Pupil:* The variable-sized opening in the center of the iris that allows light to enter into the eyeball when the eyelids are open. The pupil is the rear portion of the window of the eye through which light passes to the lens and the retina (the cornea is the front part of this window).
- *Medial canthus:* The site of union of the upper and lower eyelids near the nose.
- *Lacrimal caruncle:* A small, red, rounded elevation covered by modified skin at the medial angle of the eye; the site of the lacrimal glands (see later in the chapter).
- *Lateral canthus:* The site of union of the upper and lower eyelids away from the nose.

LACRIMAL GLANDS

The eye is kept moist and healthy by an intricate network of connected canals, ducts, and sacs that work together. The **lacrimal glands** produce tears that bathe and cleanse the exposed anterior portion of the eye. **Tears** are composed of an isotonic, aqueous solution that contains an enzyme called **lysozyme,** which acts as an antibacterial to help prevent eye infections. Tears drain into the nasal cavity through the **lacrimal ducts.**

LAYERS OF THE EYE

Overall, the eye can be thought of as having three separate anatomic layers. The fibrous outer layer of the eye has two parts that are continuous with each other: the sclera and the **cornea.** The sclera is a tough, fibrous layer that protects and maintains the shape of the eye. The cornea is a nonvascular transparent portion of the outer layer that allows light to enter the eye. It is located at the very front of the eye and is continuous with the sclera. It is pain-sensitive (a protective function) and obtains nutrition from the **aqueous humor,** the clear watery fluid that circulates in the anterior and posterior chambers of the eye.

The vascular middle layer of the eye is composed of the **iris** (to the anterior), ciliary body, and choroid (to the posterior). These three structures are collectively called the **uvea.** The iris gives color to the eye and has an adjustable opening in the center called the **pupil.** The main function of the iris is to regulate the amount of light that enters the eye by causing the size of the pupil to vary. Pupil size is controlled by two smooth muscles. The **sphincter pupillae** muscle is controlled by the parasympathetic nervous system and constricts the diameter of the pupil (called *miosis*) (Figure 57-3). In contrast, the pupil is opened (called *mydriasis*) by a radial smooth muscle called the **dilator muscle.** It is composed of radiating fibers, like spokes of a wheel, which converge from the circumference of the iris toward its center. Sympathetic nervous system impulses control this muscle (see Figure 57-3).

FIGURE 57-4 Drug classes and their effects on pupil size.

The anterior portions of both the retina and choroid merge to become the ciliary body, which produces aqueous humor. This is the clear, watery fluid that circulates in both the anterior and posterior chambers, not to be confused with tears. Aqueous humor contributes, along with **vitreous humor** to the **intraocular pressure** of the eye. This is the internal pressure of all fluids against the tunics (retina, choroid, sclera) of the eye. Given the small space of the eye, any change in the volume of aqueous humor present can lead to increased or reduced intraocular pressure. Normally, the aqueous humor is removed from the **anterior chamber** via the **canal of Schlemm** at a rate that balances out its production by the ciliary body. The ciliary body also provides a support for the suspensory ligaments to which the lens is attached. The **lens** is the transparent crystalline structure of the eye, located directly behind the iris and the pupil. It has a biconvex (oval-spherical) shape and is held in place by suspensory ligaments that are attached to the **ciliary muscle.** Contraction of the ciliary muscle changes the shape of the lens. This function is important for visual accommodation as well as the focusing of light (and visual images) onto the retina. The ciliary muscle is controlled by the parasympathetic nervous system through the oculomotor cranial nerve (cranial nerve III). The lens divides the interior of the eyeball into posterior (rear) and anterior (forward) chambers. The larger chamber behind the lens is filled with a jellylike fluid called the **vitreous body.** The lens is transparent to allow light to pass through easily. A loss of lens transparency results in a visual condition called a **cataract.** A cataract is a gray-white opacity that can be seen within the lens. If cataracts are untreated, sight may eventually be completely lost. At the onset of a cataract, vision is blurred and may be further worsened by the glare of bright lights. *Diplopia* or double vision may also develop.

Before light rays reach the retina, they are focused into a sharp image by the lens of the eye. The elasticity of the lens enables it to change its shape and focusing power. This process is called **accommodation** and is facilitated by the ciliary body. Paralysis of accommodation is called **cycloplegia. Mydriatics** are drugs that dilate the pupil (e.g., apraclonidine). Drugs that constrict the pupil are called **miotics** (e.g., acetylcholine, pilocarpine). Drugs that paralyze the ciliary body are called **cycloplegics,** but they also have mydriatic properties (e.g., atropine, cyclopentolate) (Figure 57-4).

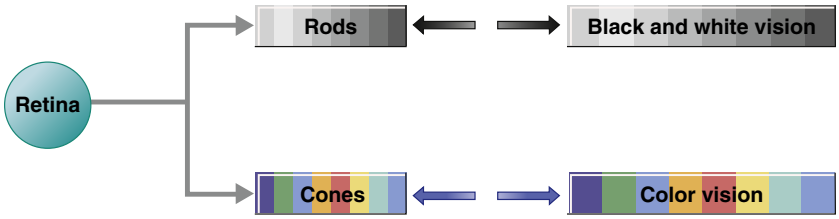

FIGURE 57-5 Function of rods and cones in relation to color vision.

FIGURE 57-6 How increased aqueous humor can result in impaired vision. *IOP,* Intraocular pressure.

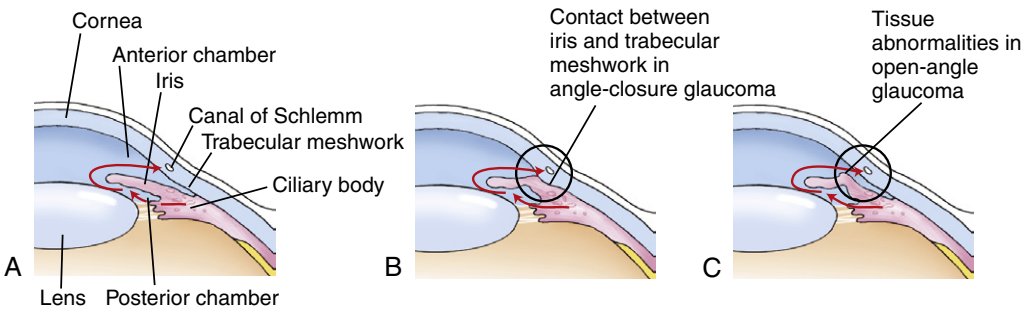

FIGURE 57-7 Main structures of the eye and an enlargement of the canal of Schlemm showing the flow of aqueous humor. **A,** Flow in a normal eye. **B,** In angle-closure glaucoma, the closure of the anterior angle due to contact between the iris and the trabecular meshwork prevents aqueous humor from exiting through the canal of Schlemm, which leads to increased intraocular pressure. **C,** In open-angle glaucoma, the anterior angle remains open, but the canal of Schlemm is obstructed by tissue abnormalities. (Modified from McKenry LM, Tessier E, Hogan MA: *Mosby's pharmacology in nursing,* ed 22, St Louis, 2006, Mosby.)

All of these medications are used to facilitate visualization of the inner eye during ophthalmic examinations.

The third and inner layer of the eye is a thin delicate layer known as the **retina.** It contains light-sensitive photoreceptors called **rods** and **cones.** The basic function of the retina is to receive the light image formed by the lens and to convert it via the rods and cones into the neural signals that support vision. Rods produce black-and-white vision, including shades of gray, and are especially sensitive in low light; cones are responsible for color vision (Figure 57-5). In addition, rods are more active in providing peripheral (to-the-side) vision, whereas cones are more active in central (straight-ahead) vision. In the posterior central part of the retina, the nerve fibers of retinal cells join to form the **optic nerve.** The function of this nerve is to connect the retina with the visual center of the brain, located within the occipital lobe that extends above and behind the cerebellum. It is this portion of the brain that interprets incoming visual stimuli.

PATHOPHYSIOLOGY OF GLAUCOMA

Glaucoma is a group of eye disorders that damages the optic nerve. In most cases, this is due to increased intraocular pressure that is caused by abnormally elevated levels of aqueous humor. Glaucoma occurs when the aqueous humor is not drained through the canal of Schlemm as quickly as it is formed by the ciliary body. The accumulated aqueous humor creates a backward pressure that pushes the vitreous humor against the retina. Continued pressure on the retina destroys its neurons, which leads to impaired vision and eventual blindness (Figure 57-6). Unfortunately, glaucoma is often without early symptoms, and many patients are not diagnosed until some permanent sight loss has occurred.

Two major types of glaucoma are discussed in this chapter: **angle-closure glaucoma** and **open-angle glaucoma.** Figure 57-7 shows the pathophysiology of each and provides an enlarged view of the involved eye structures. Table 57-1 lists additional characteristic features of each type. Glaucoma can be a primary illness (occurring on its own), or it can be secondary to another eye condition or injury (e.g., posttraumatic glaucoma). Congenital glaucoma can also occur in infants. The visual and optic nerve changes typical of glaucoma can also occur in the absence of increased intraocular pressure (normotensive glaucoma). There are a few other less common forms of glaucoma (e.g., pigmentary glaucoma, pseudoexfoliative glaucoma) that are beyond the scope of this chapter.

TABLE 57-1 GLAUCOMA: TYPES AND CHARACTERISTICS

	ANGLE-CLOSURE GLAUCOMA	OPEN-ANGLE GLAUCOMA
Synonyms	Closed-angle glaucoma, narrow-angle glaucoma, congestive glaucoma, pupillary closure glaucoma	Chronic glaucoma, wide-angle glaucoma, simple glaucoma
Chronicity	Acute (can cause rapid vision loss)	Chronic
Relative incidence	Less common	More common
Nature of angle	Narrow	Larger
Most common age of onset and race	30 yr or older, white	30 yr or older, African American
Major symptoms	Blurred vision, severe headaches, eye pain	Blurred vision, occasional headaches
Treatment	Topical or systemic drugs, surgery	Topical or systemic drugs, surgery

TABLE 57-2 ANTIGLAUCOMA DRUGS: EFFECTS ON AQUEOUS HUMOR

DRUG CLASS	INCREASED DRAINAGE	DECREASED PRODUCTION	COLOR-CODED EYEDROPPER
Miotics			
Direct-acting cholinergics	+++	0	Green
Indirect-acting cholinergics (cholinesterase inhibitors)	+++	0	Green
Mydriatics			
Sympathomimetics	++	+++	Purple
Others			
Beta blockers	+	+++	Yellow, blue
Carbonic anhydrase inhibitors	0	+++	Orange
Osmotic diuretics	+++	0	
Prostaglandin agonists	+++	0	Clear, teal

0, No effect; +, minor effect; ++, moderate effect; ++, pronounced effect.

PHARMACOLOGY OVERVIEW

Medications used to treat disorders of the eye can be divided into several major drug groups: antiglaucoma drugs, antimicrobials, antiinflammatory drugs, topical anesthetics, diagnostic drugs, antiallergic drugs, and lubricants and moisturizers. There are also a variety of combination drug products that include two or more medications from different subclasses. The reader can assume the same therapeutic indications and drug effects for these combination products as for the single-ingredient drug products corresponding to their individual components. The focus of this chapter is on commonly used therapeutic medications.

A multitude of various products are also available for use in the care of contact lenses, including contact lens–cleaning enzymes, irrigating solutions, and eye washes. Their use is fairly straightforward, and they carry limited risk. More complicated surgical drugs are beyond the scope of this chapter. The reader is advised to refer to the manufacturer's packaging information for details about any unfamiliar product encountered in clinical practice.

ANTIGLAUCOMA DRUGS

Treatment of glaucoma involves reducing intraocular pressure by either increasing the drainage of aqueous humor or decreasing its production. Some drugs may do both. Drug therapy can delay and possibly even prevent the development of glaucoma. Glaucoma eyedrops are color-coded according to medication class to aid the patient in identification, and they are listed in Table 57-2. Drug classes used to reduce intraocular pressure include the following:

- Direct-acting cholinergics (also called *miotics* and *parasympathomimetic drugs*)
- Indirect-acting cholinergics (also called *miotics, cholinesterase inhibitors,* and *parasympathomimetic drugs*)
- Adrenergics (also called *mydriatics* and *sympathomimetic drugs*)
- Antiadrenergics (beta blockers; also called *sympatholytic drugs*)
- Carbonic anhydrase inhibitors
- Osmotic diuretics
- Prostaglandin agonists

See Table 57-2 for a comparison of the effects of these drugs on aqueous humor.

CHOLINERGIC DRUGS (MIOTICS)

There are two categories of ocular parasympathetic drugs, more concisely referred to as cholinergic drugs: direct acting and indirect acting. Directing-acting cholinergics include acetylcholine, carbachol, and pilocarpine. Indirect-acting drugs, which are also called *cholinesterase inhibitors,* include echothiophate, currently the only available drug in this class. Because the primary drug effect of these drugs is pupillary constriction, or *miosis* (see later), they are also commonly called *miotics.*

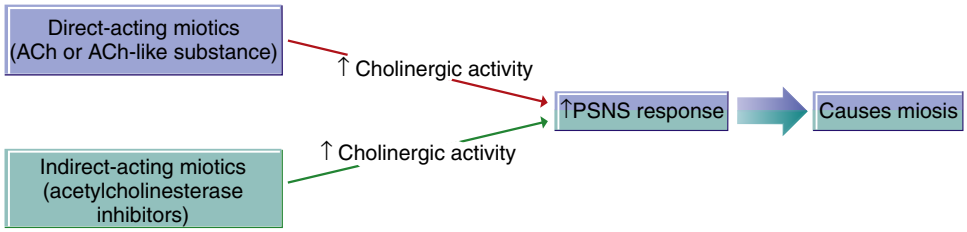

FIGURE 57-8 Cholinergic response of miosis to parasympathomimetic drugs. *ACh,* Acetylcholine; *PSNS,* parasympathetic nervous system.

FIGURE 57-9 Therapeutic effects of direct- and indirect-acting miotics on glaucoma. *IOP,* Intraocular pressure.

Mechanism of Action and Drug Effects

Acetylcholine is the neurochemical mediator of nerve impulses in the parasympathetic nervous system. It stimulates parasympathetic or cholinergic receptors located in the brain and throughout the body along parasympathetic nerve branches. This results in several effects on the eye: miosis (pupillary constriction), vasodilation of blood vessels in and around the eye, contraction of ciliary muscles, drainage of aqueous humor, and reduced intraocular pressure. Ciliary muscle contraction promotes aqueous humor drainage by widening the space where the drainage occurs. Miosis promotes aqueous humor drainage by causing the iris to stretch, which also serves to widen this space.

Both direct- and indirect-acting miotics have effects similar to those of acetylcholine, but their actions are more prolonged (Figure 57-8). The direct-acting miotics are able to directly stimulate ocular cholinergic receptors and mimic acetylcholine. Indirect-acting miotics work by binding to and inactivating the cholinesterases acetylcholinesterase and pseudocholinesterase, the enzymes that break down acetylcholine. As a result, acetylcholine accumulates and acts longer at the cholinergic receptor sites. This leads to drug effects that include miosis, ciliary muscle contraction, enhanced aqueous humor drainage, and reduced intraocular pressure by an average of 20% to 30% (Figure 57-9). Drug-induced miotic effects may be less pronounced in individuals with dark eyes (e.g., brown or hazel) than in those with lighter eyes (e.g., blue). This is because the pigment of the iris also absorbs the drug (which reduces its therapeutic effects), and dark eyes have more pigment.

Indications

The direct- and indirect-acting miotics are used for treatment of open-angle glaucoma, angle-closure glaucoma, and convergent strabismus (a condition in which one eye points toward the other, or "cross-eye") and in ocular surgery. They are also used to reverse the effect of mydriatic (pupil-dilating) drugs after ophthalmic examination. Specific indications may vary for different drugs, as shown in Table 57-3.

TABLE 57-3 MIOTICS: INDICATIONS

DRUG	INDICATIONS
acetylcholine	Need for complete and rapid miosis after cataract lens extraction, iridectomy
carbachol	Open-angle glaucoma
echothiophate	Accommodative esotropia, obstructive aqueous humor outflow, open- and angle-closure glaucoma after iridectomy
pilocarpine	Open-angle glaucoma, secondary glaucoma after iridectomy, reversal of cycloplegia

Contraindications

Contraindications to the use of miotics include known drug allergy and any serious active eye disorder in which induction of miosis might be harmful.

Adverse Effects

Most of the adverse effects from the use of cholinergic and cholinergic inhibitors (miotics) are local and limited to the eye. Adverse effects are more likely to occur with indirect-acting miotics because they have longer-lasting effects. Effects include blurred vision, drug-induced myopia (nearsightedness), and accommodative spasms. Such effects are secondary to contraction of the ciliary muscle. Miotic drugs also cause vasodilation of blood vessels supplying the conjunctiva, iris, and ciliary body, which may lead to vascular congestion and ocular inflammation. Other undesirable effects include temporary stinging upon drug instillation, reduced nighttime or low-light vision, conjunctivitis, lacrimation (tearing), twitching of the eyelids (blepharospasm), and eye or brow pain. Prolonged use can result in iris cysts, lens opacities, and, rarely, retinal detachment. Systemic effects are uncommon but are more likely to occur with cholinesterase inhibitors (indirect-acting miotics). See Chapters 20 and 21 for more information on the systemic effects of these drugs.

Interactions

Drug interactions are unlikely because of the local actions of these drugs. When miotic drugs are given with topical

DOSAGES

Selected Miotics

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
acetylcholine (Miochol-E) (C)	Direct-acting cholinergic	0.5 to 2 mL preoperatively	Need for surgical miosis
♦ echothiophate (Phospholine Iodide) (C)	Indirect-acting cholinergic	1 drop 1-2 times daily	Early and advanced chronic open-angle glaucoma; glaucoma secondary to cataract surgery; accommodative esotropia
♦ pilocarpine (Pilocar, Isopto Carpine, Akarpine, Pilopine HS) (C)	Direct-acting cholinergic	Solution: 1-2 drops 3-4 times daily Gel: 0.5-inch ribbon into lower conjunctival sac at bedtime (use any other eyedrops at least 5 min before gel)	Chronic open-angle and angle-closure glaucoma; acute angle-closure glaucoma; preoperative and postoperative intraocular hypertension; need for reversal of drug-induced mydriasis

adrenergics, antiadrenergics (e.g., beta blockers), or carbonic anhydrase inhibitors, additive lowering effects on intraocular pressure can be seen. Systemic cholinergic drugs can theoretically have additive cholinergic effects when given with miotics. Indirect-acting miotics (cholinesterase inhibitors) may also potentiate the effects of the neuromuscular blocker succinylcholine (see Chapter 11).

Dosages

For dosage information on selected miotic drugs, see the table on this page.

DRUG PROFILES

Direct-acting ocular cholinergics include acetylcholine (Miochol-E), carbachol (Carboptic), and pilocarpine (Pilocar). Indirect-acting drugs, which are also called *cholinesterase inhibitors,* include echothiophate (Phospholine Iodide). These drugs are used for management of glaucoma, as adjuncts for ocular surgery, and for treatment of various other ophthalmic conditions.

DIRECT-ACTING MIOTICS

acetylcholine

Acetylcholine (Miochol-E) is a direct-acting cholinergic drug that is used to produce miosis during ophthalmic surgery. It is a pharmaceutical form of the naturally occurring neurotransmitter in the body. It has very quick onset and may begin to work almost immediately. It is administered directly into the anterior chamber of the eye before and after securing one or more sutures.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	Instant	Instant	3 min	10 min

♦ pilocarpine

Pilocarpine (Pilocar) is a direct-acting cholinergic drug that is used as a miotic in the treatment of glaucoma. Pilocarpine is available in different strengths as an ocular gel and solution. One special formulation is the pilocarpine ocular insert system (Ocusert Pilo-20), which is applied once weekly by the patient.

Pharmacokinetics (Immediate-Release Formulation)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	10-30 min	75 min	Unknown	4-8 hr

INDIRECT-ACTING MIOTIC

♦ echothiophate

Echothiophate (Phospholine Iodide) is an indirect-acting cholinergic that has an organophosphate structure and acts by phosphorylating cholinesterase enzymes. This effect is normally irreversible until new enzymes are synthesized by the body, which may take days or even weeks. For these reasons, this drug is considered to be long acting.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	10-30 min	24 hr	Long	7-28 days

SYMPATHOMIMETICS (MYDRIATICS)

Sympathomimetic drugs are used for the treatment of glaucoma and ocular hypertension. These drugs include the alpha receptor agonists brimonidine (Alphagan P) and apraclonidine (Iopidine), as well as the alpha and beta receptor agonists epinephryl (Epinal) and dipivefrin (Propine).

Mechanism of Action and Drug Effects

Sympathomimetic drugs mimic the sympathetic neurotransmitters norepinephrine and epinephrine. They stimulate the dilator muscle to contract by means of alpha and/or beta receptor interaction. This stimulation results in increased pupil size or *mydriasis* (Figure 57-10). Dilation is seen within minutes of instillation of the ophthalmic drops and lasts for several hours, during which time the intraocular pressure is reduced (Figure 57-11). Alpha receptor stimulation reduces intraocular pressure by enhancing aqueous humor outflow through the canal of Schlemm. Production of aqueous humor by the ciliary body is also reduced. Both of these effects appear to be dose dependent.

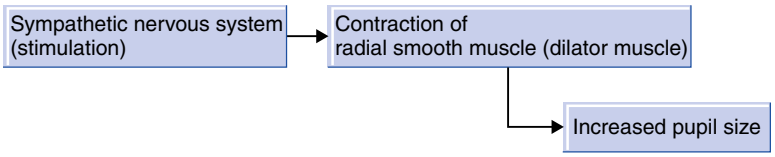

FIGURE 57-10 Mechanism of mydriasis.

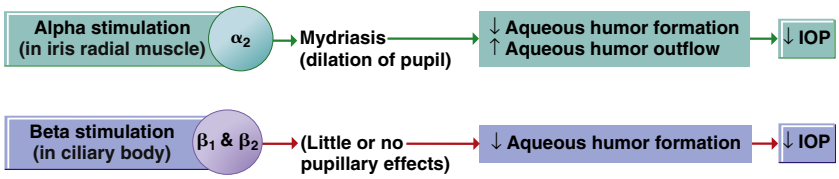

FIGURE 57-11 Ocular effects of alpha (α) and beta (β) stimulation. *IOP,* Intraocular pressure.

DOSAGES

Selected Ocular Sympathomimetics

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
apraclonidine (Iopidine) (C)	Direct acting	0.5% solution: 1-2 drops 3 times daily	Short-term adjunctive therapy for glaucoma not controlled by other drugs
♦ dipivefrin (Propine) (C)	Direct acting	1 drop q12h	Chronic open-angle glaucoma

Indications

Both epinephrine and dipivefrin are used to reduce elevated intraocular pressure in the treatment of chronic open-angle glaucoma, either as initial therapy or as long-term therapy. Increases in intraocular pressure during ophthalmic surgery are usually mediated via increased catecholamine stimulation of the sympathetic nervous system. Apraclonidine stimulates the alpha$_2$ receptors, which oppose those effects, and thus corrects the surgery-induced elevation in intraocular pressure. Brimonidine also has primarily alpha$_2$ activity but is used to lower intraocular pressure in patients with open-angle glaucoma or ocular hypertension.

Contraindications

Contraindications for the sympathomimetic ophthalmics include known drug allergy.

Adverse Effects

Adverse effects of the sympathomimetic mydriatics are primarily limited to ocular effects and include burning, eye pain, and lacrimation. Such effects are usually temporary and may subside as the patient grows accustomed to the medication. Other ocular effects may include conjunctival hyperemia, localized melanin deposits in the conjunctiva, and release of pigment granules from the iris. Although systemic effects associated with the use of sympathomimetic mydriatics are uncommon, they are theoretically possible, especially with the use of larger doses or prolonged drug therapy. They include cardiovascular effects such as extrasystoles, tachycardia, and hypertension. Other effects that may be noticed are headache and faintness.

Interactions

With sufficient topical absorption, sympathomimetic mydriatics have the potential to react with other drugs. Cardiac dysrhythmias are potentiated when mydriatic drugs are given with halogenated anesthetics, cardiac glycosides, thyroid hormones, or tricyclic antidepressants.

Dosages

For dosage information on sympathomimetic drugs, see the table on this page.

DRUG PROFILES

Sympathomimetic ophthalmic drugs include dipivefrin (Propine), epinephryl (Epinal), apraclonidine (Iopidine), and brimonidine (Alphagan P). These drugs are used for management of glaucoma and ocular hypertension, and for ocular surgery.

apraclonidine

Apraclonidine (Iopidine) is structurally and pharmacologically related to the alpha$_2$ stimulant clonidine. It reduces intraocular pressure 23% to 39% by stimulating alpha$_2$ and beta$_2$ receptors. It also prevents ocular vasoconstriction, which reduces ocular blood pressure as well as aqueous humor formation. Apraclonidine is primarily used to inhibit perioperative intraocular pressure increases, rather than to treat glaucoma. Brimonidine (Alphagan P) is a similar drug but is used primarily for glaucoma.

Pharmacokinetics (apraclonidine)

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	1 hr	3-5 hr	8 hr	12 hr

♦ dipivefrin

Dipivefrin (Propine) is a synthetic sympathomimetic miotic drug. It is a prodrug of epinephrine that has little or no pharmacologic activity until hydrolyzed in the eye to two chemically modified forms of epinephrine. These chemical alterations account for the main advantage of this drug over epinephrine: it has enhanced lipophilicity (fat solubility) and can better penetrate into the tissues of the anterior chamber of the eye. This quality also reduces the likelihood of any systemic adverse effects. Dipivefrin typically reduces mean intraocular pressure approximately 15% to 25%. On a weight basis, dipivefrin is 4 to 11 times as potent as epinephrine in reducing intraocular pressure and 5 to 12 times as potent as epinephrine in terms of its mydriatic effects. Epinephryl (Epinal) is a newer drug with similar properties and uses.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	30 min	1 hr	1-3 hr	12 hr

BETA-ADRENERGIC BLOCKERS

The antiglaucoma beta-adrenergic blockers that reduce intraocular pressure include the beta$_1$-selective drugs betaxolol and levobetaxolol.

Mechanism of Action and Drug Effects

The ophthalmic beta blockers reduce both elevated and normal intraocular pressure. They reduce intraocular pressure by reducing aqueous humor formation. In addition, timolol may produce a minimal increase in aqueous outflow.

Indications

Ophthalmic beta blockers are used to reduce elevated intraocular pressure in various conditions, including chronic open-angle glaucoma and ocular hypertension. They may also be used alone or in combination with a topical miotic (e.g., echothiophate iodide, pilocarpine), topical dipivefrin, and/or systemic carbonic anhydrase inhibitors. When used in combination, these drugs may have an additive intraocular pressure-lowering effect. They may also be used to treat some forms of angle-closure glaucoma.

Contraindications

Contraindications for ophthalmic beta blockers include known drug allergy and any ocular condition for which beta-receptor blockade might be harmful.

Adverse Effects

The adverse effects of antiglaucoma beta blockers are primarily limited to ocular effects. The most common ocular effects are transient burning and discomfort. Other effects include blurred vision, pain, photophobia, lacrimation, blepharitis, keratitis (inflammation of the cornea), and decreased corneal sensitivity. Because these drugs are administered topically, few, if any, systemic effects are expected. Theoretical systemic effects include bradycardia, bronchospasm, headache, and dizziness as described for systemic beta blockers in Chapter 19. However, ocular beta blockers have not been shown to affect glucose metabolism.

Interactions

Drug interactions with systemic drugs are unlikely due to the primarily localized nature of ophthalmically administered drugs. Theoretically, ophthalmic beta blockers can have additive therapeutic and/or adverse effects when given with systemically administered beta blockers or other cardiovascular drugs (e.g., calcium channel blockers).

Dosages

For dosage information on beta-adrenergic blockers, see the table on this page.

DRUG PROFILES

The currently available ophthalmic beta-blocking drugs are betaxolol (Betoptic), carteolol (Ocupress), levobunolol (Betagan), levobetaxolol (Betaxon), metipranolol (OptiPranolol), and timolol (Timoptic). These drugs are used to treat glaucoma and ocular hypertension.

♦ betaxolol

Betaxolol (Betoptic) is a beta$_1$-selective beta blocker. It is one of the most potent and selective beta-blocking drugs. Its ability to decrease aqueous humor formation and reduce

DOSAGES

Selected Ocular Beta Blockers

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ betaxolol (Betoptic, Betoptic S) (C)	Direct acting	1-2 drops twice daily	Chronic open-angle glaucoma; ocular hypertension
♦ timolol (Betimol, Timoptic, Timoptic-XE) (C)	Direct acting	Solution: 1 drop twice daily Gel-forming solution: 1 drop daily	Open-angle glaucoma; ocular hypertension

intraocular pressure has made it an excellent drug for the treatment of ocular disorders such as open-angle glaucoma and ocular hypertension.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	0.5-1 hr	2 hr	Unknown	More than 12 hr

♦ timolol

Timolol (Timoptic) differs slightly from the other ophthalmic beta blockers in that it may increase the outflow of aqueous humor as well as decrease its formation. The drug acts at both $beta_1$ and $beta_2$ receptors and is indicated for the treatment of open-angle glaucoma and ocular hypertension. It is available in various liquid forms, both with and without preservatives. Preservative-free products were developed because of patient allergies to benzalkonium chloride, a commonly used preservative. Timolol is also available in a gel-forming solution (with preservatives). The gel-forming products are longer acting and allow for once-daily dosing, a convenience over the twice-daily dosing that many patients require of the other timolol formulations.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	15-30 min	1-2 hr	Unknown	12-24 hr

CARBONIC ANHYDRASE INHIBITORS

Ophthalmic carbonic anhydrase inhibitors include brinzolamide (Azopt) and dorzolamide (Trusopt). These two drugs are available only in topical ophthalmic form. Systemic carbonic anhydrase inhibitors for oral use are sometimes also used as adjunct drug therapy for glaucoma and are described in Chapter 28. Both drugs are also sulfonamides and are chemically related to the sulfonamide antibiotics (see Chapter 38). They are to be used with caution in patients who are allergic to sulfa antibiotics.

Mechanism of Action and Drug Effects

Carbonic anhydrase inhibitors work by inhibiting the enzyme carbonic anhydrase, which results in decreased intraocular pressure by reduction of aqueous humor formation.

Indications

Ocular carbonic anhydrase inhibitors are used primarily for management of glaucoma, including both open-angle and angle-closure glaucoma; they may also be used preoperatively to control intraocular pressure.

Contraindications

Contraindications include known drug allergy and any ocular condition for which their use might be harmful in the judgment of an ophthalmologist. Allergy to sulfonamide antibiotics is a precaution, not a contraindication; however, patients need to be educated on the possibility of cross-reaction.

Adverse Effects

Systemic absorption of these drugs occurs, although systemic adverse effects are unlikely. The same adverse effects listed for sulfonamide antibiotics in Chapter 38 can theoretically occur with these drugs. Patients with sulfa allergies may develop cross-sensitivities to the carbonic anhydrase inhibitors.

Interactions

The systemic use of carbonic anhydrase inhibitors can result in several significant drug interactions, and the ocular carbonic anhydrase inhibitors have a theoretical (but less likely) potential for these interactions. See Chapter 28 for information on systemic drug interactions.

Dosages

For dosage information on the carbonic anhydrase inhibitor dorzolamide, see the table on this page.

DRUG PROFILE

There are currently two ocular carbonic anhydrase inhibitors: brinzolamide (Azopt) and dorzolamide (Trusopt).

♦ dorzolamide

Dorzolamide (Trusopt) is indicated for treatment of elevated intraocular pressure associated with either ocular hypertension or open-angle glaucoma. It is available only as an ophthalmic solution. The other drug in this class, brinzolamide, has comparable indications, dosages, and pharmacokinetics.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	Rapid	Variable	3-4 mo	Variable

DOSAGES

Ocular Carbonic Anhydrase Inhibitor

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ dorzolamide (Trusopt) (C)	Carbonic anhydrase inhibitor	1 drop 3 times daily	Open-angle glaucoma; ocular hypertension

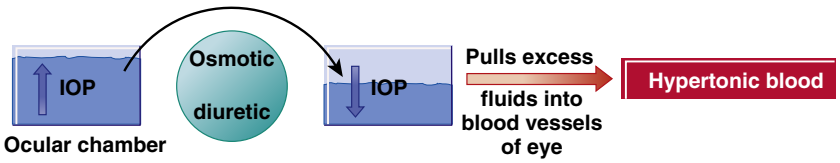

FIGURE 57-12 Mechanism and ocular effects of osmotic diuretics. *IOP,* Intraocular pressure.

TABLE 57-4 OSMOTIC DIURETICS: ADVERSE EFFECTS

BODY SYSTEM	ADVERSE EFFECTS
Cardiovascular	Edema, thrombophlebitis, hypotension, hypertension, tachycardia, angina-like chest pains, fever, chills
Central nervous	Dizziness, headache, convulsions, rebound increased intracranial pressure, confusion
Electrolytes	Fluid electrolyte imbalances, acidosis, dehydration
Eyes, ears, nose, throat	Loss of hearing, blurred vision, nasal congestion
Gastrointestinal	Nausea, vomiting, dry mouth, diarrhea
Genitourinary	Marked diuresis, urinary retention, thirst

OSMOTIC DIURETICS

Osmotic drugs may be administered either intravenously, orally, or topically to reduce intraocular pressure. The osmotic diuretics that are most commonly used for this purpose are glycerin and mannitol.

Mechanism of Action and Drug Effects

Osmotic diuretics reduce ocular hypertension by causing the blood to become hypertonic in relation to both intraocular and spinal fluids. This creates an osmotic gradient that draws water from the aqueous and vitreous humors into the bloodstream, which causes a reduction in the volume of intraocular fluid; the result is a decrease in intraocular pressure (Figure 57-12). Systemic (nonocular) effects of these drugs are discussed in Chapter 28.

Indications

Ocular uses for osmotic diuretics include treatment of acute glaucoma episodes and reduction of intraocular pressure before or after ocular surgery. Typically, glycerin is used first; if the treatment is unsuccessful, mannitol is tried. Isosorbide and urea are two other osmotic drugs that may also be used in similar situations. They are usually administered after glycerin or mannitol has failed.

Contraindications

Osmotic diuretics are contraindicated in patients with known drug allergy, pronounced anuria, acute pulmonary edema, cardiac decompensation, and severe dehydration, because they can worsen all of these conditions.

Adverse Effects

The most frequent reactions to osmotic diuretics are nausea, vomiting, and headache. The most significant adverse effects are fluid and electrolyte imbalances. Other effects are possible irritation and thrombosis at the injection site. Other potential adverse effects are listed in Table 57-4.

Interactions

The only significant drug interaction is increased lithium excretion associated with mannitol and urea.

Dosages

For dosage information on osmotic drugs, see the table on p. 928.

DRUG PROFILES

Osmotic diuretics include mannitol, glycerin, urea, and isosorbide. These drugs are normally reserved for acute reduction of intraocular pressure during glaucoma crises and perioperative reduction of intraocular pressure in ophthalmic surgery.

glycerin

Glycerin is an osmotic drug given orally to lower intraocular pressure or topically to reduce superficial corneal edema. Another use is before iridectomy in individuals with acute narrow-angle glaucoma. It is also used preoperatively and/or postoperatively in procedures such as treatment of congenital glaucoma, repair of retinal detachment, cataract extraction, and keratoplasty (corneal transplant). It may also be used in the management of secondary glaucoma.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	10-30 min	1-1.5 hr	30-45 min	4-5 hr

mannitol

Mannitol (Osmitrol) is administered by intravenous infusion to reduce elevated intraocular pressure when the pressure cannot be lowered by other methods. Mannitol is effective in treating acute episodes of angle-closure, absolute, or secondary glaucoma and in lowering intraocular pressure before intraocular surgery. Mannitol does not penetrate the eye and may be used when irritation is present, unlike some of the other osmotic drugs, such as urea.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
IV	30-60 min	1 hr	15-100 min	6-8 hr

PROSTAGLANDIN AGONISTS

The newest class of drugs used to treat glaucoma is the prostaglandin agonists. There are currently three drugs in this class: latanoprost (Xalatan), travoprost (Travatan-Z), and bimatoprost (Lumigan).

DOSAGES

Osmotic Diuretics

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS/USES
glycerin (Ophthalgan) (C)	Organic alcohol	1-2 drops before eye exam as lubricant; more if needed during exam	Gonioscopy of edematous cornea
mannitol (Osmitrol) (C)	Organic alcohol	IV: 1.5-2 g/kg infused over at least 30 min; for preoperative use, give 1-1.5 hr before surgery	Acute reduction of elevated intraocular pressure

IV, Intravenous.

DOSAGES

Ocular Prostaglandin Agonist

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
♦ latanoprost (Xalatan) (C)	Prostaglandin	1 drop every day in evening	Open-angle glaucoma and ocular hypertension in patients who are intolerant of or whose condition is uncontrolled by other drugs

Mechanism of Action and Drug Effects

Prostaglandins reduce intraocular pressure by increasing the outflow of aqueous humor between the uvea and sclera as well as via the usual exit through the trabecular meshwork (see Figure 57-7). A single dose of a prostaglandin agonist lowers intraocular pressure for 20 to 24 hours, which allows a single daily dosing regimen. The drug effects are primarily limited to these ocular effects.

Indications

Prostaglandin agonists are used in the treatment of glaucoma.

Contraindications

The only usual contraindication is known drug allergy.

Adverse Effects

Prostaglandin agonists are generally well tolerated. Adverse effects include foreign body sensation, punctate epithelial keratopathy (dotted appearance of the cornea), stinging, conjunctival hyperemia ("bloodshot" eyes), blurred vision, itching, and burning. Systemic effects occur in a small percentage of patients and include skin reactions, upper respiratory tract infections, and headache. There is one unique adverse effect associated with all prostaglandin agonists: in some people with hazel, green, or bluish-brown eye color, eye color will turn permanently brown, even if the medication is discontinued. This adverse effect appears to be cosmetic only with no known ill effects on the eye.

Interactions

Concurrent administration of prostaglandin agonists with any other eyedrops containing the preservative thimerosal may result in precipitation. It is recommended that the two medications be administered at least 5 minutes apart.

Dosages

For dosage information on the prostaglandin agonist latanoprost, see the table on this page.

DRUG PROFILE

♦ latanoprost

Latanoprost is a prodrug of a naturally occurring prostaglandin known as *prostaglandin F_2-alpha.* When it is administered, it is converted by hydrolysis (with water from ocular fluids) to prostaglandin F_2-alpha, which in turn reduces intraocular pressure. Latanoprost is available only in eyedrop form. About 3% to 10% of patients treated with latanoprost (Xalatan) have shown increased iris pigmentation after 3 to 4½ months of treatment.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	30-60 min	2 hr	17 min	24 hr

ANTIMICROBIAL DRUGS

A variety of infections can occur in the eye; many are self-limiting. However, some infections require the use of ocular antimicrobials to be eliminated. Topical antimicrobials used to treat ocular infections include antibacterial, antifungal, and antiviral drugs. All require a prescription. Many of these drugs are also available for systemic administration for treatment of infections elsewhere in the body. The most commonly used antimicrobials from the main antimicrobial drug classes are discussed in this chapter. Some common eye infections may require antibiotic therapy and are listed in Table 57-5. The choice of a particular ophthalmic antimicrobial drug is based on the following:

- Clinical experience
- Sensitivity and characteristics of the organisms most likely to have caused the infection
- Characteristics of the disease itself
- Sensitivity and response of the patient
- Laboratory results (cultures and sensitivity testing)

TABLE 57-5 COMMON OCULAR INFECTIONS

INFECTION	DESCRIPTION
Blepharitis	Inflammation of the eyelids.
Conjunctivitis	Inflammation of the conjunctiva (the mucous membrane lining the back of the eyelids and the front of the eye except the cornea). It may be bacterial or viral and is often associated with common colds. When caused by *Haemophilus* organisms, it is commonly called *pink eye*. It is highly contagious but usually self-limiting.
Hordeolum (sty)	Acute localized infection of the eyelash follicles and the glands of the anterior lid. It results in the formation of a small abscess or cyst.
Keratitis	Inflammation of the cornea caused by bacterial infection. Herpes simplex keratitis is caused by viral infection.
Uveitis	Infection of the uveal tract or the vascular layer of the eye, which includes the iris, ciliary body, and choroid.
Endophthalmitis	Inflammation of the inner eye structure caused by bacteria.

Mechanism of Action and Drug Effects

Topical antimicrobials used to treat infections of the eye work to destroy the invading organism. Their specific antimicrobial actions are similar to those described for systemically administered drugs, which are discussed in Chapters 38, 39, 40, and 42. Some antimicrobials destroy the causative organism, whereas others simply inhibit the organism's growth, allowing the body's immune system to fight the infection.

Indications

The indication for ocular antimicrobials is known or suspected infection with one or more specific microorganisms. Empirical treatment is based on reasonable clinical evaluation of presenting signs and symptoms. Topical use of antimicrobials helps prevent the antimicrobial drug resistance that could arise from unnecessary systemic use. However, systemic antimicrobials may be administered to treat more severe ocular infections.

Contraindications

Contraindications to the use of antimicrobials include known drug allergy or other severe previous adverse drug reaction.

Adverse Effects

The most common adverse effects of ocular antibiotics are local and transient inflammation, burning, stinging, urticaria, dermatitis, angioedema, and drug hypersensitivity. Topical application of antimicrobial drugs may also interfere with growth of the normal bacterial flora of the eye, which may encourage the growth of other, more harmful organisms. If large doses are given, systemic side effects are possible.

Interactions

Systemic drug interactions are unlikely due to the primarily local effects of ocular antimicrobials. One possible interaction involves the concurrent use of antibiotics and corticosteroids (e.g., dexamethasone). Corticosteroids have immunosuppressive effects that may impede the therapeutic effects of ocular antimicrobials.

Dosages

For dosage information on ocular antimicrobials, see the table on p. 930.

DRUG PROFILES

AMINOGLYCOSIDES

Aminoglycosides (see Chapter 39) are antimicrobials that destroy bacteria by interfering with protein synthesis in bacterial cells, which leads to bacteria death. Aminoglycosides used to treat ocular infections include gentamicin (Garamycin) and tobramycin (Tobrex). Adverse effects include swollen eyelids, mydriasis, and local erythema. Systemic reactions are rare because of poor topical absorption. Overgrowth of nonsusceptible organisms, which can lead to eye infections that are resistant to treatment, is a possibility.

♦ gentamicin

Gentamicin (Garamycin) is effective against a wide variety of gram-negative and gram-positive organisms. It is particularly useful against *Pseudomonas, Proteus,* and *Klebsiella* organisms. Gram-positive organisms that are effectively destroyed by gentamicin include staphylococci and streptococci that have developed resistance to other antibiotics. Gentamicin is available as an ophthalmic ointment and a solution.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	Variable	Immediate	Unknown	6-12 hr

MACROLIDE ANTIBIOTICS

Macrolide antibiotics include erythromycin, azithromycin, and other drugs (see Chapter 38). Erythromycin is the most commonly used macrolide for ophthalmic use.

♦ erythromycin

Erythromycin is a macrolide antibiotic indicated for the treatment of various ophthalmic infections, as well as other infections. It is available in oral and intravenous forms and as an ophthalmic ointment. Erythromycin eye ointment is indicated for the treatment of neonatal conjunctivitis caused by *Chlamydia trachomatis* and for the prevention of eye infections in newborns that may be caused by *Neisseria gonorrhoeae* or other susceptible organisms.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	Variable	Immediate	Unknown	Variable

DOSAGES

Selected Ocular Antimicrobials

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
Antibacterial Drugs			
♦ bacitracin (AK-Tracin) (C)	Miscellaneous antibiotic	Solution: 1-2 drops q1-4h Ointment: 0.5-inch ribbon into lower conjunctival sac 3-4 times daily	Bacterial ocular infections
♦ ciprofloxacin (Ciloxan) (C)	Quinolone	Solution: 1-2 drops every 2 hr for 2 days, and then 2 drops every 4 hr for 5 days Ointment: 0.5-inch ribbon tid for 2 days, then 0.5-inch ribbon daily for 5 days	
♦ erythromycin (Ilotycin) (C)	Macrolide	Ointment: 0.5-inch ribbon 2-6 times/day	
♦ gentamicin (Genoptic, others) (C)	Aminoglycoside	Solution: 1-2 drops every 2-4 hr Ointment: 0.5-inch ribbon 2-3 times/day	
♦ sulfacetamide (Bleph-10, others) (C)	Sulfonamide	Solution: 1-2 drops every 2-3 hr Ointment: Apply 1-4 times/day	
Antifungal Drug			
natamycin (Natacyn) (C)	Antifungal	1 drop into conjunctival sac q1-2h, and then usually reduce after first 3-4 days to 6-8 drops/day; therapy usually continues for 14-21 days	Fungal ocular infections
Antiviral Drug			
trifluridine (Viroptic) (C)	Antiviral	Initially 1 drop q2h while awake (max 9 drops/day); may later decrease to 5 drops/day	Viral ocular infections: keratitis and keratoconjunctivitis due to HSV types 1 and 2

HSV, Herpes simplex virus.
NOTE: Dosages vary based on the type and severity of infection.

POLYPEPTIDE ANTIBIOTICS

Bacitracin and polymyxin B are polypeptide antibiotics. These drugs are rarely used systemically because of their nephrotoxic effects. They are bactericidal antimicrobials that inhibit protein synthesis in susceptible organisms, which leads to cell death. They are most commonly used in the treatment of superficial infections caused by gram-positive bacteria.

♦ bacitracin

Bacitracin (AK-Tracin) is an ophthalmic antimicrobial drug used to treat various eye infections. It is available as a single-ingredient product and as a combination product with polymyxin or neomycin and polymyxin. The combination products have a broader spectrum of activity. Bacitracin is available in ointment form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	Variable	Immediate	Unknown	Variable

QUINOLONE ANTIBIOTICS

Quinolone antibiotics are very effective broad-spectrum antibiotics. They are discussed in detail in Chapter 39. They are bactericidal, destroying a wide spectrum of organisms that are often very difficult to treat. Currently five ophthalmic quinolones are available: ciprofloxacin (Ciloxan), gatifloxacin (Zymar), moxifloxacin (Vigamox), levofloxacin (Quixin), and ofloxacin (Ocuflox).

Significant adverse effects include formation of corneal precipitates during treatment for bacterial keratitis. Other reactions include corneal staining and infiltrates. Systemic reactions are limited because of poor topical absorption. Those that occur are usually taste disorders and nausea. There are no significant drug interactions.

♦ ciprofloxacin

Ciprofloxacin (Ciloxan) is a synthetic quinolone antibiotic. It is available in ointment and solution form. Ciprofloxacin is indicated for the treatment of bacterial keratitis and conjunctivitis caused by susceptible gram-positive and gram-negative bacteria. One notable adverse reaction to ophthalmic ciprofloxacin is the appearance of white, crystalline precipitates occurring within any corneal lesions. This has occurred in approximately 17% of patients, and within 1 to 7 days of starting therapy. In all cases to date, the condition has been self-limiting, has not required drug discontinuation, and has not adversely affected clinical outcome.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	Variable	Immediate	1-2 hr	Variable

SULFONAMIDES

Sulfonamides are synthetic bacteriostatic antibiotics that work by blocking the synthesis of folic acid in susceptible bacteria. Sulfacetamide sodium (Bleph-10) and sulfisoxazole (Gantrisin) are used to treat conjunctivitis and other ocular infections caused by susceptible bacteria.

The adverse effects are primarily limited to local reactions and include local irritation and stinging. Sulfonamide use can result in the overgrowth of nonsusceptible organisms. No significant topical toxic effects have been reported with the use of ophthalmic sulfonamides.

♦ sulfacetamide

Sulfacetamide (Bleph-10) is the most commonly used ophthalmic sulfonamide antibacterial drug. It is available in solution and ointment form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	Variable	Immediate	Unknown	Variable

ANTIFUNGAL DRUG

natamycin

Natamycin (Natacyn) is a polyene antifungal drug. It destroys fungi in the eye by binding to sterols in the fungal cell membrane, which disrupts the protective capabilities of the cell and results in cell death. Natamycin is used topically in the treatment of blepharitis, conjunctivitis, and keratitis caused by susceptible fungi (*Candida* and *Aspergillus* species). It is available only in suspension form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	Variable	Immediate	Unknown	Variable

ANTIVIRAL DRUGS

Three antiviral ophthalmic drugs are currently available: fomivirsen (Vitravene), ganciclovir (Vitrasert), and trifluridine (Viroptic). Fomivirsen and ganciclovir are used to treat cytomegalovirus infections; they are implanted in the eye by an ophthalmologist and are beyond the scope of this chapter.

trifluridine

Trifluridine (Viroptic, 1% ophthalmic drops) is a pyrimidine nucleoside. It inhibits viral replication by blocking the synthesis of viral deoxyribonucleic acid (DNA) by inhibiting viral DNA polymerase, an enzyme needed for DNA synthesis. It is used for ocular infections (keratitis and keratoconjunctivitis) caused by types 1 and 2 of the herpes simplex virus. Significant adverse effects include secondary glaucoma, corneal punctate defects, uveitis, and stromal edema (edema in the tough, fibrous, transparent portion of the cornea known as the *stroma*). The drugs exhibit no appreciable topical absorption, and no significant drug interactions have been reported.

BOX 57-1 OPHTHALMIC ANTIINFLAMMATORY DRUGS

Nonsteroidal Antiinflammatories

- bromfenac (Xibrom)
- diclofenac (Voltaren)
- flurbiprofen (Ocufen)
- ketorolac (Acular)

Corticosteroids

- dexamethasone (Decadron, others)
- fluocinonide (Retisert)
- fluorometholone (Fluor-Op, others)
- loteprednol (Lotemax, others)
- medrysone (HMS)
- prednisolone (Pred Forte, others)
- rimexolone (Vexol)

ANTIINFLAMMATORY DRUGS

Many of the same antiinflammatory drugs used systemically may also be used ophthalmically to treat various ocular inflammatory disorders and ocular surgery-related pain and inflammation. These drugs include both nonsteroidal antiinflammatory drugs (NSAIDs) and corticosteroids and are listed in Box 57-1.

Mechanism of Action and Drug Effects

Corticosteroids and NSAIDs, as discussed in Chapters 33 and 44, respectively, both act to reduce inflammatory responses. When tissues are damaged, the membranes of affected cells release phospholipids, which are broken down by several different enzymes within the arachidonic acid metabolic pathway. Phospholipase is one of the first enzymes involved, and its activity is inhibited by corticosteroids. A second enzyme, cyclooxygenase, is the site of action of the NSAIDs. Both drug actions reduce the production of various inflammatory mediators. This in turn reduces pain, erythema, and other inflammatory processes.

Indications

Corticosteroids and NSAIDs are applied topically for the symptomatic relief of many ophthalmic inflammatory conditions. They may be used to treat corneal, conjunctival, and scleral injuries from chemical, radiation, or thermal burns or from penetration of foreign bodies. They are used during the acute phase of the injury process to prevent fibrosis and scarring, which result in visual impairment. Corticosteroids produce a greater immunosuppressant effect than the NSAIDs. Consequently, NSAIDs are often preferred as initial topical therapy for such injuries. NSAIDs are also used in the symptomatic treatment of seasonal allergic conjunctivitis.

Corticosteroids and NSAIDs are used prophylactically before ocular surgery to prevent or reduce the intraoperative miosis. They are also used prophylactically after ocular surgery, such as cataract extraction, glaucoma surgery, and corneal transplantation, to prevent inflammation and scarring.

Contraindications

These drugs are contraindicated in cases of known drug allergy. In addition, they are not used for minor abrasions or wounds because they may suppress the ability of the eye to resist bacterial, viral, or fungal infections. This is especially true of corticosteroids, which have stronger immunosuppressant effects.

Adverse Effects

The most common adverse effect of corticosteroids is transient burning or stinging on application. The extended use of corticosteroids may result in cataracts, increased intraocular pressure, and optic nerve damage. If large doses are given, systemic absorption is possible. Systemic side effects of corticosteroids and NSAIDs are discussed in Chapters 33 and 44.

DRUG PROFILES

Corticosteroids and NSAIDs used to treat ophthalmic inflammatory disorders are listed in Box 57-1. The ophthalmic formulations share many of the same characteristics as their systemic drug counterparts. However, the ophthalmic derivatives have limited systemic absorption. Therefore, most therapeutic and toxic effects are restricted to the eye. These drugs are pregnancy category C.

CORTICOSTEROID

♦ dexamethasone

Dexamethasone (Decadron) is a synthetic corticosteroid that is available in many systemic and ophthalmic formulations. It is used to treat inflammation of the eye, eyelids, conjunctiva, and cornea, and it may also be used in the treatment of uveitis, iridocyclitis, allergic conditions, and burns and in the removal of foreign bodies. Dexamethasone is available in ointment, suspension, and solution form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	Variable	Immediate	Unknown	Variable

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

flurbiprofen

Flurbiprofen (Ocufen) is an NSAID used to treat inflammatory ophthalmic conditions, such as postoperative inflammation after a cataract extraction. It is also used to inhibit intraoperative miosis that may be induced by operative trauma and tissue injury. Flurbiprofen is available in solution form.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	30 min	90 min	Unknown	3 hr

ketorolac

Ketorolac (Acular) is an NSAID that is available in both oral and injectable formulations for systemic use. The ophthalmic formulation is used to reduce ocular inflammation caused by trauma, such as ocular surgery, and inflammation secondary to external agents, such as allergens and bacteria. Ketorolac is contraindicated in patients with known drug allergy. It is available in solution form. It is important to know that this drug may delay eye wound healing and lead to corneal epithelial breakdown; therefore, constantly monitor the eye through the duration of therapy.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	Rapid	Immediate	Unknown	4-6 hr

TOPICAL ANESTHETICS

Topical anesthetic ophthalmic drugs are local anesthetics that are used to alleviate eye pain. The two currently available topical anesthetics used for ophthalmic purposes are proparacaine and tetracaine.

Mechanism of Action and Drug Effects

As described in Chapter 11, local anesthetics stabilize the membranes of nerves, which results in a decrease in the movement of ions into and out of the nerve endings. When nerves are stabilized in this way, they cannot transmit signals about painful stimuli to the brain. Usually, the application of topical anesthetic drugs to the eye results in local anesthesia in less than 30 seconds.

Indications

Ophthalmic topical anesthetic drugs are used to produce ocular anesthesia for short corneal and conjunctival procedures. They prevent pain during surgical procedures and certain painful ophthalmic examinations, including removal of imbedded foreign objects. They are recommended only for short-term use and are not recommended for self-administration.

Contraindications

Contraindications to local ophthalmic anesthetics include known drug allergy.

Adverse Effects

Adverse effects are rare with ophthalmic anesthetic drugs and are limited to local effects such as stinging, burning, redness, lacrimation, and blurred vision. Systemic toxicity is rare but can theoretically lead to central nervous system (CNS) stimulation and/or CNS or cardiovascular depression.

Interactions

Because of limited systemic absorption and short duration of action, ophthalmic anesthetic drugs have no significant drug interactions.

DRUG PROFILE

Currently available topical ophthalmic anesthetic drugs are proparacaine (Alcaine) and tetracaine (generic only). They are very similar in their indications and dosing regimens.

tetracaine

Tetracaine is a local anesthetic of the ester type (see Chapter 11). It is applied as an eyedrop to numb the eye for various ophthalmic procedures. Tetracaine begins to work in about 25 seconds and lasts for about 15 to 20 minutes. Additional drops are applied as needed. It is currently available only in solution form. Pregnancy category C.

Pharmacokinetics

Route	Onset of Action	Peak Plasma Concentration	Elimination Half-life	Duration of Action
Ocular	Less than 30 sec	1-5 min	Short	15-20 min

DIAGNOSTIC DRUGS

DRUG PROFILES

CYCLOPLEGIC MYDRIATICS

♦ atropine sulfate

Atropine sulfate (Isopto Atropine) solution and ointment are used as mydriatic and cycloplegic drugs. The drug dilates the pupil (mydriasis) and paralyzes the ciliary muscle (cycloplegic refraction), which prevents accommodation. It is used to assist in eye examination or to treat uveal tract inflammatory states. The usual dosage for uveitis (inflammation of the choroid, iris, or ciliary body) in children and adults is 1 to 2 drops of the solution, or 0.3 to 0.5 cm of ointment, 2 to 3 times daily. The dosage for eye examination is 1 drop of solution, ideally 1 hour before the procedure. Pregnancy category C.

cyclopentolate

Cyclopentolate solution (Cyclogyl) is used primarily as a diagnostic mydriatic and cycloplegic drug. Unlike atropine, it is not used to treat uveitis. The usual adult dose is 1 to 2 drops (0.5%, 1%, or 2%). This is repeated in 5 to 10 minutes if needed. The dose for children is the same as that for adults. The drug effects usually subside within 24 hours. Other cycloplegic mydriatics are scopolamine (Isopto Hyoscine), homatropine (Isopto Homatropine), and tropicamide (Mydriacyl). All three are topical ophthalmic solutions with indications similar to those of atropine and cyclopentolate, except that tropicamide, like cyclopentolate, is generally used for diagnostic purposes only and not for treatment of inflammatory states. Pregnancy category C.

OPHTHALMIC DYE

fluorescein

Fluorescein (AK-Fluor) is an ophthalmic diagnostic dye used to identify corneal defects and to locate foreign objects in the eye. It is also used in fitting hard contact lenses. After the instillation of fluorescein, various defects are highlighted in either bright green or yellow-orange, and foreign objects have a green halo around them. Fluorescein is available for use as an ophthalmic injection, solution, and diagnostic applicator strips. Dose determination and drug administration are usually carried out by an ophthalmologist. Pregnancy category C.

ANTIALLERGIC DRUGS

DRUG PROFILES

ANTIHISTAMINES

olopatadine

Olopatadine (Patanol) is an ocular antihistamine used to treat symptoms of allergic conjunctivitis (hay fever), which can be seasonal or nonseasonal. It works by competing at the receptor sites for histamine. Histamine normally produces ocular symptoms such as itching and tearing. Other ocular antihistamines include azelastine (Optivar), emedastine (Emadine), ketotifen (Zaditor), and epinastine (Elestat). These drugs have mechanisms of action, therapeutic and adverse effects, and drug interactions similar to those of the systemic antihistamines described in Chapter 36, although systemic effects are less likely with ophthalmic administration. Recommended dosages for olopatadine are given in the Dosages table on p. 934. Pregnancy category C.

MAST CELL STABILIZERS

cromolyn

Cromolyn sodium (Crolom) is an antiallergic drug that inhibits the release of inflammation-producing mediators from sensitized inflammatory cells called *mast cells.* It is used in the treatment of vernal keratoconjunctivitis (springtime inflammation of the cornea and conjunctiva). Other mast cell stabilizers with similar effects are pemirolast (Alamast), nedocromil (Alocril), and lodoxamide (Alomide). Recommended dosages for cromolyn are given in the Dosages table on p. 934. Pregnancy category B.

DECONGESTANTS

tetrahydrozoline

Tetrahydrozoline is an ocular decongestant. It works by promoting vasoconstriction of blood vessels in and around the eye. This reduces the edema associated with allergic and inflammatory processes. It is specifically indicated to control redness, burning, and other minor irritations. Other ocular decongestants include phenylephrine (Neo-Synephrine), oxymetazoline (Visine LR), and naphazoline (Clear Eyes). Recommended dosages for tetrahydrozoline are given in the Dosages table on p. 934. Pregnancy category C.

LUBRICANTS AND MOISTURIZERS

♦ artificial tears

An array of products is available over the counter to provide lubrication or moisture for the eyes. This is helpful to patients with dry or otherwise irritated eyes. Artificial tears are isotonic and contain buffers to adjust pH. In addition, they contain preservatives for microbial control and may contain viscosity agents for extension of ocular activity. Selected over-the-counter brand names include Moisture Drops, Murine, Nu-Tears, Akwa Tears, and Tears Plus. Many similar products are available on the market both as solutions (eyedrops) and as lubrication ointments. They are often dosed to patient comfort as needed. Restasis is an ophthalmic form of the immunosuppressant drug cyclosporine (see Chapter 48). It is also used to promote tear production in the condition technically known as *keratoconjunctivitis sicca* (dry eyes). It can be used together with artificial tears, if the drugs are given 15 minutes apart. Pregnancy category B.

DOSAGES

Ocular Antiallergics

DRUG (PREGNANCY CATEGORY)	PHARMACOLOGIC CLASS	USUAL DOSAGE RANGE	INDICATIONS
cromolyn (Crolom) (C)	Mast cell stabilizer	1-2 drops in affected eye(s) 4-6 times daily	Vernal (springtime) conjunctivitis and/or keratitis (corneal inflammation)
olopatadine (Patanol 0.1%) (C)	Antihistamine	1-2 drops in affected eye(s) 2 times per day at an interval of 6-8 hours	Allergic conjunctivitis
olopatadine (Patanol 0.2%) (C)	Antihistamine	1 drop in affected eye(s) once a day	Allergic conjunctivitis
tetrahydrozoline (Murine Plus, others) (C)	Decongestant	1-2 drops in affected eye(s) up to 4 times daily	Redness, burning, or other minor irritation

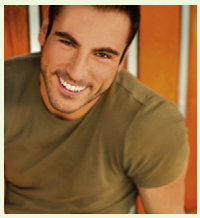
NURSING PROCESS

ASSESSMENT

Before administering any *ophthalmic drug* per the prescriber's orders, perform a baseline assessment of the eye and its structures, documenting normal and abnormal findings. It is also important to document any redness, swelling, pain, excessive tearing, eye drainage or discharge, decrease in visual acuity, or other unusual symptoms. Assess the patient for hypersensitivity to any medications or chemicals and for any drug- or disorder-related contraindications, cautions, and drug interactions. You may need to perform a visual acuity test (e.g., Snellen chart test), if indicated, noting the findings before, during, and after drug treatment. Focus the nursing history on past or present systemic disease processes and exposure to any chemicals that could be topical irritants to the eye, skin, or mucous membranes, including past or present occupational and environmental exposures.

CASE STUDY

Medications for Eye Trauma



P.L., a construction worker, is being seen in the emergency department because of a possible eye injury. He was working without eye protection, and a gust of wind sprayed metal shavings into his face. The physician has instilled fluorescein sodium and has noted areas in the eyeball with green halos around them.

1. What is the purpose of the fluorescein sodium, and what is indicated by the green halos?
2. P.L. is sent to an ophthalmologist for further treatment. What eye medication do you expect will be used for the next procedure?
3. After the procedure, P.L. receives a prescription for dexamethasone ocular ointment, to be administered three times a day. What specific patient teaching information will the nurse share with P.L.?
4. How could this have been prevented?

For answers, see http://evolve.elsevier.com/Lilley.

NURSING DIAGNOSES

1. Acute pain related to the eye disorder, infection, and/or inflammatory eye condition
2. Deficient knowledge related to lack of information about the eye disorder and associated medication therapy
3. Risk for injury (to eye) related to improper use of medication and improper instillation procedures

PLANNING

GOALS

1. Patient remains free from eye pain.
2. Patient demonstrates adequate knowledge related to the use of the medication, its application, and side effects.
3. Patient remains free from injury (to eye) related to therapy.

OUTCOME CRITERIA

1. Patient minimizes eye pain related to the eye disorder by applying warm or cold compresses as prescribed, using nonaspirin analgesics as directed, and properly applying prescribed ophthalmic medication.
2. Patient identifies rationale for use of ophthalmic medication, adverse effects associated with each medication, as well as signs and symptoms to report to the prescriber such as increase in eye pain, drainage, redness, and decreased visual acuity.
3. Patient minimizes self-injury related to the adverse effects of therapy by creating a safe environment at home, including reducing clutter and moving out any unused rugs or furniture; putting in more lighting, especially night lights; and using assistive devices as needed, if vision is altered.

IMPLEMENTATION

Always inspect the solution, and administer only clear, unexpired products (e.g., drops, ointments, solutions) to the eye. Shake all solutions, and mix contents thoroughly. Do not use solutions with any particulate matter. One of the most important standards to follow during instillation of drops or ointment is to avoid touching the eye with the tip of the dropper or container to prevent contamination of the product. Remove any excess medication promptly and apply pressure to the inner canthus for 1 minute (or other specified time frame). Applying pressure to the inner canthus after instillation of medication is needed to prevent or decrease systemic absorption and subsequent systemic adverse effects. Apply ointments and any other ophthalmic topical drug dosage form to the conjunctival

sac and never directly onto the eye itself (cornea). To facilitate the instillation of ophthalmic medication, tilt the patient's head back and have him or her look up at the ceiling. Several ophthalmic drugs with different actions may be ordered; give each drug exactly as prescribed and within the specified time period. This is particularly important when surgical procedures are being performed on the eye because several drugs with different actions may be ordered and must be given at specific times. Ointments may cause a temporary blurring of vision because of the film that bathes the eye. This film will decrease once the drug is absorbed, and vision will then become clearer. Always refer to the medication order, as well as an authoritative drug source for specific instructions and guidelines regarding application technique, length of time to apply pressure to the inner canthus, and any other special directions. See Chapter 9 for opthalmic drug administration.

Follow directions for the use of *antiviral ophthalmic preparations* closely. Administer *topical anesthetics,* as ordered, for use in removal of a foreign body or treatment of eye injury. Repeated and continuous use is not recommended because of the risk for delayed wound healing, corneal perforation, permanent corneal opacification, and vision loss. When there is an abrasion or other injury to the eye and appropriate medications are ordered, patching of the affected eye is recommended. This helps prevent further injury resulting from loss of the blink reflex due to overuse of topical anesthetic. Include education regarding any change in eye color caused by the medication. For example, latanoprost actually changes the eye color permanently from hazel, green, or bluish-brown to brown. See the Patient Teaching Tips for more information regarding ophthalmic medications.

EVALUATION

Therapeutic responses to *miotics* include decreased aqueous humor of the eye with resultant decreased intraocular pressure and decreased signs, symptoms, and long-term effects associated with glaucoma. *Beta-adrenergic blockers* are therapeutic if there is a resultant decrease in intraocular pressure. Possible adverse effects for which to evaluate include weakness, eye irritation, rash, bradycardia, hypotension, and dysrhythmias (see Chapter 19). Therapeutic responses to *antibiotic, antifungal,* and *antiviral ophthalmic drugs* include elimination of the infection or condition and resolution of symptoms, and prevention of complications. Therapeutic responses to *ophthalmic anesthetics* include prevention/relief of pain associated with the injury. Adverse effects may include CNS excitation (e.g., dizziness, tremors, restlessness, nervousness) if the drug is systemically absorbed. *Antiinflammatory ophthalmic solutions result* in a decrease in allergic reactions with a decrease in itching, tearing, redness, and eye discharge. Potential complications of these solutions include swelling of the conjunctiva (chemosis). Further monitoring includes reevaluation of goals and outcome criteria.

PATIENT TEACHING TIPS

- Educate the patient about correct administration technique. A demonstration with return demonstrations by the patient is a recommended teaching strategy.
- Encourage the patient to use only solutions that are clear and unexpired. Keep eyedroppers and solutions in containers for direct application sterile by avoiding touching the tip of the eyedropper or container to the surface of the eye.
- Educate patients receiving indirect cholinergics about adverse effects such as blurred vision, bronchospasm, nausea, vomiting, bradycardia, hypotension, and sweating.
- With any ophthalmic drug, instruct the patient to report to the prescriber any severe stinging, burning, itching, or redness of the eye; excessive tearing or excessive dryness of the eye; puffiness of the eye/eyelids; discharge from the eye; fever; eye pain, or loss of or change in vision.
- Instill sympatholytic drugs as ordered. Once these drugs (and many other drugs used in the eye) are instilled, instruct the patient to apply pressure to the inner canthus with a tissue or 2-inch by 2-inch gauze pad for 1 full minute or as directed. Application of pressure to the inner canthus helps to minimize absorption and decrease the risk of systemic adverse effects. Advise the patient to report to the prescriber immediately any blurred vision, difficulty breathing, wheezing, sweating, flushing, or loss of sight.
- Photosensitivity is an expected adverse effect of mydriatics; therefore, when these drugs are administered, encourage the patient to wear sunglasses to help minimize eye discomfort and/or headaches while in sunlight.
- With topical anesthetics, advise the patient to avoid rubbing or touching the eye while it is numb, because eye damage may result. An eye patch may be worn, if prescribed, to protect the eye because of loss of the blink reflex.
- Instruct the patient to use ophthalmic medications as prescribed and never to overuse. Stress that products with expiration dates that have passed are not to be used and are to be discarded appropriately. Advise the patient never to stop medications without consulting the prescriber first because of the possibility of adverse reactions.
- Inform the patient not to wear contact lenses while ophthalmic drugs are being instilled and for the duration of therapy, because the lenses may lead to further irritation.
- Ophthalmic ketorolac, an antiinflammatory drug, may delay eye wound healing and lead to corneal epithelial breakdown. Instruct the patient to report these problems if present or suspected.

KEY POINTS

- Glaucoma is a disorder of the eye caused by inhibition of the normal flow and drainage of aqueous humor, and treatment helps to reduce intraocular pressure either by increasing the drainage of aqueous humor or decreasing its production.
- Drugs that increase aqueous humor drainage are direct cholinergics, indirect cholinergics, sympathomimetics, and beta blockers.
- A large proportion of the inflammatory diseases of the eye are caused by viruses, and many ocular antimicrobials are available to treat bacterial, viral, and fungal infections of the eye. Common ocular infections include conjunctivitis, hordeolum (sty), keratitis, uveitis, and endophthalmitis.
- Antiinflammatory ophthalmic drugs include corticosteroids and are used to inhibit inflammatory responses to mechanical forces, chemicals, and immunologic reactions.
- Topical anesthetics are used to prevent pain to the eye and are beneficial during surgery, ophthalmic examinations, and removal of foreign bodies.
- Administer all ophthalmic preparations exactly as ordered. Always apply into the conjunctival sac. Safe and accurate application or instillation technique also includes avoiding contact of the eyedropper or tube to the eye to prevent contamination of the drug.
- Patients need to report to the prescriber immediately any increase in symptoms, such as eye pain or drainage and fever.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 The ophthalmologist has given a patient a dose of ocular atropine drops before an eye examination. Which statement by the nurse accurately explains to the patient the reason for these drops?
- **a** "These drops will cause the surface of your eye to become numb so that the doctor can do the examination."
- **b** "These drops are used to check for any possible foreign bodies or corneal defects that may be in your eye."
- **c** "These drops will reduce your tear production for the eye examination."
- **d** "These drops will cause your pupils to dilate, which makes the eye examination easier."

2 When assessing a patient who is receiving a direct-acting cholinergic eyedrop as part of treatment for glaucoma, the nurse anticipates that the drug affects the pupil in which way?
- **a** It causes mydriasis, or pupil dilation.
- **b** It causes miosis, or pupil constriction.
- **c** It changes the color of the pupil.
- **d** It causes no change in pupil size.

3 During patient teaching regarding self-administration of ophthalmic drops, which statement by the nurse is correct?
- **a** "Hold the eyedrops over the cornea, and squeeze out the drop."
- **b** "Apply pressure to the lacrimal duct area for 5 minutes after administration."
- **c** "Be sure to place the drop in the conjunctival sac of the lower eyelid."
- **d** "Squeeze your eyelid closed tightly after placing the drop into your eye."

4 When the nurse is providing teaching about eye medications for glaucoma, the nurse tells the patient that miotics help glaucoma by which mechanism of action?
- **a** Decreasing intracranial pressure
- **b** Decreasing intraocular pressure
- **c** Increasing tear production
- **d** Causing pupillary dilation

5 During the assessment of a glaucoma patient who has newly prescribed carbonic anhydrase inhibitor eyedrops, the nurse would report a history of which condition?
- **a** Allergy to sulfa drugs
- **b** Decreased renal function
- **c** Diabetes mellitus
- **d** Hypertension

6 The nurse is preparing to administer ketorolac (Acular) eyedrops. The patient asks, "Why am I getting these eyedrops?" Which is the correct answer by the nurse?
- **a** "These drops will reduce the pressure inside your eye as part of treatment for glaucoma."
- **b** "These drops are for a bacterial eye infection."
- **c** "These drops will relieve your dry eyes."
- **d** "These drops work to reduce the inflammation in your eyes."

7 A patient has undergone an eye procedure during which ophthalmic mydriatics and anesthetic drops were used. The nurse gives which instructions to the patient prior to discharge? (Select all that apply.)
- **a** "Do not rub or touch the numb eye."
- **b** "You may reinsert your contact lenses before you leave."
- **c** "Be sure to wear sunglasses when you go outside."
- **d** "Your pupils will appear very tiny until the medication wears off."
- **e** "Report any increase in eye pain or drainage to the ophthalmologist immediately."

1. d, 2. b, 3. c, 4. b, 5. a, 6. d, 7. a, c, e.

OBJECTIVES

When you reach the end of this chapter, you will be able to do the following:

1 Describe the anatomy of the ear including external, middle, and inner ear.
2 Cite the various categories of ear disorders, and describe their causes and signs and symptoms.
3 List the various types of otic preparations and their indications.
4 Discuss the mechanisms of action, dosage, cautions, contraindications, drug interactions, and specific application techniques of each of the otic drugs.
5 Develop a nursing care plan that includes all phases of the nursing process for patients taking otic drugs.

DRUG PROFILES

♦ **carbamide peroxide, p. 939**

♦ *Key drug*

KEY TERMS

Cerumen A yellowish or brownish waxy excretion produced by modified sweat glands in the external ear canal. Also called *earwax*. (p. 939)

Otitis externa Inflammation or infection of the external auditory canal. (p. 938)

Otitis media (OM) Inflammation or infection of the middle ear. (p. 938)

ANATOMY, PHYSIOLOGY, AND PATHOPHYSIOLOGY OVERVIEW

The ear is made up of four parts: the external, outer, middle, and inner ears. The external ear is composed of the pinna (outer projecting part of the ear) and the external auditory meatus or opening of the ear canal. Synonyms for the pinna are *auricle* and *ala*. The term *outer ear* refers primarily to the external auditory canal. This is the space between the external auditory meatus and the tympanic membrane (eardrum). The middle ear is composed of the tympanic cavity, which is the space that begins with the tympanic membrane and ends with the oval window. Included in the middle ear are three bony structures of the mastoid bone—the malleus ("hammer"), incus ("anvil"), and

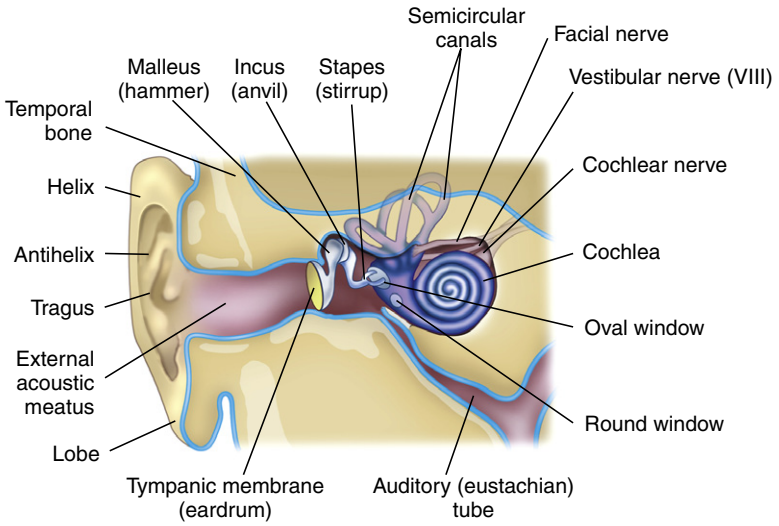

FIGURE 58-1 Structure of the ear.

stapes ("stirrup")—as well as the auditory or eustachian tube. The inner ear includes the cochlea and semicircular canals. The ear and its associated structures are illustrated in Figure 58-1.

Disorders of the ear can be categorized according to the portion of the ear affected. External ear (pinna) disorders are generally the result of physical trauma to the ear and consist of lacerations or scrapes to the skin and localized infection of the hair follicles, which often causes the development of a boil. These disorders also tend to be self-limiting and heal with time. Other examples of external ear disorders are contact dermatitis, seborrhea, and psoriasis, as evidenced by itching, local redness, inflammation, weeping, or drainage. These conditions usually respond to the same topical medications used for any other local skin disorders, as discussed in Chapter 56. However, symptoms such as drainage, pain, and dizziness are sometimes also the first signs of a more serious underlying condition (e.g., head trauma, meningitis) and warrant prompt medical evaluation. Medications for disorders affecting the outer ear (ear canal) and middle ear are the focus of this chapter. Diseases of the inner ear involve highly specialized medical practices that are beyond the scope of this book.

The most common disorders affecting the outer and middle ear are bacterial and fungal infections, inflammation, and earwax accumulation. Such disorders are often self-limiting, and treatments are usually successful. If problems persist or are left untreated, however, more serious problems such as hearing loss may result. Infections affecting the ear canal are known as **otitis externa,** whereas those affecting the middle ear are known as **otitis media (OM).** OM is a common disease of infancy and early childhood. It is often preceded by an upper respiratory tract infection. It may also occur in adults, but it is then generally associated with trauma to the tympanic membrane. Foreign objects and infection or inflammation associated with water sports are the usual sources of such trauma. In adults, the condition is also more likely to manifest as otitis externa, involving the ear canal and/or external tympanic membrane. Common symptoms of both otitis media and otitis externa are pain, fever, malaise, pressure, a sensation of fullness in the ears, and impaired hearing. If the condition is left untreated, tinnitus (ringing in the ears), nausea, vertigo, mastoiditis, and even temporary or permanent hearing deficits may occur.

OM is the second most common infection in children, accounting for more than 20 million physician visits annually. Medical management of OM is debated among the medical community, primarily due to the increased incidence of antibiotic resistance. Because of these concerns, treatment of OM has significantly changed over the last decade. In 2004, the American Academy of Pediatrics published guidelines based on expert opinion and a thorough review of the literature. A growing number of physicians do not recommend antibiotic treatment in children with mild OM without a fever (or with minimal fever). More emphasis is now given to observation and close follow-up. Many parents have concerns regarding this option. If a decision is made to treat with an antibiotic, amoxicillin should be the first-line drug for most children. If the patient fails to respond within 48 to 72 hours, the patient must be reassessed. If no antibiotics were given initially, they should be started or the initial antibiotic may need to be changed. Antibiotics are discussed in Chapters 38 and 39.

PHARMACOLOGY OVERVIEW

TREATMENT OF EAR DISORDERS

Some of the minor ailments that affect the outer or middle ear can be treated with over-the-counter medications, but persistent, painful conditions generally require prescription medications. Drugs used to treat ear conditions are known as *otic drugs,* and most are applied topically to the ear canal. Because of this, they generally are not involved in drug interactions. Adverse effects are uncommon and usually do not extend beyond localized irritation, and otic drugs are normally contraindicated only in cases of known drug allergy. Pertinent classes of otic drugs include the following:

- Antibacterials (antibiotics)
- Antifungals
- Antiinflammatory drugs
- Local analgesics

TABLE 58-1 COMMON ANTIBACTERIAL OTIC PRODUCTS

STEROID COMPONENT	ANTIBIOTIC COMPONENT	TRADE NAME
hydrocortisone (1%)	5 mg of neomycin and 10,000 units of polymyxin B per 10-mL bottle	Cortisporin Otic, others
hydrocortisone (1%)	ciprofloxacin 2 mg/mL	Cipro HT Otic
dexamethasone (0.1%)	ciprofloxacin 3 mg/mL	Ciprodex
None	ofloxacin 3 mg/mL	Floxin Otic

TABLE 58-2 COMMON ANTIFUNGAL OTIC PRODUCTS

INGREDIENTS	TRADE NAME
hydrocortisone, 1%; pramoxine, 1%; chloroxylenol, 0.1%; propylene glycol diacetate, 3%; benzalkonium chloride (amount not specified)	Cortic, Otomar, Aero Otic HC, Mediotic HC
hydrocortisone, 1%; acetic acid, 2%; propylene glycol diacetate, 3%; sodium acetate, 0.015%; benzethonium chloride, 0.02%	Acetasol HC

Neopmycin, polymixin B, and hydrocortisone otic preparations are contraindicated in patients with a perforated eardrum.

- Local anesthetics
- Corticosteroids
- Wax emulsifiers

More serious cases of ear disorders may require treatment with systemic drugs such as antimicrobial drugs, analgesics, antiinflammatory drugs, and antihistamines. These medications are discussed in detail in previous chapters dealing with the respective drug classes.

ANTIBACTERIAL AND ANTIFUNGAL OTIC DRUGS

Antibacterial and antifungal otic drugs are often combined with steroids to take advantage of the antiinflammatory, antipruritic, and antiallergic effects of the latter drugs. These drugs are used to treat outer and middle ear infections. Because they all work and are dosed very similarly, four products are profiled together here. Systemic antibiotics are also commonly prescribed for these conditions (e.g., amoxicillin; see Chapter 38), either alone or in addition to the otic drugs described in the following sections. Tables 58-1 and 58-2 list several commonly used products and their component amounts. These drugs are pregnancy category C.

DRUG PROFILES

ANTIBACTERIAL PRODUCTS

Cortisporin (and other brands) is a three-drug combination that includes hydrocortisone and two antimicrobials, neomycin (an *aminoglycoside;* see Chapter 39) and polymyxin B. Hydrocortisone is the corticosteroid most commonly used in otic drugs, although there is one preparation (Ciprodex) that contains ciprofloxacin (a *fluoroquinolone;* see Chapter 39) and dexamethasone. In either case, the purpose of the steroid component is to reduce the inflammation and itching associated with ear infections. Ciprofloxacin is also available in combination with hydrocortisone (Cipro HC Otic). Ofloxacin (Floxin Otic) is another fluoroquinolone available only as a single-drug product. All of these products are used for the treatment of bacterial otitis externa or otitis media caused by susceptible bacteria such as *Staphylococcus aureus, Escherichia coli, Klebsiella* species, and others. Neomycin, polymyxin B, and hydrocortisone otic preparations are contraindicated in patients with a perforated eardrum; ciprofloxacin and ofloxacin can be used with perforated eardrums. Their usual dosage is 4 drops three to four times daily, except for ofloxacin, which is dosed at 5 to 10 drops twice daily (5-drop dose for children younger than 12 years of age). With some otic drugs, it is recommended to saturate a retrievable cotton or tissue wick and let this wick soak inside the ear canal, as a means of dosing the drug. The wick can be periodically remoistened with additional drug or removed and further eardrops inserted directly into the ear canal. Follow the specific instructions on the drug package or the method recommended by the prescriber or pharmacist.

ANTIFUNGAL PRODUCTS

Fungal infections account for about 4% of ear infections. Antifungal otic drugs are used primarily for otitis externa. These drugs may also have antibacterial and antiviral properties. Two commonly used preparations are Cortic and Acetasol HC. Cortic, also available as Otomar, Aero Otic HC, and Mediotic HC, is composed of hydrocortisone (a steroid), pramoxine (a local anesthetic), chloroxylenol (an antiseptic antifungal), propylene glycol diacetate (an emulsifying drug), and benzalkonium chloride (an antiseptic preservative). Acetasol HC consists of hydrocortisone, acetic acid (an antifungal), propylene glycol diacetate, sodium acetate (a preservative), and benzethonium chloride (an antiseptic preservative). The local anesthetic components help ease both the pain and itching common in ear infections.

EARWAX EMULSIFIERS

An additional common ear problem is the accumulation and eventual impaction (hardening) of earwax, or **cerumen,** which can also contribute to or complicate the infectious and inflammatory conditions described earlier. Products that soften and help to eliminate earwax are referred to as *earwax emulsifiers.* Wax, or cerumen, is a natural product of the ear and is produced by modified sweat glands in the ear canal. However, it can occasionally build up and become impacted, which results in pain and partial temporary deafness. From chemistry, a nonpolar substance is one that is not water-soluble. Such a substance is said to be emulsified when it is chemically and/or physically converted to a more water-soluble form. *Earwax emulsifiers* loosen impacted cerumen, which allows it to be flushed out of the ear canal through irrigation (with water).

DRUG PROFILE

♦ carbamide peroxide

Carbamide peroxide (Debrox) is a commonly used earwax emulsifier. It is combined with other components (e.g., glycerin, a lubricant) that help soften and lubricate cerumen prior to

irrigation. Carbamide peroxide slowly releases hydrogen peroxide and oxygen when exposed to moisture. This release of oxygen imparts a weak antibacterial action to this otic drug. In addition, the *effervescence* (foaming) resulting from the release of oxygen has the mechanical effect of emulsifying impacted cerumen to release it from the walls of the ear canal. Earwax emulsifiers are not to be used without physician recommendation when ear drainage, tympanic membrane rupture, or significant pain or other irritation is present. After allowing the drug to dissolve the earwax, one can remove it by gentle flushing the ear canal with warm water from a bulb syringe. Some earwax removal products include such a syringe in the package. This drug is pregnancy category C.

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

Eardrops Do NOT Go into the Eyes!

The Institute for Safe Medication Practices (ISMP) reports that painful medication errors have occurred when eardrops have been mistakenly used in the eyes. The tissues of the eye are more sensitive than ear tissue, and eye medications are specially formulated for ophthalmic use. Patients who receive eardrops in the eyes will immediately complain of burning and stinging; redness and swelling may develop later.

It may seem to be common sense that eardrops should not be used in the eyes, but the ISMP has reported several instances of this occurrence. Some errors are blamed on the similarities between the words "otic" (meaning ear) and "optic" (meaning eye).

The ISMP recommends several actions to reduce the risk of harming patients due to administration of eardrops into the eyes, including:

- Placing an extra label on the dropper bottle that specifies "eye" or "ear"
- Keep medications in their original cartons as these often have drawings of an eye or an ear on the carton, unlike the actual vials.
- In the pharmacy, separate eardrop and eyedrop vials. Storing them together increases the chance of a mix-up between medications that have similar names.
- Nurses should confirm the medication route with the patient before administering the drops.
- If a patient is receiving both eardrops and eyedrops, administer them on different time schedules if possible.

Data from ISMP: "And the 'eyes' have it": eardrops, that is..., *ISMP Medication Safety Alert,* October 19, 2006, available at http://www.ismp.org/Newsletters/acutecare/articles/Oct06.asp#19. Accessed November 2, 2011.

NURSING PROCESS

ASSESSMENT

Before administering any of the *otic preparations,* assess baseline hearing or auditory status, if deemed appropriate, and document the findings. Assess the patient's symptoms, past and present medical history, and use of prescription drugs, over-the-counter drugs, and herbals. Document any drug or food allergies. A basic understanding of the anatomy of the ear, especially anatomic variations in patients of different age groups, is needed to ensure proper application technique. Contraindications, cautions, and drug interactions for the otic drugs, chemicals, and/or solutions have been discussed previously in the pharmacology section; always assess the patient for these and document the findings. In addition, if the patient has a perforated eardrum, this is a contraindication to the use of otic drugs.

NURSING DIAGNOSES

1. Acute pain related to ear infection or ear disorder
2. Deficient knowledge related to lack of experience with otic drugs and their method of administration
3. Noncompliance related to a lack of motivation and or lack of understanding for the need of frequent eardrop instillation, as ordered

PLANNING

GOALS

1. Patient is free from pain and other symptoms related to the ear disorder.
2. Patient demonstrates adequate knowledge about the treatment regimen, its use, application, and adverse effects.
3. Patient remains compliant and adheres to medication regimen as prescribed.

OUTCOME CRITERIA

1. Patient experiences minimal to no discomfort with use of prescribed medication.
   - Patient uses measures to enhance comfort such as use of warm compresses, as prescribed, as well as non-narcotic analgesics, as directed.
   - Patient reports immediately to the prescriber the increase in ear pain and other symptoms once therapy is initiated.
2. Patient states rationale for the use of otic medication and ways to increase the drug's effectiveness, such as accurate application or instillation and remaining supine or sitting with the affected ear upward for a short period.
3. Patient instills medication as prescribed as related to dosage, frequency, and duration of therapy.

IMPLEMENTATION

Instill *otic preparations* only after the ear has been thoroughly cleansed, all cerumen (earwax) has been removed (by irrigation if necessary, or as ordered). Eardrops, solutions, and ointments need to be stored at room temperature before instillation. Administration of solutions that are too cold may cause a vestibular type of reaction with vomiting and dizziness. If the solution has been refrigerated, allow it to warm to room temperature. Higher temperatures may affect the potency of these solutions, and storage at room temperature is recommended. When administering eardrops to adults, hold the pinna *up* and back. In children younger than 3 years of age, hold the pinna *down* and back. Allow a period of time for adequate coverage of the ear by the medication. Gentle massage to the tragus area of the ear may also help to increase coverage of the medication after the solution is given. See the Patient Teaching Tips and also Chapter 9 for more information on eardrop instillation.

CASE STUDY

Ear Medications

T.E. is 8 years old and loves to swim in the neighborhood pool. Lately she has had a feeling of fullness in her left ear, and today she tells her mother that her ear is hurting and itching and that she feels "awful." Her mother takes her temperature and finds that it is 101° F (38.3° C). She calls the pediatrician's office for an appointment, and T.E. is seen the next morning. After examining T.E., the pediatrician says that T.E. has otitis media in the left ear and some earwax buildup in both ears. The pediatrician removes some of the earwax manually, writes prescriptions for oral antibiotics for T.E., and gives instructions to use an earwax emulsifier. The nurse meets with them to review the instructions.

1. T.E.'s mother asks, "Why is the antibiotic a pill? It seems to me that if she has an ear infection, she should take eardrops!" What is the nurse's best response?
2. T.E.'s mother has another question: "What will happen if this ear infection does not get better?"
3. T.E. complains that her ear "really hurts and itches." What can be given to her for this problem? How will it be given?

For answers, see http://evolve.elsevier.com/Lilley.

EVALUATION

The therapeutic effects of *otic drugs*, as with all drugs, are gauged by evaluating whether goals and objectives have been met. Therapeutic effects of otic drugs include less pain, redness, and swelling in the ear; a reduction in fever; and resolution of any other signs and symptoms associated with the ear disorder. Improvement in hearing may also be an anticipated therapeutic effect. Monitor the ear canal for the occurrence of rash and/or any signs of local irritation, such as redness and heat at the site. Evaluate the patient for adverse effects with each application or instillation, and report any unusual appearance of the outer ear and ear canal immediately to the prescriber.

PATIENT TEACHING TIPS

- Provide thorough instructions to the patient about the proper use of eardrops or instillation of any medication into the ear. Warn the patient that dizziness may occur after application of the medication, requiring the patient to remain supine or sitting during instillation and for a few minutes thereafter.
- Medication to be applied to the ear must be at room temperature. This may be achieved by running warm water over the medication bottle, but care must be taken to prevent water from getting into the container, damaging the label so that the directions are unreadable, or making the solution too warm to use. Advise the patient not to heat the medication; for example, a microwave oven must not be used for warming—because eardrops that are overheated may lose potency. If the pharmacy indicates that the drug should be kept in a refrigerator, instruct the patient to take the drug out of the refrigerator up to 1 hour before it is to be instilled so that it may warm up to room temperature. Most medications for the ear are stored at room temperature.
- Instruct patient to lie on the side opposite to that of the affected ear for about 5 minutes after instillation of the drug. If the patient prefers, a small cotton ball may be inserted gently into the ear canal to keep the drug in place, but avoid forcing it into the ear or jamming it down into the ear canal.

KEY POINTS

- Otic drugs may include the following ingredients, either by themselves or mixed together (depending on the prescriber's order): steroids, antibacterials, antifungals, antiinflammatories, and wax-emulsifying compounds. Many of the antiinfective drugs are combined with steroids (in solution) to take advantage of the additional antiinflammatory, antipruritic, and antiallergic drug effects of the steroids.
- Some ear infections require additional drug therapy with systemic dosage forms of corticosteroids, antibiotics, antifungals, and antiinflammatory drugs, so remind the patient of oral and other dosage forms.
- Some disorders of the ear are self-limiting to a degree, but appropriate treatment is important to prevent complications to the ear and/or systemic complications. If left untreated, ear infections or disorders may lead to a decrease in or loss of hearing.
- Wax, or cerumen, is a natural product of the ear and is normally produced by modified sweat glands in the auditory canal; emulsifying otic drugs (such as carbamide peroxide) loosen and help remove this wax.
- Single drugs and combination drug products are used to treat many ear conditions, and it is important to know the indications for and specific information about these drugs to ensure their safe use.

NCLEX® EXAMINATION REVIEW QUESTIONS

1 While teaching a patient about treatment of otitis media, the nurse should mention that untreated otitis media may lead to
- **a** mastoiditis.
- **b** throat infections.
- **c** fungal ear infection.
- **d** decreased cerumen production.

2 During a teaching session about eardrops, the patient tells the nurse, "I know why an antibiotic is in this medicine, but why do I need to take a steroid?" Which is the nurse's best answer?
- **a** "The steroid will help to soften the cerumen."
- **b** "The steroid reduces itching and inflammation."
- **c** "The steroid also has antifungal effects."
- **d** "This medication helps to anesthetize the area to decrease pain."

3 The nurse is preparing to administer eardrops. Which technique for administering eardrops is correct?
- **a** Warm the solution to 100° F (37.7° C) before using.
- **b** Position the patient so that the unaffected ear is accessible.
- **c** Massage the tragus before administering the eardrops.
- **d** Gently insert a cotton ball into the outer ear canal after the drops are given.

4 The nurse is discussing treatment of earwax buildup with a patient. Which statement about earwax emulsifiers is true? These drugs:
- **a** are useful for treatment of ear infections.
- **b** loosen impacted cerumen so that it may be removed by irrigation.
- **c** are used to rinse out excessive earwax.
- **d** enhance the secretion of earwax.

5 During an examination, the nurse notes that a patient has a perforated tympanic membrane. There is an order for eardrops. Which action by the nurse is most appropriate?
- **a** Give the medication as ordered.
- **b** Check the patient's hearing, and then give the drops.
- **c** Hold the medication, and check with the prescriber.
- **d** Administer the drops with a cotton wick.

6 The nurse is preparing to administer eardrops and finds that the bottle has been stored in the medication room refrigerator. Which is the best action by the nurse?
- **a** Remove the bottle from the refrigerator, and administer the drops.
- **b** Heat the bottle for 5 seconds in the microwave oven before administering the drops.
- **c** Let the bottle sit in a cup of hot water for 15 minutes before administering the drops.
- **d** Remove the bottle from the refrigerator 1 hour before the drops are due to be given.

7 The nurse is preparing to administer carbamide peroxide (Debrox) to an adult patient with impacted cerumen. Which actions by the nurse are correct? (Select all that apply.)
- **a** Have the patient lie on his side with the affected ear up.
- **b** Chill the medication before administering it.
- **c** Pull the pinna of the ear down and back.
- **d** Pull the pinna of the ear up and back.
- **e** Gently irrigate the ear with warm water to remove the softened earwax.

1. a, 2. b, 3. d, 4. b, 5. c, 6. d, 7. a, d, e

Pharmaceutical Abbreviations

ABBREVIATION	TRANSLATION
Drug Dosage	
cc*†	Cubic centimeter (equivalent to 1 mL)
g or gm	Gram
gr	Grain
gtt	Drop
IU*†	International unit
L	Liter
Lb	Pound
mEq	Milliequivalent
min	Minute
ml or mL	Milliliter
no or #	Number
os†	Quantity sufficient, as much as needed
ss†	One half
oz	Ounce
tbsp	Tablespoon
tsp	Teaspoon
u or U*	Unit
µg*† or mcg	Microgram
Drug Route	
AD†	Right ear
AS†	Left ear
AU†	Both ears
ID	Intradermal
IM	Intramuscular
IV	Intravenous
NG	Nasogastric
OD†	Right eye
OS†	Left eye
OU†	Both eyes
PO	By mouth
SC†, SQ†, subcut	Subcutaneous
SL	Sublingual
Drug Administration	
aa	Of each
ac	Before meals
ad lib	As desired, freely
bid	Twice a day
h or hr	Hour
hs†	Hour of sleep, at bedtime
HS†	Half-strength
NPO	Nothing by mouth
pc	After meals
prn	When needed
qd*†	Every day, once a day
qh	Every hour
qid	Four times a day
qod*†	Every other day
Rx	Prescribe, take
stat	Immediately
tid	Three times a day

*As part of its 2004 National Patient Safety Goals, the Joint Commission announced that all accredited organizations must discontinue using the following abbreviations, acronyms, and symbols: U, IU, qd, qod, MS, MSO_4, and $MgSO_4$. Trailing zeros and lack of leading zeros were also discontinued. In other words, a zero should never appear by itself *after* a decimal point (1 mg instead of 1.0 mg), and a zero should always be used *before* a decimal point (0.1 mg instead of .1 mg). In addition, abbreviations for drug names should not be used because they can be misinterpreted. Other items are being considered for future inclusion on the official "do not use" list, such as the @ sign (write out the word at) and the symbols > and < (write out as *greater than* and *less than*). The abbreviations "cc" and "µg" should also be avoided and are being considered for inclusion on future lists. This National Patient Safety Goal was incorporated into the Information Management standards in 2010.

†These abbreviations are on the *List of Error Prone Abbreviations, Symbols, and Dose Designations* of the Institute for Safe Medication Practices (ISMP). These abbreviations have been reported to the ISMP as being frequently involved in medication errors. The ISMP recommends not ever using these abbreviations when communicating medical information, including medication orders and medication administration records.

SPECIAL FEATURES

Note: Case Studies, Patient Teaching Tips, Key Points, and NCLEX® Examination Review Questions are provided in each chapter (except the Photo Atlas of Drug Administration, Chapter 9). Teamwork and Collaboration: Pharmacokinetic Bridge to Nursing Practice boxes are provided in several chapters.

EVIDENCE-BASED PRACTICE

PATIENT-CENTERED CARE: CULTURAL IMPLICATIONS

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE ELDERLY PATIENT

PATIENT-CENTERED CARE: LIFESPAN CONSIDERATIONS FOR THE PEDIATRIC PATIENT

SAFETY: HERBAL THERAPIES AND DIETARY SUPPLEMENTS

SAFETY: LABORATORY VALUES RELATED TO DRUG THERAPY

SAFETY AND QUALITY IMPROVEMENT: PREVENTING MEDICATION ERRORS

TEAMWORK AND COLLABORATION: LEGAL AND ETHICAL PRINCIPLES

ABBREVIATIONS FOR DIAGNOSTIC AND LABORATORY TESTS

ALP	Alkaline phosphatase level
ALT	Glutamic-pyruvic transaminase (alanine aminotransferase) level
AST	Glutamic-oxaloacetic transaminase (aspartate aminotransferase) level
BUN	Blood urea nitrogen
CBC	Complete blood count
CPK	Creatine phosphokinase
GGT	Gamma glutamyl transferase
Hgb or Hb	Hemoglobin
Hct	Hematocrit
LDH	Lactate dehydrogenase
PSA	Prostate-specific antigen
RBC	Red blood cell count
WBC	White blood cell count
